The immune system has been known to be involved in the regulation of bone metabolism. Many cytokines whose functions are critical for the immunoregulatory system also play a role in the regulation of bone resorption and bone formation. It is intriguing to note that tail suspension is used as a disuse model but it is also used as a stress model. Three days tail suspension reduces body weight as well as spleen and thymus weight. In the absence of osteopontin, such reduction of body weight and atrophy of spleen and thymus were less evident. In addition T and B cells were reduced by tail suspension in wild-type but not in OPN-deficient mice. This change is associated with the tail suspension-induced increase in corticosterone and the increase in apoptotic cells in the spleen and thymus in the wild type and these changes were not observed in osteopontin-deficient mice. Whether such changes in the immune system were relevant to OPN effects on bone is still to be determined (Wang *et al.*, 2007).

SUMMARY

As reviewed in the chapter, OPN plays a critical role in the maintenance of bone, especially as a molecule involved in the response of bones to external stress. It is also involved in other homeostatic defense mechanism in the mammalian organism. Further investigations are required to elucidate the molecular mechanisms of OPN action in mediating responses to inflammation, mechanical stress, angiogenesis, and accelerated bone resorption. Understanding the pathways of OPN signaling will contribute to the development of novel measures to cure patients suffering from many bone diseases and other afflictions in our aging modern society.

INTRODUCTION

This chapter surveys our knowledge of the proteinases expressed in bone. Although previously the osteoclast was considered to be the main producer of proteinases in bone, it has become increasingly clear that osteoblasts play a significant role in the production of many of these proteinases. For example, it is true that the osteoclast secretes abundant lysosomal cysteine proteinases, especially cathepsin K (Vaes, 1988; Xia *et al.*, 1999; Sahara *et al.*, 2003) and produces some of the neutral proteinases, e.g., matrix metalloproteinase-9 (MMP-9; Wucherpfennig *et al.*, 1994; Delaissé *et al.*, 2000). However, osteoblasts, like their related cells fibroblasts, are able to secrete a host of proteinases, including neutral proteinases such as serine proteinases, plasminogen activators, and metalloproteinases such as collagenase-3, as well as lysosomal proteinases, e.g., cathepsins. Thus, osteoblasts, like fibroblasts, have the capacity to not only synthesize a range of matrix proteins, including type I collagen, but also have the ability to remodel their own extracellular matrix by the secretion of a range of proteinases.

Proteinases can be classified into four groups: metalloproteinases e.g., collagenase-3; serine proteinases, e.g., plasminogen activator; cysteine proteinases, e.g., cathepsin K; and aspartic proteinases, e.g., cathepsin D. This subdivision is based on the structure and the catalytic mechanism of the active site involving particular amino acid residues and/or zinc. In the following review of the proteinases synthesized in bone, we deal with each group according to this subdivision in the order just given. For some, much more is known than for others and they have warranted their own section.

METALLOPROTEINASES

Matrix metalloproteinases (MMPs) are an important group of neutral proteinases thought to be involved in bone growth and bone remodeling. According to structural and functional characteristics, human MMPs can be classified into at least six different subfamilies of closely related members: collagenases (MMP-1, -8, -13, and -18), type IV collagenases (gelatinases, MMP-2 and -9), stromelysins (MMP-3, -10, and -11), matrilysins (MMP-7 and -26), membrane-type MMPs (MT-MMPs, MMP-14, -15, -16, -17, -24, and -25), and other MMPs (MMP-12, -19, -20, and -27) (Matrisian, 1992; Vu and Werb, 2000). All matrix metalloproteinases are active at neutral pH, require Ca^{2+} for activity and contain Zn^{2+} in their active site. The catalytic domain of MMPs contains the conserved sequence HEXGH, which is believed to be the zinc-binding site. Metalloproteinases are secreted or inserted into the cell membrane in a latent form caused by the presence of a conserved cysteine residue in the prosegment, which completes the tetrad of zinc bound to three other residues in the active site. Cleavage of this pro-piece by other proteolytic enzymes (e.g., trypsin, plasmin, cathepsins, MT-MMPs, or other unknown activators) causes a loss of ~10 kDa of the pro-piece; this disrupts the cysteine association with the zinc and results in a conformational change in the enzymeyielding activation. Metalloproteinases all have homology to human fibroblast collagenase (collagenase-1, MMP-1) and all are inactivated by tissue inhibitors of metalloproteinases (TIMPs) (Varghese, 2006). It should be noted that MMPs, originally characterized

and named "gelatinases," clearly function as collagenases *in vitro* and could potentially function as collagenases *in vivo*. MMP-2, for example, when free of TIMPs, cleaves native collagens, to yield the typical 3/4 to 1/4 fragments (Ames and Quigley, 1995; Seandel *et al.*, 2001).

Activation of MMPs can occur via the plasminogen activator/plasmin pathway. Plasminogen activators convert plasminogen to plasmin, which subsequently can activate prostromelysin to stromelysin and procollagenase to collagenase. The activated MMPs can then degrade collagens and other extracellular matrix proteins. MT-MMP is necessary for MMP-2 activation in fibroblasts (Ruangpanit *et al.*, 2001), and MT-1 MMP mediated MMP-2 activation is important for invasion and metastasis of tumors (Mitra *et al.*, 2006).

Apart from the regulation of secretion, activation, and/or inhibition, MMPs are substantially regulated at the transcriptional level (Matrisian, 1992; Crawford and Matrisian, 1996). Several MMPs contain specific regulatory elements in their promoter sequences. Human and rat stromelysin-1 and -2 contain activator protein-1 (AP-1) and polyoma enhancer activator-3 (PEA-3)-binding sites that may be important for basal levels and inducibility. AP-1 and PEA-3 consensus sequences have also been found in human, rabbit, and rat collagenase genes (Brinckerhoff, 1992; Selvamurugan *et al.*, 1998; Tardif *et al.*, 2004). The transcription factors Fos and Jun form heterodimers and act through the AP-1 sequence (Lee *et al.*, 1987; Chiu *et al.*, 1988), whereas c-*ets* family members bind at the PEA-3 sequence (Wasylyk *et al.*, 1993). The urokinase plasminogen activator gene also contains AP-1 and PEA-3-binding sites and, as a result, agents acting through these sites could lead to coordinate expression of many of these genes (Matrisian, 1992; Hsieh *et al.*, 2006). Moreover, TIMP-1 is controlled by AP-1 transcription factor in the brain, along with a role for AP-1 in regulation of the neuronal MMP-9 gene (Kaczmarek *et al.*, 2002). Glucocorticoids and retinoids can suppress metalloproteinase synthesis at the transcriptional level (Brinckerhoff, 1992) by forming a complex with AP-1 transcription factors and inhibiting their action (Schroen *et al.*, 1996).

A second transcription factor-binding site was identified in the MMP-13 (collagenase-3) promoter as well as in bone-specific genes such as osteocalcin (Shah *et al.*, 2004; Selvamurugan *et al.*, 1998). This site is referred to as the runt domain (RD)-binding site or polyomavirus enhancer-binding protein-2A/osteoblast-specific element-2/nuclear matrix protein-2 binding site (Geoffroy *et al.*,1995; Merriman *et al.*, 1995). Members of the core-binding factor (CBF) protein family (renamed Runx by the Human Genome Organization), such as the osteoblastic transcription factor, Runx2 (Cbfa1), bind to these RD sites (Kagoshima *et al.*, 1993). Runx proteins are capable of binding to DNA as monomers, but can also heterodimerize with CBFbeta, a ubiquitously expressed nuclear factor (Kanno *et al.*, 1998). Runx2 is essential for the maturation of osteoblasts, and targeted disruption of the Runx2 gene in mice produces skeletal defects that are essentially identical to those found in human cleidocranial dysplasia (Banerjee *et al.*, 1997; Ducy *et al.*, 1997; Mundlos *et al.*, 1997; Otto *et al.*, 1997).

Stromelysin

Stromelysin-1 (MMP-3) degrades fibronectin, gelatin, proteoglycans, denatured type I collagen, laminin, and other extracellular matrix components (Chin *et al.*, 1985). Mesenchymal cells, such as chondrocytes and fibroblasts, are commonly found to secrete stromelysin-1 (Matrisian, 1992). Transin, the rat homologue of human stromelysin, was originally discovered in fibroblasts transformed with the polyoma virus (Matrisian *et al.*, 1985). One importance of stromelysin comes from its implication in the direct activation of procollagenases, including MMP-1, -8, -9, and -13 (Murphy *et al.*, 1987; Knauper *et al.*, 1993), and the enzyme is thought to play a role, together with collagenases, in the destruction of connective tissues during disease states (Brinckerhoff, 1992; Posthumus *et al.*, 2000). Recently, it has been identified to have a crucial role in MMP-mediated cartilage damage in osteoarthritis, as MMP-3 knockout mice were shown to have reduced MMP-mediated cartilage breakdown after induction of osteoarthritis (Blom *et al.*, 2007).

Stromelysin-1 is regulated by growth factors, oncogenes, cytokines, and tumor promoters. Epidermal growth factor (EGF) has been shown to increase stromelysin transcription through the induction of Fos and Jun, which interact at the AP-1 site in the promoter (McDonnell *et al.*, 1990). Platelet-derived growth factor is also important in the induction of stromelysin (Kerr *et al.*, 1988a). The protein kinase C activator, phorbol myristate acetate (PMA), is a notable stimulator of stromelysin transcription (Brinckerhoff, 1992; Prontera *et al.*, 1996). Transforming growth factor-β (TGF-β), however, causes an inhibition of transin (rat stromelysin) expression (Matrisian *et al.*, 1986; Kerr *et al.*, 1988b) through a TGF-β inhibitory element (Kerr *et al.*, 1990). Recent studies show that BMP-4 represses MMP-3 and -13 gene expression, but does not induce adipocyte differentiation in C3H10T1/2 cells (Otto *et al.*, 2007). IL-4 and -13 were shown to inhibit MMP-3 synthesis in human conjunctival fibroblasts (Fukuda *et al.*, 2006; Stewart *et al.*, 2007).

In bone, stromelysin-1 has been shown to be produced by normal human osteoblasts (Meikle *et al.*, 1992) after stimulation with PTH or monocyte-conditioned media (cytokine-rich). Similarly, Rifas *et al.* (1994) have shown that two human osteosarcoma cell lines (MG-63 and U2OS) secrete stromelysin and this may be increased by treatment with PMA, interleukin-1β (IL-1β), and tumor necrosis factor-α (TNF-α), but these authors were not able to find the enzyme in medium conditioned by cultured normal human osteoblasts. Mouse osteoblasts and osteoblastic cell lines also produce stromelysin-1 and demonstrate enhanced expression with $1,25(OH)_2D_3$,

interleukin-1, or interleukin-6 treatment (Thomson *et al.*, 1989; Breckon *et al.*, 1999; Kusano *et al.*, 1998; Le Maitre *et al.*, 2005). There have also been reports that this stromelysin is expressed by osteoclasts (Witty *et al.*, 1992). Despite the many papers on stromelysin-1, it is not clear what its phy-siological substrate is, nor has its role in physiological and pathophysiological skeletal resorption been established. The course of experimental arthritis and bone and cartilage destruction is not altered by null mutations in the mouse stromelysin-1 gene (Mudgett *et al.*, 1998).

Type IV Collagenases (Gelatinases)

Type IV collagenases or gelatinases are neutral metalloproteinases requiring Ca^{2+} for activity and are involved in the proteolysis and disruption of basement membranes by degradation of type IV, V, and denatured collagens. There are two types of gelatinases: 72-kDa gelatinase (gelatinase A) or MMP-2 (Collier *et al.*, 1988) and 92-kDa gelatinase (gelatinase B) or MMP-9 (Wilhelm *et al.*, 1989). There are very distinct differences between the two gelatinases. The 72-kDa gelatinase has been found complexed to TIMP-2 (Stetler-Stevenson *et al.*, 1989), whereas the 92-kDa gelatinase has been found complexed to TIMP-1 (Wilhelm *et al.*, 1989). Regulation of the two gelatinases is also very distinct. Analysis of the genomic structure and promoter of the 72-kDa gelatinase has revealed that this gene does not have an AP-1 site or TATA box in the 5′ promoter region as all the other MMPs have been shown to have (Huhtala *et al.*, 1990). This enzyme is also not regulated by PMA and, in many cases, seems to be expressed constitutively rather than in a regulated fashion. In contrast, the 92-kDa gelatinase has a promoter very similar to the other MMPs and is regulated similarly (Huhtala *et al.*, 1991). Nevertheless, expression and activity of both types of gelatinase are markedly stimulated by interleukin-1 (Kusano *et al.*, 1998).

In bone, as is to be expected, MMP-2 is expressed constitutively by many osteoblastic preparations (Overall *et al.*, 1989; Rifas *et al.*, 1989, 1994; Meikle *et al.*, 1992) and is unchanged by treatment with any of the agents tested. The zymogen form of MMP-2 is also resistant to activation by serine proteases, but MT1-MMP can initiate the activation of MMP-2 by cleavage of the Asn66-Leu peptide bond (Sato *et al.*, 1994). In 2001, Martignetti *et al.* (2001) described a form of multicentric osteolysis (Winchester/Torg syndrome) with striking tarsal and carpal bone resorption, accompanied by arthropathy, osteoporosis, subcutaneous nodules, and a distinctive facies in large, consanguineous Saudi Arabian families. They localized the gene to 16q12–21 and demonstrated two homoallelic, family-specific mutations in the region that encodes MMP-2. Nonsense and missense mutations have been documented consistent with decreased levels of MMP-2 (Al-Aqeel, 2005). *Mmp2*-null mice were first reported by Itoh *et al.* (1997) to have no phenotype except for some shortening of limb bones. Subsequent work by this group documented osteoporosis in older mice as well as altered remodeling of the canalicular system with osteocyte apoptosis, fewer canaliculi and decreased canalicular connectivity (Inoue *et al.*, 2006). They also described striking defects in formation/maintenance of osteocyte networks and connectivity in the collagenase-resistant (r/r) mice; the r/r mice had previously been shown to have osteocyte and osteoblast apoptosis and prominent emptying of osteocyte lacunae (Zhao *et al.*, 2000). We emphasize, however, that although the *Mmp2*-null mice had osteoporosis the characteristic nodulosis and severe focal osteolysis of the human NAO syndrome with mutations in *MMP-2* were not found in the *Mmp2-/-* mice. Recently, Mosig *et al.* (2007) reported that *Mmp2*-null mice obtained from Itoh *et al.* (1997) and described earlier display progressive loss of bone mineral density, articular cartilage destruction, and abnormal long bone and craniofacial development. These mice had 50% fewer osteoblasts and osteoclasts compared to control littermates at 4 days, whereas there was almost no difference after 4 weeks of age. In addition, inhibition of MMP-2 via siRNA in human SaOS2 and murine MC3T3 osteoblast cell lines caused a decrease in cell proliferation rates. These findings imply that MMP-2 is critical for normal skeletal and craniofacial development, as well as bone cell growth and proliferation. Mosig *et al.* (2007) did not comment on focal osteolysis of the NAO human syndrome in the *Mmp2*-null mice they studied nor did they examine the canalicular networks using approaches similar to those of Inoue *et al.* (2006).

Mmp7-/- (matrilysia) mice were reported to have several abnormalities such as decreased intestinal tumorigenesis but no obvious skeletal defects (Wilson *et al.*, 1997). More recent work from this group demonstrated in a prostate cancer model that MMP-7 produced by osteoclasts at the tumor-bone interface has the capacity to process cell-bound RANKL to a soluble form that further promotes osteoclast activation (Lynch *et al.*, 2005). In *Mmp7*-deficient mice, there was reduced RANKL processing and reduced tumor-induced osteolysis. It appears, however, that *Mmp7-/-* mice have no physiological abnormality in physiological skeletal remodeling (i.e., no abnormality in the absence of bone metastasis).

The 92-kDa gelatinase (MMP-9) is secreted by three osteosarcoma cell lines (TE-85, U2OS, and MG-63) (Rifas *et al.*, 1994) and, in some of the cell lines, can be stimulated by PMA, IL-1β, and TNF-α, analogous to these authors' observations regarding stromelysin. Similarly, they were unable to identify secreted MMP-9 in the media of normal human osteoblasts or the human osteosarcoma cell line SaOS-2, which has been shown to have retained many characteristics of highly differentiated osteoblasts. Likewise, Meikle *et al.* (1992) found very little immunohistochemical staining for MMP-9 in normal human osteoblasts. In fact, this enzyme has been found to be highly expressed by rabbit and human osteoclasts (Tezuka *et al.*, 1994a; Wucherpfennig *et al.*, 1994; Vu *et al.*, 1998). Indeed, a lack of expression of MMP-9 in mature osteoclasts

of c-*fos*-null mice may be one of the reasons the animals exhibit an osteopetrotic phenotype (Grigoriadis *et al.*, 1994). Furthermore, studies of mice with a targeted inactivation of the gene indicate that MMP-9 plays a role in regulating endochondral bone formation, particularly of the primary spongiosa, possibly by mediating capillary invasion. Mice containing a null mutation in the MMP-9 gene exhibit delays in vascularization, ossification, and apoptosis of the hypertrophic chondrocytes at the skeletal growth plates (Vu *et al.*, 1998). These defects result in an accumulation of hypertrophic cartilage in the growth plate and lengthening of the growth plate. The defects are reversible, and by several months of age the affected mice have an axial skeleton of normal appearance. It was postulated that MMP-9 is somehow involved in releasing angiogenic factors such as vascular endothelial growth factor (VEGF) that is normally sequestered in the extracellular matrix (Gerber *et al.*, 1999). Extracellular galectin-3 could be an endogenous substrate of MMP-9 that acts downstream to regulate hypertrophic chondrocyte death and osteoclast recruitment during endochondral bone formation. Thus, the disruption of growth plate homeostasis in MMP-9 null mice links galectin-3 and MMP-9 in the regulation of the clearance of late chondrocytes through regulation of their terminal differentiation (Ortega *et al.*, 2005).

Membrane-Type Matrix Metalloproteinases

Although most matrix metalloproteinases are secreted, a subtype called membrane-type matrix metalloproteinases (MT-MMPs) are inserted into the cell membrane (Sato *et al.*, 1997; Pei, 1999). These proteases contain a single transmembrane domain and an extracellular catalytic domain. Characteristically, MT-MMPs have the potential to be activated intracellularly by furin or furin-like proteases through recognition of a unique amino acid sequence: Arg-Arg-Lys-Arg111 (Sato *et al.*, 1996). To date, six MT-MMPs have been described, four transmembrane proteins and two glycosylphosphatidylinositol (GPI)-anchored ones. MT1-MMP, MT2-MMP, and MT3-MMP have been shown to have a wide range of activities against extracellular matrix proteins (Pei and Weiss, 1996; Velasco *et al.*, 2000). MT1-MMP is involved in endothelial cell migration and invasion (Galvez *et al.*, 2000; Collen *et al.*, 2003), and MT2-MMP and MT3-MMP are also involved in cell migration and invasion, depending on the cell type (Hotary *et al.*, 2000; Shofuda *et al.*, 2001). In a collagen-invasion model, MT1-MMP appears to be the critical MMP (Sabeh *et al.*, 2004).

A mouse cDNA homologue to MT4-MMP (mMT4-MMP) has been cloned (English *et al.*, 2000). MT4-MMP has the least degree of sequence identity to the other family members and has TNF-α convertase activity but does not activate pro-MMP2 (Puente *et al.*, 1996). Conversely, MT5-MMP and MT6-MMP may facilitate tumor progression through their ability to activate pro-MMP2 at the membrane of cells from tumor tissue (Llano *et al.*, 1999; Velasco *et al.*, 2000). As mentioned earlier, MT1-MMP (MMP-14) serves as a membrane receptor or activator of MMP-2 and possibly other secreted MMPs (Sato *et al.*, 1994). Furthermore, studies indicate that MT1-MMP may also function as a fibrinolytic enzyme in the absence of plasmin and facilitate the angiogenesis of endothelial cells (Hiraoka *et al.*, 1998). MT1-MMP is highly expressed in embryonic skeletal and periskeletal tissues and has been identified in osteoblasts by *in situ* hybridization and immunohistochemistry (Apte *et al.*, 1997; Kinoh *et al.*, 1996). Targeted inactivation of the MT1-MMP gene in mice produces several skeletal defects that result in osteopenia, craniofacial dysmorphisms, arthritis, and dwarfism (Holmbeck *et al.*, 1999; Zhou *et al.*, 2000). Several of the notable defects in bone formation include delayed ossification of the membranous calvarial bones, persistence of the parietal cartilage vestige, incomplete closure of the sutures, and marked delay in the postnatal development of the epiphyseal ossification centers characterized by impaired vascular invasion. Histological observation suggested that the progressive osteopenia noted in these animals may be attributed to excessive osteoclastic resorption and diminished bone formation. This finding was supported by evidence that osteoprogenitor cells isolated from the bone marrow of these mutant mice demonstrate defective osteogenic activity. MT1-MMP is also associated with osteoclast-mediated bone resorption in rheumatoid arthritis (Pap *et al.*, 2000).

COLLAGENASES

Collagenases generally cleave fibrillar native collagens I-III at a single helical site at neutral pH (Matrisian, 1992). The resultant cleavage products denature spontaneously at 37°C and become substrates for many enzymes, particularly gelatinases. The collagenase subfamily of human MMPs consists of three distinct members: fibroblast collagenase-1 (MMP-1), neutrophil collagenase-2 (MMP-8), and collagenase-3 (MMP-13) (Goldberg *et al.*, 1986; Freije *et al.*, 1994). An additional collagenase, called collagenase-4 (MMP-18), has been identified in *Xenopus laevis* (Stolow *et al.*, 1996), but a human homologue of this enzyme has not been identified. At the present time, only one rat/mouse interstitial collagenase has been studied thoroughly and shown to be expressed by a range of cells, including osteoblasts. This collagenase has a high degree of homology (86%) to human collagenase-3 and is aptly named collagenase-3 (Quinn *et al.*, 1990). Rat collagenase-3 is secreted by osteoblasts, smooth muscle cells, and fibroblasts, in proenzyme form at 58 kDa, and is subsequently cleaved to its active form of 48 kDa (Roswit *et al.*, 1983). Two murine orthologues of human collagenase-1, called murine collagenase-like A (Mcol-A) and murine collagenase-like B (Mcol-B), were first identified by nucleotide sequence similarity to human MMP-1, but only Mcol-A was able to degrade native type I and II collagens,

casein, and gelatins (Balbin *et al.*, 2001). In this report, the expression of Mcol-A was limited to early embryos. A murine ortholog of collagenase-2 (MMP-2) has been identified by two groups (Lawson *et al.*, 1998; Balbin *et al.*, 1998). A role for Mcol-A, Mcol-B, or murine collagenase-2 in bone cell function has not been demonstrated, although human collagenase-2 is expressed in chondrocytes and other skeletal cells. *Mmp8*-/- mice (Balbin *et al.*, 2003) have no skeletal abnormalities during development; skeletal changes in adults have not yet been reported.

As noted previously**,** it has also been shown that other MMPs [MMP-2 (gelatinase A (GelA or 72-kDa gelatinase)), and MMP-14 (MT1-MMP)] can function as collagenases *in vitro* (Aimes and Quigley, 1995**;** Seandel *et al.*, 2003; Ohuchi *et al.*, 1997). These MMPs (-1, -2, -8, -13, and -14) all cleave each of the triple helical interstitial collagens at the same locus and therefore must also be considered to be collagenases.

Collagenase-3

In developing rat calvariae, we have found ample amounts of collagenase-3 by immunohistochemistry 14 days after birth (Davis *et al.*, 1998). These are always in select areas, mostly associated with sites of active modeling. At the cellular level, staining is associated with osteocytes and bone-lining cells that have the appearance of osteoblasts. Originally, there was controversy regarding the cellular origin of bone collagenase. The osteoclast was reported to show immunohistochemical staining for collagenase (Delaissé *et al.*, 1993), but it was not determined whether this was a gene product of the osteoclast or was, perhaps, produced by osteoblasts/osteocytes and bound by the osteoclast through a receptor (see below). However, *in situ* hybridization of 17- to 19-gestational-day rat fetal long bones showed collagenase-3 (MMP-13) expression only in chondrocytes, bone surface mononuclear cells, and osteocytes adjacent to osteoclasts; there was no evidence of expression in osteoclasts (Fuller and Chambers, 1995). Similarly, Mattot *et al.* (1995) showed expression of mouse collagenase-3 in hypertrophic chondrocytes and in cells of forming bone from humeri of mice at the 18th gestational day. In human fetal cartilage and calvaria, collagenase-3 transcripts were detected in hypertrophic chondrocytes, osteoblasts, and periosteal cells by *in situ* hybridization, whereas no expression of collagenase-3 was detected in osteoclasts (Johansson *et al.*, 1997). In addition, it has been known for some time that bone explants from osteopetrotic mice (lacking active osteoclasts) continue to produce abundant collagenolytic activity, either unstimulated or stimulated by bone-resorbing hormones (Jilka and Cohn, 1983; Heath *et al.*, 1990). These studies demonstrate that the osteoblast/osteocyte and hypertrophic chondrocytes are the source of collagenases in skeletal tissue, whereas the osteoclast does not appear to express these genes. It should also be noted that the expression of MMP-13 assayed by *in situ* hybridization was strikingly reduced (Lanske *et al.*, 1996) in the distal growth plate and midshafts of bones from PTH/PTHrP receptor -/- mouse embryos (Lanske *et al.*, 1998).

The remodeling of the fracture callus mimics the developmental process of endochondral bone formation. Excess tissue accumulates as callus prior to endochondral ossification followed by osteoclast repopulation. In collaboration with Dr. Mark Bolander, we demonstrated profuse concentrations of metalloproteinases in the fracture callus of adult rat long bones (Partridge *et al.*, 1993). The predominant cells observed to stain for collagenase-3 are hypertrophic chondrocytes during the phase of endochondral ossification; marrow stromal cells (putative osteoblasts) when the primary spongiosa is remodeled; and osteoblasts/osteocytes at a time when newly formed woven bone is being remodeled to lamellar bone. This indicates that the adult long bone has the ability to produce profuse levels of collagenase-3, but only when challenged, e.g., by a wound-healing situation. Recently, it was shown that collagenase-3 (MMP-13) null mice have delayed bone fracture healing, characterized by a retarded cartilage response in the fracture callus (Kosaki *et al.*, 2007). The consistent observation here is a role for this enzyme when a collagenous matrix must undergo substantial, rapid remodeling.

Liu *et al.* (1995) have demonstrated that targeted mutation around the collagenase cleavage site in both alleles of the endogenous mouse type I collagen gene Colla1, which results in resistance to collagenase cleavage, leads to dermal fibrosis and uterine collagenous nodules. These animals are able to develop normally to adulthood, while some of the major abnormalities only become apparent with increasing age. Studies of these mice revealed that homozygous mutant (r/r) mice have diminished PTH-induced bone resorption, diminished PTH-induced calcemic responses, and thicker bones (Zhao *et al.*, 1999). These observations imply that collagenase activity is necessary not only in older animals for rapid collagen turnover, but also for PTH-stimulated bone resorption. In the r/r mice, empty osteocyte lacunae were evident in the calvariae and long bones as early as 2 weeks of age, with the number of empty lacunae increasing with age, and an increase in apoptosis was observed in osteocytes, as well as periosteal cells (Zhao *et al.*, 2000). Thus, normal osteocytes (and osteoblasts) and osteoclasts might bind to cryptic epitopes that are revealed by the collagenase cleavage of type I collagen by liganding the $\alpha_v\beta_3$ integrin and, if such signals are not induced (as postulated for the osteoclastic defect in r/r mice), they would undergo apoptosis and their lacunae would empty. Young r/r mice are also noted to develop thickening of the calvariae through the deposition of new bone predominantly at the inner periosteal surface; an increased deposition of endosteal trabecular bone was found in long bones in older r/r mice. Thus, the failure of collagenase to cleave type I collagen in r/r mice was associated with increased osteoblast and osteocyte apoptosis, and paradoxically, increased bone deposition as well.

To elucidate the functional roles of collagenase-3 during skeletal development *in vivo*, Inada *et al.* (2004) generated collagenase-3 null mice. The mice deficient for collagenase-3 were found to have lengthened growth plates, owing to an increase in the hypertrophic chondrocyte zone, as well as delayed ossification at the primary centers. Abnormalities of growth plates were apparent in the early stages of embryonic development and persisted throughout adulthood. This abnormality is most likely owing to a decrease in degradation of extracellular matrix cartilage, as was shown by the significant increase in the area of type X collagen deposition, although an increase in synthesis of type X collagen also remains a possible cause. These observations suggest that collagenase-3 plays a critical role in collagen degradation during growth plate development and endochondral ossification. Similar to these findings, Stickens *et al.* (2004) found that deletion of collagenase-3 caused abnormal endochondral bone development as a result of impaired extracellular matrix remodeling. These collagenase-3-deficient mice were viable, fertile, and had a normal life span, with no gross phenotypic abnormalities. However, an increase in the hypertrophic chondrocyte zone of the skeletal growth plate was observed, as a result of the delayed exit of chondrocytes from the growth plate. In addition, unlike the late phenotype of the collagenase-resistant mice, these mice showed an early increase in trabecular bone that persisted for months. This was owing to the absence of collagenase expression in osteoblasts, not chondrocytes, as was shown by tissue-specific knockouts. The crucial role of collagenase-3 in bone formation and remodeling is further demonstrated by a missense mutation, F56S, in the proregion domain of MMP-13 in a form of chondrodysplasia in humans. This mutation, the substitution of an evolutionarily conserved phenylalanine residue for a serine, causes the Missouri type of spondyloepimetaphyseal dysplasia (SEMD(MO)), an autosomal dominant disorder characterized by defective growth and modeling of vertebrae and long bones (Kennedy *et al.*, 2005). This is thought to be owing to intracellular autoactivation and degradation of the mutant enzyme.

Related to work in whole animals, we have shown, together with Drs. Jane Lian and Gary Stein, that collagenase-3 is expressed late in differentiation in an *in vitro* mineralizing rat osteoblast culture system (Shalhoub *et al.*, 1992; Winchester *et al.*, 1999, 2000). When osteoblasts derived from fetal rat calvariae are grown in this culture system, they undergo development from an immature preosteoblast to a mature, differentiated osteoblast, which exists within a mineralized extracellular matrix [reviewed in Stein and Lian (1993) and Stein *et al.* (1990)]. The appearance of the enzyme in late differentiated osteoblasts may correlate with a period of remodeling of the collagenous extracellular matrix.

These observations regarding the differentiation of rat osteoblasts may explain the very low levels of MMP-1 observed in cultures of normal human osteoblasts (Rifas *et al.*, 1989), where mRNAs and proteins were isolated from cells at confluence, but apparently not from mineralized cultures. Alternatively, the cultures may predominantly express MMP-13 (rather than MMP-1), which has been shown to be expressed by osteoblasts, chondrocytes, and in synovial tissue, particularly in pathologic conditions such as osteoarthritis (Johansson *et al.*, 1997; Mitchel *et al.*, 1996; Reboul *et al.*, 1996, Wernicke *et al.*, 1996). At the time that Rifas and colleagues conducted the work on human osteoblasts, human MMP-13 had not been identified.

Canalis' group has conducted considerable research on the hormonal regulation of collagenase-3 in rat calvarial osteoblasts, including demonstrating stimulation by retinoic acid (Varghese *et al.*, 1994). They have also demonstrated that triiodothyronine (T_3), platelet-derived growth factor (PDGF), and basic fibroblast growth factor (bFGF) all stimulate collagenase-3 transcription (Pereira *et al.*, 1999, Rydziel *et al.*, 2000; Varghese *et al.*, 2000). Interestingly, they have also shown that insulin-like growth factors (IGFs) inhibit both basal and retinoic-stimulated collagenase expression (Canalis *et al.*, 1995) by these cells. Recently, we have shown that TGF-beta 1 stimulates collagenase-3 expression in the rat osteoblastic cell line UMR 106-01 (Selvamurugan *et al.*, 2004).

We have conducted many studies with the clonal rat osteosarcoma line UMR 106-01, which has been described as osteoblastic in phenotype (Partridge *et al.*, 1980, 1983). This cell line responds to all of the bone-resorbing hormones by synthesizing collagenase-3 (Partridge *et al.*, 1987; Civitelli *et al.*, 1989). In contrast to the physiological regulation of collagenase in fibroblasts (Woessner, 1991), synoviocytes (Brinckerhoff and Harris, 1981), and uterine smooth muscle cells (Wilcox *et al.*, 1994), the control of expression of collagenase-3 in bone and osteoblastic cells appears to have some distinct differences. First, it is stimulated by all the bone-resorbing hormones (Partridge *et al.*, 1987; Delaissé *et al.*, 1988), which act through different pathways, including protein kinase A (PKA; PTH and PGs), protein kinase C (PKC; PTH and PGs), tyrosine phosphorylation (EGF), and direct nuclear action [$1,25(OH)_2D_3$; retinoic acid]. Second, glucocorticoids do not inhibit stimulation by PTH (Delaissé *et al.*, 1988; T. J. Connolly, N. C. Partridge, and C. O. Quinn, unpublished observations) whereas retinoic acid stimulates collagenase-3 expression rather than inhibiting it (Delaissé *et al.*, 1988; Connolly *et al.*, 1994; Varghese *et al.*, 1994). Last, in rat osteosarcoma cells, PMA is unable to elicit a pronounced stimulatory effect on collagenase-3 gene expression.

Among the bone-resorbing agents tested, PTH is the most effective in stimulating collagenase-3 production by UMR cells. A single 10^{-7} *M* PTH dose significantly stimulates transient collagenase-3 secretion with maximal enzyme concentrations achieved between 12 and 24 hours (Partridge *et al.*, 1987; Civitelli *et al.*, 1989). This level is

maintained at 48 hours, decreases to 20% of the maximum by 72 hours, and is ultimately undetectable by 96 hours. We hypothesized that collagenase-3 was removed from the media through a cell-mediated binding process because the enzyme is stable in conditioned medium and experiments showed that this disappearance was not owing to extracellular enzymatic degradation. Binding studies conducted with ^{125}I-collagenase-3 revealed a specific receptor with high affinity (K_d = 5 nM) for rat collagenase-3 (Omura *et al.*, 1994). Further studies showed that binding of collagenase-3 in this fashion is responsible for its rapid internalization and degradation. The processing of collagenase-3 in this system requires receptor-mediated endocytosis and involves sequential processing by endosomes and lysosomes (Walling *et al.*, 1998). In addition to UMR cells, we identified a very similar collagenase-3 receptor on normal, differentiated rat osteoblasts, rat and mouse embryonic fibroblasts, and human and rabbit chondrocytes (Walling *et al.*, 1998; Barmina *et al.*, 1999; Raggatt *et al.*, 2006). These results indicate that the function of these receptors is to limit the extracellular abundance of collagenase-3 and, consequently, breakdown of the extracellular matrix.

Further investigation of the collagenase-3 receptor system has led us to conclude that collagenase-3 binding and internalization requires a two-step mechanism involving a specific collagenase-3 receptor and a member of the low-density lipoprotein (LDL) receptor-related superfamily. Ligand blot analyses demonstrate that ^{125}I-labeled collagenase-3 specifically binds two proteins (approximately 170 and 600 kDa) in UMR 106-01 cells (Barmina *et al.*, 1999). Of these two binding proteins, the 170 kDa protein appears to be a high-affinity primary-binding site, and the 600 kDa protein appears to be the low-density lipoprotein receptor-related protein-1 responsible for mediating internalization. The LDL receptor superfamily represents a diverse group of receptors, including the LDL receptor, the low-density lipoprotein-related receptor protein (LRP-1), the VLDL receptor, megalin (LRP-2) and LRP 5/6 (Herz and Bock, 2002). All of these plasma membrane receptors have a single membrane-spanning domain and several stereotyped repeats, both complement-like (for ligand binding) and EGF-like (for ligand dissociation). Most receptors in this family participate in receptor-mediated endocytosis, whereby the receptor-ligand complex is directed (via an NPXY signal in the receptor) to clathrin-coated pits and then internalized. Ligands of these receptors include LDL, VLDL, uPA-or tPA-PAI-1 complexes, tPA, lactoferrin, activated α_2-macroglobulin/proteinase complexes, apolipoprotein E-enriched β-VLDL, lipoprotein lipase, *Pseudomonas* exotoxin A, Wnts, and vitellogenin (Herz and Bock, 2002).

The striking stimulation of collagenase-3 secretion by bone-resorbing agents in UMR cells was shown to be paralleled by an even more striking induction of collagenase-3 mRNA. Northern blots using a cDNA clone to rat collagenase-3 as a probe showed a ~180-fold induction of collagenase-3 mRNA 4 hours after PTH treatment (Scott *et al.*, 1992), with an initial lag period between 0.5 and 2 hours before collagenase-3 mRNA levels rose above basal. Nuclear run-on studies showed a comparable increase in transcription of the gene 2 hours after treatment with PTH. The PTH-induced increase in collagenase-3 transcription was completely inhibited by cycloheximide, whereas the transcriptional rate of β-actin was unaffected by inclusion of the protein synthesis inhibitor (Scott *et al.*, 1992). These results demonstrate that the PTH-mediated stimulation of collagenase-3 involves transcription, and requires *de novo* synthesis of a protein factor(s).

PTH treatment was found to increase the transcription of collagenase-3 in rat osteoblastic osteosarcoma cells primarily by stimulation of the cAMP signal transduction pathway (Scott *et al.*, 1992). Second messenger analogs were used to test which signal transduction pathway is of primary importance in the PTH-mediated transcriptional induction of the collagenase-3 gene. The cAMP analogue, 8BrcAMP, was capable of inducing collagenase-3 transcription to levels close to that of PTH. In contrast, neither the PKC activator, PMA, nor the calcium ionophore, ionomycin, when used alone, resulted in any increase in collagenase-3 gene transcription similar to that elicited by PTH after 2 hours of treatment. Furthermore, this effect requires protein synthesis and a 1- to 1.5-hour lag period, suggesting that the transcriptional activation of the collagenase-3 gene may be the result of interactions with immediate early gene products. PTH treatment was also found to transiently increase the mRNA expression of the AP-1 protein subunits *c-fos* and *c-jun* (Clohisy *et al.*, 1992). Both mRNA species were maximally induced within 30 minutes, well before the maximal transcription rate at 90 minutes for collagenase-3. Later, it was determined that PTH is responsible for phosphorylation of the cAMP response element-binding (CREB) protein at serine 133 (Tyson *et al.*, 1999). Once phosphorylated, the CREB protein binds a cAMP response element (CRE) in the *c-fos* promoter and activates transcription (Pearman *et al.*, 1996).

The collagenase-3 gene has 10 exons (Rajakumar *et al.*, 1993), encoding a mRNA of ~2.9 kb, which in turn encodes the proenzyme with a predicted molecular weight of the core protein of 52 kDa (Quinn *et al.*, 1990). A series of deletion and point mutants of the promoter region were generated to identify the PTH-responsive region and subsequently the primary response factors, which convey the hormonal signal and bind to this region(s) of the collagenase-3 gene. The minimum PTH regulatory region was found to be within 148 bp upstream of the transcriptional start site (Selvamurugan *et al.*, 1998). This region contains several consensus transcription factor recognition sequences including SBE (Smad binding element), C/EBP (CCAAT enhancer-binding protein site), RD (runt domain-binding sequence), p53, PEA-3 (polyoma enhancer activator-3), and AP (activator protein)-1 and -2. The AP-1 site is a major target for the Fos and Jun families

of oncogenic transcription factors (Chiu *et al.*, 1988; Lee *et al.*, 1987; Angel and Karin, 1991). The RD site is a target for core-binding factor proteins, specifically Runx2. Mice containing a targeted disruption of the Runx2 gene die at birth and lack both skeletal ossification and mature osteoblasts (Ducy *et al.*, 1997; Komori *et al.*, 1997; Otto *et al.*, 1997). These mutant mice also do not express collagenase-3 during fetal development, indicating that collagenase-3 is one of the target genes regulated by Runx2 (Jimenez *et al.*, 1999).

Additional experiments on the collagenase-3 promoter determined that both native AP-1 and RD sites and their corresponding binding proteins, AP-1 and Runx2-related proteins, are involved in PTH regulation of collagenase-3 transcription. Using gel-shift analysis, we further showed enhanced binding of Fos and Jun proteins at the AP-1 site upon treatment with PTH (Selvamurugan *et al.*, 1998), although there was no significant change in the level of Runx2 binding to the RD site. We determined that PTH induces PKA-mediated post-translational modification of Runx2 and leads to enhanced collagenase-3 promoter activity in UMR cells (Selvamurugan *et al.*, 2000b). The binding of members of the AP-1 and Runx families to their corresponding binding sites in the collagenase-3 promoter also appears to regulate collagenase-3 gene expression during osteoblast differentiation (Winchester *et al.*, 2000). As discussed earlier, collagenase-3 expression is regulated by a variety of growth factors, hormones, and cytokines, but the effects of these compounds appear to be cell type specific. Data obtained in breast cancer and other cell lines suggest that the differential expression of and regulation of collagenase-3 in osteoblastic compared to nonosteoblastic cells may depend on the expression of AP-1 factors and post-translational modifications of Runx2 (Selvamurugan and Partridge, 2000; Selvamurugan *et al.*, 2000a). The close proximity of the AP-1 and RD sites and their cooperative involvement in the activation of the collagenase-3 promoter suggests that the proteins binding to these sites physically interact; Runx2 was found to directly bind Fos and Jun in both *in vitro* and *in vivo* experiments (D'Alonzo *et al.*, 2002). To determine the importance of these regulatory sites in the expression of MMP-13 *in vivo*, transgenic mice containing the *E. coli* lacZ reporter fused to either wild-type MMP-13 promoter or that with mutated AP-1 and RD sites were generated (Selvamurugan *et al.*, 2007). The wild-type transgenic lines expressed higher levels of bacterial β-galactosidase in bone, teeth, and skin compared to the mutant and transgenic lines. Thus, the AP-1 and RD sites of the promoter most likely regulate and are necessary for gene expression *in vivo* in bone, as well as teeth and skin.

PLASMINOGEN ACTIVATORS

The plasminogen activator (PA)/plasmin pathway is involved in several processes, including tissue inflammation, fibrinolysis, ovulation, tumor invasion, malignant transformation, tissue remodeling, and cell migration. The PA/plasmin pathway is also thought to be involved in bone remodeling by osteoblasts and osteoclasts. The pathway results in the formation of plasmin, another neutral serine proteinase, which degrades fibrin and the extracellular matrix proteins fibronectin, laminin, and proteoglycans. In addition, plasmin can convert matrix metalloproteinases, procollagenase, and prostromelysin to their active forms (Eeckhout and Vaes, 1977). Plasminogen has been localized to the cell surface of the human osteosarcoma line MG63, where its activity was enhanced by endogenous cell bound urokinase-type plasminogen activator (uPA) (Campbell *et al.*, 1994).

The PA/plasmin pathway is regulated by members of the serpin family in addition to various hormones and cytokines. The primary function of this family of inhibitors is to neutralize serine proteinases by specific binding to the target enzyme. Serpins are involved in the regulation of several processes, including fibrinolysis, cell migration, tumor suppression, blood coagulation, and extracellular matrix remodeling (Potempa *et al.*, 1994). Members of this pathway involved in the regulation of the PA/plasmin pathway are plasminogen activator inhibitor-1 (PAI-1) and plasminogen activator inhibitor-2 (PAI-2), which regulate uPA and tissue type plasminogen activator (tPA); protease nexin-1, which regulates thrombin, plasmin, and uPA; and α_2-antiplasmin, which regulates plasmin. Active PAI-1 combines with uPA and tPA, forming an equimolar complex, exerting its inhibition through interactions with the active site serine. PAI-1 has been detected in media of cultured human fibrosarcoma cells (Andreasen *et al.*, 1986) and primary cultures of rat hepatocytes and hepatoma cells. PAI-1 was also detected from conditioned medium of rat osteoblast-like cells and rat osteosarcoma cells (Allan *et al.*, 1990). The expression of uPA, tPA, type I receptor for uPA, PAI-1, -2 and the broad-spectrum serine proteinase inhibitor, protease nexin I is induced by PTH treatment in primary mouse osteoblasts. The regulation of these various enzymes within bone tissue may determine the sites where bone resorption will be initiated (Tumber *et al.*, 2003).

Urokinase-Type Plasminogen Activator

The urokinase-type plasminogen activator (u-PA) is secreted as a precursor form of ~55 kDa (Nielsen *et al.*, 1988; Wun *et al.*, 1982). It is activated by cleavage into a 30-kDa heavy chain and a 24-kDa light chain, joined by a disulfide bond, with the active site residing in the 30-kDa fragment. Urokinase has a Kringle domain, serine proteinase-like active site, and a growth factor domain (GFD). The noncatalytic NH_2-terminal fragment contains the GFD and Kringle domain and is referred to as the amino-terminal fragment (ATF). The u-PA and PAI-1 are involved in regulation of the first steps of angiogenesis (Pepper, 1997). Rabbani *et al.* (1990) demonstrated that ATF stimulated proliferation

and was involved in mitogenic activity in primary rat osteoblasts and the human osteosarcoma cell line, SaOS-2. The GFD of the ATF is necessary for the binding of uPA to its specific receptor.

Tissue-Type Plasminogen Activator

The tissue-type plasminogen activator is secreted as a single-chain glycosylated 72-kDa polypeptide. This enzyme has been found in human plasma and various tissue extracts, as well as in normal and malignant cells. The cleavage of tPA forms a 39-kDa heavy chain and a 33-kDa light chain linked by a disulfide bond. The heavy chain has no proteinase activity, but contains two Kringle domains that assist in binding fibrin to plasminogen (Banyai *et al.*, 1983; Pennica *et al.*, 1983). Furthermore, the heavy chain contains a finger domain involved in fibrin binding (van Zonneveld *et al.*, 1986) and a GFD with homology to human and murine epidermal growth factor. Recently, it has been shown that tPA is expressed in osteoblastic cells with nicotine or PTH treatments (Katano *et al.*, 2006; Tumber *et al.*, 2003).

Plasminogen Activators in Bone

Plasminogen activator activity is increased in normal and malignant osteoblasts as well as calvariae by many agents, including PTH, $1,25(OH)_2D_3$, PGE_2, IL-1α, fibroblast growth factor, and EGF (Hamilton *et al.*, 1984, 1985; Thomson *et al.*, 1989; Pfeilschifter *et al.*, 1990; Cheng *et al.*, 1991; Leloup *et al.*, 1991; De Bart *et al.*, 1995). It should be noted that work suggests that PAs are not necessary for PTH- and $1,25(OH)_2D_3$-induced bone resorption (Leloup *et al.*, 1994). Expression of tissue-type plasminogen activator, urokinase-type plasminogen activator, plasminogen activator inhibitor-1, plasminogen activator inhibitor-2, protease nexin, and urokinase receptor isoform 1 (uPAR1) were detected in mouse osteoclasts using the reverse transcriptase–polymerase chain reaction (RT-PCR) (Yang *et al.*, 1997). Deletion of tPA, uPA, PAI-1, and plasminogen genes in mice can lead to fibrin deposition, some growth retardation, and inhibition of osteoclast ability to remove noncollagenous proteins *in vitro* (Carmeliet *et al.*, 1993, 1994; Bugge *et al.*, 1995; Daci *et al.*, 1999). Moreover, lack of the plasminogen activators leads to elongation of the bones and increased bone mass. Osteoblast differentiation and formation of a mineralized bone matrix are enhanced in osteoblast cultures derived from tPA-/- and uPA-/- mice (Daci *et al.*, 2003).

There are conflicting data as to whether the increase in osteoblastic PA activity is owing to an increase in the total amount of one or both of the PAs, or to a decline in the amount of PAI-1. All possible results have been observed, depending on which osteoblastic cell culture system is used or the method of identification of the enzymes. The latter have been difficult to assay categorically because there have not been abundant amounts of specific antibodies available for each of the rat PAs. Similarly, different groups have found the predominant osteoblastic PA to be uPA whereas others have obtained results indicating it to be tPA.

A range of agents have also been found to inhibit the amount of osteoblastic PA activity. These include glucocorticoids, TGF-β, bFGF, leukemia inhibitory factor, and IGF-I (Allan *et al.*, 1990, 1991; Cheng *et al.*, 1991; Forbes *et al.*, 2003; Lalou *et al.*, 1994; Pfeilschifter *et al.*, 1990). Where it has been examined, in many of these cases the decline is owing to a substantial increase in PAI-1 mRNA and protein. Nevertheless, some of these agents also markedly enhance mRNA abundance for the PAs (Allan *et al.*, 1991), although the net effect is a decline in PA activity.

CYSTEINE PROTEINASES

The major organic constituent of the ECM of bone is fibrillar type I collagen, which is deposited in intimate association with an inorganic calcium/phosphate mineral phase. The presence of the mineral phase not only protects the collagen from thermal denaturation but also from attack by proteolytic enzymes (Glimcher, 1998). The mature osteoclast, the bone-resorbing cell, has the capacity to degrade bone collagen through the production of a unique acid environment adjacent to the ruffled border through the concerted action of a vacuolar proton pump ([V]-type H^+-ATPase) (Chakraborty *et al.*, 1994; Bartkowicz *et al.*, 1995; Teitelbaum, 2000) and a chloride channel of the Cl-7 type (Kornak *et al.*, 2001). Loss-of-function mutations in the genes that encode either this proton pump (Li *et al.*, 1999; Frattini *et al.*, 2000; Kornak *et al.*, 2000) or the chloride channel (Kornak *et al.*, 2001) lead to osteopetrosis. At the low pH in this extracellular space adjacent to the ruffled border, it is possible to leach the mineral phase from the collagen and permit proteinases that act at acid pH to cleave the collagen (Blair *et al.*, 1993). Candidate acid-acting proteinases are cysteine proteinases such as cathepsin K. Cathepsin K is highly expressed in osteoclasts (Drake *et al.*, 1996; Bossard *et al.*, 1996). Cysteine proteinases contain an essential cysteine residue at their active site that is involved in forming a covalent intermediate complex with its substrates (Bond and Butler, 1987). The enzymes are either cytosolic or lysosomal. The latter have an acidic pH optimum and make up the majority of the cathepsins. These enzymes are regulated by a variety of protein inhibitors, including the cystatin superfamily (Turk and Bode, 1991) and α_2-macroglobulin (Barrett, 1986). Their extracellular abundance must consequently be regulated by cell surface receptors for α_2-macroglobulin as well as the lysosomal enzyme targeting mannose-6-phosphate/IGF-II receptors.

Involvement of lysosomal cysteine proteinases in bone resorption has been indicated by many studies showing

that inhibition of these enzymes prevents bone resorption *in vitro* as well as lowering serum calcium *in vivo* (Delaissé *et al.*, 1984; Montenez *et al.*, 1994). The more recently identified cathepsin, cathepsin K (Tezuka *et al.*, 1994b), was found to have substantial effects on bone. Mice containing a targeted disruption of cathepsin K were developed and found to exhibit an osteopetrotic phenotype characterized by excessive trabeculation of the bone marrow space (Saftig *et al.*, 1998, 2000). Cathepsin K–deficient osteoclasts are capable of demineralizing the extracellular matrix, but are unable to fully remove the demineralized bone (Gowen *et al.*, 1999). Additionally, cathepsin K mutations have been linked to pycnodysostosis, a hereditary bone disorder characterized by osteosclerosis, short stature, and defective osteoclast function (Gelb *et al.*, 1996). Recent studies show that the expression of MMP-9, TRACP for osteoclastic enzymes and osteoblastic proteases (MMP-13, MMP-14), and receptor activator of nuclear factor κB ligand (RANKL) are increased in cathepsin K – deficient mice (Kiviranta *et al.*, 2005). Moreover, cathepsin K – deficient osteoclasts compensate the lack of this enzyme by using MMPs in the resorption of bone matrix (Everts *et al.*, 2006).

Cathepsin inhibitors may be therapeutically beneficial in the treatment of osteoporosis and rheumatoid arthritis to stimulate cortical bone formation and inhibit bone resorption (Xiang *et al.*, 2007). However, cathepsin K deficiency reduces atherosclerotic plaque and induces plaque fibrosis (Lutgens *et al.*, 2006a). Use of a cathepsin K inhibitor as a possible therapeutic target for atherosclerosis and bone diseases has to be evaluated with care because cathepsin K inhibition may lead to a profibrotic, but also to a more lipogenic, plaque phenotype (Lutgens *et al.*, 2006b).

Immunohistochemistry revealed that the majority of the cysteine proteinases (cathepsins B, K, and L) and the aminopeptidases (cathepsins C and H) are products of osteoclasts (Ohsawa *et al.*, 1993; Yamaza *et al.*, 1998; Littlewood-Evans *et al.*, 1997), although immunoreactive staining for cathepsins B, C, and H was also seen in osteoblasts and osteocytes. It is notable that the most potent collagenolytic cathepsin at acid pH, cathepsin L, was strongly expressed in osteoclasts and very weakly in osteoblasts. Mathieu *et al.* (1994), however, have detected both cathepsins B and L as proteins secreted by their immortalized osteogenic stromal cell line, MN7. Everts *et al.* (2006) have shown that cathepsin L is involved in modulating MMP-mediated resorption by calvarial osteoclasts.

Oursler *et al.* (1993) have also demonstrated that normal human osteoblast-like cells produce cathepsin B and that dexamethasone can increase expression and secretion of this lysosomal enzyme by these cells. Interestingly, they also showed that dexamethasone treatment causes activation of TGF-β and, by the use of lysosomal proteinase inhibitors, ascribed a role for cathepsins B and D to activation of this growth factor.

ASPARTIC PROTEINASES

These lysosomal proteinases contain an aspartic acid residue at their active site and act at acid pH. Very little investigation has been conducted on these enzymes in bone cells except for the observations that cathepsin D, a member of this family, can be found by immunohistochemical staining in osteoblasts and osteocytes (Ohsawa *et al.*, 1993), and expression of this enzyme is increased markedly by dexamethasone treatment of human osteoblasts in culture (Oursler *et al.*, 1993). Cathepsin D is secreted into the resorbing area of human odontoclasts in order to participate in degradation of mineralized tooth matrix (Gotz *et al.*, 2000).

CONCLUSIONS

The osteoblast has the ability to produce proteinases of all four classes, but far more is known about their production of collagenase and plasminogen activators, at least *in vitro*. We still do not know the absolute role of any of these osteoblastic enzymes *in vivo*. Further work with knockouts of the respective enzymes is likely the only way we will determine their required functions. These roles may not be restricted to assisting in the resorption process but may include functions to regulate bone development. Additionally, the osteoclast produces MMP-9 and cathepsin K, which appear to have similar roles in the two diverse processes.

INTRODUCTORY REMARKS: ADHESION AND BONE CELL FUNCTION

Bone (re)modeling (see Chapters 1, 3, and 19) involves the coordinated response of osteoblasts, osteocytes, and osteoclasts. Osteoblasts (see Chapter 4) and bone-lining cells form a near-continuous layer covering the periosteal, endosteal, and trabecular bone; interactions between these cells and the organic matrix of bone are important determinants of osteoblast proliferation and differentiation. Osteocytes (see Chapter 6) are found in lacunae, set within the bone matrix, and are joined both to their neighbors and cells lining the bone surfaces by cytoplasmic processes, which pass through fine channels or canaliculi. Together, this interconnecting network of osteoblasts, bone-lining cells, and osteocytes provides a possible mechanism for the detection of physical or mechanical changes and the coordination of osteosynthetic and resorptive activity leading to remodeling. Cell–cell and cell–matrix communication is central to this process, and by inference, cell adhesion molecules will be key players in these events, both in normal skeletal homeostasis, growth, and development and in pathological situations where the balance between resorption and remodeling becomes disturbed (see Table I).

Connective tissue cells in general, and bone and cartilage cells in particular, are surrounded by an abundance of extracellular matrix. Chondroblasts, osteoblasts, and, to a lesser extent, osteocytes are responsible for the synthesis of the majority of the organic components of this matrix, whereas osteoclasts mainly degrade the matrix. The function of bone and cartilage cells reflects the matrix components that surround them; conversely, the composition of the matrix, i.e., the structure of cartilage and bone, is highly dependent on the cellular function of chondroblasts, osteoblasts, and osteoclasts.

Osteoclasts are the main cells responsible for the breakdown of the extracellular matrix of bone during normal and pathological bone turnover (see Chapters 7 and 8; Teitelbaum, 2007). Osteoclastic bone resorption involves a series of developmental and regulatory steps that include the proliferation and homing to bone of hemopoietic progenitor cells; their differentiation into postmitotic osteoclast precursors, which express features of mature osteoclasts; fusion to form multinucleated cells; and migration of osteoclasts to the area of bone to be remodeled, where they attach to the bone surface. Adhesion of mature osteoclasts to bone is critical for their resorptive capacity and is dependent on expression of functional adhesion receptors. In addition, many of the steps preceding resorption involve adhesion between mature osteoclasts, osteoclast precursors, and other cell types in the bone/bone marrow compartment and with components of the extracellular matrix of bone. Some of these possible functional events are summarized in Table I. Once attached to bone, osteoclasts polarize to create three discrete areas of plasma membrane: (1) the "basolateral membrane," which faces the marrow space and is not in contact with the bone; (2) the "sealing zone," or "clear zone" that is closely apposed to the bone matrix; and (3) the "ruffled border," a highly convoluted area of plasma membrane that faces the bone matrix and is surrounded by the sealing zone. The sealing zone forms a diffusion barrier and permits the localized accumulation of high concentrations of protons and proteases secreted via the ruffled border into an extracellular resorption compartment underneath the cell (discussed in more detail later).

Cell–matrix interactions associated with osteoclastic bone resorption have been researched extensively (reviewed in Väänänen and Horton, 1995; Horton and Rodan, 1996; Duong *et al.*, 2000; Helfrich and Horton, 2006). Much less is known about cell–cell and

Principles of Bone Biology, 3rd Edition

TABLE I Summary of Possible Functions of Cell Adhesion Receptors in Bone

Osteoclast development and function
Migration of committed osteoclast precursors from the bone marrow to sites of future resorption, exiting via specialized endothelial barriers
Homing to "bone" (using chemo-, haptotactic signals) and ingress across vascular endothelium
Recognition of, adhesion to, and migration upon "bone" matrix proteins
Fusion of postmitotic osteoclast precursors
Regulatory intercellular interactions with osteoblasts, leucocytes, and other cell types in marrow space; presentation of growth factors from extracellular matrix stores
Signal transduction (and control of osteoclast function) by interaction with matrix (via RGD and other sequences)
Cellular polarization, cytoskeletal (re)organization, tight sealing zone formation, and bone resorption
Cessation of resorption by detachment from matrix, cell migration, and regulation of osteoclast survival versus apoptosis
Osteoblasts
Transduction of mechanical signals within skeleton to regulate cell function
Adhesion to, and migration on, bone matrix, including unmineralized osteoid
Regulation of osteoblast maturation from mesenchymal stem cells
Regulation of mature cell function (gene expression, matrix synthesis, protease secretion, etc.)
Interaction with other bone cells (e.g., osteoclasts) and cells in the bone marrow compartment (e.g., marrow stroma, leukocytes)
Osteocytes
Mechanosensing and mechanotransduction
Recognition of and adhesion to matrix
Interaction with other cells (osteocytes, osteoblasts, ?osteoclasts)
Chondrocytes
Response to mechanical forces (e.g., in articular cartilage)
Maintenance of tissue integrity by matrix synthesis and assembly
Regulation of chondrocyte maturation from mesenchymal stem cells
Regulation of mature chondrocyte function (gene expression, matrix synthesis, proliferation and cell survival, etc.)
Mediation of response in cartilage to injury and disease

cell–matrix interactions in osteoblasts and related populations, although there has been considerable progress since the first published analysis (Horton and Davies, 1989; Helfrich and Horton, 2006). The best defined of these adhesive interactions are mediated by a particular class of cell adhesion molecule, the integrin receptors. Integrins are now known to be major functional proteins of osteoclasts and have become targets for potential therapeutic intervention in bone diseases such as osteoporosis. The balance of this chapter somewhat reflects this bias. However, the nature and function of other adhesion proteins and cell adhesion receptors is becoming increasingly clear and in skeletal tissues there is an increased focus outside osteoclasts and integrins. Moreover, the essential roles of adhesion molecules in skeletal function are increasingly coming from the investigation of patients with genetic conditions and from knockout or transgenic mice – data arising from such studies will also be reviewed.

OVERVIEW OF CELL ADHESION MOLECULE STRUCTURE

Adhesion Receptors and Their Ligands

Molecular and immunological approaches have led to considerable advances in our understanding of the range of cell membrane molecules that are capable of mediating cell adhesion. Detailed sequence and structural analysis have enabled many of them to be grouped into "families," with related structure based on their content of highly homologous domains. The major groupings of adhesion receptor families are summarized in Table II; this

TABLE II Classes of Cell Adhesion Receptors and Their Ligands

Family	Homology region in receptor	Examples	CD No.	Ligands	Recognition motif in ligand/counterreceptor	Extracellular matrix components with shared homology domain
Integrin	PEGG (all β chains)	gpIIbIIIa	CD41/61	Blood proteins	RGD, KQAGDV	Collagen VI, von Willebrand factor, cartilage matrix protein (integrin I domain)
	I domain (CD11, $\alpha 1 \alpha 2$)	LFA-1	CD11/18	ICAM counterreceptor	ICAMs, etc.	
		$\alpha_v \beta_3$	CD51/61	Matrix, blood proteins, matricellular (CNN) proteins	RGD	
		$\alpha_2 \beta_1$	CD49b/29	Collagen	DGEA, GER	
		$\alpha_4 \beta_1$	CD49d/29	Fibronectin	EILDV	
Ig superfamily	Ig fold	ICAMs, VCAM	CD54, etc.	Heterophilic interaction	Multiple	Perlecan (Ig fold)
		N-CAM		Homophilic	KYSFNYDGSE	Fibronectin, tenascin, thrombospondin (N-CAM type III repeat)
		CD2		LFA-3 counterreceptor		
Selectins	C-type lectin, EGF repeat Complement regulatory protein domain	L-, P-selectin	CD62	Glycam-1, PSGL-1, CD34, etc.	Sialyl Le^x (CD15), etc.	Aggrecan, versican (lectin) Laminin, tenascin, thrombospondin, aggrecan, veriscan (EGF repeat)
Cadherins	LDRE repeat (110 amino acid module)	E-, N-cadherin		Homophilic	HAV	
Leucine-rich glycoproteins (LRG)	Leucine repeat (24 amino acid repeat)	Platelet gpIb	CD42b	Blood proteins	von Willebrand factor, thrombin	Biglycan, decorin
Mucins	Mucin side chain	Leukosialin	CD43 CD34	Selectins		Muc-1
CD36 family		Platelet gpIV	CD36	Thrombospondin, collagen	SVTCG (for thrombospondin)	Aggrecan, versican, link protein
CD44	Hyaluronidate-binding site		CD44	Hyaluronic acid, etc.		Aggrecan, versican, link protein

identifies some specific examples, their regions of homology by which they are defined, their ligands, and the nature and specificity of their interactions with receptors. Individual members of the families have a diverse range of structures, tissue distribution, and functions, and it is outside the scope of this chapter to provide information other than in outline. The reader is referred to Barclay *et al.* (1997) and Isacke and Horton (2000) for further details, but some basic structural information is provided here.

Similar methods have been applied to elucidate the structure of the molecules recognized by cell adhesion proteins, i.e., their ligands. These include components of the extracellular matrix and plasma proteins and cell-associated matrix proteins (Table II; Ayad *et al.,* 1998; Humphries *et al.,* 2006) and cell membrane-associated "counterreceptors" (e.g., the "ICAMs," Table II). As with adhesion receptors, a range of structural domains are recognizable within their ligands, some of which have clearly defined functions; e.g., the well-characterized Arg-Gly-Asp (RGD) peptide motif, originally described in the protein fibronectin and now known to be present widely in many matrix proteins (Pierschbacher and Ruoslahti, 1984; Ruoslahti, 1996, 2003). Interestingly, some of the domains that have been found in extracellular matrix proteins can also be identified in adhesion receptors (Table II), suggesting a shared function; e.g., hyaluronidate-binding sites have been found in the matrix proteoglycan, versican, and the "homing" receptor, CD44.

The diversity of the types and combinations of cellular receptors and the complexity of the molecular structure of the extracellular matrix are reflected in the large number of functions that have been ascribed to "cell adhesion molecules." These include both true adhesive interactions, which are clearly seen in, for instance, cell-to-cell interactions regulating the immune response and the integrity of epithelial barriers, or via the increasingly identified signaling pathways mediated by adhesion receptors, including integrins and cadherins. This includes events mediated through linkages to the F-actin cytoskeleton, leading to changes in cell shape and motility, and activation of Src family and other tyrosine kinases or mobilization of intracellular calcium, resulting in other functional changes downstream, such as activation of early response genes or protease secretion (termed "outside-in" signaling). Similarly, intracellular events can lead to the modification of receptor affinity and activity ("inside-out" signaling; e.g., the platelet integrin gpIIbIIIa will only bind fibrinogen after alterations in integrin conformation following activation on ligand binding to other non-integrin receptors such as via the thrombin receptor).

Integrin Structure

Integrins (Hynes, 2002; see also Isacke and Horton, 2000) are heterodimeric proteins whose constituent polypeptide chains, α and β, are linked noncovalently. Although originally identified by antibodies or direct purification, the primary structure of most integrin subunits has been deduced by cDNA cloning. To date, 18 different mammalian α subunits and 8 β subunits have been identified, forming 24 distinct heterodimers. Both integrin subunits are transmembrane, N-glycosylated glycoproteins with a large extracellular domain, a single hydrophobic transmembrane region, and a short cytoplasmic domain (apart from β_4, which has a large intracellular domain not found in other integrins). Electron microscopy of several purified integrin dimers shows an extended structure with dimensions of approximately 10 by 20 nm, formed by an N-terminal globular "head" composed by the association of the two subunits, connected to the membrane by two "stalks."

α subunits vary in size from 120 to 180 kDa, and analysis of their cDNA sequences reveals several features in common. All contain seven homologous repeating domains, folded into a propeller domain with three or four of the "blades" containing divalent cation binding sites. These cation binding sites, together with one such site in the β subunit, are critically important for ligand binding – note how both the α and the β subunit contribute to the ligand binding site – and also play a role in receptor stability. Some subunits (the collagen-binding α_1, α_2, α_{10}, and α_{11} chains, α_E and the leukocyte integrins α_D, α_X, α_M, and α_L) contain an additional 200 amino acids inserted between repeats 2 and 3, known as I domain (Table II). The I domain contains a characteristic metal ion-dependent adhesion site (MIDAS) motif, which can bind Mn^{2+} and Mg^{2+} ions and is also critical in ligand binding (reviewed in detail in Luo *et al.,* 2007). Integrin α subunits without I domains are cleaved post-translationally near the transmembrane domain and disulfide bonded.

β subunits are 90 to 110 kDa in size, apart from the 210 kDa β_4 chain. Their cDNA sequences show a high cysteine content (e.g., 56 Cys residues in β_3), largely concentrated in four 40 amino acid long segments that are internally disulfide bonded. Several conserved motifs in β chains are involved in ligand binding and interaction with cytoskeletal elements. β subunits also contain an I domain with a MIDAS motif, which in physiological circumstances bind an Mg^{2+} ion (for details see Luo *et al.,* 2007).

The first electron microscopic studies to define the structure of the fibronectin receptor $\alpha_5\beta_1$ (Nermut *et al.,* 1988) showed that the large extracellular domain is organized as a globular head supported by a stalk, composed of one α and one β subunit leg with overall dimensions of $\sim 10 \times$ x20 nm.This basic three-dimensional structure has now been confirmed in a number of integrins and more recently has been refined by detailed analysis of the crystal structure of the extracellular domain of the $\alpha_v\beta_3$ integrin, both with and without bound ligand (Xiong *et al.,* 2001, 2002). These studies revealed that the integrins not only exist as straight stalk structures, but can also bend

over with the globular head facing toward the C-termini of the legs projecting from the plasma membrane. There has been extensive research to understand how the conformation of integrins changes upon cation binding. This generally results in "activation," a conformation in which the receptor can bind ligand and is important especially for the β_2- and β_3-containing integrins. The majority of data suggests that the bent form of the integrin is the inactive, nonligand bound state, whereas straightening is associated with activation and ligand binding. These switches between active and inactive conformations are comprehensively reviewed elsewhere (Luo *et al.*, 2007). Post-translational modification of integrins include the cleavage of the α subunits lacking I domains, with the exception of α_4, into heavy and light fragments that are disulphide linked, and glycosylation of α and β chains.

Ligands for integrins include a wide range of extracellular matrix proteins and Ig family members such as VCAM and ICAM (reviewed in Plow *et al.,* 2000; Humphries *et al.,* 2006). Most integrins can bind more than one ligand and often this is through recognition of a common sequence. In many extracellular matrix molecules this is an RGD peptide sequence, although in other proteins, sequences such as DGEA (in collagen) or LDV (in fibronectin) are recognized.

Cross-linking studies using radioactively labeled RGD peptide probes for the integrins $\alpha_v\beta_3$ and gpIIbIIIa, respectively (see Isacke and Horton, 2000), and mutational analysis have shown the ligand-binding site to be composed of distinct, relatively short elements in the N termini of both α and β subunits. When taken with the requirement for an "I" domain for ligand binding in some integrins, these data suggest that the interaction site depends on the composite structure formed by interplay of the two chains of the receptor, with ligand specificity reflecting subunit usage.

Integrins are linked to the F-actin cytoskeleton via interaction of the β subunit with actin-binding proteins, including α-actinin, vinculin, and talin. The cytoplasmic domain of the β subunit also associates with a signaling complex comprising kinases and phosphatases and various adaptor proteins. Ligand binding leads to the activation of one or more intracellular signal transduction pathways, which, in turn, contribute to the regulation of differentiation, cytoskeletal organization, and other aspects of cell behavior. Much information on signaling via integrins has come from studies in cells such as fibroblasts and osteosarcoma cell lines that produce focal contacts *in vitro* containing the focal adhesion kinase (FAK), which associates directly with the β subunit. Upon occupation and clustering of the integrin, FAK is targeted to focal adhesions, where it associates with the cytoskeleton and is activated by autophosphorylation. Downstream signaling pathways include association of Src family kinases with phosphorylated FAK and engagement and activation of Rho-like GTPases, Erk and Jnk signaling pathways, ultimately leading to cytoskeletal rearrangement (van der Flier and Sonnenberg, 2001). Similar pathways operate in osteoclasts, discussed in general later and in detail in Chapter 9.

Cadherins

Cadherins are a rapidly growing family (>80 members) of calcium-dependent proteins that play prominent roles in morphogenesis and the maintenance of adhesive contacts in solid tissues. They are divided into five subsets of receptors: the classical cadherins types I and II, the latter directly linked to the actin cytoskeleton, desmocollins and desmogleins, protocadherins, and a number of other, more distantly related cadherins (Patel *et al.,* 2003). Cadherins are calcium-dependent single chain single pass transmembrane glycoproteins that share "cadherin domains," which contain specific amino acid motifs that have essential roles in calcium binding and dimerization of the receptors (Yagi and Takeichi, 2000; Patel *et al.,* 2003). In the context of this review the classical cadherins are the most important subgroup. The type I cadherins (members E-, N-, M-, P-, and R- cadherin) all share a common structure and have highest homology in the short cytoplasmic domain. They have an extracellular domain containing five repeats of around 110 amino acids that contain the negatively charged, calcium-binding motifs and conserved cysteine residues in the fifth repeat. They have molecular weights of around 100–130 kD. The ligand-binding site of type I cadherins is the conserved HAV motif located at the N-terminal region of the molecule in the first conserved extracellular repeat. Type II cadherins (cadherin 5–12) share the basic cadherin structure, but have lower amino acid homology with type I cadherins. They also lack the cell adhesion HAV motif.

Cadherins are mediators of cell–cell adhesion and bind ligand mainly in a homophilic manner, although heterophilic binding between different cadherin molecules is possible, but appears restricted to cadherins from the same class (Patel *et al.,* 2003). As with integrins, cells often express a repertoire of different cadherins simultaneously, although a particular feature of cadherins is their restricted expression at specific stages of embryonic and cellular development. On the cell surface, cadherins tend to be concentrated at cell–cell junctions. The cytoplasmic tail of cadherins binds to catenins and this complex is important in gene transcription as well as regulation of adhesion. β-catenin is also the key player in the Wnt signaling pathway, a pathway important in regulation of bone mass (Westendorf *et al.,* 2004). Current work is trying to unravel interconnections between Wnt signaling and cadherin-mediated cell adhesion through regulation of free β-catenin levels in cells (Nelson and Nusse, 2004). Signal transduction through cadherins is complex and dependent upon cell type and in addition to phosphorylation of β-catenin can include activation of small GTPases and tyrosine

kinase pathways (Wheelock and Johnson, 2003; Lilien and Balsamo, 2005; Perez-Moreno and Fuchs, 2006).

Immunoglobulin Superfamily

The immunoglobulin (Ig) family of receptors all share a basic motif consisting of an Ig fold of between 70 and 110 amino acids (reviewed in Barclay *et al.,* 1997; Isacke and Horton, 2000) organized into two anti-parallel β sheets that seem to serve as a scaffold on which unique determinants can be displayed. There is considerable variation in the primary structure of the members of this family and hence in molecular weights, but their tertiary structure is well conserved. There are now over 700 human genes known that share Ig motifs, making this one of the largest superfamilies in the human genome (Brummendorf and Lemmon, 2001). Many of these are splice variants of cell adhesion molecules and Ig genes, but overall the cell adhesion molecules constitute a large part of this superfamily. Here we are concerned only with the cell adhesion molecules. Their functions are wide ranging with some members functioning as true signal-transducing receptors, whereas others have predominantly adhesive functions. Ligands for Ig family members include other Ig family members (identical, as well as non-identical members) such as NCAM binding to itself, but also members of the integrin family (such as for the ICAMs, which bind β_2 integrins) and components of the extracellular matrix, for example collagen binding for myelin-associated glycoprotein, a neuron-expressed Ig family member. Signaling pathways activated by Ig family members include MAP kinase pathways (Isacke and Horton, 2000; Hubbard and Rothlein, 2000).

Syndecans

Syndecans (Elenius and Jalkanen, 1994; Tkachenko *et al.,* 2005) are a family of cell surface proteoglycans, varying in size from 20 to 45 kD. They are type I transmembrane proteins characterized by heparin sulfate and chondroitin sulfate attachment sequences on the extracellular N-terminus of their single polypeptide chain. There is little homology in the rest of their extracellular domain, but their single transmembrane domain and short cytoplasmic domains are highly conserved. The cytoplasmic domain contains three regions: C1, closest to the plasma membrane, and C2 at the C-terminal end are highly conserved in all syndecans, contain tyrosine residues that may be important in signaling events and both allow binding of intracellular proteins. C1 additionally appears to be important in dimerization. C1 and C2 enclose a variable region that differs extensively between the four mammalian syndecans. Syndecans are thought to function predominantly as coreceptors for other receptors such as integrins, members of the fibroblast growth factor family, vascular endothelial cell growth factor, and transforming growth factor β, which need heparin sulfate for signaling. In such situations the signaling is thought to occur via the cytoplasmic domains of associated receptors rather than the syndecan molecule itself, although more recently more direct involvement with signaling events, mediated via syndecan-associated cytoplasmic molecules has been suggested (see Tkachenko *et al.,* 2005).

There are four mammalian syndecans known, with syndecan-1 best studied so far. Syndecan-1 is the major syndecan of epithelia and can function as a cell-matrix receptor binding various matrix proteins (type I collagen, fibronectin, tenascin), and in addition can bind members of the FGF family. It appears that in different cell types syndecan-1 can have different patterns of glycosaminoglycans attached to its core protein and this influences the ligand-binding capabilities. Thus, where in one cell type syndecan-I may contain heparin sulfate as well as chondroitin sulfate side chains and bind collagen, this may not be the case in another cell type in which it has heparin sulfate side chains only. Syndecan-2 is the main form in mesenchymal cells and is present in neuronal tissues alongside syndecan-3. Syndecan-4 is present in many cells that form stable adhesions and *in vitro* is consistently present in focal adhesions (Fears and Woods, 2006). The functions of syndecans are varied with roles in cell–matrix interaction and cell proliferation. Signal transduction, in addition to associated tyrosine kinases, may also include cytoskeletal proteins through association with actin and tubulin.

CD44

CD44, also known as the hyaluronate receptor, is a family of transmembrane glycoproteins with molecular weights of 85 to 250 kD. They share an N-terminal region that is related to the cartilage proteoglycan core and link proteins. Alternative splicing of 10 exons and extensive post-translational modification such as glycosylation and addition of chondroitin sulfate produces the wide variety of CD44 proteins. Chondroitin sulfate containing variants can bind fibronectin, laminin, collagen, and osteopontin in addition to hyaluronate. Finally, CD44 may also bind homotypically. CD44 therefore functions in a variety of ways including in cell–cell interaction (homing of lymphocytes or cell clustering), but also in cell–matrix adhesion. Malignant transformation of cells leads to upregulation of CD44 expression and metastatic tumors often express an altered repertoire of CD44 variants. More recently evidence has pointed to a more complex role of CD44 than simply as a cell–cell or cell–matrix adhesion molecule. It is becoming apparent that CD44 can be enzymatically cleaved and that functional fragments from the cytoplasmic domain can act as transcriptional regulators, whereas functional fragments from the ectodomain circulate in body fluids or can become incorporated in the matrix and thereby modulate cellular behavior (Cichy and Pure, 2003).

Selectins

Selectins are a family of three closely related glycoproteins (P-selectin expressed on platelets and leukocytes, E-selectin expressed on endothelial cells, and L-selectin expressed on leukocytes, monocytes, neutrophils, and eosinophils). Their common structure consists of an N-terminal Ca^{2+}-dependent lectin type domain, an EGF domain and variable numbers of short repeats homologous to complement-binding sequences, a single transmembrane region, and a short cytoplasmic domain. Their molecular weights range from 74 to 240 kD, with differently glycosylated forms expressed in different cell types. In general, the function of selectins is in leukocyte trafficking. They are involved in the earliest stages of leukocyte extravasation where binding of the selectin ligand on the leukocyte to selectins expressed on the endothelial surface results in weak intercellular interactions and "rolling" of leukocytes over the endothelial surface. These functions have now been confirmed in selectin knockout mice for L- and P-selectin In a double knockout for E- and P-selectin, it appeared that E-selectin also contributes to leukocyte homeostasis (reviewed in Frenette and Wagner, 1997). Other functions for selectins are in β integrin activation and O_2^- production by leukocytes. Selectin ligands are specific oligosaccharide sequences in sialated and often in sulfated glycans, such as sialyl-Lewis^x. There remains some uncertainty about the natural ligands for selectins. Molecules that fulfill most of the criteria for true selectin ligands (i.e., with confirmation of a biological role), such as CD24 and P-selectin glycoprotein ligand-1 PSGL-1, can, when expressed on the neutrophil surface in a properly glycosylated and tyrosine sulphated form, bind to P-selectin in vascular endothelium and to L-selectin on other neutrophils to enable "rolling" over either surface. CD34, GlyCAM-1, and MAdCAM-1 are other candidate ligands for L-selectin and E-selectin ligand-1 for E-selectin (reviewed by Ehrhardt *et al.,* 2004; Buzás *et al.,* 2006). The signal transduction pathways linked to selectins are only partially elucidated (Crockett-Torabi, 1998). As with the other classes of adhesion molecules discussed earlier they include tyrosine phosphorylation cascades and increases in intracellular calcium.

DISTRIBUTION AND FUNCTION OF ADHESION RECEPTORS IN BONE

There is a recent and increasingly extensive literature on the expression of cell adhesion molecules by the stromal and matrix-forming components of the skeleton—osteoblasts, osteocytes, and chondrocytes (further discussed later). For each cell type, a number of receptors, including integrins, have been detected and experimental data supports a functional role for adhesion molecules in bone and cartilage homeostasis. In osteoclasts only five integrins have been described, and there is little evidence for expression of other adhesion proteins by mature osteoclasts other than CD44 (Athanasou and Quinn, 1990; Hughes *et al.,* 1994; Nakamura *et al.,* 1995) and possibly some cadherin family members (Mbalaviele *et al.,* 1995, 1998; Ilvesaro *et al.,* 1998; see Chapter 18). Moreover, there is strong functional information that demonstrates that antagonism of osteoclast integrins leads to a downregulation of osteoclastic bone resorption; this effect has clinical implications with drugs based upon this effect reaching the clinic.

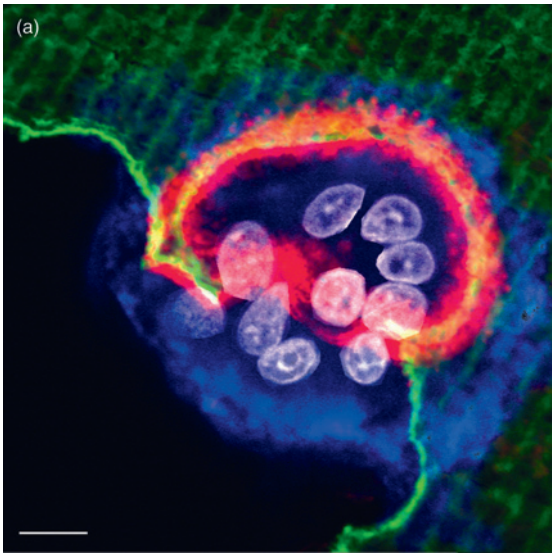
In the next sections we discuss adhesion molecule expression by osteoclasts, osteoblast lineage cells, and chondroblasts/chondrocytes separately, including evidence for their functional roles, and the targeting of adhesive interactions as therapeutic approaches in bone disease.

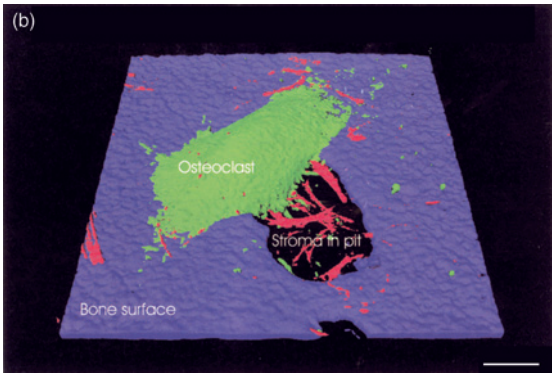
OSTEOCLASTS

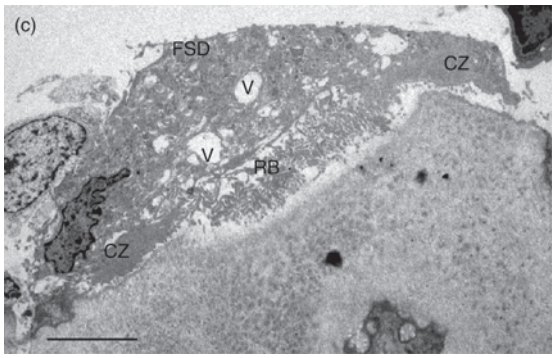
Expression of Integrins and Role in Osteoclastic Bone Resorption

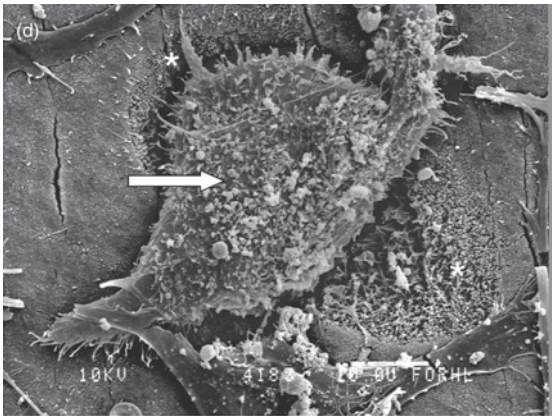
The first suggestion that adhesion receptors played a functional role in osteoclastic bone resorption was obtained when the monoclonal antibody 13C2 (Horton *et al.,* 1985) was found to inhibit bone resorption *in vitro* by human osteoclasts from the giant cell tumor of bone, osteoclastoma (Chambers *et al.,* 1986). It was later established that the inhibitory effect was mediated via the $\alpha_v\beta_3$ vitronectin receptor, a member of the integrin family of cell adhesion molecules (Davies *et al.,* 1989).

Subsequent detailed phenotypic (reviewed in Horton and Davies, 1989; Horton and Rodan, 1996; Helfrich and Horton, 2006) and biochemical analyses (Nesbitt *et al.,* 1993) demonstrated that mature mammalian osteoclasts express three integrin dimers: $\alpha_v\beta_3$, the "classical" vitronectin receptor; $\alpha_2\beta_1$, a collagen/laminin receptor; and $\alpha_v\beta_1$, a further "vitronectin receptor" (data summarized in Horton and Rodan, 1996; Helfrich and Horton, 2006; but first demonstrated for β_3 by Beckstead *et al.,* 1986 and Horton, 1986) (see Fig.1, see also color plate, and Table III). Mostly, the findings have been consistent among studies, and, where analysis has been possible, across species. More recently, a fourth integrin has been reported on mammalian osteoclasts, $\alpha_9\beta_1$, which is expressed from early osteoclast development stages through to mature osteoclasts (Rao *et al.,* 2006). A third "vitronectin receptor," $\alpha_v\beta_5$, is expressed in osteoclast precursors (Inoue *et al.,* 1998, 2000), but levels in mature mammalian osteoclasts are low to undetectable (Shinar *et al.,* 1993; Nesbitt *et al.,* 1993). There have been reports that osteoclasts may express α_3 (Grano *et al.,* 1994) and α_5 (Steffensen *et al.,* 1992; Hughes *et al.,* 1993; Grano *et al.,* 1994), although this has not been a general finding. Though less extensively studied, some differences have been noted with avian osteoclasts, which additionally express β_2 integrins (Athanasou *et al.,* 1992), $\alpha_5\beta_1$, and, unlike in mammals,









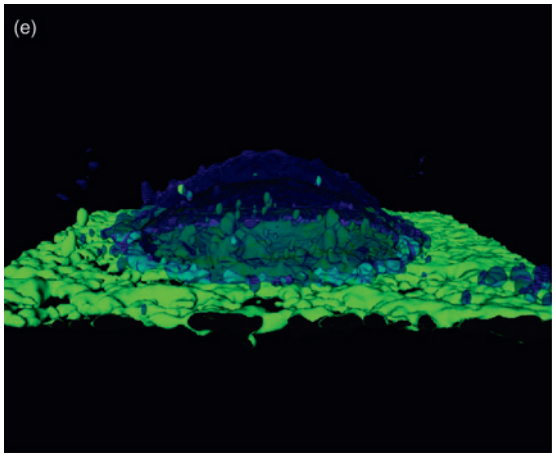


FIGURE 1 Five different microscopic views of osteoclasts to illustrate the different membrane areas involved in adhesion to matrix, bone resorption and transcytosis of resorbed matrix products (see also color plate). (a) A confocal microscopical image of a resorbing osteoclast on a piece of dentine *in vitro*. This image shows an optical slice through the area in direct contact with the matrix. The clear zone, rich in actin is shown in red (stained with phalloidin), the osteoclast membrane is stained by anti $\alpha_v\beta_3$ antibody 23C6 (blue), nuclei are stained by a DNA-binding dye (white) and the mineralized surface is stained with a fluorescent bisphosphonate (green). The resorbed area is contains no fluorescent material and shows in black. Scale bar is 10 μm. Image kindly provided by Dr. F. P. Coxon, University of Aberdeen. (b) A three-dimensional image of a site of osteoclastic bone resorption. The isosurface image of an *in vitro* site of osteoclastic resorption was constructed from a series of optical sections gathered by immunofluorescence confocal microscopy (Nesbitt *et al.*, 2000) using Bitplane Imaris software. Immunostaining shows the $\alpha_v\beta_3$ integrin in green, the matrix proteins at the bone surface in blue, and the cortical F-actin in the surrounding stromal cells in red. The osteoclast (predominantly stained green) is resorbing through bone (in blue), and a trail of resorption (in black) appears behind the osteoclast in which the stromal cells (which do not express $\alpha_v\beta_3$ and thus show as red) are seen to follow. Original magnification: ×630; scale bar 10 μm. (c) Transmission electron micrograph of an osteoclasts in a bone section illustrating the actin-rich clear zone (CZ) surrounding the ruffled border area (RB) and the basolateral surface (arrows) and the functional secretory domain (FSD) where transcytosed products are released. Osteoclasts are rich in a variety of vesicles (V), including small vesicles that only become clear at higher magnification, which transport enzymes, and protons to the RB and transcytose degraded collagens to the functional secretory domain on the opposite site of the cell. Currently little information is available about precise characterization of individual vesicles within the cells. Scale bar is 5 μm. (d) Scanning electron micrograph of an osteoclast on a slice of dentine *in vitro*. This image illustrates the adhesion of the cell in three dimensions. The functional secretory domain is rich in microvilli and is arrowed. Nonresorbing osteoclasts have a less elaborate surface structure. The resorption pit is indicated with an asterisk. Scale bar is 10 μm. Image kindly provided by Mr. K. S. Mackenzie, University of Aberdeen. (e) Computer-assisted three-dimensional reconstruction of a bone-resorbing osteoclast. The isosurface image of an *in vitro* site of osteoclastic resorption was constructed from a series of optical sections gathered by immunofluorescence confocal microscopy using Bitplane Imaris software (as described in Stenbeck and Horton, 2004). Rabbit osteoclasts plated on dentine were incubated for two minutes with low molecular weight fluorescently labeled dextran (green) before fixation and immunodecoration with antibodies directed against the $\alpha_v\beta_3$ integrin (blue). The negatively charged dextran binds to the dentine surface and accumulates in the resorption pit from where it is taken up by the cell in vesicular carriers. At early time points the dextran is found exclusively in close proximity to the bone surface and the pit. (See plate section)

TABLE III Integrin and Other Receptors Expressed by Mature Mammalian Osteoclasts[a]

	Receptor/integrin chain
Present[b,c]	$\alpha_v\beta_3$ ("vitronectin receptor") $\alpha_2\beta_1$ $\alpha_v\beta_1$ $\alpha_9\beta_1$ CD44H
"Not detected"	α_1, α_{3-9}, α_E β_2 and CD11, a, b, c, α_d β_{4-8} gpIIb (αIIb)

[a]*Data summarized from immunological analysis of human and rodent species, biochemistry of human giant cell tumor osteoclasts and gene deletion studies (as discussed in the main text). Some reports have suggested the presence of* $\alpha_5\beta_1$ (Grano *et al.*, 1994; Hughes *et al.*, 1993; Steffensen *et al.*, 1992) *and* $\alpha_3\beta_1$ (Grano *et al.*, 1994) *in osteoclasts. Some differences have been noted in avian osteoclasts* (Athanasou *et al.*, 1992). *Expression of* α_{10} *and* α_{11} *has not been examined in osteoclasts. Aside from a publication describing expression of a truncated form of* β_3 (Kumar *et al.*, 1997) *in osteoclasts, no detailed analysis of "splice variants" has been reported.*

[b]β_5 *is found on osteoclast precursors and replaced by* β_3 *in mature cells;* LFA-1 ($\alpha_L\beta_2$) *and* ICAM-1 *are expressed by osteoclast precursors only (see main text).*

[c]*There are limited data on expression of cadherins* (E-*cadherin*) *in osteoclasts* (Mbalaviele *et al.*, 1995, 1998; Ilvesaro *et al.*, 1998.

$\alpha_v\beta_5$ (Ross *et al.*, 1993); these latter integrins act as fibronectin receptors.

Adhesion of osteoclasts to the bone surface involves the interaction of osteoclast integrins with extracellular matrix proteins within the bone matrix (Table VII). There have been extensive reports on *in vitro* phenotypic analysis, and functional assays in several species. The $\alpha_v\beta_3$ vitronectin receptor mediates RGD peptide-dependent adhesion to a wide variety of proteins containing the RGD sequence, including bone sialoproteins and several extracellular matrix and plasma proteins, and osteoclast adhesion and resorption is inhibited by vitronectin receptor antibodies (Horton and Davies, 1989; Sato *et al.*, 1990, 1994; Horton *et al.*, 1991, 1993, 1995; Helfrich *et al.*, 1992a; Flores *et al.*, 1992, 1996; Hultenby *et al.*, 1993; Ross *et al.*, 1993; Ek-Rylander *et al.*, 1994; van der Pluijm *et al.*, 1994; Gronowicz and Derome, 1994). Which protein constitutes the natural ligand(s) of osteoclasts in bone remains to be determined. Co-localization studies have suggested that osteopontin is a candidate (Reinholt *et al.*, 1990), because it was found to be enriched underneath the clear zones of resorbing osteoclasts. However, because osteoclasts actively synthesize osteopontin (Dodds *et al.*, 1995) this finding should be interpreted with some reservation.

The function of $\alpha_2\beta_1$ in mammalian osteoclasts is predominantly as a receptor for type I collagen. In contrast to other cell types, adhesion of osteoclasts to collagen appears to be RGD-dependent (Helfrich *et al.*, 1996), although this could possibly be explained as a dominant-negative effect of RGD occupation of the abundant $\alpha_v\beta_3$ receptors on osteoclasts. Antibodies to α_2 and β_1 integrin inhibit resorption by human osteoclasts *in vitro*, but not to the same extent as anti-vitronectin receptor antibodies. Avian osteoclasts express abundant β_1 integrin, but do not adhere to collagen (Ross *et al.*, 1993) and probably use β_1 integrin predominantly in association with α_5 as a fibronectin-binding receptor. The role of $\alpha_v\beta_1$ on osteoclasts has not been explored in functional assays because no receptor complex-specific antibodies are available at present. This receptor is far less abundant than $\alpha_v\beta_3$ and $\alpha_2\beta_1$ in osteoclasts (Nesbitt *et al.*, 1993). By analogy with other cell types it is likely that $\alpha_v\beta_1$ functions as a receptor for collagen or fibronectin in osteoclasts. The integrin $\alpha_9\beta_1$ allows binding to the disintegrin domain of the autocrine factor ADAM8, which interestingly does not contain an RGD sequence, but instead a RX_6DLPEF sequence, which generally acts as a $\alpha_9\beta_1$ recognition sequence (Rao *et al.*, 2006). Antibodies to α_9 inhibit osteoclast formation and resorption *in vitro* (Rao *et al.*, 2006).

The demonstration that antibodies recognizing the vitronectin receptor block osteoclast adhesion, combined with the limited integrin repertoire of these cells, suggested that it may be possible to influence bone resorption *in vitro*, either by RGD-containing peptides or by function-blocking antibodies to osteoclast integrins (Chambers *et al.*, 1986; Horton *et al.*, 1991; van der Pluijm *et al.*, 1994; reviewed in Horton and Rodan, 1996; Helfrich and Horton, 2006). The observation that the RGD sequence containing snake venom protein, echistatin, blocked bone resorption supported this hypothesis (Sato *et al.*, 1990). Subsequently, these findings were confirmed using linear and cyclic RGD peptides, peptidomimetic agents (Engleman *et al.*, 1997), snake venom proteins, and antibodies to α_v and β_3 components of the vitronectin receptor and by the use of anti-sense oligodeoxynucleotides (Villanova *et al.*, 1999) in a variety of *in vitro* systems (reviewed in Horton and Rodan, 1996; Helfrich and Horton, 2006). Occupation of the vitronectin receptor by antibodies or RGD peptides *in vitro* causes osteoclasts to retract and detach from matrix, similar to the shape changes observed after administration of the potent anti-resorptive peptide hormone, calcitonin. In mammalian osteoclasts this effect is preceded by a rise in intracellular calcium localized predominantly to the nucleus (Shankar *et al.*, 1993; Zimolo *et al.*, 1994).

In vivo, echistatin and kistrin induce hypocalcemia in rats (Fisher *et al.*, 1993; King *et al.*, 1994): the former in the PTH-infused thyroparathyroidectomy model and the latter in parathyroid hormone-related protein (PTHrP)-induced hypercalcemia. Small cyclic RGD-containing peptides and peptidomimetics (Engleman *et al.*, 1997) also induce hypocalcemia in the former model. The inhibition seen *in vivo*, taken with the RGD sequence specificity observed with mutant (non-RGD sequence containing) echistatin (Fisher *et al.*, 1993; Sato *et al.*, 1994), suggests that integrins are mediating their hypocalcemic effect by

inhibiting osteoclastic bone resorption. Direct action on an osteoclast integrin was demonstrated first by showing that a function-blocking antibody, F11 (Helfrich *et al.,* 1992b), to the rat β_3 chain of the osteoclast $\alpha_v\beta_3$ integrin is hypocalcemic in the rat thyroparathyroidectomy model (Crippes *et al.,* 1996). Second, infusion of echistatin or peptidomimetics totally blocked the acute loss of trabecular bone seen in secondary hyperparathyroidism (Masarachia *et al.,* 1998) and following ovariectomy in the mouse (Engleman *et al.,* 1997; Yamamoto *et al.,* 1998). This latter observation strongly suggests that the inhibitory effect of RGD occurs via a direct action on bone, most likely via the $\alpha_v\beta_3$ integrin on osteoclasts. The impressive effects of RGD peptide analogues developed by the pharmaceutical industry on bone resorption has led to their introduction into clinical trials for bone diseases associated with excessive bone resorption such as osteoporosis (discussed later in the chapter).

Integrin Gene Knockout Studies

Gene knockout studies where β_3 integrins have been deleted in the mouse have underscored the central role of $\alpha_v\beta_3$ integrin in osteoclast biology (McHugh *et al.,* 2000). β_3 null mice are relatively normal at birth but develop a mild but progressive osteosclerosis by adulthood; this is associated with *in vitro* evidence of abnormal osteoclast adhesion and bone resorption. They are protected against bone loss after ovariectomy (Zhao *et al.,* 2005a), a finding that, together with the reported downregulation of β_3 expression by estradiol in osteoclasts *in vitro* (Saintier *et al.,* 2004), suggests that the bone-sparing effects of estrogen may be in part through direct effects on osteoclasts. The critical role of β_3 integrin in osteoclasts is also underscored by its role in promoting osteoclast survival and in regulating apoptosis (Zhao *et al.,* 2005b). α_v knockout mice die perinatally because of vascular defects (Bader *et al.,* 1998) and osteoclast defects have therefore not been studied extensively. However, mice from both single chain deletions have shown normal skeletal development, contrary to the prediction that bone modeling would be significantly affected, suggesting that other integrins compensate in the process of bone recognition by osteoclasts. Indeed, this has been confirmed in a study with peripheral blood mononuclear cell cultures from patients with Glanzmann thrombasthenia who carry a β_3 integrin null mutation and, despite which, grow to skeletal maturity without apparent abnormality. In the face of absent $\alpha_v\beta_3$ there is an upregulation of $\alpha_2\beta_1$ collagen-binding receptor in osteoclasts generated in such cultures, which enables bone resorption to proceed, albeit to a reduced extent (Horton *et al.,* 2003).

A single knockout for β_5 and a double knockout for β_3/β_5 have been made (see Sheppard, 2000) and neither show apparent osteoclast malfunction *in vivo*. However, upon ovariectomy, the β_5 knockout loses dramatically more bone and osteoclast formation *in vivo* and *in vitro* is accelerated. This shows that the β_5 integrin has the opposite effect to β_3 in osteoclasts and acts as an inhibitor of osteoclast formation (Lane *et al.,* 2005).

Deletion of β_1 integrin leads to early embryonic death. There is no specific information about β_1 function in osteoclasts from conditional knockouts and transgenic models as studies have focused mainly on osteoblast function (see further later in chapter). It would be informative to examine bone cell function in tissue-specific conditional β_1 knockout mice; these have yet to be created with the appropriate targeting characteristics though the Fässler group have created hemopoietic lineage-specific knockouts (Nieswandt *et al.,* 2001), suggesting that it should be possible to generate osteoclasts from β_1 null myeloid precursors.

Mice with a deletion of α_9 (Huang *et al.,* 2000) show an osteopetrotic phenotype in keeping with the reduced activity of osteoclasts treated with α_9 function blocking antibody *in vitro* (Rao *et al.,* 2006).

A number of other knockouts, either natural or engineered, of adhesion molecules are relevant in this context, although some unexpectedly do not show a skeletal phenotype. Osteoclasts develop from "monocytic" precursor cells that express CD11/CD18 (LFA and β_2 integrins; Lader *et al.,* 2001). Interestingly, given the severe myeloid functional defects seen in knockout mice and patients with leukocyte adhesion deficiency (LAD I), no bone (osteoclast) functional or development defect has been reported in these patients. However, animal studies suggest further studies in this patient group are required, because Tani-Ishii and coworkers (2002) reported reduced osteoclast generation from LFA-1 deficient precursors *in vitro* at the level of interaction with the osteoblast counterreceptor, ICAM-1, whereas Miura and coworkers (2005) studied mice with a deletion of β_2 and reported an osteoporotic phenotype, caused by abnormalities in the bone marrow stromal stem cell population, leading to reduced osteogenic potential. Osteoclast formation and resorptive activity was not affected in the β_2 knockout mice, probably because increased leukocytosis is balanced by the reduction in osteoclast formation owing to absence of LFA-1.

Recently, two groups have described the phenotype of α_2 knockout mice (Holtkötter *et al.,* 2002; Chen *et al.,* 2002). As in the β_3 null mouse, the skeleton is grossly normal at birth, though a detailed analysis of changes on skeletal maturation or of osteoclast function has not yet been reported. Given our results with β_3 null GT patients, such studies should be undertaken to further elucidate the role of α_2 integrin in bone and, by inference, its interplay with $\alpha_v\beta_3$.

Non-Integrin Receptors in Osteoclasts

Early studies (Horton and Davies, 1989) were carried out to assess the expression of non-integrin adhesion receptors in osteoclasts. These suggested that a range of adhesion

receptor families aside from integrins were absent from osteoclasts. More recently, data have been published indicating that indeed osteoclasts express some non-integrin adhesion proteins such as members of the cadherin family (see discussion later) and the 67-kDa laminin receptor, Mac-2 (Takahashi *et al.,* 1994).

Although some of these proteins are not major components of mature osteoclasts, or only present on a subpopulation of "immature" osteoclasts, it is possible that they could play a significant role in osteoclast development, fusion, or functional maturation from hemopoietic stem cells. They are discussed in more detail in the following section.

Cadherins

The first study on cadherin expression in mature osteoclasts (Mbalaviele *et al.,* 1995) reported expression of E-cadherin, and absence of P- and N-cadherin. This study also suggested that *in vitro* osteoclast development and fusion requires expression of E-cadherin, although it remains to be firmly established whether this is at the level of the osteoclast precursor, or whether E-cadherin expression is required in the accessory cells. In support of the former, a role for cadherin-mediated interactions in early hemopoietic development has been suggested (Puch *et al.,* 2001). In support of a role for cadherins in mature osteoclasts, it was shown that a cadherin dimer disrupting HAV peptide inhibited bone resorption (Ilvesaro *et al.,* 1998). Interestingly, pan-cadherin immunostaining in osteoclasts revealed prominent staining in the clear zone, suggesting a possible role for cadherin in creating a close contact with bone matrix (Ilvesaro *et al.,* 1998).

Immunoglobulin Family Members

There is good evidence for expression of receptors of the Ig family in osteoclasts precursors. Functional evidence implies ICAM-1 and VCAM-1 in osteoclast development *in vitro* (Feuerbach and Feyen, 1997; Harada *et al.,* 1998; Nakayamada *et al.,* 2003) and as discussed in the osteoblast section later in this chapter, osteoclast precursors, i.e., monocytes, not only express ICAM-1, but also its ligand LFA-1, allowing for cell–cell adhesion and possibly cell fusion (Harada *et al.,* 1998). Now that osteoclasts can be generated in absence of osteoblasts in defined cultures with RANKL and M-CSF, it will be possible to study in more detail the expression and functional role of this important class of adhesion molecules during osteoclast differentiation and in mature osteoclasts.

Syndecans

There is no published information about expression of syndecans in mature osteoclasts or for a role during osteoclast development.

CD44

CD44, for which several possible ligands are expressed in bone (Tables II and VII), is highly expressed in osteoclasts *in vivo* (Athanasou and Quinn, 1990; Hughes *et al.,* 1994; Nakamura *et al.,* 1995; Nakamura and Ozawa, 1996) and in osteoclasts generated *in vitro* (Flanagan *et al.,* 2000). Detailed studies of sites of expression have so far been confined to rodent osteoclasts where expression is at the basolateral membrane, rather than the clear zone or ruffled border of resorbing osteoclasts (Nakamura *et al.,* 1995). Kania and coworkers (1997) described that mouse osteoclast formation *in vitro* was inhibited by CD44 antibodies, whereas the resorptive capacity of mature osteoclasts was not affected and these *in vitro* data were confirmed when it was demonstrated that the interaction between CD44 and osteopontin is involved in osteoclast migration, fusion, and bone resorption (Suzuki *et al.,* 2002; Chellaiah *et al.,* 2003). However, two independently generated CD44 null mice show no differences in osteoclast formation, fusion, or bone resorption and only small differences in bone mass and anatomy (Cao *et al.,* 2005), suggesting that there is an increased level of complexity and redundancy in the actions of CD44 *in vivo*. This has also been highlighted by the finding that the role of CD44 in osteoclast formation *in vitro* is dependent on the culture substrate and that it plays no role when cells are grown on bone (de Vries *et al.,* 2004). In contrast, Hayer *et al.* (2005) have demonstrated a more complex relationship between CD44 and TNF-mediated inflammation; in their knockout model, increased osteoclast numbers and functional activation led to inflammatory bone loss. Because CD44 is expressed on circulating osteoclast precursors, such as $CD14^+$ cells (Kindle *et al.,* 2006), it is possible this receptor plays a role in homing to sites of future resorption (discussed later in the chapter).

Selectins

So far there are no reports describing expression of selectins on mature osteoclasts. Selectins are likely, however, to have a role during osteoclast development. Osteoclast precursors are present in the circulation and mature osteoclasts can be generated *in vitro* from mononuclear cells in blood. It remains unclear how osteoclast precursors *in vivo* reach the sites in bone where they differentiate into fully active osteoclasts, but this must at some point include extravasation, a process that, for all lymphoid cells at least, initially involves selectin-mediated interaction with endothelial cells, followed by integrin-mediated processes. Osteoclast-endothelial interactions are clearly important in osteoclast homing (McGowan *et al.,* 2001; Kindle *et al.,* 2006), and CD44 as well as ICAM-1/β_2 integrin interactions have been implicated in osteoclast precursor-endothelial adhesion and transmigration (Kindle *et al.,* 2006). The role of selectins in this setting remains unexplored. No obvious bone abnormalities

have been reported in the selectin null mice. However, mice lacking E-selectin or E- and P-selectin show accelerated development of collagen-induced arthritis in mice, demonstrating a clear role for selectins in inflammation-induced joint disease (Ruth *et al.,* 2004) even though this seems largely mediated through enhanced lymphocyte recruitment to the site. The role of selectins in recruitment of osteoclast precursors deserves further detailed study as modulation of selectin-ligand binding might offer therapeutic potential in diseases where osteoclast formation is increased.

Adhesion Molecules and Osteoclast Development

The question of which adhesion receptors are expressed during the development of osteoclasts from stem cells to committed, mononuclear, postmitotic precursors has been difficult to address *in vivo*. This, in part, reflects the difficulty in isolating these cells from bone, prior to fusion, although they are identifiable within the periosteum of developing bone anlagen as TRAP-positive, calcitonin-binding mononuclear cells that express $\alpha_v\beta_3$. Evidence has been gained by using antibody or peptide inhibition in short-term murine and human peripheral blood or bone marrow cultures. Interpretation of such studies can prove problematic, as inhibitory effects can easily be indirect via other cell types critical for osteoclast differentiation, such as osteoblasts or marrow stromal cells. Nevertheless, rodent osteoclast development *in vitro* is inhibited by the RGD-containing snake venom protein echistatin (Nakamura *et al.,* 1998a), implying a role for the vitronectin receptor or other RGD-sensitive integrin receptors. In contrast, osteoclast size or numbers are not altered greatly in rodents treated chronically with $\alpha_v\beta_3$ antagonists, suggesting no major influence on osteoclast differentiation or fusion *in vivo* as does the fact that the *formation* of multinucleated osteoclasts, albeit not their resorptive function, proceeds normally in β_3 knockout mice (McHugh *et al.,* 2000). $\alpha_v\beta_5$ integrin is expressed in osteoclast precursors such as immature bone marrow macrophages (Inoue *et al.,* 1998, 2000), but no longer present at high levels in mature osteoclasts; again knockout studies imply a more subtle role for β_5 in osteoclast biology *in vivo*, as there is no overt bone phenotype of the β_5 knockout at birth (Sheppard, 2000). Studies with antibodies to $\alpha_2\beta_1$ (Helfrich *et al.,* 1996), presently limited to resorption and adhesion assays, suggest that a role in osteoclast fusion for this class of integrin is a distinct possibility. E- (but not P- or N-) cadherin has been reported to be expressed by human and rodent osteoclasts (Mbalaviele *et al.,* 1995, 1998). Function-blocking antibodies to E-cadherin and adhesion blocking "HAV peptide" inhibit osteoclast formation and fusion *in vitro*, as well as resorption by mature osteoclasts, supporting the view that this class of receptor may be active *in vivo* (Mbalaviele *et al.,* 1995; Ilvesaro *et al.,* 1998). However, because there is strong evidence for many cadherin types in osteoblasts (see later; Chapter 18), indirect effects may be more likely. There is also some initial evidence for the involvement of the β_2 integrins Mac-1 and LFA-1 and α_4 and their respective counterreceptors ICAM-1 and VCAM-1 (Kurachi *et al.,* 1993; Duong *et al.,* 1994, 1995; Tani-Ishii *et al.,* 2002). The expression and possible role of CD44 was discussed earlier and clearly this molecule is expressed during differentiation and may have a role *in vivo* in homing of osteoclast precursors. Osteoclast cultures from isolated monocytes ($CD14^+$) with synthetic RANKL and MCSF allow for more careful monitoring of adhesion receptor expression by PCR and/or immunostaining. In these cultures no contamination with other cell types occurs. There has not, as yet, been a comprehensive study focused on adhesion molecules in this setting. Better knowledge of the range of adhesion receptors involved in osteoclast maturation prior to terminal function is important, as is further knowledge of the receptors that allow transendothelial migration and access to resorption sites. Inappropriate levels of such receptors may lead to imbalances in precursor numbers and could lead to imbalance in bone resorption.

Adhesion Molecules and Function of the Osteoclast Clear Zone

Osteoclasts resorb bone after a series of cellular polarization events (Fig.1). These compartmentalize the cell and are essential for bone resorption to proceed. After osteoclast attachment to the bone surface, the cell initiates a cytoskeletal rearrangement and creates a zone that separates the dorsal (basolateral) and ventral plasma membranes (Fig. 1a and 1c). This clear, or "sealing," zone is "organelle free" (hence the term *clear zone*), rich in actin filaments and is closely apposed to the bone surface (Holtrop and King, 1977). There has been some controversy recently about the exact mechanism that leads to the formation of the sealing zone. Early work by Väänänen and coworkers suggested that the sealing zone is derived from the "fusion" of podosomes (Lakkakorpi and Väänänen, 1991, 1996). Podosomes are actin-rich structures of cell-matrix adhesion and matrix degradation that are mainly formed by cells of the monocyte lineage. They are enriched in integrins and have unique two-part architecture: a core of F-actin and actin-associated proteins that is surrounded by a ring of plaque proteins such as talin or vinculin (Linder and Aepfelbacher, 2003). This structure is very reminiscent of the sealing zone, which is formed by a circular band of actin (Fig. 1a) surrounded by a double ring of vinculin (Väänänen *et al.,* 2000 and Chapter 8). Osteoclasts plated on glass or plastic form podosomes belts, which are enriched in matrix metalloproteases (Sato *et al.,* 1997; Delaissé *et al.,* 2000). Work by Jurdic and coworkers has shown that in mature osteoclasts these podosome belts are only

formed in cells plated on glass, whereas bone-resorbing osteoclasts form sealing zones (Saltel *et al.,* 2004). These results imply that the sealing zone is a unique structure that is related to, but not derived from, podosomes. However, more recent work using electron microscopy to analyze the sealing zone structure indicates that the structural units between individual podosome and sealing zone are very similar, the main difference being their density and interconnectivity (Luxenburg *et al.,* 2007).

The sealing zone of resorbing osteoclasts maintains close apposition to the bone surface and encloses the secretory ruffled border "isolating" the acidic microenvironment of the resorption lacuna (Fig. 1c and see Chapter 8). Protons and proteases cross the ruffled border and solubilize the adjacent bone matrix through demineralization and proteolytic activity. Subsequently, bone matrix, including calcium and type I collagen fragments, are liberated and a resorption compartment forms beneath the cell. Osteoclasts use transcytosis to remove degraded matrix from the active sites of bone resorption (Nesbitt and Horton, 1997; Salo *et al.*, 1997, Vääräniemi *et al.,* 2004), enabling the osteoclast to maintain the integrity of the enclosed resorption site and facilitate cell migration and penetration into bone. Degraded bone matrix is endocytosed along the ruffled border and transported through the osteoclast in a vesicular pathway toward the basolateral surface of the cell; finally it enters the extracellular space via a specialized exocytotic site located at the cell apex (Salo *et al.,* 1996).

The fact that the resorption area must maintain the microenvironment enabling bone resorption, i.e., acid pH and high concentration of proteases, leads to the suggestion that a specialized adhesion structure in the sealing zone mediates proton impermeable tight attachment to the bone surface. Over the years several adhesion molecules have been proposed as candidates (see also previous section on cadherins in osteoclasts). The finding that osteoclast attachment to matrix-coated glass or bone is interrupted by integrin inhibitors led to the suggestion that the osteoclast tight seal may be mediated by integrins. Some data has supported the view that $\alpha_v\beta_3$ is enriched in clear zones of resorbing osteoclasts (Reinholt *et al.,* 1990; Hultenby *et al.,* 1993; Nakamura *et al.,* 1996a), as well as podosomes of osteoclasts cultured on glass (Zambonin-Zallone *et al.,* 1989; reviewed in Aubin, 1992). Others, however, have been unable to confirm this finding, reporting that vitronectin receptor is undetectable in the sealing zone (Lakkakorpi *et al.,* 1991, 1993; Nakamura *et al.,* 1999; Duong *et al.,* 2000). We (Väänänen and Horton, 1995) have argued previously that the dimensions of the integrin molecule, when compared to a membrane to bone gap of 2 to 10 nm, precludes a direct involvement of integrins in the maintenance of a "tight seal" during resorption, as opposed to a role in initial osteoclast attachment and cell movement that is not in dispute. Additionally, the finding that formation of the sealing zone is dependent only on the presence of apatite crystals also points to an unknown adhesion molecule (Saltel *et al.,* 2004). The molecular mechanism of the *attachment* process in the established clear zone of a resorbing, nonmigratory osteoclast thus remains to be established (Väänänen and Horton, 1995; Saltel *et al.,* 2004) and is likely to involve both cell autonomous characteristics of the osteoclast in combination with chemical and physical features of the bone matrix (Nakamura *et al.,* 1996b), as described later.

Early work by Lucht suggested, using an *in vivo* model, that there is no tight sealing zone as the endocytic marker, horseradish peroxidase, could be detected in the ruffled border area as early as five minutes after injection into the animal (Lucht, 1972). However, the generation of a low pH zone underneath the actively resorbing osteoclast, against a substantially different surrounding media, requires the presence of a diffusion barrier. An alternate hypothesis is that the apposition of the osteoclast to the bone surface is not as tight as predicted, less than with high resistance, ion-impermeable epithelial tight junctions, and that the restriction of ionic movement from under the resorbing osteoclast is a combined feature of substrate (i.e., bone matrix) and osteoclast activity. Proton pumping by the osteoclast alters the properties of the bone surface (Delaissé *et al.,* 1987; Everts *et al.,* 1988), which one could envisage would result in swelling and physico-chemical modification of the extracellular matrix. In fact, incubation of type I collagen under mild acidic conditions *in vitro* leads to the formation of a gel (Chandrakasan *et al.,* 1976), a process that one could also envisage taking place *in vivo* within the resorption pit. The generation of a collagenous gel at the resorption site would have a triple effect: (1) acting as a diffusion barrier by increasing the viscosity of the medium in immediate apposition to the resorption site and this in turn would decrease the diffusion coefficient of all substances in this area; (2) acting as ion exchange matrix, as, because of the basic pI of collagen, the resorption pit would acquire an overall positive charge that could serve as a trap for negatively charged molecules; and (3) providing a matrix for hydrophobic interactions through the high content of nonpolar amino acid residues (~74%) in type I collagen. Released protons are likely to be tethered readily to the inorganic components of the bone matrix, which would reduce their free concentration and their mobility. As a consequence, a localized low pH zone would be established only at the site of proton release that could be sufficient to activate secreted lysosomal enzymes (Fig. 2). The presence of such a pH gradient has also been suggested to accommodate the different pH requirements of collagenase and lysosomal enzymes in the resorption area (Delaissé *et al.,* 1993). During the resorption process, the low pH zone, followed by the collagenous gel zone, would advance further into the bone matrix thus providing a localized microenvironment for bone resorption without the need for a static, lateral tight seal. An efficient osteoclast endocytotic mechanism would be responsible for the removal of the reaction products before they leave the resorption area by

diffusion (Fig. 2). In keeping with our model, negatively charged molecules with *Mw* up to 10,000 rapidly accumulate underneath actively resorbing osteoclasts. Live cell imaging shows that accumulation underneath the osteoclasts occurs as early as 30 sec after the addition of the low molecular weight markers (Stenbeck and Horton, 2000). As a consequence, in bone-resorbing osteoclasts externally added fluid phase markers are only endocytosed if they have access to the resorption area (Stenbeck and Horton, 2004). We could show that after internalization, these fluid phase markers follow a similar intracellular route as the digested bone matrix and we therefore used them to establish the kinetics of trafficking events originating at the ruffled border. Endocytosis and transcytosis from the ruffled border are fast processes, with a half-life of the endocytosed material inside the cells of 22 minutes (Stenbeck and Horton, 2004), providing further evidence for the dynamic model of the sealing zone (summarized in Fig. 2).

This dynamic model also accounts for the apparently contrary role of integrins in osteoclast resorption and fits well with structural features of the sealing zone (Nakamura *et al.,* 1996a; Luxenburg *et al.,* 2007). Without the need for a sterically close membrane-matrix contact zone, integrins could well be involved in the establishment and functioning of the sealing zone, in addition to their role in initial cell attachment and migration (Väänänen and Horton, 1995). Additionally, an attractive possibility is that integrins function as endocytic matrix receptors. Integrins, like the receptor $\alpha_v\beta_3$, are constantly endocytosed and recycled back to the plasma membrane making them ideal candidates for this function (Bretscher, 1996; Lawson and Maxfield, 1995). This cycling process is thought to promote cell motility by providing "fresh" adhesion receptors at the leading edge of the cell (Pellinen and Ivaska, 2006). However, several integrins have also been shown to regulate matrix turnover by endocytosis of bound ligand, which is then targeted for degradation (Ng *et al.,* 1999). This pathway is also used by several pathogens to gain access to host cells; and in an epithelial cell model transport of adenovirus across cells was increased by RGD peptides (Ivanenkov and Menon, 2000). If osteoclasts use a similar RGD-dependent mechanism in transcytosis, then candidate receptors involved in the uptake of bone matrix at the ruffled border would include $\alpha_2\beta_1$ and $\alpha_v\beta_3$ integrins that, respectively, bind native and denatured collagens (Nesbitt *et al.,* 1993; Helfrich *et al.,* 1996). Proteolysis of collagenous matrix exposes cryptic RGD sites (Holliday *et al.,* 1997) during bone resorption, and engagement with $\alpha_v\beta_3$ integrin could initiate endocytosis and subsequent transcytosis of denatured collagenous matrix. Conversely, higher concentrations of RGD peptides, produced after extensive matrix proteolysis, could inactivate matrix transcytosis and, thus, lead to cessation of resorption.

Another group of collagen-binding proteins in osteoclasts (Nesbitt *et al.,* 1994) are the annexins, a family of calcium-dependent phospholipid-binding proteins that exhibit a wide tissue distribution (reviewed by Raynal and Pollard, 1994). Annexins have been shown to participate in endocytosis, transcytosis, and exocytosis in several polarized cells (Creutz, 1992; Burgoynee, 1994; Futter and White, 2007), in addition to their role in a number of other cellular processes (Gerke *et al.,* 2005). Evidence shows that annexin II participates in matrix transcytosis during bone resorption (Nesbitt and Horton, 1999). It is found at the cell surface of resorbing osteoclasts and co-localizes with degraded bone matrix in the resorption pit; it is also highly expressed within the basolateral cell body and at apical exocytotic sites. Furthermore, the addition of exogenous annexin II to resorption cultures increases transcytosis of bone matrix and bone resorption by osteoclasts (Nesbitt and Horton, 1999). The ability of annexins to associate with membrane phospholipids in a calcium dependent

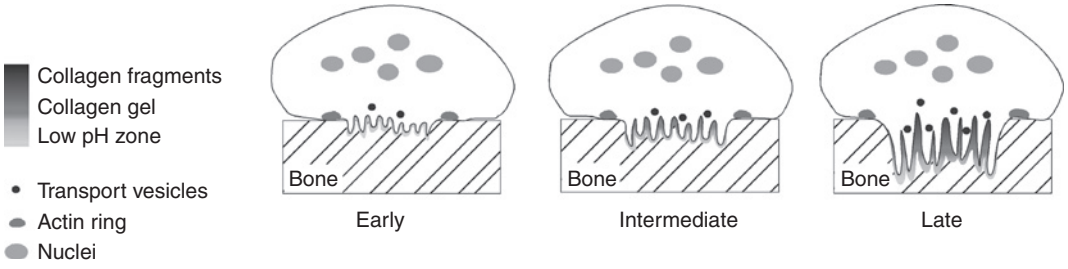

FIGURE 2 Model of the osteoclast sealing zone. During the early stages of resorption, the proton pump (VATPase) is inserted into the osteoclast plasma membrane that is enclosed by the actin ring (green). Proton extrusion by the VATPase leads to the formation of a localized low pH zone that dissolves the mineral content of the bone (yellow area). Proton movement is restricted by binding to hydroxyapatite. Lysosomal enzymes, secreted during the intermediate stages of resorption, digest the organic content of the bone in the low pH zone (red area). In the later stages of resorption, the ruffled border expands deep into the bone matrix by fusion of transport vesicles with the plasma membrane. The low pH zone moves with expansion of the ruffled border further into the bone matrix. The area behind the low pH zone consists of a collagenous "gel" that is endocytosed by the osteoclast (dark brown). This further restricts solute diffusion from below the osteoclast. However, because the net concentration of secreted and resorbed components is a balance between generation rate and limited diffusion rather than the presence of an impermeable barrier, externally added small molecules have access to the resorption area. Modified from Stenbeck and Horton (2000), with permission.

manner enables them to functionally organize membrane domains and recruit interacting proteins to these domains (Gerke *et al.,* 2005). It is thus tempting to speculate that annexins might be involved in formation and maintenance of the sealing zone by binding to hydroxyapatite and/or organization of the actin cytoskeleton (Hayes *et al.,* 2004), in addition to their function in osteoclast transcytosis. However, a detailed analysis of the role of annexins and integrins in matrix transcytosis and sealing zone maintenance has to await the possibility of performing live cell imaging of integrin turnover and annexin trafficking in bone-resorbing osteoclasts.

$\alpha_v\beta_3$-Mediated Signal Transduction

Signal transduction through osteoclast integrins is complex and discussed in detail in Chapter 9. Here we only introduce the key players involved in $\alpha_v\beta_3$ mediated signaling pathways associated with osteoclast polarization and rearrangement of the actin cytoskeleton that, as discussed before, is essential for bone resorption. A number of candidate molecules, such as c-Src, phosphatidylinositol 3-kinase (PI-3 kinase), FAK, and Pyk2, are expressed at high levels in osteoclasts (reviewed in Duong *et al.,* 2000; Golden and Insogna, 2004). c-Src knockout mice have severe osteopetrosis owing to lack of ruffled border formation in osteoclasts, clearly implicating this molecule in signaling cascade leading to polarization of osteoclasts (Soriano *et al.,* 1991). PI-3 kinase has been shown to be associated with the cytoskeleton in osteoclasts when attached to bone matrix and is associated with the β_3 subunit in bone-adherent osteoclasts (Lakkakorpi *et al.,* 1997). The importance of FAK in osteoclast function has been queried because no osteoclast abnormalities are seen in the FAK knockout mouse (Ilic *et al.,* 1995). However, Pyk2, another molecule of the FAK family with high homology to FAK and a similar role as adaptor protein orchestrating cytoskeletal architecture (Xiong and Feng, 2003), is highly expressed in osteoclasts (Tanaka *et al.,* 1995a) and seems to fulfill the role that FAK plays in less motile cell types (Duong *et al.,* 1998). Pyk2 has been shown to interact with gelsolin, an actin-binding protein involved in the formation of adhesive structures in osteoclasts and in bone resorption (Wang *et al.,* 2003; Chellaiah *et al.,* 2000). Following engagement of $\alpha_v\beta_3$ with ligand, clustering of the receptor occurs and association of its cytoplasmic domain with a complex containing Pyk2 and $p130^{CAS}$ (Lakkakorpi *et al.,* 1991). Autophosphorylation of Pyk2 then leads to recruitment of c-Src and ultimately to cytoskeletal reorganization and bone resorption (Duong *et al.,* 2000; Lakkakorpi *et al.,* 2003). Activated c-Src also recruits and phosphorylates c-Cbl, which binds to the SH3 domain of c-Src and negatively regulates Src kinase activity (Tanaka *et al.,* 1996). It is suggested that this may enable transient adhesion and allow for cell migration, a process critically dependent on turnover of adhesive structures (Sanjay *et al.,* 2001). In addition, the Src-dependent phosphorylation of c-Cbl has been shown to be critical for osteoclastic resorption (Miyazaki *et al.,* 2004). In c-Src null osteoclasts, Pyk2 has been shown to associate with PLC-γ, a process that can be induced not only by adhesion, but also by M-CSF, and can lead to recruitment of integrin to adhesion contacts and cytoskeletal reorganization (Nakamura *et al.,* 2001). More recently, a number of additional molecules in this signaling cascade have been identified, largely through loss of function studies. The tyrosine kinase Syk and the Rac-specific guanidine exchange factor Vav3 were identified as key molecules downstream of $\alpha_v\beta_3$ in osteoclasts (Miyazaki *et al.,* 2004; Faccio *et al.,* 2005). The Syk knockout mouse displays a similar osteoclast phenotype to the Src knockout with absence of polarization *in vitro* and loss of osteoclast adhesion to bone *in vivo*. The Vav3 knockout is also osteopetrotic and, similar to the $\alpha_v\beta_3$ knockout mouse, protected from bone loss induced by systemic pro-resorptive stimuli. Zou and coauthors (2007) recently showed that activated $\alpha_v\beta_3$ recruits Syk, which is then phosphorylated by c-Src, mediated by two other crucial receptors, Dap 12 and FcRγ, and that this leads to cytoskeletal reorganization mediated by Vav3. Clearly, $\alpha_v\beta_3$ signaling is complex, but careful dissection of the pathways has already pointed to crucial nonredundant mediators of polarization and hence ability to resorb, and such molecules are clear candidate targets for antiresorptive therapies (see also Teitelbaum, 2007).

$\alpha_v\beta_3$ Integrin as a Therapeutic Target for Bone Disease

Early Studies and Rationale

Osteoporosis places a large and growing medical and financial burden on health services in developed countries; however, it remains a clinical area where, despite recent advances in therapy and diagnosis, there are still unmet needs. Although potent drugs have been developed, e.g., bisphosphonates (see Chapter 78), the pharmaceutical industry is still developing novel antiresorptive agents. The $\alpha_v\beta_3$ vitronectin receptor presents a key step in the process on bone resorption (as discussed earlier), which is being exploited by the pharmaceutical industry. In part this optimism is underscored by the finding that polymorphisms in the β_3 gene confer an increase in hip fracture (Tofteng *et al.,* 2007).

The development (for reviews, see Horton and Rodan, 1996; Hartman and Duggan, 2000; Miller *et al.,* 2000; Meyer *et al.,* 2006; Tucker, 2006) of a number of orally active, nonpeptidic integrin antagonists, particularly based on modification of the RGD peptide motif identified in fibronectin by Pierschbacher and Ruoslahti in 1984, suggests that treatment of a range of bone diseases may be susceptible to strategies that involve the blockade of integrin

function or modulation of their expression. The development of $\alpha_v\beta_3$ antagonist drugs has been aided considerably by the prior existence of an analogous set of agents that have been developed for use in thrombosis (see references in Hartman and Duggan, 2000; Miller *et al.*, 2000); here, the platelet integrin fibrinogen receptor, gpIIbIIIa/$\alpha_{IIb}\beta_3$, which is structurally related to the $\alpha_v\beta_3$ integrin on osteoclasts and shares the same β chain, is targeted. These were the first of the integrin antagonist "drugs" that have been approved for clinical use (Coller, 1997; Phillips and Scarborough, 1997; Theroux, 1998) and they form the paradigm for potential application to bone disease.

The functional role of $\alpha_v\beta_3$ in osteoclast biology, first examined by Horton and colleagues in antibody studies over a decade ago, has been confirmed in a large battery of *in vitro* systems and *in vivo* proof of concept studies (as discussed earlier). Target specificity is aided by the *in vivo* distribution of $\alpha_v\beta_3$, which is expressed at high levels in osteoclasts (Horton, 1997). Much lower levels are found in platelets and megakaryocytes, kidney, vascular smooth muscle, some endothelia, and placenta (Horton, 1997). Thus, the therapeutic drug levels that would influence osteoclastic bone resorption are less likely to modify $\alpha_v\beta_3$ function at other sites. In certain pathological situations, though, tissue levels of $\alpha_v\beta_3$ are increased; for example, tumor microvessels show increased levels of $\alpha_v\beta_3$, as do melanoma cells when they metastasize (Horton, 1997), and these features are being exploited.

Strategies for Therapeutic Modification of Integrin Function

From basic principles, there are two main strategies for inhibiting cell adhesion molecule function therapeutically (Table IV). First, a direct approach: competitive antagonists of the receptor–ligand interaction can be developed, and this has been the usual pharmaceutical approach with the aim of producing orally active, synthetic nonpeptide mimetic agents. They have been identified by a variety of standard industry techniques, as summarized in Table IV

TABLE IV Strategies for Therapeutic Modification of Integrin Adhesion Receptor Function *in Vivo*

Direct approaches
Naturally occurring protein inhibitors and their engineered derivatives (e.g., RGD-containing snake venoms and proteins from ticks, leeches, etc.)[a]
Blocking antibodies, and their engineered derivatives, to adhesion molecules[b]
Arg-Gly-Asp (RGD) peptides and their chemical derivatives (e.g., designed to improve specificity and stability)[c]
Nonpeptidic mimetics,[d] produced via different compound selection strategies[e]
Indirect approaches
Altered receptor synthesis via use of antisense oligonucleotides[f]
Inhibition of adhesion receptor expression via regulatory cytokines and their receptors
Modification of integrin receptor function via regulatory integrin-associated proteins
Modulation of integrin receptor affinity (i.e., activation) for ligands
Modification of downstream receptor-associated signaling (e.g., c-Src and other kinases, adhesion-associated apoptosis genes)

[a] *Echistatin has been used as a proof of concept inhibitor of $\alpha_v\beta_3$ in bone disease studies (Fisher et al., 1993; Yamamoto et al., 1998). Barbourin snake venom protein contains* KGD *instead of* RGD *and is the basis of selective inhibitors of platelet gpIIbIIIa (Phillips and Scarborough, 1997).*

[b] *Antibodies to gpIIbIIIa (i.e.,* 7E3, ReoPro, Centocor Inc*) formed the first cell adhesion receptor inhibitor licensed for clinical use (in the various vascular/thrombotic condition, see Tcheng, 1996; Coller, 1997). A humanized $\alpha_v\beta_3$ antibody (*Abegrin, *clone* LM609; Vitaxin^R*) has been tested in clinical trials for cancer acting via induction of apoptosis in tumor vessels (Mulgrew et al., 2006; Gramound et al., 2007).*

[c] *Integrilin (*Cor Therapeutics Inc*), a cyclic* KGD*-containing peptide gpIIbIIIa inhibitor, is in clinical trial (Phillips and Scarborough, 1997; Coller, 1997), as are* RGD*-derived cyclic peptides with selectivity for $\alpha_v\beta_3$ [cyclic* RGDfVA, E. Merck *(Haubner et al., 1996; Smith, 2003)].*

[d] *A number of companies have intravenous and orally active nonpeptidic gpIIbIIIa antagonists in clinical trial for platelet-related disorders (Phillips and Scarborough, 1997; Coller, 1997; Theroux, 1998). Analogous mimetics are in late preclinical development for inhibition of $\alpha_v\beta_3$ (Horton and Rodan, 1996; Hartman and Duggan 2000; Miller et al., 2000) in bone disease and cancer and one non-peptidic agent has been tested in patients with osteoporosis (Murphy et al., 2005).*

[e] *Structure–function, combinatorial chemistry, phage display, compound/natural product library screening, etc. (Lazarus et al., 1993; Pasqualini et al., 1995; Corbett et al., 1997; Hoekstra and Poulter, 1998).*

[f] *Antisense therapeutics directed against adhesion receptors are in clinical trials; antisense oligonucleotides to α_v block bone resorption in vitro (Villanova et al., 1999).*

(e.g., see Ferguson and Zaqqa, 1999; Wang *et al.,* 2000). Other approaches, such as using receptor-specific antibodies, peptides, and naturally occurring protein antagonists, together with molecular engineering, have generally been used in proof of principle experiments rather than as clinical drug candidates, although there are some notable examples of protein therapeutics in the field (for examples, see Table IV). Directly acting antagonists have entered clinical trial to modify activation-dependent platelet aggregation in thrombotic conditions via the integrin platelet fibrinogen receptor, gpIIbIIIa/$\alpha_{IIb}\beta_3$. Thus, groundbreaking trials [EPIC, EPILOG, etc. (Tcheng, 1996)] have demonstrated efficacy of the humanized anti-gpIIIa monoclonal antibody 7E3 (ReoPro) in various ischemic heart conditions (Coller, 1997). Results from trials with RGD mimetics [e.g., lamifiban, tirofiban (Ferguson and Zaqqa, 1999; Wang *et al.,* 2000)] and the cyclic KGD peptide integrilin have, though, been less impressive (Theroux, 1998). As with gpIIbIIIa-specific agents, the possibility of developing osteoclast $\alpha_v\beta_3$ (vitronectin receptor) antagonists as resorption inhibitors in bone disease was initially demonstrated *in vitro* using a variety of techniques to disrupt receptor function, and small molecule inhibitors of $\alpha_v\beta_3$ are now at the late stage of preclinical development or entering the early stages of clinical trial evaluation (Hartman and Duggan, 2000; Miller *et al.,* 2000; Meyer *et al.,* 2006). Thus, general principles for the use of adhesion receptor antagonists in disease have been established, and useful drugs are thus likely to be available for a wide variety of indications in the future.

The second approach is indirect, with the aim of modifying expression or intracellular function (such as signal transduction) of cell adhesion molecules, especially integrins. Some examples of such strategies are given in Table IV. The furthest advanced are the use of antisense oligonucleotide inhibitors of receptor protein synthesis with the more recent RNA interference approach to knocking down α_v expression offering promise (Graef *et al.,* 2005). Because inhibitors of ICAM-1 expression are finding promise in the treatment of various inflammatory diseases, such as of the bowel or eye, then modulation of α_v expression by an antisense approach (Villanova *et al.,* 1999) could be a fruitful strategy. Likewise, a number of agents to block the function of c-Src, a cellular kinase that acts downstream in the signaling pathway of integrin receptors in bone cells, are being developed for the treatment of osteoporosis, based on the earlier finding in knockout mice that c-Src plays a central role in osteoclastic bone resorption (Soriano *et al.,* 1991).

Current Drug Development Status of $\alpha_v\beta_3$ Antagonists for Use in Bone and Other Diseases

The action in bone models of several candidate mimetic $\alpha_v\beta_3$ antagonists has been reported by a number of companies, and their evolution has been reviewed (Hartman and Duggan 2000; Miller *et al.,* 2000; Meyer *et al.,* 2006); as yet, these are not drugs but still agents used for proof of concept and pharmaceutical experiments. Compounds based on a variety of proprietary scaffolds, which have all shown varying efficacy and specificity for $\alpha_v\beta_3$ in the number of *in vitro* screening assays, have inhibitory effects on the calcemic response in thyroparathyroidectomized rodents and bone-sparing responses in ovariectomy and other rodent models of increased bone turnover. Positive findings in proof of concept studies using small molecule mimetics in models of bone metabolism underline $\alpha_v\beta_3$ antagonists as promising candidates for a new class of bone disease therapeutics, although they still require optimization. Furthermore, the expression, albeit at lower levels, of $\alpha_v\beta_3$ in other tissues suggests that their inhibition could produce unwanted side effects: for example, will they, on chronic administration, interfere with wound healing, the function of the related α_v integrins in respiratory tract or intestinal epithelium, or platelet ($\alpha_{IIb}\beta_3$-mediated) aggregation?

Humanized complex-specific monoclonals antibodies to $\alpha_v\beta_3$ have been developed and tested in cancer models and patients with solid tumors and bone metastasis (Mulgrew *et al.,* 2006; Gramoun *et al.,* 2007) where there is upregulated $\alpha_v\beta_3$ but not to the levels seen in osteoclasts. These antibodies are known to block bone resorption *in vitro* but they have not been developed in bone resorption models or patients.

Finally, although $\alpha_v\beta_3$ antagonists have been developed for use in bone diseases, other clinical targets also show promise (such as rheumatoid arthritis, angiogenesis in eye diseases and cancer, vascular restenosis following coronary angioplasty, and direct targeting of tumors expressing $\alpha_v\beta_3$). These are all being investigated for possible new applications of $\alpha_v\beta_3$ antagonist drugs.

Drug candidates with optimized pharmacokinetics/dynamics have entered clinical trial for bone disease and for other indications where $\alpha_v\beta_3$ is involved in disease pathogenesis. The Merck compound L-000845704 has been tested in a multicenter trial and efficacy at the spine and hip was demonstrated indicating that $\alpha_v\beta_3$ antagonists could be developed for the treatment of osteoporosis (Murphy *et al.,* 2005).

$\alpha_v\beta_3$-Based Clinical Imaging Tools

The high expression of $\alpha_v\beta_3$ by osteoclasts together with selective interaction to its ligands, such as RGD and peptidomimetics, have been used to develop "integrin-specific" imaging probes for use in a variety of diseases, including various forms of cancer, angiogenesis, and bone metastasis (reviewed in Lim *et al.,* 2005). These include ^{64}Cu labeled cyclic RGD peptides (Sprague *et al.,* 2007), ^{18}F-cycRGD SPECT/PET radiotracers (Sprague *et al.,* 2007), ^{111}In labeled peptidomimetic (Harris *et al.,* 2007, Jang

et al., 2007), and $\alpha_v\beta_3$ complex-specific antibodies (Cai *et al.,* 2006).

OSTEOBLASTS

Expression and Role of Adhesion Molecules in Bone formation

Osteoblasts are uniquely involved with the synthesis and maintenance of the bone matrix and lie in direct contact with the specialized extracellular matrix of bone. They also form cell–cell adhesive contacts (see Chapter 18) with other osteoblasts, but also with osteocytes embedded within the bone matrix. In their terminally differentiated form as osteocytes, they are completely surrounded by extracellular matrix and respond to mechanical forces exerted on the skeleton, suggested to be transmitted via adhesive interactions with matrix and/or between osteocytes within their vast network (see Chapter 6 and discussions by Wang and Ingber, 1994; Ruoslahti, 1997). There is also some data on the matrix in the osteocyte lacunae, including adhesion proteins synthesized by osteocytes themselves (Aarden *et al.,* 1996a and references therein).

It is increasingly clear that cell adhesion receptors play important roles in the function of cells in the osteoblast lineage. Some of the possible roles of adhesion receptors in osteoblasts are listed in Table I. Later, we discuss the expression (Table V) and known function of integrins and the other classes of adhesion molecules in osteoblasts and osteocytes and, where known, in their precursor, the mesenchymal stem cell.

TABLE V Integrin and Other Receptors Expressed by Mature Mammalian Osteoblasts[a]

	Receptor/integrin chain
Present[b,c,d]	$\alpha_v\beta_3$, $\alpha_v\beta_5$, $\alpha_v\beta_6$, $\alpha_v\beta_8$ ("vitronectin receptors") α_{1-5} associated with β_1 α_{10}–a_{11} associated with β_1 E-Cadherin, Cadherin 4 and 11 and N-cadherin ICAM-1, ICAM-2, V-CAM, LFA3, and N-CAM Syndecan 1, 2, 3, and 4 CD44H
"Not detected"[e]	β_2 and CD11, a, b, c, α_d β_4

[a] *Data summarized from immunological and biochemical analysis of human and rodent species and gene deletion studies (as discussed in the main text). Data focus on osteoblasts; there are no comprehensive studies in mammalian osteocytes.*
[b] *Definitive proof of the association of individual integrin subunits in dimers is not always available. $\alpha_5\beta_1$ is the most abundant integrin expressed in osteoblasts and osteocytes. $\alpha_v\beta_5$ is the most important vitronectin receptor on osteoblasts. There is no definitive proof for expression of the other vitronectin receptors in vivo.*
[c] *In vivo ICAM-1 appears confined to bone lining cells (Everts et al., 2002).*
[d] *Osteocytes express high levels of CD44H.*
[e] *A subpopulation of bone marrow stromal cells has recently been shown to express functional β_2 integrin (Miura et al., 2005).*

Integrins

A diverse range of integrins have been shown to be expressed by osteoblasts (Table V), especially β_1 and β_5 integrins (Horton and Davies, 1989; Brighton and Albelda, 1992; Clover and Gowen, 1992; Clover *et al.,* 1992; Hughes *et al.,* 1993; Majeska *et al.,* 1993; Grzesik and Gehron Robey, 1994; Pistone *et al.,* 1996; Ganta *et al.,* 1997; Gronthos *et al.,* 1997; reviewed by Bennett *et al.,* 2001a). β_2 and β_4 integrins have not been reported in osteoblastic cells. Cultured human primary osteoblasts also express $\alpha_v\beta_6$ and $\alpha_v\beta_8$ integrin (Lai and Cheng, 2005). There remains some contradiction between different studies as to the specific β_1 heterodimers expressed. This may reflect the heterogeneity of osteoblast-like populations (see Chapter 4) and includes the possibility that cells at successive stages of osteoblast differentiation, or from fetal or adult bone, or from different anatomical sites, or actively synthesizing osteoblasts, versus quiescent cells, show different patterns of integrin expression. In addition it has been clearly demonstrated that *in vitro*, the substrate on which cells are cultured directly influences the pattern of integrin expression by osteoblasts (Sinha and Tuan, 1996; Gronowicz and McCarthy, 1996). Generally, cultured osteoblasts express a wider integrin repertoire than osteoblasts *in situ* (Clover *et al.,* 1992; Grzesik and Robey, 1994) and in particular increased expression of the vitronectin receptor $\alpha_v\beta_3$ is seen. A new class of integrin ligands, the CCN proteins (for review see Leask and Abraham, 2006), have been found to be important in bone and cartilage formation and during fracture repair. These proteins can bind a range of integrins including $\alpha_v\beta_3$ and $\alpha_5\beta_1$ and are expressed by osteoblasts and chondroblasts (Schütze *et al.,* 2005). The six known CCN proteins are called matricellular proteins as they combine up to four modules allowing roles in attachment to matrix, migration, chondrogenesis, angiogenesis, proliferation, and others. In terms of adhesion, there is evidence that Cyr61 (CCN1) is involved in early osteoblast differentiation from mesenchymal cells (Si *et al.,* 2006).

It is yet unclear whether altered expression of integrins has an equivalent in bone pathology, because osteoblast integrin expression in bone disease is relatively unexplored. However, bone diseases such as Paget's disease and osteopetrosis (Helfrich, 2003) are accompanied by major changes in the numbers of "real" osteoblasts, i.e.,

osteoid synthesizing cells and hence differences in integrin expression in the overall osteoblastic population are likely. In addition, recent studies are beginning to examine the effects of mechanical stimuli on integrin expression and suggest that external stimuli may influence the integrin expression in the osteoblastic population. Expression profiling of osteoblasts during defined differentiation in culture is now possible, but no specific reports on adhesion molecule profiles have as yet been published.

Integrin expression in osteocytes has not been studied extensively, but there is some data from immunocytochemical analysis of human bone sections and from functional studies in the chick, where isolation procedures for osteocytes exist. Chick osteocytes and osteoblasts bind a comprehensive range of extracellular matrix proteins *in vitro* in a β_1- and partially RGD-dependent way (Aarden *et al.,* 1996b). The exact receptor involved was not determined, because of lack of α chain specific antibodies for avian integrins. Equally, isolated rat osteocytes have been reported to adhere to a wide range of matrix proteins, including, in an RGD-dependent way, to fibronectin, vitronectin, and osteopontin (Miyauchi *et al.,* 2006), although again the receptor involved was not formally identified. Expression of β_1 integrin has been confirmed in mammalian osteocytes (Hughes *et al.,* 1993; Gohel *et al.,* 1995), including the osteocytic cell line MLO-Y4 (Helfrich *et al.,* 2001) and $\alpha_v\beta_3$ has been reported specifically on mandibular osteocytes (Bennett *et al.,* 2001b). However, there are few definitive reports where integrin expression has been followed throughout osteoblastic differentiation to osteocytes within the same species. Difficulties in interpretation of immunocytochemical staining in bone sections, in particular for cells embedded within matrix, have been reported by many authors and this may well have contributed to the continuing controversies in integrin phenotype of osteoblasts/osteocytes. From the limited reports on isolated cells at different stages of differentiation, it has become clear that, at least in the mouse, $\alpha_5\beta_1$ is the most abundantly expressed integrin throughout osteoblastic differentiation and that, may be surprisingly, $\alpha_2\beta_1$ is expressed at much lower levels, in particular in more differentiated cells (Helfrich *et al.,* 2001). Expression of a wide range of β_1 and β_3 integrins has also been reported in mesenchymal stem cells, including β_4 integrin (Bruder *et al.,* 1998; Kuznetsov *et al.,* 2001; Majumdar *et al.,* 2003) and Stewart and coworkers (2003) recently showed that selection of α_1 integrin positive bone marrow cells markedly enriched the population of CFU-F, clonogenic precursors with osteogenic potential, confirming the importance of α_1 early in the osteoblast lineage. Current interest in differentiation of osteogenic cells from stem cells may reveal additional information on expression of integrins and other cell adhesion molecules during differentiation, an area that is still poorly understood. For example, treatment of α_7-positive myoblasts with BMP-2 resulted in differentiation along the osteogenic lineage with loss of α_7 but gain of strong expression of α_2 integrin, associated with increased binding to collagen (Ozeki *et al.,* 2006). Understanding integrin expression during osteogenic differentiation will require comprehensive studies in well-defined osteoblastic populations (both in developmental stage and in synthetic activity) combining immunocytochemical, biochemical, and molecular techniques.

Clearly β_1 and β_5 integrins are the classes of integrin receptors with the major functional role in cells of the osteoblast lineage. In keeping with this, osteoblasts adhere to osteopontin, bone sialoprotein, vitronectin, and fibronectin in an RGD-dependent way (with fibronectin requiring much higher peptide concentrations for inhibition), whereas binding to type I collagen and thrombospondin is less inhibited by RGD peptides (Puleo and Bizios, 1991; Majeska *et al.,* 1993; Grzesik and Robey, 1994). Next we discuss the role of osteoblast integrins as receptors for specific matrix proteins.

Function of Collagen Receptors

The $\alpha_1\beta_1$ and $\alpha_2\beta_1$, integrins reported to be expressed by osteoblasts are collagen binding receptors, whereas $\alpha_3\beta_1$ is a laminin receptor (Gullberg *et al.,* 1992). Collagen type 1 is the main protein of the bone matrix, and interactions involving collagen receptors are therefore strong candidates for a role in regulating osteoblast behavior. There is now abundant evidence this is indeed the case. In organ cultures of mineralizing fetal rat parietal bone RGD peptides decreased bone formation accompanied by a decrease in α_2 and β_1 expression and disruption of the organization in the osteoblast layer (Gronowics and DeRome, 1994). Downregulation of α_2 and β_1 integrin expression in osteoblasts by glucocorticoids has also been noted, accompanied by a similar disruption in osteoblast organization, whereas IGF-1 increased β_1 expression in osteoblasts and increased calcified bone formation (Gohel *et al.,* 1995; Doherty *et al.,* 1995). It has become clear that the role of osteoblast integrins extends beyond adhesion. Although the evidence for a role of fibronectin in osteoblast differentiation is strongest (see later in chapter), collagen is also implicated in osteoblast differentiation. Ascorbic acid deficiency, which leads to underhydroxylation of type I collagen, resulted in downregulation of $\alpha_2\beta_1$ in osteoblasts and dysregulation of differentiation and mineralization in cultures of rat calvaria (Ganta *et al.,* 1997). In addition, α_1 and α_2 integrins mediate differentiation signals, such as from BMP-2, in early osteoblastic cells (Jikko *et al.,* 1999); a role for $\alpha_2\beta_1$ and type I collagen in osteoblast differentiation from early progenitors was demonstrated (Mizuno *et al.,* 2000) and $\alpha_2\beta_1$ ligand binding was shown to lead to expression or upregulation of markers of osteoblastic

differentiation, such as Runx2, alkaline phosphatase, and osteocalcin (Xiao *et al.,* 1998, 2002), while blocking antibodies to α_2 modulate $\alpha_2\beta_1$-dependent expression of osteoblast markers (Takeuchi *et al.,* 1997), cell motility, and contraction of collagen gels *in vitro* (Riikonen *et al.,* 1995). These data correlated well with the higher levels of α_1 and α_2 collagen binding integrins in early stages of the lineage and reduced expression in more differentiated cells as discussed earlier.

Because β_1 integrins have a critical role in embryogenesis, not much information has been gained from studies of β_1 knockout mice, which are embryonic lethal at a time well before skeletal development begins (Fässler and Meyer, 1995; Stephens *et al.,* 1995). A transgenic mouse in which a dominant negative β_1 integrin is expressed under the control of the osteoblast specific osteocalcin promoter has, however, been very informative (Zimmerman *et al.,* 2000). *In vitro,* osteoblasts from these animals do not properly adhere to matrix, whereas *in vivo,* osteoblast and osteocyte morphology, polarity, and matrix secretion is severely affected, resulting in decreased bone mass, especially in females. Anatomical differences are found in older animals (Globus *et al.,* 2005). The tibia of the transgenic animals are straighter, consistent with the possibility that in absence of functional β_1 integrin, osteoblastic cells are not able to sense and/or respond adequately to load bearing, a stimulus that in wild-type animals results in the characteristic curvature of this long bone. Viable knockouts have been generated for α_1 and α_2 integrins. Surprisingly, neither has a prominent bone phenotype (Chen *et al.,* 2002; Holtkötter *et al.,* 2002; Ekholm *et al.,* 2002), although detailed bone histology has not been reported. It is possible that compensation occurs in these single knockouts for collagen binding integrins, because overall the absence of gross abnormalities in *any* tissue in the α_2 null was largely unexpected (Mercurio, 2002). In specific disease models, however, loss of α_1 or α_2 has revealed important functions in kidney, vascular, and inflammatory conditions (see Popova *et al*., 2007). Given the important roles of α_2 integrin in osteoblasts and osteoclasts (Helfrich *et al.,* 1996; Horton *et al.,* 2003), more detailed studies should be undertaken to elucidate further the role of α_2 integrin in the α_2 knockout mouse, using skeletal disease models. The α_1 knockout mouse does show abnormalities during fracture healing, with reduced callus formation compatible with an effect on mesenchymal precursors of chondrocytes and osteoblasts, which express high levels of this integrin (Ekholm *et al.,* 2002).

Single knockouts for β_3 and β_5 and α_v and a double knockout for β_3/β_5 have been made (see Sheppard, 2000) and none of these appear to have osteoblast malfunction. The relatively subtle defects seen in the skeleton of the β_3 knockout are caused by osteoclast malfunction and have been discussed earlier.

A number of other integrin gene deletions have demonstrated skeletal phenotypes that are likely to be caused by effects on cells of the osteoblast lineage (Brouvard *et al.,* 2001). The knockout of β_2, described earlier in the osteoblast section, unexpectedly showed that this myeloid integrin is indeed expressed in a stromal cell population and absence leads to abnormalities in cell adhesion, growth, and osteogenic differentiation, ultimately leading to an osteoporotic phenotype. Constitutive expression of β_2 on the contrary led to enhanced bone formation (Miura *et al.,* 2005). The α_4 knockout mouse (Yang *et al.,* 1995) exhibits defective closure of cranial sutures, although it is unclear whether this is because of a local osteoblast or other cell type defect.

Combined deletion of the laminin-binding integrins α_3 and α_6 (De Arcangelis *et al.,* 1999) results in severe skeletal abnormalities involving both the axial and peripheral skeleton that are not seen in single gene deletion animals; this phenotype is reminiscent of that seen on deletion of laminin α_5 gene.

Function of Fibronectin Receptors

Of the integrins that are fibronectin receptors, $\alpha_4\beta_1$, $\alpha_5\beta_1$, and α_v heterodimers are reported to be expressed in osteoblasts. Most are capable of binding fibronectin, but in addition a range of other extracellular matrix proteins, using both RGD-dependent and independent mechanisms (see Table VII). Here we focus on evidence for a functional role as fibronectin receptors.

The critical role of fibronectin in osteoblast differentiation was first demonstrated in the *in vitro* rat osteoblast nodule formation assay (Moursi *et al.,* 1996) and the importance of the central cell-binding domain of fibronectin in this effect suggested that the selective fibronectin receptor, $\alpha_5\beta_1$, was implicated. Later studies by this group also suggested a role for $\alpha_3\beta_1$ in osteoblast differentiation (Moursi *et al.,* 1997). In mature cells, $\alpha_5\beta_1$–ligand binding appears to be necessary for cell survival and receptor blockade leads to osteoblast apoptosis (Globus *et al.,* 1998).

Fibronectin is a normal constituent of human bone, but data on its distribution within the bone matrix are sparse, and it has been reported absent from mature lamellar bone (Carter *et al.,* 1991). Supporting evidence from rodent tissues suggests that fibronectin synthesis and expression are restricted to developing or immature bone (Weiss and Reddi, 1980; Cowles *et al.,* 1998). It is, therefore, possible that $\alpha_5\beta_1$–ligand interaction is a feature of bone formation during development or repair and may not play a prominent role in the turnover and maintenance of mature lamellar bone. There is, however, also some evidence for the involvement of the $\alpha_5\beta_1$ integrin in mechanical sensing by osteoblasts, at least *in vitro* (Salter *et al.,* 1997). Given this fact, the role of fibronectin and fibronectin receptors deserves further study in mature matrix synthesizing osteoblasts.

Unsurprisingly there is great interest in the orthopedics/biomaterials field in identification of bioactive surface coatings to enhance osteoblast attachment and matrix (reviewed by Siebers *et al.,* 2005). Coating of biomaterials with fibronectin has been shown to give the best adhesion of osteoblastic cells, which is completely in agreement with all data presented here. Many studies integrating adhesive proteins with micro- and nano-topography on biomaterials are underway and will increase our understanding of integrin-matrix interactions and applications in tissue engineering.

α_v Integrins

Several studies report expression of α_v in cells of the osteoblast lineage. However, the published literature varies with regard to which β subunit is utilized (the balance of data favoring $\alpha_v\beta_5$ expression), and staining appears more prominent in osteoblasts than osteocytes (Hughes *et al.,* 1993; Grzesik and Robey, 1994). Long-term glucocorticoid exposure has been shown to lead, *in vitro* at least, to downregulation of $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins in human osteoblasts, a phenomenon that together with the negative effect on β_1 integrin mentioned earlier, may help to explain the bone loss associated with long-term glucocorticoid usage (Cheng *et al.,* 2000). More recently it has become clear that the role of osteoblast integrins extends beyond adhesion. BMP-2, a potent stimulator of bone formation increases expression of the whole repertoire of osteoblast α_v integrins and the BMP-2 receptor co-localizes with integrins. The finding that blocking of the function of α_v inhibited the BMP-2 effects in osteoblast indicates that integrins may regulate BMP-2 effects in bone (Lai and Cheng, 2005) and suggests that there is potentially a wider role for integrins in facilitation growth factor signaling in bone.

Role of Integrins in Mechanosensing by Osteocytes

An area of increasing interest is that of the possible role of adhesion molecules, especially integrins, in mechanosensing in bone. Osteocytes and osteoblasts are known to be highly responsive to mechanical effects on bone. In other cell systems it has been demonstrated that twisting or turning of integrin molecules directly affects gene transcription (Wang and Ingber, 1994). Stretching of cells, i.e., change of cell shape and dimension, has also been shown to affect gene transcription and cell survival (Ruoslahti, 1997) and cell shape is largely controlled by extracellular matrix (Chen *et al.,* 1997). It has therefore been speculated that positive mechanical effects on bone cells resulting in bone formation may be mediated indirectly via adhesion receptors and/or cellular shape changes resulting from the bone deformation. In contrast, absence of mechanical stimuli that leads to a decrease in bone mass may be the result of lack of "cellular stretch" in particular in osteocytes, which may lead to apoptotic cell death (Noble and Reeve, 2000), a cellular phenomenon associated with induction of bone resorption (Bonewald, 2004 and Chapter 6). Despite these plausible hypotheses, the mechanisms whereby bone cells sense and respond to mechanical strain remain largely unresolved, as it remains technically challenging to subject bone cells, in particular osteocytes to defined levels of strain and measure single cell responses. A further complication is that osteocytes/osteoblasts *in vivo* exist as a syncytium and these cell–cell interactions are not readily reestablished *in vitro*. Despite these difficulties some progress has been made recently. Charras and Horton used atomic force microscopy to estimate the cellular strain necessary to elicit cellular responses in bone cells (Charras and Horton, 2002a) and then, using finite element modeling, determined the strain exerted on individual cells when stimulated by a number of commonly used methods *in vitro*, such as the magnetic bead twisting and stretch experiment described earlier (Charras and Horton, 2002b). Interestingly, fluid shear stress, the main mechanism by which osteocytes are thought to detect strain in bone (see Chapter 6) was found to give rise to the lowest cellular strain (deformation) leading to the hypothesis that cells may have different mechanisms for detecting different magnitudes of strain (Charras and Horton, 2002b). Using paramagnetic beads coated with specific integrin antibodies, it was demonstrated that drag forces (shear) applied to α_2 and β_1 integrin subunits resulted in a cellular response, in this case intracellular calcium increase (Pommerenke *et al.,* 2002). Focal adhesions in osteoblasts were found to promote mechanosensing and RGD peptides could inhibit either, again suggesting a direct requirement of adhesion mechanisms for mechanosensing (Ponik and Pavalko, 2004). *In vivo* studies supporting a role for integrins in mechanosensing are still scarce. Skeletal unloading in rats leads to an increase in osteoblast and osteocyte apoptosis, an effect shown to be directly preceded by $\alpha_5\beta_1$ downregulation (Dufour *et al.,* 2007). This effect is most likely mediated via the α_5 subunit as the effect persisted in animals with disrupted β_1 (Iwaniec *et al.,* 2005). There is also some ultrastructural evidence for the presence *in vivo* of adhesive interactions, "tethering elements," between osteocytes processes and the walls of their lacunae, although the molecular nature of this adhesive interaction remains to be identified (You *et al.,* 2004). Other studies (further discussed later) indicate that cadherins, and therefore cell–cell interactions, are also directly involved in the response to strain (Norvell *et al.,* 2004) and there is strong evidence for integrin-mediated mechanosensing in chondrocytes (see Millward-Sadler and Salter, 2004, and further discussion later). Although further

information is clearly needed, especially in osteocytes, the principle that integrins and other classes of adhesion molecules are involved in mechanosensing appears well established.

Non-Integrin Cell Adhesion Molecules in Osteoblasts

Cadherins

Osteoblasts and bone-lining cells form gap and adherens type cell junctions with each other and with the osteocytes (Palumbo *et al.,* 1990; Doty, 1981). Cadherins are among the best characterized cell–cell adhesion molecules (Isacke and Horton, 2000), localizing to sites of intercellular attachment. The expression pattern and function of cadherins in osteoblasts are covered in depth in Chapter 18 and are only reviewed briefly herein.

Cells of the osteoblast lineage express a limited repertoire of cadherins, E-cadherin, cadherin-4, cadherin-11 (OB-cadherin), and N-cadherin (Okazaki *et al.,* 1994; Cheng *et al.,* 1998; Hay *et al.,* 2000). Some differences have been found between different species, skeletal site and differentiation stage of the osteoblasts, but it is clear from a range of immunocytochemical and molecular studies that N-cadherin and cadherin-11 are abundantly expressed in osteoblastic cells in many mammalian species (reviewed in Marie, 2002, and Chapter 18).

Cadherin expression during the differentiation from early mesenchymal cells into mature osteogenic cells has been studied both *in vivo* and *in vitro*. N-cadherin appears to be expressed widely in all mesenchymal lineage cells and remains expressed at all stages of bone formation with especially high levels of expression at late stages of differentiation (Ferrari *et al.,* 2000). Cadherin-11 seems to be more specifically associated with the osteoblast lineage (Kawaguchi *et al.,* 2001). Cadherin expression is reported to be lost in osteocytes (Kawaguchi *et al.,* 2001; Monaghan *et al.,* 2001). It has been suggested that this loss is linked to osteoblast apoptosis at the end of a formation cycle and is necessary to allow a proportion of mature osteoblasts to enter into the osteoid and become osteocytes. However, it is somewhat surprising that cadherins might not contribute to maintaining the cellular contacts between osteocytes and surface osteoblasts. In fact, recent data from our lab (Huesa and Helfrich, unpublished) shows high levels of β-catenin in cell–cell junctions between MLO-Y4 cells or primary osteocytes *in vitro*, strongly suggesting that in contact sites cadherins are expressed on the osteocyte cell surface and that difficulties in detection of cadherin expression *in vivo* may be related to the difficulties in visualizing such sites in whole bone. Clearly more information is required on the molecules that form the cell–cell contacts in the osteocyte/osteoblast network.

There is good functional evidence that cadherins are important for bone cell function. HAV peptides inhibit cell–cell contacts in osteoblast cultures and matrix formation *in vitro* suggesting a role for class I cadherins in osteoblast synthetic activity (Cheng *et al.,* 1998; Ferrari *et al.,* 2000). Likewise, antibodies to E-cadherin inhibit cell–cell adhesion (Babich and Foti, 1994). Expression of a dominant negative N-cadherin *in vitro* in committed preosteoblastic cells as well as more differentiated osteoblasts inhibited expression of genes associated with bone formation and mineralization (Cheng *et al.,* 2000; Ferrari *et al.,* 2000). Recently, cadherins were implicated in the response to mechanical stimulation in cultured osteoblasts by the finding that fluid shear stress increased translocation of β-catenin to the nucleus and regulated COX-2 expression in osteoblasts, while reducing recruitment of β-catenin by N-cadherin on the cell surface (Norvell, 2004).

In mice in which the gene for cadherin-11 is deleted, a reduction in bone density is seen, strongly implying cadherin-11 in osteogenesis (Kawaguchi *et al.,* 2001). This has been further confirmed in *in vitro* studies demonstrating that cadherin-11 directly regulates differentiation of mesenchymal cell lines into osteogenic and chondrogenic lineages (Kii *et al.,* 2004). Cadherin-11 has recently been shown to be critically important in synovial lining formation in the joint and plays an essential role in the orchestration of the tissue response to inflammation during rheumatoid arthritis (Lee *et al.,* 2007), making it a strong therapeutic target in this disorder.

At present there is little *in vivo* information about the bone phenotype in absence of N-cadherin because the N-cadherin null mice die at day E10, before mature osteoblasts are present (Radice *et al.,* 1997). However a dominant negative approach (Castro *et al.,* 2004) showed that a reduction in functional N-cadherin in osteoblasts *in vivo* leads to a reduction in osteoblast number and thus in peak bone mass, while increasing the number of adipocytes suggesting a role of N-cadherin in mesenchymal cell lineage commitment. In addition, dominant negative N-cadherin expression in stromal ST2 cells *in vitro* strongly reduced RANKL expression independent of cell–cell adhesion (which was unaffected) illustrating that cadherin signaling can affect both osteoblast and osteoclast formation (Shin *et al.,* 2005). Most recently, Lai and coworkers (2006) found that haploinsufficiency of N-cadherin in heterozygous N-cadherin knockout mice leads to reduced cell–cell adhesion and osteoblast function, illustrated by increased bone loss after ovariectomy. Overall, these data provide strong evidence for an important role of N-cadherin in osteoblast lineage commitment and osteoblast function.

Osteoblast cadherins are upregulated, through as yet unknown mechanisms, by a variety of cytokines and hormones including BMP-2, FGF-2, PTH, and downregulated by IL-1 and TNFα (reviewed in Marie, 2002; and

Chapter 18) and it is plausible that some of the well-known effects of these hormones are mediated in part through modulation of cadherin function. Application of stretch to osteoblasts *in vitro* selectively upregulated expression of N-cadherin (Di Palma *et al.,* 2004), leading to increased cell–cell adhesion. The signaling pathways controlling cell–cell adhesion through osteoblast cadherins and the ways they regulate osteoblastic gene expression remain as yet largely unclear.

There is a role for this class of adhesion molecules in bone pathology. Osteoblast cadherins are implicated in malignancy: N-cadherin expression is reduced and cadherin-11 is not normally displayed on the cell surface in osteosarcoma (Kashima *et al.,* 1999) and β-catenin mutations are found in malignant bone tumors (Iwao *et al.,* 1999). Upregulation of E- and N-cadherin is found in Apert syndrome (discussed in Marie, 2002). Finally, because cadherin expression is differentially regulated in osteoblastic versus adipocytic cell populations (Shin *et al.,* 2000; Castro *et al.,* 2004), cadherins may play a role in development of osteoporosis and osteoarthritis, diseases associated with changes in the differentiation of mesenchymal cells to osteogenic versus adipocytic cells.

CD44

Immunohistochemical studies of human tissues showed CD44 expression in osteocytes, but not osteoblasts or bone-lining cells (Hughes *et al.,* 1994). This is consistent with other mammalian models in which strong expression has been observed in osteocytes, with weaker staining in cells earlier in the osteoblast lineage (Jamal and Aubin, 1996; Nakamura and Ozawa, 1996; Noonan *et al.,* 1996; Cao *et al.,* 2005). However, in a recent study expression of CD44 in immature periosteal cells was reported (Park *et al.,* 2007), suggesting that this molecule is expressed throughout mesenchymal-osteoblastic differentiation, but with highest levels in the late differentiation stages. Detailed localization studies have shown that CD44 expression in mature osteoblasts is confined to cytoplasmic processes only (Nakamura *et al.,* 1995). The functional significance of CD44 expression in the osteoblastic lineage is not fully understood as yet. *In vitro*, osteoblastic cells have been shown to bind to and degrade hyaluronate in the transition zone from cartilage to bone in the growth plate and utilize a CD44-dependent mechanism (Pavasant *et al.,* 1994). There are a variety of other known ligands for CD44, e.g., type I collagen, fibronectin, laminin, and osteopontin, and these are also produced by both osteoblasts and osteocytes (Aarden *et al.,* 1996a) and co-localize with CD44, indicating that a much wider range of functions for this molecule may exist. Cross-linking of CD44 on osteoblasts leads to upregulation of ICAM-1 and VCAM-1 (Fujii *et al.,* 2003), which in turn can lead to increased osteoclast formation (Harada *et al.,* 1998; Okada *et al.,* 2002). In addition, CD44 is involved in the upregulation of RANKL expression by hyaluronate in bone marrow stromal cell cultures (Cao *et al.,* 2005). However, the bone phenotype of the CD44 null mouse is very mild, suggesting that *in vivo* such processes may be finely balanced.

Ig Family Members

A number of Ig family members are expressed in osteoblasts. During skeletal development transient expression of NCAM is seen (Lee and Chuong, 1992; Lackie *et al.,* 1994; Chimal-Monroy and Diaz, 1999). In mature osteoblasts expression of ICAM-1 and ICAM-2, VCAM-1, and LFA-3 have been reported (Lee *et al.,* 1992; Kurachi *et al.,* 1993; Tanaka *et al.,* 1995b and 2000; Harada *et al.,* 1998; Okada *et al.,* 2002; Reyes-Botella *et al.,* 2002; Fujii *et al.,* 2003; Nakayamada *et al.,* 2003) and VCAM-1 is also seen in early osteogenic cells (Kuznetsov *et al.,* 2001). There is circumstantial evidence for expression of NCAM in human osteoblasts from studies in multiple myeloma, where NCAM antibodies blocked IL-6 production in osteoblasts-myeloma co-cultures (Barillé *et al.,* 1995). Similarly, cross-linking of ICAM-1 or VCAM-1 resulted in the production of bone resorbing cytokines by osteoblasts (Tanaka *et al.,* 1995b), suggesting that in general expression of Ig family members by osteoblasts may lead to direct cellular interaction with immune cells, which express their ligands (Table VII) and subsequently to activation of production of bone resorbing cytokines.

In addition, Ig family adhesion molecules expressed on osteoblasts are firmly implicated in osteoclast formation. VCAM-1 has been shown to be involved in the development of osteoclasts *in vitro*, an effect that could be mediated via osteoblastic cells (Feuerbach and Feyen, 1997). Further studies on involvement of ICAM-1 and its ligand LFA-1 in osteoclastogenesis suggested a role not only for osteoblast–osteoclast interaction, but also for osteoclast precursor fusion, enabled by transient expression of LFA-1 in pre-osteoclasts (Harada *et al.,* 1998). The role of ICAM-1 has also been studied in more detail. Tanaka and coworkers (2000) found that ICAM-1 expression characterized a population of osteoblasts, induced by proinflammatory cytokines that have arrested in G_0/G_1 and are uniquely equipped to sustain osteoclast differentiation. Interestingly, Everts and coworkers describe that the only cells positive for ICAM-1 on the bone surface in resorbing mouse calvaria are bone-lining cells (Everts *et al.,* 2002). Linking roles for integrins and Ig family members, it was reported how, following β_1-dependent osteoblast adhesion, signaling through FAK results in upregulation of ICAM-1 and RANKL leading to osteoclast formation (Nakayamada *et al.,* 2003). Further molecules that have been found to induce ICAM-1 expression in rodent osteoblasts

in vitro, leading to increased osteoclast formation, are PTH, IL1, TNFα, and 1,25D_3 (Kurokouchi *et al.,* 1998; Okada *et al.,* 2002). The same stimuli also independently induce expression of RANKL and it is becoming clear that efficient stimulation of osteoclast precursors by RANKL is dependent upon high affinity adhesion between osteoblast and osteoclast precursors, a process coined as "juxtacrine stimulation" (Okada *et al.,* 2002).

ICAM-1 expression on osteoblasts *in vivo* in pathologies has yet to be studied. Expression of human primary osteoblasts *in vitro* is highly variable, but has been associated with pathological status: increased expression was seen in cells derived from patients with osteoporosis and to a lesser extent patients with osteoarthritis, compared to normal individuals and increased expression was related in particular to the presence of elevated levels of IL6 and PGE_2 (Lavigne *et al.,* 2004). These data fit well with the established role of ICAM-1 in inflammatory diseases in general and especially in rheumatoid synovium, where levels are considerably increased during active periods of disease and where anti-ICAM-1 therapy has been considered (Kavanaugh *et al.,* 1996, 1997). Taken together with the experimental data it seems likely that high osteoblastic ICAM-1 levels are involved in the mechanism of diseases associated with bone loss by increasing osteoclast recruitment and formation.

Selectins

There is as yet no published data on expression of selectins in osteoblasts. As discussed for osteoclasts earlier, they may well play a role in extravasation of the mesenchymal precursors and in support of this L-selectin, but not E- or P-selectin, has been found expressed in human mesenchymal stem cells (Bruder *et al.,* 1998).

Syndecans

The expression of syndecans in bone is best studied during differentiation. Syndecan-3 (also known as N-syndecan) expression is found in cartilage (see next section) and periosteum during endochondral bone formation, where it interacts with tenascin to set boundaries in tissues (Hall and Miyake, 2002), but low levels are still seen in osteoblasts and osteocytes close to periosteal surfaces (Koyama *et al.,* 1996) and higher levels are found in osteoblasts and precursors in areas of bone regeneration after damage (Imai *et al.,* 1998). Messenger RNA for the three cloned human forms of syndecan syndecan-1, -2, and -4 are found in primary human osteoblast cultures and a number of osteoblast cell lines (Birch and Skerry, 1999; Worapamorn *et al.,* 2002), where expression levels are regulated by cytokines implicated in tissue regeneration (Worapamorn *et al.,* 2002).

Culture of osteoblastic cells under conditions that induce differentiation results in a decrease of syndecan-1 levels (Birch and Skerry, 1999). Syndecan-2 has been implicated in the mitogenic effect of GM-CSF in osteoblasts (Modrowski *et al.,* 2000). A role of syndecans in presentation of growth factors to their receptors has been suggested as their most prominent function in bone. In addition, syndecan-1 could also be an adhesion receptor regulating interaction of osteoblastic cells with the extracellular matrix. The heparin-binding growth associated molecule (HB-GAM, or pleiotrophin) that is expressed by osteoblasts and osteocytes (Imai *et al.,* 1998; Liedert *et al.,* 2004) indeed seems to act in such a way by attracting N-syndecan expressing osteoblasts resulting in enhanced bone deposition (Imai *et al.,* 1998), a process that may be important both during development as well as in response to bone injury.

ADHESION RECEPTORS IN CARTILAGE

The role of cell adhesion molecules in cartilage is beginning to be elucidated and some of their putative functions are summarized in Table I. These include roles in chondrocyte proliferation and cartilage differentiation during fetal development (see Chapter 3); responses to mechanical forces (e.g., in articular cartilage or menisci); maintenance of tissue architecture and integrity, including matrix synthesis and assembly; or cell adhesion, regulation of chondrocyte gene expression, and cell survival. Additionally, there is likely to be a role for cell adhesion molecules in the response in cartilage to injury and disease (Forster *et al.,* 1996; Lapadula *et al.,* 1997; Millward-Sadler *et al.,* 2000; Ostergaard *et al.,* 1998). The differing distribution of both integrin and matrix proteins (Salter *et al.,* 1995) in the zones of cartilage suggests a role in chondrocyte differentiation from mesenchymal precursors (Hirsch and Svoboda, 1996; Tavella *et al.,* 1997; Shakibaei *et al.,* 1995) and/or interaction with matrix, or a specialized function such as response to mechanical stresses. Next we discuss the different classes of adhesion receptors reported in chondroblasts and chondrocytes, some functional data, and information on knockout animals where relevant and available.

Integrins in Chondrocytes

As with the osteoblast lineage, the reported integrin phenotype of chondrocytes is complex, with additional inconsistency between publications (Durr *et al.,* 1993; Enomoto *et al.,* 1993; Loeser *et al.,* 1995; Salter *et al.,* 1992, 1995; Woods *et al.,* 1994; Ostergaard *et al.,* 1998; most recently reviewed in Woods *et al.,* 2007). Differences in reported integrin expression patterns could well relate, in part, to a variation in sampling site, use of fetal versus adult material, species differences, artifacts induced in culture, or influences of disease on phenotypes; indeed the first possibility is born out by the study of Salter *et al.* (1995) where the distribution of integrin clearly differs

TABLE VI Integrin and Other Receptors Expressed by Mammalian Chondroblasts/Chondrocytes[a]

	Receptor/integrin chain
Present[b,c,d]	α_{1-3} and α_{5-6} and α_{10}–α_{11}, all associated with β_1, $\alpha_v\beta_3$, $\alpha_v\beta_5$
	Cadherin 4 and 11 and N-cadherin ICAM-1, V-CAM, and N-CAM Syndecan 3 CD44H
"Not detected"[e]	β_2 and CD11, a, b, c, α_d β_4 β_{7-9}

[a]*Data summarized from immunological and biochemical analysis of human and rodent species and gene deletion studies (as discussed in the main text).*
[b]*Definitive proof of the association of individual integrin subunits in dimers is not always available.*
[c]$\alpha_5\beta_1$ *is the most abundant integrin expressed in chondrocytes.*
[d]*Osteocytes express high levels of* CD44H, *cadherin expression in osteocytes is as yet unclear.*
[e]α_4 *and* β_2 *have been reported in osteoarthritic cartilage* (Ostergaard *et al.*, 1998). β_7 *has recently for the first time been reported in differentiating chondrocytes* (Djouad *et al.*, 2007).

by site (human articular, epiphyseal, and growth plate chondrocytes were studied) and variation in expression has been observed in cartilage when comparing fetal and adult samples, but not during the endocrine-driven pubertal growth (Hausler *et al.*, 2002). Likewise, changes have been reported in *in vitro*-cultured chondrocytes (Loeser *et al.*, 1995; Shakibaei, 1995, Shakibaei *et al.*, 1993) and differences were observed in osteoarthritic versus normal cartilage (Millward-Sadler *et al.*, 2000). A synthesis of the literature suggests that human chondrocytes express the β_1 integrins α_1, α_2, α_3, α_5, and α_6, but not α_4, although a recent miroarray study of differentiating chondrocytes from mesenchymal cells did find α_4 as well as α_7 (Djouad *et al.*, 2007). β_2, β_4, and β_6 are absent, and analysis of β_{7-9} and CD11 has not been reported (Table VI). Some studies have shown high expression of α_v integrin; as in osteoblasts, this is mainly as $\alpha_v\beta_5$ and not the $\alpha_v\beta_3$ dimer seen in osteoclasts, although a subpopulation of superficial articular chondrocytes was found to be $\alpha_v\beta_3$ positive (Woods *et al.*, 1994).

Two more recently discovered integrins, α_{10} and α_{11} (Camper *et al.*, 1998; Tiger *et al.*, 2001), are collagen receptors. They show expression in or near cartilage and are also expressed in fibroblasts and they have different, in many cases complementary, roles. α_{10} is highly expressed during cartilage development, whereas α_{11} is expressed in perichondral cells and mesenchymal cells in areas of interstitial collagen formation (see Popova *et al.*, 2007a). Whereas α_{10} integrin appear to be expressed in areas with high levels of type II collagen, binding studies have shown this integrin prefers types IV and VI collagens (Tulla *et al.*, 2001); α_{11} is not really expressed in cartilage itself, but in perichondral areas and bind preferably to type I collagen. It is possible however, that expression of this integrin is influenced by its proximity to developing cartilage. The phenotypes of the respective knockout animals have been described. The α_{10} knockout mouse, in keeping with its prominent role in cartilage formation, shows growth plate abnormalities (albeit these are rather mild) owing to abnormal shape of chondrocytes and increased apoptosis, resulting in growth retardation (Bengtsson *et al.*, 2005). Mice with a deletion of α_{11} are also much reduced in size, although through a different mechanism. They do not show any gross abnormalities in skeletal structures, or in proliferation of chondrocytes. Instead, they display a tooth phenotype with abnormal incisors because of abnormal periodontal ligament cell function (Popova *et al.*, 2007b). This tooth defect leads to malnutrition and dwarfism. Knockouts of the other two collagen-binding integrins show different skeletal phenotypes: α_1 knockout mice develop osteoarthritis but no growth plate abnormalities (Zemmyo *et al.*, 2003) and the phenotype of the α_2 knockout mouse with delayed callus formation and paucity of cartilage in callus suggests mainly a problem at the level of mesenchymal precursors (Ekholm *et al.*, 2002). Loss of collagen-binding integrins is accompanied by abnormalities in collagen fibril formation, illustrating the interdependence of matrix proteins and their cellular receptors (discussed in Popova *et al.*, 2007a). Clearly, deletion of individual collagen-binding integrins does not lead to profound skeletal phenotypes in unchallenged animals. Further studies with combined deletions of integrins, or under skeletal stress conditions, may reveal additional phenotypes and help understand the nature of the redundancy between the receptors.

The most abundant integrin in cartilage is $\alpha_5\beta_1$. Many studies have been performed to address the role of $\alpha_5\beta_1$ in chondrocyte interactions with fibronectin (Durr *et al.*, 1993; Enomoto *et al.*, 1993; Loeser, 1993; Xie and Homandberg, 1993; Homandberg and Hui, 1994; Enomoto-Iwamoto *et al.*, 1997; Clancy *et al.*, 1997; Shimizu *et al.*, 1997). Function-blocking antibodies and RGD peptides have been shown to inhibit cell adhesion to fibronectin and its fragments, thus modifying chondrocyte behavior and cartilage function. In keeping with this, plating of mesenchymal stem cells on scaffolds coated with RGD peptides blocks chondrogenesis (Connelly *et al.*, 2007). Chondrocyte recognition of collagen (including types I, II, and VI collagen) has likewise been extensively studied *in vitro* (Durr *et al.*, 1993; Enomoto *et al.*, 1993; Loeser, 1993; Holmvall *et al.*, 1995; Shimizu *et al.*, 1997; Enomoto-Iwamoto *et al.*, 1997; Camper *et al.*, 1997) and shown to be mediated via β_1 integrins: $\alpha_1\beta_1$ for adhesion to type I collagen (Shakibaei, 1995; Loeser, 1997) and type VI collagen (Loeser, 1997)

and $\alpha_3\beta_1$ (Shakibaei *et al.,* 1993; Shakibaei, 1995, Loeser, 1997) or $\alpha_2\beta_1$ (Holmvall *et al.,* 1995) for adhesion to type II collagen. Blocking antibodies to these integrins directly interfere with chondrocyte survival (Hirsch *et al.,* 1997).

The important role of $\alpha_5\beta_1$ in developing cartilaginous structures is underscored by studies showing that inhibition of $\alpha_5\beta_1$ *in vivo* inhibits prehypertrophic chondrocyte differentiation and results in ectopic joint formation, whereas misexpression of this integrin leads to joint fusion by interfering with chondrocyte hypertrophy (Garciadiego-Cázares *et al.,* 2004). Given the large number of β_1 integrins with a role in chondrocyte differentiation and cartilage function, it is not surprising that a cartilage-specific knockout of β_1 integrin shows a profound cartilage phenotype with severe disruption of the growth plate through inability of cells to adhere to fibronectin and progress through mitosis (Aszódi *et al.,* 2003).

There is abundant evidence for a functional interaction between integrins and mechanical strain in cartilage, although the mechanisms differ from those seen in osteoblasts and osteocytes, and different types of strain seem to lead to different responses (Wright *et al.,* 1997; Millward-Sadler *et al.,* 1999; Lee *et al.,* 2000; Lucchinetti *et al.,* 2004 and reviewed in Millward-Sadler and Salter, 2004). Extensive studies with monolayers of isolated articular chondrocytes show that integrins, especially $\alpha_5\beta_1$ interacting with fibronectin, are critical in the hyperpolarization response to mechanical load. Strain also induces a variety of downstream signaling events and cytokine secretion (Chowdhury *et al.,* 2004, 2006). Adhesion via integrins leads to formation of focal adhesions in chondrocytes and, following mechanical stimulus, phosphorylation of focal adhesion components, including signaling molecules in the MAP kinase pathway, are seen. Synthesis of autocrine/paracrine factors known to be involved in transducing the biological effect from mechanosensor to effector cells (similar to osteocyte–osteoblast interactions described earlier) is stimulated by mechanical load on chondrocytes. In this context, IL-4 and substance P are especially important, in addition to nitric oxide and prostaglandins (Millward-Sadler *et al.,* 1999, 2003, reviewed in Millward-Sadler and Salter, 2004). Interestingly tension was recently shown to *inhibit* chondrogenesis via signaling through β_1, α_2, and α_5 integrin and FAK (Takahashi *et al.,* 2003; Onodera *et al.,* 2005). Clearly the complex forces exerted on cartilage have the potential to lead to different responses and these are currently not understood in full.

Chondrocyte adhesion to extracellular matrix proteins, especially fibronectin, is connected with chondrocyte–synovial cell interaction (Ramachandrula *et al.,* 1992), chondrocyte cell signaling (Loeser, 2002), and chondrocyte survival (Hirsch *et al.,* 1997; Cao *et al.,* 1999; Lucchinetti *et al.,* 2004, and reviewed in Millward-Sadler and Salter, 2004). Regulation of integrin expression and function by cytokines such as IL1, TGFβ and IGF1 has been linked to the release of matrix metalloproteinases (Arner *et al.,* 1995) and hence cartilage breakdown (Xie and Homandberg, 1993; Loeser, 1993, 1994; Yonezawa *et al.,* 1996; Clancy *et al.,* 1997). Such events are likely to be involved in the pathogenesis of cartilage destruction seen in osteoarthritis and rheumatoid arthritis. In addition, upregulation of α_2, α_4, and β_2 subunit expression were reported by Ostergaard *et al.* (1998) in osteoarthritic versus normal cartilage and altered responses to mechanical stress mediated by $\alpha_5\beta_1$ (Millward Sadler *et al.,* 2000). Sandya and coworkers (2007) recently reported increased levels of $\alpha_5\beta_1$ in articular cartilage in experimental arthritis and, as already indicated earlier, age-dependent cartilage degradation and synovial hyperplasia is found in α_1 knockout mice (Zemmyo *et al.,* 2003), indicating an important functional role for this integrin in cartilage homeostasis and suggesting that α_1 might be a potential drug target for osteoarthritis, a disease in urgent need of mechanism-specific therapies.

The key role for downstream signaling following integrin interaction with matrix ligands is underscored by the phenotype of integrin-linked kinase (ILK) knockout mice. ILK acts as a pleiotropic adapter interfacing β integrin cytoplasmic domains into the PKB/Akt signaling pathway. Mice with ILK deletion in the chondrocyte lineage have chondrodysplasia and show dwarfism. Isolated chondrocytes from such mice have matrix adhesion defects, similar to those seen in the cartilage-specific β_1 knockout described earlier (Grasshoff *et al.,* 2003, Terpstra *et al.,* 2003).

As discussed earlier for osteogenic cells, there is an increasing interest in articular cartilage tissue engineering. Adhesion processes, especially integrin-matrix interactions, will need to be considered when designing appropriate scaffolds, which, as the earlier discussion suggests, must in addition be able to transduce the correct types of strain to the cells for optimal proliferation and survival (van der Kraan *et al.,* 2002; Hunziker *et al.,* 2007).

Non-Integrin Cell Adhesion Molecules of Cartilage

Cadherins

Cadherin-11 is expressed in mesenchymal cells migrating from the neuroectodermal ridge that form presumptive cartilage in the developing mouse (Simonneau *et al.,* 1995). Likewise, N-cadherin is expressed in prechondrocytic cells in avian and mammalian limb buds, but not mature cartilage (Oberlender and Tuann, 1994; Tavella *et al.,* 1994; DeLise *et al.,* 2002a). There is some evidence for differential expression of cadherins (N-cadherin and cadherin-11) in prechondrocytic cells of developing limb primordia with cadherin-11 being expressed in growth plate but not articular chondrocytes (Matsusaki *et al.,* 2006). *In vitro* culture of mesenchymal cells is inhibited by neutralizing

N-cadherin antibody, suggesting a functional role for N-cadherin in early chondrogenesis (Oberlender and Tuann, 1994; Tavella *et al.,* 1994; DeLise *et al.,* 2002b) and that its function may be regulated by calciotropic factors such as $1,25D_3$ and TGFβ (Tsonis *et al.,* 1994). Unexpectedly however, the N-cadherin knockout mouse has no skeletal phenotype, suggesting that other family members, presumably cadherin-11, may compensate for loss of N-cadherin (Luo *et al.,* 2005). The cadherin-11 knockout mouse has a defect in synovial lining formation (Lee *et al.,* 2007), and defects in bone formation at specific sites (Kawaguchi *et al.,* 2001), but no direct effects in cartilaginous structures have been reported.

CD44

CD44 is expressed by cartilage and has been studied for a variety of sites and species (Hughes *et al.,* 1994; Noonan *et al.,* 1996; Stevens *et al.,* 1996, reviewed in Knudson and Loeser, 2002). The predominant isoform detected is the standard CD44H variant (Salter *et al.,* 1996). There is some evidence from the use of function-blocking antibodies showing that CD44 is involved in chondrocyte pericellular matrix assembly (Knudson, 1993; Knudson *et al.,* 1996). The full range of extracellular matrix molecules recognized by CD44 in cartilage is unclear, but interaction with hyaluronan clearly occurs (Knudson and Knudson, 2004). CD44 is upregulated during cartilage catabolism, (for example on IL1α treatment of bovine articular cartilage (Chow *et al.,* 1995) and chondrocytes have been shown to actively take up hyaluronan via CD44-mediated endocytosis (Hua *et al.,* 1993). Thus, it is reasonable to speculate that this molecule plays a regulatory role in cartilage matrix turnover in health and disease (Neidhart *et al.,* 2000; Takagi *et al.,* 2001). More recent evidence points to the presence of soluble CD44 in many tissues and especially in serum. Although mainly studied in the context of tumor biology (Hill *et al.*, 2006), there is evidence for elevated levels of soluble CD44 in inflammation such as in rheumatoid arthritis (Cichy and Pure, 2003).

Ig Family Members

NCAM is similarly distributed to N-cadherin in early cartilage development (Hitselberger Kanitz *et al.,* 1993; Tavella *et al.,* 1994), with N-cadherin expression temporally preceding N-CAM. It is therefore suggested that the role of NCAM is to stabilize cell–cell adhesions formed initially by N-cadherin (Tavella *et al.,* 1994). Primary human articular chondrocytes constitutively express VCAM-1 and ICAM-1 and this expression is increased by cytokines such as IL1β and TNFα and reduced by TGFβ and γ interferon (Davies *et al.,* 1991; Bujia *et al.,* 1996; Kienzle *et al.,* 1998). *In vitro* VCAM-1 and ICAM-1 contribute to T-cell adhesive processes suggesting that *in vivo* these molecules may be important players in mediating T cell–chondrocyte interactions at sites of inflammatory joint destruction (Horner *et al.,* 1995; Seidel *et al.,* 1997; Kienzle *et al.,* 1998).

Syndecans

Syndecan-3 is highly expressed in proliferating chondrocytes, below the tenascin-C-rich layer of articular chondrocytes; decreased levels are found in hypertrophic cartilage (Shimazu *et al.,* 1996). High levels are also found in forming perichondrium (and later in periosteum) in the developing avian limb (Seghatoleslami *et al.,* 1996) and it has been suggested that syndecan-3 is involved with tenascin-C in establishing, or maintaining, boundaries during skeletogenesis (Koyama *et al.,* 1995). Other data supports a role for syndecan-3 in the regulation of chondrocyte proliferation (Pfander *et al.,* 2001; Kirsch *et al.,* 2002).

Selectins

There is no information on selectin expression in chondrocytes.

CONCLUDING REMARKS: MODULATION OF INTEGRIN FUNCTION IN BONE — NEW THERAPEUTIC POSSIBILITIES FOR BONE DISEASE

Bone and cartilage cells express a wide variety of adhesion molecules (summarized with their known and potential functions in Table VII). Integrin expression has been studied extensively, but, generally, there is less information on expression of other adhesion molecule family members. Furthermore, there is also relatively little information on the expression and function of adhesion molecules of all classes during skeletal cell development, largely because we currently lack adequate markers to identify immature bone cells, though the phenotypes of knockout mice are increasingly informative. Adhesion receptors fulfill many functions in the skeleton, and these are frequently linked to a variety of intracellular signaling pathways, leading to a central regulatory role for this class of molecules in bone metabolism. Knowledge of their role in bone resorption and cartilage integrity is extensive, although a function for cell adhesion receptors in bone formation has only been defined recently. Although no unique osteoblast, osteoclast, or chondrocyte adhesion molecule has been identified to date, therapeutic strategies based on selectively inhibiting highly expressed receptors, such as the $\alpha_v\beta_3$ integrin in osteoclasts, have proved to be successful in regulating excessive bone resorption. Better knowledge of the expression of adhesion molecules in bone and cartilage pathology is required, and elucidation of the role of cell–matrix interactions in the etiology of skeletal disease will, therefore, remain a research challenge for the foreseeable future.

TABLE VII Key Functional Roles for Cell Adhesion Molecule Interactions in Bone

Receptor	Cell type	Ligand(s) bound[a]	Known/potential functions
Integrins			
$\alpha_v\beta_3$	Osteoclast	Vitronectin, osteopontin, bone sialoprotein, fibronectin, fibrinogen, denatured collagen, etc.	Matrix adhesion Signal transduction Osteoclast polarization through role in organization of the cytoskeleton Role in osteoclast motility ? Cessation of resorption
$\alpha_v\beta_5$	Osteoclast	As for $\alpha_v\beta_3$	Regulation of osteoclast formation
$\alpha_9\beta_1$	Osteoclast	ADAM8	Osteoclast formation and resorption
$\alpha_1\beta_1$	Osteoblast/Mesenchymal cell	Collagen	Osteoblast lineage differentiation
$\alpha_1\beta_1$	Cartilage cells/ Mesenchymal cell	Collagen	Cartilage lineage differentiation
$\alpha_2\beta_1$	Osteoclast Osteoblast Chondrocyte	Native collagens Native collagens Type II collagen	Matrix adhesion Matrix adhesion Osteoblast differentiation Matrix adhesion, orchestration of matrix deposition
$\alpha_{10}\beta_1$	Chondrocyte	Types II, IV, and VI collagens, ? type IX collagen	Matrix adhesion, orchestration of matrix deposition
$\alpha_{11}\beta_1$	Perichondral cells, Mesenchymal cells	Type I collagen, ? type XIII collagen	Organization of collagen bundles
$\alpha_5\beta_1$	Osteoblast Chondrocyte	Fibronectin (RGD) Fibronectin (RGD)	Osteoblast differentiation and survival Mechanosensing Mechanosensing Cartilage breakdown
$\alpha_6\beta_1$	Chondrocyte	Laminin	Matrix adhesion
Cadherins			
N-cadherin	Osteoblast Chondrocyte	N-cadherin N-cadherin	Osteoblast development, mineralization ? Mechanosensing Cartilage development/mesenchymal condensation
Cadherin-11	Osteoblasts/ Mesenchymal cells	Cadherin	Osteogenesis, mesenchymal fate decisions
E-cadherin	Osteoclast	E-cadherin	? Osteoclast differentiation
Ig superfamily			
ICAM-1	Osteoclast Osteoblast	LFA-1 on leukocytes LFA-1 on leukocytes	Osteoclast differentiation Osteoblast differentiation Production of cytokines
VCAM-1	Chondrocyte Osteoblast	LFA-1 on leukocytes α_4 integrins on leukocytes	Cartilage breakdown Osteoblast differentiation Production of cytokines
Cell surface proteoglycans			
Syndecan-1	Osteoblast, Osteocyte	Type I collagen, tenascin-C	? Matrix adhesion ? Osteoblast differentiation ? Role in mechanosensing
Syndecan-3	Chondrocyte	Tenascin-C	Cartilage development
CD44	Osteoclast	Hyaluronate, osteopontin, ? type I collagen, ? fibronectin	Osteoclast formation Osteoclast migration ? Osteoclast-osteoblast interaction
	Osteoblast	Hyaluronate ?	Hyaluronate degradation
	Osteocyte	Hyaluronate, ? osteopontin, ? type I collagen, ? fibronectin	? Matrix adhesion ? Role in mechanosensing ? Osteocyte-osteoblast interaction
	Chondrocyte	Hyaluronate	Pericellular matrix assembly

[a]*There is no definitive information on the natural ligands in bone or cartilage for these molecules. The range of ligands demonstrated to be bound in* in vitro *adhesion assays is shown. ?indicates where the function is highly likely, but there is no definite evidence.*

INTRODUCTION

The organization of cells in tissues and organs is controlled by molecular programs that afford cells the ability to recognize other cells and the extracellular matrix and to communicate with their neighbors. Adhesive interactions are essential not only in embryonic development, but also in a variety of other biologic processes, including the differentiation and maintenance of tissue architecture and cell polarity, the immune response and the inflammatory process, cell division and death, tumor progression and metastases (Goodenough *et al.,* 1996; Simon and Goodenough, 1998; Vleminckx and Kemler, 1999; Zbar *et al.,* 2004). Cell–cell and cell–matrix adhesion are mediated by four major groups of molecules: cadherins, immunoglobulin-like molecules, integrins, and selectins. Cadherins are an integral part of *adherens junctions*, which along with tight junctions and desmosomes, constitute the so-called anchoring junctions, which join cells by anchorage through their cytoskeletons (Halbleib and Nelson, 2006). A different type of intercellular junction is the *gap junction*, which does not provide cell anchorage but allows direct communication via specialized intercellular channels (Goodenough *et al.,* 1996). In addition to cell–cell adhesion and gap junctional communication, cell-to-cell propagation of locally generated signals, such as mechanically induced "calcium waves" can occur via short-range intercellular signaling systems that require either gap junctions or extracellular release of nucleotides and activation of purinergic receptors (Jørgensen *et al.,* 1997).

In the adult skeleton, bone remodeling occurs via repeated sequences of bone resorptive and formative cycles, which require continuous recruitment and differentiation of bone marrow precursors. The cooperative nature of bone remodeling requires efficient means of intercellular recognition and communication that allow cells to sort and migrate, synchronize their activity, equalize hormonal responses, and diffuse locally generated signals. Likewise, cell–cell interactions are critical for aggregation and condensation of immature chondro-osteoprogenitor cells and mesenchymal precursors during skeletal development (bone modeling). This chapter reviews current knowledge about the role of direct cell–cell interactions in the development and remodeling of the skeletal tissue, focusing on cell–cell adhesion via cadherins, cell–cell communication via gap junctions, and short-range calcium signals, or calcium waves, via extracellular nucleotides and purinergic receptors.

CADHERINS AND CELL–CELL ADHESION

Adherens Junctions and the Cadherin Superfamily of Cell Adhesion Molecules

Cadherins owe their name to their main function in mediating calcium-dependent cell–cell adhesion. As many as 80 members of this large superfamily of cell adhesion molecules have been cloned, and most tissues express more than one cadherin (Gumbiner, 1996; Yagi and Takeichi, 2000). These single chain integral membrane glycoproteins have a molecular mass of about 120 kDa and their structure includes a long extracellular domain (EC), a single transmembrane-spanning domain, and a relatively small intracellular (IC) C-terminus tail (Halbleib and Nelson, 2006). The EC domain, composed of five repeats (EC1 through EC5) contains calcium-binding sites and allows binding to the same cadherin on neighboring cells (Fig. 1). Structural differences allow classification of cadherins into two main subfamilies, type I, which mediate strong cell–cell adhesion via a putative His-Ala-Val motif in EC1, and include, among others, N-, E-, M-cadherin, and cadherin-4 (the human ortholog of mouse R-cadherin); and type II, comprising cadherin-5 through -12 as well as VE-cadherin, which do not have the His-Ala-Val motif. An additional group of cadherins includes those lacking the intracellular tail, i.e., T-cadherin and cadherin-13, and whose function in cell–cell adhesion remains to be determined. Close relatives of this superfamily of "classical" cadherins are protocadherins, cadherin-related neuronal receptor and other structurally related molecules present primarily in the central nervous system (Suzuki, 1996;Yagi and Takeichi, 2000), as well as desmocollins and desmogleins, which differ from the typical cadherins in their cytoplasmic domain (Buxton and Magee, 1992).

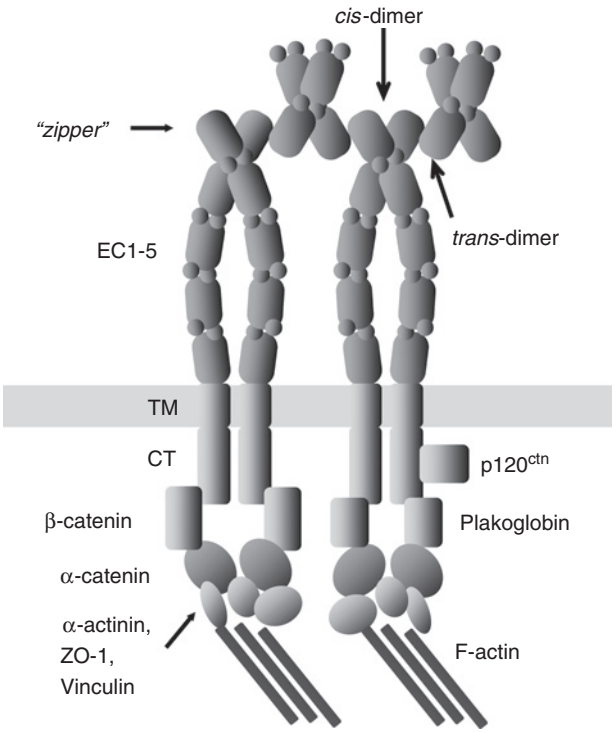

FIGURE 1 Schematic representation of the cadherin adhesion complex. Each cadherin is shown with its five extracellular domains (EC1–5), as well as their transmembrane (TM) and cytoplasmic (CT) domains. Small circles between the EC domains symbolize calcium ions. Two complete cadherin *cis* dimers are shown side by side. These engage in binding with similar complexes (only the first 2 EC domains represented) from an apposing cell, thus forming *trans* dimers. The alignment of EC1 domains forms the so-called "zipper" structure of the adhesion complex. Through their CT domain, cadherins bind to β-catenin and plakoglobin, which in turn tether the complex to the actin cytoskeleton via α-catenin and other interacting proteins, including α-actinin, ZO-1, and vinculin. Binding to $p120^{ctn}$ also contributes to stabilizing the cadherin-based adhesion structure.

Crystallographic analysis of E-cadherin ectodomains has demonstrated that cadherin-mediated cell–cell adhesion occurs via the formation of cis-homodimers upon Ca^{2+} binding (Fig. 1). As extracellular Ca^{2+} concentration increases to more than 1mM, the two cadherins participating in the dimer become rigid and form an X-shaped assembly, interfacing through their EC1 and EC2 domains (Pertz *et al.,* 1999; Shapiro *et al.,* 1995). Higher Ca^{2+} concentration allows Trp2 to dock into a hydrophobic pocket in EC1 of an apposing cadherin, thus forming a trans-homodimer and generating a "zipper" structure of multiple cis-dimers on apposing membranes (Patel *et al.,* 2006; Troyanovsky, 1999). Stabilization of cadherin dimers occurs by lateral clustering and linkage to the cytoskeleton via the highly conserved cytoplasmic tail. The IC domain binds to β-catenin and plakoglobin, which connect cadherins to the actin cytoskeleton via α-catenin, either directly or via binding to other proteins, including actinin, vinculin, or ZO-1 (Yamada and Geiger, 1997). Recent data indicate that α-catenin binding to either the cadherin/β-catenin complex or to actin filaments is mutually exclusive (Drees *et al.,* 2005), implying that the connection between the adhesion structure and the cytoskeleton is dynamic rather than static (Yamada *et al.,* 2005). Adhesion is controlled by cadherin binding to other proteins, most importantly $p120^{ctn}$, also a member of the catenin family, and IQGAP1, which contribute to stabilize cadherin-β-catenin binding and mediates regulatory effects of Rho family members, particularly RhoA, Rac1, and Cdc42 (Kaibuchi *et al.,* 1999; Reynolds and Carnahan, 2004). The assembly of cadherins and their associated cytoskeletal elements form the junctional structures known as adherens junctions, which provide anchorage between two adjoining cells (Foty and Steinberg, 2005; Gumbiner, 2005).

The catenins (α-catenin, β-catenin, plakoglobin, and $p120^{ctn}$) serve at least three distinct functions; they provide a link between cadherins and the cytoskeleton, they control the adhesive state of cadherin dimer complexes, and they interact with components of signaling pathways (Halbleib and Nelson, 2006). The most relevant example is β-catenin, which is an integral component of Wnt signaling (reviewed in detail under Chapter 6), and therefore it directly links

adhesion and signaling (Gottardi and Gumbiner, 2001; Nelson and Nusse, 2004). The most widely held belief is that by keeping β-catenin bound at adhesion structures on the cell surface, cadherins sequester β-catenin from its transcriptionally active pools (Fagotto *et al.,* 1996; Sadot *et al.,* 1998), thus potentially attenuating Wnt signaling (Ciruna and Rossant, 2001). By contrast, reduced abundance of cadherins on the cell surface would make more β-catenin available for transcriptional regulation, at the expense of destabilizing the adhesion complex with loss of cell–cell adhesion and increased cell movement (Nelson and Nusse, 2004). Thus, an inverse relationship exists between adhesion and signaling: Wnt signals induce conformational changes of β-catenin that favor the formation of transcriptional complexes, whereas β-catenin association with α-catenin favors cadherin binding and adhesion (Brembeck *et al.,* 2004; Gottardi and Gumbiner, 2004). An alternative, hypothetical view is that β-catenin bound to cadherins on the cell surface might provide a rapidly available source of this signaling molecule for transcriptional activation in response to continuous Wnt signaling. Thus, a lower level of membrane-bound β-catenin might actually attenuate signaling because less β-catenin is available for mobilization into active pools upon Wnt activation. In any case, intersection of cadherin-mediated adhesion and Wnt signaling via β-catenin represents a flexible mechanism of cell regulation (Gottardi and Gumbiner, 2001; Nelson and Nusse, 2004; Tuan, 2003), a mechanism of particular importance in the skeleton, considering that β-catenin activation is now recognized as a necessary step in osteogenic differentiation (Day *et al.,* 2005; Hu *et al.,* 2005). Recent data suggest that α-catenin and $p120^{ctn}$ also have their own roles in signaling, independent of the Wnt pathway. Both α-catenin and $p120^{ctn}$ have been shown to interact with RAS-MAPK, NFκB, hedgehog (Lien *et al.,* 2006; Vasioukhin *et al.,* 2001), and Rac and Cdc42 (Ciesiolka *et al.,* 2004; Elia *et al.,* 2006), respectively. Thus, interactions with Rho family members provide an inside-out signaling mechanism that regulates cadherin assembly and adhesion properties.

Cadherins in Skeletal Development, Growth, and Maintenance

Cells of the osteoblastic lineage express two major cadherins, N-cadherin (gene: *Cdh2*) and cadherin-11 (gene: *Cdh11*) (Cheng *et al.,* 1998; Ferrari *et al.,* 2000; Okazaki *et al.,* 1994). E-cadherin immunoreactivity has been observed in UMR 106–01 cells (Babich and Foti, 1994), and mRNA for other cadherins, including P-cadherin, VE-cadherin, cadherin-8, and cadherin-6 have been detected in primary mouse calvaria cultures and cell lines (Kawaguchi *et al.,* 2001b; Mbalaviele *et al.,* 1998). However, the abundance of these cadherins is low, and screening for all cadherin family members expressed by human trabecular bone cells using degenerate PCR primers yielded only *Cdh2* and *Cdh11* mRNA transcripts (Cheng *et al.,* 1998). A splice variant of *Cdh11* lacking the IC domain has also been described on the surface of osteoblasts, but its function remains uncertain (Kawaguchi *et al.,* 1999). In embryogenesis, N-cadherin is abundant in mesenchymal cells undergoing cartilage nodule condensation (Tsonis *et al.,* 1994); and while not present in mature cartilage, *Cdh2* expression clearly persists in mature and adult bone (Ferrari *et al.,* 2000; Hoffmann and Balling, 1995; Simonneau *et al.,* 1995). Earlier work in limb bud micromass cultures showed that although dominant negative interference with N-cadherin negatively affects cell aggregation and condensation (Oberlender and Tuan, 1994a; Tavella *et al.,* 1994), persistent expression of *Cdh2* prevents full cartilage differentiation (Cho *et al.,* 2003; DeLise and Tuan, 2002). However, a recent *in vivo* study elegantly demonstrated that *ex vivo* limb bud cultures from *Cdh2* null embryos partially rescued by transgenic expression of *E-cadherin* were able to undergo cartilage condensation and develop into structured limbs in the absence of *Cdh2* (Luo *et al.,* 2004). Therefore, N-cadherin is dispensable for early phases of embryonic skeletogenesis.

Cadherin-11 is transiently expressed in the cephalic mesoderm and then in the paraxial mesoderm of the trunk during early development, particularly in the head, somites, and limb buds (Hoffmann and Balling, 1995; Kimura *et al.,* 1995; Simonneau *et al.,* 1995). However, at later developmental stages, a wide variety of mesenchymal tissues in both mesodermal and neural crest derivatives express *Cdh11* (Simonneau *et al.,* 1995). Thus, both *Cdh2* and *Cdh11* are present in mesenchymal cells, but with distinct expression patterns; *Cdh2* is less abundant than *Cdh11* in the head and it is absent in branchial arches, in sharp contrast with the abundant presence of *Cdh11* (Kimura *et al.,* 1995). Furthermore, while *Cdh2* is present in the perichondrium (Kimura *et al.,* 1995; Oberlender and Tuan, 1994b), *Cdh11* appears only in the primary spongiosa but not in condensing or proliferating chondrocytes of the growth plate, where *Cdh2* is abundant. Nonetheless, mice with homozygous *Cdh11* null mutation have no skeletal malformations (Kawaguchi *et al.,* 2001a). Hence, absence of either *Cdh2* or *Cdh11* can be tolerated in skeletal development, and *Cdh11* may compensate for lack of *Cdh2*, as suggested by the more severe disruption of somite structure in double *Cdh2*;*Cdh11* null embryos relative to single cadherin gene deletion (Horikawa *et al.,* 1999), and by strong *Cdh11* expression at sites of chondrogenesis in *Cdh2* null mice (Luo *et al.,* 2004).

As just noted, mice genetically deficient of *Cdh11* have no major skeletal malformations, but display minor calcification defects of the cranial sutures and become osteopenic by three months of age, an abnormality seen primarily in the trabecular bone and linked to a cell autonomous functional defect of bone forming cells (Kawaguchi *et al.,* 2001a). Homozygous *Cdh2* null mutation is embryonically

lethal (Radice *et al.,* 1997), but *Cdh2* haploinsufficient mice exhibit an accentuated bone loss after ovariectomy relative to wild type mice (Fang *et al.,* 2006), demonstrating that while a single *Cdh2* allele is sufficient to maintain bone mass in resting conditions, it does hinder adaptive responses to an acute stimulation of bone remodeling. As an approach to overcome cadherin redundancy in bone, a dominant negative *Cdh2* mutant, *NCadΔC* was expressed *in vivo* selectively in bone forming cells using the mouse *osteocalcin 2* (*Og2*) promoter (*Og2- NCadΔC*). Peak bone mass acquisition is delayed in these transgenic animals, resulting in osteopenia up to four months of age. This is the consequence of decreased osteoblast number and impaired osteogenic differentiation, defects associated with both decreased cell–cell adhesion and interference with β-catenin function (Castro *et al.,* 2004). Because the inhibitory action of the mutant molecule is not restricted to a specific cadherin, the more pronounced skeletal phenotype of *Og2- NCadΔC* mice relative to *Cdh11* null mice is consistent with the concept that *Cdh2* may partially compensate for lack of *Cdh11*. The partial redundancy of these two cadherins in bone formation is further underscored by preliminary reports of dramatically decreased bone mass with microarchitectural defects of trabecular and cortical bone in mice with *Cdh2* haploinsufficiency in a *Cdh11* null background (Donsante *et al.,* 2005).

Cadherins in Commitment and Differentiation of Bone Forming Cells

In uncommitted mesenchymal cells, such as the embryonic mouse cell line C3H10T1/2, expression of *Cdh2* is increased by bone morphogenetic protein-2 (BMP-2), presumably reflecting the transition to a chondro-osteogenic phenotype (Shin *et al.,* 2000). However, N-cadherin abundance decreases in calvaria cell as they progress through their *in vitro* differentiation program (Fang *et al.,* 2006). Likewise, *Cdh2* mRNA is sharply downregulated by dexamethasone (Lecanda *et al.,* 2000a) and by IL-1 or TNF-α (Tsutsumimoto *et al.,* 1999), whereas it is upregulated by a constitutively active, mutated FGFR-2 receptor (Lemonnier *et al.,* 1998). On the other hand, *Cdh11* is upregulated in immature mesenchymal cells under stimulation by BMP-2 and other osteogenic factors, whereas it is downregulated when cells undergo adipogenic or myogenic differentiation and disappears in adipocytes (Kawaguchi *et al.,* 2001b; Shin *et al.,* 2000). Similarly, the uncommitted C2C12 cells lose *Cdh4* upon osteogenic differentiation, whereas cadherin-11 abundance increases. These cells also express M-cadherin, indicative of their myogenic potential, but transdifferentiation from myogenic to osteogenic cell phenotypes is associated with M-cadherin to cadherin-11 transition (Kawaguchi *et al.,* 2001b). Furthermore, teratomas overexpressing *Cdh11* preferentially form bone and cartilage tissue (Kii *et al.,* 2004). Therefore, it is conceivable that coexpression of *Cdh11* and *Cdh2* may allow sorting and segregation of mesenchymal progenitors committing to osteogenic differentiation from those entering the adipogenic pathway. However, as differentiation progresses, *Cdh2* is downregulated whereas *Cdh11* is present throughout the osteoblast differentiation program. In fact, in cells already committed to the osteogenic pathway, *Cdh11* expression does not change substantially with differentiation (Cheng *et al.,* 1998; Kawaguchi *et al.,* 2001b), though it is modestly downregulated by dexamethasone (Lecanda *et al.,* 2000a). Interestingly, cadherin-11 abundance decreases with aging in rat bone marrow stromal cells (Goomer *et al.,* 1998), raising the possibility that decreased cadherin-11 may contribute to the reduced osteogenic potential in the aging skeleton, an hypothesis consistent with the impaired osteoblast function of *Cdh11* null cells (Kawaguchi *et al.,* 2001a). Whether the cadherin repertoire changes with terminal differentiation into osteocytes has not been thoroughly investigated, although neither *Cdh11* nor *Cdh2* have been detected in the osteocyte-like cell line MLO-Y4 (Kawaguchi *et al.,* 2001b).

A number of *in vitro* studies consistently demonstrated that disruption of cadherin function using peptide inhibitors (Cheng *et al.,* 1998; Ferrari *et al.,* 2000), function blocking antibodies (Hay *et al.,* 2000), antisense RNA (Lemonnier *et al.,* 1998), or overexpression of dominant negative mutants (Cheng *et al.,* 1998; Ferrari *et al.,* 2000) impairs osteoblast differentiation and/or differentiated function in cell lines and in primary osteoblast cultures. Intriguingly in *Og2- NCadΔC* mice, a lower than normal bone mass was associated with a concomitant increase in percent body fat and number of bone marrow adipogenic precursors, apparently at the expense of osteogenic precursors (Castro *et al.,* 2004). This osteogenic to adipogenic shift in *Og2- NCadΔC* transgenic mice was in part consequent to reduced β-catenin signaling, because this abnormality was rescued by expression of an active β-catenin mutant (Castro *et al.,* 2004). Indeed, the dominant negative *NCadΔC* mutant sequesters β-catenin on the cell surface (Castro *et al.,* 2004), and inhibits β-catenin dependent transactivation (Shin *et al.,* 2005). These findings demonstrate that osteoblast cadherins are involved in bone marrow stromal cell lineage allocation, and support the notion that cadherins influence Wnt/β-catenin signaling. Furthermore, as in the *Og2- NCadΔC* mice the dominant negative mutant is expressed only in differentiated osteoblasts, the osteogenic to adipogenic shift in bone marrow precursors also suggests that osteoblasts may control the fate of their own precursors in a cadherin-dependent fashion. Whether this intriguing new regulatory mechanism involves cell–cell contact or paracrine mechanisms remains to be determined.

Even though the experimental evidence discussed earlier strongly points to some degree of redundancy between *Cdh2* and *Cdh11*, new and in part still preliminary *in vivo* data are uncovering specific roles of N-cadherin and cadherin-11 at

different steps of osteogenesis. In particular, N-cadherin and cadherin-11 segregate away from each other when coexpressed in the same cells, and impart different spatial organization to the cultures when expressed separately (Kii *et al.,* 2004). As noted, N-cadherin is relatively abundant compared to other cadherins in undifferentiated cells (Kawaguchi *et al.,* 2001b; Shin *et al.,* 2000), but it is downregulated during *in vitro* differentiation (Fang *et al.,* 2006), and overexpression of *Cdh2* prevents full chondrocyte differentiation (Cho *et al.,* 2003; DeLise and Tuan, 2002). These data suggest that N-cadherin may have a "braking" effect on mesenchymal/stromal cell differentiation, a notion supported by the finding of a decreased number of osteoprogenitors in bone marrow of *Cdh2* haploinsufficient mice (Fang *et al.,* 2006), and by a preliminary report showing osteopenia and altered osteoblast differentiation in mice overexpressing full length *Cdh2* in osteoblasts (Hay *et al.,* 2006).Thus, the primary function of N-cadherin may be to keep uncommitted progenitors in an undifferentiated state, perhaps favoring aggregation of bone marrow stromal (skeletal) stem cell in a niche, an organization similar to hematopoietic stem cell niches (Gregory *et al.,* 2005). In fact, stromal and hematopoietic stem cells may even coexist in the same microanatomical niches (Baksh *et al.,* 2004). In this scenario, differentiated osteoblasts and/or bone lining cells may help support and stabilize the stem cell niche via N-cadherin (and possibly cadherin-11) mediated cell–cell adhesion. Commitment to osteogenesis is associated with upregulation of *Cdh11*, whereas downregulation of *Cdh11* favors adipogenesis (Kawaguchi *et al.,* 2001b; Kii *et al.,* 2004; Shin *et al.,* 2000). As osteoblast differentiation progresses, *Cdh2* is progressively downregulated, thus allowing committed cells to escape from the niche, and *Cdh11* remains as the major osteoblast cadherin (Mbalaviele *et al.,* 2006) (Fig. 2). Although a few steps of this model remain to be demonstrated experimentally, cadherins can provide the means for cell–cell aggregation and migration of committed cells to the areas of active bone remodeling. Thus, by allowing direct interactions among cells of different lineages and by modulating β-catenin signaling, cadherins represent fundamental players in coordinating the activity of cells in the bone marrow microenvironment.

Other Cell Adhesion Molecules in Bone and Cartilage

Neural cell adhesion molecule (N-CAM), a member of the immunoglobulin superfamily, is present in chick limb buds before mesenchymal cell condensation and its abundance increases during cell aggregation in a pattern similar to that of N-cadherin (Tavella *et al.,* 1994). Both adhesion molecules are undetectable in hypertrophic chondrocytes, but are reexpressed in preosteoblastic cells (Lee and Chuong, 1992; Tavella *et al.,* 1994). Although N-CAM and N-cadherin are present during chondrogenesis, subtle differences in the timing of expression suggest that N-cadherin may initiate cell–cell aggregation while N-CAM stabilizes the aggregates, although such hypothesis has not been proven in a more mechanistic fashion. Although disappearing in differentiated cartilage, N-CAM persists in the perichondrium of long bones and sclerotomes, it is present in the calvarium during mesenchymal cell aggregation differentiation (Lee and Chuong, 1992), but is not regulated by BMP-2 (Hay *et al.,* 2000).

Cell Adhesion Molecules in Osteoclast Differentiation and Hematopoiesis

Two critical steps of osteoclastogenesis, i.e., heterotypic interactions between hematopoietic osteoclast precursors and stromal/osteoblastic cells and osteoclast precursor fusion are both dependent on cell–cell adhesion. Osteoblast/stromal cell support of osteoclastogenesis is mediated by the interaction of RANKL on the surface of osteoblasts and stromal cells and its receptor, RANK, present on osteoclast precursors. Although soluble RANKL is sufficient to induce osteoclastogenesis *in vitro*, close proximity between osteoclast precursors and their

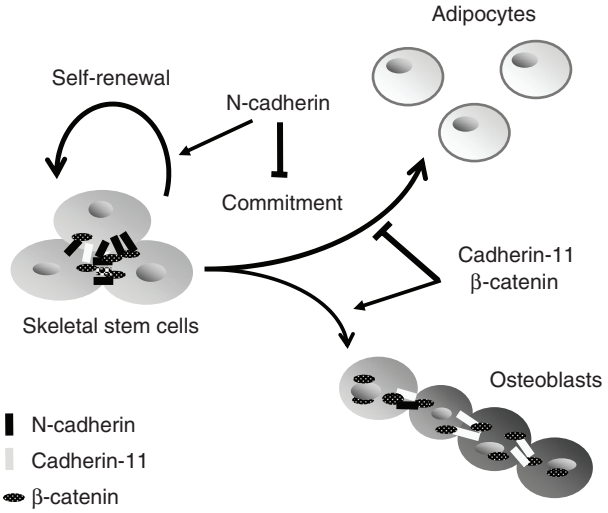

FIGURE 2 Cadherins in skeletal stem cell (SSC) maintenance and lineage allocation. In their undifferentiated stage, SSC express a relatively wide repertoire of cadherins, including *N-cadherin* (*Cdh2*), *cadherin-11* (*Cdh11*), and *R-cadherin* (*Cdh4*), with the former being the most abundant. SSC are maintained by self-renewal, i.e., production of daughter cells with conserved multipotential capacity, and are organized in microanatomical niches. The stem cell niche is held together by N-cadherin mediated cell–cell adhesion. SSC commitment to osteogenesis is associated with upregulation of *Cdh11*, whereas downregulation of *Cdh11* favors adipogenesis. As differentiation progresses, *Cdh2* is downregulated, thus allowing cells to escape from the niche and reach the areas of active bone remodeling. This switch in cadherin expression may allow more β-catenin to become available for transcriptional regulation, thus contributing to osteogenesis and anti-adipogenesis. Reproduced with modifications from Mbalaviele *et al., J. Bone Miner. Res*. 2006; **21**,1821–1827 with permission of the American Society for Bone and Mineral Research.

supporting cells is likely to be required *in vivo*, as both receptor and ligand are membrane bound (Suda *et al.,* 1999). However, it is unlikely that RANKL–RANK interaction by itself provides cell–cell adhesion, as anti-RANKL antibodies do not affect osteoblast adhesion to peripheral monocytes, whereas antibodies against vascular adhesion molecule VCAM-1 or against intercellular adhesion molecule ICAM-1 do (Tanaka *et al.,* 1995; Tanaka *et al.,* 2000). It is more likely that osteoclast precursors anchor to their supporting cells to allow stable RANK-RANKL engagement and osteoclastogenic signaling. Earlier work convincingly demonstrated that such anchorage may be mediated by cadherin-6 (*Cdh6*), the murine homologue of human K-cadherin, and its splice variant, cadherin-6/2, as expression of a dominant negative, adhesion defective *Cdh6* mutant prevented stromal cell support of osteoclastogenesis (Mbalaviele *et al.,* 1998). More recent data suggest that cadherins expressed by osteogenic cells can also control osteoclastogenesis by regulating the expression of RANKL via a β-catenin dependent mechanism (Shin *et al.,* 2005). In contrast, E-cadherin seems to be important in the fusion of mononuclear precursors, because interference with E-cadherin adhesion prevents the formation of multinucleated bone-resorbing osteoclasts (Mbalaviele *et al.,* 1995). In addition, co-localization studies have demonstrated that cadherins may be involved in the formation or maintenance of the actin ring in the osteoclast sealing zone and thus, they may control osteoclast attachment to the matrix, at least in an indirect manner (Ilvesaro *et al.,* 1998). Based on these observations, it seems plausible that interference with cadherin mediated cell–cell interactions may be a reasonable target for inhibition of osteoclast differentiation.

Growing evidence suggests that cadherin mediated heterotypic cell–cell interactions extend to hematopoiesis. Hematopoietic stem cell niches have been found in contact with cells lining the bone surface and both cell types express *Cdh2* and *β-catenin in vivo* (Zhang *et al.,* 2003; Zhu and Emerson, 2004). Furthermore, stimulation of osteoblast activity by either expression of a constitutively active PTH/PTHrP receptor, or by exogenous administration of PTH increases the number of hematopoietic stem cells via modulation of Notch signaling (Calvi *et al.,* 2003). Because Notch signaling is also based on membrane-bound ligand and receptors, close cell–cell contact is essential in this interaction, as it is for the RANK-RANKL system. Recent studies also show that the balance between self-renewal and differentiation of hematopoietic stem cells is controlled by *c-Myc* in a N-cadherin dependent fashion: *c-Myc* stimulation of differentiation and escape from the niche is associated with downregulation of *Cdh2* (Wilson *et al.,* 2004). These findings reinforce the idea that N-cadherin contributes to maintaining cells in an undifferentiated state and that its persistence prevents differentiation, as noted earlier for the stromal cell compartment. Thus, osteoblast/stromal cell support of osteoclastogenesis can be seen as a particular case of a more general mechanism of osteoblast-hematopoietic cell interactions, in which cadherins play a prominent role.

CONNEXINS AND GAP JUNCTIONAL COMMUNICATION

Connexins, Gap Junctions, and "Hemichannels"

One mechanism by which cells can rapidly and efficiently coordinate function is through gap junction-mediated intercellular communication. Gap junctions are transcellular channels that permit the diffusion of small molecules (~1.2 kDa or less), including second messengers, metabolites, and ions among coupled cells. The biologic relevance of direct intercellular communication in multicellular organisms is underscored by the evolution of two gene families, connexins (Goodenough *et al.,* 1996) and pannexins (Bruzzone *et al.,* 2003), which serve similar functions.

A connexin is the monomeric unit of a gap junction. More than 20 connexin genes have been identified in the mouse and human genomes, and most cells express more than one connexin (Goodenough *et al.,* 1996; Sohl and Willecke, 2003). Connexins are integral membrane proteins with four transmembrane domains, two small extracellular loops, a cytoplasmic loop, and cytoplasmic N- and C-terminal tails (Fig. 3A). The cytoplasmic loop and the long C-terminal tail differ widely between various connexins in both amino acid sequence and length. Connexins assemble into a hexamer in the plasma membrane, forming a unit referred to as a connexon, or "hemichannel" (Fig. 3B). When two connexons on appositional cell membranes dock to each other, a gap junction channel is formed (Fig. 3C). Docking is stabilized by disulfide linkage that forms via conserved cysteine residues in the two extracellular loops of the apposing connexins (Goodenough *et al.,* 1996; Kumar and Gilula, 1996). Growing evidence suggests that connexons may also function as hemichannels without docking to another connexon, and allow exchange of solutes and ions between the cytoplasm and the extracellular space, in a similar fashion as a membrane channel (Goodenough and Paul, 2003).

Although in most circumstances connexons formed by a single connexin (homomeric connexons) pair with like connexons on the apposing cell, heterotypic gap junction channels are possible, depending on the compatibility of the extracellular loops (White *et al.,* 1994). Likewise, co-oligomerization into heteromeric connexons may occur when more than one connexin is present in the same cell (Fig. 3D), resulting in heterotypic gap junctions with unique biophysical properties (Kumar and Gilula, 1996). The phosphorylation state of connexins controls the assembly and degradation of the protein, as well as the

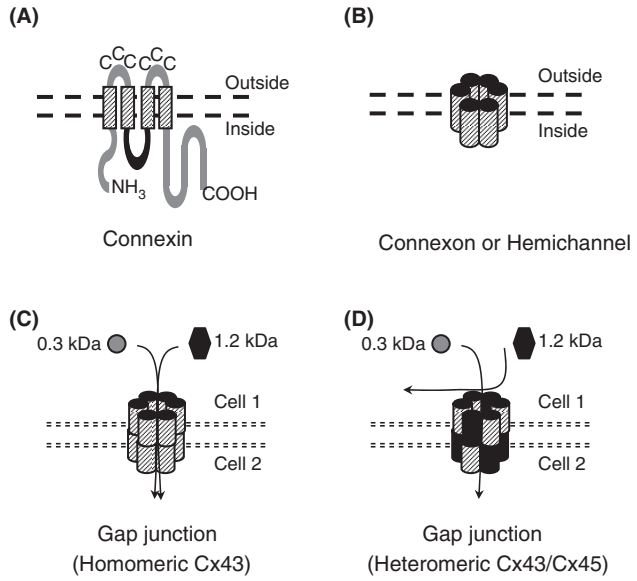

FIGURE 3 Structure and different conformations of gap junction channels. (**A**) A connexin is the monomeric unit of gap junctions and hemichannels. The cysteine residues in the extracellular loops permit docking to apposed connexins in an adjacent cell. The intracellular loop (in black) and the C-terminus tail are thought to be involved in size permeability and in opening and closing of the channel, whereas the transmembrane domains (shaded blocks) confer charge selectivity to the channel. The C-terminus also serves as a docking platform for numerous signal complexes. (**B**) Connexin monomers oligomerize into a hexameric structure, termed a connexon. A connexon is also called "hemichannel," to indicate that under certain circumstances it can function as membrane channel, thus opening a pore into the extracellular space. (**C**) When two connexons on apposed plasma membranes dock they form a gap junction channel, a transcellular pore that provides aqueous continuity between two cytoplasms and permits the diffusion of signaling molecules, ions, and nutrients among cells. In the example, homomeric Cx43 connexons pair with a similar connexon to form a homotypic gap junction that allows molecules as large as 1.2 kDa to pass from cell to cell. (**D**) Heteromeric connexons may also form when multiple connexins are expressed in the same cell. These may form heteromeric, heterotypic gap junctions, whose biophysical properties are different from those of homomeric connexons. In the example, a heteromeric Cx43 (shaded blocks)/Cx45 (black blocks) gap junction allows molecules not larger than 0.3 kDa to pass through the channel, as in such a mixed connexin environment Cx45 is functionally dominant. Homomeric heterotypic gap junctions can also form but they are usually nonfunctional.

functionality of the gap junction pore (Herve *et al.,* 2004; Laird *et al.,* 1995). Three-dimensional maps of a recombinant gap junction formed by a truncated Cx43 offer a spectacular confirmation of the predicted hexameric structure of the gap junction channel, with rings of α helices delimiting the pore crossing two plasma membranes and the intercellular gap (Unger *et al.,* 1997; Unger *et al.,* 1999).

The size and charge permeability of the aqueous pore is dictated by the specific connexins that form the gap junction (Elfgang *et al.,* 1995; White *et al.,* 1995). For example, connexin43 (Cx43; gene: *Gja1*) and connexin45 (Cx45; gene: *Gjc1*) have distinct biophysical properties. Cx43 permits the passage of molecules ~1.2 kDa or smaller and has a preference for passing negatively charged molecules. In contrast, Cx45 forms a much smaller pore, permitting the passage of molecules of ~0.3 kDa or less with preference for positively charged molecules (Elfgang *et al.,* 1995; Steinberg *et al.,* 1994; Veenstra *et al.,* 1994). As connexins may form heteromeric connexons, a wide range of molecular permeability and junctional conductance can be found in cells that express more than one connexin. For example, when Cx43 and Cx45 participate to heteromeric, heterotypic gap junctions, the permeability and conductance of the pore are closer to those of Cx45 than Cx43 (Koval *et al.,* 1995; Martinez *et al.,* 2002); and in general, the ratio between the connexins contributing to the heteromeric connexon dictates the permeability of the resulting gap junction (Cottrell *et al.,* 2002; Koval *et al.,* 1995; Martinez *et al.,* 2002). In addition to their classic function as conduits of ions and small molecules, gap junctions may serve as docking platforms for components of intracellular signaling systems, including β-catenin, c-src, extracellular signal regulated kinase (ERK), protein kinase C α and ε, phosphatidylinositol-3-kinase and p38 mitogen-activated protein kinase (Giepmans, 2004; Herve *et al.,* 2004; Saez *et al.,* 2003). As many of these interactions are connexin specific, by gating the signals passing through the gap junction pore, connexins may specify and regulate the repertoire of signaling complexes assembling at the gap junction.

Connexin Expression and Distribution in Bone and Cartilage

Gap junction plaques among adjacent osteoblasts, osteocytes, and periosteal fibroblasts were first identified in bone by electron microscopy (Doty and Schofield, 1972; Stanka, 1975), and by ultrastructural studies in histological sections of bone (Jones *et al.,* 1993; Palumbo *et al.,* 1990; Shapiro, 1997). Numerous *in vitro* studies have demonstrated the presence of functional gap junctions formed primarily by Cx43 among calvaria osteoblasts (Jeasonne *et al.,* 1979), odontoblasts (Ushiyama, 1989), primary human trabecular bone cells (Civitelli *et al.,* 1993) and a variety of osteoblastic (Donahue *et al.,* 1995b; Schiller *et al.,* 1992; Yamaguchi *et al.,* 1994), and osteocytic cell lines (Cheng *et al.,* 2001b; Yellowley *et al.,* 2000). Cx43 has also been shown to assemble in hemichannels in osteocytes (Cherian *et al.,* 2005; Genetos *et al.,* 2007), and it is likely that both gap junctions and hemichannels contribute to osteoblast–osteocyte communication. Cx43 has also been detected in osteoclasts at sites of active bone resorption, primarily at contact sites between osteoclasts and overlying marrow mononuclear cells (Ilvesaro *et al.,* 2000; Jones *et al.,* 1993; Su *et al.,* 1997), although the biological role of connexins in osteoclasts remains controversial.

Cartilage may seem an unlikely tissue for gap junctions as mature chondrocytes are isolated and embedded in the

extracellular matrix. However, both articular and growth plate chondrocytes may express Cx43 when grown in culture (D'Andrea and Vittur, 1996; Donahue *et al.,* 1995a; Schwab *et al.,* 1998), and formation of functional gap junctions in the superficial zone of articular chondrocytes has been documented *in vivo* (Chi *et al.,* 2004). Although the functionality of Cx43 in growth plate chondrocytes *in vivo* has not yet been proven, Cx43 is functional among adult bovine articular chondrocytes in culture (Donahue *et al.,* 1995a), suggesting that gap junctional communication may be reestablished in mature cartilage in conditions that lead to cell proliferation and tissue repair.

Bone forming cells are intimately associated with the vasculature and hematopoietic cells. *In vitro* work has shown that vascular endothelial cells can form functional gap junctions with bone marrow stromal cells in co-culture (Villars *et al.,* 2002); and the formation of gap junctional communication among vascular endothelial cells and bone marrow stromal cells supports differentiation of the latter toward the osteogenic lineage. Conversely, inhibition of intercellular communication among these two cell types can attenuate osteogenic potential (Guillotin *et al.,* 2004; Villars *et al.,* 2002).

Although less abundant than Cx43, other connexins are expressed by bone cells, but their biological role in the skeleton remains unknown. As noted, Cx45 is present at appositional membranes in osteoblast cultures (Civitelli *et al.,* 1993; Donahue *et al.,* 2000), and forms functional gap junctions of different molecular permeability than those formed by Cx43 (Koval *et al.,* 1995; Martinez *et al.,* 2002). Cx46 is also present in osteoblastic cells, but it is never found on the cell surface, it is retained in trans-Golgi compartments, and does not oligomerize to form gap junctions in these cells (Koval *et al.,* 1997). Connexin40 (Cx40; gene: *Gja3*) is detected in the embryonic skeleton, primarily in developing limbs, ribs, and sternum (Pizard *et al.,* 2005), but there is no evidence that *Gja3* is also expressed in the adult skeleton.

Regulation of Connexin Expression and Function in Skeletal Cells

Osteoblasts and Osteocytes

A number of *in vitro* studies have highlighted the critical role of Cx43 for the differentiation and function of bone forming cells. *Gja1* expression and intercellular communication increase upon osteoblast differentiation, whereas *Gjc1* expression does not change (Donahue *et al.,* 2000; Schiller *et al.,* 2001a). Interference with Cx43 function (Lecanda *et al.,* 1998; Stains *et al.,* 2003) or *Gja1* expression (Li *et al.,* 2006) alters the expression of osteoblast gene products critical for bone formation, including alkaline phosphatase, bone sialoprotein, and osteocalcin. Furthermore, chemical inhibition of gap junctional communication leads to delayed bone nodule formation and disruption of osteoblast gene expression in human murine osteoblasts (Donahue *et al.,* 2000; Schiller *et al.,* 2001a). Accordingly, primary osteoblast cell cultures isolated from *Gja1* null mice exhibit defective expression of osteoblast genes and delayed ability to form mineralized nodules *in vitro* (Lecanda *et al.,* 2000b). Closely similar defects are also seen in mice with an osteoblast specific deletion of *Gja1* (Chung *et al.,* 2006).

The presence of Cx43 gap junctions is also permissive for normal cell responsiveness to hormonal and physical stimuli. Osteoblastic cells rendered communication deficient by expression of a Cx43 antisense construct display a reduced cAMP response to parathyroid hormone (Van der Molen *et al.,* 1996), impaired contraction of osteoblast populated collagen lattices (Bowman *et al.,* 1998), and reduced alkaline phosphatase induction in response to electromagnetic fields (Van der Molen *et al.,* 2000). The reduced hormonal response of Cx43 deficient cells occurs despite a normal adenylate cyclase system, indicating that Cx43 gap junctions amplify the signals generated by local receptor activation, perhaps by allowing diffusion of signaling molecules or ions from responsive to non-responsive cells, thus equalizing differences in receptor distribution and hormonal responses in osteoblastic populations (Civitelli *et al.,* 1992; Civitelli *et al.,* 1994). Emerging *in vitro* data have led to hypothesize that the pharmacologic action of the bisphosphonate, alendronate, a strong inhibitor of bone resorption, also include an anti-apoptotic effect on osteoblasts and osteocytes, an effect dependent on Cx43 (Plotkin *et al.,* 2002). This action is mediated by alendronate-induced opening of Cx43 hemichannels, in a src-ERK dependent fashion (Plotkin *et al.,* 2005). *In vivo* testing of this intriguing hypothesis should be forthcoming.

Several osteoblast regulatory factors, including BMP-2 and TGF-β can enhance gap junctional communication, and the former increases Cx43 abundance (Rudkin *et al.,* 1996). In contrast, retinoic acid (Chiba *et al.,* 1994) and cytoplasmic acidification (Yamaguchi *et al.,* 1995) decrease gap junctional communication and Cx43 expression. The effects of prostaglandin E_2 (PGE_2) and PTH have been studied more in depth for different reasons. PGE_2 enhances gap junctional communication in murine osteoblastic cells (Shen *et al.,* 1986) via increased Cx43 assembly into gap junction channels (Civitelli *et al.,* 1998). PTH also stimulates gap junctional communication among osteoblasts and upregulates *Gja1* mRNA in a cAMP dependent fashion (Civitelli *et al.,* 1998; Donahue *et al.,* 1995b; Schiller *et al.,* 1992). Both PGE_2 and PTH effects result in feed-forward mechanisms, as upregulation of *Gja1* expression enhances a cell's ability to respond to PTH. Likewise, PGE_2, which upregulates Cx43 abundance is released by osteoblasts and osteocytes in a Cx43 dependent fashion, as discussed later.

The number of gap junctions declines in weightlessness conditions (Doty and Morey-Holton, 1982), and application of intermittent compressive load increases the number of gap junctions in osteocytes (Lozupone *et al.,* 1996). Furthermore, *Gja1* expression is increased in periodontal ligament after experimental tooth movement and in osteocytes after tooth extraction (Gluhak-Heinrich *et al.,* 2006; Su *et al.,* 1997). At the cellular level, application of cyclical equibiaxial strain by deformation of the tissue culture substrate leads to a rapid increase of Cx43 abundance at cell–cell contact sites and intercellular communication among osteoblastic cells (Ziambaras *et al.,* 1998), and to upregulation of *Gja1* expression in tendon cells (Wall and Banes, 2005). Fluid flow also increases *Gja1* expression and function in osteocytic cells (Alford *et al.,* 2003; Cheng *et al.,* 2001b; Cheng *et al.,* 2001a; Cherian *et al.,* 2003), although opposite effects have also been reported (Thi *et al.,* 2003). Nonetheless, gap junction-deficient cells are dramatically less responsive to fluid flow (Saunders *et al.,* 2001; Saunders *et al.,* 2003) and electric fields (Van der Molen *et al.,* 2000) than are normal osteoblastic cells. Thus, as in the case of PTH (Chung *et al.,* 2006; Van der Molen *et al.,* 1996), GJIC increases the sensitivity of bone cells to mechanical signals (Donahue, 2000).

Chondrocytes

In vitro studies have demonstrated that articular chondrocytes are not only capable of forming communicative gap junctions, but mechanical perturbation can amplify chondrocyte response by permitting diffusion of second messengers through the gap junction channel (Capozzi *et al.,* 1999; D'Andrea *et al.,* 1998; D'Andrea *et al.,* 2000). Although the role of Cx43 in chondrocytes has not been extensively studied, Cx43 is not absolutely required in the growth plate for bone growth during embryogenesis, as long bones of *Gja1* null mice at birth are of normal length and size (Lecanda *et al.,* 2000b). Nevertheless, micromass cultures of chondrocytes have demonstrated that gap junctions affect chondrocyte differentiation, as inhibition of gap junctional communication reduces production of proteoglycans and type II collagen (Zhang *et al.,* 2002). Other connexins may contribute to chondrocyte function and cartilage formation. For example, *Gja3* is highly expressed in the periarticular perichondrium, and *Gja3* null mice exhibit malformations and decreased length of limb bones (Pizard *et al.,* 2005). Moreover, Connexin29 (Cx29; gene: *Gje1*) promoter activity has recently been detected in chondrocytes *in vivo* (Eiberger *et al.,* 2006), although expression of *Gje1* has yet to be confirmed.

Osteoclasts

Although no osteoclast abnormalities have been reported thus far in different *Gja1* mutant mouse models (see later section), *in vitro* work has implicated Cx43 in the process of monocyte precursor fusion into osteoclasts and in osteoclast activity. Treatment of osteoclasts with pharmacologic gap junction inhibitors reduces the number of multinucleated osteoclasts and the ability to form resorption pits (Ilvesaro *et al.,* 2000; Ilvesaro *et al.,* 1998; Ransjo *et al.,* 2003). Similarly, the ability of PTH and vitamin D_3 to stimulate osteoclast activity is markedly inhibited by interference with gap junction function (Ransjo *et al.,* 2003), an effect that may be independent of the RANK/RANKL/OPG axis (Matemba *et al.,* 2006).

Connexins in Mechanotransduction

Intercellular communication is important for mechanotransduction, not only because mechanical and physical factors can modulate gap junctional communication, but also because gap junctions may provide the means by which mechanical signals can be received and propagated (Donahue, 2000). As discussed in the next section, gap junctions among cultured chondrocytes and osteoblastic cells are involved in propagation of certain types of intercellular Ca^{2+} waves produced by plasma membrane deformation (D'Andrea and Vittur, 1996; Donahue *et al.,* 1995a; Jørgensen *et al.,* 1997; Jørgensen *et al.,* 2000). Participation of Cx43 in Ca^{2+} wave propagation is not limited to providing transcellular conduits through which second messengers can flow from cell to cell, but it may also allow ATP to flow in the extracellular space through gap junction hemichannels, thus contributing to Ca^{2+} wave diffusion (see later in this chapter). Although functional hemichannels present in osteoblastic cells (Jørgensen *et al.,* 2003) do not seem to be involved in ATP release (Romanello *et al.,* 2001), application of fluid flow or mechanical perturbation of the plasma membrane can induce PGE_2 release via opening of Cx43 hemichannels in osteoblast and osteocytes (Cherian *et al.,* 2005). Studies in a novel co-culture system where osteocytic and osteoblastic cells were physically separated but could establish gap junctional communication, showed that application of fluid flow to the osteocytic cells results in increased alkaline phosphatase in the osteoblasts, whereas direct mechanical stimulation of osteoblasts does not (Taylor *et al.,* 2007). These experiments provide initial proof to the concept that gap junctions may convey mechanically generated signals from osteocytes to osteoblasts.

Modulation of Cell Signaling by Connexins

Recent work has begun to unravel the molecular details of how connexins can affect gene expression and ultimately, osteoblast function. As noted, osteoblasts isolated from *Gja1*$^{-/-}$ and conditional osteoblast *Gja1* ablated mice express lower levels of many markers of osteogenic differentiation (Chung *et al.,* 2006; Lecanda *et al.,* 2000b). Furthermore, interference with Cx43-dependent

gap junctional communication by either overexpression of chick *Gjc1* or pharmacologic inhibitors results in transcriptional downregulation of osteoblast genes, primarily *osteocalcin*, and α_1*(I) collagen* (Lecanda *et al.,* 1998; Schiller *et al.,* 2001b; Upham *et al.,* 2003). Conversely, expression of *Gja1* in poorly coupled cells upregulates osteoblast gene transcription (Gramsch *et al.,* 2001; Lecanda *et al.,* 1998). Moreover, using *Gjc1* overexpression to modulate Cx43 channels, a DNA element binding Sp1/Sp3 transcription factors was identified in the rat *osteocalcin* promoter. This element, named connexin response element (CxRE), is necessary and sufficient to confer connexin sensitivity to both the *osteocalcin* and α_1*(I) collagen* promoters (Stains *et al.,* 2003). Thus, the permeability properties of homomeric Cx43 junctional channels interact with signaling pathways involved in regulation of gene activity.

Further studies demonstrated that either *Gja1* deficiency or interference with Cx43 function alters ERK signaling, and this in turn modulates gene transcription from several osteoblast gene promoters (Stains *et al.,* 2003; Stains and Civitelli, 2005b). Downstream effects of gap junction modulation of ERK signaling converge upon the CxRE in the *osteocalcin* and α_1*(I) collagen* promoters. When Cx43 is abundant, both the activator Sp1 and the repressor Sp3 can occupy the promoter, with prevalence of Sp1; resulting in high transcriptional activity. When Cx43 function is inhibited, Sp3 almost exclusively occupies the CxRE, resulting in low transcriptional activity. Thus, ERK cascade dependent phosphorylation of Sp1 mediates preferential recruitment of Sp1 over Sp3 in well coupled cells, and loss of Sp1 phosphorylation results in the preferential recruitment of Sp3 (Stains and Civitelli, 2005b). Interestingly, osteocyte stimulation by fluid flow is also dependent upon ERK activation (Genetos *et al.,* 2007), thus suggesting that the ERK pathway may be involved in transmission of mechanically induced signals from osteocytes to osteoblasts, resulting in transcriptional upregulation of gene involved in bone formation. The current knowledge on connexin modulation of gene expression can be integrated into a model predicting that activation of signaling cascades by extracellular cues triggers a "primary response," which depends upon ligand availability and receptor abundance. Signals generated by this "primary" response, for example, cAMP, inositol-trisphosphate (IP_3) or cADP-ribose, are propagated to adjacent cells through gap junction channels formed by Cx43, thus resulting in a "secondary response," which potentiates the "primary" response and equalizes cell responses throughout a communicating network (Stains and Civitelli, 2005a; Stains and Civitelli, 2005b) (Fig. 4).

Connexins in Normal Skeletal Development

Earlier immunohistochemical studies in chick embryos demonstrated the presence of connexins in developing tooth germs of neonatal rats (Pinero *et al.,* 1994) and on mesenchymal cells at early stages of intramembranous bone formation in chick mandible, preceding the appearance of osteogenic cells (Minkoff *et al.,* 1994). Underscoring the importance of Cx43 in the heart, germline *Gja1* ablation causes severe malformations of the outflow tract incompatible with postnatal life (Reaume *et al.,* 1995). The skeleton of *Gja1* null ($Gja1^{-/-}$) mutants at birth reveals delayed intramembranous and endochondral ossification and skull abnormalities, with brittle, misshapen ribs and hypoplastic skull. The delayed development and hypomineralization of all the cranial vault elements results in a flattened skull and open parietal foramen (Lecanda *et al.,* 2000b). Most facial and axial skeletal elements are hypomineralized at E15.5, indicating approximately a two-day delay in skeletal ossification (Fig. 5A). Such phenotype is associated with an osteoblast autonomous cell defect, leading to defective production of mineralized bone matrix (Lecanda *et al.,* 2000b).

Malformations of facial bone development leading to aberrant maxillary and mandibular primordium and nasal pit defects have been produced in chick embryos after treatment with *Gja1* antisense oligonucleotides (Becker *et al.,* 1999; McGonnell *et al.,* 2001a). These abnormalities are associated with downregulation of the homeobox transcription factor Msx1 (McGonnell *et al.,* 2001b), a critical modulator of cranial development and patterning (Alappat *et al.,* 2003; Cohen, Jr., 2000). Additional evidence of the

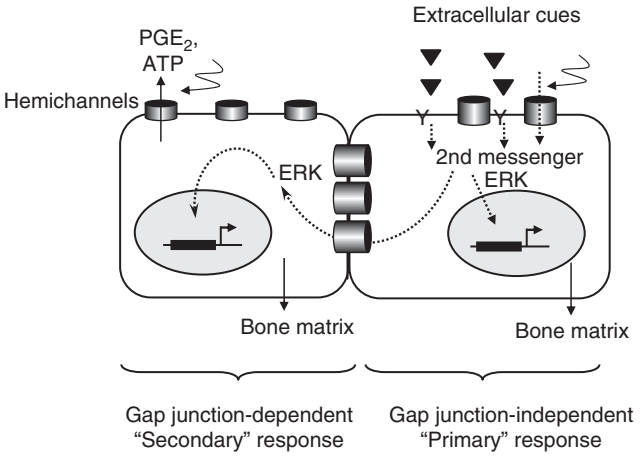

FIGURE 4 Gap junctions coordinate and amplify cellular activities by transmitting signals among a coupled cell network. Extracellular cues in the form of hormonal, paracrine (black triangles), or mechanical signals (jagged arrow) activate signaling cascades ("primary" response) generating second messengers that may be directly transmitted from cell to cell via gap junctions. Many of these signals regulate activation of ERK signaling and converge upon specific regulatory elements that modulate osteoblast gene transcription. By amplifying the signal or by diffusing the signal response to cells that might not be autonomously responsive to a certain stimulus, gap junctions contribute to generate a more coordinated, "secondary" response at the tissue level. In addition, hemichannels may contribute to cell responses by allowing release of factors (i.e., ATP, PGE_2 after mechanical stimulation) that in turn may act as autocrine signals for response amplification.

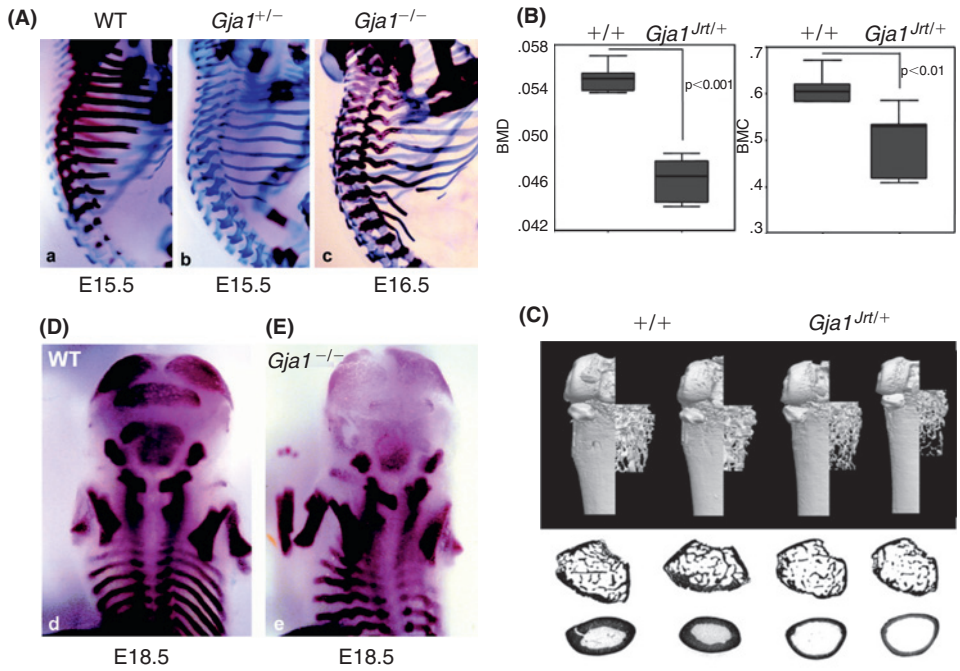

FIGURE 5 Skeletal consequences of *Gja1* mutations. (**A**) Genetic ablation of *Gja1* in mice leads to a developmental delay in ossification of the ribs (**A**–**C**), vertebrae and the skull (**D**,**E**), as seen in these alizarin red/alcian blue stained whole mount embryos. (**B**) Similarly, adult $Gja1^{jrt/+}$ mutant mice, which reproduce the human disease oculodentodigital dysplasia, exhibit decreased whole body bone mineral density (BMD) and bone mineral content (BMC). (**C**) MicroCT scanning of the femoral distal metaphysis shows rarefied trabecular structure and thinner cortical bone in $Gja1^{jrt/+}$ mutant mice relative to wild type mice, on 2D cross-sections. Reproduced from Lecanda *et al.,* (2000) *J. Cell Biol.*, **151**, 931–943. Copyright 2000 Rockefeller University Press (panel **A**); and from Flenniken *et al.* (2005) (panels **B** and **C**). (See plate section)

role of Cx43 in skeletal development across different species has emerged from work in zebrafish. The length of the zebrafish fin skeleton is determined by the number and size of fin bony segments (Iovine and Johnson, 2000). The short fin (*sof*) mutation, which was mapped to the *Gja1* locus, results in segments that are approximately one-third the length of wild type bony segments. These zebrafish *Gja1* mutations appear to cause defects of cell proliferation and osteogenic differentiation (Iovine *et al.,* 2005).

Considering the evidence for a role of Cx43 in skeletal growth and patterning, it may seem surprising that *Gja1* ablation does not cause a more severe skeletal phenotype. One possible explanation is the presence of compensatory mechanisms, as other connexins are present in bone cells. The obvious candidate is Cx45, but *Gjc1* null mutants die very early in embryogenesis, before condensation of skeletal elements (Kumai *et al.,* 2000), thus the role of Cx45 remains to be determined. Cx40 may provide another compensatory mechanism in early skeletogenesis, as demonstrated by studies in a mouse model of Holt-Oram syndrome, a human disorder caused by haploinsufficiency of T-box transcription factor, Tbx5, and characterized by limb malformations, shortened arms, abnormal sternum, and heart disease (Basson *et al.,* 1997). Tbx5 regulates expression of *Gja5*, and many of the skeletal abnormalities present in $Tbx5^{+/-}$ mice are shared by $Gja5^{+/-}$ and $Gja5^{-/-}$ mice (Pizard *et al.,* 2005). Interestingly, although dysmorphisms of phalanges, carpal bones, and sternum are common to $Tbx5^{+/-}$ and *Gja5* mutant mice, other features, such as rib and hindlimb defects are observed only in $Gja5^{-/-}$ mice, strongly suggesting that Cx40 is involved in skeletal patterning during development.

Connexin43 in the Postnatal Skeleton

The biologic role of Cx43 in the postnatal skeleton has only begun to emerge with the recent development of conditional *Gja1* deletion in mice (Castro *et al.,* 2003; Chung *et al.,* 2006). Not surprisingly, *Gja1* ablation using the Cre/*loxP* system, in which Cre recombinase is expressed by a 2.3 kb fragment of the $\alpha_1(I)$ *collagen* promoter, active in differentiated osteoblasts, does not cause skeletal malformations, nor the ossification defects seen in germline $Gja1^{-/-}$ mutants. Lack of dysmorphisms in these mice most likely reflects the timing of conditional gene inactivation, which occurs around birth, therefore after most of the skeleton has been modeled. However, conditional *Gja1* ablation in osteoblasts results in low bone mass at maturity and throughout adult life (Chung *et al.,* 2006). This phenotype is the result of a reduced number of active bone-forming cells and reduced bone formation rate. In addition to adult osteopenia, these animals exhibit a severely attenuated bone anabolic response to intermittent PTH administration, the

consequence of a failure of Cx43 deficient osteoblasts to mount a full response to the hormone (Chung *et al.,* 2006). These results have important ramifications for translational research, as PTH analogs are currently used as anabolic therapy for osteoporosis (Neer *et al.,* 2001). It would be important to determine whether other bone anabolic stimuli, such as mechanical loading, are also attenuated in conditions of *Gja1* deficiency.

Recent and emerging data expand the role of Cx43 to the hematopoietic compartment of the bone marrow microenvironment. *Gja1* null marrow stromal cells fail to support hematopoietic cell differentiation (Cancelas *et al.,* 2000), and mice with conditional deletion of *Gja1* in bone marrow cells have severely impaired recovery of hematopoiesis after cytoablative treatment, (Presley *et al.,* 2005). These intriguing data, which require further development, suggest that Cx43 serves critical functions in both stromal and hematopoietic bone marrow stem cell commitment and differentiation.

Connexin43 Mutations and Oculodentodigital Dysplasia

The human autosomal dominant disorder oculodentodigital dysplasia (ODDD) has been linked to a number of mutations in the *GJA1* locus (Kjaer *et al.,* 2004; Paznekas *et al.,* 2003; Richardson *et al.,* 2004). Affected patients have neurologic abnormalities, heart conduction defects, but primarily skeletal malformations including widened mandibular alveolar ridge, microdontia, anodontia, and enamel hypoplasia, as well as cranial hyperostosis (Loddenkemper *et al.,* 2002; Schrander-Stumpel *et al.,* 1993). Some affected patients also have type III syndactyly of hands and feet, and/or hypoplasia or aplasia of the middle phalanges and broad tubular bones (Schrander-Stumpel *et al.,* 1993). Functional characterization of many ODDD *Gja1* mutants has demonstrated that most of the resultant proteins translocate to the plasma membrane but do not support intercellular communication, nor hemichannel activity (Lai *et al.,* 2006; Shibayama *et al.,* 2005). In fact, most of them function as dominant negative on wild type Cx43 (Roscoe *et al.,* 2005).

A mouse strain was identified from random N-ethyl N-nitrosourea mutagenesis with a phenotype closely resembling that of ODDD, including syndactyly, enamel hypoplasia, craniofacial abnormalities, and cardiac dysfunction (Flenniken *et al.,* 2005) (Fig. 5B–C). These mice ($Gja1^{Jrt/+}$) carry a G60S missense mutation of *Gja1*, never reported in patients with ODDD, generating a full-length Cx43 protein with dominant negative function. The $Gja1^{Jrt/+}$ mouse is only a partial phenocopy of human ODDD; the most notable difference is absence of thickened bones of the cranial vault, frequently seen in ODDD patients (Schrander-Stumpel *et al.,* 1993). On the other hand, abnormalities not typically described in ODDD are present in $Gja1^{Jrt/+}$ mice, such as severe osteopenia, myelofibrosis, and hematopoietic defects (Flenniken *et al.,* 2005). Such discrepancies might be related to species differences. Nonetheless, the fact that skeletal abnormalities represent the major phenotypic feature of ODDD, in humans and in a mouse model, provides genetic proof that skeletal development is one of the major sites of action of Cx43.

It is important to note that aside from skull hyperostosis, no actual data on whole body or regional bone mass have ever been reported in ODDD patients. Both $Gja1^{Jrt/+}$ and osteoblast *Gja1* ablated mice exhibit a similar degree of osteopenia throughout life (Chung *et al.,* 2006; Flenniken *et al.,* 2005); however, although *Gja1* ablation severely impairs osteoblast differentiation and mineralization potential, resulting in decreased new bone formation (Chung *et al.,* 2006), the cellular bases of the low bone mass in $Gja1^{Jrt/+}$ mice are unclear. Unlike *Gja1* deletion, expression of ODDD mutants in osteoblast-enriched calvaria cells does not lead to major functional abnormalities (McLachlan *et al.,* 2005). Thus, it is theoretically possible that the dominant negative effect of ODDD mutants may not be sufficient to alter differentiation of committed osteoblastic cells, although it may be able to interfere with earlier steps of osteogenesis. Preliminary results from a new mouse model in which *Gja1* is deleted embryonically in cells that give raise to chondro-osteoprogenitors support this hypothesis, showing much more severe osteogenic defects than osteoblast-specific *Gja1* ablated mice (Watkins *et al.,* 2006).

SHORT-RANGE INTERCELLULAR SIGNALING AMONG SKELETAL CELLS

Transient and oscillatory elevations of cytosolic free calcium concentrations ($[Ca^{2+}]_i$) initiate and modulate a number of cellular activities, including cell growth, motility, and secretion. Many studies have investigated intracellular calcium homeostasis and the mechanisms by which extracellular signals are transduced into intracellular calcium transients; less attention has been paid to the mechanisms by which groups of cells propagate calcium transients among themselves, and to the biologic significance of these short-range intercellular signals. Two mechanisms of intercellular calcium signaling have been identified: gap junctional communication and release of soluble mediators that act on nearby cells. The latter involves activation of P2 ("purinergic") receptors by extracellular adenosine triphosphate (ATP) and other nucleotides (Osipchuk and Cahalan, 1992; Schlosser *et al.,* 1996).

Purinergic Receptors in Bone

Specific receptors that recognize extracellular ATP and other phosphorylated nucleotides such as adenosine 5′-diphosphate (ADP), uridine 5′-triphosphate (UTP),

and uridine 5'-diphosphate, but not adenosine, are termed P2 purinoceptors and are distinct from the P1 purinoceptors that bind adenosine. Two different families of P2 purinergic receptors exist, P2X and P2Y, which differ in structure and sensitivity to nucleotides (Brake *et al.*, 1996). Seven isotypes of P2X ($P2X_1$–$P2X_7$) and eight of P2Y receptors ($P2Y_{1,2,4,6,11,12,13,14}$) have been identified, all products of different genes (Ralevic and Burnstock, 1998). P2X receptors are ligand-gated ion channel receptors; ligand binding induces cell depolarization followed by a rapid increase in $[Ca^{2+}]_i$ via an influx of calcium ions through the channel. Conversely, P2Y receptors belong to the heptahelix G protein-coupled receptor superfamily (Dubyak and el-Moatassim, 1993) and are distributed more diffusely than P2X receptors. Binding of a ligand to a P2Y receptor activates the phospholipase C (PLC) system, with production of IP_3 and subsequent release of intracellular calcium from IP_3-sensitive stores.

The presence of P2 receptors in osteoblasts had been postulated by observations of transient $[Ca^{2+}]_i$ responses to extracellular ATP or ADP (Dixon *et al.*, 1997; Kumagai *et al.*, 1991; Schofl *et al.*, 1992). Indeed, several P2X and P2Y isotypes have been identified on the surface of human and rat osteoblastic cells, including $P2X_{1,4,5,6,7}$; $P2Y_{1,2,4,6,11}$ (Bowler *et al.*, 1995; Hoebertz *et al.*, 2000; Jørgensen *et al.*, 1997; Jørgensen *et al.*, 2002; Naemsch *et al.*, 2001). Osteoclasts also respond to extracellular nucleotides by increasing intracellular Ca^{2+} concentrations. Because both extracellular calcium influx and calcium release from intracellular stores are involved in the osteoclast response to ATP (Weidema *et al.*, 1997; Yu and Ferrier, 1993), both the P2X and P2Y families of receptors seem to be functional in these cells. Accordingly, $P2X_2$ (Hoebertz *et al.*, 2000), $P2X_4$ (Hoebertz *et al.*, 2000; Naemsch *et al.*, 1999), and $P2X_7$ (Hoebertz *et al.*, 2000) have been identified in rat osteoclasts. $P2Y_2$ is also expressed but it does not localize to the cell surface (Bowler *et al.*, 1995).

Function of Purinergic Receptors in Bone

In vitro studies demonstrate that extracellular nucleotides inhibit bone nodules formation and matrix mineralization in calvaria cultures (Hoebertz *et al.*, 2002; Jones *et al.*, 1997), and stimulate both osteoclast differentiation and bone resorption (Bowler *et al.*, 1995; Morrison *et al.*, 1998). The latter effect may be mediated by ATP upregulation of RANKL (Buckley *et al.*, 2002). Among all P2 receptors, $P2X_7$ has received particular attention as a potential regulator of osteoclast differentiation, based upon the observation that $P2X_7$ promotes giant cell formation from macrophages (Falzoni *et al.*, 1995). Initial *in vitro* studies supported this hypothesis, demonstrating that formation of multinucleated osteoclasts from human peripheral blood monocytes can be inhibited by a $P2X_7$ receptor blocking antibody (Gartland *et al.*, 2003a). Furthermore, osteoclast precursor cells lacking the $P2X_7$ receptor fail to form multinucleated osteoclast-like cells in response to RANKL (Hiken and Steinberg, 2004). However, apparently normal osteoclasts have been reported in two different mouse models of $P2X_7$ gene (*P2X7*) ablation (Gartland *et al.*, 2003b; Ke *et al.*, 2003), thus suggesting that $P2X_7$ receptors are dispensable for osteoclast precursor fusion, or for the function of mature osteoclasts. In fact, osteoclast number is actually increased in one of the *P2X7* null mouse models, an observation in keeping with decreased cortical and trabecular bone mass in these animals (Ke *et al.*, 2003). Intriguingly, cross-sectional area of long bones is smaller in these animals relative to wild type mice, arguing for an involvement of $P2X_7$ in periosteal bone formation (Ke *et al.*, 2003). On the other hand, only a modest increase in cortical thickness was described in the other *P2X7* null model, without substantial changes in bone formation (Gartland *et al.*, 2003b). One possible explanation for such discrepancies might be related to the different strain backgrounds in which the mutations were introduced. In fact, the C57BL/6 strain carries a natural mutation of *P2X7*, which reduces sensitivity to ATP (Adriouch *et al.*, 2002), and this genetic background is represented in different proportions in the two *P2X7* null mouse strains. In any case, the relatively mild phenotype found in both models may also reflect compensatory mechanisms, as other P2X receptor isotypes may complement some of the functions of $P2X_7$.

Subsequent studies have shown that *P2X7* null osteoclasts are less susceptible to apoptosis than are normal osteoclasts (Korcok *et al.*, 2004), findings consistent with the idea that lack of *P2X7* may actually increase osteoclast activity *in vivo*. This notion is supported by results of a clinical study in postmenopausal Danish women demonstrating a threefold higher 10-year fracture rate in subjects homozygous for a single nucleotide polymorphism of *P2X7* (Glu496Ala) relative to individuals with the "normal" allele (Ohlendorff *et al.*, 2007). Furthermore, the frequency of apoptosis in osteoclasts derived from peripheral blood monocytes of subjects homozygous for the Glu496Ala polymorphic variant is 50% lower compared to cells from individuals with the other genotypes (Ohlendorff *et al.*, 2007). Thus, it is possible that despite the relatively minor phenotype of *P2X7* mice, this purinergic receptor may contribute to control bone homeostasis in humans.

It has been hypothesized that short-range autocrine signals may modulate the set point for activation of certain signal transduction pathways (Ostrom *et al.*, 2000). For example, nucleotides potentiate PTH-induced increases in $[Ca^{2+}]_i$, but not the effect of PTH on cAMP production (Buckley *et al.*, 2001; Kaplan *et al.*, 1995; Sistare *et al.*, 1995). Furthermore, activation of P2 receptors in primary human osteoblasts potentiates PTH-induced *c-fos* gene expression (Bowler *et al.*, 1999). In fact, PTH by itself might not be able to fully activate PLC in osteoblasts if P2 receptors are not activated

(Sistare *et al.,* 1995). Because ATP is released upon mechanical stimulation (Bowler *et al.,* 2001), such a potentiation of PTH action may represent a mechanism of local control of hormonal effects, by focusing the response in areas under active loading, while leaving unloaded areas with cells that remain less sensitive to PTH action.

Intercellular Signaling and Mechanotransduction in Bone

As already noted, bone and cartilage cells propagate $[Ca^{2+}]_i$ signals upon mechanical perturbation of the plasma membrane. One mechanism of $[Ca^{2+}]_i$ wave propagation is dependent on the passage of an unknown signaling molecule through gap junctions and regeneration of the calcium transient in neighboring cells by calcium-induced calcium release (Xia and Ferrier, 1992), or by depolarization of the plasma membrane of the neighboring cell and opening of voltage-operated calcium channels (Jørgensen *et al.,* 2003). Notably, these "slow" types of $[Ca^{2+}]_i$ waves occur in cells that express abundant Cx43. The other type of $[Ca^{2+}]_i$ waves propagate with faster dynamics, and are mediated by the autocrine action of an extracellular nucleotide, probably ATP, on P2 receptors on adjacent cells and are independent of Cx43 (Jørgensen *et al.,* 1997) (Fig. 6). The biological significance of two mechanisms of short-range signal propagation in bone cell networks remains to be fully clarified. Interestingly, primary cultures of human bone marrow stromal cells can propagate mechanically induced $[Ca^{2+}]_i$ waves via both the gap junction mediated and the P2 mediated mechanisms (Jørgensen *et al.,* 2000), but their activity seems to change with differentiation. In relatively immature stromal cells, wave propagation occurs primarily via the $P2Y_2$ mechanism, while the gap junction mediated wave propagation prevails after long-term culture (four months), even though the cells still respond to ATP stimulation with an increase in $[Ca^{2+}]_I$ (Henriksen *et al.,* 2006). Corroborating such conclusion, expression of P2 receptors and response to nucleotide stimulation vary during osteoblast differentiation, in a manner consistent with gradual loss of P2 dependent paracrine signaling upon differentiation (Orriss *et al.,* 2006).

ATP released from osteoblasts not only acts on other osteoblasts but also on osteoclasts. P2 receptors are present on both cell types, and calcium transients can be propagated bidirectionally between these two cell types. This signal requires the presence of functional $P2X_7$ receptors on the osteoclast (Jørgensen *et al.,* 2002). This raises the possibility that the activity of the two cell types can be regulated independently by modulation of either the $P2Y_2$ or the $P2X_7$ receptor subtype, resulting in modulation of either bone formation or resorption without affecting the other. Demonstrating the critical importance of these receptors in mechanotransduction, *in vivo* mechanical loading of the ulna produces a profoundly attenuated anabolic response in *$P2X_7$* null mice relative to wild type mice (Li *et al.,* 2005).

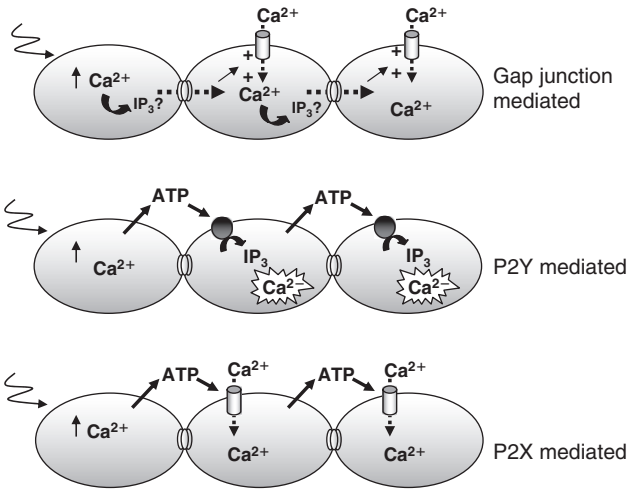

FIGURE 6 Mechanisms for the propagation of intercellular calcium signals. Gap junction-mediated calcium waves (top): the increase in intracellular-free calcium concentration caused by mechanical stimulation (jagged arrow) produces a signaling molecule, perhaps inositol-triphosphate (IP_3) that passes through the gap junction channel into adjacent cells where it releases calcium from intracellular stores, or induces depolarization of the plasma membrane and subsequent opening of voltage-operated calcium channels with an influx of calcium from the extracellular space. The intracellular calcium increase is then propagated to the next cell through the same mechanism, thus producing a calcium wave. Ligand-mediated calcium waves: mechanical stimulation increases intracellular-free calcium concentration in the stimulated cell. As a consequence, ATP or a related nucleotide is released to the extracellular space and binds to surface receptors on neighboring cells. If ATP binds to P2Y receptors (middle), IP_3 is generated, inducing the release of calcium from IP_3-sensitive intracellular calcium stores. If ATP binds to P2X receptors (bottom), conformational changes of the receptor/channel are induced, resulting in the opening of the channel, with a subsequent influx of extracellular calcium. In both cases, a calcium wave is generated by successive activation of P2 receptors in neighboring cells.

Articular chondrocytes can also propagate intercellular calcium waves in response to mechanical stimulation of single chondrocytes (D'Andrea *et al.,* 2000; Guilak *et al.,* 1999). Even in these cells, calcium wave propagation occurs via either gap junctional communication (D'Andrea *et al.,* 2000; D'Andrea and Vittur, 1996; Donahue *et al.,* 1995a), or via P2 receptor mediated mechanisms (Millward-Sadler *et al.,* 2004; Yellowley *et al.,* 1999). Mechanically induced calcium waves can also propagate from chondrocytes to synovial cells in culture via mechanisms involving both extracellular ATP release and gap junctions (D'Andrea *et al.,* 1998; Grandolfo *et al.,* 1993). The biologic significance of this intercellular signaling mechanism among chondrocytes remains to be determined.

Chapter 22

Histomorphometric Analysis of Bone Remodeling

David W. Dempster*

Regional Bone Center, Helen Hayes Hospital, West Haverstraw, New York, and Department of Pathology, College of Physicians and Surgeons, Columbia University, New York, New York

INTRODUCTION

Iliac crest bone biopsy followed by histomorphometric analysis has provided invaluable information about the pathogenesis and treatment of metabolic bone diseases. The purpose of this chapter is threefold: first, to provide an overview of the methods used to procure, process, and analyze the biopsy; second, to summarize and illustrate the changes that occur in histomorphometric indices in common metabolic bone diseases; and third, to describe the effects of commonly used osteoporosis drugs, assessed by bone biopsy.

TETRACYCLINE LABELING AND THE SURGICAL PROCEDURE

Prelabeling the patient with tetracycline prior to biopsy allows the histomorphometrist to quantify precisely the rate of bone formation at the time of the biopsy (Frost, 1983). About 3 weeks prior to the biopsy, the patient is given a 3-day course of tetracycline. This is followed by a 12 drug-free days and then another 3-day course of tetracycline. This is termed a 3:12:3 sequence. The biopsy should not be performed until at least 5 days after the last tetracycline dose to prevent the last label from leaching out during the processing of the biopsy. This is often denoted as a 3:12:3:5 sequence. The tetracycline binds irreversibly to recently formed hydroxyapatite crystals at sites undergoing new deposition. When the histomorphometrist cuts and visualizes thin sections of the biopsy in a microscope equipped with ultraviolet illumination, the tetracycline fluoresces to label the sites of new bone formation (Fig. 1). The labels can be either double labels if bone formation at that site is continuous throughout the labeling sequence or single labels if formation started after the first, or stops before the second label is administered. Demeclocycline, tetracycline, and oxytetracycline can all be used as fluorochrome labels. In our laboratory, our preference is for demeclocycline, 600 mg/ day (4 × 150-mg tablets), taken on an empty stomach. Dairy products and antacids containing aluminum, calcium, or magnesium should be avoided because they impair absorption. Tetracyclines can cause nausea, vomiting, and diarrhea in some patients, and all patients should be cautioned to avoid excessive exposure to sunlight and UV light because tetracyclines can cause skin phototoxicity. Tetracyclines should not be given to children less than 8 years of age or to pregnant women because, just as it is incorporated into bones, it is incorporated into growing teeth and discolors them.

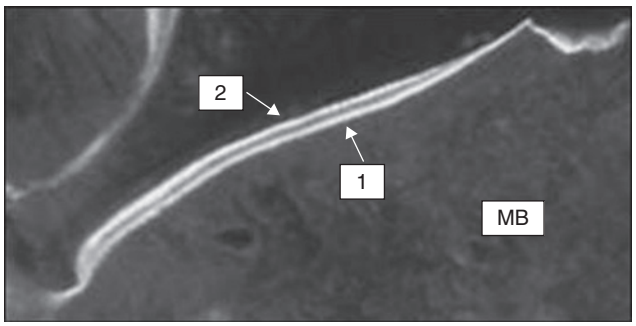

FIGURE 1 Double tetracycline label in an iliac crest bone biopsy. The patient was labeled with demeclocycline in a 3:12:3 sequence. 1, label 1; 2, label 2; MB, mineralized bone.

Principles of Bone Biology, 3rd Edition

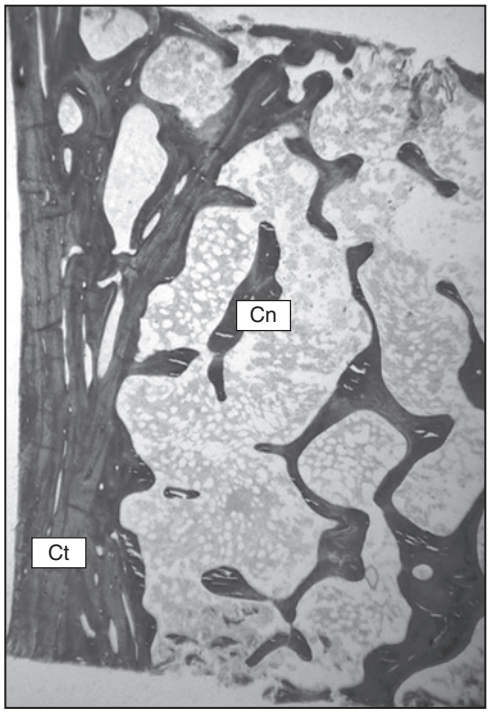

FIGURE 2 Low-power photomicrograph of an iliac crest bone biopsy section showing cancellous (Cn) and cortical (Ct) bone.

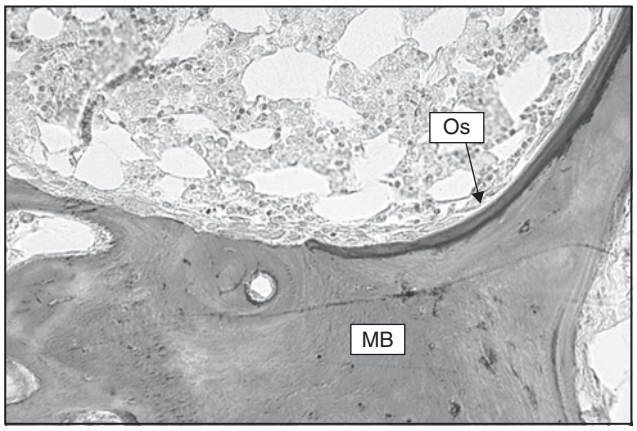

FIGURE 3 Photomicrograph of an iliac crest bone biopsy section showing an osteoid seam (Os) on the surface of mineralized bone.

Although the original site for bone biopsy was the rib, it is now performed exclusively at the anterior iliac crest, which is easily accessible, and the biopsy can be performed with minimal complications. This site also allows one to sample both cancellous and cortical bone in a single biopsy (Figs. 2 and 3). The structure and cellular activity at this site have been well characterized in a number of laboratories and have been shown to correlate with other clinically relevant skeletal sites, such as the spine and hip (Bordier *et al*., 1964; Parfitt, 1983a; Rao, 1983; Dempster, 1988).

The biopsy generally is performed with a standard trephine with an internal diameter of at least 8 mm to obtain sufficient tissue and to minimize damage to the sample (Bordier *et al*., 1964; Rao,1983). Immediately before the procedure, the patient should be sedated, usually with intravenous meperidine hydrochloride (Demerol) and diazepam (Valium). The skin, subcutaneous tissue, muscle, and, in particular, the periosteum covering both the lateral and the medial aspects of the ilium, should be thoroughly anesthetized with local anesthetic. Access to the iliac crest is achieved through a 2- to 3-cm skin incision made at a point 2 cm posterior and 2 cm inferior to the anterior superior iliac spine. It is important to locate this site carefully because there is considerable variation in bone structure around this location. In order to avoid damage to the biopsy, which could render it uninterpretable, the trephine should be rotated back and forth with gentle but firm pressure so that it cuts rather than pushes through the ilium. The patient should refrain from excessive activity for 24 hours after the procedure and a mild analgesic may be required. Significant complications from transiliac bone biopsy are rare. In an international multicenter study involving 9131 transiliac biopsies, complications were recorded in 64 patients (0.7%) (Rao, 1983). The most common complications were hematoma and pain at the biopsy site that persisted for more than 7 days; rarer complications included wound infection, fracture through the iliac crest, and osteomyelitis.

Sample Preparation and Analysis

The biopsy should be fixed in 70% ethanol because more aqueous fixatives may leach the tetracycline from the bone. After a fixation period of 4 to 7 days, the biopsy is dehydrated in ethanol, cleared in toluene, and embedded in methyl methacrylate without decalcification. The polymerized methyl methacrylate allows good-quality, thin (5 to 10 μm) sections to be cut on a heavy-duty microtome. The sections are then stained with a variety of dyes to allow good discrimination between mineralized and unmineralized bone matrix, which is termed "osteoid" (Figs. 4 and 5) and clear visualization of the cellular components of bone and marrow (see Fig. 7). Unstained sections are also mounted to allow observation of the tetracycline labels by fluorescence microscopy (see Fig. 1) (Baron *et al*., 1983; Weinstein, 2002). The sections are subjected to morphometric analysis, according to standard stereological principles, using either simple "point-counting" techniques or computer-aided image analysis (Parfitt, 1983b; Malluche and Faugere, 1987; Compston, 1997).

Routine Histomorphometric Variables

A large number of histomorphometric variables can be measured or derived. Because the morphometric analysis is extremely time-consuming, the number of variables evaluated depends on whether the biopsy specimen is being

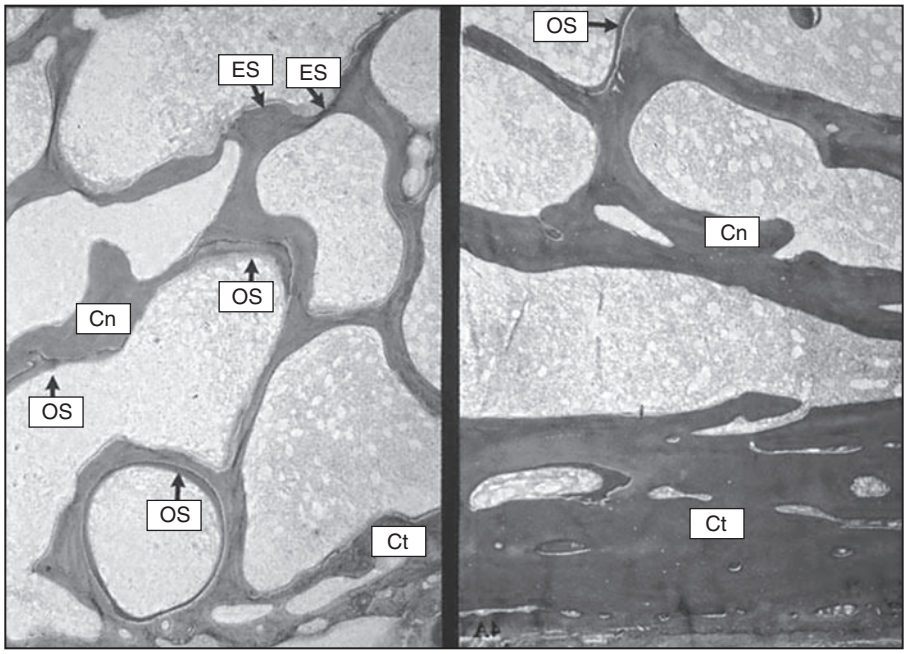

FIGURE 4 Photomicrographs of iliac bone biopsy sections from a subject with primary hyperparathyroidism (PHPT) (*left*), compared with a control subject (*right*). Note preservation of cancellous bone (Cn) and loss of cortical bone (Ct) in the subject with PHPT. Also note the marked extension of eroded surface (ES) and osteoid surface (OS) in PHPT.

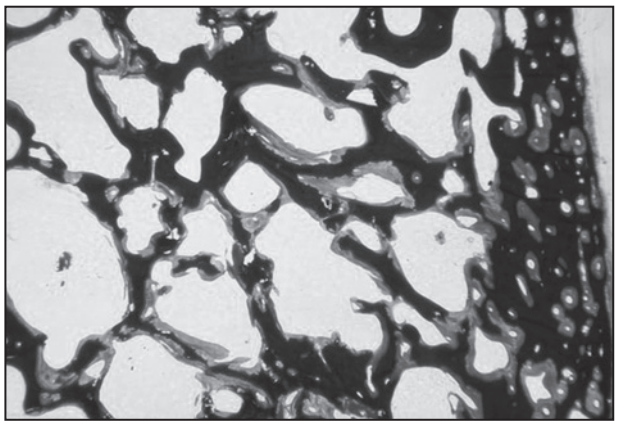

FIGURE 5 Photomicrograph of a bone biopsy section from a patient with severe osteomalacia. Note the dramatic extension of osteoid surface (stained light gray) and the increase in osteoid thickness.

analyzed for diagnostic or research purposes. Listed next are eight indices of trabecular bone that are of particular clinical relevance. For a detailed account of more theoretical aspects of bone biopsy analysis, see Parfitt (1983a) and Frost (1983).

It is conventional to divide histomorphometric parameters into two categories: Static variables yield information on the amount of bone present and the proportion of bone surface engaged the different phases of the remodeling cycle. Dynamic variables provide information on the rate of cell-mediated processes involved in remodeling. This category can only be evaluated in tetracycline-labeled biopsies. By measuring the extent of tetracycline-labeled surface and the distance between double-tetracycline labels, the bone formation rate can be computed directly in a single biopsy. Conversely, the resorption rate can only be calculated indirectly, using certain indices of bone formation, in a single biopsy specimen or from two sequential biopsy specimens (Frost, 1983; Eriksen, 1986).

Static Parameters

A list of five commonly used static variables is given here. The terms and abbreviations for all histomorphometric variables have been standardized by the Bone Histomorphometry Nomenclature Committee of the American Society for Bone and Mineral Research, whose recommendations have been widely adopted (Parfitt *et al*., 1987).

Cancellous bone volume (Cn-BV/TV, %). The fraction of a given volume of whole cancellous bone tissue (i.e., bone + marrow) that consists of mineralized and nonmineralized bone.

Osteoid volume (OV/BV, %). The fraction of a given volume of bone tissue (mineralized bone + osteoid bone) that is osteoid (i.e., unmineralized matrix).

Osteoid surface (OS/BS, %). The fraction of the entire trabecular surface that is covered by osteoid seams.

Osteoid thickness (O.Th, μm). The average thickness of osteoid seams.

Eroded surface (ES/BS, %). The fraction of the entire trabecular surface that is occupied by resorption bays (Howship lacunae), including both those with and without osteoclasts.

Dynamic Parameters

Following is a list of commonly use dynamic parameters:

Mineral apposition rate (MAR, μm/day). This is calculated by dividing the average distance between the first and second tetracycline labels by the time interval (e.g., 15 days) separating them. It is a measure of linear rate of production of calcified bone matrix by the osteoblasts.

Mineralizing surface (MS/BS, %). This is the fraction of trabecular surface bearing double-tetracycline-labeled plus one-half of the singly labeled surface. It is a measure of the proportion of bone surface on which new mineralized bone was being deposited at the time of tetracycline labeling.

Bone Formation Rate (BFR/BS, $\mu m^3/\mu m^2$ per day). This is the volume of mineralized bone made per unit surface of trabecular bone per year. It is calculated by multiplying the mineralizing surface by the mineral apposition rate.

In the following section, we will briefly review the remodeling process in normal bone and the changes that occur in a number of common disease states, as assessed by bone histomorphometry (Table I).

Normal Bone

Bone undergoes a continuous process of renewal with approximately 25% of trabecular bone and 3% of cortical bone being replaced annually. This remodeling process is referred to as a quantum phenomenon because it occurs in discrete units or "packets." Osteoclasts resorb the old bone and osteoblasts replace it. The group of cells that work cooperatively to create one new packet of bone is called a bone-remodeling unit (BRU). In normal trabecular bone, approximately 900 bone remodeling units are initiated each day. In cortical bone, about 180 remodeling units are initiated per day (Frost, 1973; Parfitt, 1983a, 1988; Dempster, 2002).

Hyperparathyroidism

Increased circulating parathyroid hormone (PTH) levels increase the activation frequency of bone-remodeling units, resulting in increased osteoclast and osteoblast number. As a result, histomorphometric analysis of a biopsy from a patient with either primary or secondary hyperparathyroidism reveals increases in eroded surface, osteoid surface, and mineralizing surface (see Fig. 4) (Melsen *et al*., 1983; Malluche and Faugere, 1987; Parisien *et al*., 1990; Silverberg *et al*., 1990). Mineralizing surface is increased, but mineral apposition rate is slightly reduced. However, the increased mineralizing surface overcompensates for the decrease in mineral apposition rate, so that the bone formation rate, the product of these two variables, is increased. Bone turnover is higher in hyperparathyroid patients with vitamin D insufficiency (Silverberg *et al*., 1990). Cancellous bone volume and trabecular connectivity are preserved in primary hyperparathyroidism (Parisien *et al*., 1992). The elevated bone turnover is often accompanied by increased deposition of immature (woven) bone and marrow fibrosis, in particular, in cases of severe secondary hyperparathyroidism.

Because the biopsy reflects the long-term effects of excessive remodeling activity (e.g., increased eroded surface) it can be a sensitive indicator of parathyroid gland hyperactivity, especially when this is mild or intermittent. However, examination of the biopsy alone does not allow one to distinguish between primary and secondary hyperparathyroidism.

Osteomalacia

The hallmark of osteomalacia, regardless of the underlying pathogenetic mechanism, is inhibition of bone mineralization. Although mineralization is inhibited, the osteoblasts continue to synthesize and secrete organic matrix leading to an accumulation of osteoid (see Fig. 5). Although the cancellous bone volume is normal in osteomalacia, the amount of mineralized bone is actually reduced.

Careful analysis of the dynamic parameters is called for in suspected cases of osteomalacia. At some formation sites, mineral is still deposited, but at a reduced rate, resulting in low values for mineral apposition rate. At other sites, mineralization may be completely inhibited, resulting in reduced mineralizing surface. The decrease in both these variables markedly reduces bone formation rate. The accumulation of osteoid is reflected in increased osteoid thickness, osteoid surface, and osteoid volume. If PTH secretion is elevated, the activation frequency of bone-remodeling units is enhanced and the biopsy may show an increase in eroded surface. However, as osteoid surface increases, eroded surface often declines because osteoid is resistant to osteoclastic resorption. An elevated activation frequency, when accompanied by mineralization failure, will enhance the rate at which osteoid is deposited (Teitelbaum, 1980; Jaworski, 1983; Malluche and Faugere, 1987; Siris *et al*., 1987).

Renal Osteodystrophy

Chronic renal failure is usually accompanied by phosphate retention and hyperphosphatemia, which leads to a reciprocal decrease in serum-ionized calcium concentration and secondary hyperparathyroidism. Furthermore, as functional renal mass decreases, the plasma 1,25-dihydroxyvitamin D level falls, leading to impaired intestinal calcium absorption, which exacerbates hypocalcemia and ultimately may impair bone mineralization. As a result of these marked disturbances in metabolism, it is perhaps not surprising that the bone biopsy findings in renal osteodystrophy are heterogeneous (Malluche *et al*., 1976; Boyce

TABLE I Bone Biopsy Variables in a Variety of Disease States[a]

Disease state	Cancellous bone volume	Osteoid volume	Osteoid surface	Osteoid thickness	Eroded surface	Mineral apposition rate	Mineralizing surface	Bone formation rate
Hyperparathyroidism[b]	N or ↑	↑	↑	N	↑	↓	↑	↑

Indeed, in allowing a better understanding of the skeletal status in patients with chronic renal failure, the bone biopsy continues to play an important role in the management of this disease. Thus, renal osteodystrophy has been subdivided into two broad types, primarily on the basis of histomorphometric features. One type is characterized by normal or high bone turnover and a second is characterized by low bone turnover.

The most frequently observed biopsy changes in patients with end-stage renal disease are the result of chronic excess PTH secretion on the skeleton. These are classified as normal/high turnover, and include osteitis fibrosa, mild hyperparathyroidism, and mixed bone disease (Fig. 6). These features are characterized histomorphometrically by increased eroded surface, osteoid surface, and mineralizing surface. In osteitis fibrosa, however, woven osteoid is often present and there are variable amounts of peritrabecular marrow fibrosis in contrast to the minimal or absent fibrosis observed in mild hyperparathyroidism. On the other end of the spectrum, low bone turnover is frequently observed in patients undergoing dialysis, albeit less often than high turnover disease. The low turnover states are classified as osteomalacia and aplastic or adynamic bone disease. Patients with osteomalacia have evidence of reduced values for dynamic variables accompanied by the accumulation of excess osteoid, whereas patients with aplastic or adynamic disease have a reduced tetracycline-based bone formation rate, but normal or reduced osteoid volume. In the 1970s and 1980s, most symptomatic patients with osteomalacia or aplastic bone disease showed evidence of aluminum accumulation with more than 25% of surfaces displaying aluminum stain. They were considered to have aluminum-related bone disease (Boyce *et al.*, 1982; Hodsman *et al.*, 1982; Dunstan *et al.*, 1985; Parisien *et al.*, 1988). The aluminum was primarily derived from aluminum-containing phosphate binders used to control hyperphosphatemia and dialysis solutions that were contaminated with aluminum. Like tetracycline, aluminum accumulates at sites of new bone formation, where it may directly inhibit mineralization, which is manifested in an increase in osteoid thickness and osteoid surface. However, aluminum also is toxic to osteoblasts and may impair their ability both to synthesize and mineralize bone matrix, resulting in a decrease in mineral apposition rate and the mineralizing surface. However, if matrix production is also reduced, osteoid thickness will not be elevated. With appreciation of the sources of aluminum contamination and increased use of calcium-containing phosphate binders, aluminum-related bone disease has become much less common in recent years.

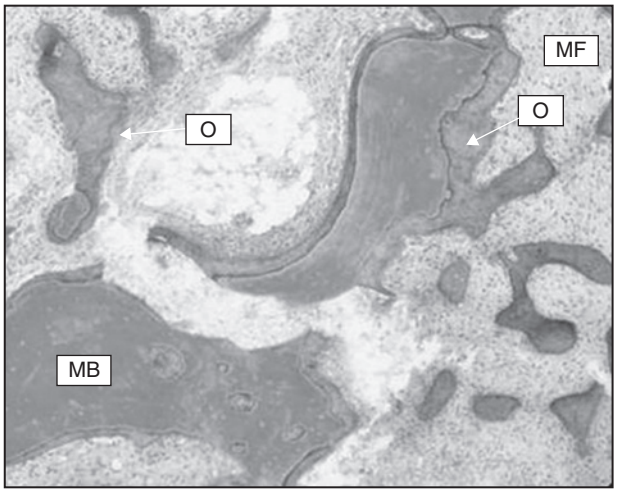

FIGURE 6 Photomicrograph of an iliac crest bone biopsy section from a patient with "mixed" renal osteodystrophy. Note deposition of woven osteoid (O) and marrow fibrosis (MF). MB, mineralized bone.

Another form of low turnover bone disease has been described that is not accompanied by significant aluminum accumulation. This is called idiopathic aplastic or adynamic bone disease. Its pathogenesis is unclear but may be related to various therapeutic maneuvers designed to prevent or reverse hyperparathyroidism in patients undergoing dialysis, including the use of dialysates with higher calcium concentrations (3.0 to 3.5 mEq/L), large doses of calcium-containing phosphate binders, and calcitriol therapy. As a rule, these patients have few symptoms of bone disease, and this "disease" ultimately may prove to be a histological rather than a clinically relevant form of bone disorder. However, it unknown whether patients with aplastic bone disease are at increased risk of the development of skeletal problems in the future.

Osteoporosis

The classic feature of bone biopsies in osteoporosis is the reduction in cancellous bone volume. Approximately 80% of patients with vertebral crush fractures have values that are lower than normal. In postmenopausal osteoporosis the reduction in cancellous bone volume is primarily caused by loss of entire trabeculae and, to a lesser degree, by the thinning of those that remain (Fig. 7) (Meunier *et al.*, 1981; Parfitt *et al.*, 1982; Whyte *et al.*, 1982; Meunier, 1988; Dempster, 2000).

With respect to the changes in the other static and dynamic variables in osteoporosis, there has been debate over whether patients can be stratified into high, normal, or low turnover groups. Even if they can, the pathogenetic and clinical significance of this so-called histological heterogeneity in patients with osteoporosis is unclear. In a study of 50 postmenopausal women with untreated osteoporosis, two subsets of patients were identified: one with normal turnover and one with high turnover, with the high turnover

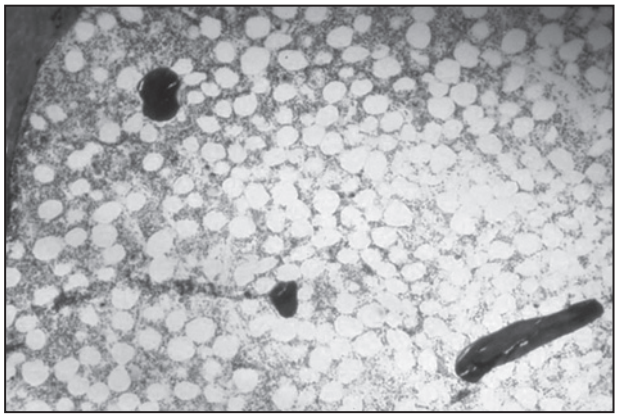

FIGURE 7 Photomicrograph of an iliac crest bone biopsy section from a patient with severe osteoporosis. Note marked reduction in cancellous bone volume in isolated trabecular profiles (arrowheads), which are cross-sections of thin, rod-like structures in three dimensions.

representing 30% of the cases (Arlot *et al*., 1990). However, this conclusion was based on the finding of a bimodal distribution in the static parameter, osteoid surface. The tetracycline-based bone formation rate, a dynamic measure of turnover rate, displayed a normal distribution. Based on the interval between the 10th percentile and the 90th percentile for calculated bone resorption rate in a group of normal postmenopausal women, another study classified 30% of women with untreated postmenopausal osteoporosis as having high turnover, whereas 64% and 6% had normal and low turnover, respectively (Eriksen *et al*., 1990). When bone formation rate was used as the discriminant variable, 19% were classified as having high turnover, 72% as having normal turnover, and 9% as having low turnover. On the other hand, in two studies of postmenopausal women with osteoporosis and their normal counterparts, the same wide variation in turnover indices was found in both groups, leading the investigators to conclude that there were no important subsets of patients with osteoporosis (Garcia Carasco *et al*., 1989; Kimmel *et al*., 1990). These studies, however, confirmed earlier observations that some patients with osteoporosis show profoundly depressed formation with little or no tetracycline uptake (Whyte *et al*., 1982).

From a clinical viewpoint, the desire to classify patients with osteoporosis according to their turnover status stems from the notion that the turnover rate may influence the response to particular therapeutic agents. For example, patients with high turnover rates may respond better to anticatabolic treatments. There was early evidence that this was the case for calcitonin (Civitelli *et al*., 1988). However, in clinical practice, the biopsy is an impractical way to determine turnover status. It was once believed that biochemical markers of bone resorption and formation would be useful in this regard, but this has yet to materialize.

Note that, in most cases, bone biopsy is performed when the disease is severe, with multiple fractures having already occurred. It is probable that, in many cases, the disturbances in bone metabolism that led to the reduction in bone mass and strength took place several years before the time of the biopsy and are no longer evident (Steiniche *et al*., 1994). Another confounding factor is that most patients who undergo biopsy for osteoporosis have already received treatment with one or more pharmaceutical agents.

Clinical Indications for Bone Biopsy

In general, a bone biopsy is only helpful in metabolic bone diseases. Only rarely is a biopsy indicated in patients with localized skeletal disease such as Paget's disease of bone, primary bone tumors, or bone metastases involving the iliac crest. The biopsy usually does not provide significantly greater insight into the disease process in postmenopausal women with osteoporosis. However, bone biopsy can be useful in patients who are less frequently affected by osteoporosis, such as young men and premenopausal women. Patients with osteopenia or women with postmenopausal osteoporosis should not have biopsies simply to measure cancellous bone volume to confirm the diagnosis of osteoporosis. The intraindividual and interindividual variability in cancellous bone volume is too great, and there is too much overlap between cancellous bone volume in patients with clinical osteoporosis and normal subjects to make this useful. However, bone biopsy is useful to exclude subclinical osteomalacia. In one study, 5% of patients with vertebral fractures displayed definitive evidence of osteomalacia on biopsy despite normal biochemical and radiological findings (Meunier, 1981). Moreover, the biopsy can be useful in identifying more precisely the probable cause of bone loss in individual patients with osteoporosis. For example, if the biopsy reveals or confirms a high bone turnover rate, it would be important to rule out endocrine disorders, such as hyperthyroidism and hyperparathyroidism. Finally, the biopsy is the best available way to evaluate the effect of various therapeutic maneuvers on bone cell function (e.g., Holland *et al*., 1994a,b; Marcus *et al*., 2000). This is discussed in detail in the context of therapies for osteoporosis in the following section.

As noted earlier, the bone biopsy can be extremely useful in patients with renal osteodystrophy, although the large number of patients with renal disease precludes its use in every case. In general, if a symptomatic patient has biochemical evidence of secondary hyperparathyroidism (hyperphosphatemia, hypocalcemia, and markedly elevated intact PTH levels), biopsy is not necessary because one can predict with reasonable certainty that it would reveal osteitis fibrosa. However, patients with renal disease who have bone pain and fractures without the biochemical profile of secondary hyperparathyroidism should undergo biopsy to determine whether they have osteomalacia or idiopathic, aplastic bone disease. Although aluminum accumulation is much less common nowadays, the biopsy will also permit

the physician to determine whether it is a significant contributory factor. Although the biopsy can be useful in the clinical management of certain patients with bone disease, its principal use today is as a research tool.

HISTOMORPHOMETRIC STUDIES OF THE EFFECTS OF OSTEOPOROSIS DRUGS

In this section we will review what histomorphometry has revealed about the effects of drugs used to treat osteoporosis. The drugs will be covered under the headings of their two principal mechanisms of action: anticatabolic, also known as antiresorptive, and anabolic (Riggs and Parfitt, 2005).

Anticatabolic Agents

Calcitonin

Intranasal calcitonin is approved to reduce the risk of vertebral fractures, but its efficacy in nonvertebral fractures has not been established (Silverman, 2003). There have been several histomorphometric studies of the effects of calcitonin in subjects with osteoporosis or with rheumatoid arthritis (Gruber *et al*., 1984; Marie and Caulin, 1986; Alexandre *et al*., 1988; Palmieri *et al*., 1989; Kroger *et al*., 1992; Gruber *et al*., 2000; Pepene *et al*., 2004; Chesnut *et al*., 2005). In cancellous bone, calcitonin treatment reduced eroded surface (Kroger *et al*., 1982; Gruber *et al*., 1984) and active resorption surface (Alexandre *et al*., 1988) and mean resorption rate (Chesnut *et al*., 2005) with no observed decrease in osteoclasts (Marie and Caulin, 1986; Palmieri *et al*., 1989; Gruber *et al*., 2000). Most studies failed to reveal any differences in bone formation parameters, e.g., osteoblast number and perimeter, osteoid perimeter and thickness, mineralized perimeter, mineral apposition rate (Gruber *et al*., 1984; Marie and Caulin, 1986; Alexandre *et al*., 1988; Chesnut *et al*., 2005). However, one report (Gruber *et al*., 2000;) suggested that bone formation was not reduced to the same extent as resorption. Cancellous bone volume was shown to be unchanged (Alexandre *et al*., 1988; Gruber *et al*., 2000; Chesnut *et al*., 2005) or increased (Gruber *et al*., 1984; Alexandre *et al*., 1988; Palmieri *et al*., 1989; Marie and Caulin, 1986; Kroger *et al*., 1992).

Hormone Therapy (HT)

Bone histomorphometry has been used by several investigators to assess the effects of HT on both cancellous and, in some studies, cortical bone of the ilium (Steiniche *et al*., 1989; Lufkin *et al*., 1992; Holland *et al*., 1994; Eriksen *et al*., 1999; Vedi and Compston, 1996, 2003). One of the most interesting studies was by Eriksen *et al*. (1999) who showed that two years of HT decreased resorption parameters, reducing bone formation at the BMU level. Cancellous wall thickness was similar in treated and placebo groups, but there was a significant reduction in resorption rate in the HT group. This was in contrast to the placebo group which showed a significant increase in erosion depth and a modest increase in resorption rate. The reduction in the size of the resorption cavity with HT was confirmed in a later study (Vedi *et al*., 1996), although that study also demonstrated a compensatory decrease in the wall width of trabecular bone packets. These findings were not replicated in a study (Steiniche *et al*., 1989) in which HT was only given for one year.

Estrogen treatment has been shown to stimulate bone formation in animal models (Chow *et al*., 1992a, 1992b; Edwards *et al*., 1992) but this remains controversial in humans (Steiniche *et al*., 1989; Lufkin *et al*., 1992; Holland *et al*., 1994; Vedi and Compston, 1996; Wahab *et al*., 1997; Eriksen *et al*., 1999; Patel *et al*., 1999; Vedi *et al*., 1999, 2003). Standard doses of HT reduce osteoid and mineralizing surfaces and bone formation rate, with no change or a decrease in wall width (Steiniche *et al*., 1989; Lufkin *et al*., 1992; Holland *et al*., 1994; Vedi and Compston, 1996; Eriksen *et al*., 1999; Patel *et al*., 1999; Vedi *et al*., 2003). On the other hand, long-term, high-dose HT was reported to increase cancellous wall width and to decrease eroded cavity area. Similarly, six years of subcutaneous HT increased cancellous bone volume with an increment in trabecular thickness and number as well as wall width (Khastgir *et al*., 2001). Such anabolic actions of HT have also been reported in Turner's syndrome treated with HT (Khastgir *et al*., 2003). The improvements in bone structure demonstrated by two-dimensional histomorphometric analysis are supported by micro-CT findings of a higher ratio of plate- to rod-like structures (Jiang *et al*., 2005). In addition to these changes in histomorphometric variables, HT has also been shown to increase the degree of collagen cross-linking and bone mineralization, consistent with its primary action to lower bone turnover (Walters and Eyre, 1980; Holland *et al*., 1994a,b; Rey *et al*., 1995; Yamauchi, 1996; Khastgir *et al*., 2001; Boivin and Meunier, 2002; Burr *et al*., 2003; Paschalis *et al*., 2004; Boivin *et al*., 2005).

Selective Estrogen Receptor Modulators (SERMs)

Selective estrogen receptor modulators (SERMs) bind to the estrogen receptor and exhibit agonist actions in some tissues, such as bone, and antagonist actions in others, such as breast (Lindsay *et al*., 1997). Bone histomorphometry studies are primarily limited to raloxifene. Two

years of raloxifene treatment in the MORE trial (Ettinger *et al*., 1999) decreased the bone formation rate, without changes in eroded surface and osteoclast number at the 60-mg dose, whereas the dose of 120 mg also decreased the bone formation rate and showed a trend toward a decrease in eroded surface and osteoclast number (Ott *et al*., 2000). Cancellous bone volume, trabecular thickness, and cortical width were unchanged compared with baseline and the placebo group (Ott *et al*., 2000). A significant decrease in activation frequency was observed with a higher dose (150 mg) of raloxifene (Weinstein *et al*., 2003). In that study, raloxifene was shown to have effects similar to those of HT. However, a 6-month treatment with 60 mg of raloxifene did not suppress activation frequency and bone formation rate to the same extent as HT (Prestwood *et al*., 2000). Reductions in activation frequency, bone formation rate, and resorption cavity area have also been demonstrated for another SERM, tamoxifen (Wright *et al*., 1994). In contrast to HT, raloxifene had little effect on mineralization density as assessed by quantitative microradiography of the biopsy sections (Boivin *et al*., 2003).

Bisphosphonates

The bisphosphonates have been the mainstay of osteoporosis therapy and will continue to be so for some time to come (Fleisch, 1998). The effects of alendronate, the first bisphosphonate to be approved in the United States, have been investigated in patients with postmenopausal osteoporosis (Bone *et al*., 1997; Chavassieux *et al*., 1997; Arlot *et al*., 2005), as well as in patients with glucocorticoid-induced osteoporosis (Chavassieux *et al*., 2000). Alendronate reduced osteoid surface and thickness, mineralizing surface, bone formation rate, and activation frequency. The mineral apposition rate was unchanged (Bone *et al*., 1997; Chavassieux *et al*., 1997; Arlot *et al*., 2005). Although the primary target of bisphosphonates is the osteoclast, alendronate, like other anticatabolic agents, had little, if any effect on histomorphometric variables of bone resorption, including eroded surface and volume, osteoclast number, and erosion depth. This is inconsistent with the marked reductions seen in biochemical markers of bone resorption. The discrepancy is most likely explained by the fact that histomorphometric indices of bone resorption are static parameters, in contrast to bone formation indices, which are dynamic. In one study (Chavassieux *et al*., 1997), wall thickness of trabecular bone packets was increased after two years of treatment, but this effect was not observed after three years. Histomorphometric studies failed to show an improvement in cancellous bone microarchitecture compared with placebo-treated subjects, but such an effect has been reported for three-dimensional structural parameters obtained by microcomputed tomography (Recker *et al*., 2005), with the assumption that alendronate prevented the loss of structural integrity experienced by the placebo-treated patients. Consistent with its primary action to reduce the activation frequency, alendronate increased the degree of mineralization of the matrix (Meunier and Boivin, 1997; Boivin *et al*., 2000; Hernandez *et al*., 2001; Roschger *et al*., 1997, 2001).

There have also been extensive studies of the effects of risedronate on the bone biopsy. Here, a paired biopsy design was employed with biopsies being obtained before and after treatment in the same subjects (Eriksen *et al*., 2002; Dufresne *et al*., 2003; Borah *et al*., 2004, 2005, 2006; Seeman and Delmas, 2006; Zoehrer *et al*., 2006). Like alendronate, three years of risedronate treatment decreased mineralizing surface, bone formation rate, and activation frequency (Eriksen *et al*., 2002). Again, no significant change was noted in eroded surface and depth, but there was a significant decrease in resorption rate after risedronate treatment, with a significant increase in erosion depth in placebo-treated subjects. Also similar to alendronate's effects, risedronate preserved cancellous microarchitecture, as assessed by microcomputed tomography (Dufresne *et al*., 2003; Borah *et al*., 2004, 2005). No significant changes were seen in three-dimensional structural variables compared to baseline in risedronate-treated women, whereas trabecular microstructure deteriorated significantly in a subset of placebo-treated women who exhibited higher bone turnover at baseline (Borah *et al*., 2004). Furthermore, the degree of structural deterioration was positively correlated with the bone turnover, confirming that high turnover has a deleterious effect on bone structure. Similar results were reported for early postmenopausal women who were treated for just one year with risedronate (Dufresne *et al*., 2003). The reduction in bone turnover was associated with an increase in bone mineralization density, but there was no evidence of an abnormally high degree of mineralization, even when treatment was extended to five years (Borah *et al*., 2006; Durchschlag *et al*., 2006; Seeman and Delmas, 2006; Zoehrer *et al*., 2006).

There are a number of other studies on the effects of different bisphosphonates, such as zoledronate and ibandronate, on iliac bone (Recker *et al*., 2004, 2008). In general, the data obtained in patients with osteoporosis treated with these bisphosphonates are similar to those obtained with alendronate and risedronate (Recker *et al*., 2004, 2008). It should also be noted that there is evidence of dramatic improvements in bone structure and turnover in children with osteogenesis imperfecta treated with bisphosphonates (Munns *et al*., 2005).

Anabolic Therapies

Bone histomorphometry has confirmed that the mechanism of action of anabolic agents is fundamentally different from that of anticatabolic drugs (Frost, 1983). Rather

than reducing the activation frequency of bone remodeling, anabolic agents elevate it with a positive bone balance. In each bone-remodeling unit, more bone is formed than was resorbed. Bone formation is increased prior to the increase in bone resorption. Consequently, anabolic agents are able to improve, rather than simply preserve cancellous and cortical bone microarchitecture.

PTH(1–34) and PTH(1–84)

The first bone biopsy studies of the effects of PTH(1–34) were conducted in postmenopausal women with osteoporosis who were treated concurrently with PTH(1–34) and HT for six or twelve months (Reeve *et al*., 1980, 1991; Bradbeer *et al*., 1992). Hodsman and colleagues (1993, 2000) also used bone biopsy to study the effects of a cyclical regimen of 28 days of PTH(1–34) every three months, with or without sequential calcitonin, for two years. Dempster *et al*. (2001) and Misof *et al*. (2003) performed paired biopsies in men with osteoporosis treated with PTH(1–34) for eighteen months, as well as in postmenopausal women treated with a combination of PTH(1–34) and HT for three years. Biopsy studies of the effects of monotherapy with PTH(1–34) were completed as part of a multinational fracture trial (Neer *et al*., 2001; Jiang *et al*., 2003; Dobnig *et al*., 2005; Paschalis *et al*., 2005; Ma *et al*., 2006). Arlot and colleagues (2005) compared the effects of PTH(1–34) with those of alendronate in postmenopausal women with osteoporosis. The effects of the two agents on activation frequency and bone formation rate were diametrically opposed. Compared with appropriate reference ranges (Arlot *et al*., 1990; Chavassieux *et al*., 1997), the bone formation rate was 10% of normal in the alendronate-treated group and 150% higher than normal in the PTH(1–34)-treated group. The higher activation frequency in the PTH(1–34) group led to an increase in cortical porosity, which may explain observations of transient reductions in bone mineral density following treatment with PTH(1–34) (Neer *et al*., 2001; Finkelstein *et al*., 2003; Ettinger *et al*., 2004). A recent study (132) used a novel, quadruple tetracycline-labeling regimen to perform a longitudinal study of the early effects of PTH(1–34) treatment on bone formation. Within 4 weeks of treatment, PTH(1–34) increased mineralized perimeter, mineral apposition rate, and bone formation rate (Hodsman *et al*., 1993, 2000; Lindsay *et al*., 2006). Lindsay *et al*.'s study (2006) suggested that PTH(1–34) stimulates osteoblastic activity in preexisting remodeling units. This could be accomplished by a variety of mechanisms, including an increase in the work rate of preexisting osteoblasts, enhanced recruitment of new osteoblasts, or a prolongation of osteoblast life span (Jilka *et al*., 1999). Regardless of the mechanism, one noteworthy feature of PTH(1–34) is its ability to extend

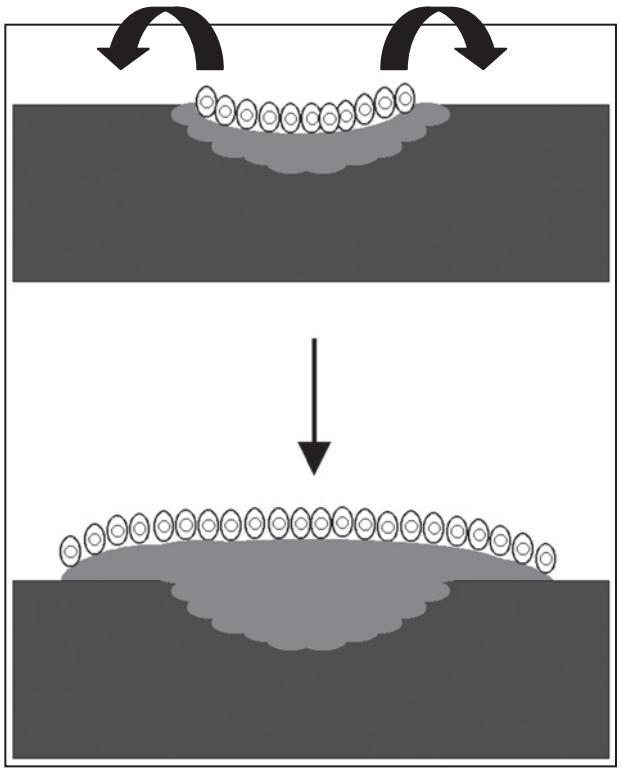

FIGURE 8 Proposed mechanism whereby PTH(1–34) could extend bone formation beyond the limits of the remodeling unit to annex the surrounding bone surface. Reproduced with permission from Lindsay *et al*. (2006).

formation to quiescent surfaces surrounding the original remodeling unit (Fig. 8) (Lindsay *et al*., 2006). Bone-remodeling indices were increased after 1 month (Holland *et al*., 1994b), 2 months (Chow *et al*., 1992b), and 6 months (Reeve *et al*., 1980; Arlot *et al*., 2005) of treatment, and they returned toward baseline between 12 (Reeve *et al*., 1991) and 36 months of continuous treatment (Hodsman *et al*., 2000; Dempster *et al*., 2001). This temporal sequence of remodeling activation and deactivation, derived from biopsy studies, is confirmed by parallel changes in bone markers (Lindsay *et al*., 1997; Kurland *et al*., 2000; Cosman *et al*., 2001; Arlot *et al*., 2005; McClung *et al*., 2005).

The striking stimulation of bone formation by PTH (1–34) provides a mechanism for the reported increases in wall thickness of bone packets on cancellous and endocortical surfaces (Bradbeer *et al*., 1992; Hodsman *et al*., 2000; Dempster *et al*., 2001; Ma *et al*., 2006), which in turn leads to improvements in cancellous bone mass, trabecular connectivity, and cortical thickness (Dempster *et al*., 2001; Jiang *et al*., 2003) (Figs. 9 and 10). These improvements in cancellous bone structure were correlated with the early increases in bone formation markers (Dobnig *et al*., 2005). The deposition of new bone brought about an increase in the proportion of bone matrix with lower

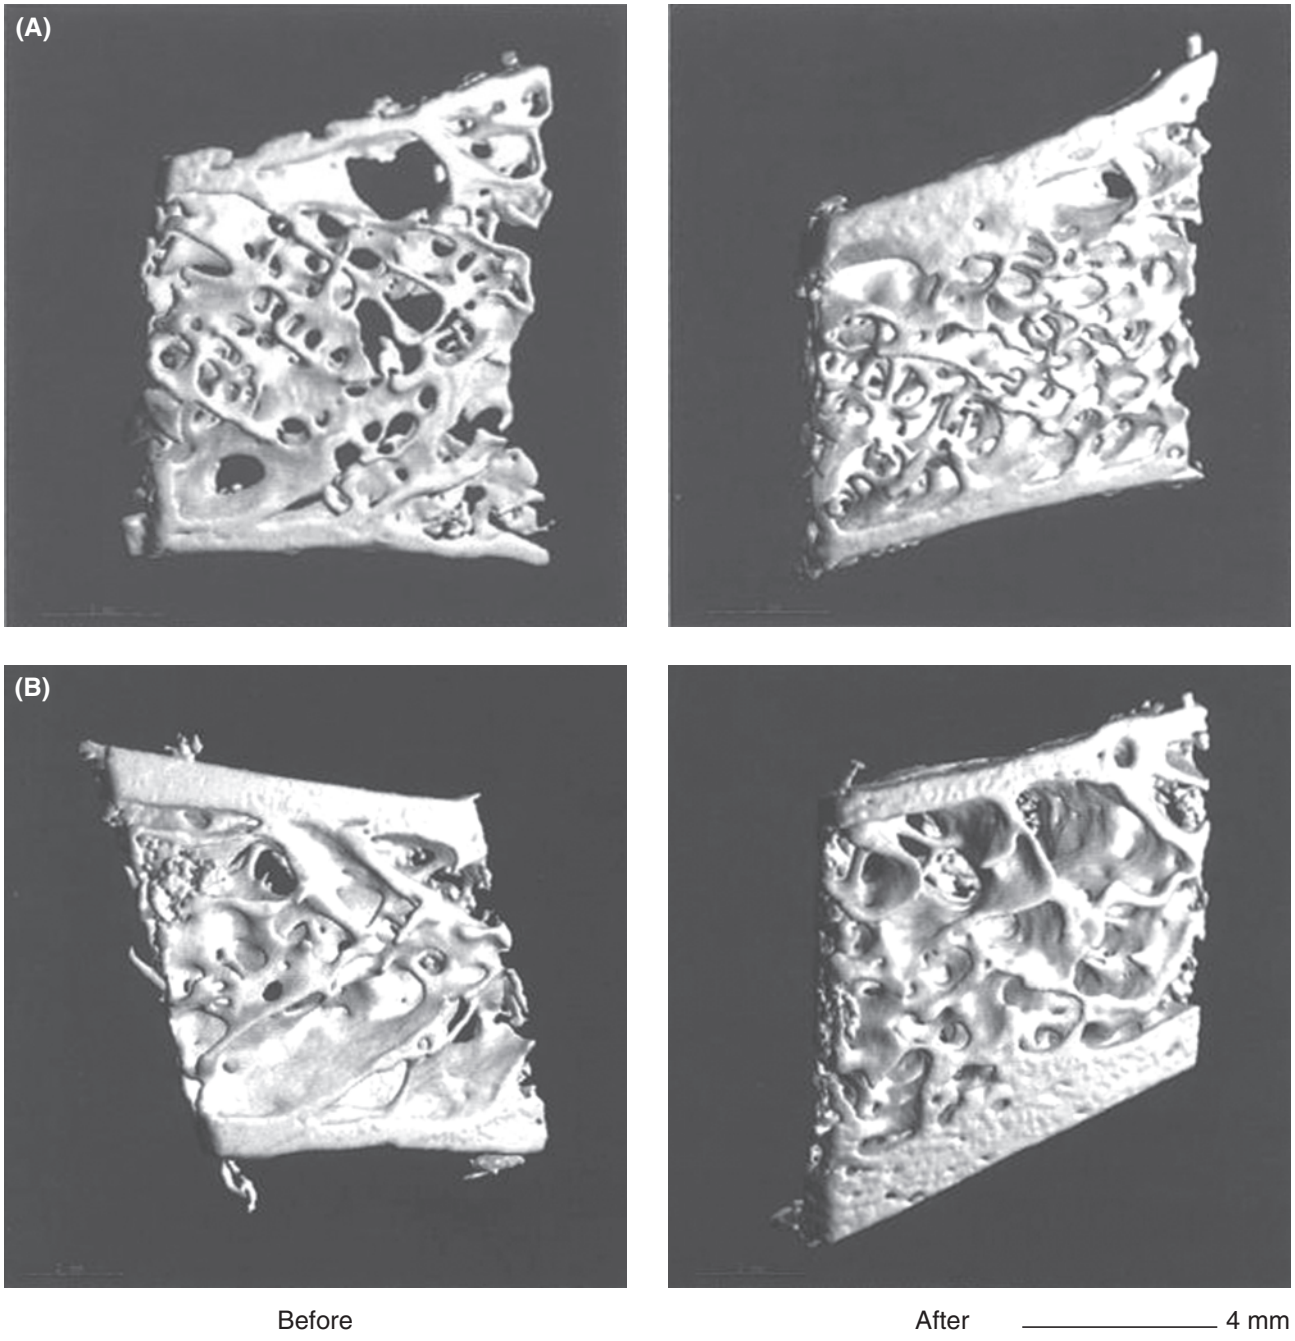

FIGURE 9 Microcomputed tomographic images of paired biopsies before (*left*) and after (*right*) treatment with PTH(1–34) in a 64-year-old woman (**A**) and a 47-year-old man (**B**). Note improvement in cancellous and cortical bone structure after treatment. Reproduced with permission from Dempster *et al.* (2001).

mineralization, mineral crystallinity, and collagen cross-link ratio (Misof *et al.*, 2003; Paschalis *et al.*, 2005).

The first study of the effects of PTH(1–34) raised the specter that the improvement in cancellous bone mass and structure may have been gained at the expense of cortical bone (Reeve *et al.*, 1980). This was not confirmed in animal models where cortical thickness and diameter were improved by PTH(1–34) treatment (Hirano *et al.*, 1999, 2000; Jerome *et al.*, 1999; Burr *et al.*, 2001; Mashiba *et al.*, 2001). Histomorphometric and microcomputed tomographic studies in humans revealed an increase in cortical thickness at the iliac crest, which was accompanied by stimulation of bone formation on the endosteal surface (see Figs. 9 and 10) (Dempster *et al.*, 2001; Jiang *et al.*, 2003; Lindsay *et al.*,

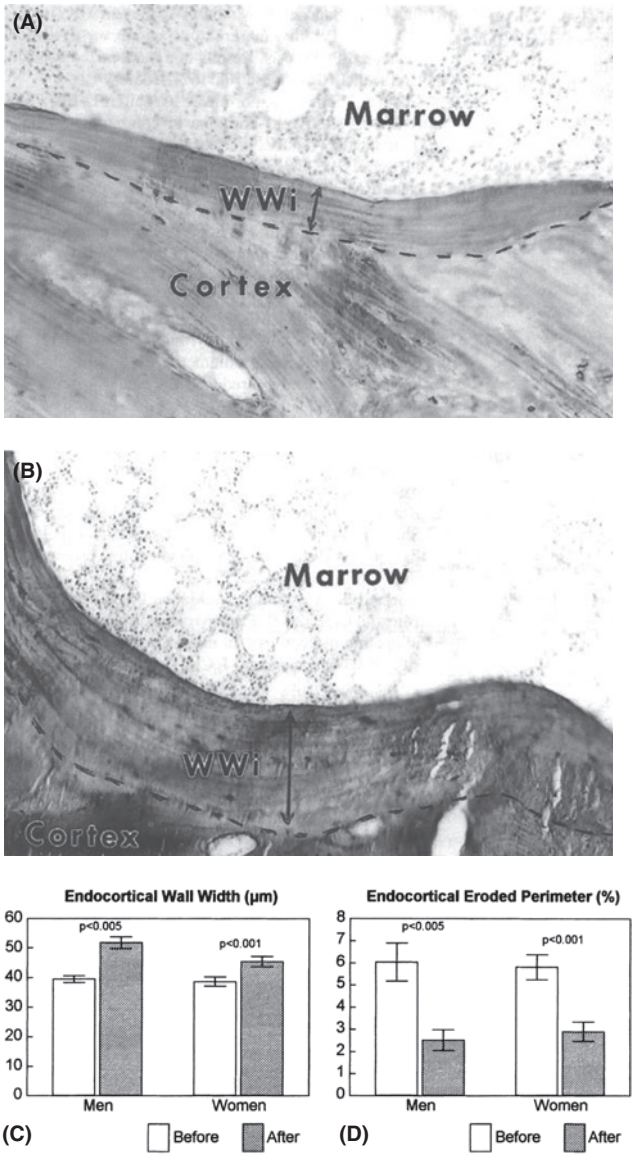

FIGURE 10 Bone packets on the endocortical surface of a 52-year-old man before (**A**) and after (**B**) 18 months of treatment with PTH(1–34). Note that after treatment the packet is almost twice as wide as the one before treatment. (**C** and **D**) Endocortical wall width and eroded perimeter before and after treatment of men and women with teriparatide. Note the increase in wall width and reduction in eroded perimeter after treatment. Reproduced with permission from Dempster *et al*. (2001).

2006). However, whether PTH(1–34) is able to stimulate periosteal bone formation in humans as it does in animals is not yet clear. Noninvasive techniques have yielded conflicting data on the effects of PTH(1–34) on bone diameter in humans (Zanchetta *et al*., 2003; Uusi-Rasi *et al*., 2005). However, recent biopsy studies suggest that PTH(1–34) can enhance periosteal bone formation (Ma *et al*., 2006; Lindsay *et al*., 2007). Although there are currently few data, the effects of PTH(1–84) on the human ilium appear to be broadly similar to those of PTH(1–34) (Fox *et al*., 2005).

Chapter 23

Phosphorus Homeostasis and Related Disorders

Marc K. Drezner*

Department of Medicine, Section of Endocrinology, Diabetes, and Metabolism, University of Wisconsin, Madison, Wisconsin 53792

Phosphorus plays an important role in cellular physiology and skeletal mineralization, serving as a constituent of nucleic acids and hydroxyapatite, a source of the high-energy phosphate in adenosine triphosphate, an essential element of the phospholipids in cell membranes, and a factor influencing a variety of enzymatic reactions (e.g., glycolysis) and protein functions (e.g., the oxygen-carrying capacity of hemoglobin by regulation of 2,3-diphosphoglycerate synthesis). Indeed, phosphorus is one of the most abundant components of all tissues, and disturbances in phosphate homeostasis can affect almost any organ system. Most phosphorus within the body is in bone (600–700 g); the remainder is largely distributed in soft tissue (100–200 g). As a consequence, less than 1% of the total is in extracellular fluids. The plasma contains about 12 mg/dL of phosphorus, of which approximately 8 mg is organic and contained in phospholipids, a trace is an anion of pyrophosphoric acid, and the remainder is inorganic phosphate (P_i) (Yanagawa *et al.*, 1994). Inorganic phosphate is present in the circulation as divalent monohydrogen phosphate and monovalent dihydrogen phosphate. At normal pH, the relative concentrations of monohydrogen and dihydrogen phosphate are 4:1.

The critical role that phosphorus plays in cell physiology has resulted in development of elaborate mechanisms designed to maintain phosphate balance. These adaptive changes are manifest by a constellation of measurable responses, the magnitude of which is modified by the difference between metabolic P_i need and exogenous P_i supply. Such regulation maintains plasma and extracellular fluid phosphorus within a relatively narrow range and depends primarily on gastrointestinal absorption and renal excretion as mechanisms to affect homeostasis. Although investigators have recognized a variety of hormones that influence these various processes, in concert with associated changes in other metabolic pathways, the sensory system, the messenger, and the mechanisms underlying discriminant regulation of P_i balance remain incompletely understood.

Whereas long-term changes in P_i balance depend on these variables, short-term changes in phosphate concentrations can occur as a result of redistribution of phosphate between the extracellular fluid and either bone or cell constituents. Such redistribution results secondary to various mechanisms, including elevated levels of insulin and/or glucose; increased concentrations of circulating catecholamines; respiratory alkalosis; enhanced cell production or anabolism; and rapid bone remineralization. In many of these circumstances, hypophosphatemia manifests in the absence of phosphorus depletion or deprivation.

REGULATION OF PHOSPHATE HOMEOSTASIS

Phosphate is sufficiently abundant in natural foods that phosphate deficiency is unlikely to develop except under conditions of extreme starvation, as a consequence of administration of phosphate binders, or secondary to renal phosphate wasting. Indeed, the major proportion of ingested phosphate is absorbed in the small intestine, and hormonal regulation of this process plays only a minor role in normal phosphate homeostasis. In contrast, absorbed phosphate, in response to complex regulatory mechanisms, is eliminated by the kidney, incorporated into organic forms in proliferating cells, or deposited as calcium-phosphate complexes in soft tissue and/or as a component of bone mineral (hydroxyapatite). The vast majority of the absorbed phosphate, however, is excreted in the urine. Thus, under usual conditions, phosphate homeostasis depends for the most part on the renal mechanisms that regulate tubular phosphate transport. Alternatively, during times of severe phosphate deprivation, the phosphate contained in bone mineral provides a source of phosphate

TABLE I Summary of Known Parameters of the Type II and Type III Na/P_i Transporters

	Type II			
	Type IIa	Type IIc	Type IIb	Type III
Chromosomal location (human)	5	9	4	2 (P_iT-1) 8 (P_iT-2)
Amino acids	~640	601	~690	679 656
Function	Na–P_i cotransport; electrogenic, pH dependent	Na–P_i cotransport; neutral	Na–P_i cotransport; electrogenic	Na–P_i cotransport; electrogenic
Substrate	P_i	P_i	P_i	P_i
Affinity for P_i	0.1–0.2 mM	0.1–0.2 mM	0.05 mM	0.025 mM
Affinity for Na	50–70 mM	50 mM	33 mM	40–50 mM
Na^+–P_i coupling	3	2	3	3
Tissue expression (mRNA, protein)	Kidney, parathyroid	Kidney	Small intestine, lung, other tissues	Ubiquitous
Major regulator(s)	PTH, dietary P_i, calcitriol, FGF-23	PTH, dietary P_i, FGF-23	Dietary P_i, calcitriol, estrogen, epidermal growth factor, glucocorticoids	Dietary P_i

FGF, *fibroblast growth factor*; PTH, *parathyroid hormone*.

for the metabolic needs of the organism. The specific role that the intestine and kidney play in this complex process is discussed later.

Mechanism of Phosphate Transport

Cells obtain phosphorus in the form of negatively charged P_i from the extracellular environment by means of secondary-active transport. In vertebrates, P_i transporters use the inwardly directed electrochemical gradient of Na^+ ions, established by the Na^+,K^+-ATPase, to drive P_i influx. Two unrelated families of Na^+-dependent P_i transporters manage the active transport (Virkki *et al.*, 2007). The SCL34 or type II Na^+/P_i family prefer divalent HPO_4^{2-} and comprises both electrogenic and electroneutral members that are expressed in various epithelia and other polarized cells. Through regulated activity in apical membranes of the gut and kidney, they maintain body P_i homeostasis, and in salivary and mammary glands, liver, and testes they play a role in modulating the P_i content of luminal fluids. The SLC20 or type III Na^+/P_i family transport monovalent $H_2PO_4^-$ and consist of P_iT-1 and P_iT-2 receptors, which are electrogenic and ubiquitously expressed, likely serving a housekeeping role for cell P_i homeostasis. However, more specific roles are emerging for these transporters in bone P_i metabolism and vascular calcification.

The two families of Na^+–P_i cotransporters share no significant homology in their primary amino acid sequence and exhibit substantial variability in substrate affinity, pH dependence, and tissue expression (Table I). The tissue expression, relative renal abundance, and overall transport characteristics of type II and III Na–P_i cotransporters suggest that the type II transporters play a key role in brush border membrane P_i flux (Miyamoto *et al.*, 2007).

The most detailed studies of the cellular events involved in P movement from the luminal fluid to the peritubular capillary blood have been performed in proximal tubules and cultured cells derived from them. These investigations indicate that P reabsorption occurs principally by a unidirectional process that proceeds transcellularly with minimal intercellular backflux from the plasma to the lumen. Across the luminal membrane, P_i entry into the tubular cell proceeds by a saturable active transport system that is sodium dependent (Fig. 1).

The active transport of phosphate across the apical membrane in renal proximal tubules is mediated by two members of the SLC34 family of solute carriers, NaP_i-IIa (*SLC34A1*) and NaP_i-IIc (*SLC34A3*; see Table I). These receptors mediate the reabsorption of phosphate from the urine by using the free energy provided by the electrochemical gradient for Na^+. NaP_i-IIa is electrogenic and transports divalent P_i preferentially. It functions with a Na^+: P_i stoichiometry of 3:1, which results in the net movement inward of one positive charge per cotransport cycle. In contrast, NaP_i-IIc is electroneutral and exhibits a 2:1 stoichiometry. In mice, NaP_i-IIa is the protein primarily responsible for P_i reabsorption in the adult kidney, whereas

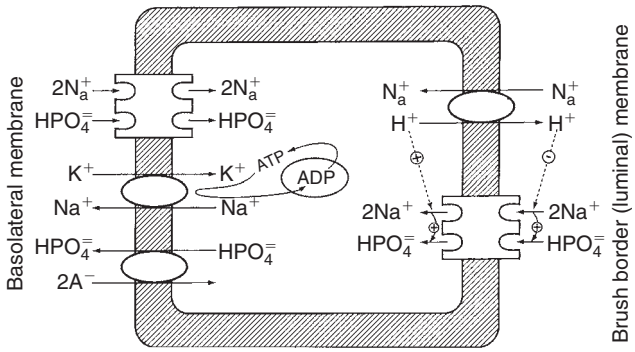

FIGURE 1 Model of inorganic phosphate ($HPO_4^=$) transcellular transport in the proximal convoluted tubule of the mammalian kidney. On the brush border or luminal membrane, a Na^+/H^+ exchanger and $Na/HPO_4^=$ cotransporters operate. ($HPO_4^=$) that enters the cell across the luminal surface mixes with the intracellular metabolic pool of phosphate and is eventually transported out of the cell across the basolateral membrane via an anion (A-) exchange mechanism. On the basolateral membrane there is also a $2Na/HPO_4^=$ cotransporter and a Na^+/K^+-ATPase system. The ATPase transports the Na^+ out of the cell, maintaining the Na^+ gradient-driving force for luminal phosphate entry.

NaP_i-IIc is seemingly more important in weanling animals. The phenotype of NaP_i-IIa knockout mice suggests that that this cotransporter is responsible for the bulk of renal P_i reabsorption with a very small percentage potentially due to the NaP_i-IIc transporter. However, recent data indicate that in humans, NaP_i-IIc may have a previously unpredicted importance (see the later subsection on Hereditary Hypophosphatemic Rickets with Hypercalciuria: Pathophysiology and Genetics). The expression of the sodium-dependent phosphate cotransporters is regulated to adapt the renal reabsorption of P_i to the needs of the organism. Thus, the phosphaturic effects associated with parathyroid hormone or the phosphatonins, such as fibroblast growth factor (FGF)-23, are due to the membrane retrieval of both cotransporters, whereas in conditions of P_i deprivation their expression is increased.

The phosphate that enters the tubule cell plays a major role in governing various aspects of cell metabolism and function and is in rapid exchange with intracellular phosphate. Under these conditions, the relatively stable free P_i concentration in the cytosol implies that P_i entry into the cell across the brush border membrane must be tightly coupled with its exit across the basolateral membrane (see Fig. 1). The transport of phosphate across the basolateral membrane is mediated by a transporter that remains unidentified. Regardless, basolateral P_i transport serves at least two functions: (1) complete transcellular P_i reabsorption when luminal P_i entry exceeds the cellular P_i requirements and (2) guaranteed basolateral P_i influx if apical P_i entry is insufficient to satisfy cellular requirements (Schwab *et al.*, 1984).

Gastrointestinal Absorption of Phosphorus

The average dietary phosphate intake in humans, derived largely from dairy products, meat, and cereals, is 800 to 1600 mg/day, one and one-half to threefold greater than the estimated minimum requirement. This phosphate is in both organic and inorganic forms, but the organic forms, except for phytates, are degraded in the intestinal lumen to inorganic phosphate, which is the form absorbed. Absorption occurs throughout the small intestine with transport greatest in the jejunum and ileum and less in the duodenum. Essentially no absorption occurs in the colon (Walling, 1977).

The absorption of phosphorus in the intestine is dependent on the amount and availability of phosphorus present in the diet. In normal subjects, net P absorption is a linear function of dietary P intake. Indeed, for a dietary P range of 4 to 30 mg/kg/day, the net P absorption averages 60 to 65% of the intake (Lee *et al.*, 1986). Intestinal P absorption occurs via two routes: transcellular and paracellular pathways. Transcellular phosphorus flux is regulated by a variety of hormones and metabolic factors, whereas the paracellular pathway appears dependent on the magnitude of the electrochemical gradients across the intestinal epithelium. The latter transport pathway is still controversial and may predominate at high intraluminal concentrations of phosphorus, such as during the intake of a meal.

Transcellular intestinal absorption of phosphorus is initiated by the sodium-dependent transport of P_i across the apical (brush border) membrane. Phosphate incorporated into intestinal cells by this mechanism is ferried from the apical pole to the basolateral pole likely through restricted channels such as microtubules. At the basolateral membrane, phosphate is released from intestinal cells by a passive mechanism, which is carrier mediated and occurs in accord with the electrochemical gradient. The apparent K_m for P_i is between 0.1 and 0.2 m*M*, and lowering the external pH value results in a modest increase of the transport rate.

The transepithelial transport of P_i occurs predominantly in the small intestine and is determined largely by the abundance of the Na/P_i-IIb transporter in the brush border membrane vesicles (see Table I). Thus, regulation of transepithelial intestinal absorption of P_i is mainly explained by alterations in the apical abundance of Na/P_i-IIb. Indeed, modulation of P_i transport through the cotransporter is regulated by various physiological effectors. Epidermal growth factor, and glucocorticoids inhibit intestinal sodium-dependent absorption and Na/P_i-IIb gene expression, whereas $1,25(OH)_2D$, estrogen and dietary P_i deprivation stimulate sodium-dependent absorption and Na/P_i-IIb gene expression.

To date numerous studies have shown that the intestinal absorption of P_i is regulated by $1,25(OH)_2D$. The effects of $1,25(OH)_2D$ on this process are modulated by the calcitriol-induced transcription of messenger RNA. Because low

dietary intake of P_i stimulates the synthesis of calcitriol, the enhanced P_i absorption that occurs concomitantly has been attributed to the effects of this vitamin D metabolite on the abundance of the apical Na/P_i-IIb protein. Because in the adult mouse, the calcitriol dependent increase in the Na/P_i-IIb protein is paralleled by an increase in Na/P_i-IIb mRNA, the upregulation of the receptors in response to this stimulus has been considered secondary to a genomic mechanism possibly involving the VDR. However, recent studies (Capuano *et al.,* 2005) indicate that upregulation of the Na/P_i-IIb receptors by a low P_i diet occurs normally in $VDR^{-/-}$ and 25(OH)D-1α-hydroxylase-deficient mice, indicating that the increase in receptors likely involves a genomic mechanism that does not require VDR and is not dependent on an increased $1,25(OH)_2D$ level. The mechanism for this effect, however, remains unknown.

Although the active transport systems are responsive to various hormones (Lee *et al.*, 1986; Rizzoli *et al.*, 1977; Xu *et al.,* 2001), such hormonal provocation plays a relatively minor role in normal phosphate homeostasis (Takeda *et al.,* 2004). For example, during vitamin D deficiency, the percentage of P absorbed from the diet is reduced by only 15%. Moreover, a substantial portion of this decline is secondary to the failure to absorb calcium, which results from vitamin D deficiency and the resultant formation of calcium phosphate that reduces the free phosphate concentration.

The minimal effects of hormone stimulation on P_i absorption are expected, because the vast majority of phosphate absorption occurs via the process of diffusional absorption. This results as a consequence of the relatively low K_m of the active transport process (2 m*M*); the luminal P content during feeding, which generally exceeds 5 m*M* throughout the intestine; and the occurrence of net diffusional absorption of P whenever luminal P concentration exceeds 1.8 m*M* (a concentration generally exceeded even when fasting; Karr and Abbott, 1935; Walton and Gray, 1979; Wilkinson, 1976). Given these conditions, the active component of transport becomes important only under unusual circumstances, such as when dietary P or vitamin D is extremely low. Regardless, the bulk of intestinal P absorption is mediated by a diffusional process, presumably through the paracellular space, and therefore is primarily a function of P intake. Because most diets contain an abundance of P, the quantity of phosphate absorbed almost always exceeds the need both under normal circumstances and disease states such as uremia. Thus, active, transcellular P absorption becomes predominant only under conditions of low luminal P availability, such as dietary P deprivation and/or excessive luminal P binding (Lee *et al.*, 1979; Kurnik and Hruska, 1984). Factors that may influence the diffusional process adversely are the formation of nonabsorbable calcium, aluminum, or magnesium phosphate salts in the intestine and age, which reduces P absorption by as much as 50%.

Renal Excretion of Phosphorus

The kidney is immediately responsive to changes in serum levels or dietary intake of phosphate. Renal adaptation is determined by the balance between the rates of glomerular filtration and tubular reabsorption (Mizgala and Quamme, 1985).

The concentration of phosphate in the glomerular ultrafiltrate is approximately 90% of that in plasma because not all of the phosphate in plasma is ultrafilterable (Harris *et al.*, 1977). Nondiffusable phosphorus includes plasma P that is protein bound and a small fraction of plasma P that complexes with calcium and magnesium. With increasing serum calcium levels, the calcium–phosphate–protein colloid complex increases, reducing the ultrafilterable plasma P to as little as 75% (Rasmussen and Tenenhouse, 1995). Because the product of the serum phosphorus concentration and the glomerular filtration rate (GFR) approximates the filtered load of phosphate, a change in the GFR may influence phosphate homeostasis if uncompensated by commensurate changes in tubular reabsorption.

Normally, 80% to 90% of the filtered phosphate load is reabsorbed, primarily in proximal tubules, with higher rates at early segments (S_1/S_2 versus S_3) and in deep nephrons (Agus, 1983; Cheng and Jacktor, 1981; Dousa and Kempson, 1982; Suki and Rouse, 1996). The transcellular transport of phosphate is a carrier-mediated, saturable process limited by a transfer maximum or T_{max}. The T_{max} varies considerably as dietary phosphorus changes, and the best method to approximate this variable is to measure maximum phosphate reabsorption per unit volume of glomerular filtrate (T_mP/GFR) during acute phosphate infusions. Alternatively, the nomogram developed by Bijvoet allows estimation of the T_mP/GFR with measurement of phosphate and creatinine excretion and plasma phosphate concentration (Walton and Bijvoet, 1975).

The major site of phosphate reabsorption is the proximal convoluted tubule, at which 60% to 70% of reabsorption occurs (Fig. 2). Along the proximal convoluted tubule the transport is heterogeneous. In the most proximal portions, the S_1 segment, phosphate reabsorption exceeds that of sodium and water, whereas more distally, phosphate reabsorption parallels that of fluid and sodium. Additional reabsorption in the proximal straight tubule accounts for 15% to 20% of phosphate reclamation. In contrast, there is little evidence to suggest net P transport in the thin and thick ascending loops of Henle. However, increasing, but not conclusive, data support the existence of a P reabsorptive mechanism in the distal tubule. Currently, however, definitive proof for tubular secretion of phosphate in humans is lacking (Knox and Haramati, 1981).

At all three sites of phosphate reabsorption—the proximal convoluted tubule, proximal straight tubule, and distal tubule—several investigators have mapped parathyroid hormone (PTH)-sensitive adenylate cyclase (see Fig. 2;

	Phosphate reabsorption	PTH sensitive adenylate cyclase	PTH inhibited phosphate reabsorption	Calcitonin sensitive adenylate cyclase	Calcitonin inhibited phosphate reabsorption
PCT	60–70%	++	++	–	++
PST	15–20%	++	++	–	++
DCT	5–10%	++	++	++	–
CAL	0%	++	–	++	–
MAL	0%	–	–	++	–

FIGURE 2 Model of the renal tubule and distribution of phosphate reabsorption and hormone-dependent adenylate cyclase activity throughout the structure. The renal tubule consists of a proximal convoluted tubule (PCT), composed of an S_1 and S_2 segment, a proximal straight tubule (PST), also known as the S_3 segment, the loop of Henle, the medullary ascending limb (MAL), the cortical ascending limb (CAL), the distal convoluted tubule (DCT), and three segments of the collecting tubule: the cortical collecting tubule (CCT), the outer medullary collecting tubule (OMCT), and the inner medullary collecting tubule (IMCT). Phosphate reabsorption occurs primarily in the PCT but is maintained in the PST and DCT as well. In general, parathyroid hormone (PTH) influences phosphate reabsorption at sites where PTH-dependent adenylate cyclase is localized. FGF-23 modifies phosphate reabsorption in the PCT, where receptors for the phosphatonin are located. However, colocalization of the klotho protein, which is necessary for receptor activation, is controversial, because it is found primarily in the DCT. Calcitonin alters phosphate transport at sites distinct from those where calcitonin-dependent adenylate cyclase is present, suggesting that response to this hormone occurs by a distinctly different mechanism.

Knox and Haramati, 1981; Morel, 1981). Not surprisingly, there is clear evidence that PTH decreases phosphate reabsorption at these loci by a cAMP-dependent process, as well as a cAMP-independent signaling mechanism. Likewise, several investigators have identified FGF-23 receptors in the proximal tubule, the primary site at which phosphatonins decrease phosphate reabsorption. However, the colocalization of klotho proteins at these sites is controversial despite the need for these proteins to activate the FGF-23 receptors. In fact, the primary localization of the klotho proteins is the DCT. Calcitonin-sensitive adenylate cyclase maps to the medullary and cortical thick ascending limbs and the distal tubule (see Fig. 2; Berndt and Knox, 1984). Nevertheless, calcitonin inhibits phosphate reabsorption in the proximal convoluted and proximal straight tubule, certainly by a cAMP-independent mechanism that may be mediated by a rise in intracellular calcium (Murer *et al.*, 2000). An action of calcitonin on the distal tubule is uncertain, despite the abundant calcitonin-sensitive adenylate cyclase.

Hormonal/Metabolic Regulation of Phosphate Transport

Many hormonal and nonhormonal factors regulate renal reabsorption of P_i. The effects of PTH and dietary P_i, and more recently phosphatonins (most notably FGF-23), on this process have been the subject of detailed investigation. These studies suggest that NaP_i-IIa receptor regulation depends on its shuttling to/from the brush border membrane of the renal tubule. Thus, reduced P_i reabsorption (on PTH or phosphatonin release) is achieved by downregulation of the receptors at the brush border membranes. Such downregulation is dependent on endocytic removal of the receptors from the membranes and subsequent degradation in lysosomes. As a consequence, subsequent restoration of P_i transport upon removal of the hormonal stimulus depends on *de novo* synthesis. The detailed mechanism for recycling of the receptors is provided in a review by Forster *et al.* (2006). In concert with these findings, studies indicate that expression of the Na/P_i-IIa protein at renal tubular sites is increased in parathyroidectomized rats and decreased after PTH treatment. In addition, Northern blot analysis of total RNA shows that the abundance of Na/P_i-IIa-specific mRNA is not changed by parathyroidectomy, but is decreased minimally in response to the administration of parathyroid hormone. These data are consistent with the concept that parathyroid hormone regulation of renal Na^+–P_i cotransport is determined predominantly by changes in expression of the Na/P_i-IIa protein in the renal brush border membrane (Kempson *et al.*, 1995).

In contrast, a requirement for increased P_i reabsorption (in response to a sustained low P_i diet) is met by increasing expression of NaP_i-IIa (and NaP_i-IIc) at the brush border membrane. Such upregulation is independent of changes in transcription or translation. Therefore, increased expression of the receptors is due to both the stabilization of the transporter at the membrane and an increased rate of insertion in the membrane. Thus, dietary-induced upregulation is modulated by the presence of scaffolding proteins, which stabilize action, and the microtubule network, which facilitates an increased rate of insertion.

Despite these advances in understanding the mechanisms regulating the abundance of Na/P_i receptors, there remains a void in our knowledge regarding the manner in which the organism maintains overall P_i balance. Although historically PTH is accepted as the most important physiologic influence on renal P excretion and the major determinant of plasma P concentrations through its effect on P_i transport, repeated observations have confirmed that the balance between urinary excretion and dietary input of P is maintained not only in normal humans but in patients with hyper- and hypoparathyroidism. In fact, the renal tubule has a seemingly intrinsic ability to adjust the reabsorption rate of P according to dietary P_i intake and the need and availability of P_i to the body (Levi *et al.*, 1994). Thus P_i reabsorption is increased under conditions of greater P need, such as rapid growth, pregnancy, lactation, and dietary restriction. Conversely, in times of surfeit, such as slow growth, chronic renal failure, or dietary excess, renal P reabsorption is curtailed. This adaptive response is localized in the proximal convoluted tubule and involves an alteration in the apparent V_{max} of the high-affinity Na^+–phosphate cotransport systems. Such changes in response to chronic changes in P_i availability are characterized by parallel changes in Na^+–phosphate cotransport activity, the Na/P_i transporter mRNA level, and protein abundance. In contrast, the acute adaptation to altered dietary P_i is marked by parallel changes in Na^+–phosphate cotransporter activity and Na/P_i-IIa protein abundance in the absence of a change in mRNA. Thus, in response to chronic conditions, protein synthesis is requisite in the adaptive response, whereas under acute conditions, the number of Na/P_i-IIa cotransporters is changed rapidly by mechanisms independent of *de novo* protein synthesis, such as insertion of existing transporters into the apical membrane or internalization of existing transporters. Although the signal for the adaptive alteration in phosphate transport is not yet known, several lines of evidence suggest that renal adaptations to changes in dietary phosphate occur independently of the known regulators of renal phosphate transport. In this regard, adaptations to changes in dietary phosphate mediated by the vitamin D endocrine system, PTH, and the phosphatonins generally occur over a period of hours to days and cannot account for the modulation of renal phosphate excretion that rapidly occurs after a phosphate-containing meal. Recently, Berndt *et al.* (2007) presented data that support the existence of an intestinal-renal axis specific for phosphate that is mediated by an as yet unknown factor, an intestinal "phosphatonin." These observations suggest that the rapid renal response to increased dietary phosphate concentrations is due to the regulated production in the duodenum of a hormone, which increases the renal excretion of phosphate. This response dampens large increases in serum phosphate concentrations that could have a deleterious effect by enhancing the precipitation of calcium phosphate salts in soft tissues.

CLINICAL DISORDERS OF PHOSPHATE HOMEOSTASIS

The variety of diseases, therapeutic agents, and physiological states that affect phosphate homeostasis are numerous and reflect a diverse pathophysiology. Indeed, rational choice of an appropriate treatment for many of these disorders depends on determining the precise cause for the abnormality. The remainder of this chapter reviews several clinical states that represent primary disorders of phosphate homeostasis. These include X-linked hypophosphatemic rickets/osteomalacia (XLH); autosomal-dominant hypophosphatemic rickets (ADHR); autosomal recessive hypophosphatemic rickets (ARHR); tumor-induced osteomalacia (TIO); hereditary hypophosphatemic rickets with hypercalciuria (HHRH); Dent's disease; Fanconi's syndrome (FS), types I and II; and tumoral calcinosis (TC). Table II documents the full spectrum of diseases in which disordered phosphate homeostasis occurs. Many of these are discussed in other chapters.

Impaired Renal Tubular Phosphate Reabsorption

X-Linked Hypophosphatemic Rickets

X-linked hypophosphatemic rickets/osteomalacia is the archetypal phosphate-wasting disorder, characterized in general by progressively severe skeletal abnormalities and growth retardation. The syndrome occurs as an X-linked dominant disorder with complete penetrance of a renal tubular abnormality resulting in phosphate wasting and consequent hypophosphatemia (Table III). The clinical expression of the disease is widely variable even in members of the same family, ranging from a mild abnormality, the apparent isolated occurrence of hypophosphatemia, to severe bone disease (Lobaugh *et al.*, 1984). On average, disease severity is similar in males and females, indicating minimal, if any, gene dosage effect (Whyte *et al.*, 1996). The most common clinically evident manifestation is short stature. This height deficiency is a consequence of abnormal lower extremity growth, averaging 15% below normal. In contrast, upper segment growth is not affected. The majority of children with the disease exhibit enlargement of the wrists and/or knees secondary to rickets, as well as bowing of the lower extremities. Additional signs of the disease may include late dentition, tooth abscesses secondary to poor mineralization of the interglobular dentin, enthesopathy (calcification of tendons, ligaments, and joint capsules), and premature cranial synostosis. However, many of these features may not become apparent until age 6 to 12 months or older (Harrison *et al.*, 1966). Despite marked variability in the clinical presentation, bone biopsies in affected children and adults invariably reveal osteomalacia, the severity of which has no relationship to sex, the extent of the biochemical abnormalities, or the severity

TABLE II Diseases of Disordered Phosphate Homeostasis

Increased phosphate
Reduced renal phosphate excretion
Renal failure
Hypoparathyroidism
Tumoral calcinosis[a]
Hyperthyroidism
Acromegaly
Diphosphonate therapy
Increased phosphate load
Vitamin D intoxication
Rhabdomyolysis
Cytotoxic therapy
Malignant hyperthermia
Decreased phosphate
Decreased gastrointestinal absorption

of the clinical disability. In untreated youths and adults, serum 25(OH)D levels are normal and the concentration of $1,25(OH)_2D$ is in the low-normal range (Haddad *et al.*, 1973; Lyles *et al.*, 1982). The paradoxical occurrence of hypophosphatemia and normal serum calcitriol levels is due to the aberrant regulation of renal 25(OH)D-1α-hydroxylase activity as a direct result of abnormal phosphate transport or of elevated circulating levels of phosphatonins (e.g., FGF-23), independent of the effects on phosphate transport. Studies in *hyp*-mice, the murine homologue of the human disease, have established that defective regulation is confined to enzyme localized in the proximal convoluted tubule, the site of the abnormal phosphate transport (Lobaugh and Drezner, 1983; Nesbitt *et al.*, 1986, 1987; Nesbitt and Drezner, 1990).

Pathophysiology

Investigators generally agree that the primary inborn error in XLH results in an expressed abnormality of the renal proximal tubule that impairs P_i reabsorption. This defect has been indirectly identified in affected patients and directly demonstrated in the brush border membranes of the proximal nephron in *hyp*-mice. Until recently, whether this renal abnormality is primary or secondary to the elaboration of a humoral factor has been controversial. In this regard, demonstration that renal tubule cells from *hyp*-mice maintained in primary culture exhibit a persistent defect in renal P_i transport (Bell *et al.*, 1988; Dobre *et al.*, 1990), likely due to decreased expression of the Na^+–phosphate cotransporter mRNA and immunoreactive protein (Tenenhouse *et al.*, 1994, 1995; Collins and Ghishan, 1994), supported the presence of a primary renal abnormality. In contrast, transfer of the defect in renal P_i transport to normal and/or parathyroidectomized normal mice parabiosed to *hyp*-mice implicated a humoral factor in the pathogenesis of the disease (Meyer *et al.*, 1989a, 1989b). Subsequent studies, however, have provided compelling evidence that the defect in renal P_i transport in XLH is secondary to the effects of a circulating hormone or metabolic factor. Thus, immortalized cell cultures from the renal tubules of *hyp*-mice exhibit normal Na^+–phosphate transport, suggesting that the paradoxical effects observed in primary cultures may represent the effects of impressed memory and not an intrinsic abnormality (Nesbitt *et al.*, 1995, 1996). Moreover, the report that cross-transplantation of kidneys in normal and *hyp*-mice results in neither transfer of the mutant phenotype nor its correction unequivocally established the humoral basis for XLH (Nesbitt *et al.*, 1992). Subsequent efforts, which resulted in localization of the gene encoding the primary renal Na^+–phosphate cotransporter to chromosome 5, further substantiated the conclusion that the renal defect in brush border membrane phosphate transport is not intrinsic to the kidney (Kos *et al.*, 1994). Although these data establish the presence of a humoral abnormality in XLH, the identity of the putative

factor, the spectrum of its activity, and the cells producing it have not been definitively elucidated until recently.

Genetic Defect

Efforts to better understand XLH have more recently included attempts to identify with certainty the genetic defect underlying this disease. In 1986, Read and coworkers and Machler and colleagues reported linkage of the DNA probes DXS41 and DXS43, which had been previously mapped to Xp22.31–p21.3, to the *HYP* gene locus. In subsequent studies, Thakker *et al.* (1987) and Albersten *et al.* (1987) reported linkage to the *HYP* locus of additional polymorphic DNA, DXS197, and DXS207 and, using multipoint mapping techniques, determined the most likely order of the markers as Xpter-DXS85-(DXS43/-DXS197)-*HYP*-DXS41-Xcen and Xpter-DXS43-*HYP*-(DXS207/DXS41)-Xcen, respectively. The relatively small number of informative pedigrees available for these studies prevented definitive determination of the genetic map along the Xp22–p21 region of the X chromosome and only allowed identification of flanking markers for the *HYP* locus 20 cM apart. However, the HYP consortium (HYP Consortium, 1995), in a study of some 20 multigenerational pedigrees, used a positional cloning approach to refine mapping of the Xp22.1–p21 region of the X chromosome, identify tightly linked flanking markers for the *HYP* locus, construct a YAC contig spanning the *HYP* gene region, and eventually clone and identify the disease gene as *PHEX*, a phosphate-regulating gene with homologies to endopeptidases located on the X chromosome. The *PHEX* locus was mapped to Xp22.1 and more than 140 loss-of-function *PHEX* mutations (see http://www.envbiocourse.rutgers.edu/eu-us/pages/extras/software/DatabasesListNAR2002/summary/145.html) have been reported to date in patients with XLH (Holm *et al.*, 1997). However, no genotype/phenotype correlations have been recognized, albeit changes in conserved amino acids more often result in clinical disease than changes in nonconserved amino acids (Filisetti *et al.*, 1999). Further studies documented that the murine homologue of the human

disease, the *hyp*-mouse, has a phenotype identical to that evident in patients with XLH and is due to a large deletion of the 3' region of the *Phex* gene (Beck *et al.,* 1997). Collectively, these findings indicate that a mutation in the *PHEX/Phex* gene is responsible for the phenotypic changes in patients with XLH and the *hyp*-mouse.

The *PHEX* gene has 22 exons and encodes for a 749-amino-acid glycoprotein, which has homology with members of the M13 membrane-bound zinc metalloendopeptidase family. Investigation of murine tissues and cell cultures revealed that *Phex* is predominantly expressed in bones and teeth (Du *et al.,* 1996; Ruchon *et al.,* 1998), although detectable Phex mRNA and/or protein have been found in lung, brain, muscle gonads, skin and parathyroid glands. The *PHEX/Phex* expression in bone is limited to cells of the osteoblast lineage (Ruchon *et al.,* 1998; Thompson *et al.,* 2002), osteoblasts and osteocytes.

The physiological function of the *PHEX/Phex* gene product and the mechanisms that lead to the biochemical and skeletal abnormalities evident in patients with XLH and in the *hyp*-mouse remain ill-defined. Because *PHEX/Phex* codes for a membrane-bound enzyme, several groups have postulated that *PHEX/Phex* activates or degrades a putative phosphate- and bone mineralization-regulating factor(s), "phosphatonin" or "minhibin," which are involved in the regulation of phosphate and mineralization processes (Rasmussen and Tenenhouse 1995; Nesbitt *et al.,* 1992; Ecarot *et al.,* 1992; Econs and Drezner 1994; Bowe *et al.,* 2001). Studies in patients with XLH and the *hyp*-mouse, as well as in a wide variety of other P_i wasting disorders, have identified several candidate proteins as the phosphatonin(s) or minhibin(s), including FGF-23 (Fukomoto and Yamashita 2002; Liu *et al.,* 2006), sFRP4 (Kumar, 2002; Berndt *et al.,* 2003), MEPE (Argiro *et al.,* 2001; Rowe *et al.*, 2004) and FGF-7 (Carpenter *et al.,* 2005). Because abnormal production or circulating levels of several of these factors have been identified in patients with XLH and in *hyp*-mice, until recently it remained unknown whether a single phosphatonin is responsible for the physiological abnormalities of the disease or a family of proteins works cooperatively to create the *HYP* phenotype.

Progress in this regard has been limited by unsuccessful efforts to rescue the *HYP* phenotype and determine the physiologically relevant site for the *PHEX* mutation. In attempts to determine whether abnormal *PHEX/Phex* expression in bone cells alone is the determining abnormality underlying the pathogenesis of XLH, several investigators have used osteoblast/osteocyte targeted overexpression of *Phex* in order to normalize osteoblast mineralization *in vitro* and rescue the *HYP* phenotype *in vivo* (Liu *et al.,* 2002; Bai *et al.,* 2002). Surprisingly, however, these studies documented that restoration of *Phex* expression and enzymatic activity to immortalized *hyp*-mouse osteoblasts, by retroviral mediated transduction, does not restore their capacity to mineralize extracellular matrix *in vitro*, under conditions supporting normal mineralization. Moreover, in complementary studies Liu *et al.* (2002) and Bai *et al.* (2002) found that transgenic *hyp*-mice maintained characteristic hypophosphatemia and abnormal vitamin D metabolism, as well as histological evidence of osteomalacia, despite expressing abundant Phex mRNA and enzyme activity in mature osteoblasts and osteocytes, under the control of the bone-specific promoters osteocalcin and ColA1 (2.3 kb). These findings suggest that expression of *Phex* at sites other than bone is responsible for the *Hyp* phenotype. However, similar studies performed with transgenic mice in which *Phex* overexpression was under the regulation of the ubiquitous human β-actin promoter likewise failed to normalize the phosphate homeostasis (Erben *et al.,* 2005).

In recent studies, however, Yuan *et al.* (2007) attempted to explore this apparent paradox by evaluating whether conditional inactivation of *Phex* in osteoblasts and osteocytes generates a biochemical phenotype similar to that in mice with a global *Phex* knockout and comparable to that in *hyp*-mice. To accomplish this goal they generated mouse lines with global and targeted deletion of exon 17 from the *Phex* gene, which codes a portion of the protein crucial for bioactivity. Their studies established unequivocally that the mutation of the *Phex* gene in osteoblasts and osteocytes alone is sufficient to generate the classical *HYP* phenotype. Indeed, the targeted knockout mice exhibit a biochemical phenotype (phosphorus homeostatic abnormalities and aberrant vitamin D metabolism) no different than that of the global knockout mice and indistinguishable from that in the *hyp*-mouse. Moreover, investigation of the bone pathology in the targeted knockout mice further established that mutation of the *Phex* gene in the osteoblasts and osteocytes is a sufficient abnormality to produce the *HYP* phenotype. Hence, bone biopsies from the targeted knockout mice displayed histomorphological evidence of osteomalacia and cannicular disorganization indistinguishable from those observed in bone biopsies from the global knockout mice, as well as those from *hyp*-mice.

Although these observations provide compelling evidence that aberrant *PHEX*/*Phex* function in osteoblasts and osteocytes alone underlies the characteristic biochemical and pathological phenotype in *hyp*-mice and likely XLH, a surprising discordance between the biochemical phenotype in the targeted knockout mice from that in both the global knockout and *hyp*-mice became apparent with further study. Previous investigations have implicated the phosphatonins as critical factors in the pathogenesis of XLH and have identified that the production rate and/or the circulating level of FGF-23, MEPE, and sFRP-4, are increased in affected humans and/or the *hyp*-mouse. However, Yuan *et al.* (2007) found that the targeted knockout mice had only an increased osseous production rate and serum level of FGF-23, whereas the global knockout and *hyp*-mice exhibited increased production and serum levels of FGF-23, MEPE, and sFRP-4. These observations provide the first successful attempt to discern whether

integrated effects of these hormones or the activity of a single phosphatonin is essential for expression of the disease phenotype in *hyp*-mice and affected patients with XLH. Indeed, the data suggest that increased bone production and serum levels of MEPE and sFRP-4 are not critical for development of the classical *HYP* phenotype, whereas increased osseous production and serum FGF-23 concentration appear requisite for this biological function. Therefore, FGF-23 is likely the phosphatonin pivotal to the pathogenesis of XLH, and the role of MEPE and sFRP-4, if any, remains uncertain.

Pathogenesis

Despite the remarkable advances that have been made in understanding the genetic abnormality and pathophysiology of XLH, the detailed pathogenetic mechanism underlying this disease remains unknown. Nevertheless, several observations suggest the likely cascade of events that result in the primary abnormalities characteristic of the syndrome. In this regard, the X-linked dominant expression of the disorder with little, if any, gene dosage effect likely results from PHEX mutations that result in a haploinsufficiency defect, in which one half the normal gene product (or null amounts) causes the phenotype. The alternative possibility that the PHEX gene results in a dominant-negative effect is unlikely because, inconsistent with this prospect, several mutations reported in affected humans (Francis *et al.*, 1997) and the murine *Gy* mutation almost certainly result in the lack of message production (Meyer *et al.*, 1998). In any case, it is tempting to speculate that the PHEX gene product acts directly or indirectly on a phosphaturic factor (e.g., FGF-23) that regulates renal phosphate handling. Given available data, the PHEX gene product, a putative cell membrane-bound enzyme, may function normally to inactivate "phosphatonin," a phosphaturic hormone. However, data from parabiotic studies of normal and *hyp*-mice argue strongly that extracellular degradation of the phosphaturic factor does not occur. Indeed, such activity would preclude transfer of the *hyp*-mouse phenotype to parabiosed normals. Alternatively, the PHEX gene product may function intracellularly to regulate phosphatonin production. In this regard, Jalal *et al.* (1991) reported the internalization of neutral endopeptidase and a potential role for this enzyme in intracellular metabolism. In addition, Thompson *et al.* (2002) reported that the PHEX protein in osteoblasts is found predominantly in the Golgi apparatus and the endoplasmic reticulum.

In any of these cases, a defect in the PHEX gene will result in overproduction and circulation of phosphatonin and consequent decreased expression of the renal Na^+–phosphate cotransporter, the likely scenario in the pathogenesis of XLH. The possible mechanism by which PHEX regulates the production of FGF-23, the requisite phosphatonin for the expression of the *HYP* phenotype, was recently discovered by Yuan and Drezner (unpublished observations). Their studies indicate that the loss of function *Phex* mutation in *hyp*-mice results in decreased production of 7B2, an intracellular chaperone protein, which proteolytically activates subtilin-like prohormone convertase 2 (SPC2), enabling cleavage of hormones to inactive peptides and prohormones to active hormones. The decreased activity of the 7B2–SPC2 enzyme complex decreases FGF-23 degradation in the osteoblast, increasing the concentration of the intact active FGF-23. In addition, the decreased 7B2–SPC2 activity limits conversion of DMP1 (104 kDa) to active DMP1 (57 kDa), the relative absence of which increases FGF-23 mRNA and consequent protein production. These concordant effects on FGF-23 degradation and production result in the increased circulating FGF-23 and production of the *HYP* phenotype.

Treatment

In past years, physicians employed pharmacologic doses of vitamin D as the cornerstone for treatment of XLH. However, long-term observations indicate that this therapy fails to cure the disease and poses the serious problem of recurrent vitamin D intoxication and renal damage. Current treatment strategies for children directly address the combined calcitriol and phosphorus deficiency characteristic of the disease. Generally, the regimen includes a period of titration to achieve a maximum dose of calcitriol, 40 to 60 ng/kg/day in two divided doses, and phosphorus, 1 to 2 g/day in four to five divided doses (Friedman and Drezner 1991, 1993). Such combined therapy often improves growth velocity, normalizes lower extremity deformities, and induces healing of the attendant bone disease. Of course treatment involves a significant risk of toxicity that is generally expressed as abnormalities of calcium homeostasis and/or detrimental effects on renal function secondary to abnormalities such as nephrocalcinosis. In addition, refractoriness to the growth-promoting effects of treatment is often encountered, particularly in youths presenting at below the 5th percentile in height (Friedman *et al.*, 1993). Several studies, however, indicate that the addition of growth hormone to conventional therapy increases growth velocity significantly. Unfortunately, such a benefit is realized more frequently in younger patients, and disproportionate growth of the trunk often continues to manifest. Moreover, the definitive impact of growth hormone treatment on adult height remains unknown (Wilson, 2000).

More recently, several investigators have suggested that the effects of combination therapy with calcitriol and phosphate may be enhanced with the concurrent use of cinacalcet, a calcimimetic agent, which reduces parathyroid hormone. Use of cinacalcet decreases the elevated parathyroid hormone observed occasionally in untreated patients and frequently in treated patients, limiting the phosphaturic effects of PTH and permitting more optimal restoration to normal of the renal TmP/GFR and serum phosphorus concentration in treated patients.

Therapy in adults is reserved for episodes of intractable bone pain and refractory nonunion bone fractures.

Hereditary Hypophosphatemic Rickets with Hypercalciuria

This rare genetic disease is characterized by hypophosphatemic rickets with hypercalciuria (Tieder *et al.*, 1985). The cardinal biochemical features of the disorder include hypophosphatemia due to increased renal phosphate clearance and normocalcemia. In contrast to other diseases in which renal phosphate transport is limited, patients with HHRH exhibit increased $1,25(OH)_2D$ production (see Table III). The resultant elevated serum calcitriol levels enhance gastrointestinal calcium absorption, which in turn increases the filtered renal calcium load and inhibits parathyroid secretion (Tieder *et al.*, 1985). These events cause the hypercalciuria observed in affected patients.

The clinical expression of the disease is heterogeneous, although initial symptoms, evident at 6 months to 7 years of age, generally consist of bone pain and/or deformities of the lower extremities. The bone deformities vary from genu varum or genu valgum to anterior external bowing of the femur and coxa vara. Additional features of the disease include short stature, muscle weakness, and radiographic signs of rickets or osteopenia. These various symptoms and signs may exist separately or in combination and may be present in a mild or severe form. Relatives of patients with evident HHRH may exhibit an additional mode of disease expression. These subjects manifest hypercalciuria and hypophosphatemia, but the abnormalities are less marked and occur in the absence of discernible bone disease (Tieder *et al.*, 1987). Bone biopsies in children with characteristic HHRH exhibit classical osteomalacia, but the mineralization defect appears to vary in severity with the magnitude of the hypophosphatemia. Histological measurements are within the normal range in family members with idiopathic hypercalciuria.

Pathophysiology and Genetics

Liberman and co-workers (Tieder *et al.*, 1985, 1987 Liberman, 1988) have presented data that indicate the primary inborn error underlying this disorder is an expressed abnormality in the renal proximal tubule, which impairs phosphate reabsorption. They propose that this pivotal defect results in enhanced renal 25(OH)D-1α-hydroxylase, thus promoting the production of $1,25(OH)_2D$ and increasing its serum levels. Consequently, intestinal calcium absorption is augmented, resulting in the suppression of parathyroid function and an increase of the renal filtered calcium load. The concomitant prolonged hypophosphatemia diminishes osteoid mineralization and accounts for the ensuing rickets and/or osteomalacia.

The suggestion that abnormal phosphate transport results in increased calcitriol production remains untested. Indeed, the elevation of $1,25(OH)_2D$ in patients with HHRH is a unique phenotypic manifestation of the disease that distinguishes it from other disorders in which abnormal phosphate transport is likewise manifest. Such heterogeneity in the phenotype of these disorders suggests that disease at variable anatomical sites along the proximal convoluted tubule uniformly impairs phosphate transport but not 25(OH)D-1α-hydroxylase activity. Alternatively, the aberrant regulation of vitamin D metabolism in other hypophosphatemic disorders may occur independently (e.g., in XLH secondary to the PHEX gene abnormality or FGF-23) and override the effects of the renal phosphate transport.

Extensive studies in a large consanguineous Bedouin kindred have established that HHRH is transmitted in an autosomal recessive inheritance pattern. Under such circumstances, the variability in this disorder may be explained by assuming that individuals with HHRH or idiopathic hypercalciuria are homozygous and heterozygous, respectively, for the same mutant allele. Early studies focused on Na/P_i-IIa as a candidate gene underlying HHRH. Indeed, Beck *et al.* (1998) reported that homozygous ablation of this murine gene (*SLC34a1*) leads to hypophosphatemia, renal phosphate wasting, increased serum $1,25(OH)_2D$ levels, and hypercalciuria. These findings were evident at weaning, but the magnitude of the changes decreased with increasing age. Furthermore, Na/P_i-IIa-ablated mice lack the typical features of rickets (Beck *et al.*, 1998; Gupta *et al.*, 2001; Tenenhouse, 2005). Therefore, it was not surprising that *SLC34A1* mutations were excluded in genomic DNA from affected members of several kindred with HHRH (Jones *et al.*, 2001; van den Heuvel *et al.*, 2001). More recently, Bergwitz *et al.* (2006) performed a genome-wide linkage scan, combined with a homozygosity mapping approach in an extended Bedouin kindred to map the genetic defect responsible for HHRH to a 1.6-Mbp interval in chromosome region 9q34. Na/P_i-IIc (*SLC34A3*), a plausible candidate gene in this region, was sequenced and all individuals with HHRH were homozygous for a 1-nt deletion, c 228delC. This mutation produces a nonfunctional Na/P_i-IIc protein that is truncated within the first membrane-spanning domain. Consistent with these observations, several compound heterozygous missense mutations or deletions were found in affected individuals from three additional unrelated kindreds, which were not present in healthy controls. Moreover, several investigators (Ichikawa *et al.*, 2006; Lorenz-Depiereux *et al.*, 2006) have confirmed mutations in *SLC34A3* in multiple additional families.

Although the function of the NaPi-IIc receptor in the regulation of renal phosphate transport was considered minimal, the identification of a mutation in the *SLC34A3* gene as the cause of HHRH has brought new perspective to the role of this receptor. Indeed, a recent series of studies (Tenenouse *et al.*, 2003; Miyamoto *et al.*, 2004) provide undeniable evidence that NaP_i-IIC appears to be critically involved in regulating phosphate homeostasis.

Treatment

In accord with the hypothesis that a singular defect in renal phosphate transport underlies HHRH, affected

patients have been treated successfully with high-dose phosphorus (1–2.5 g/day in five divided doses) alone. In response to therapy, bone pain disappears and muscular strength improves substantially. Moreover, the majority of treated subjects exhibit accelerated linear growth and radiologic signs of rickets disappear completely within 4 to 9 months. Concordantly, serum phosphorus values increase toward normal, the $1,25(OH)_2D$ concentration decreases, and alkaline phosphatase activity declines. Despite this favorable response, limited studies indicate that such treatment does not heal the associated osteomalacia. Therefore, further investigation is necessary to determine whether phosphorus alone is truly sufficient for this disorder.

Autosomal-Dominant Hypophosphatemic Rickets

Several studies have documented an autosomal-dominant inheritance, with incomplete penetrance, of a hypophosphatemic disorder similar to XLH (Harrison and Harrison, 1979). The phenotypic manifestations of this disorder include lower extremity deformities and rickets/osteomalacia. Indeed, affected patients display biochemical and radiographic abnormalities indistinguishable from those of individuals with XLH. These include hypophosphatemia secondary to renal phosphate wasting and normal levels of parathyroid hormone and 25(OH)D, as well as inappropriately normal (relative to the serum phosphorus concentration) $1,25(OH)_2D$ (see Table III). However, unlike patients with XLH, some with ADHR display variable incomplete penetrance and delayed onset of penetrance (Econs and McEnery, 1997). Thus, long-term studies indicate that a few of the affected female patients exhibit delayed penetrance of clinically apparent disease and an increased tendency for bone fracture, uncommon occurrences in XLH. Moreover, these individuals present in the second through the fourth decade with weakness and bone pain but do not have lower extremity deformities. Further, other patients with the disorder present during childhood with phosphate wasting, rickets, and lower extremity deformity but manifest postpubertal loss of the phosphate-wasting defect. Finally, a few apparently unaffected individuals have been identified, who seemingly are carriers for the ADHR mutation.

An apparent forme fruste of this disease, (autosomal-dominant) hypophosphatemic bone disease, has many of the characteristics of XLH and ADHR, but reports indicate that affected children display no evidence of rachitic disease (Scriver *et al.*, 1977, 1981). Because this syndrome is described in only a few small kindreds and radiographically evident rickets is not universal in children with familial hypophosphatemia, these families may have ADHR. Further observations are necessary to discriminate this possibility.

Pathophysiology and Genetics

The primary inborn error in ADHR results in an expressed abnormality of the renal proximal tubule that impairs P_i reabsorption. Until recently, whether this renal abnormality is primary or secondary to the elaboration of a humoral factor has been controversial. However, identification of the genetic defect underlying this disease has established that hormonal dysregulation is the pivotal abnormality in this disorder. In this regard, studies localized the ADHR gene to a 6.5-cM interval on chromosome 12p13 (Econs *et al.*, 1997). Moreover, extending these studies, the ADHR Consortium (2000) used a positional cloning approach to identify 37 genes within 4 Mb of the genomic sequence in the 6.5-cM interval and identified missense mutations in a gene encoding FGF-23. Three different mutations were found in four kindreds, each resulting in amino acid substitutions in the FGF-23 at R176Q, R179Q, and R179W. These mutations occur at a protease cleavage site (RXXR) and the resulting mutant FGF-23 molecules are resistant to cleavage (White *et al.*, 2001a, 2001b; Shimada *et al.*, 2002; Bai *et al.*, 2003). The impact of these mutations is the inability to degrade the FGF-23, a relevant abnormality because only the full-length molecule has biological effects *in vivo* (Shimada *et al.*, 2002). Hence the resulting abundance of full-length FGF-23 results in the hypophosphatemia and attendant rickets and osteomalacia characteristic of the disorder. The relationship of the elevated FGF-23 concentration to active disease has recently been investigated by Imel *et al.* (2007). They discovered that FGF-23 concentrations are not universally elevated in ADHR. Rather, the ADHR symptoms and disease severity likely fluctuate with the FGF-23 concentration and the ability to alter the FGF-23 concentration changes the clinical phenotype, resulting in the observed delayed penetrance, and also in at least temporary resolution of the phenotype in some individuals. Such variability likely involves an intrinsic but unknown physiological alteration in the metabolism of FGF-23 leading to resolution of ADHR features.

Treatment

Although studies of treatment in patients with ADHR are not available, the pathogenetic role of FGF-23 in the development of the disease suggests that therapy effective in patients with XLH will likewise benefit those with ADHR. Hence, treatment with calcitriol and phosphorus supplementation has been employed in a limited number of the affected patients. Evaluation of treatment outcome will likely reveal only partial success, similar to that in patients with XLH.

Autosomal Recessive Hypophosphatemic Rickets

Recent studies have identified ARHR in two unrelated, consanguineous kindreds as a genetically transmitted form of hypophosphatemic rickets. Affected individuals present with renal phosphate wasting, rachitic changes, and lower limb deformity. In family 1 there were three affected sisters and in family 2 a single affected female. The parents and siblings of these individuals did not exhibit any clinical or biochemical evidence of the disease.

At presentation members of family 1 in mid- to late infancy had radiographic evidence of rickets or clinically evident rickets with progressive lower limb deformity. In family 2 the affected individual presented at 8 years of age with a mild genu valgum. Biochemical abnormalities at baseline included hypophosphatemia, renal phosphate wasting, normal parathyroid function, normocalcemia, normal urinary calcium, and elevated alkaline phosphatase. Serum $1,25(OH)_2D$ levels were inappropriately normal in the presence of hypophosphatemia (see Table III). Bone biopsy in an affected individual confirmed severe osteomalacia, marked by excess osteoid and extended mineralization lag time, as well as a disrupted osteocyte lacunocanalicular system. Serum FGF-23 levels were overtly elevated or overlapped the upper normal range. Biochemical studies obtained during adulthood showed persistent renal phosphate wasting, and consequent hypophosphatemia and linear growth was heterogeneous. Testing for *FGF-23* and *PHEX* mutations was negative.

Studies of the *Dmp1*-null mouse provided insight to the genetic defect underlying ARHR. Dmp1 is a member of the SIBLING family (Fisher and Fedarko 2003) that is primarily expressed in mineralized tissues, most notably osteocytes (Toyosawa *et al.,* 2001). Absence of this protein in null mice results in mild hypocalcemia and severe hypophosphatemia secondary to increased renal phosphate clearance. The enhanced renal phosphate clearance is due to an elevated serum FGF-23 concentration, which is associated with increased FGF-23 mRNA expression in bone. Moreover, newborn mice lacking *Dmp1* develop radiological evidence of rickets and an osteomalacia phenotype with age (Ling *et al.,* 2005). These observations highlight that genetic removal of *Dmp1* from the skeletal matrix in mice leads to altered skeletal mineralization and disturbed phosphate homeostasis associated with increased FGF-23 production, abnormalities similar to those observed in individuals with ARHR.

Thus, Feng *et al.* (2006) undertook a candidate gene approach using direct sequence analyses to test ARHR families for a mutation in *DMP1*. In the affected individuals in family 1, they detected a homozygous deletion of nucleotides 1484–1490 (1484–1490del) in DMP1 exon 6, resulting in a frameshift that replaced the conserved C-terminal 18 residues with 33 unrelated residues. The affected individual in family 2 had a biallelic nucleotide substitution in the DMP1 start codon (ATG to GTG, or A1→G) and a consequent substitution of the initial methionine with valine (M1V), resulting in predicted loss of the highly conserved 16-residue DMP1 signal sequence. These mutations segregated with the disorder in both kindreds, and neither DMP1 mutation was found in 206 control alleles. Mutational analyses of an additional 19 hypophosphatemic individuals negative for PHEX and FGF-23 mutations, with no known history of consanguinity, did not uncover any disease-causing changes in DMP1.

Treatment

Studies in the *Dmp1*-null mice revealed that restoring serum phosphate to normal level by feeding a high-phosphate diet rescues the radiological appearance of rickets owing to correction of the mineralization defect at the growth plate. However, although the osteomalacia improved with a high-phosphate diet, the bone phenotype was not completely rescued, consistent with similar observations in *hyp*-mice. Thus, the treatment strategy for ARHR will likely include use of high-dose phosphate supplements and calcitriol, albeit complete bone healing is not anticipated.

Tumor-Induced Osteomalacia

Since 1947 there have been reports of well more than 200 patients in whom rickets and/or osteomalacia has been induced by various types of tumors. In at least half of the reported cases a tumor has been clearly documented as causing the rickets/osteomalacia, because the metabolic disturbances improved or disappeared completely on removal of the tumor. In the remainder of cases, patients had inoperable lesions, and investigators could not determine the effects of tumor removal on the syndrome or surgery did not result in complete resolution of the evident abnormalities during the period of observation.

Affected patients generally present with bone and muscle pain, muscle weakness, rickets/osteomalacia, and occasionally recurrent fractures of long bones. Additional symptoms common to younger patients are fatigue, gait disturbances, slow growth, and bowing of the lower extremities. Biochemistries include hypophosphatemia secondary to renal phosphate wasting and normal serum levels of calcium and 25(OH)D. Serum $1,25(OH)_2D$ is overtly low or low relative to the prevailing hypophosphatemia (see Table III). Aminoaciduria, most frequently glycinuria, and glucosuria are occasionally present. Radiographic abnormalities include generalized osteopenia, pseudofractures, and coarsened trabeculae, as well as widened epiphyseal plates in children. The histologic appearance of trabecular bone in affected subjects most often reflects the presence of low-turnover osteomalacia. In contrast, bone biopsies from the few patients who have tumors that secrete a non-parathyroid hormone factor(s), which activates adenylate cyclase, exhibit changes consistent with enhanced bone turnover, including an increase in osteoclast and osteoblast number.

The large majority of patients with this syndrome harbor tumors of mesenchymal origin and include primitive-appearing, mixed connective tissue lesions, osteoblastomas, nonossifying fibromas, and ossifying fibromas. However, the frequent occurrence of Looser zones in the radiographs of moribund patients with carcinomas of epidermal and endodermal derivation indicates that the disease may be secondary to a variety of tumor types. Indeed, the observation

of tumor-induced osteomalacia concurrent with breast carcinoma (Dent and Gertner, 1976), prostate carcinoma (Lyles *et al.*, 1980; Murphy *et al.*, 1985; Hosking *et al.*, 1975), oat-cell carcinoma (Leehey *et al.*, 1985), small-cell carcinoma (Shaker *et al.*, 1995), multiple myeloma, and chronic lymphocytic leukemia (McClure and Smith, 1987) supports this conclusion. In addition, the occurrence of osteomalacia in patients with widespread fibrous dysplasia of bone (Dent and Gertner, 1976; Saville *et al.*, 1995), neurofibromatosis (Weidner and Cruz, 1987; Konishi *et al.*, 1991), and linear nevus sebaceous syndrome (Carey *et al.*, 1986) could also be tumor induced. Although proof of a causal relationship in these disorders has been precluded in general by an inability to excise the multiplicity of lesions surgically, in one case of fibrous dysplasia, removal of virtually all of the abnormal dysplastic lesions did result in appropriate biochemical and radiographic improvement.

Regardless of the tumor cell type, the lesions at fault for the syndrome are often small and difficult to locate and present in obscure areas, which include the nasopharynx, a sinus, the popliteal region, and the suprapatellar area. In any case, a careful and thorough examination is necessary to document or exclude the presence of such a tumor. Indeed, attempts at PET/CT and/or MRI localization of the tumor are often required. In addition, several groups have used octreotide scanning and other forms of nucleotide scintigraphy to identify suspected, but nonlocalized, tumors.

Pathophysiology

The relatively infrequent occurrence of this disorder has confounded attempts to determine the pathophysiological basis for TIO. Nevertheless, most investigators agree that tumor production of a humoral factor(s) that may affect multiple functions of the proximal renal tubule, particularly phosphate reabsorption, is the probable pathogenesis of the syndrome. This possibility is supported by (1) the presence of phosphaturic activity in tumor extracts from three of four patients with TIO (Aschinberg *et al.*, 1977; Yoshikawa *et al.*, 1977; Lau *et al.*, 1979); (2) the absence of parathyroid hormone and calcitonin from these extracts and the apparent cyclic AMP-independent action of the extracts; (3) the occurrence of hypophosphatemia and increased urinary phosphate excretion in heterotransplanted tumor-bearing athymic nude mice (Miyauchi *et al.*, 1988); (4) the demonstration that extracts of the hetero-transplanted tumor inhibit renal 25-hydroxyvitamin D-1 α-hydroxylase activity in cultured kidney cells (Miyauchi *et al.*, 1988); and (5) the coincidence of aminoaciduria and glycosuria with renal phosphate wasting in some affected subjects, indicative of complex alterations in proximal renal tubular function (Drezner and Feinglos, 1977). Indeed, partial purification of "phosphatonin" from a cell culture derived from a hemangioscleroma causing tumor-induced osteomalacia has reaffirmed this possibility (Cai *et al.*, 1994). These studies revealed that the putative phosphatonin may be a peptide with a molecular mass of 8 to 12 kDa that does not alter glucose or alanine transport, but inhibits sodium-dependent phosphate transport in a cyclic AMP-independent fashion. However, studies, which document the presence in various disease states of additional phosphate transport inhibitors (and stimulants), indicate that the tumor-induced osteomalacia syndrome may be heterogeneous. In this regard, excessive tumor production and secretion of FGF-23 (White *et al.*, 2001b) and matrix extracellular phosphoglycoprotein (MEPE) have been identified in large numbers of patients with tumor-induced osteomalacia. Moreover, secreted frizzled related protein 4 (sFRP4) has recently been identified as a putative phosphatonin in patients with TIO. Indeed, the gene for this protein was reported as a highly expressed transcript in hemangiopericytomas that caused TIO and a differential expression cloning approach also identified sFRP4 as highly expressed in TIO tumors. Thus, it seems certain that ectopic hormone production of a phosphatonin by a tumor underlies the syndrome. As a result, suspicion of the syndrome is often confirmed by measurement of serum FGF-23. Indeed, Imel *et al.* (2006) studied 22 patients with suspected TIO, 13 of whom had confirmed tumors. They found elevated FGF-23 concentrations in 16 of the 22 patients, using the Immunotopics C-terminal assay (sensitivity 73%), in 5 of the 22 patients using the Immunotopics Intact assay (sensitivity 23%), and in 19 of the 22 patients using the Kainos Intact assay (sensitivity 86%). In the 13 patients with confirmed tumors, the sensitivity was higher with all assays. Of course, the presence of normal FGF-23 levels in some patients with putative TIO suggests that FGF-23 is not responsible for the hypophosphatemia in all affected patients.

In contrast to these observations, patients with TIO secondary to hematogenous malignancy manifest abnormalities of the syndrome due to a distinctly different mechanism. In these subjects the nephropathy induced with light-chain proteinuria or other immunoglobulin derivatives results in the decreased renal tubular reabsorption of phosphate characteristic of the disease. Thus, light-chain nephropathy must be considered a possible mechanism for the TIO syndrome.

Treatment

The first and foremost treatment of TIO is complete resection of the tumor. However, recurrence of mesenchymal tumors, such as giant-cell tumors of bone, or inability to resect certain malignancies completely, such as prostate carcinoma, has resulted in the development of alternative therapeutic intervention for the syndrome. In this regard, administration of calcitriol alone or in combination with phosphorus supplementation has served as effective therapy for TIO. Doses of calcitriol required range from 1.5 to 3.0 μg/day, whereas those of phosphorus are 2 to 4 g/day. Although little information is available regarding the long-term consequences of such treatment, the high doses of medicine required raise the possibility that nephrolithiasis, nephrocalcinosis, and hypercalcemia may frequently

complicate the therapeutic course. Indeed, hypercalcemia secondary to parathyroid hyperfunction has been documented in at least five treated subjects. All of these patients received phosphorus as part of a combination regimen, which may have stimulated parathyroid hormone secretion and led to parathyroid autonomy. Thus, a careful assessment of parathyroid function, serum and urinary calcium, and renal function is essential to ensure safe and efficacious therapy.

In an effort to diminish the complications of high-dose calcitriol and phosphorus therapy, addition of cinacalcet to the therapeutic regimen has been tested (Geller *et al.*, 2007). The resultant decrease of serum PTH resulted in an increase of renal phosphate reabsorption and serum phosphorus and allowed for a decrease in phosphate supplementation to a dose that was more tolerable. Moreover, one such treated patient exhibited significant bone healing, indicated by resolution of activity on a bone scan and lack of osteomalacia as assessed by histomorphometry.

Dent's Disease (X-Linked Recessive Hypophosphatemic Rickets)

In the past several decades, multiple syndromes have been described that are characterized by various combinations of renal proximal tubular dysfunction (including renal phosphate wasting), proteinuria, hypercalciuria, nephrocalcinosis, nephrolithiasis, renal failure, and rickets; these disorders, referred to as Dent's disease, include X-linked recessive hypophosphatemic rickets (see Table III), X-linked recessive nephrolithiasis with renal failure, and low-molecular-weight proteinuria with nephrocalcinosis. The spectrum of phenotypic features in these diseases is remarkably similar, except for differences in the severity of bone deformities and renal impairment. The observation that all of these syndromes are caused by mutations affecting a chloride channel clarifies the interrelationship between them and establishes that they are variants of a single disease (Scheinman, 1998).

Urinary loss of low-molecular-weight proteins is the most consistent abnormality in the disease, present in all affected males and in almost all female carriers of the disorder (Wrong *et al.*, 1994; Reinhart *et al.*, 1995). Other signs of impaired solute reabsorption in the proximal tubule, such as renal glycosuria, aminoaciduria, and phosphate wasting, are variable and often intermittent. Hypercalciuria is an early and common feature, whereas hypokalemia occurs in some patients. Urinary acidification is normal in over 80% of affected subjects, and when it is abnormal, the defect has been attributed to hypercalciuria or nephrocalcinosis (Wrong *et al.*, 1994; Reinhart *et al.*, 1995; Buckalew *et al.*, 1974). The disease apparently does not recur after kidney transplantation (Scheinman, 1998).

These phenotypic features indicate the presence of proximal tubular dysfunction but do not suggest its pathophysiologic basis. The gene causing Dent's disease, *CLCN5*, encodes the chloride/proton antiporter, CLC-5, which is expressed predominantly in the kidney and in particular the proximal tubule, the thick ascending limb of Henle, and the alpha intercalated cells of the collecting duct (Scheinman, 1998; Lloyd *et al.*, 1996; Hoopes *et al.*, 1998; Igarashi *et al.*, 1998). Mapping studies have established linkage of this gene to the short arm of the X chromosome (Xp11.22; Scheinman *et al.*, 1997). The gene is a member of a family of genes encoding voltage-gated chloride channels and is critical for acidification in the endosomes that participate in solute reabsorption and membrane recycling in the proximal tubule. CLC-5 also alters membrane trafficking via the receptor-mediated-endocytic pathway that involves megalin and cubulin. CLC-5 mutations associated with Dent's disease impair chloride flow and likely lead to impaired acidification of the endosomal lumen, and thereby disruption of endosome trafficking to the apical surface, resulting in abnormal solute reabsorption by the renal tubule.

It is not clear how this process leads to the increased intestinal calcium absorption and high serum $1,25(OH)_2D$ levels in this disorder (Reinhart *et al.*, 1995), because the 25(OH)D-1α-hydroxylase that catalyzes calcitriol formation is located in the mitochondria of proximal tubular cells, whereas C1C-5 is expressed in the thick ascending limb of Henle's loop (Devuyst *et al.*, 1999), a major site of renal calcium reabsorption. The role of this channel in the reabsorption of calcium in the thick ascending limb remains unknown.

Fanconi Syndrome

Rickets and osteomalacia are frequently associated with Fanconi syndrome, a disorder characterized by phosphaturia and consequent hypophosphatemia, aminoaciduria, renal glycosuria, albuminuria, and proximal renal tubular acidosis (De Toni, 1933; McCune *et al.*, 1943; Brewer, 1985; Chan and Alon, 1985; Chesney, 1990). Damage to the renal proximal tubule, secondary to genetic disease (see Table II) or environmental toxins, represents the common underlying mechanism of this disease. Resultant dysfunction results in renal wasting of those substances primarily reabsorbed at the proximal tubule. The associated bone disease in this disorder is likely secondary to hypophosphatemia and/or acidosis, abnormalities that occur in association with aberrantly (Fanconi syndrome, type I) or normally regulated (Fanconi syndrome, type II) vitamin D metabolism.

Type I

The type I disease resembles in many respects the more common genetic disease, X-linked hypophosphatemic rickets (see Table III). In this regard, the occurrence of abnormal bone mineralization appears dependent on the prevailing renal phosphate wasting and resultant hypophosphatemia. Indeed, subtypes of the disease in which isolated wasting of amino acids, glucose, or potassium occur are

not associated with rickets and/or osteomalacia. Further, in the majority of patients studied, affected subjects exhibit abnormal vitamin D metabolism, characterized by serum $1,25(OH)_2D$ levels that are overtly decreased or abnormally low relative to the prevailing serum phosphorus concentration (Chesney *et al.*, 1984). Although the aberrantly regulated calcitriol biosynthesis may be due to the abnormal renal phosphate transport, proximal tubule damage and acidosis may play important roles.

A notable difference between this syndrome and XLH is a common prevailing acidosis, which may contribute to the bone disease. In this regard, several studies indicate that acidosis may exert multiple deleterious effects on bone. Such negative sequelae may be related to the loss of bone calcium that occurs due to calcium release for use in buffering. Alternatively, several investigators have reported that acidosis may impair bone mineralization secondary to the direct inhibition of renal 25(OH)D-1α-hydroxylase activity. Others dispute these findings and claim that acidosis does not cause rickets or osteomalacia in the absence of hypophosphatemia. Most likely, hypophosphatemia and abnormally regulated vitamin D metabolism are the primary factors underlying rickets and osteomalacia in this form of the disease.

Type II

Tieder *et al.* (1988) have described two siblings (from a consanguineous mating) who presented with classic characteristics of Fanconi syndrome, including renal phosphate wasting, glycosuria, generalized aminoaciduria, and increased urinary uric acid excretion. However, these patients had appropriately elevated (relative to the decreased serum phosphorus concentration) serum $1,25(OH)_2D$ levels and consequent hypercalciuria (see Table III). Moreover, treatment with phosphate reduced the serum calcitriol in these patients into the normal range and normalized the urinary calcium excretion. In many regards, this syndrome resembles HHRH and represents a variant of Fanconi syndrome, referred to as type II disease. The bone disease in affected subjects is likely due to the effects of hypophosphatemia. In any case, the existence of this variant form of disease is probably the result of renal damage to a unique segment of the proximal tubule. Further studies will be necessary to confirm this possibility.

Treatment

Ideal treatment of the bone disease in this disorder is correction of the pathophysiological defect influencing proximal renal tubular function. In many cases, however, the primary abnormality remains unknown. Moreover, efforts to decrease tissue levels of causal toxic metabolites by dietary (such as in fructose intolerance) or pharmacological means (such as in cystinosis and Wilson's syndrome) have met with variable success. Indeed, no evidence exists that indicates whether the proximal tubule damage is reversible on relief of an acute toxicity. Thus, for the most part, therapy of this disorder must be directed at raising the serum phosphorus concentration, replacing calcitriol (in type I disease) and reversing an associated acidosis. However, use of phosphorus and calcitriol in this disease has been limited. In general, such replacement therapy leads to substantial improvement or resolution of the bone disease (Schneider and Schulman, 1983). Unfortunately, growth and developmental abnormalities, more likely associated with the underlying genetic disease, remain substantially impaired. More efficacious therapy, therefore, is dependent on future research into the causes of the multiple disorders that cause this syndrome.

Tumoral Calcinosis

Tumoral calcinosis, also referred to as hyperphosphatemic familial tumoral calcinosis, is a rare genetic disease characterized by periarticular cystic and solid tumorous calcifications. Biochemical markers of the disorder include hyperphosphatemia and a normal or an elevated serum $1,25(OH)_2D$ concentration (see Table III). Using these criteria, evidence has been presented for autosomal recessive inheritance of this syndrome. However, an abnormality of dentition, marked by short bulbous roots, pulp stones, and radicular dentin deposited in swirls, is a phenotypic marker of the disease that is variably expressed (Lyles *et al.*, 1985). Thus, this disorder may have multiple formes frustes that could complicate genetic analysis. Indeed, using the dental lesion, as well as the more classic biochemical and clinical hallmarks of the disease, an autosomal dominant pattern of transmission has been documented.

The hyperphosphatemia characteristic of the disease results from an increase in capacity of renal tubular phosphate reabsorption. Hypocalcemia is not a consequence of this abnormality, however, and the serum parathyroid hormone concentration is normal. Moreover, the phosphaturic and urinary cAMP responses to parathyroid hormone are not disturbed. Thus, the defect does not represent renal insensitivity to parathyroid hormone, or hypoparathyroidism. Rather, the genetic basis for the disease has recently been revealed with inactivating mutations encoding the *FGF-23*, UDP-*N*-galactosamine polypeptide *N*-acetylgalactosaminyl transferase 3 (*GALNT3*), or Klotho genes.

- The mutations of *FGF-23* lead to destabilized protein and resultant increased intracellular proteolysis of FGF-23, most likely due to furin-like proteases (Araya *et al.*, 2005). This process increases circulating levels of the bioinactive C-terminal fragment of FGF-23 and markedly decreases concentration of the bioactive intact molecule. Such absence of FGF-23 bioactivity results in the enhanced renal phosphate reabsorption and hyperphosphatemia observed in affected patients. Indeed, several investigators have discovered that FGF-23 gene knockout mice develop hyperphosphatemia and severe soft-tissue calcification as expected.
- GALNT3 is a Golgi-associated enzyme that initiates *O*-glycosylation of mature polypeptides This enzyme

selectively *O*-glycosylates a furin-like convertase recognition sequence in FGF-23, thereby impairing the normal function of this protein (Ichikawa *et al.,* 2005; Specktor *et al.,* 2006). This process decreases circulating intact, bioactive FGF-23 as described earlier for the destabilizing mutations of FGF-23.

- Recent studies revealed that FGF-23 requires an additional cofactor, klotho (KL), to bind and signal through its cognate FGF receptors. Not surprisingly, therefore, diminished *KL* expression in mice results in a phenotype characterized by severe hyperphosphatemia, increased serum $1,25(OH)_2D$ levels, and ectopic vascular and soft-tissue calcifications. Indeed the *KL*-deficient phenotype broadly overlaps with the phenotype of *Fgf-23*-null mice, reaffirming the functional crosstalk between KL and FGF-23 and underscoring the observed interactions between KL, FGF-23 and its cognate FGF receptors. In accord, Ichikawa *et al.* (2007)have recently reported a point mutation in the *KL* gene, which attenuates the ability of KL to support FGF-23 signaling and thereby causes the deranged phosphate, vitamin D and calcium homeostasis, characteristic of tumoral calcinosis.

Clearly, therefore, the basis of the disease is diminished FGF-23 function, which results in enhanced renal phosphate reabsorption and increased calcitriol production. Undoubtedly, calcific tumors result from the elevated calcium–phosphorus product. The observation that long-term phosphorus depletion alone or in association with administration of acetazolamide, a phosphaturic agent, leads to resolution of the tumor masses supports the assumption that an increased calcium–phosphorus product underlies the calcific tumor formation.

An acquired form of this disease is rarely seen in patients with end-stage renal failure. Affected patients manifest hyperphosphatemia in association with either (1) an inappropriately elevated calcitriol level for the degree of renal failure, hyperparathyroidism, or hyperphosphatemia or (2) long-term treatment with calcium carbonate, calcitriol, or high-calcium-content dialysates. Calcific tumors again likely result from an elevated calcium–phosphorus product. Indeed, complete remission of the tumors occurs on treatment with vinpocetine, a mineral scavenger drug, dialysis with low-calcium-content dialysate, and renal transplantation

Chapter 24

Magnesium Homeostasis

Robert K. Rude, M.D.
Keck School of Medicine, University of Southern California Los Angeles, California

INTRODUCTION

Magnesium (Mg) is the fourth most abundant cation and the second most abundant intracellular cation in vertebrates. Mg is involved in numerous biological processes and is essential for life (Rude and Shils, 2006). This mineral has evolved to become a required cofactor in literally hundreds of enzyme systems (Laires *et al.,* 2004; Maguire and Cowan, 2002; Romani, 2006; Rude and Shils, 2006). Examples of the physiological role of Mg are shown in (Table I). Mg may be required for enzyme substrate formation. For example, enzymes that utilize ATP do so as the metal chelate, MgATP. Free Mg^{2+} also acts as an allosteric activator of numerous enzyme systems, as well as playing a role in ion channels and for membrane stabilization. Mg is therefore critical for a great number of cellular functions, including oxidative phosphorylation, glycolysis, DNA transcription, and protein synthesis.

TABLE I Examples of the Physiological Role of Magnesium

I. Enzyme substrate (ATP Mg, GTP Mg)
A. ATPase or GTPase (Na^+, K^+-ATPase, Ca^{2+}-ATPase)
B. Cyclases (adenylate cyclase, guanylate cyclase)
C. Kinase (hexokinase, creatine kinase, protein kinase)
II. Direct enzyme activation
A. Adenylate cyclase
B. Phospholipase C
C. Na^+, K^+-ATPase
D. Ca^{2+}-ATPase
E. K^+, H^+-ATPase
F. G proteins
G. 5′-Nucleotidase
H. Creatine kinase
I. Phosphofructokinase
J. 5-Phosphoribosyl-pyrophosphate synthetase
K. Lipoprotein lipase
III. Influence membrane properties
A. K^+ channels
B. Ca^{2+} channels
C. Nerve conduction

MAGNESIUM METABOLISM

The normal adult total body Mg content is approximately 25 grams (2000 mEq or 1 mol) of which 50% to 60% resides in bone (Elin, 1987; Wallach, 1988). Mg constitutes 0.5% to 1% of bone ash (200 mmol/kg ash weight). One-third of skeletal Mg is surface limited and exchangeable, and this fraction may serve as a reservoir for maintaining a normal extracellular Mg concentration (Wallach, 1988; Rude and Shils, 2006; Laires *et al.,* 2004). The remainder of Mg in bone is an integral component of the hydroxyapatite lattice, which may be released during bone resorption. The rest of body Mg is mainly intracellular. The Mg content of soft tissues varies between 6 and 25 mEq/kg wet weight (Elin, 1987; Rude and Shils, 2006). In general, the higher the metabolic activity of the cell, the higher the Mg content. The concentration of Mg within cells is in the order of 5–20 mmol/liter, of which 1% to 5% is ionized or free (Elin, 1987; Romani, 2006; Rude and Shils, 2006). The distribution of Mg in the body is shown in (Table II) and (Fig. 1).

Extracellular Mg accounts for about 1% of total body Mg. Mg concentration or content may be reported as mEq/liter, mg/dl, or mmol/liter. Values reported as mEq/liter can be converted to mg/dl by multiplying by 1.2 and to mmol/liter by dividing by 0.5. The normal serum Mg concentration is 1.5–1.9 mEq/liter (0.7–1.0 mmol/liter) (Elin, 1987; Rude and Shils, 2006). About 70% to 75% of plasma Mg is ultrafilterable, of which the major portion (55% of total serum Mg) is ionized or free, and the remainder is complexed to citrate, phosphate, and other anions as represented schematically in (Fig. 2). The remainder is protein bound; 25% of total serum Mg is bound to albumin and 8% to globulins.

Intestinal Mg Absorption

Mg homeostasis is dependent on the amount of Mg ingested, efficiency of Mg intestinal absorption, and renal reabsorption and excretion. Intestinal Mg absorption is proportional

Principles of Bone Biology, 3rd Edition

to the amount ingested (Fine *et al.,* 1991; Schweigel and Martens, 2000). The mechanism(s) for intestinal Mg absorption includes passive diffusion and active transport (Fine *et al.,* 1991; Kayne and Lee, 1993; Bijvelds *et al.,* 1998; Schweigel and Martens, 2000). Shown in (Fig. 3) is a schematic model (Schlingmann *et al.*, 2004) as suggested by rat (Ross, 1962) and human studies (Fine *et al.,* 1991; Kayne and Lee, 1993), which may account for the higher fractional intestinal Mg absorption at low dietary Mg intakes. Others have concluded that intestinal Mg absorption in humans increases linearly with Mg intake (for review, see Schweigel and Martens, 2000). The report of a patient with primary hypomagnesemia who was shown to malabsorb Mg during low Mg concentration in the intestine suggested an active transport process (Milla *et al.,* 1979). A familial defect in intestinal Mg absorption has been mapped to chromosome 9q22 (Walder *et al.,* 1997; Schlingmann *et al.*, 2002; Schlingmann *et al.*, 2004). This gene encodes for TMP6 in the intestinal epithelium for an Mg permeable channel (Schlingmann and Gudermann, 2005), which is evidence for at least one active Mg transport process. TMPR7 has also been demonstrated to play a role in Mg transport (Schlingmann and Gudermann, 2005; Chubanov *et al.,* 2004). Under normal dietary conditions in healthy individuals, approximately 30% to 50% of ingested Mg is absorbed (Brannan *et al.,* 1976; Hardwick *et al.,* 1990; Fine *et al.,* 1991; Kayne and Lee, 1993; Schweigel and Martens, 2000). Mg is absorbed along the entire intestinal tract, including the large and small bowel, but the sites of maximal Mg absorption appear to be the ilium and distal jejunum (Hardwick *et al.,* 1990; Fine *et al.,* 1991; Kayne and Lee, 1993; Schweigel and Martens, 2000).

The recommended daily allowance for Mg is 420 mg per day for adult males and 320 mg per day for adult females

TABLE II Distribution of Magnesium in Adult Humans[a]

Tissue	Body mass, kg (wet wt)	Mg concentration, mmol/kg (wet wt)	Mg content (mmol)	% of total body Mg
Serum	3.0	0.85	2.6	0.3
Erythrocyte	2.0	2.5	5.0	0.5
Soft tissue	22.7	8.5	193.0	19.3
Muscle	30.0	9.0	270.0	27.0
Bone	12.3	43.2	530.1	52.9
Total	70.0		1000.7	100.0

(Institute of Medicine, 1997). The dietary Mg intake in Western culture, however, appears to fall below that in a large section of the population across all ages, ranging from approximately 150 to 350 mg per day, suggesting that occult Mg depletion may be relatively prevalent (Morgan *et al.,* 1985; Marier, 1986). A recent study, however, has suggested that the dietary Mg requirement may be lower (Hunt and Johnson, 2006). The major sources of Mg are nuts, cereals, green leafy vegetables, and meats.

A principal factor that regulates intestinal Mg transport has not been described. Vitamin D, as well as its metabolites 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D [1,25$(OH)_2$D] have been observed in some studies to enhance intestinal Mg absorption but to a much lesser extent than they do calcium absorption (Brannan *et al.,* 1976; Hodgkinson *et al.,* 1979; Krejs *et al.,* 1983). Although net intestinal calcium absorption in humans correlates with plasma 1,25$(OH)_2$D concentrations, Mg does not (Wilz *et al.,* 1979). A low Mg diet has been shown to increase intestinal calbindin-D_{9k}, suggesting that this vitamin D-dependent, calcium-binding protein may play a role in intestinal Mg absorption (Hemmingsen *et al.,* 1994).

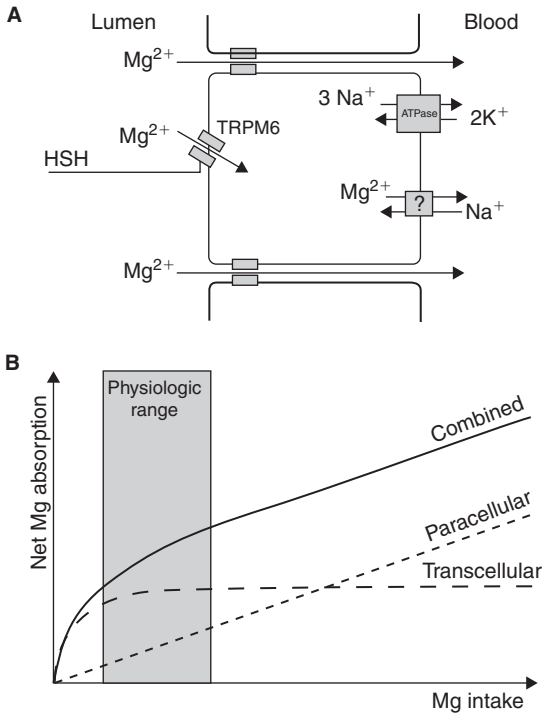

FIGURE 3 **A**. Schematic model of intestinal magnesium absorption via two independent pathways: passive absorption via the paracellular pathway and active transcellular transport consisting of an apical entry through a putative magnesium channel and a basolateral exit mediated by a putative sodium-coupled exchange. **B**. Kinetics of human intestinal magnesium absorption. Paracellular transport linearly rising with intraluminal concentration (dotted line) and saturable active trancellular transport (dashed line) together yield a curvilinear function for net magnesium absorption (solid line). (Schlingmann *et al.,* 2004, with permission).

Bioavailability of Mg may also be a factor in Mg intestinal absorption as other nutrients may affect Mg absorption. Although dietary calcium has been reported to both decrease and increase Mg absorption, human studies have shown no effect (Brannan *et al.,* 1976; Fine *et al.,* 1991). The presence of excessive amounts of substances such as free fatty acids, phytate, oxalate, polyphosphates, and fiber may bind Mg and impair absorption (Seelig, 1981; Franz, 1989).

Renal Mg Handling

The kidney is the principal organ involved in Mg homeostasis (Cole and Quamme, 2000; Satoh and Romero, 2002). During Mg deprivation in normal subjects, the kidney conserves Mg avidly and less than 1–2 mEq is excreted in the urine per day (Barnes *et al.,* 1958). Conversely, when excess Mg is taken, it is excreted into the urine rapidly (Heaton and Parson, 1961). The renal handling of Mg in humans is a filtration–reabsorption process; there appears to be no tubular secretion of Mg. Micropuncture studies of the nephron in several mammalian species have indicated that Mg is absorbed in the proximal tubule, thick ascending limb of Henle, and distal convoluted tubule (Quamme and De Rouffignac, 2000; Cole and Quamme, 2000), as illustrated in (Fig. 4).

About 2,400 mg of Mg is filtered daily through the normal adult. Of this, approximately 15% to 20% of filtered Mg is reabsorbed in the proximal convoluted tubule. Current data suggest that Mg transport in this segment is reabsorbed passively through the paracellular pathway (Cole and Quamme, 2000; Satoh and Romero, 2002). The majority, approximately 65% to 75%, of filtered Mg is reclaimed in the loop of Henle with the major site at the cortical thick ascending limb. Magnesium transport in this segment appears to be dependent on the transepithelial potential generated by NaCl absorption (Cole and Quamme, 2000; Satoh and Romero, 2002). Mutation of the CLDN16 gene, which encodes for a defect in paracellin-1 in the thick asending limb of Henle, results in renal Mg and calcium wasting (Schlingmann *et al.,* 2002; Konrad *et al.,* 2004). Micropuncture studies have also demonstrated that hypermagnesemia or hypercalcemia will decrease Mg reabsorption in this segment independent of NaCl transport (Cole and Quamme, 2000). Studies suggest that the concentration of calcium and/or Mg in the extracellular fluid may regulate absorption of Mg in the thick ascending limb of Henle by activation of the Ca^{2+}-sensing receptor in this segment of the nephron (Brown and Hebert, 1996; Cole and Quamme, 2000). Inactivating and activating mutations of the Ca^{2+}-sensing receptor will result in hypermagnesemia and hypercalcemia with decreased urine excretion of both cations or hypomagnesemia and hypocalcemia with increased excretion of both cations, respectively (Konrad *et al.,* 2004). Approximately 5% to 10% of Mg is reclaimed in the distal tubule where reabsorption is trancellular and active in

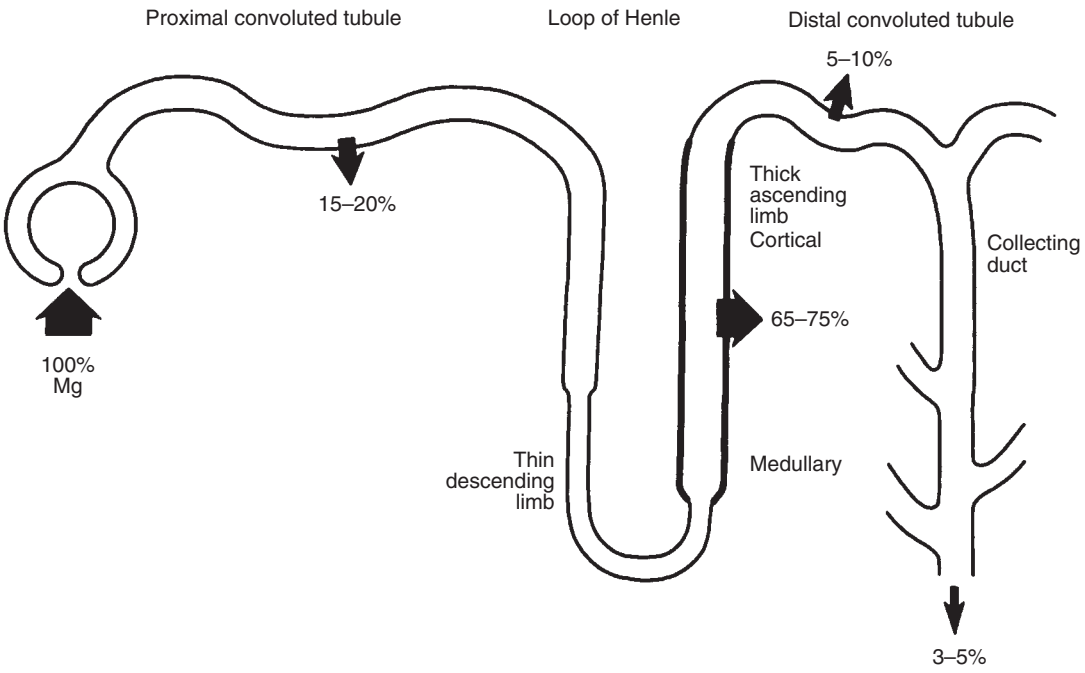

FIGURE 4 Summary of the tubular handling of magnesium. Schematic illustration of the cellular transport of magnesium within the thick ascending limb of the loop of Henle (Cole and Quamme, 2000).

nature (Cole and Quamme, 2000). A genetic defect on chromosome 11q23, gene FXYD2 results in a defect in Na-K-ATPase resulting in renal Mg wasting (Konrad *et al.*, 2004; Meij *et al.*, 2002). TRPM6, TRMP7, and TRMP9, members of the TRMP family of cation channels, may also affect Mg transport as genetic defects of these proteins have resulted in renal Mg wasting (Schmitz *et al.*, 2003; Schlingmann *et al.,* 2002; Schlingmann *et al.,* 2004). It is speculated that transport at this site may be regulated hormonally and serve to finely regulate Mg homeostasis.

Micropuncture studies performed during a time in which the concentration of Mg was increased gradually, in either the tubular lumen or in the extracellular fluid, have failed to demonstrate a tubular maximum for Mg (TmMg) in the proximal tubule (Quamme and De Rouffignac, 2000). The rate of Mg reabsorption is dependent on the concentration of Mg in the tubule lumen. Similarly, a TmMg was not reached in the loop of Henle during a graduated increase in the luminal-filtered Mg load. Hypermagnesemia, as discussed earlier, however, results in a marked depression of Mg resorption in this segment. *In vivo* studies in animals and humans, however, have demonstrated a TmMg that probably reflects a composite of tubular reabsorption processes, as shown in Fig. 5 (Rude *et al.,* 1980; Rude and Ryzen, 1986).

During Mg deprivation, Mg virtually disappears from the urine (Barnes *et al.,* 1958). Despite the close regulation of Mg by the kidney, there has been no hormone or factor described that is responsible for renal Mg homeostasis. Micropuncture studies have shown that PTH changes the potential difference in the cortical thick ascending limb and increases Mg reabsorption (Quamme and De Rouffignac, 2000; Cole and Quamme, 2000). When given in large doses in humans or other species, PTH decreases urinary Mg excretion (Bethune *et al.,* 1968; Massry *et al.,* 1969). However, patients with either primary hyperparathyroidism or hypoparathyroidism usually have a normal serum Mg concentration and a normal TmMg, suggesting that PTH is not an important physiological regulator of Mg homeostasis (Rude *et al.,* 1980). Glucagon, calcitonin, and ADH also affect Mg transport in the loop of Henle in a manner similar to PTH (Quamme and De Rouffignac, 2000; Cole and Quamme, 2000); the physiological relevance of these actions is unknown. Little is known about the effect of vitamin D on renal Mg handling. An overall view of Mg metabolism is shown in (Fig. 6).

Intracellular Mg

Within the cell, Mg is compartmentalized and most of it is bound to proteins and negatively charged molecules such as ATP, ADP, RNA, and DNA; in the cytoplasm, about 80% of Mg is complexed with ATP (Gupta and Moore, 1980; Frausto da Silva and Williams, 1991; Romani, 2006). Significant amounts of Mg are found in the nucleus, mitochondria, and endoplasmic and sarcoplasmic reticulum as well as in the cytoplasm (Gunther, 1986; Romani, 2006).

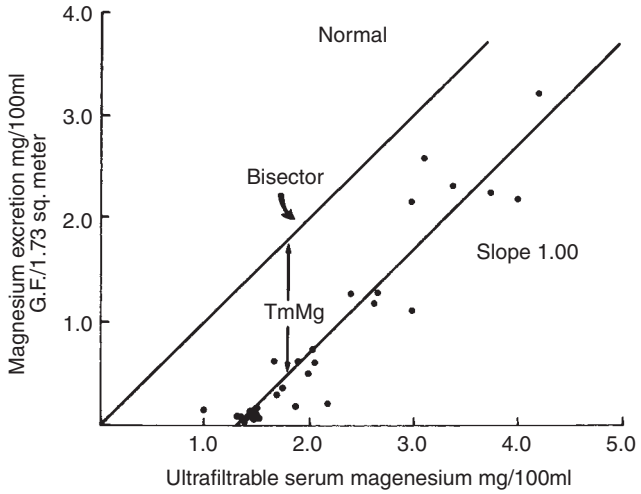

FIGURE 5 Urinary magnesium excretion is plotted against ultrafiltrable serum Mg in normal subjects before and during magnesium infusion. Data are related to a bisector that corresponds to the theoretical value of magnesium excretion if no magnesium were reabsorbed (Rude *et al.,* 1980).

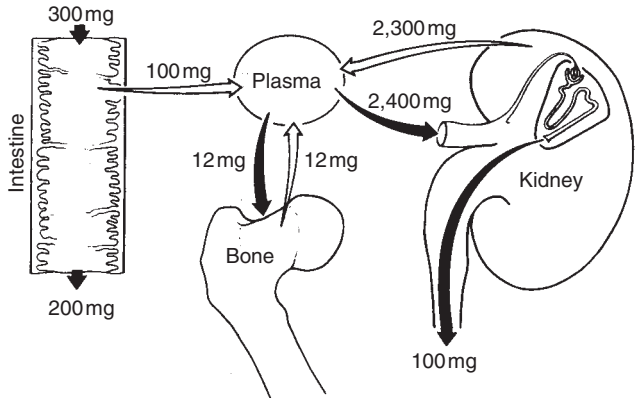

FIGURE 6 Schematic representation of magnesium metabolism.

Total cell Mg concentration has been reported to range between 5 and 20 mM (Gunther, 1986; Romani, 2006). The concentration of free ionized Mg^{2+}, which has been measured in the cytoplasm of mammalian cells, has ranged from 0.2 to 1.0 mM, depending on cell type and means of measurement (Raju *et al.,* 1989; London, 1991; Romani and Scarpa, 1992; Romani, 2006). It constitutes 1% to 5% of the total cellular Mg. The Mg^{2+} concentration in the cell cytoplasm is maintained relatively constant even when the Mg^{2+} concentration in the extracellular fluid is experimentally varied to either high or low nonphysiological levels (Dai and Quamme, 1991; Quamme *et al.,* 1993; Romani *et al.,* 1993). The relative constancy of the Mg^{2+} in the intracellular milieu is attributed to the limited permeability of the plasma membrane to Mg and to the operation of specific Mg transport systems, which regulate the rates at which Mg is taken up by cells or extruded from cells (Flatman, 1984; Romani, 2006; Murphy, 2000). Although the concentration differential between the cytoplasm and the extracellular fluid for Mg^{2+} is minimal, Mg^{2+} enters cells down an electrochemical gradient because of the relative electronegativity of the cell interior. Maintenance of the normal intracellular concentrations of Mg^{2+} requires that Mg be actively transported out of the cell (Murphy, 2000; Romani, 2006).

Studies in mammalian tissues and isolated cells suggest the presence of specific Mg transport systems. Early *in vivo* studies, using the radioactive isotope ^{28}Mg, suggested that tissues vary with respect to the rates at which Mg exchange occurs and the percentage of total Mg that is readily exchangeable (Rogers and Mahan, 1959). The rate of Mg exchange in heart, liver, and kidney exceeded that in skeletal muscle, red blood cells, brain, and testis (Romani, 2006). These studies do show that, albeit slow in some tissues, there is a continuous equilibration of Mg between cells and the extracellular fluid. Buffering of intracellular Mg by ATP and other negatively charged molecules may also play a role in maintaining a constant intracellular Mg concentration (Romani, 2006). An increased cellular Mg content has been reported for rapidly proliferating cells, indicating a possible relationship between the metabolic state of a cell and the relative rates of Mg transport into and out of cells (Cameron *et al.,* 1980).

Mg transport out of cells appears to require the presence of carrier-mediated transport systems, possibly regulated by the concentration of Mg^{2+} within the cell (Romani, 2006; Gunther, 1993; Gunther, 2006). The efflux of Mg from the cell is coupled to Na transport and requires energy (Romani, 2006; Gunther, 1993; Murphy, 2000; Gunther, 2006). Muscle tissue, which is incubated in isotonic sucrose, a low sodium buffer, or in the presence of ouabain as a metabolic inhibitor, has been shown to accumulate large amounts of Mg. These studies also suggest that the efflux of Mg from the cell is coupled with the movement of sodium down its electrochemical gradient into the cell. Maintenance of this process would require the subsequent extrusion of sodium by the Na^+, K^+-ATPase. There is also evidence for a Na-independent efflux of Mg, however (Gunther, 1993, 2006). Mg influx appears to be linked to Na and HCO_3 transport, but by a different mechanism than efflux (Gunther, 1993; Gunther and Hollriegl, 1993; Romani, 2006). The molecular characteristics of the Mg transport proteins have not been described. Studies in prokaryotes, however, have identified three separate transport proteins for Mg (Smith and Maguire, 1993). TRPM6, TRPM7, and TRMP9, members of the TRPM family of cation channels, have also been demonstrated to influence Mg transport across the plasma membrane (Schmitz *et al*., 2003; Schlingmann *et al*., 2002, Schlingmann *et al.*, 2004).

Mg transport in mammalian cells is influenced by hormonal and pharmacological factors. Mg^{2+} efflux from isolated perfused rat heart and liver (Romani and Scarpa, 1990; Gunther *et al.,* 1991; Gunther, 1993) or thymocytes

(Gunther and Vormann, 1990) is stimulated after short-term acute exposure to β-agonists and permeant cAMP. Because intracellular Mg^{2+} does not change, a redistribution from the mitochondria was suggested, as cAMP can induce Mg^{2+} release from this compartment (Romani and Scarpa, 1992) or by altered buffering of Mg within the cell (Murphy, 2000). In contrast, Mg^{2+} influx was stimulated by β-agonists after a more prolonged exposure in hepatocytes, as well as in adipocytes and vascular smooth muscle, presumably mediated by protein kinase A (Zama and Towns, 1986; Ziegler *et al.,* 1992; Gunther, 1993; Romani *et al.,* 1993). However, the rate of Mg uptake by the mouse lymphoma S49 cell line is inhibited by β-adrenergic agents (Maguire, 1984). Activation of protein kinase C by diacyl-glycerol or by phorbol esters also stimulates Mg^{2+} influx and does not alter efflux (Grubbs and Maguire, 1986; Romani, 2006). Mg^{2+} extrusion is also elicited by $\propto$1-adrenergic receptors in a cAMP-independent manner (Fagen and Romani, 2001; Romani, 2006).

Growth factors may also influence Mg^{2+} uptake by cells. Epidermal growth factor has been shown to increase Mg transport into a vascular smooth muscle cell line (Grubbs, 1991). Insulin and dextrose were found to increase ^{28}Mg uptake by a number of tissues, including skeletal and cardiac muscle, in which total cellular Mg content increased as well (Lostroh and Krahl, 1973). Increased amounts of total intracellular Mg following treatment with insulin *in vitro* have been reported in uterine smooth muscle and chicken embryo fibroblasts (Aikawa, 1960; Sanui and Rubin, 1978). An insulin-induced transport of Mg into cells could be one factor responsible for the fall in the serum Mg concentration observed during insulin therapy of diabetic ketoacidosis (Kumar *et al.,* 1978). The effect of insulin on total cellular Mg may differ from its effects on intracellular-free Mg^{2+}. Measurements of intracellular-free Mg^{2+} in frog skeletal muscle failed to show an effect of insulin (Gupta and Moore, 1980); however, other studies demonstrated that insulin increases Mg^{2+} in human red blood cells, platelets, lymphocytes, and heart (Hwang *et al.,* 1993; Barbagallo *et al.,* 1993; Hua *et al.,* 1995; Romani *et al.,* 2000).

It is hypothesized that this hormonally regulated Mg uptake system controls intracellular Mg^{2+} concentration in cellular subcytoplasmic compartments. The Mg^{2+} concentration in these compartments would then serve to regulate the activity of Mg-sensitive enzymes.

Risk Factors and Causes of Magnesium Deficiency

Prevalence

The many risk factors for magnesium depletion shown in (Table III) suggest that this condition is not a rare occurrence in acutely or chronically ill patients. A survey of 2,300 patients in a Veterans Administration hospital found 6.9% were hypomagnesemic; 11% of patients having routine magnesium determinations were hypomagnesemic (Whang *et al.*, 1984. Similar high rates of depletion have been reported in studies of ICU patients (Whang *et al.*, 1994; Ryzen *et al.*, 1985; Chernow *et al.*, 1989; Fiaccadori *et al.*, 1988). The true prevalence of magnesium depletion is not known, because this ion is not included in routine electrolyte testing in many clinics or hospitals (Whang *et al.*, 1994).

Gastrointestinal Disorders

Gastrointestinal disorders (Table III) may lead to magnesium depletion in various ways. The Mg content of upper intestinal tract fluids is approximately 1 mEq/L. Vomiting and nasogastric suction therefore may contribute to Mg depletion. The Mg content of diarrheal fluids is much higher (up to 15 mEq/L), and consequently Mg depletion

TABLE III Causes of Magnesium Deficiency

1. Gastrointestinal Disorders
   a. Prolonged nasogastric suction/vomiting
   b. Acute and chronic diarrhea
   c. Intestinal and biliary fistulas
   d. Malabsorption syndromes
   e. Extensive bowel resection or bypass
   f. Acute hemorrhagic pancreatitis
   g. Protein-calorie malnutrition
   h. Primary intestinal hypomagnesemia (neonatal)
2. Renal Loss
   a. Chronic parenteral fluid therapy
   b. Osmotic diuresis (glucose, urea, manitol)
   c. Hypercalcemia
   d. Alcohol
   e. Diuretics (furosemide, ethacrynic acid)
   f. Aminoglycosides
   g. Cisplatin
   h. Cyclosporin
   i. Amphotericin B
   j. Pentamidine
   k. Tacolimus
   l. Metabolic acidosis
   m. Renal disorders with Mg wasting
   n. Primary renal hypomagnesemia
3. Endocrine and Metabolic Disorders
   a. Diabetes mellitus (glycosuria)
   b. Phosphate depletion
   c. Primary hyperparathyroidism (hypercalcemia)
   d. Hypoparathyroidism (hypercalciuria, hypercalcemia owing to overtreatment with vitamin D)
   e. Primary aldosteronism
   f. Hungry bone syndrome
   g. Chronic renal disease
   h. Excessive lactatation

is common in acute and chronic diarrhea, regional enteritis, ulcerative colitis, and intestinal and biliary fistulas (Thoren, 1963; LaSala *et al*., 1985; Nyhlin *et al.*, 1985). Malabsorption syndromes towing to nontropical sprue, radiation injury resulting from therapy for disorders such as carcinoma of the cervix, and intestinal lymphangiectasia may also result in Mg deficiency (Booth *et al.,* 1963; Goldman *et al.,* 1962; Habtezion *et al*., 2002). Steatorrhea and resection or bypass of the small bowel, particularly the ileum, often results in intestinal Mg loss or malabsorption (Dyckner *et al.,* 1982; Van Gaal *et al.,* 1987). Lastly, acute severe pancreatitis is associated with hypomagnesemia, which may be owing to the clinical problem causing the pancreatitis, such as alcoholism, or to saponification of Mg in necrotic parapancreatic fat (Weir *et al.*, 1975; Ryzen and Rude, 1990). A primary defect in intestinal Mg absorption, which presents early in life with hypomagnesemia, hypocalcemia, and seizures, has been described as an autosomal recessive disorder linked to chromosome 9q22 as discussed earlier (Walder *et al.,* 1997; Schlingmann *et al*., 2002; Schlingmann *et al*., 2004), a disorder appears to be caused by mutations in TRPM6, which expresses a protein involved with active intestinal Mg transport.

Renal Disorders

Excessive excretion of Mg into the urine may be the basis of Mg depletion (Table III). Renal Mg reabsorption is proportional to tubular fluid flow as well as to sodium and calcium excretion. Therefore, chronic parenteral fluid therapy, particularly with saline, and volume expansion states such as primary aldosteronism, and hypercalciuric states may result in Mg depletion (Massry *et al.*, 1967; Coburn, 1970; McNair *et al*., 1982). Hypercalcemia have been shown to decrease renal Mg reabsorption probably mediated by calcium binding to the calcium-sensing receptor in the thick ascending limb of Henle and decreasing transepithelial voltage and is probably the cause of renal Mg wasting and hypomagnesemia observed in many hypercalcemic states (Brown and Hebert, 1995; Cole and Quamme, 2000). Osmotic diuresis because of glucosuria will result in urinary Mg wasting (McNair *et al*., 1982).

Many pharmaceutical drugs may cause renal Mg wasting and Mg depletion. The major site of renal Mg reabsorption is at the loop of Henle, therefore diuretics such as furosemide and ethacrynic acid have been shown to result in marked Mg wasting (Quamme, 1981). Aminoglycosides have been shown to cause a reversible renal lesion that results in hypermagnesuria and hypomagnesemia (Zaloga *et al*., 1984; Kes and Reiner, 1990). Similarly, amphotericin B therapy has been reported to result in renal Mg wasting. Other renal Mg-wasting agents include cisplatin, cyclosporin, tacrolimus, and pentamidine (Meyer and Madias, 1994). A rising blood alcohol level has been associated with hypermagnesuria and is one factor contributing to Mg depletion in chronic alcoholism. Metabolic acidosis because of diabetic ketoacidosis, starvation, or alcoholism may also result in renal Mg wasting (Lau *et al*., 1987).

Several renal Mg wasting disorders have been described that may be genetic or sporadic as discussed earlier in renal Mg metabolism (Konrad *et al.*, 2004; Meij *et al*., 2002). Gitelman's syndrome (familial hypokalemia-hypomagnesemia syndrome) is an autosomal recessive disorder owing to a genetic defect of the thiazide-sensitive NaCl cotransporter gene on chromosome 16 (Simon *et al*., 1996). Recently, mutations in the tight-junction gene Claudin 19 have been associated with renal Mg wasting and renal failure and ocular abnormalities (Konrad *et al.*, 2006). Mutations of other cation channels, TMPR6, TMPR7, and TMPR9, have also recently been associated with renal Mg wasting (Schmitz *et al*., 2003; Schlingmann *et al.,* 2002; Schlingmann *et al.*, 2004). Other undefined genetic defects also exist (Kantorovich *et al*., 2002).

Hypomagnesemia may accompany a number of other disorders (for review see Rude, 1996). Phosphate depletion has been shown experimentally to result in urinary Mg wasting and hypomagnesemia. Hypomagnesemia may also accompany the "hungry bone" syndrome, a phase of rapid bone mineral accretion in subjects with hyperparathyroidism or hyperthyroidism following surgical treatment. Finally, chronic renal tubular, glomerular, or interstitial diseases may be associated with renal Mg wasting. Rarely, excessive lactation may result in hypomagnesemia.

Diabetes Mellitus

Special consideration must be given to diabetes mellitus. It is the most common disorder associated with magnesium deficiency (McNair *et al*., 1982; Rude, 1996; Song *et al.,* 2004; Lopez-Ridaura *et al*., 2004). It is generally thought that the mechanism for magnesium depletion in diabetics is owing to renal magnesium wasting secondary to osmotic diuresis generated by hyperglycosuria. Dietary magnesium intake, however, falls below the RDA in diabetics. Magnesium deficiency has been reported to result in impaired insulin secretion as well as insulin resistance (Song *et al.,* 2004; Lopez-Ridaura *et al*., 2004). The mechanism is unclear but may be because of abnormal glucose metabolism as magnesium is a cofactor in several enzymes in this cycle. In addition, magnesium depletion may decrease tyrosine kinase activity at the insulin receptor and magnesium may influence insulin secretion by the beta cell. Diabetics given magnesium therapy appear to have improved diabetes control. Recently, two studies have reported that the incidence of type-2 diabetes is significantly greater in people on a lower magnesium diet (Song *et al.,* 2004; Lopez-Ridaura *et al*., 2004). Magnesium status should therefore be assessed in patients with diabetes

mellitus as a vicious cycle may occur; diabetes out of control leading to magnesium loss and the subsequent magnesium deficiency resulting in impaired insulin secretion and action and worsening diabetes control.

ROLE OF MAGNESIUM IN BONE AND MINERAL HOMEOSTASIS

Because of the prevalence of Mg in both cells and bone, as well as its critical need for numerous biological processes in the body, it is not surprising that this mineral plays a profound role in bone and mineral homeostasis. Our understanding of the role of magnesium has developed principally through observations of the effect of Mg depletion in both humans and animals. Mg influences the formation and/or secretion of hormones that regulate skeletal homeostasis and the effect of these hormones on bone. Mg can also directly affect bone cell function as well as influence hydroxyapatite crystal formation and growth. These areas are discussed later and are outlined in Table IV.

Parathyroid Hormone Secretion

Calcium is the major regulator of PTH secretion. Mg, however, modulates PTH secretion in a manner similar to calcium. A number of *in vitro* and *in vivo* studies have demonstrated that acute elevations of Mg inhibit PTH secretion, whereas an acute reduction stimulates PTH secretion (Sherwood *et al.*, 1970; Cholst *et al.,* 1984; Ferment *et al.,* 1987; Toffaletti *et al.,* 1991, Rude, 1994; Rude and Shils, 2006). These data suggest that Mg could be a physiologic regulator of PTH secretion. Although early investigations indicated that Mg was equipotent to calcium in its effect on parathyroid gland function (Sherwood *et al.,* 1970), more recent studies demonstrated that Mg has approximately 30 to 50% the effect of calcium on either stimulating or inhibiting PTH secretion (Wallace and Scarpa, 1982; Ferment *et al.,* 1987; Toffaletti *et al.,* 1991; Rude, 1994). The finding in humans that a 5% (0.03 mM) decrease in serum ultrafilterable Mg did not result in any detectable change in intact serum PTH concentration while a 5.5% (.07 mM) decrease in ionized calcium resulted in a 400% increase in serum PTH supports this concept (Toffaletti *et al.,* 1991).

The inhibitory effects of Mg on PTH secretion may be dependent on the extracellular calcium concentration (Brown *et al.,* 1984). At physiological calcium and Mg concentrations, these divalent cations were found to be relatively equipotent at inhibiting PTH secretion from dispersed bovine parathyroid cells (Brown *et al.,* 1984). At a low calcium concentration (0.5 mM), however, a threefold greater Mg concentration was required for similar PTH inhibition. Altering the Mg concentration did not diminish the ability of calcium to inhibit PTH secretion. Differences

TABLE IV Effect of Mg Depletion on Bone and Mineral Metabolism

	Effect	Potential mechanism(s)
1.	Decreased PTH secretion	Altered phosphoinositol activity Decreased adenylate cyclase activity
2.	Decreased PTH action	Decreased adenylate cyclase activity Altered phosphoinositol activity
3.	Decreased serum $1,25(OH)_2D$	Decreased serum PTH Renal PTH resistance (decrease in 1α-hydroxylase activity)
4.	Impaired vitamin D metabolism and action	Decreased $1,25(OH)_2D$ formation Decreased intestinal epithelial cell and osteoblast activity Skeletal resistance to vitamin D
5.	Impaired bone growth/osteoporosis	Decreased PTH and $1,25(OH)_2D$ formation and action Decreased effect of insulin and IGF-1 Direct effect to decrease bone cell activity
6.	Increased bone resorption/osteoporosis	Increased cytokine production Increased substance P, TNFα, IL-1, IL-6 Increased RANKL, decreased OPG
7.	Altered hydroxyapatite crystal formation	Impaired calcium binding to hydroxyapatite Directly alter crystal growth

have also been noted in the effect of Mg and calcium on the biosynthesis of PTH *in vitro*. Changes in calcium over the range of 0 to 3.0 mM resulted in increased PTH synthesis (Hamilton *et al.,* 1971; Lee and Roth, 1975), whereas changes in Mg over the range of 0 to 1.7 mM had no effect.

The effect of Mg on PTH secretion appears to act through the Ca^{2+}-sensing receptor, which mediates the control of extracellular calcium on PTH secretion (Brown *et al.,* 1993). Mg^{2+} was shown to bind to this receptor, but with much less efficiency than Ca^{2+} (Hebert, 1996). Mg may also regulate calcium transport into the cell through other ion channels (Miki *et al.,* 1997). Acute changes in the serum Mg concentration may therefore modulate PTH secretion and should be considered in the evaluation of the determination of serum PTH concentrations.

Mg Depletion and Parathyroid Gland Function

While acute changes in extracellular Mg concentrations will influence PTH secretion qualitatively similar to calcium, it is clear that Mg deficiency markedly perturbs mineral homeostasis (Rude *et al.,* 1976; Rude, 1994; Rude and Shils, 2006). Hypocalcemia is a prominent manifestation of Mg deficiency in humans (Rude *et al.,* 1976; Rude, 1994; Rude and Shils, 2006), as well as in most other species (Shils, 1980; Anast and Forte, 1983; Rude and Shils, 2006). In humans, Mg deficiency must become moderate to severe before symptomatic hypocalcemia develops. A positive correlation has been found between serum Mg and calcium concentrations in hypocalcemic hypomagnesemic patients (Rude *et al.,* 1976). Mg therapy alone restored serum calcium concentrations to normal in these patients within days (Rude *et al.,* 1976). Calcium and/or vitamin D therapy will not correct the hypocalcemia (Rude *et al.,* 1976; Rude, 1994). Even mild degrees of Mg depletion, however, may result in a significant fall in the serum calcium concentration, as demonstrated in experimental human Mg depletion (Fatemi *et al.,* 1991). One major factor resulting in the fall in serum calcium is impaired parathyroid gland function. Low Mg in the media of parathyroid cell cultures impairs PTH release in response to a low media calcium concentration (Targovnik *et al.,* 1971). Determination of serum PTH concentrations in hypocalcemic hypomagnesemic patients has shown heterogeneous results. The majority of patients have low or normal serum PTH levels (Anast *et al.,* 1972; Suh *et al.,* 1973; Chase and Slatopolsky, 1974; Rude *et al.,* 1976; Rude *et al.,* 1978). Normal serum PTH concentrations are thought to be inappropriately low in the presence of hypocalcemia. Therefore, a state of hypoparathyroidism exists in most hypocalcemic Mg-deficient patients. Some patients, however, have elevated levels of PTH in the serum (Rude *et al.,* 1976, 1978; Allgrove *et al.,* 1984). The administration of Mg will result in an immediate rise in the serum PTH concentration regardless of the basal PTH level (Anast *et al.,* 1972; Rude *et al.,* 1976, Rude *et al.,* 1978). As shown in (Fig. 7), 10 mEq of Mg administered intravenously over 1 minute caused an immediate marked rise in serum PTH in patients with low, normal, or elevated basal serum PTH concentrations. This is distinctly different from the effect of an Mg injection in normal subjects where, as discussed earlier, Mg will cause an inhibition of PTH secretion (Cholst *et al.,* 1984; Fatemi *et al.,* 1991). The serum PTH concentration will gradually fall to normal within several days of therapy with return of the serum calcium concentration to normal (Anast *et al.,* 1972; Rude *et al.,* 1976; Rude *et al.,* 1978). The impairment in PTH secretion appears to occur early in Mg depletion. Normal human subjects placed experimentally on a low Mg diet for only 3 weeks showed similar but not as marked changes in the serum PTH concentrations (Fatemi *et al.,* 1991) in which there was a fall in both serum calcium and PTH concentrations in 20 of 26 subjects at the end of the dietary Mg deprivation period. The administration of intravenous Mg at the end of this Mg depletion period resulted in a significant rise in the serum PTH concentration qualitatively similar to that observed in hypocalcemic

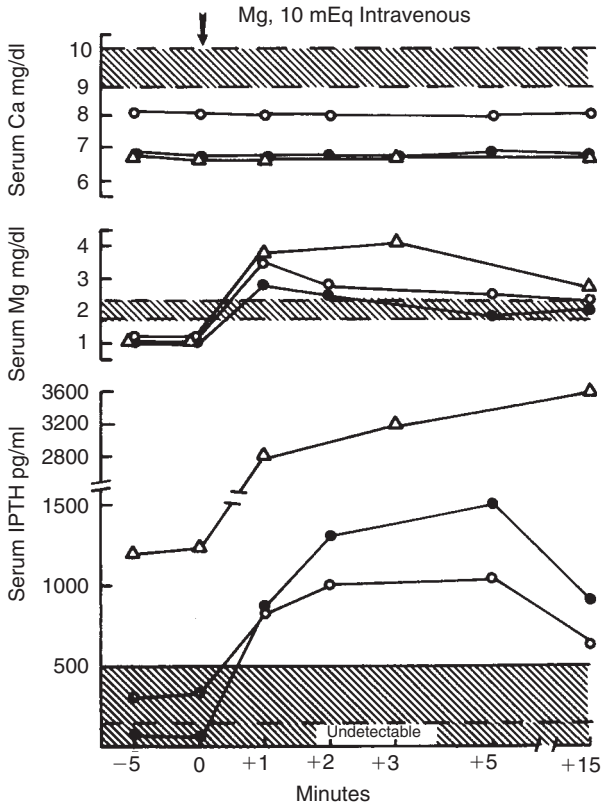

FIGURE 7 The effect of an IV injection of 10 mEq Mg on serum concentrations of calcium, magnesium, and immunoreactive parathyroid hormone (IPTH) in hypocalcemic magnesium-deficient patients with undetectable (•), normal (O), or elevated (Δ) levels of IPTH. Shaded areas represent the range of normal of each assay. The broken line for the IPTH assay represents the level of detectability. The magnesium injection resulted in a marked rise in PTH secretion within 1 minute in all three patients (Rude *et al.,* 1978).

Mg-depleted patients shown in Fig. 7, whereas a similar Mg injection suppressed PTH secretion prior to the low Mg diet. In this study, as with hypocalcemia hypomagnesemic patients, some subjects had elevations in the serum PTH concentration. The heterogeneous serum PTH values may be explained on the severity of Mg depletion. As the serum Mg concentration falls, the parathyroid gland will react normally with an increase in PTH secretion. As intracellular Mg depletion develops, however, the ability of the parathyroid to secrete PTH is impaired, resulting in a fall in serum PTH levels with a resultant fall in the serum calcium concentration. This concept is supported by the observation that the change in serum PTH in experimental human Mg depletion is correlated positively with the fall in red blood cell intracellular-free Mg^{2+} (Fatemi *et al.,* 1991). A slight fall in red blood cell Mg^{2+} resulted in an increase in PTH. However, a greater decrease in red blood cell Mg^{2+} correlated with a progressive fall in serum PTH concentrations.

It is conceivable that either PTH synthesis and/or PTH secretion may be affected. However, as the *in vitro* biosynthesis of PTH requires approximately 45 minutes (Hamilton *et al.,* 1971), the immediate rise in PTH following the administration of intravenous magnesium to Mg-deficient patients strongly suggests that the defect is in PTH secretion.

Mg Depletion and Parathyroid Hormone Action

The previous discussion strongly supports the notion that impairment in the secretion of PTH in Mg deficiency is a major contributing factor in the hypocalcemia. However, the presence of normal or elevated serum concentrations of PTH in the face of hypocalcemia (Rude *et al.,* 1976; Rude *et al.,* 1978; Rude, 1994) suggests that there may also be end-organ resistance to PTH action. In hypocalcemic Mg-deficient patients treated with Mg, the serum calcium concentration does not rise appreciably within the first 24 hours, despite elevated serum PTH concentrations (Rude *et al.,* 1976; Rude, 1994), which also suggests skeletal resistance to PTH because exogenous PTH administered to hypoparathyroid patients causes a rise in the serum calcium within 24 hours (Bethune *et al.,* 1968). Clinical studies have reported resistance to exogenous PTH in hypocalcemic Mg-deficient patients (Estep *et al.,* 1969; Woodard *et al.,* 1972; Rude *et al.,* 1976; Rude, 1994; Mihara *et al.,* 1995; Klein and Herndon, 1998; Sahota *et al.,* 2006). In one study, parathyroid hormone did not result in elevation in the serum calcium concentration or urinary hydroxyproline excretion in hypocalcemic hypomagnesemic patients as shown in (Fig. 8) (Estep *et al.,* 1969). Following Mg repletion, however, a clear response to PTH was observed. PTH has also been shown to have a reduced calcemic effect in Mg-deficient animals (MacManus *et al.,* 1971; Levi *et al.,* 1974; Forbes and Parker, 1980). The ability of PTH to resorb bone *in vitro* is also diminished greatly in the presence of low media Mg (Raisz and Niemann, 1969). In one study of isolated perfused femur in the dog, the ability of PTH to simulate an increase in the venous cyclic AMP was impaired during perfusion with low Mg fluid, suggesting skeletal PTH resistance (Freitag *et al.,* 1979). Not all studies have shown skeletal resistance to PTH, however (Salet *et al.,* 1966; Stromme *et al.,* 1969; Suh *et al.,* 1973, Chase and Slatopolsky, 1974). It appears likely that skeletal PTH resistance may be observed in patients with more severe degrees of Mg depletion. Patients in whom a normal calcemic response to PTH was demonstrated were in subjects who had been on recent Mg therapy (Salet *et al.,* 1966; Stromme *et al.,* 1969; Suh *et al.,* 1973, Chase and Slatopolsky, 1974). Patients who have been found to be resistant to PTH have, in general, not had prior Mg administration (Estep *et al.,* 1969; Woodard *et al.,* 1972; Rude

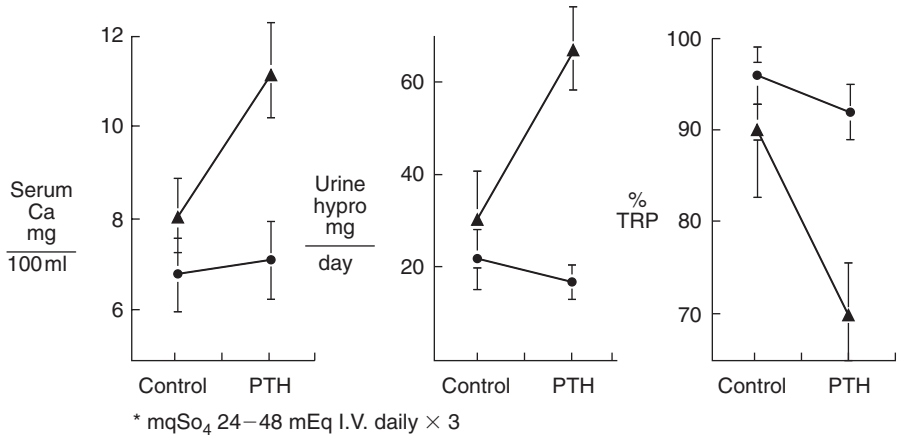

FIGURE 8 Mean and standard deviations of serum calcium concentration and urinary hydroxyproline and phosphate excretion in hypocalcemic magnesium-deficient patients before (•) and after (▲) 3 days of parenteral magnesium therapy (Estep *et al.,* 1969).

et al., 1976; Rude, 1994). Consistent with this notion is that in the Mg-depleted rat, normal responses to PTH were observed when the serum Mg concentration was 0.95 mg/dl (Hahn *et al.,* 1972); however, in another study, rats with a mean serum Mg of 0.46 mg/dl were refractory to PTH (MacManus *et al.,* 1971). In addition, a longitudinal study of Mg deficiency in dogs demonstrated a progressive decline in responsiveness to PTH with increasing degrees of Mg depletion (Levi *et al.,* 1974).

Calcium release from the skeleton also appears to be dependent on physicochemical processes as well as cellular activity (Pak and Diller, 1969; MacManus and Heaton, 1970). Low Mg will result in a decrease in calcium release from bone (Pak and Diller, 1969; MacManus and Heaton, 1970) and may be another mechanism for hypocalcemia in Mg deficiency.

The renal response to PTH has also been assessed by determining the urinary excretion of cyclic AMP and/or phosphate (Figs. 8 and 9) in response to exogenous PTH. In some patients, a normal effect of PTH on urinary phosphate and cyclic AMP excretion has been noted (Anast *et al.,* 1972; Suh *et al.,* 1973; Chase and Slatopolsky, 1974). In general, these were the same subjects in which a normal calcemic effect was also seen (Anast *et al.,* 1972; Suh *et al.,* 1973; Chase and Slatopolsky, 1974). In other studies, with more severely Mg-depleted patients, an impaired response to PTH has been observed (Estep *et al.,* 1969; Rude *et al.,* 1976; Medalle and Waterhouse, 1973; Rude, 1994; Mihara *et al.*, 1995). A decrease in urinary cyclic AMP excretion in response to PTH has also been described in the Mg-deficient dog and rat (Levi *et al.,* 1974; Forbes and Parker, 1980).

Mechanism of Impaired Mineral Homeostasis in Mg Depletion

The mechanism for impaired PTH secretion and action in Mg deficiency remains unclear. It has been suggested that there may be a defect in the second messenger systems in Mg depletion. PTH is thought to exert its biologic effects through the intermediary action of cyclic AMP (Bitensky *et al.,* 1973; Neer, 1995). Adenylate cyclase has been universally found to require Mg for cyclic AMP generation, both as a component of the substrate (Mg-ATP) and as an obligatory activator of enzyme activity (Northup *et al.,* 1982). There appears to be two Mg^{2+}-binding sites within the adenylate cyclase complex: one resides on the catalytic subunit and the other on the guanine nucleotide regulatory protein, Ns (Cech *et al.,* 1980; Maguire, 1984). The requisite role that Mg^{2+} plays in adenylate cyclase function suggests that factors that would limit the availability of Mg^{2+} to this enzyme could have significant effects on the cyclic nucleotide metabolism of a cell and hence overall cellular function. It is clear that some patients with severe Mg deficiency have a reduced urinary excretion of cyclic AMP in response to exogenously administered PTH (Rude *et al.,* 1976). In addition, PTH was shown to have a blunted effect in causing a rise in cyclic AMP from isolated perfused tibiae in Mg-deficient dogs (Freitag *et al.,* 1979). These observations correspond well with the impaired calcemic and phosphaturic effects of PTH in Mg-deficient patients and animals as discussed earlier.

While Mg^{2+} is stimulatory for adenylate cyclase, Ca^{2+} may inhibit or activate enzyme activity (Sunahara *et al.,* 1996). Nine isoforms of adenylate cyclase have been identified whose activities are modulated by both Mg^{2+} and Ca^{2+} (Sunahara *et al.,* 1996). In plasma membranes from parathyroid, renal cortex, and bone cells, Ca^{2+} will competitively inhibit Mg^{2+}-activated adenylate cyclase activity (Rude, 1983; Rude, 1985; Oldham *et al.,* 1984). In parathyroid plasma membranes, at a Mg^{2+} concentration of 4 mM, Ca^{2+} was found to inhibit adenylate cyclase in a bimodal pattern described in terms of two calcium inhibition constants with K_i values of 1–2 and 200–400 μM (Oldham *et al.,* 1984). At a lower Mg^{2+} concentration (0.5 mM) the only adenylate cyclase activity expressed was that inhibitable by the high-affinity Ca^{2+}-binding site. With increasing Mg concentrations, the fraction of total adenylate cyclase activity subject to high-affinity calcium inhibition became progressively less. Thus, the ambient Mg^{2+} concentrations can markedly affect the susceptibility of this enzyme to the inhibitory effects of Ca^{2+}. Total intracellular calcium has been observed to rise during Mg depletion (George and Heaton, 1975; Ryan and Ryan, 1979). Mg is not only important for the operation of Mg^{2+}, Ca^{2+}-dependent ATPase, but may also be countertransported during the uptake and release of calcium through calcium channels (Romani and Scarpa, 1992; Romani, 2006). The combination of higher intracellular Ca^{2+} and increased sensitivity

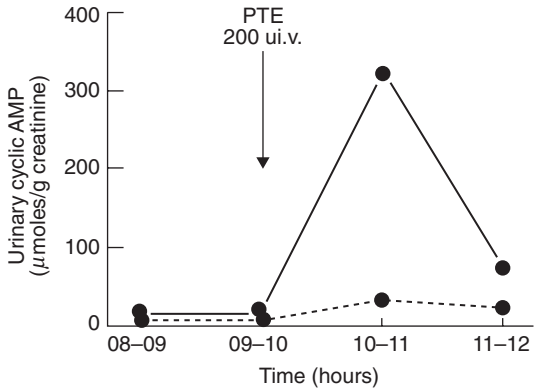

FIGURE 9 The effect of an IV injection of 200 units of parathyroid extract on the excretion of urinary cyclic AMP in a magnesium-deficient patient before (• --- •) and after (• — •) 4 days of magnesium therapy. Urine was collected for four consecutive 1-hour periods, two before and two after the PTE injection. Although Mg-deficient, the patient had a minimal rise in urinary cyclic AMP in response to PTH, but following Mg therapy the response was normal (Rude *et al.,* 1976).

to Ca^{2+} inhibition because of Mg depletion could explain the defective PTH secretion in Mg deficiency. An increase in the release of intracellular Ca^{2+} via the phosphoinositol system is also possible, as discussed later. A similar relationship between Mg^{2+} and Ca^{2+} was described for adenylate cyclase obtained from bone (Rude, 1985). Ca^{2+} caused a competitive inhibition of Mg^{2+}-activated skeletal adenylate cyclase with a high-affinity Ca^{2+}-binding site with a K_iCa of 1–2 μM. Lowering the Mg^{2+} concentration increased overall Ca^{2+} inhibition. Thus, a fall in the intracellular Mg^{2+} concentration would render the adenylate cyclase enzyme more susceptible to inhibition by the prevailing intracellular Ca^{2+} concentrations and may be a mechanism by which both PTH secretion and PTH end-organ action are compared in Mg deficiency.

Adenylate cyclase is a widely distributed enzyme in the body, and if the hypothesis just given were true, the secretion and action of other hormones mediated by adenylate cyclase might also exhibit impaired activity in Mg deficiency. This has not been found to be true, as the actions of ACTH, TRH, GnRH, and glucagon are normal in Mg depletion (Cohan *et al.,* 1982). Prior investigations have suggested that Mg affinity for adenylate cyclase is higher (lower K_aMg) in liver, adrenal, and pituitary than in parathyroid (for reviews, see Rude and Oldham, 1985; Rude, 1994). In one study, investigation of K_aMg and K_iCa in tissues from one species (guinea pig) demonstrated that under agonist stimulation, the K_aMg from liver is less than thyroid less than kidney, which equals bone, and the K_iCa^{2+} for liver greater than renal greater than kidney also equals bone (Rude and Oldham, 1985). These data suggest that adenylate cyclase regulation by divalent cations varies from tissue to tissue and may explain the greater propensity for disturbed mineral homeostasis in Mg deficiency.

Although cyclic AMP is an important mediator of PTH action, current studies do not suggest an important role in mediating Ca^{2+}-regulated PTH secretion (Brown, 1991; Dunlay and Hruska, 1990). PTH has been shown to activate the phospholipase C second messenger system (Dunlay and Hruska, 1990). PTH activation of phospholipase C leads to the hydrolysis of phosphatidylinositol 4,5-bisphosphate to inositol-1,4,5-triphosphate (IP_3) and diacylglycerol. IP_3 binds to specific receptors on intracellular organelles (endoplasmic reticulum, calciosomes), leading to an acute transient rise in cytosolic Ca^{2+} with a subsequent activation of calmodulin-dependent protein kinases. Diacylglycerol activates protein kinase C. Mg depletion could perturb this system via several mechanisms. First, an Mg^{2+}-dependent guanine nucleotide-regulating protein is also involved in the activation of phospholipase C (Babich *et al.,* 1989; Litosch, 1991). Mg^{2+} has also been shown to be a noncompetitive inhibitor of IP_3-induced Ca^{2+} release (Volpe *et al.,* 1990). A reduction of Mg^{2+} from 300 to 30 μM increased Ca^{2+} release in response to IP_3 by two- to threefold in mitochondrial membranes obtained from canine cerebellum (Volpe *et al.,* 1990). The Mg concentration required for a half-maximal inhibition of IP_3-induced Ca^{2+} release was 70 μU. In these same studies, Mg^{2+} was also found to inhibit IP_3 binding to its receptor. Mg, at a concentration of 500 μM, decreased maximal IP_3 binding threefold (IC_{50} 200 μM) (Volpe *et al.,* 1990). These Mg^{2+} concentrations are well within the estimated physiologic intracellular range (200–500 μ*M*) and therefore Mg^{2+} may be an important physiological regulator of the phospholipase C second messenger system. These effects may be related to Mg deficiency-induced activation of the α-subunit of the Ca-sensing receptor (Quitterer *et al.,* 2001; Vetter and Lohse, 2002).

The effect of Mg depletion on cellular function in terms of the second messenger systems is most complex, potentially involving substrate availability, G protein activity, release and sensitivity to intracellular Ca^{2+}, and phospholipid metabolism.

Mg Depletion and Vitamin D Metabolism and Action

Mg may also be important in vitamin D metabolism and/or action. Patients with hypoparathyroidism, malabsorption syndromes, and rickets have been reported to be resistant to therapeutic doses of vitamin D until Mg was administered simultaneously (for review, see Rude, 1994). Patients with hypocalcemia and Mg deficiency have also been reported to be resistant to pharmacological doses of vitamin D (Medalle *et al.,* 1976; Leicht *et al.,* 1990), 1α hydroxyvitamin D (Ralston *et al.,* 1983; Selby *et al.,* 1984) and 1,25-dihydroxyvitamin D (Graber and Schulman, 1986). Similarly, an impaired calcemic response to vitamin D has been found in Mg-deficient rats (Lifshitz *et al.,* 1967), lambs (McAleese and Forbes, 1959), and calves (Smith, 1958).

The exact nature of altered vitamin D metabolism and/or action in Mg deficiency is unclear. Intestinal calcium transport in animal models of Mg deficiency has been found to be reduced in some (Higuchi and Lukert, 1974) but not all (Coburn *et al.,* 1975) studies. Calcium malabsorption was associated with low serum levels of 25-hydroxyvitamin D in one study (Lifshitz *et al.,* 1967), but not in another (Coburn *et al.,* 1975), suggesting that Mg deficiency may impair intestinal calcium absorption by more than one mechanism. Patients with Mg deficiency and hypocalcemia frequently have low serum concentrations of 25-hydroxyvitamin D (Rude *et al.,* 1985; Fuss *et al.,* 1989) and therefore nutritional vitamin D deficiency may be one factor. Therapy with vitamin D, however, results in high serum levels of 25-hydroxyvitamin D without correction of the hypocalcemia (Medalle *et al.,* 1976), suggesting that the vitamin D nutrition is not the major reason. In addition, conversion of radiolabeled vitamin D to 25-hydroxyvitamin D was found to be normal in three

Mg-deficient patients (Lukert, 1980). Serum concentrations of 1,25-dihydroxyvitamin D have also been found to be low or low normal in most hypocalcemic Mg-deficient patients (Rude *et al.,* 1985; Fuss *et al.,* 1989; Leicht *et al.,* 1992; Rude and Shils, 2006). Mg-deficient diabetic children, when given a low calcium diet, did not exhibit the expected normal rise in serum 1,25-dihydroxyvitamin D or PTH (Saggese *et al.,* 1988); the response returned to normal following Mg therapy (Saggese *et al.,* 1991). Because PTH is a major trophic for 1,25-dihydroxyvitamin D formation, the low serum PTH concentrations could explain the low 1,25-dihydroxyvitamin D levels. In support of this is the finding that some hypocalcemic Mg-deficient patients treated with Mg have a rise in serum 1,25-dihydroxyvitamin D to high normal or to frankly elevated levels, as shown in (Fig. 10) (Rude *et al.,* 1985). Most patients, however, do not have a significant rise within 1 week after institution of Mg therapy, despite a rise in serum PTH and normalization of the serum calcium concentration (Fig. 10) (Rude *et al.,* 1985). These data suggest that Mg deficiency in humans also impairs the ability of the kidney to synthesize 1,25-dihydroxyvitamin D. This is supported by the observation that the ability of exogenous administration of 1–34 human PTH to normal subjects after 3 weeks of experimental Mg depletion resulted in a significantly lower rise in serum 1,25-dihydroxyvitamin D concentrations than before institution of the diet (Fatemi *et al.,* 1991). It appears, therefore, that the renal synthesis of 1,25-dihydroxyvitamin D is sensitive to Mg depletion. Although Mg is known to support 25-hydroxy-1α-hydroxylase *in vitro* (Fisco and Traba, 1992), the exact Mg requirement for this enzymatic process is not known. Bone-specific binding sites for 1,2-dihydroxyvitamin D have also been described to be reduced in Mg deficiency (Risco and Traba, 2004).

The association of Mg deficiency with impaired vitamin D metabolism and action therefore may be because of several factors, including vitamin D deficiency (Rude *et al.,* 1985; Carpenter, 1988; Fuss *et al.,* 1989; Leicht and Biro, 1992) and a decrease in PTH secretion (Anast *et al.,* 1972; Suh *et al.,* 1973; Chase and Slatopolsky, 1974; Rude *et al.,* 1976; Rude *et al.,* 1978), as well as a direct effect of Mg depletion on the ability of the kidney to synthesize 1,25-dihydroxyvitamin D (Rude *et al.,* 1985; Fuss *et al.,* 1989; Fatemi *et al.,* 1991). Osteoporotic patients with a blunted response to PTH exhibit Mg deficiency (Sahota *et al.,* 2006). In addition, Mg deficiency may directly impair intestinal calcium absorption (Higuchi and Lukert, 1974; Rude *et al.,* 1976; Rude *et al.,* 1985). Skeletal resistance to vitamin D and its metabolites may also play an important role (Lifshitz *et al.,* 1967; Ralston *et al.,* 1983; Selby *et al.,* 1984; Graber and Schulman, 1986). It is clear, however, that the restoration of normal serum 1,25-dihydroxyvitamin D concentrations is not required for normalization of the serum calcium level (Fig. 9). Most Mg-deficient patients who receive Mg therapy exhibit an immediate rise in PTH, followed by normalization of the serum calcium prior to any change in serum 1,25-dihydroxyvitamin D concentrations (Rude *et al.,* 1985; Fuss *et al.,* 1989). An overall view of the effect of Mg depletion on calcium metabolism is shown in Fig. 11.

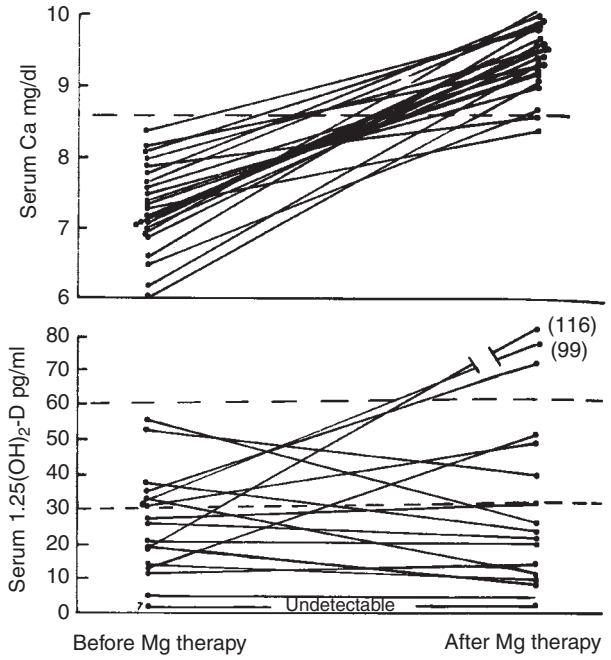

FIGURE 10 Serum concentrations of calcium and 1,25-diydroxyvitamin D in hypocalcemic magnesium-deficient patients before and after 5–8 days of parenteral magnesium therapy. The broken line represents the upper and lower limits of normal for serum 1,25-dihydroxyvitamin D and the lower limit of normal for the serum calcium (Rude *et al.,* 1985).

MAGNESIUM DEPLETION: SKELETAL GROWTH AND OSTEOPOROSIS

Women with postmenopausal osteoporosis have decreased nutrition markers, suggesting that osteoporosis is associated with nutritional deficiencies (Rico *et al.,* 1993; Ames, 2006). A low calcium intake is one of these nutritional factors (Rico *et al.,* 1993) and predicts bone mineral density and fracture rate (Dawson-Hughes *et al.,* 1990; Chapuy *et al.,* 1992). A large segment of our population also has low dietary Mg intake (Morgan *et al.,* 1985; Marier, 1986; Cleveland *et al.,* 1994). Mg deficiency, when severe, will disturb calcium homeostasis markedly, resulting in impaired PTH secretion and PTH end organ resistance, leading to hypocalcemia (Rude, 1998). Mg exists in macronutrient quantities in bone, and long-term, mild-to-moderate dietary Mg deficiency has been implicated as a risk factor for osteoporosis (Sojka and Weaver, 1995; Cohen and Kitzes, 1981).

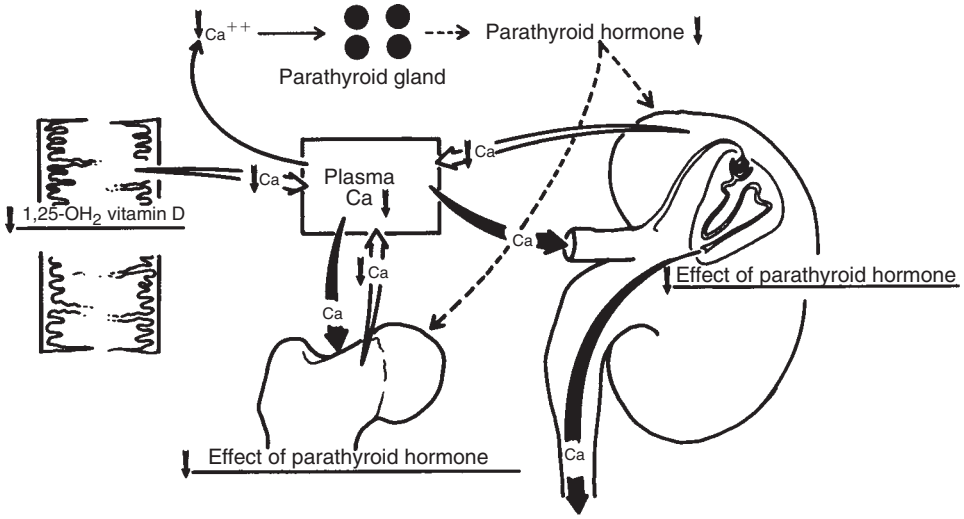

FIGURE 11 Disturbance of calcium metabolism during magnesium deficiency. Hypocalcemia is caused by a decrease in PTH secretion, as well as renal and skeletal resistance to the action of PTH. Low serum concentrations of 1,25-dihydroxyvitamin D may result in reduced intestinal calcium absorption (Rude and Oldham, 1990).

Epidemiological Studies

Epidemiological studies have provided a major link associating dietary Mg inadequacy to osteoporosis. One cross-sectional study assessed the effect of dietary nutrients on appendicular (radius, ulna, and heel) bone mineral density (BMD) in a large group of Japanese Americans living in Hawaii (Yano *et al.,* 1985). In 1,208 males (ages 61–81), whose mean Mg intake was 238±111 mg/day, no correlation of Mg intake with BMD was observed at any site. In a subgroup of 259 of these subjects who took Mg supplements, however (mean Mg intake of 381 mg/day), BMD was correlated positively with Mg intake at one or more skeletal sites. In 912 females (ages 43–80) whose Mg intake was 191±36 mg/day, a positive correlation with BMD was also observed. In contrast to males, no correlation with BMD was found in females who took Mg supplements (total Mg intake of 321 mg/day). In a smaller study of women ages 35–65 (17 premenopausal, mean Mg intake 243±44 mg/day; 67 postmenopausal, mean Mg intake 249±68 mg/day) in which BMD was measured in the distal forearm, no cross-sectional correlation was observed with Mg intake in either group (Freudenheim *et al.,* 1986). Longitudinal observation over 4 years, however, demonstrated that loss of bone mass was related inversely to Mg intake in premenopausal women ($p < 0.05$) and had a similar trend in the postmenopausal group ($p < 0.085$). In another cross-sectional study, a positive correlation of BMD of the forearm (but not femur or spine) was found in a larger group of 89 premenopausal women (age 37.8±0.8; Mg intake of 243±9 mg/day), but no similar correlation was found in 71 recently menopausal women ages 58.9±0.9 (Mg intake of 253±11 mg/day) (Angus *et al.,* 1988). In contrast, a study of 194 older postmenopausal women (ages 69–97; mean Mg intake of 288 mg/day) demonstrated a significant positive correlation with BMD of the forearm (Tranquilli *et al.,* 1994).

Other studies have concentrated on BMD of the axial skeleton. Sixty-six premenopausal women (ages 28–39) whose Mg intake was 289±73 mg/day had a significant relationship between dietary Mg intake and rate of change of BMD of the lumbar spine and total body calcium over a 1-year period (Houtkooper *et al.,* 1995). A cross-sectional study that combined 175 premenopausal and postmenopausal women ages 28–74 (mean Mg intake was 262±70 mg/day) found no correlation with BMD at the lumbar spine, femoral neck, or total body calcium (Michaelsson *et al.,* 1995). In a study of 994 premenopausal women ages 45–49, whose Mg intake was 311±85 mg/day, New *et al.* (1997) found a significant correlation of BMD of the lumbar spine with Mg intake. A significant difference was also observed in lumbar spine BMD between the highest and the lowest quartiles of dietary Mg intake. A report by this same group in a study of 65 pre- and postmenopausal women ages 45–55 again found higher bone mass of the forearm (but not femoral neck or hip) in subjects consuming a Mg intake of 326±90 mg/day (New *et al.,* 2000). Women with a high childhood intake of fruits (Mg and potassium) did have higher femoral neck BMD than those on a lower fruit intake, however. Another cross-sectional study assessed Mg intake in older males and females (ages 69–97) (345 males and 562 females), as well as a 2-year longitudinal study of a subset of these subjects (229 males and 399 females) (Tucker *et al.,* 1999). In the cross-sectional analysis in males, Mg intake (300±110 mg/day) was correlated

with BMD of the radius and hip. In the 4-year longitudinal study of these subjects, a positive inverse relationship between bone loss of the hip and Mg intake was observed. A positive cross-sectional correlation of BMD of the hip was also observed in females (Mg intake of 288±106 mg/day), but not in the longitudinal assessment. Dietary Mg intake in a large population of non-Hispanic white males and females from the NHANES III database was also found by multiple regression analysis to predict BMD at several sites in the proximal femur (Carpenter *et al.,* 2000). Most recently, Mg intake was significantly correlated with whole body and hip BMD in elderly white females and males (Ryder *et al*., 2005).

In a study of younger individuals, the effect of dietary Mg intake of preadolescent girls (ages 9–11) on bone mass/quality in these young women was evaluated at age 18–19 (Wang *et al.,* 1999). Ultrasound determination of bone mass of the calcaneus in 35 African American women (Mg intake 237±83 mg/day) and in 26 Caucasian women (Mg intake 240±61 mg/day) was performed. Mg intake was related positively to quantitative ultrasound properties of bone, suggesting that this nutrient was important in skeletal growth and development. Bounds *et al*. (2005) reported that bone mineral content was significantly related to Mg intake at age 8, including longitudinal intake from age 2 to 8.

In summary, these epidemiological studies link dietary Mg intake to bone mass. Exceptions appear to include women in the early postmenopausal period in which the effect of acute sex steroid deficiency may mask the effect of dietary factors such as Mg. In addition, diets deplete in Mg are usually deficient in other nutrients, which affect bone mass as well. Therefore, further investigations are needed to provide a firm relationship of dietary Mg inadequacy with osteoporosis.

Bone Turnover

In two of the epidemiological studies cited earlier, markers of bone turnover were determined. In one, where no correlation was found between BMD and dietary Mg intake, serum osteocalcin did not correlate with Mg (or any other nutrient) intake (Michaelsson *et al.,* 1995). New *et al.* (2000) also found that serum osteocalcin was not associated with the dietary intake of Mg or other nutrients. Mg intake, however, was significantly negatively correlated with the urinary excretion of pyridinoline and deoxypyridinoline, suggesting that a low Mg diet was associated with increased bone resorption (New *et al.,* 2000).

The affect of short-term administration of Mg on bone turnover in young normal subjects has been conflicting. Magnesium, 360 mg per day, was administered for 30 days to 12 normal males age 27 (mean dietary intake prior to supplementation was 312 mg/day) and markers of bone formation (serum osteocalcin and C terminus of type I procollagen) and bone resorption (type I collagen telopeptide) were compared with 12 age-matched controls (Dimai *et al.,* 1998). Markers of both formation and resorption were suppressed significantly however, only during the first 5–10 days of the study. A similar trial of 26 females ages 20–28 in a double-blind, placebo-controlled, randomized crossover design has been reported (Doyle *et al.,* 1999). Magnesium, 240 mg/day, or placebo was administered for 28 days (mean dietary Mg intake was 271 mg/day prior to and during the study). No effect of Mg supplementation was observed on serum osteocalcin, bone-specific alkaline phosphatase, or urinary pyridinoline and deoxypyridinoline excretion.

Mg Status in Osteoporosis

Significant correlation between serum Mg and bone metabolism has been observed. Gur *et al*. (2002) demonstrated lower serum values of Mg in 70 osteoporotic subjects compared to 30 nonosteoporotic postmenopausal women. In a similar study involving 20 perimenopausal and 53 postmenopausal women, women with severe osteoporosis had significantly lower ionized Mg levels (Brodowski, 2002). This was also confirmed in another study (Saito *et al*., 2004). In a study of 168 patients with Crohn's disease, higher serum Mg predicted higher BMD at the femur (Habtezion *et al*., 2002). A study of a family with primary hypomagnesemia owing to renal Mg wasting demonstrated significant reductions in serum and lymphocyte Mg concentrations; affected members had significantly reduced BMD at the lumbar spine and proximal femur (Kantorovich *et al.*, 2002). Mg is principally an intracellular cation, therefore serum Mg concentration may not reflect Mg status. Researchers have employed Mg tolerance testing, red blood cell Mg, and skeletal Mg content. A small group of 15 osteoporotic subjects (10 female, 5 male) ages 70–85 (the presence or absence of osteoporosis was determined by radiographic features) was compared to 10 control nonosteoporotic subjects (Cohen and Kitzes, 1983). Both groups had normal serum Mg concentrations, which were not significantly different from each other. The Mg tolerance test, however, revealed a significantly greater retention in the osteoporotic patients (38%) as compared to 10% in the control subjects, suggesting Mg deficiency. In a second study by this group, 12 younger women ages 55–65 with osteoporosis (as determined by x-ray) had significantly lower serum Mg concentrations than 10 control subjects; however, no difference in the Mg tolerance test was observed (Cohen *et al.,* 1983). Red blood cell Mg was found to be significantly lower in 10 postmenopausal women who had at least one vertebral fracture as compared to 10 subjects with degenerative osteoarthritis; however, no difference in plasma Mg was found (Reginster *et al.,* 1985). In a second report, 10 postmenopausal women ages

68.9±9 with vertebral crush fracture were compared to 10 nonosteoporotic women ages 67.2±6 years (Reginster, 1989). In comparison to the 10 controls, the osteoporotic subjects had a significantly lower serum Mg, but no difference was noted in red blood cell Mg.

The majority of body Mg (50–60%) resides in the skeleton, and skeletal Mg reflects Mg status. In the two studies cited earlier in which an Mg deficit was suggested by either Mg tolerance testing or low serum Mg concentration, the Mg content of iliac crest trabecular bone was reduced significantly in osteoporotic patients (Cohen and Kitzes, 1983; Cohen *et al.,* 1983). Two additional studies also found a lower bone Mg content in elderly osteoporotic patients (Manicourt *et al.,* 1981; Milachowski *et al.,* 1981). However, no difference in bone Mg content between osteoporotic subjects and bone obtained from cadavers was found (Reginster, 1989). Another study found no difference between patients with osteoporosis and control subjects in cortical bone (Basle *et al.,* 1990), while two studies reported higher bone Mg content in osteoporosis (Basle *et al.,* 1990; Burnell *et al.,* 1982).

In summary, Mg status has been assessed in very few osteoporotic patients. Low serum and red blood cell Mg concentrations, as well as a high retention of parenterally administered Mg, suggest an Mg deficit; however, these results are not consistent from one study to another. Similarly, although a low skeletal Mg content has been observed in some studies, others have found normal or even high Mg content. Larger scale studies are needed.

Effect of Mg Therapy in Osteoporosis

The effect of dietary Mg supplementation on bone mass in patients with osteoporosis has not been studied extensively. Administration of 600 mg of Mg per day to 19 patients over 6–12 months (Abraham, 1991) was reported to increase BMD of the calcaneus (11%) compared to a 0.7% rise in 7 control subjects. All subjects were postmenopausal (ages 42–75) and on sex steroid replacement therapy. Subjects who received Mg also received 500 mg of calcium per day, as well as many other dietary supplements, making if difficult to conclude if Mg alone was the sole reason for the increase in bone mass. In a retrospective study, Mg (200 mg per day) given to 6 postmenopausal women (mean age 59) was observed to have a small nonsignificant 1.6% rise in bone density of the lumbar spine; no change was seen in the femur (Eisinger and Clairet, 1993). Stendig-Lindberg *et al.* (1993) conducted a 2-year trial in which 31 postmenopausal osteoporotic women were administered 250 mg Mg per day, increasing to a maximum of 750 mg per day for 6 months depending on tolerance. All subjects were given 250 mg Mg per day from months 6 to 24. Twenty-three age-matched subjects served as controls. At 1 year there was a significant 2.8% increase in bone density of the distal radius. Twenty-two of the 31 subjects had an increase in bone density while 5 did not change. Three subjects that showed a decrease in bone density had primary hyperparathyroidism and one underwent a thyroidectomy. No significant effect of Mg supplementation was shown at 2 years, although only 10 subjects completed the trial. In a small uncontrolled trial, a significant increase in bone density of the proximal femur and lumbar spine in celiac sprue patients who received approximately 575 mg Mg per day for 2 years was reported (Rude and Olerich, 1996). These subjects had demonstrated evidence of reduced free Mg in red blood cells and peripheral lymphocytes. Recently, Carpenter *et al.* (2006) administered 300 mg Mg to girls ages 8–14 over 1 year and noted a significantly greater increase in hip bone mineral content in the Mg-treated group.

In summary, the effect of Mg supplements on bone mass has generally led to an increase in bone mineral density, although study design limits useful information. Larger, long-term, placebo-controlled, double-blind investigations are required.

Osteoporosis in Patients at Risk for Mg Deficiency

Osteoporosis may occur with greater than usual frequency in certain populations in which Mg depletion is also common. These may include diabetes mellitus (Levin *et al.,* 1976; McNair *et al.,* 1979, McNair *et al.,* 1981; Hui *et al.,* 1985; Saggese *et al.,* 1988; Krakauer *et al.,* 1995), chronic alcoholism (Bikle *et al.,* 1985; Lindholm *et al.,* 1991; Peris *et al.,* 1992), and malabsorption syndromes (Molteni *et al.,* 1990; Mora *et al.,* 1993). Changes in bone and mineral metabolism in patients with diabetes mellitus and alcoholism are surprisingly similar to those in Mg depletion as discussed earlier. Serum PTH and/or $1,25(OH)_2D$ concentrations have been found to be reduced in both human and animal studies (McNair *et al.,* 1979; Hough *et al.,* 1981; Imura *et al.,* 1985; Ishida *et al.,* 1985; Nyomba *et al.,* 1986; Saggese *et al.,* 1988; Verhaeghe *et al.,* 1990). A prospective study of pregnant diabetic women demonstrated a fall in serum $1,25(OH)_2D$ during pregnancy rather than the expected rise observed in normal women (Kuoppala, 1988). These subjects were also found to have reduced serum Mg concentrations. Diabetic children, with reduced serum Mg and calcium concentrations and low bone mineral content, were shown to have an impaired rise in serum PTH and $1,25(OH)_2D$ in response to a low calcium diet; this defect normalized following Mg repletion (Saggese *et al.,* 1988, Saggese *et al.,* 1991). Similar observations were found in the diabetic rat (Welsh and Weaver, 1988). Duodenal calcium absorption has also been reported to be low in diabetic rats (Nyomba *et al.,* 1989; Verhaeghe *et al.,* 1990). The calcium malabsorption may be because of low serum

$1,25(OH)_2D$, as duodenal calbindin D_{9K} has been found to be reduced (Nyomba *et al.,* 1989; Verhaeghe *et al.,* 1990).

The reduction in bone mass in diabetes mellitus and alcoholism also appears to be related to a decrease in bone formation, similar to what is observed in experimental Mg depletion (see later; section 6). A histomorphometric study of bone has shown decreased bone formation, bone turnover, osteoid, and osteoblast number (Tamayo *et al.,* 1981; Goodman and Hori, 1984; Verhaeghe *et al.,* 1990; Hough *et al.,* 1981; Bouillon, 1991). Reduced bone turnover is supported by the finding that serum osteocalcin, a marker of osteoblast activity, is low in humans (Pietschmann *et al.,* 1988; Rico *et al.,* 1989) and in rats (Ishida *et al.,* 1988; Verhaeghe *et al.,* 1990). Patients with vitamin D insufficiency and osteoporosis were shown to have a blunted PTH response that was related to Mg deficiency (Sahota *et al*., 2006).

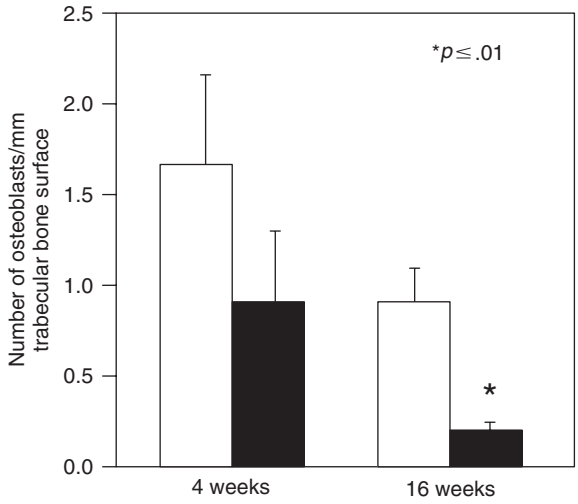

FIGURE 12 After 16 weeks of magnesium deficiency in the rat (solid bars), the osteoblast number was reduced significantly compared to controls (open bars) (Rude *et al.,* 1999) $^*p < 0.01$.

Magnesium Depletion and Osteoporosis: Experimental Animal Models

The effect of dietary Mg depletion on bone and mineral homeostasis in animals has been studied since the 1940s. Most studies have been performed in the rat. Dietary restriction has usually been severe, ranging from 0.2 to 8 mg per 100 chow (normal = 50–70 mg/100 g). A universal observation has been a decrease in growth of the whole body as well as the skeleton (Lai *et al.,* 1975; McCoy *et al.,* 1979; Mirra *et al.,* 1982; Carpenter *et al.,* 1992; Boskey *et al.,* 1992; Kenny *et al.,* 1994; Gruber *et al.,* 1994). The epiphyseal and diaphyseal growth plate is characterized by thinning and a decrease in the number and organization of chrondrocytes (Mirra *et al.,* 1982). Osteoblastic bone formation has been observed by quantitative histomorphometry to be reduced, as shown in (Fig. 12) (Carpenter *et al.,* 1992; Gruber *et al.,* 1994, Rude *et al.,* 1999). Serum and bone alkaline phosphatase (Mirra *et al.,* 1982; Loveless and Heaton, 1976; Lai *et al.,* 1975), serum and bone osteocalcin (Boskey *et al.,* 1992; Carpenter *et al.,* 1992; Creedon *et al.,* 1999), and bone osteocalcin mRNA (Carpenter *et al.,* 1992; Creedon *et al.,* 1999) have been reduced, suggesting a decrease in osteoblastic function. This is supported by an observed decrease in collagen formation and sulfation of glycosaminoglycans (Trowbridge and Seltzer, 1967). A decrease in tetracycline labeling has also suggested impaired mineralization (Carpenter *et al.,* 1992; Jones *et al.,* 1980). Dietary calcium supplementation in the Mg-depleted rat will not prevent loss of trabecular bone; indeed, a high calcium intake suppressed bone formation even more (Matsuzaki and Miwa, 2006). Data on osteoclast function have been conflicting. A decrease in urinary hydroxyproline (MacManus and Heaton, 1969) and dexoypyridinoline (Creedon *et al.,* 1999) has suggested a decrease in bone resorption; however, Rude *et al.* (1999) reported an increase in the number and activity of osteoclasts in the Mg-deficient rat, as shown in (Fig. 13). Bone from Mg-deficient rats has been described as brittle and fragile (Lai *et al.,* 1975; Duckworth *et al.,* 1940). Biomechanical testing has directly demonstrated skeletal fragility in both rat and pig (Boskey *et al.,* 1992; Kenny *et al.,* 1992; Miller *et al.,* 1965; Heroux *et al.,* 1975; Smith and Nisbet, 1968). Osteoporosis has been observed to occur in dietary Mg depletion by 6 weeks or longer (Boskey *et al.,* 1992; Carpenter *et al.,* 1992; Rude *et al.,* 1999; Heroux *et al.,* 1975; Smith and Nisbet, 1968), as shown in (Fig. 14). Bone implants into Mg-deficient rats have also shown osteoporosis in the implanted bone (Belanger *et al.,* 1975; Schwartz and Reddi, 1979). A high calcium diet will not affect this Mg deficiency-induced reduction of bone mass (Matsuzaki *et al*., 2005). The effect of higher than the recommended dietary Mg intake on mineral metabolism in the rat has been reported (Toba *et al.,* 2000). In this study, increasing dietary Mg from 48 to 118 mg/100 g chow resulted in a decrease in bone resorption and an increase in bone strength in ovariectomized rats. No loss of BMD was observed, suggesting a beneficial effect of Mg in acute sex steroid deficiency.

These severe degrees of Mg deficiency are unlikely to commonly occur in the human population. We have recently reported less severe degrees of Mg restriction in the rat (10%, 25%, and 50% of the recommended nutrient requirement) and also observed detrimental effect on bone (Rude *et al*., 2004; Rude *et al*., 2005; Rude *et al*., 2006) including reduced trabecular bone, decreased bone formation, and increased bone resorption. The effect of an Mg diet at 10% of the recommended nutrient requirement on trabecular bone is demonstrated in Fig. 14. These inadequate dietary Mg levels are present in segments of the human population as discussed earlier and implicate Mg deficiency as a possible risk factor for osteoporosis.

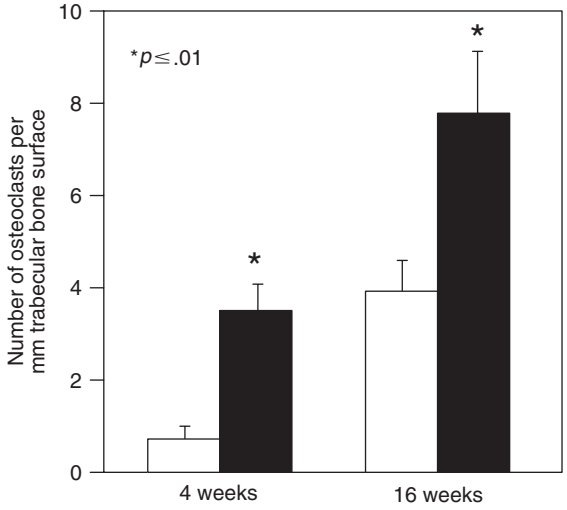

FIGURE 13 After 4 and 16 weeks of magnesium deficiency in the rat (solid bars), the osteoclast number was elevated significantly compared to controls (open bars) (Rude *et al.*, 1999) $^{*}p < 0.01$.

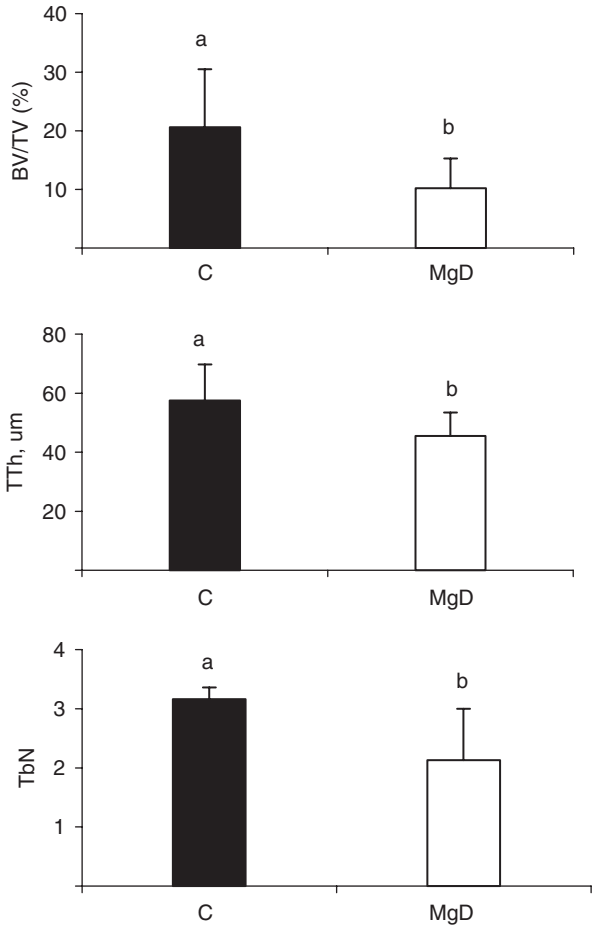

FIGURE 14 Effect of a low Mg diet at 10% of nutrient requirement on trabecular bone volume (BV/TB), mean trabecular width (TTh), and trabecular number (TbN) in rats fed Control (C) or low magnesium (MgD) diets as determined by microcomputed tomography. Values are means ± SD, $n = 7$. Bars without a common letter differ ($p < 0.01$). (Rude *et al.*, 2004).

Possible Mechanisms for Mg Deficiency-Induced Osteoporosis

Several potential mechanisms may account for a decrease in bone mass in Mg deficiency. Mg is mitogenic for bone cell growth, which may directly result in a decrease in bone formation (Liu *et al.*, 1988). Mg also affects crystal formation; a lack of Mg results in a larger, more perfect crystal, which may affect bone strength, as discussed later (Cohen and Kitzes, 1983).

Mg deficiency can perturb calcium homeostasis and result in a fall in both serum PTH and $1,25(OH)_2D$ as discussed earlier (Rude *et al.*, 1978; Fatemi *et al.*, 1991). Because $1,25(OH)_2D$ stimulates osteoblast activity (Azria, 1989) and the synthesis of osteocalcin and procollagen (Francheschi *et al.*, 1988), decreased formation of $1,25(OH)_2D$ may be a major cause of decreased bone formation, such as that observed in experimental Mg deficiency (Heroux *et al.*, 1975; Jones *et al.*, 1980; Kenney *et al.*, 1994). A decrease in bone-specific binding sites for $1,25(OH)_2$-D has also been described, which could account for vitamin D resistance (Risco and Traba, 2004). Similarly, PTH has been demonstrated to be trophic for bone (Marcus, 1994) and therefore impaired PTH secretion or PTH skeletal resistance may result in osteoporosis.

Because insulin promotes amino acid incorporation into bone (Hahn *et al.*, 1971), stimulates collagen production (Wettenhall *et al.*, 1969), and increases nucleotide synthesis by osteoblasts (Peck and Messinger, 1970), insulin deficiency or resistance may alter osteoblast function in diabetes. However, insulin also causes an increase in intracellular Mg, and because Mg has been shown to be trophic for the osteoblast (Liu *et al.*, 1988), insulin deficiency may result in intracellular Mg depletion and impaired osteoblast activity. Serum IGF-1 levels have also been observed to be low in the Mg-deficient rat, which could affect skeletal growth (Dorup *et al.*, 1991).

Although the explanation just given may explain low bone formation, it does not explain the observation of an increase in osteoclast bone resorption. Each year about 25% of trabecular bone is resorbed and replaced in human adults, whereas only 3% of cortical bone undergoes remodeling (Papanicolou *et al.*, 1998). This suggests that the rate of locally controlled bone remodeling is important in the development of osteoporosis. Mg has been shown to inhibit the N-methyl-D-aspartate (NMDA) receptor (McIntosh, 1993). Activation of the NMDA receptor induces the release of neurotransmitters, such as substance P (McIntosh, 1993). Reduction of extracellular Mg lowers the threshold level of excitatory amino acids (i.e., glutamate) necessary to activate this receptor. In one study, dietary Mg deficiency produced raised serum levels of neuropeptides such as substance P and calcitonin gene related protein in rodents (Weglicki *et al.*, 1996a). This neurogenic response is followed by release of proinflammatory

cytokines, such as TNFα, IL-1β, IL-6, by T lymphocytes during the first week of dietary Mg depletion (Weglicki *et al.,* 1996a; Weglicki *et al*., 1996b; Kramer *et al*., 1997). Many of the actions of substance P are mediated through the neurokinin 1 (NK-1) receptor. Elevated plasma cytokines and the inflammatory cardiac lesions observed in Mg-deficient rats have been shown to be prevented by administration of a NK-1 receptor antagonist (Weglicki *et al*., 1996a; Weglicki *et al.,* 1996b; Kramer *et al*., 1997). Studies have demonstrated that there are nerve fibers containing a number of neuropeptides including substance P in bone (Lerner, 2000). Substance P has also been shown to increase the release of IL-1β and IL-6 by bone marrow cells (Rameshwar *et al*., 1994). These cytokines, which are systemically released as well as locally produced in the bone microenvironment, are known to stimulate the recruitment and activity of osteoclasts and increase bone resorption (Miyaura *et al*., 1995; Nanes, 2003). Increased amount of substance P, TNFα, and IL-1β have been found in Mg-depleted mice (Rude *et al*., 2003) and/or rats (Rude *et al*., 2004; Rude *et al*., 2005; Rude *et al*., 2006). These cytokines could contribute to an increase in osteoclastic bone resorption and explain the uncoupling of bone formation and bone resorption observed in the rat. Increased production of these cytokines has been implicated in the development of sex steroid deficiency or postmenopausal osteoporosis (Pacifici, 1996; Manolagas *et al*., 1995). Evidence also suggests that inducible nitric oxide synthetase is stimulated by these cytokines and may mediate localized bone destruction associated with metabolic bone diseases (Ralston, 1994; Brandi *et al.,* 1995). Mg-deficient rodents have increased free radical formation, which may affect the cytokine cascade and influence skeletal metabolism (Kramer *et al*., 1997). These cytokines could contribute to an increase in osteoclastic bone resorption and explain the uncoupling of bone formation and bone resorption observed in the rat (Rude *et al*., 1999; Rude *et al*., 2004; Rude *et al*., 2005; Rude *et al*., 2006). The final pathway of osteoclastogenesis has been proposed to involve three constituents of a cytokine system: receptor activator of nuclear factor kB ligand (RANKL); its receptor, receptor activator of nuclear factor kB (RANK); and its soluble decoy receptor, osteoprotegerin (OPG) (Hofbauer and Heufelder, 2000; Manolagas, 2000). RANKL is a membrane-bound, cytokine-like molecule that is expressed in preosteoblastic cells. It stimulates the differentiation, survival, and fusion of osteoclastic precursor cells to activate mature RANK expressed in hematopoietic osteoclast progenitors, and serves as an essential factor for osteoclastic differentiation and activation. RANKL binds to RANK with high affinity and this interaction is essential for osteoclastogenesis. OPG is expressed in a variety of cell types, however, in bone it is mainly produced by cells of osteoblastic lineage. OPG has very potent inhibitory effects on osteoclast formation. It acts like a decoy receptor and blocks the RANKL/RANK interaction (Hofbauer and Heufelder, 2000). The relative presence of RANKL and OPG therefore dictates osteoclast bone resorption activity. Osteoclasts can be formed or activated in a RANKL and/or a RANKL-independent mechanism by TNFα (Hofbauer and Heufelder, 2001; Horowitz *et al*., 2001; Nanes, 2003). The immunohistochemical presence of these two cytokines in Mg-deficient vs. control animals was examined and a decrease in OPG and an increase in RANKL were observed (Rude *et al*., 2005). Whether or not these mechanisms for Mg-induced bone loss are valid for suboptimal chronic dietary Mg deficit in human osteoporosis is unknown.

Magnesium and Mineral Formation

Mg may also independently influence bone mineral formation. In *in vitro* studies, Mg has been shown to bind to the surface of hydroxyapatite crystals and to retard the nucleation and growth of hydroxyapatite and its precrystalline intermediate, amorphorous calcium phosphate (Blumenthal *et al.,* 1977; Bigi *et al.,* 1992; Sojka and Weaver, 1995). Mg has also been demonstrated to compete with calcium for the same absorption site on hydroxyapatite (Aoba *et al.,* 1992). Therefore, surface-limited Mg may play a role in modulating crystal growth in the mineralization process.

In vivo studies have demonstrated that as the Mg content of bone decreases, the hydroxyapatite crystal size increases, whereas high Mg content results in smaller crystals. Rats fed excess Mg have smaller mineral crystal in their bone than control pair-fed animals (Burnell *et al.,* 1986). In contrast, Mg-deficient rats have a significant increase in hydroxyapatite crystal size (Boskey *et al.,* 1992). Clinical studies are also consistent with this effect of Mg on crystal formation. A crystallinity index determined by infrared spectrophotometry has shown larger and more perfect bone mineral crystals along with decreased bone Mg in bone samples obtained from patients with diabetes mellitus, postmenopausal osteoporosis, and alcoholic osteoporosis (Blumenthal *et al.,* 1977; Cohen and Kitzes, 1981; Cohen *et al.,* 1983; Sojka and Weaver, 1995). These conditions are known to have a high incidence of Mg depletion. In contrast, uremic patients, characterized by high serum Mg levels, have smaller, less perfect crystals and high bone Mg (Blumenthal *et al.,* 1977; Cohen and Kitzes, 1981; Cohen *et al.,* 1983; Sojka and Weaver, 1995). An inverse correlation was found to exist between bone Mg and crystallinity index. The effect of these findings on crystallization in terms of bone strength and bone metabolism has yet to be elucidated.

Mg may also have another indirect effect on crystallization by influencing both osteocalcin formation and osteocalcin binding to hydroxyapatite. Osteocalcin has been shown to inhibit the conversion of brushite to hydroxyapatite and the nucleation of mineral formation (Wians *et al.,* 1990). Therefore, the decrease in osteocalcin production, as

suggested by decreased serum and bone osteocalcin, in Mg depletion may influence mineralization. However, Mg has also been demonstrated to inhibit the binding of osteocalcin to hydroxyapatite by reducing the number of available hydroxyapatite-binding sites for osteocalcin (Wians *et al.*, 1983). Maximal inhibition occurred at 1.5 mM Mg, which is within the physiologically relevant concentration range.

Chapter 25

Metals in Bone: Aluminum, Boron, Cadmium, Chromium, Lanthanum, Lead, Silicon, and Strontium

Felix Bronner*
The University of Connecticut Health Center, Farmington, Connecticut 06030-6125

INTRODUCTION

The mineral phase of bone, made up principally of calcium and phosphate, acts as a sink for metals in the blood that circulates to the skeleton. Uptake by bone mineral is a function of the metal's plasma concentration, its affinity for the bone mineral, and its effect on the extracellular matrix. It is also a function of the degree of mineralization of the skeleton. Bone lead content, for example, was found to be higher in persons who were on a low calcium intake and presumably had lower bone calcium than in individuals on high calcium intake (Hernandez-Avila *et al.*, 1996). If, in addition, the metal interacts with bone cells, their metabolism may be affected and this in turn may alter osteoblast and osteoclast function. Fluoride and bisphosphonates are examples of compounds that become part of the bone mineral, but also have an inhibitory effect on osteoclasts.

Once a metal becomes incorporated in the bone mineral, its return to the circulation depends on how much and how long the metal is associated with the bone mineral surface and on the rate of osteoclast-mediated bone turnover. Metals deposited or exchanged with other elements on the surface of the bone mineral tend to be exchanged rapidly. As additional bone mineral is deposited, the opportunity for isoionic or heteroionic exchange diminishes and osteoclastic resorption becomes the dominant process responsible for the metal's reentry into the circulation. There it is subject to the stochastic processes of loss from the circulation via excretion (urine and stool), redeposition in bone, or soft-tissue uptake. Excretion typically accounts for only a small fraction of the loss from the circulation, but constitutes the only significant route to clear the organism of the metal load. Bone turnover is greater in trabecular than in cortical bone and differs in regions of the skeleton. Metal is taken up in the skeletal regions with the highest turnover rate, whereas retention is highest in regions with lowest turnover. Bone may therefore be thought of not only as a metal reservoir, but as the storage site of body burdens.

Conditions that affect the rate of bone turnover may alter uptake of a given mineral from the circulation. For example, fetal bone formation and calcification are at a maximum during the third trimester of pregnancy, when deposition of maternal bone mineral in the fetal skeleton becomes important (Franklin *et al.*, 1997). This is even more so with a low-birth-weight newborn (Gonzalez-Cossio *et al.*, 1997). Similarly, end-stage renal failure patients with secondary hyperparathyroidism mobilize lead or lanthanum at a significantly greater rate than do healthy persons. This rate is dramatically decreased following parathyroidectomy (Kessler *et al.*, 1999).

The time-dependent increase in the concentration of a bone-seeking metal is due to continued input, as true, for example, in smelter workers, but the increase in the blood will be far less steep and may seem to reach an equilibrium. This is why measuring the level of a metal on the bone surface (Farias, 1998) may be a better approach to estimating the body burden.

ALUMINUM

Interest in the interaction between aluminum (Al) and bone was stimulated as a result of the observation that patients with renal dystrophy accumulated aluminum in their skeleton in quantities that tended to exceed those accumulated by patients with comparable rates of bone turnover, as in hyperparathyroidism (Goodman and Duarte, 1991). Moreover, all accumulation was markedly enhanced as a result of long-term dialysis, leading to bone disease characterized by impaired mineralization and diminished bone cell activity (Goodman and Duarte, 1991). Bone disease

*Corresponding author: Felix Bronner, 263 Farmington Avenue, Bldg. 26, Rm 1007, Farmington, Connecticut 06030-6125, E-mail bronner@neuron.uchc.edu

of this type has also been described in individuals with chronic renal disease who are not on dialysis (O'Brien *et al.,* 1990) and in persons receiving total parenteral nutrition (Klein *et al.*, 1982), as well as in aluminum welders (Elinder *et al.*, 1991). In patients with chronic renal failure, Al poisoning may lead to one of three disorders: aluminum-induced bone disease, microcytic anemia, and encephalopathy (Hellstrom *et al.*, 2006).

Aluminum is the third most common element in the crust of the earth, is its most abundant metal, and has found wide application in a variety of industries (Hellstrom *et al.*, 2006). Aluminum is present in many foods and food containers.

The majority of healthy subjects have Al plasma concentrations that approximate 2 μg/liter (Sharp *et al.*, 1993), a concentration that reflects the Al content of the diet. Al retention is said to be 4% in healthy subjects with normal renal function (Hellstrom *et al.,* 2006). With age, the bone content of Al increases, as it does with increased Al input into the body (Klein, 2005). Al is a contaminant of solutions used for intravenous support of hospitalized or ambulatory patients (Klein, 1995) and is a major constituent of many commercial food containers. As with all bone-seeking metals, as the input of Al from the environment continues over a lifetime, the plasma Al concentration will rise, though relatively slowly, but bone content is proportional to the accumulation rate. Therefore the increase in bone content of Al will be much steeper than would appear on the basis of the time-dependent rise in plasma Al concentrations. This is undoubtedly the reason why Kausz and colleagues (1999) concluded that a patient's plasma Al level does not predict well the presence of aluminum bone disease.

The effect of greater Al input from the food and the environment has not been explored systematically, nor have differences due to gender (Sharp *et al.*, 1993) or metabolism (absorption, excretion and bone turnover). Al accumulation in bone increases not only due to increased or longer-lasting intake, as in old compared to young persons, but also due to decreased capacity for excretion, as in renal osteodystrophy. Bone accumulation of Al can also increase when turnover is diminished, as in diabetes mellitus (Pei *et al.*, 1993). At sufficiently high concentrations, as may occur in newly laid bone or at bone mineral surfaces, Al inhibits mineralization and acts on bone cells, although it has been difficult to separate physicochemical from biological effects (Goodman and Duarte, 1991).

Aluminum appears to enter skeletal tissue by the same routes as calcium. It inhibits hydroxyapatite formation *in vitro* (Blumenthal and Posner, 1984). Data on the *in vivo* effect of Al on bone mineralization point to the overall toxicity of Al. Al concentrations that interfere with calcification *in vivo* are bound to be higher than when Al is added to bone cells in culture. Bouglé *et al.* (1998) report that in low-birth-weight infants mineral density and mineral content of the lumbar spine decreased significantly as serum Al levels increased. This was not true for full-term infants. One explanation may be that in low-birth-weight infants there is less bone mineral than in full-term infants. Therefore the amount of Al that interferes with initiation and progression of bone mineralization in the low-birth-weight newborn is too small to have the same effect in the full-term neonate. Similarly, patients with end-stage renal disease (ESRD) undergoing dialysis have less bone than comparable healthy adults and their Al body burden is relatively greater than in healthy controls. Moreover, as pointed out earlier, they may, as a result of undergoing dialysis, be receiving a greater Al load, so that their bone Al load is greater both relatively and absolutely than that of healthy subjects.

Bone uptake, as stated previously, is proportional to the Al concentration of the plasma. However, once Al is taken up by bone, it is the relative distribution of surface to deep bone Al and the rate of transfer from surface to interior that will determine what remains in that bone site. Cancellous bone, constituting about 20% of the skeletal mass in normal individuals, but perhaps less in patients undergoing dialysis, turns over faster than cortical bone (Marshall *et al.,* 1973). For this reason, the Al content of cancellous bone may be smaller than that of cortical bone. This has been reported for strontium (Boivin *et al.,* 1996).

The plasma Al concentration at any time reflects Al ingestion, the fraction of ingested Al that is absorbed, and the rate of excretion, as well as the amount of Al that is released by osteolysis. High bone levels, to be sure, indicate high prior exposure, but single plasma or bone analyses are unlikely to provide information on Al toxicity. This statement is illustrated by the report of Suzuki *et al.* (1995), who found significant bone accumulation of Al in patients on chronic hemodialysis, even though the water and dialysis fluid provided over the preceding decade had contained less than 10 μg Al per liter. Goodman and Duarte (1991) point out that Al may have to reach concentrations of 30 to 40 mg Al/kg dry bone before affecting bone structure and function. That concentration is equivalent to 1% to 2% of the calcium content of bone (Widdowson and Dickerson, 1964), whereas the Al concentration in bone of normal subjects is only 5–7 mg/kg dry bone (Hodsman *et al.*, 1982). Similarly, Hellstrom *et al.* (2006) report no significant association between the Al content of bone and the bone mineral density or content of the femoral neck. The authors conclude that the Al content of the skeleton over a lifetime has no effect on the incidence of osteoporosis. A higher than normal Al intake at the time bone mass begins to decrease, typically in the fifth decade, may, however, enhance the development of osteoporosis.

In addition to inhibiting the formation of calcium hydroxyapatite, detectable only at high rates of Al entry into the skeleton, Al also interferes with the formation of calcified and uncalcified nodules in primary cultures of neonatal mouse calvarial cells (Sprague *et al.*, 1993). Those nodules are specific for osteoblastic calvarial cells. Bellows

and colleagues (1995) have shown that Al inhibits *in vitro* initiation and progression of osteoid nodule mineralization. Working with long-term rat calvarial cell cultures, these investigators showed that Al initially accelerated the rate of osteoprogenitor cell differentiation. Al also initially accelerated the formation of osteoid nodules, at the same time inhibiting mineralization. Ultimately, however, Al exerted toxic effects, with nodules and matrix disintegrating by days 17 to 19 of the cultures (Bellows *et al.*, 1999). Kidder *et al.* (1993) have reported that Al suppressed proliferation of marrow fibroblast-like stromal cells and of calvarial osteoblasts (cf. Sprague *et al.*, 1993). Interestingly, in more mature, confluent cultures, Al addition stimulated DNA synthesis and collagen production even in the absence of 1,25-dihydroxycholecalciferol (Kidder *et al.*, 1993). It is uncertain whether fluoride inhibits Al accumulation in rat bone (Ittel *et al.*, 1993) by interfering with binding to the osteoclasts, by blocking Al from substituting for calcium in hydroxyapatite, or whether Al does both. Iwasaki *et al.* (2006) point out that uncalcified osteoid covers the bone surface in osteomalacia, a condition that can also be induced by Al accumulation.

Goodman and Duarte (1991) state that the amount of surface stainable aluminum is the best available indicator of aluminum toxicity and estimate that when surface levels of Al exceed 30%, bone formation and/or mineralization are adversely affected. *In vivo* neutron activation is the current method for measuring Al accumulation in the body noninvasively. Pejovic-Milic and colleagues (2005) have published a neutron activation method with a detection limit of 0.24 mg Al, superior to the method at Brookhaven National Laboratory. Both methods use thermalized neutrons.

Al toxicity that results from Al accumulation is a well-known complication of patients in chronic renal failure. Chelators are the treatment of choice for ridding the body of metals. In the case of Al toxicity, desferrioxamine treatment and elimination of all exogenous Al sources are indicated, with careful attention paid to avoid or minimize side affects, including infections (D'Haese *et al.*, 1996). Two experimental studies are of interest in this connection: Haynes and colleagues (2004) report that aluminum ingestion of eucalypt leaves, part of the natural diet of koalas, small mammals native to Australia, is associated with a high incidence of renal failure in these animals. Baydar *et al.* (2005) report that rats fed folic acid in high-Al diets for 8 weeks had lower Al accumulation in bone and in a variety of soft tissues.

Specific mechanisms by which Al acts on bone and other cells have not been elucidated. Jeffery *et al.* (1996) discuss possible effects on cell signaling, mechanisms by which Al inhibits hemoglobin synthesis, and effects of Al on PTH secretion. These reviewers also list a series of recommendations for further study of the multiple actions of Al in the mammalian organism.

One topic that has received attention is the result of incorporating Al in a total metal-to-metal hip replacement. Grubl and colleagues (2006) report that 1 year after hip replacement, there was no change in the serum Al levels of 13 patients. Inasmuch as the rates at which plasma levels of metals increase with metal input are relatively modest, it is not surprising that plasma levels of Al did not increase significantly in a year. No bone measurements were made by these investigators. .

Lima *et al.* (2006), who studied the effect of a metal alloy made of zinc, aluminum, and copper—Zinalco—implanted into bone, found all three metals diffused into tissue, thereby "promoting nonhomogeneous bone." Cointry and colleagues (2005) studied the effect of Al accumulation in rat cortical bone and concluded that Al intoxication (27 mg Al/day for 26 weeks) significantly reduced the load bone can sustain and the postyield fraction of that load. Treatment reduced mineralization of the cortical bone and had a negative impact on bone stiffness and on the yield stress of the bone.

Notwithstanding the deleterious effects of high-level deposits of Al in bone, most reports of healthy aging subjects have found no demonstrable effect of long-term normal Al intake (Hellstrom *et al.*, 2006). This is not true for individuals with diminished renal function or patients on dialysis. For example, in a study by London *et al.* (2004) of arterial calcification in 58 patients with ESRD on hemodialysis, patients with elevated arterial calcification scores had low numbers of osteoclasts, smaller osteoblast surfaces, and a high percentage of aluminum-stained surfaces. Thus there seems to exist a relationship between low bone turnover and adynamic bone disease, on one hand, and arterial calcification, on the other. For this reason it is important for clinicians to remain alert for potential Al effects when dealing with patients with diminished renal function—not uncommon among the elderly—or patients with renal disease.

BORON

It is uncertain whether boron, B, an essential element for many plant species, is essential for mammals. However, as reported by Nielsen and Hunt (cited by King *et al.*, 1991), a low-B diet appears to exacerbate the effects of vitamin D deficiency in chicks, B supplementation reducing the effects of vitamin D deficiency. It was therefore suggested that B may play a role in bone metabolism. Moreover, Nielsen *et al.* (1987) had reported that increasing the dietary intake of B from 0.25 to 3.25 mg/day in postmenopausal women increased plasma estradiol and testosterone concentrations and decreased urinary calcium output.

A more extensive study on the effect of dietary B supplementation (5 ppm per day for 5 weeks) on the action of estrogen in ovariectomized rats, carried out by Sheng *et al.* (2001), found that B alone had no effect on various bone

parameters in these animals, but when the ovariectomized rats were treated with estrogen and B, the addition of B significantly enhanced the beneficial effects of estrogen on bone quality.

For this reason, B may play a role in postmenopausal osteoporosis. This possibility was investigated by Beattie and Peace (1993), who studied six postmenopausal women volunteers on a metabolic ward. Each subject took two levels of B, 0.33 and 3.33 mg/day, for 3 weeks. B had no effect on mineral, steroid, or urinary pyridinium crosslink excretion, the last a measure of collagen turnover. As the subjects shifted from the low- to the high-B diet, Ca absorption and urinary Ca excretion increased. The stimulation of calcium metabolism may have been the result of supplementation with an adequate amount of B. However, this does not exclude an action of B on some pathway other than calcium. This inference is confirmed by a study of Armstrong and colleagues (2002), who reported that in young pigs on a low-B diet that was supplemented with B, the bending moment of femurs was improved, but that B supplementation to a diet with a normal B content (6.7 mg B/kg diet) had no effect. In 2001 Armstrong and Spears found that increasing B from 5 to 15 mg/kg diet increased growth and bone strength in barrows (male pigs), but it is not clear whether the higher dietary B concentration represents a nutritionally adequate level. Finally, Armstrong and colleagues, a year later, studied the effect of B addition at 5 mg/kg to a diet for gilts (young sows) that is otherwise low in B and found that B addition had beneficial effects on reproduction and bone characteristics. It thus appears that some basic dietary content of B is needed for normal metabolism, including that of bone, but neither the precise amount nor the mechanism of action—whether direct or indirect—has been established.

Hegsted and colleagues (1991) studied the effect of B addition on vitamin D deficiency in rats. They placed weanling rats, 21 days of age, on a vitamin D–deficient diet, and 12 weeks later, when both the B-supplemented and B-deficient rats were hypocalcemic, the supplemented groups had higher net calcium absorption and were in somewhat more positive balance. However, there were no effects on soft-tissue calcium levels and none on a variety of bone parameters (bone mineral density and length of femur, bone and ash weight, bone Ca, Mg, and P). Hypocalcemia, which can be brought about in 2 to 3 weeks when the rats are on a low-calcium diet, takes much longer to develop and is less severe when calcium intake has been high (Bronner and Freund, 1975). It is also uncertain whether these animals developed genuine vitamin D deficiency, because their intestinal calbindin D_{9k} content, the molecular measure of vitamin D deficiency (Bronner and Freund, 1975), had not been determined.

In a careful study of the effect of B on chick nutrition, Hunt and colleagues (1994) found that B addition modified the effects of vitamin D deficiency and proposed that the plasma B level is homeostatically regulated. The effects on vitamin D_3 deficiency were minor and the inference concerning B homeostasis was not based on rigorous experimentation, because urinary B output was not measured. Conceivably a zero intake of B may aggravate metabolic defects due to vitamin D deficiency, but B is so widely distributed in nature that a genuine B deficiency can probably be achieved only under strict laboratory conditions.

Chapin *et al.* (1997), utilizing young adult male rats, have studied the effect of increasing B intake, in the form of boric acid, from 0 to 9000 ppm boric acid for 9 weeks. They found that bone B had increased in all treated animals and that even though within 1 week of the cessation of feeding B in the diet, serum and urine B values had dropped to normal, bone retained its B level for as long as 32 weeks after cessation of the B diet. The only change in bone these investigators found was a 5% to 10% increase in vertebral resistance to crush force. The authors point out that these increases occurred at exposure levels that were "substantially below those that were previously reported to be toxic."

Probably the most conservative conclusion from the dietary effect of B, whether on bone metabolism alone, on the metabolism of Ca and P, or on overall body function, including reproduction, is that some dietary level of B is needed for full expression of body function, but that supplementation beyond that level probably has no effect.

Finally, a novel B polymerization technique applied to a material for craniofacial bone repair has been shown to be sufficiently biocompatible to indicate a potential for use of the material (Gough *et al.,* 2003).

CADMIUM

Cadmium intoxication, whether acute or chronic, is principally the result of heavy metal mining, i.e., for lead, zinc, or copper, with Cd often not the object of the mining process, but constituting a contaminant. Cd mining, as in certain areas of Belgium, and Cd smelting also constitute major sources of Cd and lead to Cd toxicity in exposed workers. The most dramatic and attention-drawing incident of Cd poisoning occurred in Japan during the latter part of World War II, although the nature of the disease, which became known as the itai-itai disease, and its relationship to Cd poisoning were not fully understood until the 1960s (Nogawa, 1981). *Itai* is Japanese for the exclamation "ouch," associated with tenderness and pain to the touch. The main symptoms of this disease were osteomalacia in postmenopausal women, traced to a high Cd content of rice grown in certain areas whose irrigation water came from a river that had become severely contaminated with Cd because of upstream mining (Nogawa, 1981; Tsuchiya, 1981).

The three organ systems that are principally affected by Cd poisoning are the respiratory system, implicated particularly in acute poisoning due to Cd contamination of dust, the kidney, and the skeleton. Principal renal symptoms

are proteinuria, glycosuria and microglobulinuria. Osteomalacia and osteoporosis are the skeletal symptoms that have been identified in patients with itai-itai disease and in others that have had a chronic low-dose exposure for a long time (Tsuchiya, 1981). Uriu and colleagues (2000) have shown that "chronic Cd exposure exacerbated the uncoupling between bone formation and resorption in ovariectomized rats." Their findings thus add weight to the reported bone effects of chronic Cd exposure, including decreased mechanical strength. In a similar earlier study, Hiratsuka *et al.* (1997) also showed that chronic Cd intoxication caused osteomalacic lesions in ovariectomized rats. In individuals with skeletal symptoms, calcium deficiency aggravated the disease, and high doses of vitamin D, leading to increased calcium absorption, overcame or minimized the symptoms (Nogawa, 1981).

The effect of Cd is very much a function of the dose taken in Cd appears to have an effect on epithelial cells in the intestine (Hietanen, 1981) and to react with bone cells. It causes diminished calcium absorption and increased calcium loss from bone (Wilson and Bhattacharyya, 1997). It appears to bind to cells as well as to proteins, causing cell desquamation in the intestine and changes in cell-to-cell binding in the kidney. The latter leads to direct or indirect interference with the hydroxylation of 25-hydroxyvitamin D_3 (Kjellstrom, 1992), so that the biosynthesis of the intestinal and renal calbindins is diminished (Kimura, 1981; Sagawara, 1974). This in turn leads to a diminution of the active, transcellular transport of calcium in the duodenum (Bronner *et al.*, 1986), and to diminished active reabsorption of calcium in the distal convoluted tubule (Bronner, 1989, 1991). Moreover, Cd binds to calbindin 9kD, displacing Ca^{2+} (Fullmer and Wasserman, 1977), so that active calcium transport is interfered with. A direct linear relationship exists between Cd intake and calcium excretion in the urine (Nogawa, 1981), doubtless due to Cd-induced damage of the tight junctions of the renal tubule. As a result, less calcium is reabsorbed in the renal distal tubule and calciuria results. Thus, Cd input induces Ca loss.

The effect of Cd on bone is a dual one: direct interaction with bone cells, diminishing their ability to mineralize (Miyahara *et al.*, 1988), inhibiting procollagen C-proteinases (Hojima *et al.*, 1994), thereby preventing collagen self-assembly in the extracellular matrix and effectively decreasing collagen production (Miyahara *et al.*, 1988). Cd may also affect gene expression. Regunathan and coworkers (2003) developed an *in vivo* model for cadmium-induced bone loss. In this model mice excrete bone mineral in the feces after Cd gavage. Using microarray to evaluate gene changes in bone cells, the authors hypothesize on the basis of their results that Cd stimulates demineralization via a P38 MARK pathway that activates osteoclasts.

Brzoska and colleagues have in recent years carried out extensive studies in a rat model of human exposure to Cd (Brzoska *et al.*, 2005a, 2005b, and added self-citations in these papers). Their overall results, qualitatively similar to what has been reported by others (see earlier discussion), indicate that low-level Cd exposure affects the mineral and biomechanical properties of growing bone, with collagen and glycosoaminoglycan affected. Thus the mechanical weakness of the femur, the bone studied most extensively by the Polish group, can be attributed to a decrease in the cross-linking of collagen, leading to increased collagen solubility (Galicka *et al.*, 2004), to diminished regulation of fibril assembly, diminished calcium supply, and, as discussed in the next paragraph, to inhibition of hydroxyapatite nucleation and growth. Brzoska *et al.* also observed that male rats were less susceptible than female rats to the effects of Cd. A possible explanation, as also for Al (cf. previous section), is that the female skeleton is smaller than that of males and therefore the amount of Cd ingested during the experimental period is proportionately greater in the female than the male.

Blumenthal and colleagues (1995) report that Cd has an inhibitory effect on hydroxyapatite formation *in vitro* and suggest that "the interference of Cd with mineralization can be partially explained by its inhibitory effect on hydroxyapatite nucleation and growth." This would be in addition to any direct effect of Cd on bone cell function. Thus, Long (1997) has reported that the concentration of 200 to 500 mM Cd in the culture medium caused changes in cell morphology and a decrease in osteoblast and osteoclast number and in alkaline phosphatase activity. All of these changes are likely to contribute to diminished collagen production and impaired mineralization. A second, indirect effect of Cd is to accelerate bone turnover, particularly bone resorption (Chang *et al.*, 1981), a result of the induced calcium deficiency. It is uncertain whether the increase is due to stimulation of parathyroid hormone release in response to hypocalcemia.

Shank and Vitter Vitter (1981) have calculated that if Cd is administered five times, with intervals of 48 hours between each administration, then 48 hours after the last dose the liver content would account for about two thirds of the dose and the kidney for 7% to 8%. It is not surprising, therefore, that bone effects are manifested only with chronic exposure, as a result of Cd acting directly on bone cells, modulating hydroxyapatite formation, as well as inducing changes in calcium metabolism. Because these changes are similar to those of calcium and vitamin D deficiency, bone effects resulting from Cd accumulation are aggravated by conditions that intensify or aggravate calcium needs.

It is not surprising therefore that Cd may be a risk factor for osteoporosis (Jarup *et al.*, 1998; Kazantzis, 2004), a reason for studies like those by Brzoska and colleagues.

CHROMIUM

The element chromium, Cr, belongs to the first series of the transition elements, occurs in several oxidation states,

with the trivalent being the most stable (Mertz, 1969). Cr is thought to be an essential micronutrient. It appears essential for optimal glucose utilization and its deficiency "can be a cause of or an aggravating factor in the glucose intolerance of infants" that suffer from protein-calorie insufficiency or have non-insulin-dependent diabetes (Hambidge, 1974). Its role in skeletal metabolism is largely unexplored, with interest stimulated by the increasing use, especially in elderly adults, of metal-containing prostheses, where Cr constitutes part of the alloy. For example, Berry *et al.* (1993) have reported that extensive osteolysis occurred around an aseptic, well-fixed, stable, uncemented total knee prosthesis and concluded that debris resulting from wear, in the form of polyethylene, metal, or both, may be responsible for the breakdown of bone. For this reason, Sankaramanivel *et al.* (2006), on the hypothesis that chromium interferes with bone remodeling, treated rats with chromium intraperitoneally for 5 days and found, as expected, significant accumulation of chromium in the skeleton and reduced activity of alkaline phosphatase and tartrate-resistant acid phosphatase, with changes in bone formation rate and structure that suggested an alteration in bone turnover. There was also an unexplained rise in serum phosphate. Dunstan *et al.* (2005) studied urine and blood levels of various metals, including Cr, in patients who had metal-on-metal or metal-on-polyethylene articulations *in situ* for over 30 years. Urinary excretion of Cr was significantly elevated in all arthroplasty groups, compared to controls, with a tendency for the urinary output to increase more in the metal-on-metal groups, particularly those with loose articulation. In patients with loose metal-on-metal articulations there was a huge increase in the urinary cobalt output, cobalt being part of the metal prosthesis. It seems logical to infer that more body fluids can enter loose than tight articulations and cause more metal to be dissolved. This inference is supported by the report of Chojnacka (2005), who found that animal bones are an efficient sorbent for Cr, with sorption a function of Cr concentration.

Kinetic analyses of the distribution of Cr in the body have shown (Onkelinx, 1977) that in rats, about 40% of the ^{51}Cr that is lost out of the central compartments flows to a "sink", consisting of various soft tissues and bone. Total bone content is some 2.5 times higher than that of all other tissues after 262h, i.e. when uptake approaches a plateau. DoCauto *et al.* (1995) did a kinetic study in humans and found that the compartment with slowest turnover, presumably similar to the "sink" in the rat study (Onkelinx, 1977), reached a near-plateau of about 35% of the injected dose of Cr(III) between days 7 and 58 after dose administration; thereafter this compartment began to empty out, so that by day 248 it contained only 17% of the dose. In the rat study (Onkelinx, 1977), the bone gained Cr with time, whereas the other tissues either lost or held on to their Cr. Thomann *et al.* (1994) have identified a "major storage compartment" in rats that received Cr in their drinking water for 6 weeks and were studied 140 days later, a period during which they no longer received Cr. The half-life of Cr in that storage compartment, made up of bone, skin, hair, and muscle, was in excess of 100 days. Their study thus confirms the essential findings reported by Onkelinx (1977). Thomann *et al.* (1994) suggest, as can also be inferred from the Onkelinx (1977) study, that the storage compartment functions to maintain "elevated body burdens and tissue concentrations of Cr." In other words, Cr, as true for other metals stored in bone, is released from bone mineral by ion exchange and by osteoclast-mediated resorption Cr and thus constitutes a Cr reservoir.

Cr deficiency or Cr excess leads to bone changes. Deficiency is difficult to produce in the laboratory and is unlikely to be encountered in humans, even though low intakes in the elderly have been associated with glucose intolerance (Hambidge, 1974). The association of high local metal concentrations including Cr with failed joint prostheses has been reported (James *et al.,* 1993; Dunstan *et al.,* 2005), but the specifics of how Cr excess acts on bone cells and tissues have not. A report by Gralak and colleagues (2002) may be of interest in this connection. These investigators found that a semipurified diet containing 10% soybean led to lower bone content of Cr in rats fed the diet for 28 days than in controls fed the diet without soybean.

LANTHANUM

Lanthanum, La, atomic weight 138.09, is a rare-earth element with chemical affinities similar to those of Ba, Sr, and Ca. It occurs naturally at low levels in drinking water and some foods. It is of interest because in recent years lanthanum carbonate has been studied as a possible replacement for calcium-based phosphate binders, which, for many years, have constituted the principal treatment for lowering the plasma phosphate of hyperphosphatemic patients with ESRD. The reason for replacing calcium-based phosphate binders is that the high intake of calcium has in some patients led to hypercalcemia and cardiovascular calcification, with an increase in the risk of death from cardiovascular disease. Whereas calcium absorption even at high intakes exceeds 10% (Bronner, 1991), La absorption is extremely low, less than 0.002% (Bronner *et al.*, submitted). As La enters the circulation, it is deposited in the liver during the first pass, is endocytosed into liver cell cytosomes and then appears to be transported directly to the bile (Yang *et al.,* 2006). The remainder of the La in circulation is either excreted in the urine or deposited in bone, both at the bone surface and in the bone interior, with the rate of La movement from surface to bone much slower than in the case of Ca (Bronner *et al.,* submitted). With continued high intake of La, as in hyperphosphatemic ESRD patients, bone becomes the major site of La in the body. Yet, the total quantity of La accumulated in bone as

a result of ingesting 3 g elemental La daily for a decade is predicted, on the basis of a four-compartment model based on experimental findings, to be less than 70 mg, with about 90% in deep bone, the mineral surface of the skeleton accounting for some 9% (Bronner *et al.,* submitted).

When La intake stopped, La was lost from bone at a rate of 13% per annum in a dialysis population (Bronner *et al.,* submitted). This rate of loss, due to ionic exchange at the bone surface and osteoclast-mediated bone resorption leading to bone turnover, is much higher than that estimated for healthy adults (Marshall *et al.,* 1973). Hyperphosphatemic ESRD patients tend to have high bone turnover because of secondary hyperparathyroidism. Also, La tends to accumulate at the bone surface; this increases the opportunity for bone surface La to exchange with the body's fluid compartments. Specific differences notwithstanding, the overall fate of La in the body is similar to that of calcium.

LEAD

Lead (Pb) contamination of the environment, largely due to the widespread use of Pb compounds in paints and in gasoline, has become a major public health problem. Although the use of Pb-containing gasoline has been severely restricted in the United States, and although paints, both exterior and interior, are now formulated without Pb in many countries, Pb contamination continues to remain an important problem throughout the world. As is true for many trace elements, the major body site of Pb is the skeleton (Aufderheide and Wittmers, 1992). Even if Pb ingestion or inhalation is stopped, Pb from bone continues to enter the circulation as bone turns over (Durbin, 1992). Consequently the skeleton is the major deposit site of Pb and is also the principal source of endogenous Pb (Berglund *et al.*, 2000). Rust *et al.* (1999) have reported that even when removal of Pb paint reduces a child's exposure by 50%, the blood level of Pb may decrease only 25%. This can be explained by the fact that Pb absorbed from the diet and released from bone turnover are the two major sources of Pb in the circulation. Bone turnover is a continuing process, at an average rate of 3.6% per year in healthy adults (Marshall *et al.,* 1973) and perhaps at twice that rate in children. It is Pb that enters soft tissues from the circulation that constitutes the principal health hazard.

It may be obvious that greater bone turnover leads to greater Pb release. A telling illustration is the report by Hac and Krechniak (1996), who showed that after cessation of Pb exposure, the accumulated Pb content of rat hair declined very rapidly to the preexposure level, whereas in that same period only one third of the accumulated bone Pb was lost, hair turning over much faster than bone. Moreover, as indicated earlier, a portion of resorbed bone that enters the circulation reenters bone (Manton, 1985).

The importance of bone as a reservoir for Pb and the effects of bone turnover have been illustrated in several reports. Stack, in his review (1990), points out that the bone Pb level is a positive, linear function of the blood level. Even when the blood Pb concentration reaches a plateau, bone Pb will continue to go up, although ultimately the bone Pb level will also plateau (Stack, 1990). Gulson *et al.* (1998) have shown that the blood Pb concentration in women who breast-fed their infants was significantly higher than during their pregnancy. Breast milk calcium is partly of skeletal origin (Bronner, 1960), and women who breast-feed have higher bone turnover.

The importance of bone turnover is exemplified by the report that Pb is a risk factor for hypertension (Houston and Johnson, 1999; Hu *et al.*, 1996). A possible explanation may be that higher calcium intakes favor lower blood pressure (McCarron *et al.*, 1989) and that Pb in bone, in replacing calcium, lowers, if only slightly, the blood calcium level. This in turn may affect blood pressure by lowering angiotension release or by an indirect effect on the vasculature. This inference derives support from deCastro and Medley (1997), who, on the basis of blood pressure and blood Pb measurements in high school students, suggested a possible association between chronic bone Pb accumulation and later adolescent hypertension. This has been also observed in older adults. Working with a community-based cohort of 964 men and women, aged 50 to 70 years, Martin *et al.* (2006) report that the blood lead level was a strong and consistent predictor of systolic and diastolic blood pressure, whether or not the analysis was adjusted for race/ethnicity and socioeconomic status. Moreover, this was true for recent doses of lead and their acute effect on blood pressure, as well as for cumulative doses from chronic lead exposure.

To study health effects of Pb, blood is sampled and plasma is analyzed, with inductively coupled plasma/mass spectrometry currently the most reliable procedure. Timchalk and colleagues (2006) gave rats oral doses of Pb by gavage and observed that Pb saliva concentrations correlated well with plasma concentrations. Because saliva sampling is less invasive than blood sampling, this may be a useful approach to epidemiological studies of Pb.

When Pb is ingested, it largely follows the routes of calcium. It binds to calbindin (CaBP 9kD) in the duodenum; therefore vitamin D enhances Pb absorption (Fullmer, 1992). In situations of calcium deficiency, when intestinal (calbindin levels are high, Pb absorption is enhanced (Fullmer, 1992). On high calcium intakes, most of the calcium and therefore, presumably, most of the Pb is absorbed by the paracellular route, largely in the ileum (Marcus and Lengemann, 1962; Pansu *et al.*, 1993; Duflos *et al.*, 1995). Pb that has entered the body fluids leaves these via the urine, via the intestine and by entry into bone. Figure 1 is a model of the rates of Pb entry to and return from the two major bone compartments, cortical and trabecular, and

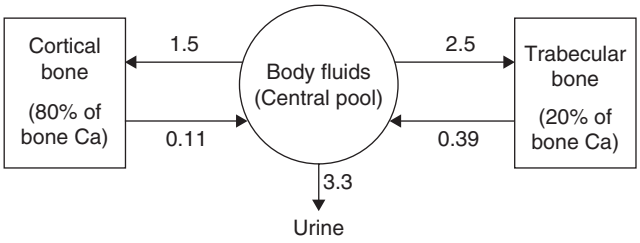

FIGURE 1 Model of how the adult body handles lead. The arrows refer to turnover rates per year. Based on data of chronically exposed lead workers (Christofferson *et al.*, 1987).

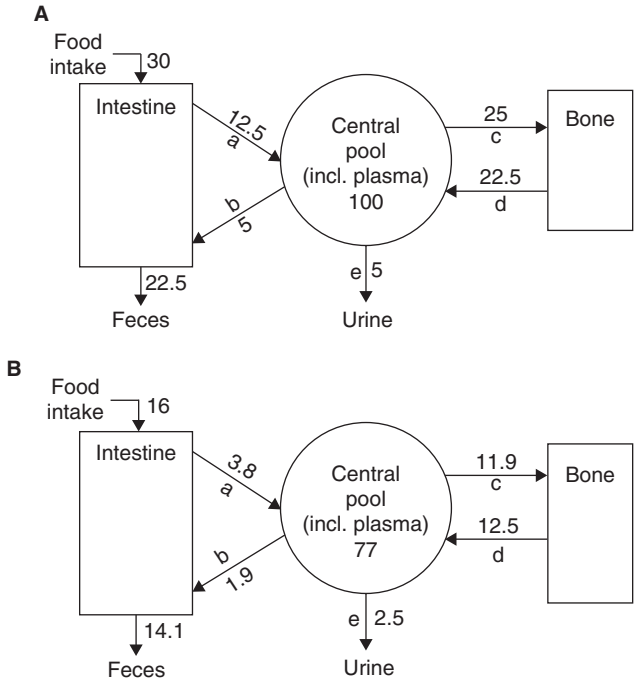

FIGURE 2 Models of calcium metabolism in a 14–year-old girl (**A**) and a 62–year-old postmenopausal woman (**B**). The arrows refer to flows, mmol Ca day^{-1}; the units for the central pools are mmol Ca (from Bronner, 1994).

of the loss rate via urine. The model, derived from findings in chronically exposed Pb workers, does not take into account losses of endogenous Pb in the stool; O'Flaherty (1993) states that the ratio for urinary Pb clearance to that of endogenous Pb in the feces varies from 1:1 to 3:1. O'Flaherty (1993) also states that Pb behaves like calcium in movements into, within, and out of bone. If one assumes that Pb in general behaves like calcium, one can calculate from. Figure 2 that when Pb leaves the body pool, it has a 70% chance of entering bone, whereas the corresponding figure from Fig. 1 would be 55%, neglecting endogenous fecal output. Also, according to Figure 1, nearly two thirds of the Pb flow would be to cortical bone and a little over one third to trabecular bone. However, trabecular bone turns over faster than cortical bone (Marshall *et al.*, 1973); therefore, more than one third of Pb reentering the circulation from bone would be of trabecular origin. This may be the reason why menopausal and postmenopausal women, whose loss of bone is largely trabecular, have higher blood levels of Pb than premenopausal women with a comparable exposure history (Potula and Kaye, 2006; Potula *et al.*, 2006). Potula and Kaye (2006) call attention to the fact that in menopausal women who have received hormone replacement therapy, blood and bone Pb levels were lower than in untreated menopausal women. This can be attributed to the higher bone turnover of untreated menopausal women, inasmuch as hormone therapy after menopause reduces bone loss (Lindsay *et al.*, 1976, quoted by Potula and Kaye, 2006). Also, in the population of women who had been exposed to lead as a result of working in a lead smelter, women whose menopause was induced tended to have lower Pb levels than women who had had a natural menopause (Potula and Kaye, 2006). Women whose menopause is induced tend to be younger than the typical, menopausal woman; their period of bone loss is longer and their Pb blood levels should be higher. However, a much larger percentage of women with induced menopause were on hormone replacement therapy than women with a natural menopause and as a result the Pb levels of the women with natural menopause were higher.

Rabinowitz *et al.* (1976) did a kinetic analysis of Pb, given as a stable isotope tracer, in five healthy male volunteers and found that 54% to 78% of the Pb leaving the blood per day was excreted in the urine, and that the body pool of Pb consisted of three compartments, with the third and largest assigned to bone. Pb in the first compartment had a mean life of 36±5 days, of 30 to 55 days in compartment 2, and a much longer life (10^4 days) in compartment 3. Pb absorption was calculated to vary from 6.5% to 13.7%, averaging 10%.

O'Flaherty (1991) has listed the various routes by which Pb, like calcium, enters bone, i.e., exchange with calcium in the bone mineral, and accretion, i.e., the net transfer into a single microscopic volume of bone, by either increase in volume (apposition) or mineralization (increase in density). The end result is that some 90% of the body burden of Pb accumulates in bone (Aufderheide and Wittmers, 1992). Because the surface uptake or binding of calcium and therefore presumably of Pb to the bone mineral is the dominant process of entry into bone (Bronner and Stein, 1992), the bone surface tends to have the highest Pb content. Ultimately, some of the surface Pb is lost by removal or by being "buried" by newly deposited bone mineral. For this reason, the microdistribution of Pb in bone is of importance; that is why bone surface content of Pb has been considered more important for evaluating the body Pb burden than total bone content. How this can and should be evaluated is controversial (Jones *et al.*, 1992).

Some studies have reported on the effect of Pb addition on cultured bone cells. Schanne *et al.* (1989) found that Pb concentrations in the culture medium of 5 and 25 μM

increased the intracellular free calcium ion concentration in ROS 17/2.8 cells, classified as osteoblastic osteosarcoma cells, and speculated that Pb toxicity may be mediated by disturbances of intracellular [Ca^{2+}]. However, it seems unlikely that raising the intracellular [Ca^{2+}] from 0.13 to 0.25 μM would significantly impair the cell's ability to function. In a later paper these authors (Schanne *et al.*, 1992) report that the addition of Pb to a culture of ROS 17/2.8 cells interfered with a 1,25-$(OH)_2$-D_3-induced increase in intracellular Ca^{2+}. Somewhat similar observations have been reported by Long and Rosen (1994). Klein and Wiren (1993), studying the same cell line, found that Pb concentrations between 2 and 200 μM had no effect on cell number, DNA, or protein synthesis. However, Pb addition caused a decrease in mRNA concentrations of alkaline phosphatase, of type 1 procollagen, and of osteocalcin.

Hicks *et al.* (1996) have reported that sublethal doses of Pb in isolated chick chondrocytes caused suppression of alkaline phosphatase, as well as of type II and type X collagen expression, and a decrease in thymidine incorporation. The authors suggest that Pb may inhibit endochondral bone formation. Gonzalez-Risla and colleagues (1997) found that Pb exposure inhibited development of the cartilage growth plate of rats and suggest this may be one cause of the adverse effects of Pb exposure on skeletal development. Another cause may involve disruption of mineralization during growth (Hamilton and O'Flaherty, 1995).

Dowd *et al.* (1994) have reported that submicromolar concentrations of free Pb compete with Ca^{2+} binding to osteocalcin. Because Pb^{2+} inhibits osteocalcin binding to hydroxyapatite, enough osteocalcin may become inactivated to affect bone mineral dynamics. A related observation was made by Sauk *et al.* (1992), who found that Pb addition inhibited the release of osteonectin/SPARC by ROS 17/2.8 cells and lowered the cellular content of osteonectin/SPARC mRNA. How these *in vitro* effects relate to the *in vivo* effects of Pb poisoning is not known.

Miyahara *et al.* (1994) reported that Pb may induce the formation of osteoclast-like cells by increasing the intracellular concentrations of Ca^{2+} and cAMP. Conceivably therefore, Pb alters Ca channels in a way that allows increased inflow of extracellular Ca^{2+}. Those Pb-sensitive channels—which also permit increased Pb inflow (Schanne *et al.*, 1989)—appear therefore to be located in both osteoclasts and osteoblasts. Carmouche *et al.* (2005) exposed mice to varying concentrations of Pb, but found no effect on osteoclasts isolated from the exposed animals. However, even low Pb doses affected the rate of fracture healing, and high doses induced fibrous nonunions by inhibiting the progression of endochondral ossification.

In a recent review, Holtz and colleagues (2007) summarized the effects of Pb on osteoblasts, indicating (see also above) that Pb inhibits synthesis of collagen type I, secretion of osteonectin, alkaline phosphatase activity, and adversely affects osteoblast proliferation. The authors suggest that "the mechanism by which lead has its effects on bone formation may involve a decrease in the pool of phosphorylated Smads [smoxprotein, drosophila] in exposed cells."

In the same review, Holtz *et al.* (2007) discuss the effects of Pb on articular chondrocytes. The metal seems to release these cells from an arrested state and allows them to progress along a hypertrophic pathway, which in turn leads to matrix degradation, mineralization and apoptosis, processes that in articular cartilage bring about arthritis.

The overall effect of Pb poisoning on bone metabolism is not clear. Koo *et al.* (1991) failed to find significant changes in vitamin D metabolism, bone mineral content, and Ca and P_i plasma concentrations in children of adequate nutritional status who had been chronically exposed to low to moderate Pb levels. Needleman and colleagues (1996) conclude from their study of the relationship between body Pb burden and social adjustment in public school children that high bone Pb levels are associated with attention deficit, aggression and delinquency and that these effects follow a developmental course. Indeed, it is the overall effect of raised blood levels of Pb on development and behavior of children that led to the advocacy of Pb removal from the environment and to the policy of minimizing Pb contamination.

Whatever the direct effect of Pb on bone, the skeleton clearly constitutes the major Pb store in the body. For example, when rats were fed a marginal zinc diet that leads to retarded bone growth and diminished bone mass, bone lead concentration was enhanced, compared to that of controls (Jamieson *et al.*, 2006). It is apparent, therefore, that skeletal Pb content determines overall exposure and risk.

Lead removal from bone, as of other metal contaminants, is best accomplished by chelators, typically administered systemically. The best way to prevent Pb accumulation is to eliminate it from the immediate environment, such as by making paint or gasoline lead-free. Another approach is to prevent or diminish Pb absorption. That it can be achieved is claimed on the basis of rat studies, with the aid of calcium alginate and calcium pectate. Both of these compounds appear to act by binding exogenous or endogenous lead in the intestine and therefore may find use in preventing and treating lead poisoning (Khotimchenko *et al.*, 2006).

SILICON

Silicon, Si, atomic number 14, atomic weight 28.0, belongs to periodic group IVb and is classified as part of the carbon family, which includes germanium, tin, and Pb (Moeller, 1952). Carlisle (1986) has listed the Si concentration in various soft tissues of rats and monkeys as varying typically between 1 and 2 μg/g wet weight; in people the Si concentration appears to be about one order of magnitude

higher. Connective tissues tend to have a high Si content, mainly because Si is an integral component of the glycosaminoglycans and their protein complexes that contribute to the tissue structures (Carlisle, 1986).

In 1972, Schwarz and Milne reported that the addition of 50 mg Si/100 g diet increased the growth rate of rats by some 30%, and Carlisle, in the same year, found a comparable increase in the daily weight gain of chicks. Carlisle (1986) has reported that the addition of Si hastened mineralization in weanling rats and that Si deficiency in chicks (Carlisle, 1972) led to abnormally shaped bones. Over the past decades, there have been many reports that have or have not verified the initial findings (see Carlisle, 1986, for a review of reports through mid-1980). Thus, Seaborn and Nielsen (1994) have reported that when Si, as sodium metasilicate, was fed to weanling rats at the rate of 25 μg/g fresh diet, the decreased Ca and Mg content of the femur found in the control animals was reversed. In these experiments, it proved possible to substitute germanium for Si, but germanium did not replace Si in other effects that result from Si deficiency. On the other hand, Eliot and Edwards (1991) concluded on the basis of 16-day experiments with broiler chicks that "dietary silicon supplementation has no effect on growth and skeletal development." Eisinger and Clairet (1993) analyzed bone mineral density in 53 women with osteoporosis and found that in eight subjects Si supplementation induced a statistically significant increase in femoral bone mineral density.

Rico and colleagues (2000) studied the effect of 30-day Si supplementation in ovariectomized rats and showed that supplementation overcame the losses of bone mass in the 5th lumbar vertebra and in the femur found in the ovariectomized controls. The authors concluded that Si "may have a potential therapeutic application in the treatment of involutive osteoporosis."

In the same year, DeAza and colleagues (2000) showed that a compound made of alpha-$CaSiO_3$, called pseudowollastonite, is integrated into the structure of living bone tissue through a dissolution–precipitation–transformation mechanism, with osteoblasts migrating to the interface and colonizing the bone surface.

One reason for interest in possible Si effects on bone is that granules of special glasses have been used to repair bone defects in the dental field (Gatti and Zaffe, 1991a). These vitreous materials contain Si, as do materials used to complete suturectomy for the treatment of craniosynostosis (Antikainen, 1993). In the case of the granules, analyses of the embedded jaws showed (Gatti and Zaffe, 1991b) that Si had diffused into the surrounding tissue. There also was no osteoinduction, but it is not clear whether this was caused by Si or the procedure.

Lai *et al.* (2002) implanted bioactive glass granules in the tibiae of rabbits and determined the biopathway of the Si released from the bioactive glass. As expected, the urinary output of the rabbits with implants was significantly higher than that of the controls and the amount of silicon excreted matched that implanted after 24 weeks. The authors conclude that the resorbed Si is excreted in the urine in a soluble and harmless form.

Gorustovich and colleagues (2002), in a somewhat similar study in rats, implanted titanium and bioactive glass particles and killed the animals at 14, 30, and 60 days. They found increased bone thickness in the peri-implant of the Ti/bioglass group, as compared to the group with Ti implants only, suggesting an increase in medullary bone formation in the group with Si-containing bioglass.

Seaborn and Nielsen (2002a), having shown in an earlier study that Si deprivation decreases the collagen concentration in 9-week-old rats (2002b), showed that hydroxyproline was significantly diminished in tibiae from Si-deficient as compared to Si-supplemented animals. They also found that collagen formation from proline in bone and other sites was corrected by Si addition to the diet, concluding that Si is a nutrient of concern in wound healing and bone formation.

Porter and colleagues (2003) have shown that incorporation of silicate into hydroxyapatite increases the rate of bone apposition to bioceramic implants of hydroxyapatite. It does so by increasing dissolution from the implanted hydroxyapatite, thereby increasing the in vivo bioactivity over an implant that consists of pure hydroxyapatite. Similarly, Pabbruwe *et al.* (2004) demonstrated that doping a bioinert ceramic with small amounts of Si can significantly improve tissue ingrowth and osteogenesis. In a later paper, Porter *et al.* (2006) studied in greater detail the structure of the bond between bone and Si-containing bioceramic implants and found that organized, mineralized collagen fibrils had grown into the strut porosity at the interface between the Si-containing implant and the surface of the surrounding bone. Porter (2006) has reviewed the role played by Si in bone mineralization and formation and applied this knowledge and the findings of the studies by her and her colleagues (Porter *et al.*, 2003, 2006) to the interaction between bone and Si-containing ceramic implants and on their performance.

STRONTIUM

Strontium, Sr, like calcium, is a periodic group IIa element and, although not very abundant, constituting only 0.03% of the igneous rocks of the earth, is usually classified as a "familiar element" because of the existence of readily available natural sources (Moeller, 1952). It is not an essential element, and interest in Sr metabolism stems from the fact that ^{90}Sr "is an abundant and potentially hazardous by-product of nuclear fission" (Underwood, 1977). Although tests of nuclear explosions have largely ceased, the fact that Sr behaves metabolically much like calcium has helped maintain interest in this element (Blumsohn *et al.*, 1994; Kollenkirchen, 1995).

In a detailed formal study (Bronner *et al.*, 1963) it was found that although Sr and Ca followed the same metabolic pathway qualitatively, there were significant quantitative differences in how the body handled these two elements. The major difference was in the urine, with the fraction of Sr excreted in the urine three times that of Ca, on the average. In the stool, the fecal loss of endogenous Sr was greater than that of Ca, but only moderately so (by ~10%). In terms of the fraction of injected isotope that was calculated to reach bone, there was no difference on the average, but the ratio "varied from patient to patient and was not consistent in a given patient." Blumsohn *et al.* (1994) have reexplored the relationship between Sr and Ca absorption in patients with osteoporosis and with chronic renal failure. Sr absorption was approximately half that of Ca, but the time course of the two was similar, when evaluated by deconvolution. Stable Sr is less expensive than stable Ca, but differences in absorption between the two elements are sufficiently great that measuring calcium absorption with a calcium isotope seems more meaningful. Treatment with 1,25-$(OH)_2D_3$ stimulated Sr absorption more than Ca absorption. A possible explanation is that Sr binds more tightly than Ca^{2+} to the newly induced calbindin (Fullmer and Wasserman, 1977).

Fed in large amounts, Sr has long been known to cause rickets in experimental animals (Lehnerdt, 1910, quoted by Neufeld and Boskey, 1994). In Turkish children growing up in regions where the soil Sr content was greater than 350 ppm, the incidence of rickets was nearly twice that in children from regions where the Sr content was lower (Ozgur *et al.*, 1996). Strontium interferes with intestinal calcium absorption and synthesis of 1,25-$(OH)_2D_3$ (Omdahl and DeLuca, 1972) and interferes with mineralization (Sobel and Hanok, 1952), apparently via direct action on bone cells (Neufeld and Boskey, 1994), although the nature of this action is not clear. One way in which bone formation may be interfered with by Sr is to delay the natural progression of osteoid to bone, i.e., at the stage when cartilage is converted to bone. This interference is consistent with the greater accumulation of complexed acidic phospholipids in Sr-fed rats or in mesenchymal cell micromass cultures (Neufeld and Boskey, 1994). Davis *et al.* (2000) report that Sr becomes associated with the collagen matrix produced in cell culture. It would be interesting to know to what extent the inhibitory effect of Sr can be attributed to displacing Ca^{2+} in other calcium-mediated processes.

There have been reports that nontoxic amounts of Sr may be beneficial in osteoporosis (Storey, 1961, and McCaslin and James, 1981, quoted by Morohashi *et al.* 1994; Brandi, 1993) and in rats, where 0.19% $SrCl_2$ in the diet stimulated bone formation (as evaluated histomorphometrically) and raised the trabecular calcified bone volume by 10% (Marie *et al.* 1985). In 1993, Marie *et al.* reported that an organic distrontium salt, S12911, now known as strontium ranelate, inhibited the increase in bone resorption in ovariectomized rats, without reducing bone formation. It is unclear, however, how much of this effect is due to Sr. In mice, 0.27% $SrCl_2$ in the diet increased the osteoid surface, but had no effect on trabecular calcified bone volume (Marie and Hott, 1985). Grynpas *et al.* (1996) fed 0.2% Sr to 28-day-old rats consuming a 0.5% Ca and 0.5% P diet and found that the number of bone-forming sites and the vertebral bone volume had increased by 17% compared with controls. No detectable adverse effects on mineralization, mineral profile, or mineral chemistry were observed in the Sr-fed animals. Similarly, Morohashi *et al.* (1994) found no harmful effects when rats were fed 0.05% or 0.10% Sr in a semisynthetic vitamin D–deficient diet, whereas 0.5% Sr depressed bone calcium content and the bone calcium deposition rate. In these studies, the limiting Sr concentration was 175 μM; beyond that level, calcium metabolism was depressed. However, at the lower Sr intakes, there also was no beneficial effect of Sr intake. It would thus seem that as Sr replaces Ca, the metabolism of calcium is depressed, with high Sr intakes leading to rickets and poor bone formation and mineralization.

In recent years, strontium ranelate (Fig. 3) has been prescribed in Europe for treatment of osteoporosis. In monkeys, the compound did not induce acute or subchronic toxic effects on the gastric mucosa (Fisch *et al.*, 2006). Absorption of the cation, ranelate, is said to be nil or very low, with the strontium anion absorbed, presumably mostly paracellularly, even though Sr binds tightly to the calcium-binding protein, CaBP 9kD, which effects transcellular calcium transport in the duodenum and proximal jejunum (Bronner and Pansu, 1999). At high calcium intakes, as

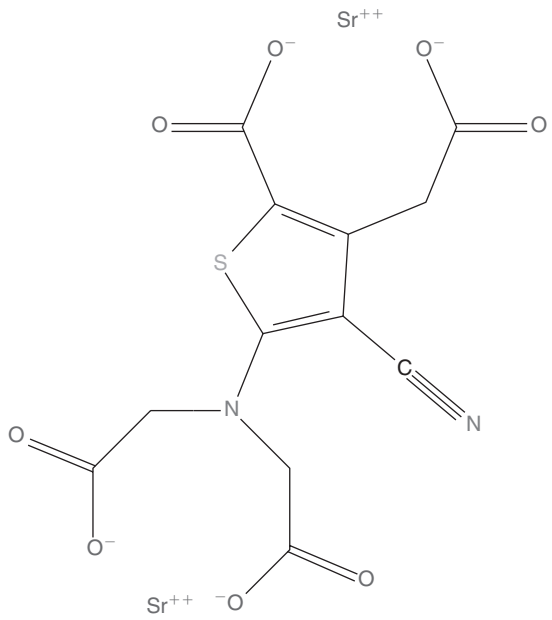

FIGURE 3 The structure of strontium ranelate. (http://pubchem.ncbi.nlm.nih.gov/summary/summary.cgi?cid=6918182).

recommended to patients with osteoporosis, most calcium and presumably most strontium is absorbed in the ileum (Bronner and Pansu, 1999), where transport is paracellular.

Meunier and colleagues (2004) studied 1442 patients with osteoporosis and history of at least one vertebral fracture, half of whom received 2 g daily of strontium ranelate, the other half receiving a placebo and serving as controls. The group on strontium had a lower risk of fracture at the end of 1 and 3 years; their bone mineral density was higher, as was their bone-specific alkaline phosphatase, an index of bone formation, whereas their urinary output of C-telopeptide, a marker of bone resorption, was diminished. The mechanism of action of strontium under these conditions is not known. Strontium competes with calcium for bone deposition, but only modestly. In monkeys that had been placed on increasing levels of Sr intake, only one in 10 calcium ions in the bone crystal was replaced by strontium in the group that had been fed the highest level of Sr ranelate (Boivin *et al.,* 1996). Conceivably, strontium in quantities that do not lead to strontium rickets, by competing with calcium, may cause an increase in bone formation, being initially deposited in new bone and especially in trabecular bone, which turns over faster than cortical bone (Marshall *et al.,* 1973). Normally this would lead to higher bone turnover and therefore higher bone resorption. This was not true in the Meunier *et al.* study. Marie and colleagues, in an earlier review (2001), suggested that Sr may act directly on osteoclasts, inhibiting recruitment and activity, without exerting toxic effects. At the time of the review, fewer studies had dealt with bone formation, but Marie *et al.* suggest preosteoblast replication and collagen synthesis provide the mechanism for stimulating osteoblast activity.

Recommendations for the therapeutic use of strontium ranelate are mixed. A long editorial in *Joint Bone Spine* (Naveau, 2004), after reviewing experimental data, the pharmacology and therapeutic trials, concludes that "if preliminary clinical results are confirmed by ongoing studies [strontium ranelate] should prove a useful addition to the armamentarium for osteoporosis." The editorial does point out that bone mineral density evaluations following Sr therapy tend to overestimate the benefit, inasmuch as Sr incorporation in bone mineral increases the attenuation of x-rays, resulting in an overestimate of bone mineral content, with the overestimate proportional to the bone Sr content (see also Blake and Fogelman, 2005).

An unsigned article in *Revue Prescrire* (Anonymous, 2005) points out that Sr was first used to treat osteoporosis in the 1950s, and that it was then abandoned because its use leads to osteomalacia in animals and dialysis patients, at least when bone contains more than 5% Sr. The article warns about the use of Sr in patients more than 80 years of age, as they often have moderate renal failure. It quotes assessments in Norway, Germany, Sweden, and Finland, which call attention to the risks of venous thrombosis and neurological disorders, with the German assessment stating "that strontium ranelate has a negative risk-benefit balance." The article concludes that "women with osteoporosis can do without strontium . . . avoiding the poorly documented risks associated with strontium."

An interesting use of Sr has been in the radiotherapy with ^{89}Sr of painful bone metastases (Robinson *et al.*, 1995; Pons *et al.,* 1997; Papatheophanis, 1997). Such treatment has been more widely reported for pain relief in patients with prostatic cancer, but has also found application in patients with breast cancer (Pons *et al.*, 1997). Immediately following the injection of $^{89}SrCl_2$, patients experienced a flare reaction of pain. Thereafter pain relief lasted on the average 6 months, with treatment effectively repeatable for another 6 months (Pons *et al.*, 1997). As yet there is no indication that ^{89}Sr is tumoricidal.

The promotion of strontium led Cheung *et al.* (2005) to develop a strontium-containing bioactive cement and compare it with the more conventional cements of polymethylacrylate and hydroxyapatite. Cements are used to treat osteoporotic spine fractures. A good cement has a relatively low setting temperature, exhibits good osteointegration, and matches the stiffness of osteoporotic bone. The Sr-containing cement had a relatively low setting temperature and adequate compressive and bending strengths, with bending strength and modulus fairly close to those of human cancellous bone. The report concludes that the Sr-containing bioactive cement is appropriate for vertebroplasty and kyphoplasty. The authors attribute this to the local delivery of Sr, but it is not clear whether the same formula using calcium—not necessarily as hydroxyapatite—would not be as or even more effective.

CONCLUDING REMARKS

All metals discussed in this chapter enter the skeleton, but in nearly all reports there is no clear distinction between cellular effects and those due to accumulation in the bone mineral. Significant accumulation of a given metal may alter mineral characteristics, but the details of these changes have yet to be established. Furthermore, study of the mechanisms of metal accumulation—heteroionic exchange and/or deposition and inclusion in the bone crystals—may help us learn more about mineralization. Similarly, understanding the qualitative and quantitative effects of metal addition to bone cell cultures may reveal mechanisms of cellular action. It is also important to explore the possible toxic effects of metals used in prostheses. Thus Wang *et al.* (1996) found a metal-induced increase in the release of bone cytokines and wondered whether this led to the osteolysis they observed, an event that can severely compromise the outcome of joint arthroplasty. On the other hand, Pohl and colleagues (2000) and also Piatelli *et al.* (1998) found no impairment of periodontal healing following the insertion of titanium implants. Studies of

the use of aluminum oxide in bioceramics have generally found no major biocompatibility problems (Chang *et al.*, 1996; Piatelli *et al.*, 1996, 1998; Shinzato *et al.*, 1999; Okada *et al.*, 2000), but truly long-term results are still outstanding. Clearly the study of metals in bone continues to provide ample research opportunities to all with an interest in a given metal or the biology of bone.

INTRODUCTION

Complex, free-living terrestrial organisms, such as humans, maintain their level of extracellular ionized calcium (Ca_o^{2+}) within a narrow range of about 1.1 to 1.3 m*M* (Bringhurst *et al*., 1998; Brown, 1991). This near constancy of Ca_o^{2+} ensures that Ca^{2+} ions are available for their extracellular roles, including serving as a cofactor for clotting factors, adhesion molecules, and other proteins and controlling neuronal excitability (Brown, 1991). Moreover, calcium and phosphate salts form the mineral phase of bone, which affords a rigid framework that protects vital bodily structures and permits locomotion and other movements. The skeleton also provides a nearly inexhaustible reservoir of these ions when their availability in the diet is insufficient for the body's needs (Bringhurst *et al*., 1998).

In contrast to Ca_o^{2+}, the cytosolic-free calcium concentration (Ca_i^{2+}) has a basal level—about 100 n*M*—that is nearly 10,000-fold lower (Berridge *et al*., 2003). Ca_i^{2+}, however, can increase 10-fold or more when cells are stimulated by extracellular signals acting on their respective cell surface receptors as a result of influx of Ca^{2+} and/or its release from intracellular stores (Berridge *et al*., 2003). Ca_i^{2+} plays central roles in regulating cellular processes as varied as muscular contraction, cellular motility, differentiation and proliferation, hormonal secretion, and apoptosis (Berridge *et al*., 2003). Because all intracellular Ca_o^{2+} ultimately originates from that present in the extracellular fluids (ECF), maintaining near constancy of Ca_o^{2+} also ensures that this ion is available for its myriad intracellular roles.

The level of Ca_o^{2+} is maintained by a homeostatic mechanism in mammals that comprises the parathyroid glands, calcitonin (CT)-secreting C cells, kidney, bone, and intestine (Bringhurst *et al*., 1998; Brown, 1991). Key elements of this system are cells that are capable of sensing small deviations in Ca_o^{2+} from its usual level and responding in ways that normalize it (Brown, 1991). Calcium ions have long been known to traverse the plasma membrane through various types of ion channels and other transport mechanisms (Berridge *et al*., 2003); however, the actual mechanism by which Ca_o^{2+} was "sensed" remained an enigma for many years. This chapter provides an update on our present understanding of the process of Ca_o^{2+} sensing, which has increased greatly over the past 10 to 15 years, especially as it relates to the mechanisms that maintain Ca_o^{2+} homeostasis.

It is becoming increasingly clear that Ca_o^{2+} serves as a versatile extracellular first messenger—in many instances acting via the Ca^{2+}-sensing receptor (CaR)—that controls numerous physiological processes beyond those governing Ca_o^{2+} homeostasis (for review, see Tfelt-Hansen and Brown, 2005). Although it is beyond the scope of this chapter to review the "nonhomeostatic" roles of the CaR in detail, an emerging body of evidence supports the concept that the receptor participates in important interactions between the system regulating Ca_o^{2+} metabolism and other homeostatic systems (i.e., that controlling water metabolism). These interactions may be crucial for the successful adaptation of complex life forms to the terrestrial environment. This chapter will likewise address these recently emerging homeostatic relationships.

CLONING OF THE CaR

Just 15 years ago, the concept that there was a specific Ca_o^{2+}-sensing "receptor" was only supported by indirect evidence derived from studies of a limited number of Ca_o^{2+}-sensing cells, particularly parathyroid cells (Brown, 1991; Juhlin *et al*., 1987; Nemeth and Scarpa, 1987; Shoback *et al*., 1988). It was necessary, therefore, in devising a strategy for cloning the putative receptor to employ an approach that detected its Ca_o^{2+}-sensing

Principles of Bone Biology, 3rd Edition

activity using a bioassay—namely, expression cloning in *Xenopus laevis* oocytes. Racke *et al*. (1993) and Shoback and co-workers (Chen *et al*., 1994) both demonstrated that *X. laevis* oocytes became responsive to Ca_o^{2+}-sensing receptor agonists after they were injected with messenger RNA (mRNA) extracted from bovine parathyroid glands. Brown *et al*. (1993) were then able to utilize this strategy to isolate a full-length, functional clone of the Ca_o^{2+}-sensing receptor. The use of conventional, hybridization-based approaches subsequently permitted the cloning of cDNAs coding for CaRs from human parathyroid (Garrett *et al*., 1995b) and kidney (Aida *et al*., 1995b), rat kidney (Riccardi *et al*., 1995), brain (namely striatum; Ruat *et al*., 1995), and C cell (Garrett *et al*., 1995c); rabbit kidney (Butters *et al*., 1997); and chicken parathyroid (Diaz *et al*., 1997; reviewed in Brown *et al*., 1999). All exhibit very similar predicted structures and represent tissue and species homologues of the same ancestral gene.

PREDICTED STRUCTURE OF THE CAR AND ITS RELATIONSHIPS TO OTHER G PROTEIN-COUPLED RECEPTORS

The topology of the CaR protein predicted from its nucleotide sequence is illustrated in Figure 1. It has three principal structural domains, which include (a) a large, ~600-amino-acid extracellular amino-terminal domain (ECD), (b) a "serpentine" seven membrane-spanning motif that is characteristic of the superfamily of G protein-coupled receptors (GPCRs), and (c) a sizable carboxyl-terminal (C-) tail of about 200 amino acids. Several GPCRs have been identified that share striking topological similarities with the CaR, particularly in their respective, large ECDs, as well as a modest (20−30%) overall degree of amino acid identity. These structurally related GPCRs are designated family C receptors (Kolakowski, 1994; Brauner-Osborne *et al*., 2007). The mammalian family C receptors include

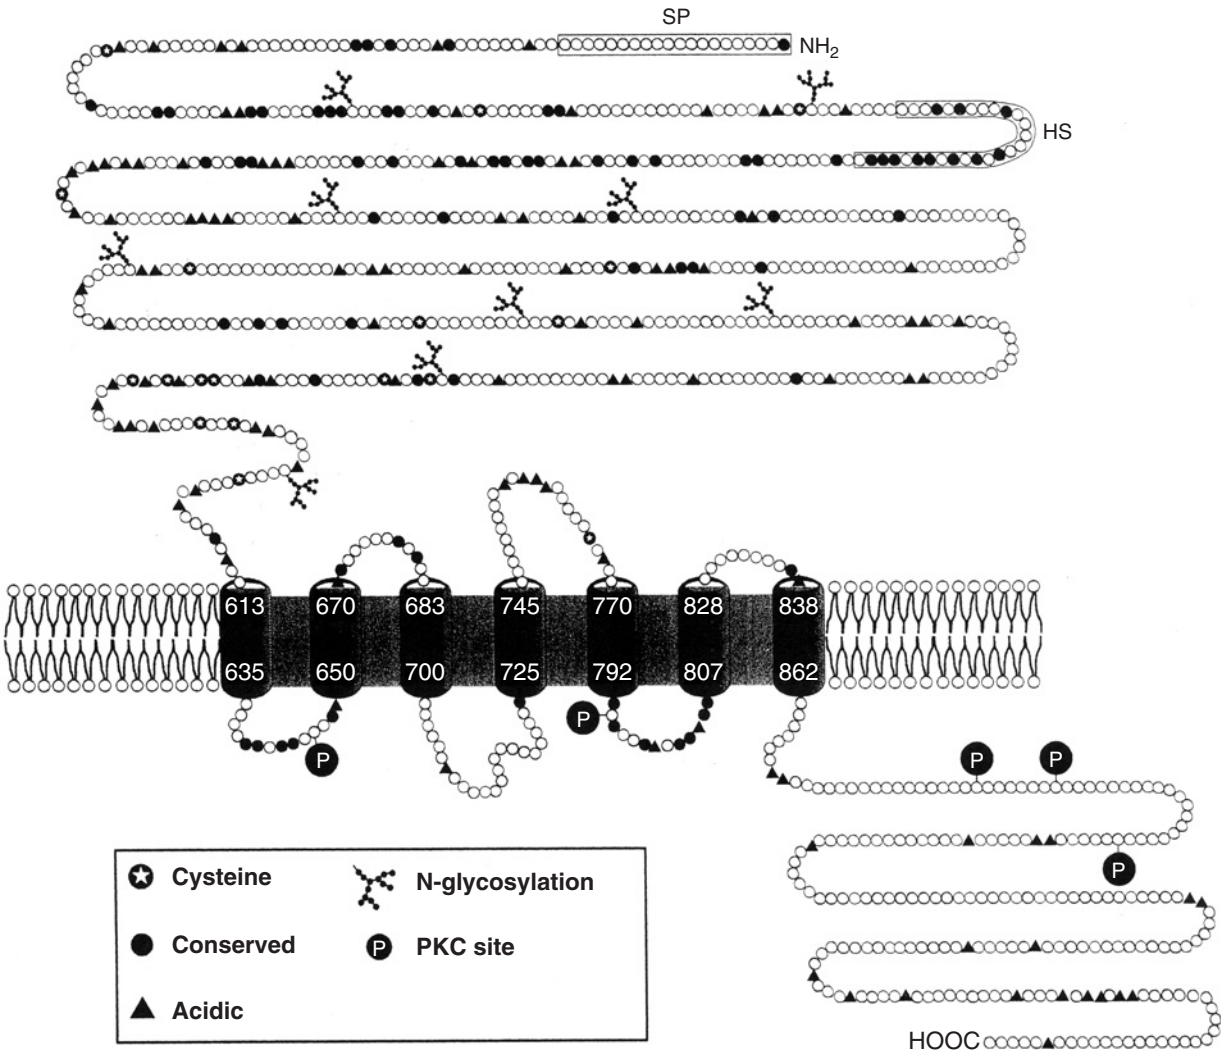

FIGURE 1 Predicted structure of the CaR (see text for additional details). SP, signal peptide; HS, hydrophobic segment. Reproduced with permission from Brown *et al*. (1993).

eight metabotropic glutamate receptors (mGluRs), two $GABA_B$ receptors, the CaR, 3 taste receptors (T1R1-T1R3), the V2R pheromone receptors, and a promiscuous amino acid-sensing receptor, GPRC6A (Christiansen *et al*., 2007), that may also serve as a second Ca_o^{2+}-sensing receptor (see later discussion; Pi *et al*., 2005).

mGluRs are activated by glutamate, the major excitatory neurotransmitter in the central nervous system (CNS; Nakanishi, 1994). The $GABA_B$ receptors are GPCRs that recognize γ-aminobutyric acid (GABA), the principal inhibitory neurotransmitter of the CNS (Kaupmann *et al*., 1997; Ng *et al*., 1999). The putative pheromone receptors reside solely in neurons of the vomeronasal organ in rodents (VNO; Matsunami and Buck, 1997), which controls instinctual behavior, via input from environmental pheromones. The taste receptors enable us to taste sweet substances (and artificial sweeteners) as well as so-called "umami" (i.e., the taste of monosodium glutamate; Hoon *et al*., 1999; Xu *et al*., 2004).

Therefore, all of the family C GPCRs share the property of having small molecules as their ligands that provide environmental cues (i.e., pheromones) or serve as extracellular messengers within the CNS (e.g., glutamate or GABA) or in bodily fluids more generally (i.e., Ca_o^{2+}, amino acids). As detailed later, ligands of the CaR and the other family C GPCRs are thought to bind principally to their respective ECDs. In contrast, most other GPCRs binding small ligands, such as epinephrine or dopamine, have binding sites within their TMDs and/or extracellular loops (ECLs). The ligand-binding capacity of the family C ECDs probably has its origin in a family of extracellular binding proteins in bacteria (Felder *et al*., 1999), the so-called periplasmic binding proteins (PBPs). These serve as receptors for a wide variety of small ligands present in the environment, including ions (including Mg_o^{2+}, but apparently not Ca_o^{2+}), amino acids, and other nutrients (Tam and Saier, 1993). PBPs promote bacterial chemotaxis toward these environmental nutrients and other substances and facilitate their cellular uptake by activating specific transport systems in the cell membrane (Tam and Saier, 1993).

The family C GPCRs, therefore, can be thought of as representing fusion proteins, which comprise an extracellular ligand-binding motif (the ECD) linked to a signal-transducing motif (the seven transmembrane domains) that couples the sensing of extracellular signals to intracellular signaling systems (i.e., G proteins and their associated second messenger pathways). It is of interest that some of the biological functions regulated by the CaR are the same as those controlled by the PBPs, namely chemotaxis (e.g., of monocytes toward elevated levels of Ca_o^{2+}; Sugimoto *et al*., 1993) and cellular transport (i.e., of Ca_o^{2+} by CaR-regulated, Ca^{2+}-permeable channels; Chang *et al*., 1995). Moreover, as described later, the CaR binds not only Ca_o^{2+} but also additional ligands, including amino acids (Conigrave *et al*., 2000), which further supports its evolutionary and functional relationships to the other family C GPCRs and, ultimately, to PBPs.

BIOCHEMICAL PROPERTIES OF THE CaR

Studies using chimeric receptors comprising the ECD of the CaR coupled to the TMDs and C tail of the mGluRs (and vice versa) have demonstrated the existence of key binding sites for Ca_o^{2+} within the CaR's ECD (Brauner-Osborne *et al*., 1999; Silve *et al*., 2005), although even a receptor lacking the entire ECD still has the capacity to respond to polyvalent cations (Hu and Spiegel, 2003). Studies have indicated that specific residues within the ECD (e.g., Ser147 and Ser170) may be involved, directly or indirectly, in the binding of Ca_o^{2+} (Silve *et al*., 2005; Huang *et al*., 2007b). Given the apparent "positive cooperativity" of the CaR and the resultant steep slope of the curve describing its activation by various polycationic agonists (e.g., Ca_o^{2+} and Mg_o^{2+}; Brown, 1991), however, it is likely that the CaR binds several calcium ions. This positive cooperativity is essential to ensure that the CaR responds over the narrow range of Ca_o^{2+} regulating, for instance, PTH secretion. This cooperativity could result, at least in part, from the presence of Ca_o^{2+}-binding sites on both of the individual ECDs within the dimeric CaR (see later discussion) as well as the existence of more than one binding site within each receptor monomer. Further work is needed, therefore, in defining more precisely the identity of the CaR's Ca_o^{2+}-binding site(s). Eventual solution of the three-dimensional structure of the receptor's ECD by x-ray crystallography will no doubt illuminate how the CaR binds Ca_o^{2+} and its other agonists and modulators.

As noted earlier, the CaR resides on the cell surface primarily in the form of a dimer (Bai *et al*., 1998a; Ward *et al*., 1998). CaR monomers within the dimeric receptor are linked by disulfide bonds within their ECDs that involve the cysteines at amino acid positions 129 and 131 (Ray *et al*., 1999). Moreover, functional interactions can occur between the monomeric subunits of the dimeric CaR because two individually inactive CaRs that harbor inactivating mutations in different functional domains (e.g., the ECD and C tail) can reconstitute substantial biological activity when they heterodimerize after cotransfection in human embryonic kidney (HEK293) cells (Bai *et al*., 1999). Therefore, even though the individual CaRs lack biological activity, they "complement" one another's defects through a mechanism that must involve intermolecular interactions to form a partially active heterodimer. In addition to forming homodimers with itself, the CaR can also heterodimerize with the mGluRs (Gama *et al*., 2001)as well as the $GABA_B$ receptors (Cheng *et al*., 2006). In the latter case, heterodimerization changes the cell surface expression as well as the functional properties of the CaR (Cheng *et al*., 2006).

The ECD of the CaR on the cell surface is N-glycosylated extensively with complex carbohydrates (Bai *et al*., 1996). Eight of the predicted N-glycosylation sites in the ECD of the human CaR are glycosylated (Ray *et al*., 1998). Disrupting four or five of these sites decreases the cell surface expression of the receptor by 50% to 90%. Therefore, glycosylation of at least three sites is required for robust cell surface expression, although glycosylation per se does not appear to be critical for the capacity of the CaR to activate its intracellular signaling pathways (Ray *et al*., 1998).

Within its intracellular loops and C tail, the human CaR harbors five predicted protein kinase C (PKC) and two predicted protein kinase A (PKA) phosphorylation sites (Bai *et al*., 1998b; Garrett *et al*., 1995b). Activation of PKC diminishes CaR-mediated stimulation of phospholipase C (PLC), and studies utilizing site-directed mutagenesis have demonstrated that phosphorylation of a single, key PKC site in the C tail of the CaR at Thr888 can account for most of the inhibitory effect of PKC on the function of the receptor (Bai *et al*., 1998b; Davies *et al*., 2007). Therefore, PKC-induced phosphorylation of the C tail may afford a means of conferring negative feedback regulation on the coupling of the receptor to PLC. That is, PLC-elicited activation of protein kinase C—through the ensuing phosphorylation of the CaR at Thr888—limits further activation of this pathway. The functional significance of the PKA sites is not fully elucidated, although one study found that PKA synergized with PKC in inhibiting CaR-mediated activation of PLC (Bosel *et al*., 2003).

BINDING PARTNERS OF THE CaR AND THEIR BIOLOGICAL ROLES

A number of molecular binding partners of the CaR have been identified that provide insights into the molecular details of the receptor's trafficking to the cell surface, its signaling and other biological functions, and its desensitization and degradation. During its initial biosynthesis, the capacity of the CaR to successfully reach the cell surface depends, at least in some cells, on its capacity to bind to receptor activity-modifying proteins (RAMPs; Bouschet *et al*., 2005). The CaR in parathyroid and likely in other cells resides within caveolae, flask-like invaginations of the plasma membrane (Kifor *et al*., 1998), where it binds directly or indirectly to caveolin-1, a key structural protein within caveolae that binds to multiple other proteins, including signaling molecules such as G proteins (Williams and Lisanti, 2004). The C tail of the cell surface CaR interacts with filamin-A, an actin-binding protein that, like caveolin-1, serves a scaffolding function by binding multiple classes of proteins (Hjalm *et al*., 2001); (Awata *et al*., 2001). The CaR's capacity to activate MAPKs, such as ERK1/2 (see next section) depends, in part, on its physical interaction with filamin-A (and likely the latter's capacity to bind various MAPK components; Hjalm *et al*., 2001; (Awata *et al*., 2001). The CaR's capacity to activate the low-molecular-weight G protein, Rho, via the Rho guanine nucleotide exchange factor, RhoGEF, also depends on the receptor's binding to filamin-A (Pi *et al*., 2002). The CaR's C tail has recently been shown to bind to two potassium channels, Kir4.1 and 4.2, an interaction that inhibits the activities of these channels (Huang *et al*., 2007a). The CaR is noteworthy for the limited extent to which it is desensitized on repeated exposure to Ca_o^{2+} and other polycationic agonists, e.g., in parathyroid cells, which depends, in part, on its tethering to the actin-based cytoskeleton by filamin-A (Zhang and Breitwieser, 2005). However, it does desensitize in heterologous systems following its phosphorylation by (1) PKC, which reduces the CaR's capacity to activate PLC or (2) G protein-coupled receptor kinases (GRK) and subsequent binding of the phosphorylated receptor to the adapter protein, β-arrestin (Lorenz *et al*., 2007). The latter decreases its capacity to activate G proteins. Although there is only limited information on the fate of the desensitized receptor, a portion of it can undergo proteasomal degradation after binding to the ubiquitin ligase, dorfin, and subsequent ubiquitination (Huang *et al*., 2006).

INTRACELLULAR SIGNALING BY THE CaR

Activation of the CaR by its agonists stimulates the activities of phospholipases C, A_2 (PLA_2), and D (PLD) in bovine parathyroid cells and in HEK293 cells stably transfected with the human CaR (Kifor *et al*., 1997). In most cells, CaR-evoked activation of PLC involves the participation of the pertussis toxin-insensitive G protein(s), $G_{q/11}$ (Brown and MacLeod, 2001), although in some it can take place through a pertussis toxin-sensitive pathway, most likely via one or more isoforms of the G_i subfamily of G proteins (Emanuel *et al*., 1996). In bovine parathyroid cells and CaR-transfected HEK293 cells, CaR-mediated stimulation of PLA_2 and PLD occurs through PKC-dependent mechanisms, presumably via receptor-dependent activation of PLC (Kifor *et al*., 1997), although some studies have shown that CaR-mediated activation of PLD involves $G_{12/13}$ (Huang *et al*., 2004).

The high Ca_o^{2+}-induced, transient increase in Ca_i^{2+} in bovine parathyroid cells and CaR-transfected HEK293 cells likely results from activation of PLC (Kifor *et al*., 1997) and resultant IP_3-mediated release of intracellular Ca^{2+} stores (Bai *et al*., 1996). High Ca_o^{2+} also elicits sustained elevations in Ca_i^{2+} in both CaR-transfected HEK293 cells (Bai *et al*., 1996) and bovine parathyroid cells (Brown, 1991), acting through an incompletely defined influx pathway(s) for Ca^{2+}. Via the patch-clamp technique, we have shown that the CaR activates a Ca_o^{2+}-permeable, nonselective cation channel (NCC) in

CaR-transfected HEK cells (Ye *et al*., 1996). An NCC with similar properties is present in bovine parathyroid cells and is likewise activated by high Ca^{2+}—an effect presumably mediated by the CaR (Chang *et al*., 1995). This latter NCC may participate in the high Ca_o^{2+}-induced, sustained elevation in Ca_i^{2+} in parathyroid cells (Brown *et al*., 1990). Activation of the CaR by Ca_o^{2+} initiates oscillations in Ca_i^{2+} in several cell types (Breitwieser and Gama, 2001; Young and Rozengurt, 2002; De Luisi and Hofer, 2003), through a mechanism involving activation of PLC (Rey *et al*., 2005) and the Ca^{2+}-permeable channel, TRPC1, and this process can be modulated by PKC (Young *et al*., 2002). Amino acids stimulate a different pattern of oscillations (Young and Rozengurt, 2002), indicating that the nature of the CaR agonist can affect the signals generated by the receptor.

High Ca_o^{2+} reduces agonist-stimulated cAMP accumulation in bovine parathyroid cells markedly (Chen *et al*., 1989; Gerbino *et al*., 2005; Corbetta *et al*., 2000), an action that is thought to involve inhibition of adenylate cyclase by one or more isoforms of G_i, as it is pertussis toxin-sensitive (Chen *et al*., 1989). Other cells, however, can exhibit high Ca_o^{2+}-elicited diminution of cAMP accumulation that involves indirect pathways, including inhibition of a Ca_i^{2+}-inhibited isoform of adenylate cyclase due to the associated rise in Ca_i^{2+} (de Jesus Ferreira *et al*., 1998) or by increasing the degradation of cAMP (Geibel *et al*., 2006). The CaR also activates mitogen-activated protein kinases (MAPK) in several types of cells, including rat-1 fibroblasts (McNeil *et al*., 1998b), ovarian surface cells (McNeil *et al*., 1998a), and CaR-transfected but not non-transfected HEK293 cells (Kifor *et al*., 2001). As is the case with other GPCRs, the CaR stimulates the activity of MAPK (e.g. extracellar signal regulated kinases 1and 2 and p38 MAPK) through both PKC- and tyrosine kinase-dependent pathways. The latter involves, in part, c-Src-like cytoplasmic tyrosine kinases. The PKC-dependent activation of MAPK is presumably downstream of G_q-mediated activation of PLC, whereas that involving tyrosine kinases may utilize the G_i-dependent pathway involving $\beta\gamma$ subunits released as a consequence of the activation of this G protein (Kifor *et al*., 2001; McNeil *et al*., 1998b).

THE CaR GENE AND ITS REGULATION

Relatively little is presently known regarding the structure of the CaR gene, especially its upstream regulatory regions and the factors controlling its expression. The human CaR gene is on the long arm of chromosome 3, as demonstrated by linkage analysis (Chou *et al*., 1992), and in band 3q13.3−21, as documented by fluorescent *in situ* hybridization (Janicic *et al*., 1995). The rat and mouse CaR genes reside on chromosomes 11 and 16, respectively (Janicic *et al*., 1995). The CaR gene has seven exons: The first includes the upstream untranslated region, the next five encode various regions of the ECD, and the last encodes the rest of the CaR from its first TMD to the C terminus (Pearce *et al*., 1995). Characterization of the upstream regulatory regions of the gene will be of great interest because expression of the CaR can change in a various physiologically relevant circumstances—some of which are delineated hereafter.

Several factors increase CaR expression. Both high Ca_o^{2+} and $1,25(OH)_2D_3$ upregulate expression of the gene in certain cell types. High Ca_o^{2+} increases expression of the CaR in ACTH-secreting, pituitary-derived AtT-20 cells (Emanuel *et al*., 1996) as well as in avian (Yarden *et al*., 2000) and human parathyroid glands (Mizobuchi *et al*., 2004), whereas administration of $1,25(OH)_2D_3$ elevates expression of the CaR *in vivo* in kidney and parathyroid gland of the rat in some (Brown *et al*., 1996; Canaff and Hendy, 2002) but not all studies (Rogers *et al*., 1995). Interleukin-1β increases the level of CaR mRNA modestly in bovine parathyroid gland fragments (Nielsen *et al*., 1997) as well as in rat parathyroid and kidney (Canaff and Hendy, 2005), which may contribute to the associated reduction in PTH secretion that was observed in the former study. In rat kidney, substantial upregulation of the CaR takes place during the perinatal and immediate postnatal period; the resultant higher level of expression of the receptor then persists throughout adulthood (Chattopadhyay *et al*., 1996). There is likewise a developmental increase in expression of the CaR in rat brain. In contrast to that occurring in the kidney, however, the rise in the expression of the CaR in the brain occurs about a week postnatally (Chattopadhyay *et al*., 1997). Moreover, the increase in CaR expression in the brain is only transient—it decreases severalfold approximately 2 weeks later and reaches a lower level that remains stable thereafter (Chattopadhyay *et al*., 1997). The biological importance of these developmental changes in the expression of the receptor is currently unknown. The CaR is overexpressed in some cancers (Li *et al*., 2005), and it has been suggested to be a marker of breast cancer cells that have a propensity for metastasis to bone (Mihai *et al*., 2006) to act as a factor contributing to lytic bone disease in animal models of prostate cancer (Liao *et al*., 2006).

In contrast, several instances have been defined in which CaR expression decreases. Calf parathyroid cells exhibit a rapid, marked (80−85%) reduction in expression of the receptor after they are placed in culture (Brown *et al*., 1995; Mithal *et al*., 1995), which is likely to be a major factor that contributes to the associated reduction in high Ca_o^{2+}-evoked inhibition of PTH secretion. The expression of the CaR in rat kidney decreases in a model of chronic renal insufficiency induced by subtotal nephrectomy (Mathias *et al*., 1998). This latter reduction in CaR expression might contribute to the hypocalciuria that occurs in human renal insufficiency, as reduced renal CaR expression and/or activity increases tubular reabsorption of Ca^{2+} in humans

with inactivating mutations of the receptor (Brown, 1999). Because $1,25(OH)_2D_3$ upregulates renal CaR expression (Brown *et al.,* 1996; Canaff and Hendy, 2005), the reduction in CaR expression in the setting of impaired renal function could be the result, in part, of the concomitant decrease in circulating levels of $1,25(OH)_2D_3$ (Bringhurst *et al.,* 1998). As in parathyroid cells, the CaR in several other cells types is thought to serve as an inhibitor of cell proliferation, e.g., in cells from the colonic crypts (Kallay *et al.,* 2003) and in keratinocytes (Tu *et al.,* 2004). Therefore, the reduced expression in some colon cancers may contribute to tumorigenesis (Kallay *et al.,* 2003; Bhagavathula *et al*., 2005).

ROLES OF THE CaR IN TISSUES MAINTAINING Ca_o^{2+} HOMEOSTASIS

Parathyroid

The parathyroid glands of several species express high levels of CaR mRNA and protein, including those of humans (Kifor *et al*., 1996), rats (Autry *et al*., 1997), mice (Ho *et al.,* 1995), rabbits (Butters *et al.,* 1997), and chickens (Diaz *et al.,* 1997). Indeed, the level of CaR expression in the parathyroid chief cells is one of the highest, if not the highest, in the cells and tissues examined to date. Abundant evidence supports the importance of the CaR as the key mediator of the inhibitory action of elevated Ca_o^{2+} on PTH secretion. As noted earlier, the reduced CaR expression in bovine parathyroid cells maintained in culture is associated with a progressive loss of high Ca_o^{2+}-induced inhibition of PTH secretion (Brown et al., 1995; Mithal *et al.,* 1995). In addition, individuals with familial hypocalciuric hypercalcemia (FHH), who are heterozygous for inactivating mutations of the CaR gene (Brown, 1999), or mice that are heterozygous for targeted disruption of the CaR gene (Ho *et al.,* 1995) exhibit modest right shifts in their set points for Ca_o^{2+}-regulated PTH secretion (the level of high Ca_o^{2+} half-maximally inhibiting PTH release), indicative of "Ca_o^{2+} resistance" Moreover, humans and mice homozygous for loss of the normal CaR (Brown, 1999; Ho *et al.,* 1995) show much greater impairment of high Ca_o^{2+}-elicited suppression of PTH release, showing that that the "Ca_o^{2+} resistance" of the parathyroid is related inversely to the number of normally functioning CaR alleles. Therefore, the biochemical findings in mice in which the CaR has been "knocked out," as well as in humans with naturally occurring inactivating mutations of the CaR, prove the central role of the CaR in Ca_o^{2+}-regulated PTH release. Despite several decades of study, however, the principal intracellular signaling mechanism(s) through which the CaR inhibits PTH secretion remains enigmatic (for review, see Diaz *et al.,* 1998). However, recent evidence indicates that activation of the $G_{q/11}$ pathway is essential, since mice with knockout of both of these G proteins have severe hyperparathyroidism mimicking that present in mice homozygous for knockout of the CaR itself (Wettschureck *et al.,* 2007). By a series of poorly defined steps, the CaR eventually induces polymerization of the actin-based cytoskeleton in a way that may provide a physical impediment to the release of PTH-containing secretory vesicles (Quinn *et al.,* 2007).

Another aspect of parathyroid function that is likely to be CaR regulated is PTH gene expression. Garrett *et al.* (1995a) showed in preliminary studies that the "calcimimetic" CaR activator NPS R-568, which activates the receptor allosterically through a mechanism involving an increase in the apparent affinity of the CaR for Ca_o^{2+} (Nemeth *et al.,* 1998b), decreases the level of PTH mRNA in bovine parathyroid cells. More recent studies (Levi *et al.,* 2006) have documented that the same calcimimetic reduces the elevated level of preproPTH mRNA in rats with experimentally induced secondary hyperparathyroidism owing to subtotal nephrectomy. This effect is post-transcriptional and involves modulation of the binding of the transacting factor, AUF1, to preproPTH mRNA. Finally, the CaR, directly or indirectly, tonically inhibits the proliferation of parathyroid cells, because persons homozygous for inactivating mutations of the CaR (Brown, 1999) or mice homozygous for "knockout" of the CaR gene (Ho *et al.,* 1995) exhibit marked parathyroid cellular hyperplasia. Treatment of rats with experimentally induced renal impairment with calcimimetics prevents the parathyroid hyperplasia that would otherwise be anticipated to occur in this setting (Wada *et al.,* 1998; Colloton *et al.,* 2005), providing further evidence that activation of the CaR suppresses parathyroid cellular proliferation.

C Cells

Unlike the effect of Ca_o^{2+} on PTH release, elevating Ca_o^{2+} stimulates CT secretion—a response that conforms to the classical, positive relationship between Ca_o^{2+} and activation of exocytosis in most other hormone-secreting cells (Bringhurst *et al.,* 1998; Brown, 1991). This observation was one of several pieces of indirect evidence that the mechanism underlying Ca_o^{2+} sensing in C cells might differ in a fundamental way from that in parathyroid cells. More recent data, however, have demonstrated that rat, human, and rabbit C cells express the CaR (Butters *et al.,* 1997; Freichel *et al.,* 1996; Garrett *et al.,* 1995c). Moreover, cloning of the CaR from a rat C cell tumor cell line showed it to be identical to that expressed in rat kidney (Garrett *et al.,* 1995c). Available evidence, albeit limited, indicates that the CaR mediates the stimulatory effect of high Ca_o^{2+} on CT secretion; namely, there is a shift to the right in the relationship between the serum calcium concentration and CT levels in mice heterozygous for knockout of the CaR gene (Fudge and Kovacs, 2004). Tamir and co-workers have suggested that the following sequence of steps mediates CaR-stimulated CT secretion (McGehee *et al.,* 1997). High Ca_o^{2+} first stimulates phosphatidylcholine-specific PLC,

which generates diacylglycerol, thereby activating an NCC through a PKC-dependent mechanism. The activated NCC then enhances cellular uptake of Na^+ and Ca^{2+}, producing cellular depolarization and consequent stimulation of voltage-dependent, principally L-type Ca^{2+} channels that elevate Ca_i^{2+} and activate exocytosis of 5-hydroxytryptamine- and CT-containing secretory granules.

Kidney

In the kidney of the adult rat, the CaR is expressed along almost the entire nephron, with the highest levels of protein expression at the basolateral aspect of the epithelial cells of the cortical thick ascending limb (CTAL; Riccardi *et al.,* 1998). The CTAL plays a key role in the hormone (e.g., PTH-regulated reabsorption of divalent minerals (De Rouffignac and Quamme, 1994; Friedman and Gesek, 1995)). The CaR is also present on the basolateral membranes of the cells of the distal convoluted tubule (DCT), where Ca^{2+} reabsorption—similar to that in the CTAL—is stimulated by PTH. Further sites of renal CaR expression include the base of the microvilli of the proximal tubular brush border (Riccardi *et al.,* 1998), the basolateral surface of the tubular cells of the medullary thick ascending limb (MTAL; Riccardi *et al.,* 1998), and the luminal side of the epithelial cells of the inner medullary collecting duct (IMCD; Sands *et al.,* 1997). None of these latter three nephron segments play major roles in renal Ca_o^{2+} handling, but the CaR expressed in them could conceivably modulate the handling of other solutes and/or water. As will be discussed in more detail later, the CaR in the CTAL, in addition to modulating reabsorption of Ca^{2+} and Mg^{2+}, also participates in controlling the renal handling of Na^+, K^+, and Cl^- (Hebert *et al.,* 1997). Finally, the CaR expressed in the IMCD likely mediates the well-recognized inhibitory action of high Ca_o^{2+} on vasopressin-evoked water reabsorption (Sands *et al.,* 1997, 1998), which is one cause of the defective urinary-concentrating ability in some patients with hypercalcemia (Brown, 1999; Brown *et al.,* 1999).

In the proximal tubule, activation of the CaR inhibits PTH-stimulated phosphaturia (Ba *et al.,* 2003) and increases expression of the vitamin D receptor (Maiti and Beckman, 2007), which could conceivably contribute to the direct, high calcium-induced lowering of $1,25(OH)_2D_3$ levels in parathyroidectomized, PTH-infused rats (Weisinger *et al.,* 1989). The localization of the CaR on the basolateral membrane in the CTAL indicates that it might represent the mediator of the previously demonstrated inhibitory effect of high peritubular but not luminal levels of Ca_o^{2+} on Ca^{2+} and Mg^{2+} reabsorption in perfused tubular segments from this portion of the nephron (De Rouffignac and Quamme, 1994). Figure 2 shows a schematic illustration

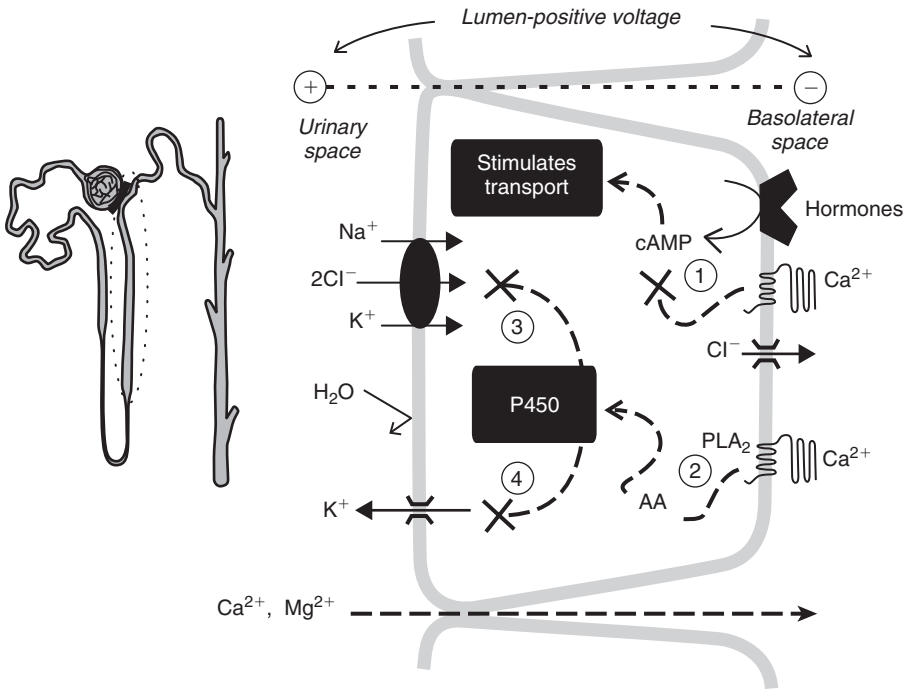

FIGURE 2 Possible mechanisms by which the CaR modulates intracellular second-messenger pathways and ionic transport in the CTAL. Hormones that elevate cAMP (i.e., PTH) stimulate paracellular Ca^{2+} and Mg^{2+} reabsorption by increasing the activities of the Na^+-K^+-$2Cl^-$ cotransporter and an apical K^+ channel and, therefore, increasing the magnitude of V_t. The CaR, which like the PTH receptor is on the basolateral membrane, inhibits PTH-stimulated adenylate cyclase and activates PLA_2 (2). This latter action increases free arachidonic acid, which is metabolized by the P450 pathway to an inhibitor of the apical K^+ channel (4) and, perhaps, the cotransporter (3). Actions of the CaR on both adenylate cyclase and PLA_2 will reduce V_t and, therefore, diminish paracellular divalent cation transport. Reproduced with permission from Brown and Hebert (1997a).

of how the CaR may inhibit PTH-enhanced divalent cation reabsorption in the CTAL. As indicated in detail in Figure 2, the CaR acts in a "Lasix-like" fashion to diminish overall activity of the Na^+-K^+-$2Cl^-$ cotransporter, which generates the lumen-positive, transepithelial potential gradient that normally drives passive paracellular reabsorption of about 50% of NaCl and most of the Ca^{2+} and Mg^{2+} in this part of the nephron (Hebert *et al.,* 1997). Some studies, however, while demonstrating inhibition of calcium transport in CTAL by elevating peritubular Ca_o^{2+}, failed to show any concomitant reduction in NaCl or magnesium transport or in the transepithelial potential (DesFleurs *et al.,* 1998), or else have documented inhibitory effects of peritubular calcium on not only paracellular but also transepithelial Ca^{2+} transport (Motoyama and Friedman, 2002). Further studies are needed to resolve these differences. It is of interest that individuals with FHH manifest a markedly reduced ability to upregulate urinary excretion of Ca^{2+} despite their hypercalcemia—even when they have been rendered aparathyroid by total parathyroidectomy (Attie *et al.*, 1983). Thus, the PTH-independent, excessive reabsorption of Ca^{2+} in FHH likely results, in part, from a decreased complement of normally functioning CaRs in the CTAL. This defect renders the tubule "resistant" to Ca_o^{2+} and reduces the normal, high Ca_o^{2+}-evoked hypercalciuria that occurs in this nephron segment (Brown, 1999). Thus, in normal persons, hypercalcemia-evoked hypercalciuria likely has two distinct CaR-mediated components: (1) suppression of PTH secretion and (2) direct inhibition of tubular reabsorption of Ca^{2+} in the CTAL.

It is not presently known whether the CaR modulates PTH-stimulated Ca^{2+} reabsorption in the DCT, which could potentially occur via inhibition of PTH-stimulated cAMP accumulation. In addition, extracellular Ca^{2+} has been shown to modulate the expression of key, vitamin D—inducible genes involved in transcellular Ca^{2+} transport in this nephron segment, namely, the apical uptake channel TRPV5, calbindin D and the basolateral calcium pump, PMCA2b, and exchanger, NCX1 (Thebault *et al.,* 2006). These changes take place both indirectly, by high Ca^{2+}-elicited changes in PTH secretion and pari passu $1,25(OH)_2D_3$ production, as well as by apparently direct renal actions of Ca_o^{2+} that are independent of $1,25(OH)_2D_3$. The contribution of these actions of Ca_o^{2+} to the function of DCT in tubular reabsorption of Ca^{2+} under normal circumstances is not currently known.

Intestine

The intestine is a key participant in maintaining Ca_o^{2+} homeostasis by virtue of its capacity for regulated absorption of dietary Ca_o^{2+} through the action of $1,25(OH)_2D_3$, the most active naturally occurring metabolite of vitamin D (Bringhurst *et al.,* 1998; Brown, 1991). The duodenum is the principal site for 1,25-dihydroxyvitamin D_3 $[1,25(OH)_2D_3]$-stimulated intestinal Ca^{2+} absorption through a transcellular pathway of active transport. The latter is thought to involve initial Ca^{2+} entry through the recently identified Ca^{2+}-permeable channel, TRPV6 (previously known as CaT1 or ECaC2; Peng *et al.,* 1999; Hoenderop *et al.,* 1999). As with the transcellular transport of Ca^{2+} in DCT, calcium ions subsequently diffuse across the cell—a process facilitated by the vitamin D − dependent Ca^{2+}-binding protein, calbindin D_{9K}—and are eventually extruded at the basolateral cell surface by the Ca^{2+}-ATPase and, perhaps, the Na^+-Ca^{2+} exchanger (Thebault *et al.,* 2006). Jejunum and ileum absorb less Ca^{2+} than duodenum (particularly when expressed as absorption per unit surface area). They also secrete Ca^{2+}, which may chelate fatty acids and bile acids, thereby producing insoluble "calcium soaps" and mitigating possible damaging effects of free fatty acids and bile salts on colonic epithelial cells. The major function of the colon in fluid and electrolyte metabolism is the absorption of water and Na^+. Nevertheless, it absorbs substantial amounts of Ca^{2+} in humans by both vitamin D-dependent and -independent routes, especially in its proximal segments (Favus, 1992), where it expresses levels of TRPV6 similar to those in the duodenum (Peng *et al.,* 1999).

The CaR is expressed in all segments of the intestine in the rat. The highest levels of expression of the receptor are on the basal surface of the small intestinal absorptive cells, the epithelial cells of the crypts of both the small intestine and colon, and in the enteric nervous system (Chattopadhyay *et al.,* 1998). Does the CaR have any role in systemic Ca_o^{2+} homeostasis in these locations? There are several direct actions of Ca_o^{2+} on intestinal function. Hypercalcemia inhibits dietary Ca^{2+} absorption (Krishnamra *et al.,* 1994). Recent studies have also shown apparently direct actions of dietary and/or extracellular Ca^{2+} on the expression of TRPV6, calbindin D_{9K}, and PMCA2B in mice with knockout of the 1-hydroxylase gene, which are of uncertain physiological significance at present but document the capacity of the GI tract to sense Ca_o^{2+} (Hoenderop *et al.,* 2004). Moreover, direct measurements of Ca_o^{2+} within the interstitial fluid underneath small intestinal absorptive epithelial cells has shown that Ca_o^{2+} increases by nearly twofold if luminal levels of Ca_o^{2+} are elevated to 5 to 10 mM—similar to those achieved after the intake of Ca^{2+}-containing foods (Mupanomunda *et al.,* 1999). This level of Ca_o^{2+} would be more than sufficient to stimulate the CaR expressed on the basolateral surface of small intestinal absorptive cells. The CaR expressed in the enteric nervous system, which regulates the secretomotor functions of the gastrointestinal tract, could potentially mediate known effects of high and low Ca_o^{2+} to reduce and increase GI motility, respectively, in hyper- and hypocalcemic individuals (Bringhurst *et al.,* 1998). Such an effect on gastrointestinal motility, however, even if it were CaR-mediated, would not have any obvious relevance to

systemic Ca_o^{2+} homeostasis, other than perhaps indirectly, by modulating the time available for absorption of Ca^{2+} and other nutrients.

Bone and Cartilage

The levels of Ca_o^{2+} achieved within the bony microenvironment probably vary substantially during the regulated turnover of the skeleton via osteoclastic resorption of bone followed by its restoration by bone-forming osteoblasts—a process that totally replaces the human skeleton approximately every 10 years (Bringhurst *et al.,* 1998). In fact, Ca_o^{2+} directly beneath resorbing osteoclasts can be as high as 8 to 40 m*M* (Silver *et al.,* 1988). Moreover, Ca_o^{2+} has a variety of actions on bone cell functions *in vitro* that could serve physiologically useful purposes, although it is not yet known whether these same actions occur *in vivo.* For example, high Ca_o^{2+} stimulates parameters of osteoblastic functions that could enhance their recruitment to sites of future bone formation, including chemotaxis and proliferation, and promote their differentiation to osteoblasts with a more mature phenotype (Quarles, 1997; Yamaguchi *et al.,* 1999; Dvorak *et al.,* 2004). Furthermore, elevated levels of Ca_o^{2+} suppress both the formation (Kanatani *et al.,* 1999) and the activity (Zaidi *et al.,* 1999) of osteoclasts *in vitro.* Therefore, Ca_o^{2+} has effects on cells of both the osteoblastic and osteoclastic lineages and/or their precursors that are homeostatically appropriate. Raising Ca_o^{2+} would, for example, produce net movement of Ca^{2+} into bone by stimulating bone formation and inhibiting its resorption. In addition, locally elevated levels of Ca_o^{2+} produced by osteoclasts at sites of active bone resorption could potentially contribute to "coupling" bone resorption to the ensuing replacement of the missing bone by osteoblasts, by promoting proliferation and recruitment of preosteoblasts within the vicinity to these sites and enhancing their differentiation (Quarles, 1997; Yamaguchi *et al.,* 1999). As detailed later, the molecular identity of the Ca_o^{2+}-sensing mechanism(s) in bone cells remain(s) controversial, although the CaR has been found by several groups of investigators to be present in at least some cells of both osteoblast and osteoclast lineages and could, therefore, potentially participate in this process.

Substantial indirect evidence amassed prior to and around the time that the CaR was cloned suggested that the Ca_o^{2+}-sensing mechanism in osteoblasts and osteoclasts differed in certain pharmacological and other properties from those exhibited the CaR (Quarles, 1997; Zaidi *et al.,* 1999). Moreover, some investigators have been unable to detect expression of the CaR in osteoblast-like (Pi *et al.,* 1999) and osteoclast-like cells (Seuwen *et al.,* 1999). More recent studies, however, have provided strong support for the presence of the CaR in a variety of cells originating from the bone and bone marrow, although its physiological and functional implications in these cells remain uncertain. These CaR-expressing cells include hematopoietic stem cells (Adams *et al.,* 2006), erythroid and platelet progenitors, cells of the monocytic lineage (Yamaguchi *et al.,* 1998d) [but not granulocytes (House *et al.,* 1997)], and cells of both the osteoblast and osteoclast lineages when studied *in situ* in sections of bone (Yamaguchi *et al.,* 1999; Chang *et al.,* 1999b; Dvorak *et al.,* 2004). ST-2 stromal cells (Yamaguchi *et al.,* 1998a), a stromal cell line derived from the same mesenchymal stem cells giving rise to osteoblasts, express CaR mRNA and protein, as do osteoblast-like cell lines (e.g., the Saos-2, MC-3T3-E1, UMR-106, and MG-63 cell lines; Chang *et al.,* 1999b; Yamaguchi *et al.,* 1998b, 1998c). Regarding cells of the osteoclast lineage, more than 80% of human peripheral blood monocytes, which arise from the same hematopoietic lineage that gives rise to osteoclast precursors, express abundant levels of CaR mRNA and protein (Yamaguchi *et al.,* 1998d). Preosteoclast-like cells generated *in vitro* also show expression of the CaR (Kanatani *et al.,* 1999), and osteoclasts isolated from rabbit or mouse bone likewise express the receptor (Kameda *et al.,* 1998; Mentaverri *et al.,* 2006). In murine, rat, and bovine bone sections, in contrast, only a minority of the multinucleated osteoclasts expressed CaR mRNA and protein (Chang *et al.,* 1999b). Additional studies are required to clarify whether primarily osteoclast precursors, rather than mature osteoclasts, express the CaR and whether the CaR actually mediates some or even all of the known actions of Ca_o^{2+} on these cells. One study failed to detect expression of the CaR in transformed osteoblast-like cells derived from either wild-type mice or those with knockout of the CaR (Pi *et al.,* 2000). However, these cells still showed some responses to Ca_o^{2+} and Al^{3+} (e.g., mitogenesis), suggesting the presence of another Ca_o^{2+} sensor, as this group has suggested in earlier studies (Quarles *et al.,* 1997). This group has recently suggested that the basic amino acid-sensing, family C receptor, GPRC6A, represents the key Ca_o^{2+}–sensing mechanism present in osteoblasts (Pi *et al.,* 2005).

Although chondrocytes—the cells that form cartilage—do not participate directly in systemic Ca_o^{2+} homeostasis, they play a key role in skeletal development and growth by providing a cartilaginous model of the future skeleton that is gradually replaced by actual bone. Furthermore, the growth plate represents a site where chondrocytes play a crucial role in the longitudinal growth that persists until the skeleton is fully mature at the end of puberty. The availability of Ca^{2+} is important for ensuring proper growth and differentiation of chondrocytes and resultant skeletal growth *in vivo* (Jacenko and Tuan, 1995; Reginato *et al.,* 1993). Moreover, changing the level of Ca_o^{2+} *in vivo* modulates the differentiation and/or other properties of cells of the cartilage lineage (Bonen and Schmid, 1991; Wong and Tuan, 1995). Chondrocytes arise from the same mesenchymal stem cell lineage that gives rise to osteoblasts,

smooth muscle cells, adipocytes, and fibroblasts (Boyan *et al.,* 1999; Dennis *et al.,* 1999). It is interesting, therefore, that the rat cartilage cell line, RCJ3.1C5.18, showed readily detectable levels of CaR mRNA and protein (Chang *et al.,* 1999a). In addition, some cartilage cells in sections of intact bone express CaR mRNA and protein, including the hypertrophic chondrocytes in the growth plate, which are key participants in the growth of long bones (Chang *et al.,* 1999b). Thus the CaR is a candidate for mediating, at least in part, the previously described direct actions of Ca_o^{2+} on chondrocytes and cartilage growth.

In fact, elevating Ca_o^{2+} exerts several direct effects on RCJ3.1C5.18 cells, namely, dose dependently reducing the levels of the mRNAs that encode a major proteoglycan in cartilage, aggrecan, the α_1 chains of type II and X collagens, and alkaline phosphatase (Chang *et al.,* 1999a). In addition, treatment of this cell line with a CaR antisense oligonucleotide for 48 to 72 hours reduced the level of CaR protein expression significantly, in association with enhanced expression of aggrecan mRNA (Chang *et al.,* 1999a), suggesting a mediatory role of the CaR in regulating this gene. This same group has recently shown that chondrocytes isolated from CaR knockout mice retain responsiveness to Ca_o^{2+}. However, this residual activity may result from the fact that these mice are able to splice out exon 5, which was inactivated by insertion of the neomycin gene, to yield an in-frame, modestly truncated receptor that may have residual biological activity (Rodriguez *et al.,* 2005). These results demonstrate, therefore, that (1) Ca_o^{2+} modulates the expression of several important genes in chondrocytic cells, (2) chondrocytic cells express CaR mRNA and protein, and (3) the CaR mediates at least some of these actions of Ca_o^{2+} in this cell type. Thus the CaR could potentially not only modulate bone turnover and/or the coupling of bone resorption to its later replacement by osteoblasts through its actions on bone cells and/or their precursors, but might also participate in the control of skeletal growth through its effects on chondrocytes.

THE CaR AND INTEGRATION OF CALCIUM AND WATER METABOLISM

In addition to its roles in tissues involved directly in Ca_o^{2+} homeostasis, increasing evidence indicates that the CaR is located in other cells and tissues where it contributes to integrating the functions of distinct homeostatic systems, as discussed in this section. An illustrative example is the capacity of the CaR to integrate certain aspects of mineral and water metabolism. Some hypercalcemic patients exhibit reduced urinary concentrating capacity and, occasionally, frank nephrogenic diabetes insipidus (Gill and Bartter, 1961; Suki *et al.,* 1969). In addition, simply the presence of hypercalciuria, without accompanying hypercalcemia, can impair urinary concentrating ability, as illustrated by the enuresis present in some hypercalciuric children, which resolves with dietary calcium restriction and resolution of the hypercalciuria (Valenti *et al.,* 2002). The presence of the CaR in several segments of the nephron that participate in regulating urinary concentration (Riccardi *et al.,* 1998; Sands *et al.,* 1997) has suggested a novel mechanism(s) underlying the long-recognized but poorly understood inhibitory actions of high Ca_o^{2+} on renal-concentrating capacity. Studies have shown that high Ca_o^{2+}, probably by activating CaRs residing on the apical membrane of cells of the IMCD, reversibly inhibits vasopressin-elicited water flow by about 35% to 40% in perfused rat IMCD tubules (Sands *et al.,* 1997). Indeed, the CaR is present in the same apical endosomes that contain the vasopressin-regulated water channel, aquaporin-2 (Sands *et al.,* 1997). This observation indicates that the receptor potentially reduces vasopressin-enhanced water flow in the IMCD by either promoting the endocytosis or, more likely, blocking the exocytosis of these endosomes (Procino *et al.,* 2004). Furthermore, induction of chronic hypercalcemia in rats through treatment with vitamin D reduces the level of expression of the aquaporin-2 protein but not its mRNA (Sands *et al.,* 1998), which would further decrease vasopressin-activated water flow in the terminal-collecting duct. In addition to the mechanisms just described, high Ca_o^{2+}-elicited, CaR-mediated reduction in the reabsorption of NaCl in the MTAL (Wang *et al.,* 1996, 2001), by decreasing the medullary countercurrent gradient, would diminish even further the maximal urinary-concentrating power of hypercalcemic patients (Figure 3). CaR-evoked generation of prostaglandins, especially PGE_2, due to upregulation of Cox-2 in MTAL, may impair NaCl reabsorption in this nephron segment and, in turn, generation of the hypertonic interstitium needed for normal urinary concentrating ability (Wang *et al.,* 2001).

What is the evidence that these effects of high Ca_o^{2+} on the renal concentrating mechanism are mediated by the CaR? Of interest in this regard, persons with inactivating mutations of the CaR are capable of concentrating their urine normally despite their hypercalcemia (Marx *et al.,* 1981), presumably because they are "resistant" to the usual suppressive effects of high Ca_o^{2+} on the urinary-concentrating mechanism. Conversely, individuals with activating CaR mutations can develop symptoms of diminished urinary-concentrating capacity (e.g., polyuria and polydipsia), even at normal levels of Ca_o^{2+}, when treated with vitamin D and calcium supplementation, probably because their renal CaRs are overly sensitive to Ca_o^{2+} (Pearce *et al.,* 1996). These experiments in nature, therefore, support the postulated, CaR-mediated link between Ca_o^{2+} and water homeostasis.

Is the defective renal handling of water in hypercalcemic patients of any physiological relevance? We have suggested previously that it provides a mechanism that integrates the renal handling of divalent cations, especially

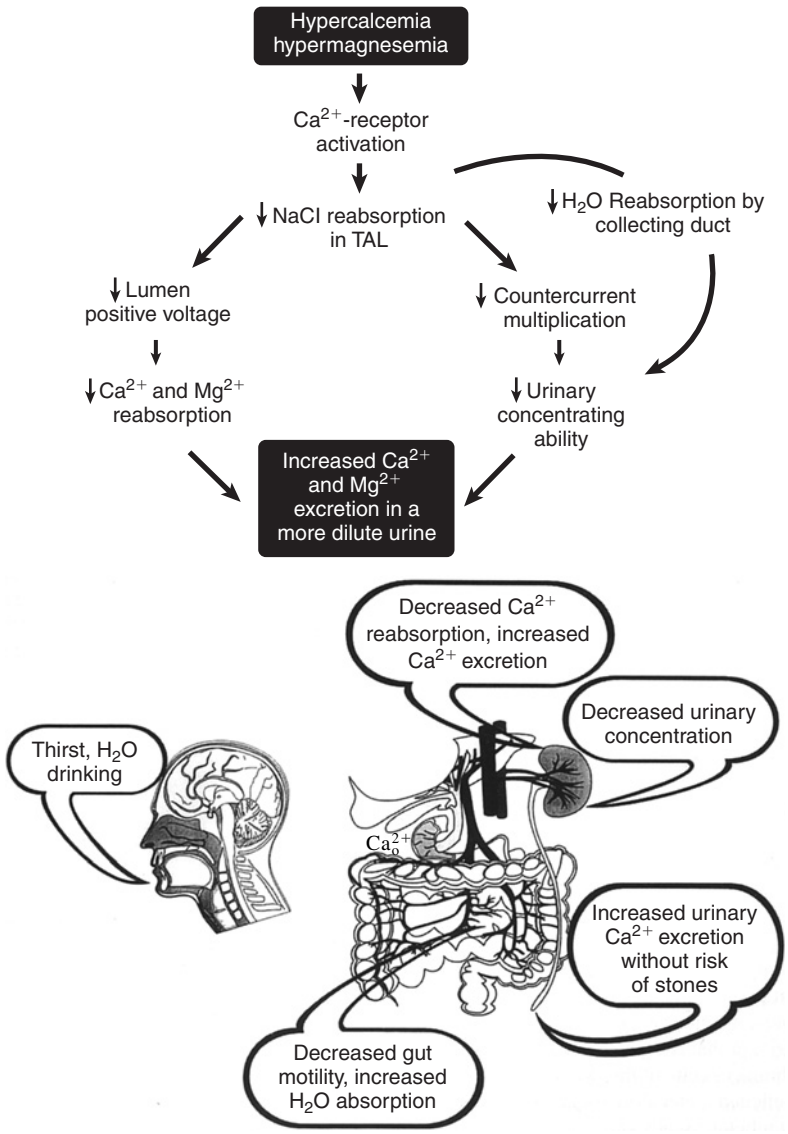

FIGURE 3 Mechanisms that may interrelate systemic Ca_o^{2+} and water homeostasis (see text for further details). (*Top*) Mechanisms through which the CaR reduces maximal urinary-concentrating ability. Reproduced with permission from Brown and Hebert (1997b). (*Bottom*) Additional extrarenal mechanisms integrating Ca_o^{2+} and water homeostasis, such as Ca_o^{2+} -evoked activation of the CaR in the SFO, which would enhance water intake and mitigate loss of free water that would otherwise result from a diminished maximal urinary-concentrating capacity. Reproduced with permission from Brown *et al*. (1996).

Ca^{2+}, and water, thereby allowing appropriate "trade-offs" in how the kidney coordinates calcium and water metabolism under specific physiological conditions (Hebert *et al.,* 1997; see Fig. 3). For example, in a situation where a systemic load of Ca^{2+}, must be disposed of, the resultant CaR-mediated inhibition of PTH secretion and direct inhibition of tubular reabsorption of Ca^{2+}, promote calciuria. The consequent elevation in luminal Ca_o^{2+} in the IMCD, particularly in a dehydrated individual, could predispose to the formation of Ca^{2+}-containing renal stones, were not for the concomitant, CaR-mediated inhibition of maximal urinary concentration. Furthermore, there are abundant CaRs in the subfornical organ (SFO; Rogers *et al.,* 1997)—an important hypothalamic thirst center (Simpson and Routenberg, 1975)—that may ensure a physiologically appropriate increase in drinking. This increased intake of free water could prevent dehydration that might otherwise be a consequence of renal loss of free water due to the concomitant, CaR-induced inhibition of the urinary-concentrating mechanism (see Fig. 3).

Finally, available data support the existence of a "calcium appetite" in rats (Tordoff, 1994) that may furnish a mechanism for modulating the intake of calcium-containing foods in a physiologically relevant manner

during hypo- and hypercalcemia. Some reduction in the intake of Ca_o^{2+}-containing foods might also occur as a result of the activation of CaRs in the area postrema of the brain—a "nausea center" (Rogers *et al.,* 1997)—due to the resultant anorexia/nausea. Calcium appetite, in contrast, appears to be mediated by the subfornical organ (McCaughey *et al.,* 2003). The role of the CaR in either of these actions, however, is currently conjectural. We have hypothesized, therefore, that the CaR mediates multiple layers of integration and coordination of the homeostatic systems governing water and calcium metabolism. In doing so, it may contribute to the ability of terrestrial organisms to adjust to the only intermittent availability of environmental calcium and water (Hebert *et al.,* 1997).

CaR-mediated modulation of vasopressin-induced water flow in the IMCD represents an example of "local" Ca_o^{2+} homeostasis. That is, Ca_o^{2+} within a specific microenvironment, which is outside of the blood and the various compartments of the ECF in direct contact with the circulation, is only allowed to rise to a certain level (Brown *et al.,* 1999). Interestingly, changes in the level of Ca_o^{2+} resulting from the mechanism governing systemic Ca_o^{2+} homeostasis are traditionally thought to occur through fine adjustments of the movements of Ca^{2+} into or out of the ECF (i.e., by intestine, bone, or kidney; Brown, 1991). In contrast, CaR-mediated regulation of Ca_o^{2+} in the IMCD primarily results from alterations in the movement of water. Perhaps even this formulation is oversimplified. On the one hand, vasopressin is known to increase distal tubular reabsorption of calcium (Hoenderop *et al.,* 2000), which would also reduce the level of Ca_o^{2+} in the collecting duct. On the other, the increased thirst in hypercalcemic patients, in addition to providing more free water so as to mitigate any associated rise in Ca_o^{2+} in the IMCD, would also dilute Ca_o^{2+} in the ECF. Further studies will no doubt illuminate additional subtleties related to how the body integrates divalent mineral and water metabolism.

OTHER CaR AGONISTS AND MODULATORS: THE CaR AS AN INTEGRATOR OF PHYSIOLOGICAL SIGNALS AND AS A "NUTRIENT SENSOR"

A variety of divalent cations (Sr_o^{2+}), trivalent cations (e.g., Gd_o^{3+}), and even organic polycations (i.e., spermine; Quinn *et al.,* 1997) are effective CaR agonists. It is likely that they all interact with one or more binding sites within the ECD of the receptor (Brown *et al.,* 1999). Only a few of these polycationic agonists, however, are thought to be present within biological fluids at levels that would activate the CaR (Quinn *et al.,* 1997). In addition to Ca_o^{2+}, Mg_o^{2+} and spermine are two such putative, physiological CaR agonists. It is probable that in specific microenvironments [e.g., within the gastrointestinal (GI) tract and central nervous system] the concentrations of spermine are high enough to activate the CaR even at levels of Ca_o^{2+} that are insufficient to do so by themselves (Brown *et al.,* 1999; Quinn *et al.,* 1997). In fact, all of the polycationic CaR agonists potentiate one another's stimulatory effects on the receptor. In other words, only small increments in the level of a given agonist (i.e., spermine) may be sufficient to activate the CaR when a threshold level of another agonist is present in the local microenvironment (e.g., Ca_o^{2+}; Brown *et al.,* 1999).

Is the CaR also a Mg_o^{2+}-sensing receptor? Some evidence supporting the role of the CaR in sensing and, therefore, "setting" Mg_o^{2+} comes from the experiments in nature that firmly established the role of the CaR as a central element in Ca_o^{2+} homeostasis. Namely, persons with hypercalcemia due to heterozygous-inactivating mutations of the CaR (e.g., FHH) exhibit serum Mg^{2+} levels that are in the upper part of the normal range or mildly elevated. Moreover, some patients with neonatal severe hyperparathyroidism due to homozygous inactivating CaR mutations can have more pronounced hypermagnesemia (Aida *et al.,* 1995a). Conversely, persons harboring activating mutations of the CaR can manifest mild reductions in Mg_o^{2+} (Brown, 1999). Mg_o^{2+} is about twofold less potent than Ca_o^{2+} on a molar basis in activating the CaR (Brown *et al.,* 1993; Butters *et al.,* 1997). One might justifiably ask, therefore, how Mg_o^{2+} could regulate its own homeostasis by modulating PTH secretion—an important component of CaR-mediated control of Ca_o^{2+}—when circulating levels of Mg_o^{2+} are, if anything, lower than those of Ca_o^{2+} (Bringhurst *et al.,* 1998)? It is possible that even small changes in Mg_o^{2+} can modulate the activity of the CaR in parathyroid cells because the receptor has been sensitized by ambient levels of Ca_o^{2+} that are close to its "set point" (i.e., on the steepest portion of the curve relating PTH to Ca_o^{2+}). A more likely scenario, however, is that acts on the CaR in the CTAL to regulate its own level in the ECF, as follows: The fraction of Mg^{2+} reabsorbed in the proximal tubule is less than for other solutes (e.g., Ca^{2+}, Na^+, Cl^-, and water). As a result, there is a 1.6- to 1.8-fold rise in the level of Mg_o^{2+}, in the tubular fluid of the CTAL (De Rouffignac and Quamme, 1994), which should, therefore, reach a sufficiently high level to activate the CaR in this nephron segment and, therefore, reduce the reabsorption of Mg_o^{2+}. Recall that not only Ca_o^{2+} but also Mg_o^{2+} inhibits the reabsorption of both divalent cations in perfused CTAL (De Rouffignac and Quamme, 1994).

Another factor modulating the actions of Ca_o^{2+} and other polycations on the CaR is ionic strength per se (e.g., alterations in the concentration of NaCl; Quinn *et al.,* 1998). Elevating ionic strength decreases and reducing ionic strength enhances the sensitivity of the CaR to activation by Ca_o^{2+} and Mg_o^{2+}. The impact of changing ionic strength on the responsiveness of the CaR to divalent cations may be especially relevant in particular microenvironments, such as the GI or urinary tracts, where

ionic strength can vary greatly, easily encompassing the range over which this parameter modulates the function of the receptor (Quinn *et al.,* 1998).

In addition to the polycationic CaR agonists just noted, novel "calcimimetic," allosteric activators of the receptor have been developed. These are small hydrophobic molecules, which are derivatives of phenylalkylamines and activate the CaR by increasing its apparent affinity for Ca_o^{2+}. They do so by interacting with the transmembrane domains of the receptor (Nemeth *et al.,* 1998b), in contrast to Ca_o^{2+} which binds to the ECD (Hammerland *et al.,* 1999). Calcimimetics are called "modulators" rather than "agonists" because they only activate the CaR in the presence of Ca_o^{2+}. In contrast, the polycationic agonists of the CaR (e.g., Gd_o^{3+}) activate it even in the nominal absence of Ca_o^{2+} (Nemeth *et al.,* 1998b). Calcimimetics have been approved for use in patients with stage 5 chronic kidney disease (i.e., on dialysis) and those with parathyroid cancer, where they provide an effective medical means of lowering PTH secretion through their direct action on the parathyroid CaR. A detailed discussion of the therapeutic utility of these agents is beyond the scope of this review, but detailed descriptions of their mechanism of action and clinical use can be found in recent reviews (Nemeth, 2004). CaR antagonists, so-called "calcilytics," are also entering clinical trials. The principal therapeutic application envisioned for these agents at the moment is in the treatment of osteoporosis (Nemeth, 2004). Because intermittent exogenous administration of PTH can produce sizable increases in bone mineral density, once-daily administration of a short-acting calcilytic would presumably accomplish the same goal by producing a "pulse" of endogenous PTH secretion (Gowen *et al.,* 2000; Nemeth *et al.,* 1998a).

Amino acids represent another class of endogenous CaR modulators (Conigrave *et al.,* 2000; Figure 4). Activation of the CaR by specific amino acids, particularly the aromatic amino acids, phenylalanine, tyrosine, histidine, and tryptophan, only occurs when Ca_o^{2+} is 1 m*M* or higher. Although individual amino acids are of relatively low potency (e.g., they act at concentrations of 0.1 to 1 m*M* or higher), a mixture of amino acids with a composition similar to that present in human serum under fasting conditions substantially enhances the sensitivity of the CaR to Ca_o^{2+}. That is, optimal concentrations of the mixture reduce the EC_{50} for Ca_o^{2+} (the level of Ca_o^{2+} half-maximally activating the receptor) by nearly 2 mM (e.g., by 40% to 50%) in HEK293 cells stably transfected with the CaR (Conigrave *et al.,* 2000). Amino acids also inhibit PTH secretion in vitro from human parathyroid cells, further supporting their biological relevance as CaR activators (Conigrave *et al.,* 2004).

Although the implications of these direct actions of amino acids on the CaR are not yet clear, they could potentially explain several long-standing but poorly understood observations appearing to link protein and Ca_o^{2+} metabolism. Additionally, they suggest future lines of research directed at elucidating the possible role of the receptor in "nutrient-sensing" more generally, rather than just as a sensor of divalent cations. For example, ingestion of a high-protein diet nearly doubles the rate of urinary calcium excretion relative to that observed on a low protein intake (Insogna and Broadus, 1987). This effect of dietary protein has traditionally been ascribed to the buffering of acidic products of protein metabolism by bone as well as a calciuric action of the acid load (Lemann *et al.,* 1966). However, direct activation of CaRs in the CTAL as a result of increases in serum levels of amino acids might contribute as well. Moreover, reducing dietary protein intake has been shown to have marked effects on circulating calciotropic hormones, nearly doubling serum PTH and $1,25(OH)_2D_3$ levels in normal women (Kerstetter *et al.,* 1997). Could these latter changes result from the concomitant decrease in the circulating levels of amino acids, despite little, if any, change in Ca_o^{2+}? Is it possible

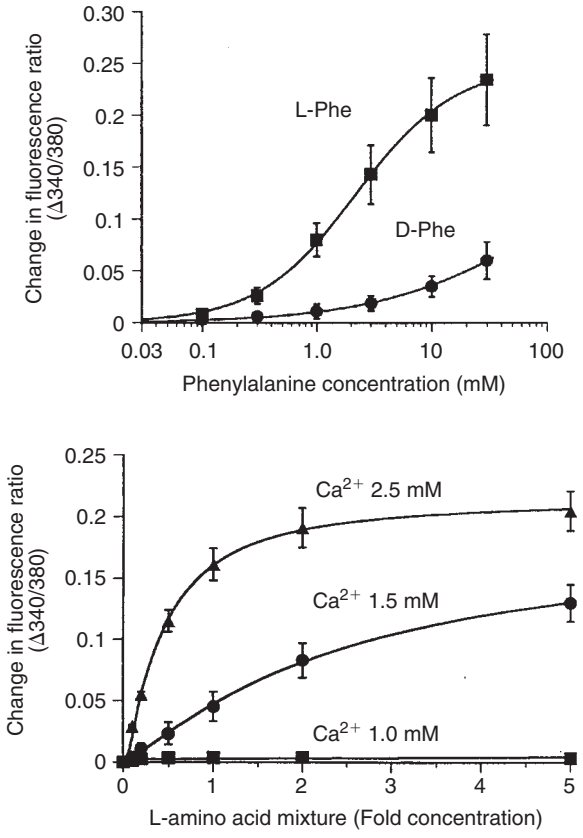

FIGURE 4 Amino acid sensing by the CaR. (*Top*) Activation of the CaR by phenylalanine (L-phenylalanine > D-phenylalanine) at 2.5 mM Ca_o^{2+} in HEK293 cells transfected stably with the CaR as reflected by amino acid-induced increases in the cytosolic Ca_o^{2+} concentration in cells loaded with the Ca_o^{2+}-sensitive intracellular dye fura-2. Increases in the fluorescence ratio (340/380 nm) indicate CaR-mediated increases in Ca_i^{2+}. (*Bottom*) Marked impact on the level of Ca_o^{2+} on the capacity of the CaR to sense the mixture of l-amino acids that emulates that present in the blood under fasting conditions (see text for details). Reproduced with permission from Conigrave *et al.* (2000).

that the reduced intake of dietary protein commonly recommended for patients with chronic renal insufficiency (Bringhurst *et al.,* 1998) actually exacerbates their secondary hyperparathyroidism?

These observations suggest that the CaR is not solely a Ca_o^{2+} (and probably a Mg_o^{2+}) receptor but may also serve as a more general "nutrient" and environmental sensor, which detects changes in Ca_o^{2+} and Mg_o^{2+}, not in isolation, but in the context of the ambient levels of certain amino acids. Further testing of this hypothesis may enhance our understanding of the mechanisms by which complex organisms coordinate homeostatic systems that have traditionally been thought of as functioning largely independently, such as those controlling protein and mineral metabolism. This homeostatic integration may be particularly important within specific parts of the life cycle, such as during somatic growth. Skeletal growth in childhood requires the precisely coordinated deposition of both bone matrix and mineral. Moreover, mineral ions and amino acids must also be assimilated during the growth of soft tissues—all of which contain varying mixtures of mineral ions and protein. For instance, smooth muscle cells contain half as much calcium as bone when expressed on the basis of wet weight (Brown and MacLeod, 2001).

Coordinating mineral ion and protein metabolism might be particularly relevant in the GI tract. Indeed, the presence of an "amino acid receptor" regulating the secretion of gastrin, gastric acid, and cholecystokinin has been postulated (Conigrave *et al.,* 2000). Furthermore, the pharmacological profile of the actions of different amino acids on these parameters is strikingly similar to that for the effects of the same amino acids on the CaR (Mangel *et al.,* 1995; McArthur *et al.,* 1983; Taylor *et al.,* 1982; Conigrave *et al.,* 2000). CaRs in the GI tract system could serve as a particularly suitable target for sensing the availability of dietary protein and mineral ions, which are generally ingested together (i.e., in milk). Further studies are needed, therefore, to investigate whether the CaR represents, in fact, this putative amino acid receptor. Such investigations may reveal whether the sensing of amino acids by the CaR, taken in the context of ambient levels of Ca_o^{2+} and Mg_o^{2+} within the GI tract and elsewhere, provides the molecular basis for a physiologically important link between the systems governing protein and mineral metabolism.

ARE THERE ADDITIONAL Ca_o^{2+} SENSORS?

As noted earlier and described in detail in other reviews (Quarles, 1997; Zaidi *et al.,* 1999; Pi *et al.,* 2005), Ca_o^{2+} sensors in addition to the CaR may exist on osteoblasts and osteoclasts. Moreover, studies have revealed that some of the mGluRs can sense Ca_o^{2+} in addition to recognizing glutamate as their principal physiological agonist, although the physiological importance of this Ca_o^{2+} sensing is not clear at present. Kubo *et al.* (1998) showed that mGluRs 1, 3, and 5 sense levels of Ca_o^{2+} between 0.1 and 10 mM, whereas mGluR2 is substantially less responsive to Ca_o^{2+}. All three of the mGluRs that are capable of sensing Ca_o^{2+} have identical serines and threonines, respectively, at amino acid positions that are equivalent to amino acid residues 165 and 188 in mGluR1a (Brauner-Osborne *et al.,* 1999). These two residues have been shown to play key roles in the binding of glutamate to the respective ECDs of the MGluRs (O'Hara *et al.,* 1993). In contrast, whereas mGluRs 1a, 3, and 5 have serines at positions equivalent to amino acid residue 166 in mGluR1a, mGluR2 has an aspartate rather than a serine at this position (Kubo *et al.,* 1998). Changing this serine to an aspartate in mGluRs 1a, 3, and 5 substantially reduces their capacities to sense Ca_o^{2+}, whereas substituting the aspartate in mGluR2 with a serine enhances its apparent affinity for Ca_o^{2+} to a level comparable to those of mGluRs 1, 3, and 5 (Kubo *et al.,* 1998). Thus the serines in mGluRs 3 and 5 at amino acid positions homologous to residue 166 in mGluR1a appear to play important roles in the capacities of these three receptors to sense Ca_o^{2+}.

Interestingly, another study has shown that changes in Ca_o^{2+} also modulate the function of the activated $GABA_B$ receptors, whereas Ca_o^{2+} has no effect on these receptors in the absence of added GABA (Wise *et al.,* 1999). Ca_o^{2+} potentiates the stimulatory effect of GABA on the binding of GTP to the receptor and increases the coupling of the $GABA_B$ receptor to stimulation of a K^+ channel and inhibition of forskolin-stimulated adenylate cyclase activity. The effects of Ca_o^{2+} on the $GABA_B$ receptor, unlike those on the CaR, were not reproduced by other polyvalent cations. Thus, similar to the CaR, which senses Ca_o^{2+} but is modulated by various amino acids (although not by glutamate; Conigrave *et al.,* 2000), mGluRs and $GABA_B$ receptors sense their primary physiological ligands, glutamate and GABA, respectively, as well as Ca_o^{2+}. These observations further emphasize the structural, functional, and evolutionary relationships among the three types of receptors.

Finally, Ca_o^{2+} could also, of course, modulate the functions of proteins other than GPCRs. For instance, the recently cloned Ca_o^{2+} channels TRPV5 and 6 can be viewed as operating on a macroscopic level as facilitated transporters. That is, they exhibit Michaelis–Menten-like kinetics, their activities (measured as $^{45}Ca^{2+}$ uptake in *X. laevis* oocytes) increase with the level of Ca_o^{2+} until Ca^{2+} uptake saturates above about 1 m*M* Ca_o^{2+}. They could potentially function, therefore, as Ca_o^{2+} sensors. That is, they would tend to "set" the level of Ca_o^{2+} within the local ECF by increasing Ca^{2+} uptake when Ca_o^{2+} is high and reducing it when it is low.

SUMMARY

The discovery of the CaR has provided a molecular mechanism that mediates many of the known actions of Ca_o^{2+} on the cells and tissues that participate directly in systemic Ca_o^{2+} homeostasis, such as parathyroid and certain renal

cells. There is still much to be learned, however, about the various functions of the receptor in these tissues, particularly in intestinal and bone cells, as well as in the numerous other CaR-expressing cells that are not directly involved in systemic Ca_o^{2+} homeostasis. In these latter, "nonhomeostatic" cells, the CaR probably serves a variety of roles that enable it to serve as a versatile first messenger, capable of regulating numerous cellular functions. Moreover, the ability of the CaR to integrate and coordinate several different ionic and nutritional signals may permit it to act as a central homeostatic element not only for mineral ion homeostasis, but also for processes relevant to Mg_o^{2+}, water, and protein metabolism.

INTRODUCTION

The biological actions of parathyroid hormone (PTH) and parathyroid hormone-related protein (PTHrP) have attracted ever wider interest in recent years because of the rapid advances in the study of the developmental biology of bone in which PTHrP and its receptor play a major role, as well as demonstration of the therapeutic potential of PTH in fracture prevention in osteoporosis.

One principal receptor, the type-1 PTH/PTHrP receptor (PTH1R), is the chief mediator of both the homeostatic actions of PTH and the paracrine actions of PTHrP on endochondral bone development. As discussed later, however, additional receptors may interact differentially with PTH versus PTHrP and/or with regions of the two ligands other than their amino-terminal domains. The tools of molecular biology have been central in the efforts to characterize both ligand-binding requirements and signaling properties of these receptors. Work with the principal receptor for PTH and PTHrP, the PTH1R, has proved pivotal in studies aimed at understanding in greater depth the physiological role of PTH in calcium and phosphate homeostasis and the critical paracrine role played by PTHrP in the complex network of different signaling factors that directs endochondral bone development.

At the same time that the reductionist approaches based on analyses of cloned receptors expressed in cell lines have helped clarify initial steps in PTH action and provided a detailed analysis of ligand/receptor/signaling events *in vitro*, the tools of molecular biology have also made possible a new level of integrative physiological analyses of bone biology *in vivo* through the use of mice modified genetically through selective gene knockout and/or transgenic overexpression of the PTH1R and/or its ligands. Much of this latter work, as well as the overall biological actions and physiological role of PTH, is outlined in subsequent chapters on PTH. This chapter focuses on the receptors per se, particularly the cloned and well characterized PTH1R, and those that are still uncloned but of potential biological significance in overall PTH or PTHrP action, especially the receptor for the carboxyl-terminal portion of PTH for which much recent biochemical data have accumulated.

RECEPTORS FOR PTH, PTHrP, AND TIP39: THE PTH1R AND PTH2R

Cloning, Gene Structure, Evolution, and Expression

Because of the pleiotropic actions of PTH, which involve both direct and indirect effects, as well as multiple signal transduction mechanisms, it was initially thought that several different receptors mediated the biological responses of this peptide hormone. Furthermore, the realization that

Principles of Bone Biology, 3rd Edition

some of these actions were PTHrP rather than PTH dependent seemed to increase the probability that more than one receptor would be involved. It was somewhat surprising, therefore, that initial cloning approaches led to the isolation of cDNAs encoding only a single G protein-coupled receptor, PTH1R. The recombinant PTH1R interacts well with PTH and PTHrP and activates several distinct second messenger pathways: adenylate cyclase/protein kinase A (AC/PKA) and phospholipase C/protein kinase C (PLC/PKC; Abou-Samra *et al.*, 1992; Jüppner *et al.*, 1991; Schipani *et al.*, 1993). Based on subsequent findings, such as the similar phenotypes observed in mice that are null for either PTHrP or the PTH1R (Karaplis *et al.*, 1994; Lanske *et al.*, 1996; Vortkamp *et al.*, 1996), it now seems that most of the endocrine actions of PTH and paracrine/autocrine actions of PTHrP on bone development are mediated through the PTH1R. Subsequent to the cloning of the PTH1R, another G protein-coupled receptor that is closely related to the PTH1R was identified in humans and rodents. This receptor, the PTH2R, shows some capacity to interact with PTH ligands but interacts much more efficiently with a peptide isolated from the hypothalamus called TIP39, the presumed native ligand for this receptor (Usdin, 1999; Usdin *et al.*, 1995). Another related receptor, the PTH-3 receptor (PTH3R), was identified in zebrafish and displays functionality more similar to that of the PTH1R (Rubin and Jüppner, 1999; Hoare *et al.*, 2000b). A review of the published sequence of the human genome indicates that there is no gene sequence detected that might be expected to yield the PTH-3 receptor (Venter *et al.*, 2001; Fredriksson and Schioth, 2005).

The PTH1R belongs to a distinct family of G protein-coupled receptors (GPCRs), called class II (or family B) receptors (Cardoso *et al.*, 2006; Fredriksson and Schioth, 2005). The first cDNAs encoding mammalian PTH1Rs were isolated through expression cloning techniques from cell lines that had been widely used in classical PTH/PTH receptor studies: the opossum kidney cell line OK and the rat osteosarcoma cell line ROS 17/2.8 (Abou-Samra *et al.*, 1992; Jüppner *et al.*, 1991). Subsequently, cDNAs encoding human (Eggenberger *et al.*, 1997; Schipani *et al.*, 1993; Schneider *et al.*, 1993), mouse (Karperien *et al.*, 1994), rat (Pausova *et al.*, 1994), chicken (Vortkamp *et al.*, 1996), pig (Smith *et al.*, 1996), dog (Smock *et al.*, 1999), frog (Bergwitz *et al.*, 1998), and fish (Rubin and Jüppner, 1999) PTH1Rs were isolated through hybridization techniques from various tissue and cell sources (i.e., kidney, brain, whole embryos, osteoblast-like cells, and embryonic stem cells). Northern blot and *in situ* studies (Tian *et al.*, 1993; Urena *et al.*, 1993; van de Stolpe *et al.*, 1993), as well as data provided through available public [expressed sequence tag (EST)] databases, confirmed that the PTH1R is expressed in a wide variety of fetal and adult tissues. With the exception of the tetraploid African clawed frog, *Xenopus laevis*, which expresses two nonallelic isoforms of the PTH1R (Bergwitz *et al.*, 1998), all investigated species have only one copy of the PTH1R per haploid genome. Evolutionary studies have identified PTH1Rs in all vertebrate species (Fig. 1), as well as an apparent PTH1R homologue in the urochordate tunicate *Ciona intestinalis* (Cardoso *et al.*, 2006).

The possible existence of other receptors for PTH or PTHrP with unique, organ-specific pharmacological characteristics had been suggested by the distinct ligand binding (Chorev *et al.*, 1990a, 1990b; McKee *et al.*, 1988) and second messenger signaling profiles observed in different clonal cell lines (Cole *et al.*, 1987; Yamaguchi *et al.*, 1987a, 1987b). However, the molecular cloning of identical full-length PTH1R cDNAs from human kidney, brain, and bone-derived cells (Eggenberger *et al.*, 1997; Schipani *et al.*, 1993; Schneider *et al.*, 1993) suggested that the previously observed pharmacological differences arose from species-specific variations in the receptor primary sequence rather than the tissue-specific expression of distinct receptors.

The gene encoding the human PTH1R is located on chromosome 3 (locus 3p22-p21.1). The intron/exon structure of the gene has been analyzed in detail (Bettoun *et al.*, 1997; Manen *et al.*, 1998; Schipani *et al.*, 1995) and was shown to have an organization similar to that of genes encoding the rat and mouse homologues (Kong *et al.*, 1994; McCuaig *et al.*, 1994; Fig. 2). In each of these mammals, the PTH1R gene spans at least 20 kbp of DNA and consists of 14 coding exons and at least three noncoding exons. The size of the coding exons in the human PTH1R gene ranges from 42 bp (exon M7) to more than 400 bp (exon T); the size of the introns varies from 81 bp (between exons M6 and M6/7) to more than 10 kbp (between exons S and E1). Two promoters for the PTH1R have been described in rodents (Joun *et al.*, 1997; Kong *et al.*, 1994; McCuaig *et al.*, 1994, 1995). The P1 promoter (also referred as U3) is active mainly in the adult kidney, whereas the P2 promoter (also referred to as U1) is active in several fetal and adult tissues, including cartilage and bone. In humans, a third promoter, P3 (also referred to as S), also appears to be active in some tissues, including kidney and bone (Bettoun *et al.*, 1998; Giannoukos *et al.*, 1999; Manen *et al.*, 1998). Several frequent polymorphisms were identified within the human PTH1R gene; these include an intronic *Bsm*I polymorphism located between the 5′ noncoding exon U1 and the coding exon S (Hustmyer *et al.*, 1993) and a silent *Bsr*DI polymorphism in exon M7 (nucleotide 1417 of human PTH1R cDNA; Schipani *et al.*, 1994).

At the protein level, all mammalian PTH1Rs have a relatively long amino-terminal extracellular domain (~170 amino acids in the human PTH1R after removal of the signal sequence by signal peptidase cleavage). This domain is encoded by five exons: S (encoding the signal sequence) and E1, E2, E3, and G (encoding the four N-linked glycosylation sites; Zhou *et al.*, 2000). Genes encoding other class II G protein-coupled receptors for which the genomic structure has been explored have a similar organization, except that the equivalent of exon E2

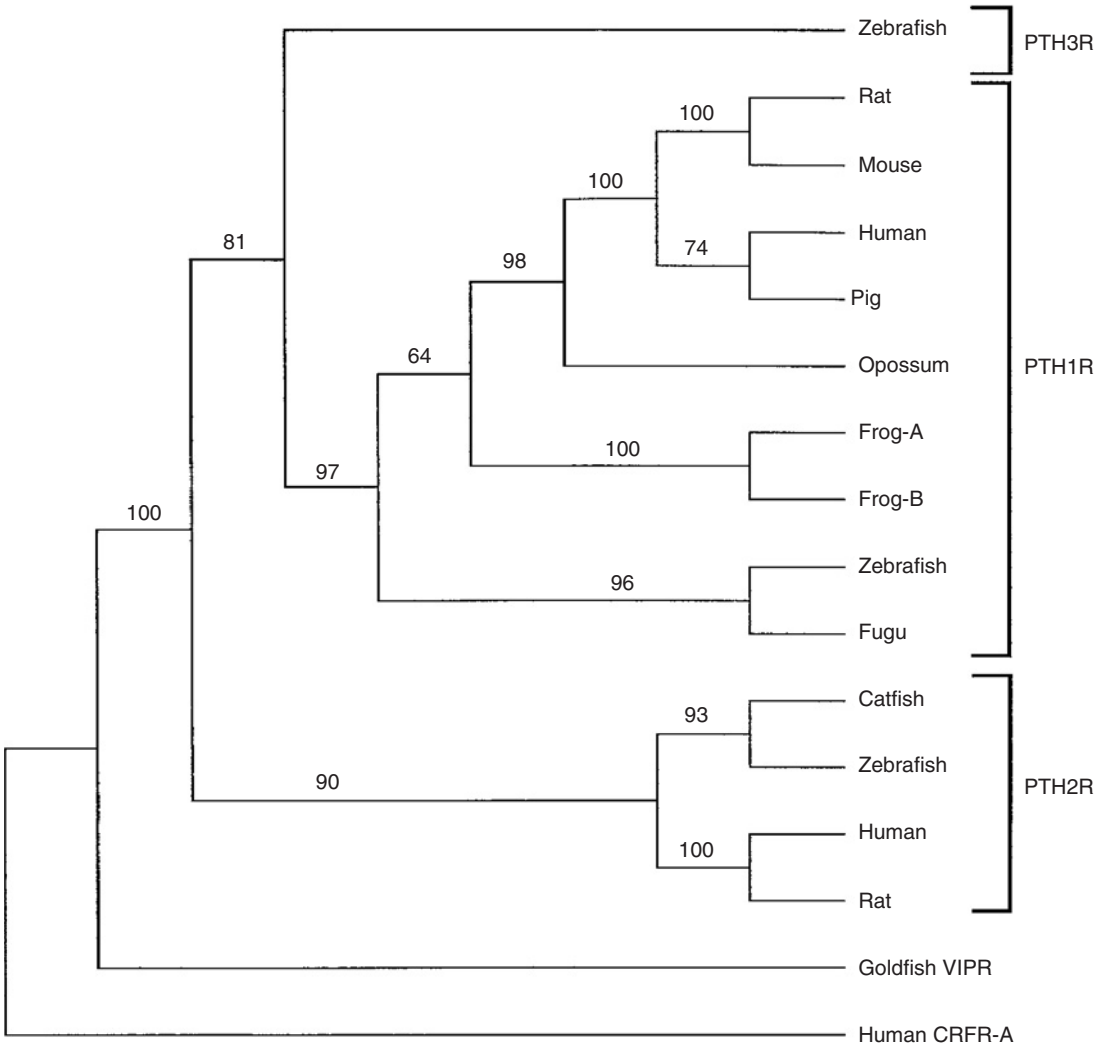

FIGURE 1 Evolutionary tree diagram of all known receptors for parathyroid hormone (PTH) and PTH-related peptide (PTHrP) from different vertebrate species. The tree was generated by comparing the amino sequences of the corresponding proteins derived from cDNA cloning or genome analysis. (Reproduced with permission from Rubin, D.A., and Jüppner, H. *J. Biol. Chem.*, 1999).

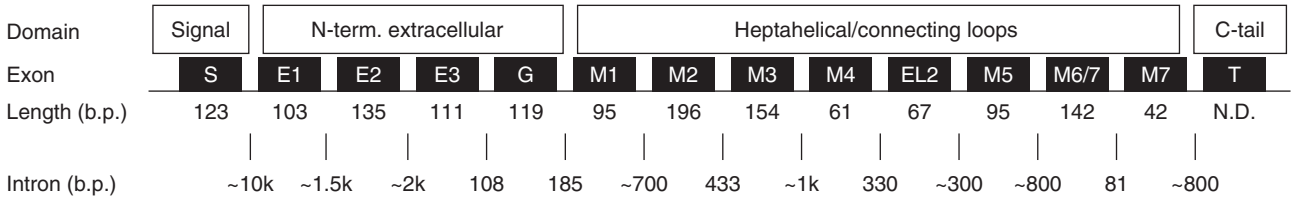

FIGURE 2 Intron/exon structure of the human PTH1R gene. The 14 coding exons of the human PTH1R gene are indicated as black boxes, and the corresponding receptor domains are indicated above in open boxes. The lengths in nucleotide base pairs (k = 1/1000) of the exons and the intervening introns are also indicated.

is lacking (Jüppner, 1994; Jüppner and Schipani, 1996). The protein segment encoded by exon E2 is also missing in the PTH2Rs, as well as in the PTH1Rs from *X. laevis* and zebrafish (Bergwitz *et al.*, 1998; Rubin *et al.*, 1999). Earlier *in vitro* mutational studies showed that the E2 segment of the PTH1R can be modified or deleted without a measurable impact on receptor surface expression or function (Jüppner *et al.*, 1994; Lee *et al.*, 1994). Taken together, these findings led to the conclusion that the addition of this exon in the mammalian PTH1Rs was a relatively

recent evolutionary modification to the PTH1R gene (Rubin and Jüppner, 1999); the biological role of this receptor region, if any, is unknown.

Class II Receptor Family

The molecular cloning of the PTH1R (Abou-Samra *et al.*, 1992; Jüppner *et al.*, 1991), along with the receptors for secretin (Ishihara *et al.*, 1991) and calcitonin (Lin *et al.*, 1991) that same year, made it clear that these peptide hormone receptors formed a distinct GPCR family. This GPCR family, called the class II or family B GPCRs, includes in humans 15 unique receptors, each of which binds a peptide ligand of moderate size (Cardoso *et al.*, 2006; Fredriksson and Schioth, 2005). Except for the structural similarity provided by the seven membrane-spanning helices, members of the class II (family B) peptide hormone GPCR family share virtually no amino acid sequence homology with most other GPCRs, such as the β2-adrenergic receptor, a class I GPCR. All members of the secretin/calcitonin/PTH receptor family, including an insect and several other invertebrate peptide hormone receptors (Cardoso *et al.*, 2006; Reagan, 1994, 1996; Sulston *et al.*, 1992) share about 45 strictly conserved amino acid residues. Furthermore, all receptors of this family have a relatively long amino-terminal, extracellular domain, and most use at least two different signal transduction pathways, adenylate cyclase and phospholipase C (Jüppner, 1994; Jüppner and Schipani, 1996). The amino-terminal extracellular domain of each of these related receptors typically contains four sites for potential asparagine-linked glycosylation, as well as six conserved cysteine residues that most likely form a disulfide network important for proper domain folding (Gaudin *et al.*, 1995; Grace *et al.*, 2007; Knudsen *et al.*, 1997; Lee *et al.*, 1994; Parthier *et al.*, 2007, Qi *et al.*, 1997; Sun *et al.*, 2007). Within the amino-terminal domain, as well as in the body of the receptor, there are several other "signature" residues conserved among the class II receptors (Cardoso *et al.*, 2006). It is predicted that within the membrane-embedded region there is an overall topological similarity between these class II heptahelical receptors and G protein-coupled receptors of the other families, such as the β2-adrenergic receptor, a class I GPCR (Sheikh *et al.*, 1999) for which an x-ray crystal structure has been solved (Cherezov *et al.*, 2007; Rasmussen *et al.*, 2007; Rosenbaum *et al.*, 2007), and those represented by the metabotropic glutamate receptor and the calcium-sensing receptor (class III receptors; reviewed in Chapter 23), although the receptors from each class share no primary sequence homology.

TIP39 AND THE PTH2R

The PTH2R subtype was initially identified through hybridization cloning methods in a human brain cDNA library. At the amino acid level, this receptor is 51% identical to the human PTH1R (Usdin *et al.*, 1995). The cloning of the PTH2R prompted a search for a peptide ligand that is its naturally occurring agonist and would selectively activate the PTH2R. The effort resulted in the discovery of a peptide of 39 amino acids that potently activates both rat and human PTH2R subtypes without activating the PTH1R (Usdin, 1999). The human PTH2R responds to PTH but not to PTHrP, whereas the rat PTH2R responds to neither PTH nor PTHrP (Hoare *et al.*, 1999a). The newly discovered peptide, called TIP39 (tuberoinfundibular peptide of 39 amino acids), was initially purified from bovine hypothalamus extracts and was shown to be only weakly homologous to PTH and PTHrP (Usdin, 1999; Fig. 3).

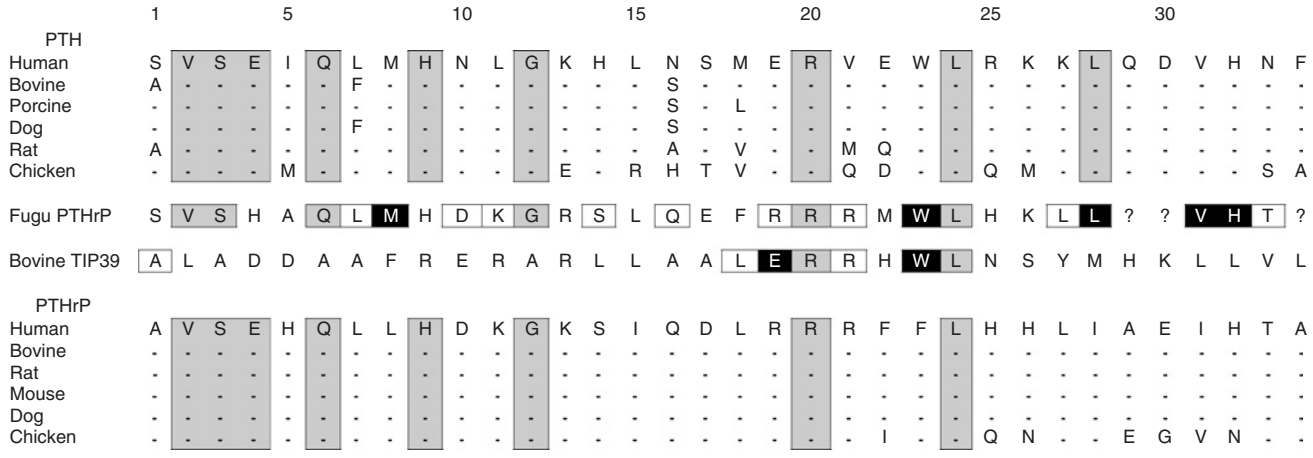

FIGURE 3 Alignment of the PTH(1–34) amino acid sequences of all known vertebrate PTH and PTHrP species, as well as fugu PTHrP and bovine TIP39. Amino acid residues that are conserved in all PTH and PTHrP species are shown in shaded boxes. Amino acid residues found in either fugu PTHrP or bovine TIP39 that are also found in all known PTH species are shown in black boxes with white letters, and residues found either in fugu PTHrP or in bovine TIP39 that are also found in all PTHrP species are boxes; numbers indicate amino acid positions in mammalian PTH or PTHrP. Question marks refer to sequence positions in fugu fish PTHrP not definitely deduced from nucleotide sequence. (Reproduced with permission from Jüppner et al., 2006).

Although TIP39 fails to activate the PTH1R, it binds to it with moderate affinity (~100 n*M*; Hoare *et al.*, 2000a). Interestingly, TIP(7-39) and TIP(9–39) bind with higher affinity to the PTH1R than TIP39 and the truncated peptides function as PTH1R-specific antagonists (Hoare and Usdin, 2000; Jonsson *et al.*, 2001). The physiological role of TIP39 and the PTH2R has not yet been identified, but their abundant expression in the central nervous system suggests a possible neuroendocrine function (Usdin, 2000) that is apparently preserved in evolution, as the PTH2R is found in zebrafish (Rubin and Jüppner, 1999).

MECHANISMS OF LIGAND RECOGNITION AND ACTIVATION BY PTH RECEPTORS

Current data indicate that the PTH receptor interacts with multiple regions of PTH peptide ligands; these contacts establish binding affinity and/or promote receptor activation. Much information on these interactions has been gained from studies that used intact native PTH receptors expressed in various cell systems and synthetic PTH and PTHrP analogues. PTH(1–34) and PTHrP(1–34) bind to and activate the PTH1R with affinities and potencies in the low nanomolar range. The first 13 amino acids of PTH and PTHrP have been highly conserved in evolution with six identities; the (15–34) regions share only moderate homology with three amino acid identities. The N-terminal portions of the two peptides play key roles in receptor activation, whereas the (15–34) portions are required for high-affinity receptor binding (Abou-Samra *et al.*, 1989; Caulfield *et al.*, 1990; Nussbaum *et al.*, 1980).

Ligand Determinants of PTH Receptor Activation

cAMP Signaling Response

Amino-terminally truncated PTH or PTHrP analogues, such as PTH(3-34), PTH(7-34), and PTHrP(7-34), bind to the PTH1R with high affinity and elicit little or no increase in cAMP accumulation. Such fragments yield the most potent PTH1R competitive antagonists (Nutt *et al.*, 1990). Bulky amino acid modifications within the amino-terminal portion of (1–34)-length peptides (e.g., at positions 2, 3, and 6) also confer antagonistic properties to the peptides (Behar *et al.*, 1999; Carter *et al.*, 1999a; Cohen *et al.*, 1991; Gardella *et al.*, 1991). Peptides consisting only of the amino-terminal residues of PTH exhibit severely diminished receptor-binding affinity and hence cAMP-signaling potency. The shortest amino-terminal peptide of the native sequence that retains full PTH1R-binding affinity and cAMP-signaling potency is PTH(1–31; Whitfield and Morley, 1995). PTH(1–14) has been shown to be the shortest native amino-terminal PTH peptide for which at least some cAMP agonist activity can be detected, albeit the EC_{50} of the cAMP response induced by PTH(1–14) in LLC-PK1 porcine kidney cells transfected stably with high levels of the human PTH1R (~100 μM) is markedly higher than that observed for PTH(1–34) (~3 nM; Luck *et al.*, 1999). A series of structure–activity relationship studies on the PTH(1–14) scaffold peptide was undertaken as part of an effort to better understand how residues in the amino-terminal portion of PTH mediate receptor activation (Carter and Gardella, 2001; Luck *et al.*, 1999; Shimizu *et al.*, 2000b, 2001a). An alanine scan analysis of PTH(1–14) demonstrated the functional importance of residues (1–9) and suggested that this sequence represents a minimum-length receptor-activation domain (Luck *et al.*, 1999). Further substitution analyses revealed that the PTH(1–14) sequence could accommodate amino acid changes at a number of positions (Carter and Gardella, 2001; Shimizu *et al.*, 2000b, 2001b) many of which improved signaling potency and binding affinity. The most active analogue was [$Aib^{1,3}$, Gln^{10}, $homoArg^{11}$, Ala^{12}, Trp^{14}]PTH(1–14), which is several thousandfold more potent as a cAMP agonist in stably transfected LLC-PK1 cells than is native PTH(1–14) and approximately as potent as PTH(1–34) (Shimizu *et al.*, 2001b). The relevant substitutions also conferred activity to the otherwise inactive PTH(1–11) fragment; these modified PTH(1–11) analogues are currently the shortest free peptide sequences that can activate the PTH1R (Shimizu *et al.*, 2001b, 2004).

Non-cAMP Signaling Responses

Although it is well established that the amino-terminal residues of PTH mediate AC/PKA signaling, there is still some uncertainty regarding the ligand determinants of PLC/PKC/calcium signaling. Several studies have indicated that residues in the C-terminal portion of PTH(1–34) mediate PKC activation; perhaps most notably, the tetrapeptide PTH(29–32) was shown to be sufficient for activating PKC in ROS 17/2 rat osteosarcoma cells (Jouishomme *et al.*, 1994), as well as in Chinese hamster ovary cells transfected with the rat PTH1R (Azarani *et al.*, 1996). Stimulation of PKC is generally thought to be mediated through PLC signaling; however, other data indicate that determinants of PLC activation reside at the amino terminus of PTH. Thus, even minor N-terminal truncations, as in [$desNH_2$-Gly^1]PTH(1–34), PTH(2–34), or PTH(3–34), severely diminish the capacity of the peptide to stimulate inositol polyphosphate (IP) production via PLC in porcine kidney LLC-PK1 cells transfected with the human PTH1R (Takasu *et al.*, 1999a). In addition, the activity-enhanced PTH(1–14) analogues mentioned above stimulate IP production in transfected COS-7 cells, indicating that residues in this N-terminal portion of the ligand can be sufficient for PLC signaling (Shimizu *et al.*, 2000b).

One possible explanation for the apparent discrepancy in the mapping of PKC and PLC activation determinants is that residues (29–32) of PTH mediate PKC activation via a phospholipase other than PLC. In support of this possibility, Friedman and co-workers (1999) have shown that in the distal tubule cells of the kidney, the PTH1R couples to phospholipase D, whereas in the proximal tubule cells it couples to phospholipase C; moreover, distinct structural components of the ligand were required for the altered signaling responses in the two different cell types. Stern and co-workers have shown that PTH(1–34) can activate PLD in primary and transformed (UMR 106) osteoblastic cells through a Gα12/13-coupled pathway involving activation of the small GTP-binding protein RhoA (Radeff *et al.*, 2004; Singh *et al.*, 2003, 2005). Weaker stimulation of PLD was observed with PTH(3–34) and PTH(1–31) (Singh *et al.*, 1999). The PTH1R may therefore be capable of recognizing different portions of the ligand as activation determinants for various phospholipases, a capacity that may be modulated by the cellular milieu (Whitfield *et al.*, 2001).

Ligand stimulation of the PTH1R can also result in modulation of the mitogen-activated protein kinase (MAPK) or extracellular signal-regulate (ERK)-1/2 signaling cascade via both G protein–dependent and G protein-independent mechanisms. It was shown in distal convoluted tubule cells of the kidney that PTH stimulates activation of ERK2 via a PKC-dependent, PKA-independent mechanism, and this ERK activation likely plays a role in the calcium transport processes mediated by these cells (Sneddon *et al.*, 2000). In transfected HEK-293 cells, PTH stimulates activation of ERK1/2 via both a Gq/PLC-mediated pathway, as well as an arrestin-mediated pathway that is linked to the clathrin-mediated receptor internalization process, does not require activation of the cAMP pathway, and may be induced by the PTH(7-34) fragment (Gesty-Palmer *et al.*, 2006; Rey *et al.*, 2006; Syme *et al.*, 2005).

Ligand Determinants of PTH Receptor Binding

For both PTH and PTHrP, the (15–34) fragment can inhibit the binding of either radiolabeled PTH(1–34) or PTHrP (1–34) to the PTH1R with an IC_{50} in the micromolar range, thus demonstrating that the (15–34) domain contains the principal determinants of receptor-binding affinity (Abou-Samra *et al.*, 1989; Caulfield *et al.*, 1990). The (15–34) domains of both ligands are predicted to form amphiphilic α helices with the hydrophobic face of PTH being formed principally by Trp-23, Leu-24, and Leu-28 (Epand *et al.*, 1985; Neugebauer *et al.*, 1992). Substitution of Leu-24 or Leu-28 in PTH(1–34) by glutamate results in 100-fold reductions in binding affinity, consistent with the view that the hydrophobic face plays a key role in receptor binding (Gardella *et al.*, 1993). It has been suggested for PTH (Epand *et al.*, 1985; Neugebauer *et al.*, 1992; Rölz *et al.*, 1999) that this role involves nonspecific interaction of the hydrophobic surface of the peptide with the phospholipid bilayer of the cell membrane, which then facilitates a two-dimensional diffusion of the hormone to the receptor. Such a model has been suggested for other peptide hormones (Sargent and Schwyzer, 1986). However, more recent structure–activity studies (Dean *et al.*, 2006a) strongly suggest that the hydrophobic surface of the PTH (15–34) domain directly contacts the amino-terminal domain of the receptor. The crosslinking of a PTHrP(1–36) analogue having tryptophan-23 replaced by the photolabile benzophenone-containing amino acid analogue benzoylphenylalanine (Bpa) to a 16-amino-acid segment at the extreme amino terminus of the PTH1R further suggests that at least some residues in the (15–34) domain of the ligand interact with the amino-terminal domain of the receptor (Mannstadt *et al.*, 1998).

MECHANISMS OF PTH1R FUNCTION

Role of the Amino-Terminal Receptor Domain

The large glycosylated amino-terminal extracellular domain of the PTH1R contains six highly conserved cysteine residues that are likely to form an intramolecular network of disulfide bonds. A possible arrangement of these disulfide bonds has been suggested from a biochemical study on a recombinant protein corresponding to the amino-terminal domain of the PTH1R (Tyr^{23}-Ile^{191}) that was overproduced in *Escherichia* coli (Grauschopf *et al.*, 2000). The purified protein was refolded in a glutathione-containing redox buffer system to a homogeneous state and was shown to retain specific, but predictably weak ($K_d \sim 4\,\mu M$), binding affinity for PTH(1–34). The biochemical behavior of this protein suggests that the observed disulfide bond pattern, illustrated in Fig. 4, may faithfully replicate that which occurs in native PTH1Rs expressed in eukaryotic cells. Indeed, this disulfide bonding pattern is confirmed in the three-dimensional structures of isolated amino-terminal domains of several other family B GPCRs solved either by solution-phase NMR (Grace *et al.*, 2007; Sun *et al.*, 2007) or x-ray crystallography (Parthier *et al.*, 2007). These structures, which were obtained as complexes with the C-terminal binding domain of the cognate ligand, show a consistent, beta sheet-rich folding pattern stabilized by three predicted disulfide bonds.

Functional studies on PTH receptor chimeras and mutants generated by site-directed mutagenesis and expressed in COS-7 cells have shown that the amino-terminal domain of the receptor provides important contact sites for at least some residues in the C-terminal-binding

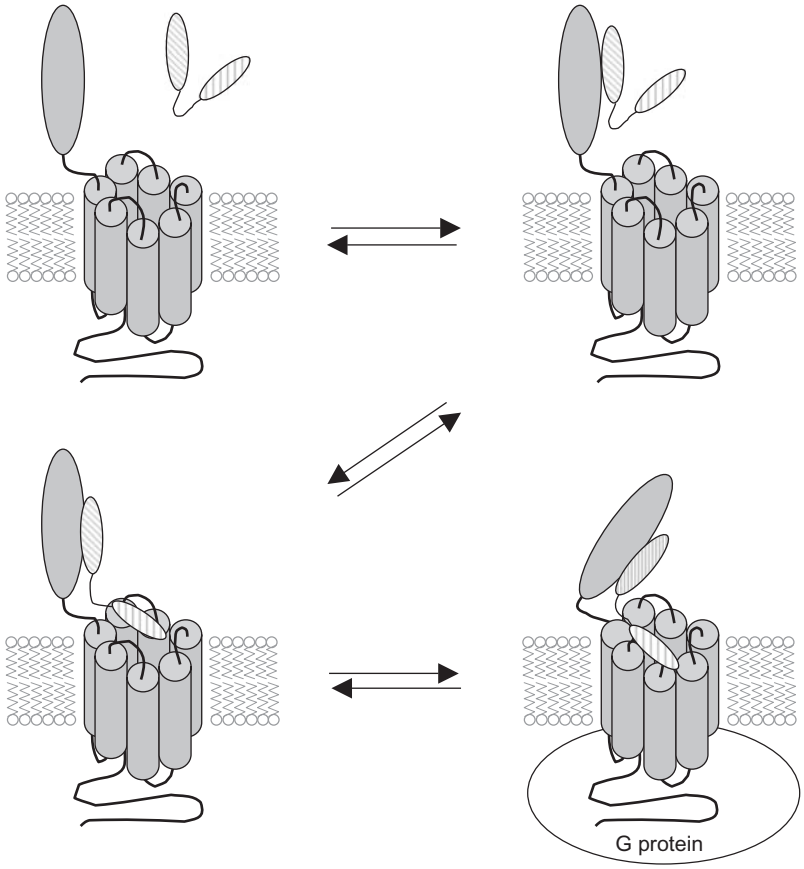

FIGURE 4 Hypothetical model of the PTH–PTH receptor interaction mechanism. The schematic illustrates current hypotheses regarding the mechanism by which PTH binds to the PTH1 receptor and induces G protein coupling. The interaction with PTH(1-34) (hatched ovals) involves two principal components: (1) binding of the C-terminal domain of PTH(1-34) to the amino-terminal extracellular domain of the receptor and (2) the association of the amino-terminal domain of PTH with the juxtamembrane region of the receptor. These two components of the interaction contribute predominantly to affinity and activation, respectively, and may occur in a sequential manner, as depicted. Upon association of the N-terminal portion of the ligand with the juxtamembrane region, a conformational change occurs, which results in the formation of a "closed" high-affinity ligand-receptor complex that is coupled to G protein. (Reproduced with permission from Hoare *et al.*, 2001.)

domains of PTH(1–34) and PTHrP(1–34) (Bergwitz *et al.*, 1996; Jüppner *et al.*, 1994). The crosslinking studies with [Bpa^{23}]PTHrP(1–36) mentioned earlier support this conclusion (Mannstadt *et al.*, 1998; see also Chapter 26). Within the 17-amino-acid interval identified with the Bpa-23 analogue, the specific residues of threonine-33 and glutamine-37 were shown by functional methods to be determinants of PTH(7–34) binding affinity (Mannstadt *et al.*, 1998). A second segment of the amino-terminal extracellular domain involved in ligand interaction maps to the boundary of the amino-terminal domain and the first transmembrane helix. A PTH(1–34) analogue having the benzophenone photophore attached to the ε amino group of lysine 13 crosslinked to this region, most likely at Arg-186 (Adams *et al.*, 1998), and point mutations at the neighboring hydrophobic residues of Phe-184 and Leu-187 and Ile-190 impaired interaction with PTH(3–34) and PTH(1–14) but not PTHrP(15–36) (Carter *et al.*, 1999b). Residues in this segment of the receptor thus appear to be important interaction determinants for residues in the (3–14) region of the ligand.

Residues in the midportion of the amino-terminal domain of the PTH1R are also likely to contribute to ligand interaction, but candidate contact points have not been identified. Use of PTHrP(1–36) analogues modified with Bpa at positions 27 and 28 revealed crosslinking to the E2 region of the receptor's amino-terminal domain, which does not appear to be involved in ligand binding (Gensure *et al.*, 2001). This same study found that Bpa at position 33 resulted in crosslinking to the segment 151–172 of the amino-terminal domain, which may contain determinants of binding (Lee *et al.*, 1995b), although, again, none has been identified. Another study using PTH(1–34) analogues modified with Bpa at positions 11, 15, or 21 found photocrosslinking to the amino-terminal regions: [165–176], [183–189], and [165–176], respectively (Wittelsberger *et al.*, 2006). Overall, the combined crosslinking studies suggest that a rather broad surface of contact between the

mid- to C-terminal portion of PTH(1-34) and the receptor's amino-terminal extracellular domain is involved in establishing and maintaining the affinity with which PTH or PTHrP ligands bind to the PTH1R.

Juxtamembrane Region

A number of studies have indicated that interactions between the amino-terminal portion of PTH and the juxtamembrane region of the PTH receptor are important for inducing receptor activation. One such study that utilized PTH1R/calcitonin receptor chimeras and PTH/calcitonin hybrid ligands showed that efficient functional responses were obtained only when a chimeric receptor was paired with a hybrid ligand such that the amino-terminal portion of the ligand was cognate to the juxtamembrane region of the receptor (Bergwitz *et al.*, 1996). Some specific residues in the juxtamembrane region have been identified as candidate interaction sites for the amino-terminal residues of PTH, such as Ser-370 and Leu-427 at the extracellular ends of transmembrane domain(TM)5 and 6, respectively, which determine the agonist/antagonist response profile observed with [Arg^2]PTH(1–34) (Gardella *et al.*, 1994), and Trp-437 and Gln-440 in the third extracellular loop, at which mutations impair the binding of PTH(1–34) but not PTH(3–34) (implying an interaction site for ligand residues 1 and 2; Lee *et al.*, 1995a). Consistent with these mutational data, the receptor crosslinking sites for [Bpa^1]PTH(1–34) (Bisello *et al.*, 1998) and [Bpa^2]PTHrP(1–36) (Behar *et al.*, 1999) were mapped to the extracellular end of TM6 (Behar *et al.*, 1999). Interestingly, both of these ligands utilized Met-425 for covalent attachment, although [Bpa^2]PTHrP(1–36), an antagonist, utilized an additional second site in TM6, whereas [Bpa^1]PTH(1–34), an agonist, utilized only the methionine. These results raise the possibility that the photochemical crosslinking approach can be used to discern differences in the active and inactive states of the PTH1R (Behar *et al.*, 1999).

Other receptor residues involved in interactions with the amino-terminal portion of the ligand have been identified in studies aimed at elucidating the molecular basis by which the human PTH2R discriminates between PTH and PTHrP, an effect that is largely due to the amino acid divergence at position 5 in these ligands (Ile in PTH and His in PTHrP; Behar *et al.*, 1996; Gardella *et al.*, 1996c). Four PTH2R residues involved in this specificity were identified at the extracellular ends of several of the TM helices: Ile-244 in TM3, Tyr-318 in TM5, and Cys-397 and Phe-400 in TM7, corresponding to Leu-289, Ile-363, Tyr-443, and Leu-446, respectively, in the human PTH1R (Bergwitz *et al.*, 1997; Turner *et al.*, 1998). Other residues in the TM domains that have been identified as determinants of PTH(1-34) agonist responsiveness include Ser-229, Arg-233, Ser-236, which may form a hydrophilic surface on TM2 (Turner *et al.*, 1996), and the conserved Gln-451 in TM7 (Gardella *et al.*, 1996a).

A series of studies conducted with a truncated PTH1R (P1R-delNt) that lacks most (residues 24–181) of the amino-terminal extracellular domain has helped discern the role of interactions between the N-terminal residues of PTH and the juxtamembrane region of the receptor in mediating signal transduction. Thus, the modified PTH (1–14) peptides described earlier stimulate cAMP formation with this truncated receptor nearly as effectively as they do with the intact wild-type receptor (Shimizu *et al.*, 2000b, 2001b). The near-full activity of the PTH(1–14) analogues with P1R-delNt stands in dramatic contrast to the markedly (approximately 1000-fold) reduced activity that unmodified PTH(1–34) exhibits with P1R-delNt, as compared to the intact receptor (Shimizu *et al.*, 2000b, 2001). The weak activity of PTH(1–34) on P1R-delNt highlights the importance of interactions between the (15–34) domain of PTH(1–34) and the N-terminal extracellular domain of the receptor in stabilizing the native hormone–receptor complex (see later), whereas the potent activity of modified PTH(1–14) on P1R-delNt indicates that most, if not all, of the key functional residues in the amino-terminal peptide interact primarily, if not exclusively, with the juxtamembrane region of the receptor.

The most potent PTH(1–14) analogues so far, exhibiting low nanomolar potency on both the intact wild-type PTH1R and on P1R-delNt have conformationally constraining substitutions at positions 1 and/or 3 (Shimizu *et al.*, 2004, 2001b). Presumably, the modifications in these peptides stabilize a ligand conformation that has high affinity for the juxtamembrane region of the receptor. Most likely, this conformation is α-helical, as suggested by nuclear magnetic resonance spectroscopy analysis of PTH fragment analogues (Chen *et al.*, 2000; Fiori *et al.*, 2007; Rölz *et al.*, 1999; Tsomaia *et al.*, 2004a, 2004b), as well as X-ray crystallographic analysis of unmodified PTH(1–34) (Jin *et al.*, 2000). At least some of the substitutions in the multisubstituted PTH(1–14) analogues described by Shimizu *et al.* (2000b, 2001b), are likely to provide new and favorable interactions with the receptor that compensate for the loss of binding energy that normally derives from residues in the (15–34) domain of PTH; some, however, may directly facilitate the receptor activation process without affecting binding affinity. One of the goals of the research on these short N-terminal PTH peptides is to discern how individual key residues in the ligand contribute to binding affinity and receptor activation. Data so far on the PTH(1–14) analogues demonstrate that it is possible to achieve full potency and efficacy with a peptide ligand as short as 14 amino acids, and also that a relatively small agonist ligand can fully activate the PTH receptor by interacting solely with the juxtamembrane region of the receptor. As an extension of these studies, a PTH1R mutant was constructed in which residues (1–9)

or (1–11) of PTH were tethered directly to the juxtamembrane region of the receptor (at Glu-182). When expressed in COS-7 cells, these constructs resulted in basal cAMP levels that closely approached the cAMP level seen with the wild-type PTH1R fully stimulated with the PTH(1–34) agonist ligand (Shimizu *et al.*, 2000a). A similar result has been reported for corticotropin-releasing factor (CRF) and its class II GPCR (Nielsen *et al.*, 2000). A radiolabeled modified PTH(1-14) peptide was also used in drug screening research to identify small molecules that bind to the PTHR, and this approach indeed revealed a compound that inhibited the binding of the radioligand with micromolar affinity and behaved as a competitive antagonist, suggesting an orthosteric binding mechanism (Carter *et al.*, 2007). An unrelated, activity-based PTHR screening effort identified another small molecule ligand for the PTHR which acts as a weak, micromolar agonist, possibly via an allosteric, rather than an orthosteric, mechanism (Rickard *et al.*, 2006). These studies together suggest promise in the search for potent non-peptidic compounds for the PTHR that can be used to treat diseases such as osteoporosis.

Two-Site Model of PTH/PTH Receptor Interaction

Combined functional and crosslinking data are consistent with a mechanism for the PTH–PTH receptor interaction that involves two principal components: (1) an interaction between the C-terminal domain of the ligand and the amino-terminal domain of the receptor, which contributes predominantly to binding affinity, and (2) an interaction between the amino-terminal portion of the ligand and the juxtamembrane region of the receptor, which contributes to signaling (Fig. 4). This general interaction model is likely to apply to at least some of the other class II receptors, including those for CRF, calcitonin, secretin, and glucagon (Bergwitz *et al.*, 1996; Nielsen *et al.*, 2000; Stroop *et al.*, 1995; Turner *et al.*, 1998). It has been proposed that the interactions at the two receptor domains occur in a sequential manner (Hoare *et al.*, 2001; Ji *et al.*, 1998; see Fig. 4). There is also the possibility that a higher order of folding is involved. In support of this possibility is the crosslinking study showing that a PTH(1–34) agonist analogue having a benzophenone group attached to lysine-27 contacts the first extracellular loop of the PTH1R (Greenberg *et al.*, 2000); thus the amino-terminal extracellular domain of the receptor [and (15–34) portion of the ligand] must be close to the juxtamembrane region of the receptor, at least in the agonist bound state (Piserchio *et al.*, 2000). The model proposed in Fig. 4, based on binding of modified short amino-terminal PTH(1–14) sequences versus the amino-terminally truncated PTH(3–34) antagonist peptide, suggests that the binding steps may even be independent such that the binding of PTH(1–14) analogues to the juxtamembrane regions cannot be blocked by binding of the carboxyl portion of PTH(3–34) to the extracellular domain of the receptor (Hoare *et al.*, 2001). This finding, demonstrated in membrane preparations of receptors, is not seen in cell-based assays that have higher receptor number and differ in other respects (internalization, phosphorylation, etc.; Shimizu *et al.*, 2000b).

Data seen and the models proposed regarding PTH/PTH1R interaction mechanisms have clear implications for drug discovery efforts aimed at finding new PTH receptor agonists. Clinical trial data showing that PTH (given as daily subcutaneous injections) can effectively treat osteoporosis (Neer *et al.*, 2000) are likely to heighten interest in developing orally available nonpeptide mimetics for this receptor. So far, however, no such compounds have been reported. Although it is possible that the agonist-dependent activation of the PTH1R requires multiple ligand contacts to a large and diffuse surface of the receptor, including the amino-terminal extracellular domain, the finding that short peptide sequences [modified PTH(1–11) and (1–14), as well as PTH(1–9) in a tethered construct] can activate the receptor (Shimizu *et al.*, 2000a) suggests, as the model in Figure 27.5 predicts, that it should be possible for a small nonpeptide molecule that interacts only with the juxtamembrane region of the receptor to function as a potent PTH1R agonist.

Conformational Changes in the PTH1R

As for all GPCRs, the binding of an agonist peptide to the PTH1R is thought to induce conformational changes in the receptor, including movements of the TM domains that render the cytoplasmic loops more accessible to G proteins (Gether, 2000). The model shown in Fig. 4 deduced from kinetic data (Hoare *et al.*, 2001) that G protein association by a ligand-bound receptor results in a "tightening" of the receptor–ligand complex reflects this proposed conformational change. An agonist-induced movement of TM3 away from TM6 has been demonstrated for the PTH1R by Sheikh *et al.* (1999), who showed that the chelation of zinc between histidine residues (native and introduced) at the intracellular ends of TM3 and TM6 blocked receptor-mediated G protein activation. An analogous movement was also shown in the β_2-adrenergic receptor, suggesting that the mechanisms of activation for the class I and class II GPCRs are fundamentally similar (Sheikh *et al.*, 1999). Several residues on the cytoplasmic surface of the PTH1R have been identified within regions that are candidate G protein interaction sites. In intracellular loop 3, these include Val-384 and Leu-385 (PLC coupling), Thr-387 (AC coupling), and Lys-388 (AC and PLC coupling; Huang *et al.*, 1996). In intracellular loop 2, Lys-319 has been implicated in PLC signaling (Iida-Klein *et al.*, 1997). Mutation of this Lys to Glu, together with the adjacent mutations of Glu-317→Asp, Lys-318→Ser and Tyr-320→Leu, results in a

mutant PTHR that is strongly defective in PLC signaling but maintains near-normal cAMP signaling (Iida-Klein *et al.*, 1997). Guo and colleagues generated "knock in" mice having this "DSEL" mutant PTHR allele in place of the normal PTHR allele, and thus were able to show that the PLC signaling pathway does not play a critical role in PTHR-mediated control of the endochondral bone formation process (Guo *et al.*, 2002).

Three different activating mutations in the PTH1R have been identified in patients with Jansen's metaphyseal chondrodysplasia (see later discussion). These mutations occur at the cytoplasmic termini of TM2 (Arg-233→His), TM6 (Thr-410→Pro), and TM7 (Ile-458→Arg) and each results in agonist-independent cAMP signaling. Whether the conformational changes induced by the activating mutations are the same as those that occur in the agonist occupied wild-type PTH receptor is unknown, but the study of these mutant PTH1Rs, along with certain peptide ligand analogues, such as [Leu^{11}, D-Trp^{12}]PTHrP(7–34), that behave as inverse agonists with the mutant receptors and depress their basal signaling (Carter *et al.*, 2001; Gardella *et al.*, 1996b) is likely to provide insights into the conformational states that are possible for active and inactive PTH1Rs.

CONFORMATIONAL SELECTIVITY OF LIGAND BINDING

Pharmacological binding studies performed in membranes prepared from cells expressing transfected or endogenous PTHRs have suggested that the PTHR can adopt different conformational states, and that these states can be differentially stabilized by structurally distinct ligands to produce quantitatively different biological response profiles (Dean *et al.*, 2007; Hoare *et al.*, 2001). The studies thus suggest two distinct high-affinity PTH1R conformations: a G protein-coupled conformation, RG, and a novel, G protein-uncoupled conformation, R^0. The findings further suggest a shift in the mechanistic view of how a PTH ligand engages the receptor, and the role of G proteins. Previous views, based largely on the classical ternary complex models of GPRC action (Kenakin, 2003), hold that the initial binding of the ligand to the receptor produces a low-affinity state complex, denoted LR in Figure 27.5, which converts to a high-affinity state only upon engaging a heterotrimeric G protein to form the classical ternary complex, denoted LRG. This model predicts that uncoupling the G protein from the LRG complex—for example, by adding the nonhydrolyzable GTP analogue, GTPγS—would produce the low-affinity LR state and result in the rapid release of bound ligand.

In testing this prediction for the cloned PTHR in membranes from transfected LLC-PK-1 cells, however, it was found that the major fraction of radiolabeled PTH(1–34) which initially bound to the receptor remained stably bound upon GTPγS addition (Dean *et al.*, 2006b). On the other hand, parallel studies showed that a PTH(1–15) radioligand analogue mostly dissociated from the receptor upon addition of GTPγS. PTHrP(1–36) dissociated rapidly from the receptor after GTPγS addition, although more slowly than PTH(1–15). Moreover, in membranes prepared from mouse embryonic fibroblast cells genetically lacking $G\alpha_s$, ^{125}I-PTH(1–34) bound well whereas ^{125}I-PTH(1–15) did not (Dean *et al.*, 2006b). The studies thus suggested that certain PTH1R ligands—e.g., PTH(1–34)—could stabilize a novel high-affinity PTHR conformation, R^0, whereas other ligands—e.g., PTH(1–15) or PTHrP(1–36)—bound more selectively to the RG conformation. Because PTH(1–34) interacts with both the N and J domains of the receptor, and PTH(1–15) interacts solely with the J domain, the findings suggested that stable binding to R^0 involves interactions to both the N and J domains of the receptor, a binding weaker for PTHrP(1–36) than for PTH(1–34).

The biological implications for the apparent selectivity that different ligands can exhibit for different PTHR conformations is still uncertain but has become a topic of considerable focus for our group. PTH(1–34) bound more stably to R^0 and produced a more prolonged cAMP response in intact cells than did PTHrP(1–36) (Dean *et al.*, 2007). Thus, stable binding to R^0 was found to correlate with the capacity to produce prolonged cAMP signaling responses in intact cells. The mechanism of this prolonged cAMP signaling response is unknown. It may simply reflect the isomerization, over time, of stable LR^0 complexes to the active-state LRG conformation. Alternatively, the mechanism of the persistent signaling may be more complex involving binding of other proteins to the ligand–receptor complex or even persistent signaling after receptor internalization. Although most earlier studies suggest largely similar binding and activation mechanisms for PTH and PTHrP, these newer kinetic studies suggest differences in the conformational selectivity exhibited by the two ligands.

Biophysical studies of the process using the technique of fluorescence resonance energy transfer (FRET) illustrates a rapid drop in FRET signal with activation. PTH(1–34) remains bound to the receptor with persistence of the FRET signal associated with activation, despite a washing step to remove ligand. However, such maneuvers with PTH(1–15) or PTHrP(1–36), though illustrating the same change in FRET signal with initial binding, reveal immediate or rapid reversal of the FRET signal, respectively, with the washing step. These results thus mirror the persistent ligand binding after use of GTPγS and prolonged cAMP signaling following the buffer washing step with PTH(1–34), in contrast to results with PTH(1–15) or PTHrP(1–36).

These differences for PTH and PTHrP may well have biological and pharmacological relevance *in vivo*. For

example, they may underlie the difference reported in the endogenous actions of the two ligands—i.e., endocrine versus paracrine—as well some of the differences seen in clinical studies reported by Stewart and co-workers for PTH(1–34) and PTHrP(1–36), in that the former appears to have a greater tendency to promote bone-resorption and stimulate synthesis of 1,25-vitamin D_3 than does the latter (Horwitz *et al.*, 2003, 2005, 2006). Recently, our group has designed analogues that further accentuate the R^0 binding affinity noted with PTH(1–34). On such an analogue, Ala_1,Aib_3[M]PTH(1–28) exhibits remarkably persistent activity in *in vitro* test systems with renal cell models and *in vivo* with prolonged duration of hypercalcemia and hypophosphatemia when compared to results even with PTH(1–34) (Nagai *et al.*, 2007; Okazaki *et al.*, 2007).

PTH1R REGULATION

The agonist-dependent response capacity of the PTH1R is diminished markedly within minutes following an initial exposure to agonist (Bergwitz *et al.*, 1994; Fukayama *et al.*, 1992). This desensitization is accompanied by rapid internalization of the PTH–PTH1R complex (Ferrari *et al.*, 1999; Huang *et al.*, 1999; Malecz *et al.*, 1998). Phosphorylation of other G protein-coupled receptors on cytoplasmic domains is known to play an important role in the internalization/desensitization process (Lefkowitz, 1998). The PTH1R is phosphorylated on its cytoplasmic tail immediately following agonist activation (Blind *et al.*, 1996), specifically on as many as seven serine residues that cluster to within the midregion of the cytoplasmic tail (Malecz *et al.*, 1998; Qian *et al.*, 1998). The second messenger–activated kinases PKA and PKC both appear to contribute to PTH1R phosphorylation, because both forskolin and phorbol 12-myristate 13-acetate increase PTH1R phosphorylation (Blind *et al.*, 1995). The inhibitory effect of staurosporine on PTH1R phosphorylation (Qian *et al.*, 1998) and internalization (Ferrari *et al.*, 1999) supports a role for PKC, and potentially other kinases, in these processes. Cotransfection experiments have indicated that the G protein receptor kinase-2 (GRK-2) also contributes to PTH1R phosphorylation (Dicker *et al.*, 1999; Malecz *et al.*, 1998).

With other G protein-coupled receptors, receptor phosphorylation enables the binding of β-arrestin2 (ββ-Arr2), which then interferes sterically with G protein coupling and, in an adapter role, binds the receptor directly to clathrin (Lefkowitz, 1998). PTH1R endocytosis occurs largely via a clathrin-coated vesicle-mediated process (Huang *et al.*, 1995). By expressing moderate levels of a phosphorylation-deficient PTH1R mutant having the clustered serines of the C-tail replaced by alanine, Qian *et al.* (1999) found that agonist-induced internalization in LLC-PK1 cells was reduced markedly in comparison to the wild-type receptor. Moreover, these workers genetically engineered a model mouse strain in which the wild-type PTH receptor gene was replaced at both alleles by the phosphorylation-deficient PTHR mutant; the mutant "PD" mice, although viable and fertile, exhibited a markedly exaggerated, and ultimately fatal, calcemic response to infused PTH(1–34) peptide administered by an Alzet mini pump (Bounoutas *et al.*, 2006). There does not appear to be a simple relationship between phosphorylation of the C-terminal tail of the PTH1R and receptor internalization/desensitization, however. Thus, Malecz *et al.* (1998) found that a similar alanine-substituted phosphorylation-deficient PTH1R mutant expressed at high levels in HEK-293 cells was internalized upon agonist binding just as efficiently as the wild-type receptor; in cotransfection experiments, Dicker *et al.* (1999) found that GRK-2 efficiently crosslinked to, coimmunoprecipitated with, and inhibited agonist-induced PLC signaling by a PTH1R mutant deleted for the C-terminal tail; and finally, using fluorescent confocal microscopy methods, Ferrari and Bisello (2001) found that a PTH1R deleted for the C-tail was internalized upon agonist binding just as efficiently as the intact receptor. This last study also showed that, like the intact receptor, the agonist-occupied C-terminally truncated receptor recruited β-Arr2 tagged with green fluorescent protein (GFP) from the cytosol to the membrane, but where the GFP-β-Arr2 remained associated with the internalized intact receptor, it dissociated rapidly from the internalized truncated receptor. Thus, phosphorylation of the C-terminal tail of the PTH1R appears to play a role in stabilizing the complex formed with the intracellular trafficking and regulatory proteins, but these proteins must also utilize other cytoplasmic components of the receptor for additional docking interactions.

Studies with the constitutively active mutant PTH receptors of Jansen's disease have begun to shed light on how conformational changes in the receptor might play a role in the internalization process. Both the H223R and the T410P mutant receptors spontaneously recruit β-Arr2 from the cytosol to the membrane (Ferrari and Bisello, 2001), but where the H223R mutant, as well as the wild-type receptor, exhibited little or no internalization of antagonist ligands, the T410P mutant internalized antagonist ligands to levels comparable to those seen with the agonist-occupied wild-type receptor (Carter *et al.*, 2001; Ferrari and Bisello, 2001). Thus, cAMP signaling and β-Arr2 binding by the PTH1R are not sufficient to induce internalization. In addition, it appears that a specific receptor conformation, which is presumably induced by agonist binding (or in some way mimicked by the T410P mutation), must be accessed for this process to occur. Further investigation with these PTH1R mutants, new ligand analogues, and fluorescently labeled regulatory proteins should help to elucidate further the molecular mechanisms involved in regulating the PTH1R-mediated signaling response, a possibly important feature of overall physiological regulation of PTH action and its pharmacological use. Paradoxically, the PTH(7–34) fragment

can induce internalization of the PTHR in renal distal tubule as well as in rat osteoblastic cells via a mechanism that appears to differ from that used by PTH(1–34), in that the former is inhibited by the presence of the PTH1R-scaffolding protein Na/H exchanger regulatory factor 1 (NHERF1; Mahon *et al.*, 2002, 2003; Mahon and Segre, 2004), whereas the latter is not (Sneddon *et al.*, 2003, 2004).

PTH1R MUTATIONS IN HUMAN DISEASE

Several diseases of bone and mineral metabolism have been linked to mutations in the PTH1R. As mentioned earlier, Jansen's metaphyseal chondrodysplasia is a rare disease associated with skeletal abnormalities, dwarfism, and hypercalcemia and is caused by heterozygous-dominant activating mutations in the PTHR (Calvi and Schipani, 2000). Mutations at the three sites have been found, each located at or near the cytoplasmic termini of one of the transmembrane domain helices: TM2 (Arg-233→His), TM6 (Thr-410→Pro), and TM7 (Ile-458→Arg) (see Fig. 4). The mutations cause constitutive, ligand-independent signaling of the receptor via the Gαs pathway, such that when transfected into COS-7 cells the mutant receptors produce basal cAMP levels that are severalfold higher than those observed for the wild-type PTH1R. Consistent with the skeletal phenotype of the affected individuals and the complex role that the PTHR plays in bone remodeling, transgenic mice having targeted expression of the PTHR1-H223R allele to osteoblasts exhibit increased bone in trabecular compartments but decreased bone in cortical areas (Calvi *et al.*, 2001). A different heterozygous activating mutation was identified in a patient with enchondromatosis (Ollier and Maffucci diseases), a rare disease characterized by cartilage tumors of the bone. The mutation, Arg-150→Cys, is located in the receptor's amino-terminal extracellular domain. When the corresponding receptor mutant was transfected into COS-7 cells and the lower expression levels were corrected for, a moderate elevation of ligand-independent basal cAMP, relative to wild-type, was observed (Hopyan *et al.*, 2002). The mechanism by which this mutation, located on the extracellular surface of the receptor, results in an apparent increase in the efficiency of coupling of the receptor to Gαs is unclear. Another mutation in the receptor's amino-terminal domain, Pro-132→Leu has been found in cases of Blomstrand's chondrodysplasia, a neonatal lethal disorder characterized by dramatically advanced endochondral bone maturation. Investigations into the underlying molecular defects of this disease revealed that Pro-132→Leu was present on both alleles, and when the corresponding mutant was analyzed in COS-7 cells, a loss-of-function phenotype was observed (Karaplis *et al.*, 1998; Zhang *et al.*, 1998). Whether this proline, situated in the core region of the amino-terminal domain, is directly involved in ligand interaction or provides a scaffolding function, as might be inferred from its preservation in all class II receptors, has not yet been determined. Finally, a nonsense mutation, Arg-485→Stop, was found in the C-terminal tail of the PTHR in a patient with Eiken syndrome, a rare homozygous recessive skeletal dysplasia (Duchatelet *et al.*, 2005). The phenotype associated with this mutation is opposite to that of Blomstrand's disease, in that skeletal ossification is extremely delayed. The Eiken skeletal phenotype appears consistent with an activating effect of the mutation, but the underlying mechanism is not yet clear. In any case, the absence of a phenotype for the Arg-485→Stop allele in the heterozygous carrier state, as well as the location of the mutation in the C-terminal tail of the receptor, point to a mechanism that is distinct from that which underlies the effects of the heterozygous activating mutations found in Jansen's chondrodysplasia.

OTHER RECEPTORS FOR PTH AND/OR PTHrP

Receptors for Mid- and Carboxyl-Terminal Portions of PTH and PTHrP

There is a substantial amount of pharmacological evidence in the literature for additional nonclassical receptors for PTH and PTHrP (Jüppner *et al.*, 2006). Competition binding studies and other functional assays have suggested that distinct receptors exist for midregional and carboxyl-terminal fragments of PTH or PTHrP, although the biological importance of such receptors remains to be established. For example, intact PTH and/or larger carboxyl-terminal PTH fragments have been shown to interact with a novel cell surface receptor (see later discussion). Other receptors appear to mediate the effects of midregional PTHrP on placental calcium transport (Kovacs *et al.*, 1996; Wu *et al.*, 1996) and in the skin (Orloff *et al.*, 1996). Carboxyl-terminal portions of PTHrP also have effects on osteoblasts (Cornish *et al.*, 1997, 1999; Fenton *et al.*, 1991a, 1991b), as well as the central nervous system (Fukayama *et al.*, 1995). A novel receptor that interacts with the amino-terminal portion of PTHrP, but not the amino-terminal portion of PTH, has been characterized in the rat supraoptic nucleus, and this PTHrP-selective receptor can regulate the synthesis and release of arginine vasopressin (Yamamoto *et al.*, 1998). Still other receptors that interact with amino-terminal portions of PTH and PTHrP have been identified pharmacologically that signal through changes in intracellular free calcium but not through increases in cAMP (Gaich *et al.*, 1993; Orloff *et al.*, 1995; Soifer *et al.*, 1992). Clearly there is strong interest in isolating complementary cDNAs, which encode such nonclassical receptors for PTH and PTHrP, but so far none have been identified. Such interest is highlighted by studies on the carboxyl-terminal portion of PTH.

Receptors Specific for Carboxyl-Terminal PTH in Bone (CPTHR)

The traditional view of PTH biology has been that the major biologic actions of PTH on bone, cartilage, and kidney result from activation of PTH1R, which is fully achieved by the N-terminal sequence PTH(1–34) (or the homologous N-terminal portion of PTHrP). This concept has derived largely from a heavy focus in the years following the isolation and structural identification of PTH on the use of cAMP production and of biologic responses now known to be largely cAMP dependent. These include calcemia and phosphaturia, as indices of PTH action *in vivo* and *in vitro*, although, as reviewed earlier, it is now known that PTH1R can also trigger cAMP-independent signaling events, including activation of PLC, PLD, PLA2, PKC, and increased cytosolic calcium, and that the structural determinants within both the PTH(1–34) ligand and the PTH1R itself that are required for these activities are not fully congruent.

Until very recently, the possibility that the C-terminal portion of the intact PTH(1–84) molecule might be physiologically important has received inadequate attention in part because (a) peptides such as PTH(39–84) or PTH(53–84) cannot be shown to bind or activate PTH1Rs; (b) the expressed PTH1R interacts equivalently with PTH(1–34) and PTH(1–84); (c) even minimal truncation at the N terminus of PTH(1–34) ablates PTH1R activation; and (d) differences in the bioactivity of PTH(1–34) and PTH(1–84) have not been demonstrated consistently in the usual "PTH bioassays" *in vitro* or *in vivo* (Potts and Jüppner, 1998). Moreover, the rapid production of C-terminal PTH fragments via endopeptidic cleavage of intact PTH *in vivo* (mainly in liver and kidney) has been regarded as the major route of metabolic clearance of active PTH, whereby the active N terminus of the molecule is destroyed *in situ* and long-lived C fragments are released back into the circulation (Potts and Jüppner, 1998). However, large portions of the C-terminal sequence of PTH(1–84) have been tightly conserved during evolution, active N-terminal fragments of PTH have not been demonstrated convincingly in blood of normal subjects, and C fragments of PTH (with N termini between residues 24 and 43) are cosecreted with intact hormone by the parathyroid glands in a manner whereby the ratio of intact fragments to C fragments is subject to regulation by blood calcium (Potts and Jüppner, 1998). Uncertainty regarding the potential importance of these observations, vis-à-vis a possible physiologic role for circulating C-terminal PTH peptides (CPTH), resulted mainly from a lack of evidence for specific receptors, distinct from the PTH1R (upon which all major PTH bioassays have been based), at which these peptides might act.

Initial indications that receptors for CPTH (CPTHRs) might exist actually appeared in the 1980s, when techniques were first developed to radiolabel intact PTH(1–84) in a biologically active form. At that time, careful analysis of ^{125}I-bPTH(1–84) binding to renal membranes and intact osteoblastic cells provided clear evidence of a second binding site that had a 10-fold lower affinity than that now known to pertain to the PTH1R and was specifically displaced by CPTH peptides (Demay *et al.*, 1985; Rao and Murray, 1985; Rao *et al.*, 1983). More recently, Inomata *et al.* reported the first direct measurements of CPTHR binding in ROS 17/2.8 rat osteosarcoma cells and rat parathyroid-derived cells, using radioiodinated recombinant peptides ^{125}I-[Tyr^{34}]hPTHrP(19–84) and ^{125}I-[Leu^{8,18}, Tyr^{34}]hPTHrP(1–84) as tracers (Inomata *et al.*, 1995). These two radioligands, which bind minimally, if at all, to the PTH1R, exhibited binding affinity comparable to that of hPTH(1–84) itself. These results suggested that all of the binding determinants of intact PTH(1–84) for the CPTHR reside within the PTH(19–84) sequence. Specific CPTHR binding was observed for hPTH(53–84), hPTH(39–94), and hPTH(1–84) but not hPTH(44–68) or hPTH(1–34); chemical crosslinking demonstrated a predominant 90-kDa receptor band (Inomata *et al.*, 1995). Unequivocal evidence that these CPTHR sites are distinct from the PTH1R subsequently was obtained via the demonstration of specific ^{125}I-[Tyr^{34}]hPTHrP(19–84) binding to clonal osteoblasts and osteocytes in which both PTH1R alleles had been ablated by gene targeting (Divieti *et al.*, 2001). The apparent binding affinity of these CPTHR sites for intact PTH and longer CPTH fragments (K_d = 0–20 nM) was 10-fold lower than that of the PTH1R for PTH(1–84) or PTH(1–34) (1–2 nM). Interestingly, this difference in affinity of PTH1Rs and CPTHRs for intact PTH and CPTH fragments, respectively, mirrors their relative levels in blood, where evidence suggests a 5- to 10-fold higher concentration of CPTH peptides than intact hormone.

Early work in several laboratories documented increased alkaline phosphatase expression following exposure of rat of human osteosarcoma cells to CPTH peptides, and subsequent research has identified a variety of biologic effects of CPTH fragments, including regulation of collagen and IGFBP-5 mRNA in UMR-106 rat osteosarcoma cells, stimulation of ^{45}Ca uptake in SaOS-2 cells, promotion of osteoclast formation in primary murine bone and marrow cell cultures, regulation of collagen II and X mRNA in primary fetal bovine hypertrophic chondrocytes, induction of cytosolic calcium transients in human primary fetal hypertrophic chondrocytes, and control of dentin and enamel formation in organ-cultured embryonic mouse tooth germ (Erdmann *et al.*, 1996, 1998; Fukayama *et al.*, 1994; Kaji *et al.*, 1994; Murray *et al.*, 1991; Nakamoto *et al.*, 1993; Nasu *et al.*, 1998; Sutherland *et al.*, 1994; Takasu *et al.*, 1996; Tsuboi and Togari, 1998). Most often, these effects of CPTH peptides were different from, if not opposite to, those of PTH(1-34), although mediation by PTH1Rs could not be definitely excluded because all of the cells studied were known, or could be assumed, to

express PTH1Rs. More recent work, however, using cells genetically devoid of functional PTH1Rs, has clearly documented biologic responses to CPTHRs that must be distinct from the PTH1R (Divieti *et al.*, 2001). The structural features of the PTH ligand required for CPTHR activation have yet to be fully defined, although the importance of an intact C terminus for some, but not all, responses has been emphasized (Takasu *et al.*, 1996).

It is of interest that CPTHRs have been identified so far primarily in cells of skeletal origin, i.e., marrow stromal cells, osteoblasts, osteocytes, and chondrocytes. However, CPTHRs were also described for cells derived from rat parathyroid cells (rPTs), which have characteristics of fibroblasts (Potts and Jüppner, 1998). The highest levels of CPTHR expression reported to date ($2 - 3 \times 10^6$/cell) were observed in clonal cell lines, conditionally transformed by a temperature-sensitive SV40 transgene and isolated from embryonic PTH1R-null mice, with phenotypic features of osteocytes (i.e., a dendritic morphology and abundant expression of osteocalcin and connexin-43 but not of alkaline phosphatase or cbfa-1; Divieti *et al.*, 2001). In such cells, genetically devoid of PTH1Rs, PTH(1–84) could not elicit cAMP generation and, as expected, no binding of ^{125}I-[Tyr^{34}]hPTHrP(1-36) could be detected (Divieti *et al.*, 2001). Analysis of the structural requirements for CPTHR ligand binding in these cells, using the ^{125}I-[Tyr^{34}]hPTH(19–84) radioligand, demonstrated equivalent affinity of hPTH(1–84), [Tyr^{34}]hPTH(19–84), and hPTH(24–84) ($IC_{50} = 20 - 50$ nM) that declined substantially with further truncation to hPTH(39–84) ($IC_{50} = 20 - 50$ nM), indicating the presence of important binding determinants within the sequence hPTH(24–38). Interestingly, hPTH(1–34), which contains most of this region, also weakly displaced the CPTHR radioligand ($IC_{50} > 10{,}000$ nM). These key features of ligand recognition were shared in common with PTH1R-null chondrocytes, marrow stromal cells, osteoblasts, and osteocytes (P. Divieti, and F. R. Bringhurst, unpublished data), suggesting that these various cell types may express structurally identical CPTHRs.

A possible physiologic role for CPTHRs expressed by cells of the osteoblast lineage was suggested by observations that, in PTH1R-null clonal osteocytes, intact PTH, as well as CPTH fragments, such as hPTH(39–84) and hPTH(53–84), promote apoptosis. This contrasts with the antiapoptotic effect of PTH1R activation in such cells (Jilka *et al.*, 1998) and suggests that the PTH1R and the still-uncloned CPTHR may exert functionally antagonistic actions upon osteoblastic cells *in vivo*. CPTHR activation in clonal osteocytes also modified expression of connexin-43, suggesting a possible role in the regulation of cell-to-cell communication via gap junctions. The signal transduction mechanisms that may underlie these CPTHR effects remain unknown, although, as noted earlier, coupling to G_s is unlikely.

In summary, evidence that receptors with specificity for the carboxyl-terminal portion of intact PTH(1-84) (i.e., CPTHRs) exist in bone is now unequivocal (Divieti *et al.*, 2001). These receptors, most clearly defined *in vitro* using cell systems genetically devoid of PTH/PTHrP receptors (PTH1Rs), can bind and be activated by intact PTH(1–84) and various synthetic CPTH fragments, such as hPTH(19–84), hPTH(39–84), and hPTH(53–84) (Divieti *et al.*, 2001; Murray *et al.*, 1991). Numerous biologic responses to CPTHR activation have been identified, including regulation of calcium transients, alkaline phosphatase, collagen gene expression, osteoclast formation, connexin-43 expression, and apoptosis (Demay *et al.*, 1985; Divieti *et al.*, 2001; Erdmann *et al.*, 1996, 1998; Fukayama *et al.*, 1994; Kaji *et al.*, 1994; Murray *et al.*, 1991; Nakamoto *et al.*, 1993; Nasu *et al.*, 1998; Rao and Murray, 1985; Rao *et al.*, 1983; Sutherland *et al.*, 1994; Takasu *et al.*, 1996; Tsuboi and Togari, 1998). Observations *in vivo* indicate that the fragment hPTH(7–84), which may exist normally *in vivo* but which clearly can bind CPTHRs with high affinity, antagonizes the PTH1R-mediated calcemic effect of PTH *in vivo* (Nguyen-Yamamoto *et al.*, 2000; Slatopolsky *et al.*, 2000). This *in vivo* action is mirrored in *in vitro* studies showing antagonism by hPTH(7–84) but not by hPTHrP(7–34) of calvarial bone resorption induced by PTH(1–34), suggesting a possible role for CPTHR activation in blocking the bone resorption (P. Divieti and F. R. Bringhurst, unpublished data). Finally, evidence that CPTHR activation promotes apoptosis in cells of the osteoblast lineage, an effect opposite that of PTH(1–34) in such cells, points to a potentially important interaction of PTH1Rs and CPTHRs in control of osteoblast and osteocyte number (Divieti *et al.*, 2001).

Carboxyl fragments of intact PTH are secreted in a calcium-regulated manner by the parathyroid glands, are generated rapidly from secreted or injected PTH(1–84) via peripheral metabolism in liver and kidney, circulate normally at molar levels 5-to 10-fold higher than those of intact PTH(1–84), and accumulate to much higher concentrations in renal failure (Potts and Jüppner, 1998). The possibility that CPTHR activation may play a role in modulating osseous responses to full-length (versus N-terminal) PTH administered as a therapeutic for osteoporosis or in the pathogenesis of currently unexplained features of renal osteodystrophy clearly is worthy of further investigation in light of all the accumulating evidence about high concentrations of CPTH fragments, the distinct CPTHR, and the variety of biological effects seen *in vitro* following the interactions of C fragments with the CPTHR.

THE PARATHYROID HORMONE GENE

The PTH Gene

The human parathyroid hormone (PTH) gene is localized on the short arm of chromosome 11 at 11p15 (Antonarakis *et al.*, 1983; Zabel *et al.*, 1985). The human and bovine genes have two functional TATA transcription start sites, and the rat has only one. The two homologous TATA sequences flanking the human PTH gene direct the synthesis of two human PTH gene transcripts both in normal parathyroid glands and in parathyroid adenomas (Igarashi *et al.*, 1986). The PTH genes in all species that have been cloned have two introns or intervening sequences and three exons (Kronenberg *et al.*, 1986). Strikingly, even though fish do not have discrete parathyroid glands, they do synthesize PTH by using two distinct genes that share the same exon–intron pattern found in tetrapod PTH genes (Danks *et al.*, 2003; Gensure *et al.*, 2004). The locations of the introns are identical in each case (Bell *et al.*, 2005b). Intron A splits the 5′-untranslated sequence of the mRNA five nucleotides before the initiator methionine codon. Intron B splits the fourth codon of the region that codes for the pro sequence of preproPTH. The three exons that result thus are roughly divided into three functional domains. Exon I contains the 5′-untranslated region. Exon II codes for the pre sequence or signal peptide and exon III codes for PTH and the 3′-untranslated region. The structure of the PTH gene is thus consistent with the proposal that exons represent functional domains of the mRNA (Kemper, 1986; Bell *et al.*, 2005b). Although the introns are at the same location, the size of the large intron A in humans is about twice as large as those in the rat and bovine (3500,1714, and 1600 nt, respectively). It is interesting that the human gene is considerably longer in both intron A and the 3′-untranslated region of the cDNA than the bovine, rat, and mouse. Knowledge of the structures of other PTH genes from other species will be necessary in order to determine whether extra sequences were inserted or are less susceptible to deletion in the human gene. Both introns have the characteristic splice site elements. The second exon, containing 106 and 121 nt in the human and bovine pre-mRNA is much smaller and more homologous in size among the genes than intron A. The genes for PTH and PTHrP (PTH-related protein) are located in similar positions on sibling chromosomes 11 and 12. It is therefore likely that they arose from a common precursor by chromosomal duplication.

The PTH mRNA

Complementary DNA encoding for human (Hendy *et al.*, 1981; Vasicek *et al.*, 1983), bovine (Kronenberg *et al.*, 1979; Weaver *et al.*, 1982), rat (Schmelzer *et al.*, 1987), mouse (He *et al.*, 2002), pig (Schmelzer *et al.*, 1987), chicken (Khosla *et al.*, 1988; Russell and Sherwood, 1989), dog (Rosol *et al.*, 1995), cat (Toribio *et al.*, 2002), horse (Caetano *et al.*, 1999), macaca (Malaivijitnond *et al.*, 2002), fugu fish (Danks *et al.*, 2003), and zebrafish (Gensure *et al.*, 2004) PTH have all been cloned. The PTH gene is a typical eukaryotic gene with consensus sequences for initiation of RNA synthesis, RNA splicing, and polyadenylation. The primary RNA transcript consists of RNA transcribed from both introns and exons, and then RNA sequences derived from the introns are spliced out. The product of this RNA processing, which represents the exons, is the mature PTH mRNA, which will then be translated into preproPTH. There is considerable identity among mammalian PTH genes, which is reflected in an 85% identity between human and bovine proteins

[1]Corresponding author: Henry M. Kronenberg MD, Endocrine Unit, Massachusetts General Hospital, Harvard Medical School, Boston, MA 02114. E mail: kronenberg.henry@mgh.harvard.edu

and 75% identity between human and rat proteins. There is less identity in the 3′-noncoding region. The actual initiator ATG codons for the human and bovine have been identified by sequencing *in vitro* translation products of the mRNAs (Habener *et al.*, 1975; Kemper *et al.*, 1976). In the bovine sequence, the first ATG codon is the initiator codon, in accord with many other eukaryotic mRNAs (Kozak, 1991a, 1991b). The human and rat sequences have ATG triplets prior to the probable initiator ATG, which are present ten nucleotides before the initiation codon and are immediately followed by a termination codon. The termination codon immediately following the codon for glutamine at position 84 of PTH indicates that there are no additional precursors of PTH with peptide extensions at the carboxyl position. A more extensive review of the structure and sequences of the PTH gene has been published elsewhere in the book, *Molecular Biology of the Parathyroid* (Bell *et al.*, 2005b).

DEVELOPMENT OF THE PARATHYROID AND TISSUE-SPECIFIC EXPRESSION OF THE PTH GENE

The thymus, thyroid, and parathyroid glands in vertebrates develop from the pharyngeal region, with contributions both from pharyngeal endoderm and from neural crest cells in the pharyngeal arches. Studies of gene knockout mice have shown that the hoxa3, pax 1, pax 9, and Eya1 transcription factors are needed to form parathyroid glands as well as many other pharyngeal pouch derivatives, such as the thymus. Hoxa3 mutant homozygotes have defects in the development of all three organs and are completely missing parathyroid glands (Manley and Capecchi, 1998). Pax 1 and Pax 9 mouse mutants are similarly missing parathyroid glands and other pharyngeal pouch structures (Su *et al.*, 2001; Peters *et al.*, 1998). Eyes absent (Eya) genes regulate organogenesis in both vertebrates and invertebrates. Mutations in human EYA1 cause congenital Branchio-Oto-Renal (BOR) syndrome, whereas targeted inactivation of murine Eya1 impairs early developmental processes in multiple organs, including the ears, kidneys, and skeletal system. Eya1 is also important to the morphogenesis of organs derived from the pharyngeal region, including thymus, parathyroid, and thyroid (Xu *et al.*, 2002). The thymus and parathyroid are derived from 3rd pharyngeal pouches and their development is initiated via inductive interactions between neural crest-derived arch mesenchyme, pouch endoderm, and possibly the surface ectoderm of 3rd pharyngeal clefts. Eya1 is expressed in all three cell types during thymus and parathyroid development from E9.5, and the organ primordia for both of these structures failed to form in Eya1−/− embryos. These results indicate that Eya1 is required for the initiation of thymus and parathyroid gland formation. Six1 expression is markedly reduced in the arch mesenchyme, pouch endoderm, and surface ectoderm in the pharyngeal region of Eya1−/− embryos, indicating that Six1 expression in those structures is Eya1 dependent (Xu *et al.*, 2002). In addition, in Eya1−/− embryos, the expression of Gcm2 (see later) in the 3rd pouch endoderm is undetectable at E10.5; however, the expression of Hox and Pax genes in the pouch endoderm is preserved at E9.5–10.5. Therefore, Eya1 controls critical early inductive events involved in the morphogenesis of thymus, parathyroid, and thyroid and is independent of Hox and Pax genes and upstream of Gcm2 in the development of the parathyroid.

The DiGeorge syndrome is a human genetic condition resulting from deletion of contiguous genes. The specific gene causing the hypoparathroidism found in DiGeorge syndrome and the closely related CATCH-22 syndrome (cardiac defects, abnormal facies, thymic hypoplasia, cleft palate, hypocalcemia, associated with chromosome 22 microdeletion) is likely to be Tbx1 (Baldini, 2005). In the DiGeorge syndrome, malformations include absence of the parathyroid glands and thymus as well as the heart outflow tract, and most DiGeorge syndrome patients are hemizygous for a 1.5–3.0 Mb region of 22q11. In mice deletion of one copy of Tbx1 (in the equivalent genetic region in the mouse) affects the development of the parathyroids, the thymus, and the fourth pharyngeal arch arteries, whereas homozygous mutation severely disrupts cardiac outflow as well (Merscher *et al.*, 2001; Lindsay *et al.*, 2001). These data in mice suggest that Tbx1 has a major role in the molecular etiology of the DiGeorge syndrome phenotype.

In addition to the genes just discussed, which function in early differentiation of parathyroid cells in the context of effects more broadly during development of pharyngeal pouches, other genes have more specific effects on parathyroid gland development. Gunther *et al.* (2000) studied Glial cells missing2 (Gcm2), a mouse homologue of *Drosophila* Gcm, a transcription factor whose expression is restricted to the parathyroid glands. They showed that Gcm2-deficient mice lacked parathyroid glands and exhibited hypoparathyroidism, identifying Gcm2 as a master regulatory gene of parathyroid gland development. Thymus development was not affected by Gcm2 deletion. Gcm2-deficient mice were viable and fertile and had only a mildly abnormal bone phenotype. Despite their lack of parathyroid glands, Gcm2-deficient mice had PTH serum levels similar to those of wild-type mice (in the presence of hypocalcemia), as did parathyroidectomized wild-type mice. Expression and ablation studies identified the thymus, where Gcm1, another Gcm homologue, is expressed as the additional, down-regulatable source of PTH. Thus, Gcm2 deletion uncovered an auxiliary mechanism for the regulation of calcium homeostasis in the absence of parathyroid glands. A human patient with a defective Gcm B gene, the human equivalent of Gcm-2, exhibited hypoparathyroidism and complete absence of PTH from the bloodstream (Ding *et al.*, 2000).

Two other genes needed for the formation of parathyroid glands are GATA3 and SOX3. Humans with one mutated

copy of the GATA3 transcription factor exhibit hypoparathyroidism, sensorineural deafness, and renal anomalies (Van Esch *et al.*, 2000). Humans with X-linked hypoparathyroidism manifest a deletion–insertion near the end of the SOX3 gene, a finding that suggests an important role for Sox3 in parathyroid development (Bowl *et al.*, 2005).

Okabe and Graham (2004) performed elegant studies that demonstrate a role for Gcm-2 even in fish, which do not have discrete parathyroid glands. They showed that the parathyroid gland of tetrapods and the gills of fish both express Gcm-2 and require this gene for their formation. They also showed that the gill region expresses mRNA encoding the two PTH genes found in fish, as well as mRNA encoding the calcium-sensing receptor. They speculate that gcm-2, PTH, and the calcium-sensing receptor might, therefore be found in the fish equivalent of parathyroid cells. This hypothesis about the origin of parathyroid cells, however, is not supported by other studies that show that fish parathyroid hormones are not synthesized in the gill but instead in lateral line neuromasts, mechanosensory cells that are distributed along the fish's body surface. The relationship between these cells and parathyroid cells of tetrapods is unknown. Thus, the conserved role of Gcm-2 in forming pharyngeal structures is established, but the relationship between Gcm-2 and parathyroid hormone-producing cells in fish requires further experimentation.

PROMOTER SEQUENCES

Regions upstream of the transcribed structural gene often determine tissue specificity and contain many of the regulatory sequences for the gene. For PTH, analysis of this region has been hampered by the lack of a parathyroid cell line. Arnold's group has demonstrated, however, that the 5 kb of DNA upstream of the start site of the human PTH gene was able to direct parathyroid gland-specific expression in transgenic mice (Hosokawa *et al.*, 1997). Analysis of the human PTH promoter region identified a number of consensus sequences by computer analysis (Kel *et al.*, 2005). These included a sequence resembling the canonical cAMP-responsive element 5′-TGACGTCA-3′ at position −81 with a single-residue deviation. This element was fused to a reporter gene (CAT) and then transfected into different cell lines. Pharmacological agents that increase cAMP led to an increased expression of the CAT gene, suggesting a functional role for the cAMP-responsive element (CRE). The role of this putative CRE in the PTH gene in the parathyroid remains to be established. Specificity protein (Sp) and the nuclear factor-Y (NF-Y) complex are thought to be ubiquitously expressed transcription factors associated with basal expression of a host of gene products. Sp family members and NF-Y can cooperatively enhance transcription of a target gene. Koszewski and colleagues (Alimov *et al.*, 2005) identified and characterized a highly conserved Sp1 DNA element present in mammalian PTH promoters. They showed that coexpression of Sp proteins and NF-Y complex leads to synergistic transactivation of the hPTH promoter, with alignment of the Sp1 DNA element essential for full activation (Alimov *et al.*, 2005). They also identified a similar arrangement of DNA response elements and synergism in the bovine PTH (bPTH) promoter, suggesting that this may be a conserved mechanism to enhance transcription of the PTH gene. They demonstrated the presence of a proximal NF-Y-binding site in the hPTH promoter and highlight the potential for synergism between distal and proximal NF-Y DNA elements to strongly enhance transcription (Koszewski *et al.*, 2004). Moreover, their data raised the possibility that the repressive effects of vitamin D on hPTH gene transcription may involve displacement of NF-Y binding to the proximal site by the $1,25(OH)_2D_3$ receptor (VDR) heterodimer, which subsequently attenuates synergistic transactivation (Koszewski *et al.*, 2004).

Several groups have identified DNA sequences that might mediate the negative regulation of PTH gene transcription by 1,25-dihydroxyvitamin D [$1,25(OH)_2D_3$]. Demay *et al.* (1992) identified DNA sequences in the human PTH gene that bind the $1,25(OH)_2D_3$ receptor. Nuclear extracts containing the $1,25(OH)_2D_3$ receptor were examined for binding to sequences in the 5′-flanking region of the hPTH gene. A 25-bp oligonucleotide containing sequences from −125 to −101 from the start of exon 1 bound nuclear proteins that were recognized by monoclonal antibodies against the $1,25(OH)_2D_3$ receptor. The sequences in this region contained a single copy of a motif (AGGTTCA) that is homologous to the motifs repeated in the upregulatory $1,25(OH)_2D_3$ response element of the osteocalcin gene. When placed upstream to a heterologous viral promoter, the sequences contained in this 25-bp oligonucleotide mediated transcriptional repression in response to $1,25(OH)_2D_3$ in GH4C1 cells but not in ROS 17/2.8 cells. Therefore, this downregulatory element differs from upregulatory elements both in sequence composition and in the requirement for particular cellular factors other than the $1,25(OH)_2D_3$ receptor (VDR) for repressing PTH transcription (Demay *et al.*, 1992). Russell *et al.* (1999) have shown that there are two negative VDREs in the rat PTH gene. One is situated at −793 to −779 and bound a VDR/RXR heterodimer with high affinity and the other at −760 to −746 bound the heterodimer with a lower affinity. Transfection studies with VDRE-CAT constructs showed that they had an additive effect. Liu *et al.* (1996) identified such sequences in the chicken PTH gene and demonstrated their functionality after transfection into the opossum kidney (OK) cell line. They converted the negative activity imparted by the PTH VDRE to a positive transcriptional response through selective mutations introduced into the element. They showed that there was a p160 protein that specifically interacted with a heterodimer complex bound to the wild-type VDRE, but was absent from complexes bound to response elements associated with positive

transcriptional activity. Thus, the sequence of the individual VDRE appears to play an active role in dictating transcriptional responses that may be mediated by altering the ability of a vitamin D receptor heterodimer to interact with accessory factor proteins. Further work is needed to demonstrate that any of these differing negative VDREs function in this fashion in parathyroid cells.

The transrepression by 1,25-$(OH)_2D_3$ has also been shown to depend on another promoter element. Kato's laboratory have identified an E-box (CANNTG)-like motif as another class of nVDRE in the human 1α(OH)ase promoter (Murayama *et al.*, 2004; Fujiki *et al.*, 2005). In sharp contrast to the previously reported DR3-like motif in the hPTH gene promoter, a basic helix-loop-helix factor, designated VDR interacting repressor (VDIR), transactivates through direct binding to this E-box-type element (1αnVDRE). However, the VDIR transactivation function is transrepressed through ligand-induced protein–protein interaction of VDIR with VDR/RXR. In the absence of 1,25-$(OH)_2D_3$, VDIR appears to bind to 1αnVDRE for transactivation through the histone acetylase (HAT) coactivator, p300/CBP. Binding of 1α,25$(OH)_2D_3$ to VDR induces interaction with VDIR and dissociation of the HAT coactivator, resulting in recruitment of histone deacetylase (HDAC) corepressor for ligand-induced transrepression (Murayama *et al.*, 2004). They have also characterized the functions of VDIR and E-box motifs in the human (h) PTH and hPTHrP gene promoters (Kim *et al.*, 2007). They identified E-box-type elements acting as nVDREs in both the hPTH promoter (hPTHnVDRE; −87 to −60 bp) and in the hPTHrP promoter (hPTHrPnVDRE; −850 to −600 bp; −463 to −104 bp) in a mouse renal tubule cell line. The hPTHnVDRE alone was enough to direct ligand-induced transrepression mediated through VDR/retinoid X receptor and VDIR. Direct DNA binding of hPTHnVDRE to VDIR, but not VDR/retinoid X receptor, was observed and ligand-induced transrepression was coupled with recruitment of VDR and histone deacetylase 2 (HDAC2) to the hPTH promoter. They concluded that negative regulation of the hPTH gene by liganded VDR is mediated by VDIR directly binding to the E-box-type nVDRE at the promoter, together with recruitment of an HDAC corepressor for ligand-induced transrepression (Kim *et al.*, 2007). These studies were specific to a mouse proximal tubule cell line and await the development of a parathyroid cell line to confirm them in a homologous cell system.

MUTATIONS IN THE PTH GENE

Rare patients have been found with abnormal parathyroid hormone genes that result in hypoparathyroidism (Gafni and Levine, 2005). The PTH gene of a patient with familial isolated hypoparathyroidism (Ahn *et al.*, 1986) was studied by Arnold *et al.* (1990), and a point mutation in the hydrophobic core of the signal peptide-encoding region of preproPTH was identified. This T-to-C point mutation changed the codon for position 18 of the 31-amino-acid prepro sequence from cysteine to arginine, and in functional studies the mutant protein was processed inefficiently. The mutation impaired interaction of the nascent protein with signal recognition particles and the translocation machinery, and cleavage of the mutant signal sequence by solubilized signal peptidase was slow (Karaplis *et al.*, 1995). Sunthornthepvarakul *et al.* (1999) reported a novel mutation of the signal peptide of the prepro-PTH gene associated with autosomal recessive familial isolated hypoparathyroidism. The affected members in this family presented with neonatal hypocalcemic seizures. Their intact PTH levels were undetectable during severe hypocalcemia. A replacement of thymine with a cytosine was found in the first nucleotide of position 23 in the 25-amino-acid signal peptide. This results in the replacement of the normal Ser (TCG) with a Pro (CCG). Only affected family members were homozygous for the mutant allele, whereas the parents were heterozygous, supporting autosomal recessive inheritance. Because this mutation is at the −3 position in the signal peptide of the prepro-PTH gene, the authors hypothesized that the prepro-PTH mutant might not be cleaved by signal peptidase at the normal position and might be degraded in the rough endoplasmic reticulum. Parkinson and Thakker (1992) studied one kindred with autosomal recessive isolated hypoparathyroidism and identified a G-to-C substitution in the first nucleotide of intron 2 of the parathyroid hormone gene. Restriction enzyme cleavage revealed that the patients were homozygous for mutant alleles, unaffected relatives were heterozygous, and unrelated normals were homozygous for the wild-type alleles. Defects in messenger RNA splicing were investigated by the detection of illegitimate transcription of the PTH gene in lymphoblastoid cells. The mutation resulted in exon skipping with a loss of exon 2, which encodes the initiation codon and the signal peptide, thereby causing parathyroid hormone deficiency. Somatic mutations identified in the PTH gene in some parathyroid adenomas are discussed elsewhere in this book. Goswami *et al.* (2004) studied 51 patients with sporadic idiopathic hypoparathyroidism. Neither the clinical manifestations nor the biochemical indexes of the disease were related to the occurrence of mutations or SNPs in the PTH gene. Because neither patient nor control samples exhibited any variations in the sequence of their 3′-UTR regions, they concluded that it is unlikely that mRNA instability is a factor in the pathogenesis of the disease (Goswami *et al.*, 2004).

REGULATION OF PTH GENE EXPRESSION

1,25-Dihydroxyvitamin D

PTH regulates serum concentrations of calcium and phosphate, which, in turn, regulate the synthesis and secretion

of PTH. 1,25-Dihydroxyvitamin D (calcitriol) has independent effects on calcium and phosphate levels and also participates in a well-defined feedback loop between calcitriol and PTH.

PTH increases the renal synthesis of calcitriol. Calcitriol then increases blood calcium largely by increasing the efficiency of intestinal calcium absorption. Calcitriol also potently decreases transcription of the PTH gene. This action was first demonstrated *in vitro* in bovine parathyroid cells in primary culture, where calcitriol led to a marked decrease in PTH mRNA levels (Silver *et al.*, 1985; Russell *et al.*, 1984) and a consequent decrease in PTH secretion (Cantley *et al.*, 1985a, 1985b; Karmali *et al.*, 1989; Chan *et al.*, 1986). The physiological relevance of these findings was established by *in vivo* studies in rats (Silver *et al.*, 1986). The localization of $1,25(OH)_2D_3$ receptor mRNA (VDR mRNA) to parathyroids was demonstrated by *in situ* hybridization studies of the thyroparathyroid and duodenum. VDR mRNA was localized to the parathyroids in the same concentration as in the duodenum, the classic target organ of calcitriol (Naveh-Many *et al.*, 1990). Rats injected with amounts of calcitriol that did not increase serum calcium had marked decreases in PTH mRNA levels, reaching $<4\%$ of control at 48 hours. This effect was shown to be transcriptional both in *in vivo* studies in rats (Silver *et al.*, 1986) and in *in vitro* studies with primary cultures of bovine parathyroid cells (Russell *et al.*, 1986). When 684 bp of the 5′-flanking region of the human PTH gene was linked to a reporter gene and transfected into a rat pituitary cell line (GH4C1), gene expression was lowered by $1,25(OH)_2D_3$ (Okazaki *et al.*, 1988). These studies suggest that $1,25(OH)_2D_3$ decreases PTH transcription by acting on the 5′-flanking region of the PTH gene, probably at least partly through interactions with the vitamin D receptor-binding sequences and/or the E-box that binds VDIR noted earlier. The effect of $1,25(OH)_2D_3$ may involve heterodimerization with the retinoid acid receptor. This is because 9 *cis*-retinoic acid, which binds to the retinoic acid receptor, when added to bovine parathyroid cells in primary culture, led to a decrease in PTH mRNA levels (MacDonald *et al.*, 1994). Moreover, combined treatment with 1×10^{-6} M retinoic acid and 1×10^{-8} M $1,25(OH)_2D_3$ decreased PTH secretion and preproPTH mRNA more effectively than either compound alone (MacDonald *et al.*, 1994). Alternatively, retinoic acid receptors might synergize with VDRs through actions on distinct sequences.

A further level at which $1,25(OH)_2D_3$ might regulate the PTH gene would be at the level of the $1,25(OH)_2D_3$ receptor. $1,25(OH)_2D_3$ acts on its target tissues by binding to the $1,25(OH)_2D_3$ receptor, which regulates the transcription of genes with the appropriate recognition sequences. Concentration of the $1,25(OH)_2D_3$ receptor in $1,25(OH)_2D_3$ target sites could allow a modulation of the $1,25(OH)_2D_3$ effect, with an increase in receptor concentration leading to an amplification of its effect and a decrease in receptor concentration dampening the $1,25(OH)_2D_3$ effect. Naveh-Many *et al.* (1990) injected $1,25(OH)_2D_3$ into rats and measured the levels of $1,25(OH)_2D_3$ receptor mRNA and PTH mRNA in the parathyroid tissue. They showed that $1,25(OH)_2D_3$ in physiologically relevant doses led to an increase in VDR mRNA levels in the parathyroid glands in contrast to the decrease in PTH mRNA levels. This increase in VDR mRNA occurred after a time lag of 6 hours, and a dose response showed a peak at 25 pmol. Weanling rats fed a diet deficient in calcium were markedly hypocalcemic at 3 weeks and had very high serum $1,25(OH)_2D_3$ levels. Despite the chronically high serum $1,25(OH)_2D_3$ levels, there was no increase in VDR mRNA levels; furthermore, PTH mRNA levels did not fall and were increased markedly. The low calcium in the bloodstream may have prevented the increase in parathyroid VDR levels, which may partially explain PTH mRNA suppression. Whatever the mechanism, the lack of suppression of PTH synthesis in the setting of hypocalcemia and increased serum $1,25(OH)_2D_3$ is crucial physiologically because it allows an increase in both PTH and $1,25(OH)_2D_3$ at a time of chronic hypocalcemic stress. Russell *et al.* (1993) studied the parathyroids of chicks with vitamin D deficiency and confirmed that $1,25(OH)_2D_3$ regulates PTH and VDR gene expression in the avian parathyroid gland. Brown *et al.* (1995) studied vitamin D-deficient rats and confirmed that calcitriol upregulated parathyroid VDR mRNA. Rodriguez *et al.* (2007) showed that administration of the calcimimetic R-568 resulted in increased VDR expression in parathyroid tissue. *In vitro* studies of the effect of R-568 on VDR mRNA and protein were conducted in cultures of whole rat parathyroid glands. Incubation of rat parathyroid glands *in vitro* with R-568 resulted in a dose-dependent decrease in PTH secretion and an increase in VDR expression. Together with previous work on the effect of extracellular calcium to increase parathyroid VDR mRNA *in vitro* (Garfia *et al.*, 2002), they concluded that activation of the CaR upregulates the parathyroid VDR mRNA.

All these studies show that $1,25(OH)_2D_3$, and calcium in certain circumstances, increases the expression of the VDR gene in the parathyroid gland, which would result in increased VDR protein synthesis and increased binding of $1,25(OH)_2D_3$. This ligand-dependent receptor upregulation would lead to an amplified effect of $1,25(OH)_2D_3$ on the PTH gene and might help explain the dramatic effect of $1,25(OH)_2D_3$ on the PTH gene.

Vitamin D may also amplify its effect on the parathyroid by increasing the activity of the calcium receptor (CaR). Canaff and Hendy (2002) showed that, in fact, there are VDREs in the human CaR promoter. The calcium-sensing receptor (CaR), expressed in parathyroid chief cells, thyroid C-cells, and cells of the kidney tubule, is essential for maintenance of calcium homeostasis. They showed that parathyroid, thyroid, and kidney CaR mRNA levels increased 2-fold at 15 hours after intraperitoneal injection of $1,25(OH)_2D_3$ in rats. Human thyroid C-cell (TT) and

kidney proximal tubule cell (HKC) CaR gene transcription increased approximately 2-fold at 8 and 12 hours after $1,25(OH)_2D_3$ treatment. The human CaR gene has two promoters yielding alternative transcripts containing either exon 1A or exon 1B 5′-untranslated region sequences that splice to exon 2 some 242 bp before the ATG translation start site. Transcriptional start sites were identified in parathyroid gland and TT cells; the transcriptional start site for promoter P1 lies 27 bp downstream of a TATA box, whereas that for promoter P2, which lacks a TATA box, lies in a GC-rich region. In HKC cells, transcriptional activity of a P1 reporter gene construct was 11-fold and of P2 was 33-fold above basal levels. $1,25(OH)_2D_3$ (10^{-8} M) stimulated P1 activity 2-fold and P2 activity 2.5-fold. Vitamin D response elements (VDREs), in which half-sites (6 bp) are separated by three nucleotides, were identified in both promoters and shown to confer $1,25(OH)_2D_3$ responsiveness to a heterologous promoter. This responsiveness was lost when the VDREs were mutated. In electrophoretic mobility shift assays with either *in vitro* transcribed/translated vitamin D receptor and retinoid X receptor-alpha, or HKC nuclear extract, specific protein–DNA complexes were formed in the presence of $1,25(OH)_2D_3$ on oligonucleotides representing the P1 and P2 VDREs. In summary, functional VDREs have been identified in the CaR gene and probably provide the mechanism whereby $1,25(OH)_2D_3$ upregulates parathyroid, thyroid C-cell, and kidney CaSR expression.

The use of calcitriol is limited by its hypercalcemic effect, and therefore a number of calcitriol analogs have been synthesized that are biologically active but are less hypercalcemic than calcitriol (Brown, 2005). These analogs usually involve modifications of the calcitriol side chain, such as 22-oxa-$1,25(OH)_2D_3$, which is the chemical modification in oxacacitriol (Nishii *et al.*, 1991), or a cyclopropyl group at the end of the side chain in calcipotriol (Kissmeyer and Binderup, 1991; Evans *et al.*, 1991). Brown *et al.* (1989) showed that oxacalcitriol *in vitro* decreased PTH secretion from primary cultures of bovine parathyroid cells with a similar dose response to that of calcitriol. *In vivo* the injection of both vitamin D compounds led to a decrease in rat parathyroid PTH mRNA levels (Brown *et al.*, 1989). However, detailed *in vivo* dose–response studies showed that *in vivo* calcitriol is the most effective analog for decreasing PTH mRNA levels, even at doses that do not cause hypercalcemia (Naveh-Many and Silver, 1993). Oxacalcitriol and calcipotriol are less effective for decreasing PTH RNA levels but have a wider dose range at which they do not cause hypercalcemia; this property might be useful clinically. The marked activity of calcitriol analogs *in vitro* compared with their modest hypercalcemic actions *in vivo* probably reflects their rapid clearance from the circulation (Bouillon *et al.*, 1991). There is much interest in the development and marketing of new calcitriol analogs to decrease PTH gene expression and serum PTH levels without causing hypercalcemia, but there have been few rigorous comparisons of their biological effects compared with those of calcitriol itself (Brown, 1998; Verstuyf *et al.*, 1998). There has been a lot of debate about the relative advantages of the so-called "nonhypercalcemic" vitamin D analogs over $1,25(OH)_2$ vitamin D_3. Drueke (2005) has analyzed the clinical trials that have been performed and concluded that all clinical studies were retrospective in nature and suffered from the limitations of retrospective data analysis. The question is still open.

However, the ability of calcitriol to decrease PTH gene transcription is used therapeutically in the management of patients with chronic renal failure. They are treated with calcitriol, or its prodrug 1α(OH)-vitamin D_3 in order to prevent the secondary hyperparathyroidism of chronic renal failure. The poor response in some patients may well result from poor control of serum phosphate, decreased vitamin D receptor concentration in the patients' parathyroids (Fukuda *et al.*, 1993), an inhibitory effect of a uremic toxin(s) on VDR-VDRE binding (Patel and Rosenthal, 1985), or tertiary hyperparathyroidism with monoclonal parathyroid tumors (Arnold *et al.*, 1995).

Calreticulin and the Action of $1,25(OH)_2D_3$ on the PTH Gene

Another possible level at which $1,25(OH)_2$ vitamin D_3 might regulate PTH gene expression involves calreticulin. Calreticulin is a calcium-binding protein present in the endoplasmic reticulum of the cell and may also have a nuclear function. It regulates gene transcription via its ability to bind a protein motif in the DNA-binding domain of nuclear hormone receptors of sterol hormones. It has been shown to prevent vitamin D's binding and action on the osteocalcin gene *in vitro* (Wheeler *et al.*, 1995). Sela-Brown *et al.* (1998) showed that calreticulin might inhibit the action of vitamin D on the PTH gene. Both rat and chicken VDRE sequences of the PTH gene were incubated with recombinant VDR and retinoic acid receptor (RXR) proteins in a gel retardation assay and showed a clear retarded band. Purified calreticulin inhibited binding of the VDR-RXR complex to the VDREs in gel retardation assays. This inhibition was caused by direct protein–protein interactions between VDR and calreticulin. OK cells were transiently cotransfected with calreticulin expression vectors and either rat or chicken PTH gene promoter-CAT constructs. The cells were then assayed for $1,25(OH)_2D_3$-induced CAT gene expression. $1,25(OH)_2D_3$ decreased PTH promoter-CAT transcription. Cotransfection with sense calreticulin, which increases calreticulin protein levels, completely inhibited the effect of $1,25(OH)_2D_3$ on the PTH promoters of both rat and chicken. Cotransfection with the antisense calreticulin construct did not interfere with the effect of vitamin D on PTH gene transcription. Calreticulin expression had no effect on basal CAT mRNA levels. In order to determine a

physiological role for calreticulin in regulation of the PTH gene, levels of calreticulin protein were determined in the nuclear fraction of rat parathyroids. The rats were fed either a control diet or a low calcium diet, which leads to increased PTH mRNA levels, despite high serum $1,25(OH)_2D_3$ levels that would be expected to inhibit PTH gene transcription (Sela-Brown *et al.*, 1998). It was postulated that high calreticulin levels in the nuclear fraction would prevent the effect of $1,25(OH)_2D_3$ on the PTH gene. In fact, hypocalcemic rats had increased levels of calreticulin protein, as measured by Western blots, in their parathyroid nuclear faction. This may help explain why hypocalcemia leads to increased PTH gene expression, despite high serum $1,25(OH)_2D_3$ levels, and may also be relevant to the refractoriness of the secondary hyperparathyroidism of many chronic renal failure patients to $1,25(OH)_2D_3$ treatment. These studies, therefore, indicate a role for calreticulin in regulating the effect of vitamin D on the PTH gene and suggest a physiological relevance to these studies (Sela-Brown *et al.*, 1998).

Calcium

In Vitro Studies

A remarkable characteristic of the parathyroid is its sensitivity to small changes in serum calcium, which leads to large changes in PTH secretion. This remarkable sensitivity of the parathyroid to increase hormone secretion after small decreases in serum calcium levels is unique to the parathyroid. All other endocrine glands increase hormone secretion after exposure to a high extracellular calcium. This calcium sensing is also expressed at the levels of PTH gene expression and parathyroid cell proliferation. *In vitro* and *in vivo* data agree that calcium regulates PTH mRNA levels, but data differ in important ways. *In vitro* studies with bovine parathyroid cells in primary culture showed that calcium regulated PTH mRNA levels (Russell *et al.*, 1983; Brookman *et al.*, 1986), with an effect mainly of high calcium to decrease PTH mRNA. These effects were most pronounced after more prolonged incubations, such as 72 hours. The physiological correlates of these studies in tissue culture are hard to ascertain, because the parathyroid calcium sensor might well have decreased over the time period of the experiment (Mithal *et al.*, 1995). This may explain why the dose response differs from *in vivo* data, but the dramatic difference in time course suggests that *in vivo* data reflect something not seen in cultured cells.

In Vivo Studies

Calcium and phosphate both have marked effects on the levels of PTH mRNA *in vivo*. The major effect is for low calcium to increase PTH mRNA levels and low phosphate to decrease PTH mRNA levels (Fig. 1). Naveh-Many *et al.* (1989) studied rats *in vivo*. They showed that a small decrease in serum calcium from 2.6 to 2.1 mmol/L led to large increases in PTH mRNA levels, reaching threefold that of controls at 1 and 6 hours. A high serum calcium had no effect on PTH mRNA levels even at concentrations as high as 6.0 mmol/L. Interestingly, in these same thyroparathyroid tissue RNA extracts, calcium had no effect on the expression of the calcitonin gene (Naveh-Many, 1989; Naveh-Many *et al.*, 1992b). Thus, whereas a high calcium is a secretagogue for calcitonin, it does not regulate calcitonin gene expression. Yamamoto *et al.* (1989) also studied the *in vivo* effect of calcium on PTH mRNA levels in rats. They showed that hypocalcemia induced by a calcitonin infusion for 48 hours led to a sevenfold increase in PTH mRNA levels. Rats made hypercalcemic (2.9–3.4 mM) for 48 hours had the same PTH mRNA levels as controls that had received no infusion (2.5 mM); these levels were modestly lower than those found in rats that had received a calcium-free infusion. In further studies, Naveh-Many *et al.* (1992b) transplanted Walker carcinosarcoma 256

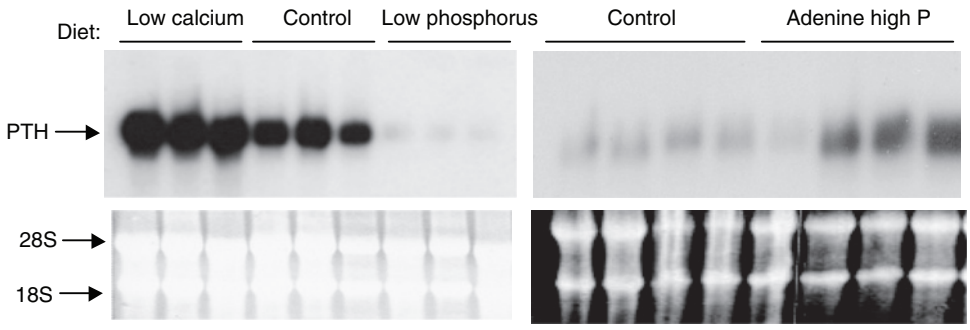

FIGURE 1 The effect of dietary phosphorus and calcium depletion and adenine high phosphorus-induced renal failure on PTH mRNA levels. PTH mRNA levels are shown for individual weanling rats fed diets containing low calcium, control, or low phosphorus, and mature rats fed control or adenine-high phosphorus.

cells into rats. Serum calciums increased to 18 mg/dL at day 10 after transplantation. There was no change in PTH mRNA levels in the rats with marked chronic hypercalcemia (Naveh-Many *et al.*, 1992b). Differences between *in vivo* and *in vitro* results probably reflect the instability of the *in vitro* system, but it is also impossible to eliminate the possibility that *in vivo* effects are influenced by indirect effects of a high or low serum calcium or by other variables changed in the *in vivo* protocols. Nevertheless, the physiological conclusion is that common causes of hypercalcemia *in vivo* do not importantly decrease PTH mRNA levels; these results emphasize that the gland is geared to respond to hypocalcemia and not hypercalcemia.

Mechanisms of Regulation of PTH mRNA by Calcium

The mechanism whereby calcium regulates PTH gene expression is particularly interesting. Changes in extracellular calcium are sensed by a calcium sensor that then regulates PTH secretion (Brown *et al.*, 1993; Yano and Brown, 2005). Signal transduction from the CaSR involves activation of phospholipase C, D, and A_2 enzymes (Kifor *et al.*, 1997). It is not known what mechanism transduces the message of changes in extracellular calcium leading to changes in PTH mRNA. However, it has been shown that the response to changes in serum calcium involve the protein phosphatase type 2B, calcineurin (Bell *et al.*, 2005a). *In vivo* and *in vitro* studies demonstrated that inhibition of calcineurin by genetic manipulation or pharmacological agents affected the response of PTH mRNA levels to changes in extracellular calcium (Bell *et al.*, 2005a).

Okazaki *et al.* (1992) identified a negative calcium regulatory element (nCaRE) in the atrial natiuretic peptide gene, with a homologous sequence in the PTH gene. They identified a redox factor protein (ref1), which bound a putative nCaRE, and the level of ref1 mRNA and protein were elevated by an increase in extracellular calcium concentration (Okazaki *et al.*, 1992). They suggested that ref1 had transcription repressor activity in addition to its function as a transcriptional auxiliary protein (Okazaki *et al.*, 1992). Because no parathyroid cell line is available, these studies were performed in nonparathyroid cell lines, so their relevance to physiological PTH gene regulation remains to be established.

Moallem *et al.* (1998) have performed *in vivo* studies on the effect of hypocalcemia on PTH gene expression. The effect is post-transcriptional *in vivo* and involves protein–RNA interactions at the 3′-untranslated region of the PTH mRNA (Moallem *et al.*, 1998). A similar mechanism is involved in the effect of phosphate on PTH gene expression so the mechanisms involved will be discussed after the independent effect of phosphate on the PT is considered.

Phosphate

Phosphate Regulates the Parathyroid Independently of Calcium and 1,25$(OH)_2D_3$

The demonstration of a direct effect of high phosphate on the parathyroid *in vivo* has been difficult. One of the reasons is that the various maneuvers used to increase or decrease serum phosphate invariably leads to a change in the ionized calcium concentration. In moderate renal failure, phosphate clearance decreases and serum phosphate increases; this increase becomes an important problem in severe renal failure. Hyperphosphatemia has always been considered central to the pathogenesis of secondary hyperparathyroidism, but it has been difficult to separate the effects of hyperphosphatemia from those of the attendant hypocalcemia and decrease in serum $1,25(OH)_2D_3$ levels. In the 1970s, Slatopolsky and Bricker (1973) showed in dogs with experimental chronic renal failure that dietary phosphate restriction prevented secondary hyperparathyroidism. Clinical studies (Portale *et al.*, 1984) demonstrated that phosphate restriction in patients with chronic renal insufficiency is effective in preventing the increase in serum PTH levels (Lucas *et al.*, 1986; Portale *et al.*, 1984; Lafage *et al.*, 1992; Aparicio *et al.*, 1994; Combe and Aparicio, 1994). The mechanism of this effect was not clear, although at least part of it was considered to be caused by changes in serum $1,25(OH)_2D_3$ concentrations. *In vitro* (Tanaka and DeLuca, 1973; Condamine *et al.*, 1994) and *in vivo* (Portale *et al.*, 1984, 1989) phosphate directly regulated the production of $1,25(OH)_2D_3$. A raised serum phosphate decreases serum $1,25(OH)_2D_3$ levels, which then leads to decreased calcium absorption from the diet and eventually a low serum calcium. The raised phosphate complexes calcium, which is then deposited in bone and soft tissues and decreases serum calcium. However, a number of careful clinical and experimental studies suggested that the effect of phosphate on serum PTH levels was independent of changes in both serum calcium and $1,25(OH)_2D_3$ levels. In dogs with experimental chronic renal failure, Lopez-Hilker *et al.* (1990) showed that phosphate restriction corrected their secondary hyperparathyroidism independent of changes in serum calcium and $1,25(OH)_2D_3$ levels. They did this by placing the uremic dogs on diets deficient in both calcium and phosphate. This led to lower levels of serum phosphate and calcium, with no increase in the low levels of serum $1,25(OH)_2D_3$. Despite this, there was a 70% decrease in PTH levels. This study suggested that, at least in chronic renal failure, phosphate affected the parathyroid cell by a mechanism independent of its effect on serum $1,25(OH)_2D_3$ and calcium levels (Lopez-Hilker *et al.*, 1990). Therefore, phosphate plays a central role in the pathogenesis of secondary hyperparathyroidism, both by its effect on serum $1,25(OH)_2D_3$ and calcium levels and possibly independently. A raised serum phosphate also stimulates

the secretion of FGF23, which in turn decreases PTH gene expression and serum PTH levels (T.N.-M. and J.S., work in progress). This effect would act as a counterbalance to the stimulatory effect of phosphate on the parathyroid and is discussed separately in this chapter.

Kilav *et al.* (1995) were the first to establish *in vivo* that the effects of serum phosphate on PTH gene expression and serum PTH levels were independent of any changes in serum calcium or $1,25(OH)_2D_3$. In a particularly informative experiment, they bred second-generation vitamin D-deficient rats and then placed the weanling vitamin D-deficient rats on a diet with no vitamin D, low calcium, and low phosphate. After one night of this diet, serum phosphate had decreased markedly with no changes in serum calcium or $1,25(OH)_2D_3$. These rats with isolated hypophosphatemia had marked decreases in PTH mRNA levels and serum PTH. However, the very low serum phosphates in these *in vivo* studies may have no direct relevance to possible direct effects of high phosphate in renal failure. It is necessary to separate nonspecific effects of very low phosphate from true physiological regulation. To establish that the effect of serum phosphate on the parathyroid was indeed a direct effect, *in vitro* confirmation was needed, which was provided by three groups. Rodriguez was the first to show that increased phosphate levels increased PTH secretion from isolated parathyroid glands *in vitro*; the effect required maintenance of tissue architecture (Almaden *et al.*, 1996). The effect was found in whole glands or tissue slices but not in isolated cells. This result was confirmed by Slatopolsky *et al.* (1996). Olgaard's laboratory provided elegant further evidence of the importance of cell–cell communication in mediating the effect of phosphate on PTH secretion (Nielsen *et al.*, 1996). The requirement for intact tissue suggests either that the sensing mechanism for phosphate is damaged during the preparation of isolated cells or that the intact gland structure is important to the phosphate response.

Parathyroid responds to changes in serum phosphate at the level of secretion, gene expression, and cell proliferation, although the mechanism of these effects is unknown. The effect of high phosphate to increase PTH secretion may be mediated by phospholipase A_2-activated signal transduction. Bourdeau *et al.* (1992, 1994) showed that arachidonic acid and its metabolites inhibit PTH secretion. Almaden *et al.* (2000) showed *in vitro* that a high phosphate medium increased PTH secretion, which was prevented by the addition of arachidonic acid. When dog parathyroid tissue was cultured in a high calcium and normal phosphate medium, there was an increase in arachidonic acid production at 30 and 45 min, returning to baseline at 60 min. A high phosphate medium prevented the increase in arachidonic acid production at 30 and 45 min, and there was a modest increase in PTH secretion only after 2 and 3 hours of incubation. These results suggest that phosphate decreases the production of arachidonic acid in the parathyroid and that arachidonic acid decreases PTH secretion, but it is less clear to what extent the effect of phosphate on PTH secretion depends on this pathway. The use of inhibitors of the phospholipase A_2 pathway may help clarify this question. We can now provide some of the answers for the effect of phosphate and calcium on PTH gene expression.

Protein–PTH mRNA Interactions Determine the Regulation of PTH Gene Expression by Serum Calcium and Phosphate

The clearest rat *in vivo* models for effects of calcium and phosphate on PTH gene expression are diet-induced hypocalcemia with a large increase in PTH mRNA levels and diet-induced hypophosphatemia with a large decrease in PTH mRNA levels (Fig. 1). In both instances the effect was post-transcriptional, as shown by nuclear transcript run-on experiments (Kilav *et al.*, 2005). Parathyroid cytosolic proteins were found to bind *in vitro*-transcribed PTH mRNA, with three bands at about 50, 60, and 110 kDa (Moallem *et al.*, 1998). Interestingly, this binding was increased with parathyroid proteins from hypocalcemic rats (with increased PTH mRNA levels) and decreased with parathyroid proteins from hypophosphatemic rats (with decreased PTH mRNA levels). Proteins from other tissues bound to PTH mRNA, but this binding is regulated by calcium and phosphate only with parathyroid proteins. Intriguingly, binding requires the presence of the terminal 60 nucleotides of the PTH transcript.

PTH mRNA is Degraded *in vitro* by Parathyroid Cytosolic Proteins, which are Regulated by Calcium and Phosphate

Naveh-Many and colleagues utilized an *in vitro* degradation assay to study the effects of hypocalcemic and hypophosphatemic parathyroid proteins on PTH mRNA stability (Moallem *et al.*, 1998). In this assay, control rats' parathyroid cytosolic proteins led to the degradation of a radiolabeled PTH transcript in about 40–60 min (Fig. 2). Hypocalcemic parathyroid proteins degraded the transcript only in 180 min, whereas hypophosphatemic parathyroid proteins degraded the transcript within 5 min. Moreover, the rapid degradation of PTH mRNA by hypophosphatemic proteins was totally dependent on an intact 3′-untranslated region (UTR) and, in particular, on the terminal 60 nucleotides. Proteins from other tissues in these rats were not regulated by calcium or phosphate. Therefore, calcium and phosphate change the properties of parathyroid cytosolic proteins, which bind specifically to the PTH mRNA 3′-UTR and determine its stability. What are these proteins?

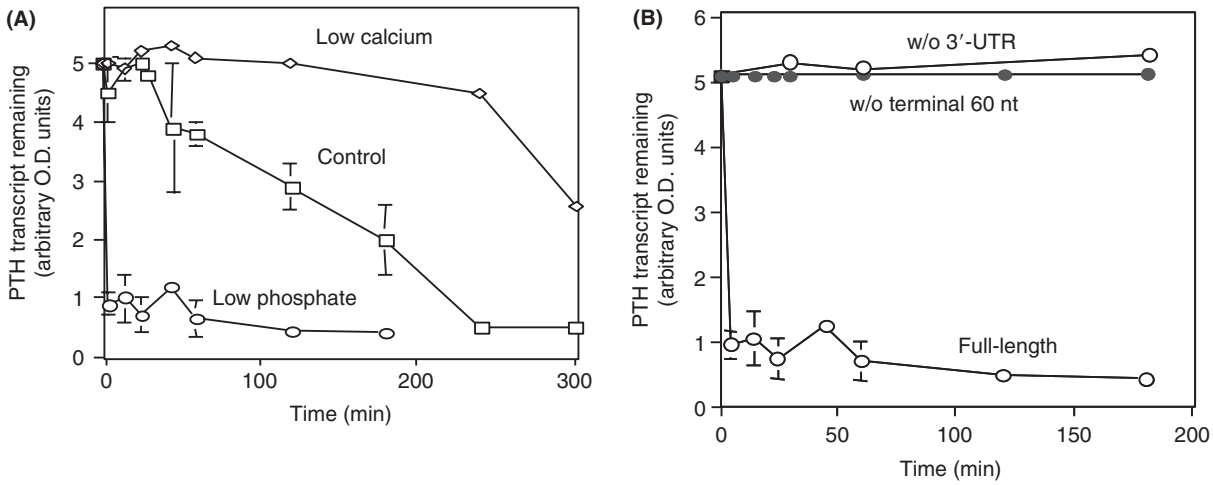

FIGURE 2 *In vitro* degradation of PTH mRNA by parathyroid cytosolic proteins. **(A)** Time–response curves of intact full-length PTH mRNA after incubation with parathyroid cytosolic proteins. Each point represents the mean±SE of three to four different experiments. At some points the SE is less than the size of the graphic symbols. The PTH transcript was degraded very rapidly by proteins from −P rats and remained intact for a longer time period with proteins from −Ca rats. **(B)** Mapping a region in the PTH 3′-UTR that mediates degradation by proteins from −P rats. PTH mRNA probes used were intact PTH mRNA (probe A), without the 3′-UTR (probe C), and without the 3′-terminal 60 nucleotides of the 3′-UTR (probe B). Reproduced with permission from Moallem *et al*. (1998).

Identification of the PTH mRNA 3′-UTR-Binding Proteins that Determines PTH mRNA Stability

AU-rich Binding Factor (AUF1)

Sela-Brown *et al*. (2000) and Dinur *et al*. (2006) utilized affinity chromatography to isolate these RNA-binding proteins.. The proteins, which bind the PTH mRNA, are also present in other tissues, such as brain, but only in the parathyroid is their binding regulated by calcium and phosphate. The PTH RNA 3′-UTR-binding proteins were purified by PTH 3′-region RNA affinity chromatography of rat brain S-100 extracts. The eluate from the column was enriched in PTH RNA 3′-UTR-binding activity. Addition of eluate to the *in vitro* degradation assay with parathyroid protein extracts stabilized the PTH transcript. A major band from the eluate at 50 kDa was sequenced and was identical to AU-rich binding factor (AUF1) (Sela-Brown *et al*., 2000). Recombinant AUF1 bound the full-length PTH mRNA and the 3′-UTR. Added recombinant AUF1 also stabilized the PTH transcript in the *in vitro* degradation assay. These results showed that AUF1 is a protein that binds to the PTH mRNA 3′-UTR and stabilizes the PTH transcript.

The regulation of protein–PTH mRNA binding involves post-translational modification of AUF1. AUF1 levels are not regulated in PT extracts from rats fed calcium- and phosphorus-depleted diets. However, two-dimensional gels showed post-translational modification of AUF1 that included phosphorylation (Bell *et al*., 2005a). There is no parathyroid cell line, but a PTH mRNA *cis*-acting 63-nt element (Kilav *et al*., 2001) is recognized in HEK 293 cells as an instability element (Fig. 3). RNA interference for AUF1 decreased human PTH secretion in cotransfection experiments (Bell *et al*., 2005a). Stably transfected cells with a chimeric GH gene containing the PTH 63-nt *cis*-acting element were used to study the signal transduction pathway that regulates AUF1 modification and chimeric gene mRNA stability. Cyclosporine A, the calcineurin inhibitor, regulated AUF1 post-translationally, and this correlated with an increase in the stability of GH-PTH 63-nt mRNA but not of the control GH mRNA. Mice with genetic deletion of the calcineurin Aβ gene had markedly increased PTH mRNA levels that were still regulated by low-calcium and -phosphorus diets. Therefore, calcineurin regulates AUF1 post-translationally *in vitro* and PTH gene expression *in vivo* but still allows its physiological regulation by calcium and phosphate (Bell *et al*., 2005a).

Most patients with chronic kidney disease develop secondary hyperparathyroidism with disabling systemic complications. Calcimimetic agents are effective tools in the management of secondary hyperparathyroidism, acting through allosteric modification of the calcium-sensing receptor (CaR) on the parathyroid gland to decrease PTH secretion and parathyroid cell proliferation. R-568 decreased both PTH mRNA and serum PTH levels in adenine high-P-induced uremia (Levi *et al*., 2006). The effect of the calcimimetic on PTH gene expression was post-transcriptional and correlated with differences in protein–RNA binding and post-translational modifications of the *trans*-acting factor AUF1 in the parathyroid. The AUF1 modifications as a result of uremia were reversed to those of normal rats by treatment with R-568. Therefore, uremia and activation of the CaR mediated by calcimimetics modify AUF1 post-translationally. These modifications in AUF1 correlate with changes in protein–PTH mRNA binding and PTH mRNA levels (Levi *et al*., 2006).

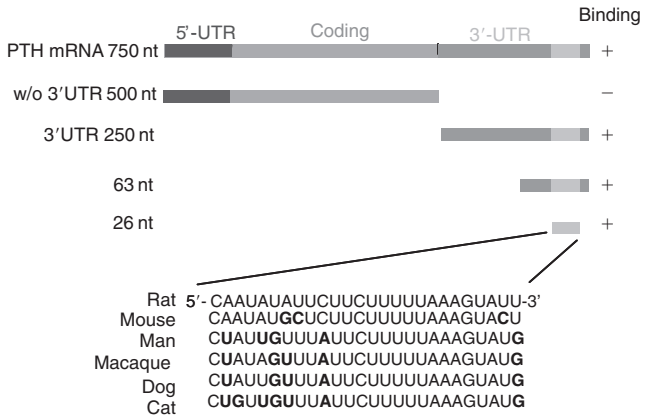

FIGURE 3 Schematic representation of the rat PTH mRNA and the sequence of the PTH mRNA protein-binding *cis*-acting element in the PTH mRNA 3′-UTR in different species. The full-length PTH mRNA and transcripts for different regions of PTH mRNA were analyzed for binding with parathyroid cytosolic proteins by UV and REMSA and their binding summarized by +/ − . The 26-nt minimal proximal *cis*-acting element of the PTH mRNA 3′-UTR is indicated and its sequence in different species is shown. The nucleotides that are different from the rat sequence are shown in bold.

Unr (Upstream of N-Ras)

A second parathyroid cytosolic protein that is part of the stabilizing PTH mRNA 3′-UTR-binding complex was shown to be Unr by affinity chromatography (Dinur *et al.*, 2006). Recombinant Unr bound the PTH 3′-UTR transcript and supershift experiments with antibodies to Unr showed that Unr is part of the parathyroid RNA-binding complex. Depletion of Unr by small interfering RNA decreased PTH mRNA levels in HEK293 cells transiently cotransfected with the human PTH gene. Overexpression of Unr increased the rat full-length PTH mRNA levels but not a PTH mRNA lacking the terminal 60-nucleotide *cis*-acting protein-binding region. Therefore, Unr binds to the PTH *cis*-element and increases PTH mRNA levels, as does AUF1. Unr, together with the other proteins in the RNA-binding complex, determines PTH mRNA stability (Dinur *et al.*, 2006). Recent findings have identified an additional decay-promoting protein that differentially interacts with PTH mRNA to recruit the degradatory machinery (T.N.-M., manuscript in preparation). The balance between the stabilizing and destabilizing proteins determines PTH mRNA levels in response to physiological stimuli (Fig. 4).

A Conserved Sequence in PTH mRNA 3′-UTR Binds Parathyroid Cytosolic Proteins and Determines RNA Stability in Response to Changes in Calcium and Phosphate

Kilav *et al.* (2001) have identified the minimal sequence for protein binding in the PTH mRNA 3′-UTR and determined its functionality. A minimum sequence of 26 nucleotides was sufficient for PTH RNA–protein binding and competition (see Figure 3). Significantly, this sequence was preserved among species (Bell *et al.*, 2005b). To study the functionality of the sequence in the context of another RNA, a 63-bp cDNA PTH sequence consisting of the 26 nucleotide and flanking regions was fused to growth hormone (GH) cDNA. The conserved PTH RNA protein-binding region was necessary and sufficient for responsiveness to calcium and phosphate and determines PTH mRNA stability and levels (Kilav *et al.*, 2001) (see Fig. 2).

The PTH mRNA 3′-UTR binding element is AU rich and is a type III AU-rich element (ARE). Sequence analysis of the PTH mRNA 3′-UTR of different species revealed a preservation of the 26-nt protein-binding element in rat, murine, human, macaque, feline, and canine 3′-UTRs (Bell *et al.*, 2005b). In contrast to protein-coding sequences that are highly conserved, UTRs are less conserved. The conservation of the protein-binding element in the PTH mRNA 3′-UTR suggests that this element represents a functional unit that has been evolutionarily conserved. The *cis*-acting element is at the 3′ distal end in all species where it is expressed. This element is not present in the 3′-UTRs of bovine, porcine, and gallus PTH mRNA. Protein–RNA-binding experiments using bovine PT gland extracts and RNA probes for different regions of the bovine PTH mRNA 3′-UTR identified a protein-binding element in bovine PTH mRNA at the proximal end of the 3′-UTR that is different from the distal protein-binding element. The human 3′-UTR contains both elements, but only the distal element binds proteins (Bell *et al.*, 2005b). Functional studies with HEK293 cells transiently transfected with reporter genes containing the different elements showed that the human distal, but not the proximal element, destabilized a reporter mRNA similarly to the effect of this element in the rat. A reporter mRNA containing the single bovine PTH mRNA protein-binding element was also destabilized in transfected cells (Bell *et al.*, 2005b). Therefore, different species have alternative protein-binding elements involved in the regulation of PTH mRNA stability.

Dynein Light Chain (M_r 8000) Binds the PTH mRNA 3′-Untranslated Region and Mediates its Association with Microtubules

To isolate other proteins binding to the 3′-UTR of parathyroid hormone, mRNA expression cloning was used. Epstein *et al.* (2000) screened an expression library for proteins that bound the PTH mRNA 3′-UTR, and the sequence of one clone was identical to dynein light chain (M_r 8000) (LC8). LC8 is part of the cytoplasmic dynein complexes that function as molecular motors that translocate along microtubules. Recombinant LC8 bound PTH

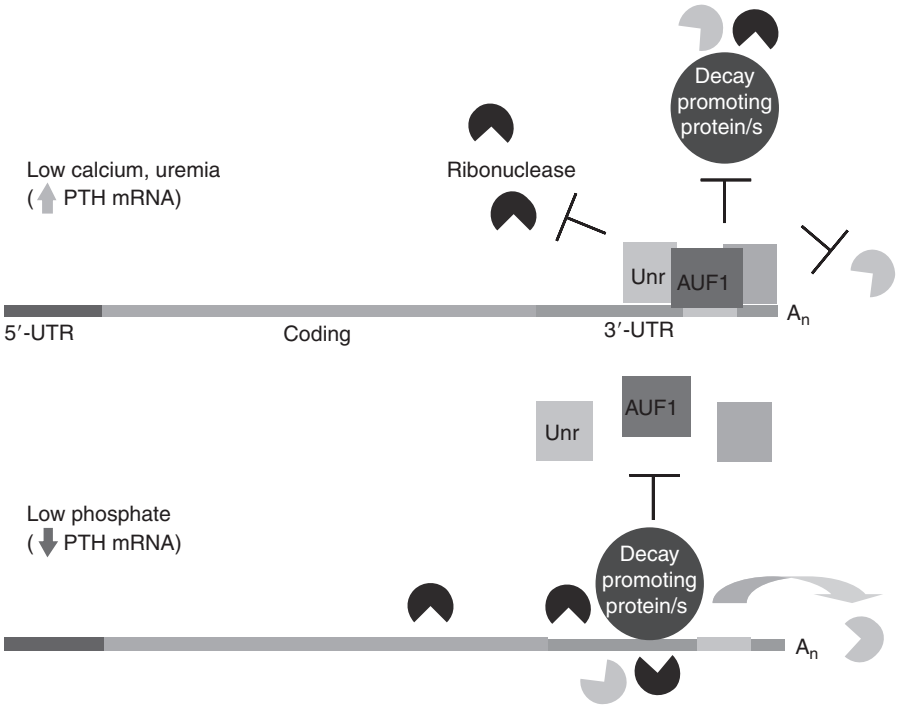

FIGURE 4 Model for the regulation of PTH mRNA stability by calcium and phosphorus depletion. Low P decreases and low Ca increases PTH mRNA stability and levels *in vivo*. Low Ca^{2+} induces the binding of a stabilizing protein complex consisting of AUF1 and Unr, and possibly other unidentified proteins to a defined cis element in the PTH mRNA 3′-UTR and this involves post-translational modifications of AUF1. This complex competes for the binding of decay-promoting proteins and thereby inhibits PTH mRNA degradation leading to increased PTH mRNA stability and levels. Low P increases the association of PTH mRNA with decay-promoting proteins. These proteins then recruit the degradation machinery, consisting of ribonucleases to decrease PTH mRNA stability and levels. The decay-promoting protein KSRP, has recently been identified as a regulator of PTH mRNA decay (Nechama et al., 2008). The cleavage mechanism of PTH mRNA remains to be added.

mRNA 3′-UTR by the RNA mobility shift assay. PTH mRNA colocalized with polymerized microtubules in the parathyroid gland, as well as with a purified microtubule preparation from calf brain, and this was mediated by LC8. This was the first report of a dynein complex protein binding a mRNA. Therefore, the dynein complex may be the motor for the transport and localization of mRNAs in the cytoplasm and the subsequent asymmetric distribution of translated proteins in the cell.

Sex Steroids

PTH is anabolic to bone and is an effective means of treating postmenopausal osteoporosis (Dempster *et al.*, 1993; Finkelstein *et al.*, 1994). In postmenopausal women with osteoporosis, time series analysis has shown that there is a loss in the periodicity of PTH secretion (Prank *et al.*, 1995; Fraser *et al.*, 1998). This suggests that estrogens may have an effect on the parathyroid. Estradiol and progesterone both increased the secretion of PTH from bovine parathyroid cells in primary culture (Greenberg *et al.*, 1987). However, transdermal estrogen did not increase serum PTH levels in postmenopausal patients (Prince *et al.*, 1990). Estrogen receptors were not detected in parathyroid tissue by a hormone-binding method (Prince *et al.*, 1991), but were detected by immunohistochemistry and PCR for the estrogen receptor mRNA (Naveh-Many *et al.*, 1992a). In *in vivo* ovariectomized rats, both estrogen and progestins regulated PTH gene expression. Estrogen receptor mRNA and protein were shown to be present in the parathyroid suggesting that these are target organs for estrogen.

Further studies were performed on the effect of progestins on PTH gene expression (Epstein *et al.*, 1995). The 19-nor progestin R5020 given to weanling rats or mature ovariectomized rats led to a twofold increase in thyroparathyroid PTH mRNA levels. In addition, *in vitro*, in primary cultures of bovine parathyroid cells, progesterone increased PTH mRNA levels. The progesterone receptor (PR) mRNA was demonstrated in rat parathyroid tissue by *in situ* hybridization and in human parathyroid adenoma by immunohistochemistry. Changes in PTH mRNA levels during the rat estrous cycle were also studied. At proestrus and estrus, PTH mRNA levels were increased significantly by three- and fourfold compared with diestrus (Epstein *et al.*, 1995). These results confirm that the parathyroid gland is a target organ for the ovarian sex steroids estrogen and progesterone and are of physiological relevance, as shown by the changes during estrus.

FIBROBLAST GROWTH FACTOR 23 AND THE PARATHYROID

Phosphate homeostasis is maintained by a counterbalance between efflux from the kidney and influx from intestine and bone. Fibroblast growth factor-23 (FGF23) is a bone-derived phosphaturic hormone that acts on the kidney to increase phosphate excretion and suppress biosynthesis of $1,25(OH)_2$ vitamin D. FGF23 signals through fibroblast growth factor receptors (FGFRs) bound by the transmembrane protein Klotho (Kurosu *et al.*, 2006). Because most tissues express FGFRs, expression of Klotho virtually determines FGF23 target organs. Takeshita *et al.* (2004) were the first to show that Klotho protein is expressed not only in the kidney but also in the parathyroid, pituitary, and sino-atrial node. In addition, Urakawa *et al.* (2006) injected rats with FGF23 and demonstrated increased Egr-1 (early growth response gene-1) mRNA levels in the parathyroid, suggesting that the parathyroid may be a further FGF23 target organ. Imura *et al.* (2007) extended these observations with elegant studies showing that after challenge with a low extracellular Ca^{2+}, Klotho is necessary for the association of Na^+,K^+-ATPase with the plasma membrane. In addition, they showed that Klotho may have a role in the secretion of PTH. In ongoing studies on the functionality of the effect of FGF23 on the parathyroid, we have preliminary results showing that the administration of recombinant FGF23 led to an increase in parathyroid Klotho levels (T.N.-M. and J.S., unpublished work). Using *in vivo* and *in vitro* models, we show that FGF23 suppresses parathyroid hormone (PTH) gene expression and secretion. These data indicate that FGF23 acts directly on the parathyroid to decrease serum PTH. This novel bone–parathyroid endocrine axis adds a new dimension to the understanding of mineral homeostasis.

SUMMARY

The PTH gene is regulated by a number of factors. Calcitriol acts on the PTH gene to decrease its transcription, and this action is used in the management of patients with chronic kidney disease. The major effect of calcium on PTH gene expression *in vivo* is for hypocalcemia to increase PTH mRNA levels, and this is mainly post-transcriptional. Phosphate also regulates PTH gene expression *in vivo*, and this effect appears to be independent of the effect of phosphate on serum calcium and $1,25(OH)_2D_3$. The effect of phosphate is also post-transcriptional. *Trans*-acting parathyroid cytosolic proteins bind to a defined *cis*-element in the PTH mRNA 3′-UTR. This binding determines the degradation of PTH mRNA by degrading enzymes and thereby PTH mRNA half-life. The post-transcriptional effects of calcium and phosphate are the result of changes in the balance of these stabilizing and degrading factors on PTH mRNA. These interactions also regulate PTH mRNA levels in experimental uremia. In diseases such as chronic renal failure, secondary hyperparathyroidism involves abnormalities in PTH secretion and synthesis. FGF23 also acts on its receptors, the Klotho-FGFR1, 2c, and 3c to decrease PTH mRNA levels and secretion. An understanding of how the parathyroid is regulated at each level will help devise rational therapy for the management of such conditions, as well as treatment for diseases, such as osteoporosis, in which alterations in PTH may have a role.

Chapter 29

Parathyroid Hormone–Receptor Interactions

Angela Wittelsberger and Michael Rosenblatt*
Department of Physiology and Medicine, Tufts University School of Medicine, Boston, Massachusetts

INTRODUCTION

One impetus for elucidating the nature of parathyroid hormone (PTH) receptor − ligand interactions in atomic detail is the desire to design therapeutic agents for osteoporosis with characteristics superior to currently available PTH and related analogs. Such agents should be anabolic for bone and conveniently administered. To date, the only truly anabolic drug approved for treatment of osteoporosis is PTH-(1–34) (Neer *et al*., 2001). Its mode of administration (subcutaneous injection) and side effects make it far from optimal as therapy. Therefore, the drive to understand structure − function − conformation relations of PTH-(1–34) and its cognate G protein-coupled receptor (GPCR), PTHR1, remains strong as a prerequisite to the design of improved analogs.

The first two parts of this chapter summarize our knowledge on the structure and function of the ligand, PTH-(1–34) (and sometimes PTHrP-(1–36)), and the receptor, PTHR1, respectively. The third part reviews newest approaches to integrated studies of the bimolecular ligand—PTHR1 complex. Significant advances in our understanding of GPCR activation combined with increasing knowledge on the diversity of signaling pathways for PTHR1 make for a fast pace in the flow of new data and new experimental approaches to study of the PTH − PTHR1 system.

THE LIGAND: STRUCTURE AND FUNCTION

Early work on the structure–activity relations of PTH and PTHrP has been covered in extensive reviews (Chorev and Rosenblatt, 1994, 1996; Potts *et al*., 1997). It established that the N-terminal 1–34 amino acid sequence of both calciotropic hormones is sufficient to induce the entire spectrum of *in vitro* and *in vivo* PTHR1-mediated activities (Dempster *et al*., 1993; Whitfield and Morley, 1995). Both PTH-(1–34) and PTHrP-(1–36) have similar affinities to PTHR1 and are equipotent in stimulating adenylyl cyclase and intracellular Ca^{2+} transients in cells expressing PTHR1. Significant sequence homology between PTH and PTHrP is limited to the first 13 residues, of which 8 are identical (Fig. 1). The molecular architecture consists of two functional domains. The "activation domain" is assigned to the homologous N-terminal sequences, and the principal "binding domain," located at the structurally divergent mid- and C-terminal sequences, is assigned to residues 14–34 (Abou-Samra *et al*., 1989; Caulfield *et al*., 1990; Gardella *et al*., 1993; Nussbaum *et al*., 1980). Truncation of 2–6 residues from the N terminus converts the 1–34/36 agonists into potent antagonists (Rosenblatt, 1986; Rosenblatt *et al*., 1993). The functional similarity of two domains in two hormones that also share a common receptor has promoted the hypothesis that they have similar conformations, despite their limited sequence homology (Caulfield *et al*., 1990; Mierke *et al*., 1997).

The new challenges facing structural studies of PTH- and PTHrP-derived ligands originate from advances along several avenues of PTH-related biology. Subtype receptor multiplicity raises the need for receptor subtype- or target-specific ligands. Exploring the multiplicity of signaling pathways and their relevance to physiological and pathophysiological processes requires the development of signaling selective analogs. The concept that a series of receptor conformational states are induced by specific categories of ligand (agonist, antagonist, partial agonist, etc.) represents a new impetus to investigate the structure/activity relations and the pharmacology of PTH and PTHrP analogs. It implies that specific signaling and biological response can be obtained with the right ligand stabilizing the right receptor conformation (Kenakin, 2003). The design of a PTH-like drug with a better therapeutic window than PTH, i.e., a more favorable ratio of anabolic to catabolic activities, remains a goal of great interest.

Principles of Bone Biology, 3rd Edition

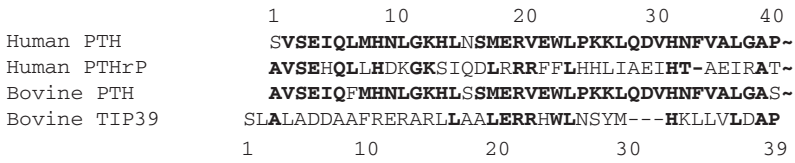

FIGURE 1 Alignment of human PTH-(1–40) with human PTHrP-(1–39), bovine PTH-(1–40), and bovine TIP39 sequences. Amino acid residues in bold indicate direct homology. Gaps in the sequences of PTHrP and TIP are introduced to maximize homology. Numbering at the top and bottom refers to mature PTH and mature TIP39, respectively. The wavy line indicates C-terminal truncated sequences. It can be appreciated that the highest homology observed is between human and bovine PTH. There is much less homology between human PTH and human PTHrP. The homology among TIP39 and PTH or PTHrP is very limited.

PROBING THE PRIMARY STRUCTURE

A wealth of data has been generated by exhaustively scanning either the entire sequence of PTH-(1−36) or portions thereof. These studies employ both synthetic and biosynthetic methodologies to generate new insights into the tolerance and significance of certain portions and residues with regard to bioactivity (Gardella *et al*., 1991; Gombert *et al*., 1995; Oldenburg *et al*., 1996). Both Gardella and Oldenburg and their coworkers used recombinant DNA methodologies to generate analogs, either by randomly mutating codons coding for positions 1–4 in hPTH (Gardella *et al*., 1991) or by replacing individual codons with [(A/G)(A/G)G] (coding for Lys, Arg, Glu, or Gly) (Oldenburg *et al*., 1996). Conversely, Gombert *et al*. (1995) used a parallel multisynthesis approach to generate D-Ala, L-Ala, and D-Xxx scans of hPTH-(1–36), where D-Xxx is the enantiomeric form of the native amino acid residue in the particular position.

The D-Ala scan reveals segments 2–8 and 20–28 to be the least tolerant. Substitutions with D-Ala within these segments result in large decreases in binding affinity and are accompanied by a large loss in ligand-stimulated adenylyl cyclase activity. The latter is most pronounced for substitutions of Arg^{20}, Trp^{23}, Leu^{24}, and Leu^{28} in the sequence 20−28, which overlaps with the principal binding domain (Gombert *et al*., 1995). A high correlation between binding and adenylyl cyclase activation was observed in the L-Ala scan. The largest loss in adenylyl cyclase activity occurs when the substitutions are within the activation domain (residues 2–8) (Gombert *et al*., 1995). Only substituting L-Ala for Lys^{13}, Asn^{16}, or Glu^{19} yielded analogs that are slightly more active. The D-Xxx scan resulted in an overall loss of affinity and efficacy. The most affected region was the putative amphiphilic helical domain (residues 23–29) and, to a lesser extent, the C-terminal segment 32–36 (Gombert *et al*., 1995).

Gardella *et al*. (1991) focused on the evolutionarily conserved, first four N-terminal residues in PTH. Residues Glu^4 and Val^2 are less tolerant to substitution than the other two positions, suggesting an important role in receptor binding and activation. The most intriguing finding of this study was the divergent activity displayed by $[Arg^2,Tyr^{34}]$PTH-(1−34)NH_2 in two different cell lines expressing the wild-type PTHR1: ROS 17/2.8, a rat osteosarcoma cell line, and OK, an opossum kidney cell line (Gardella *et al*., 1991). This analog is a weak partial agonist for stimulation of adenylyl cyclase in ROS 17/2.8 cells, whereas it is a full agonist for cAMP increases in the OK cell system (Gardella *et al*., 1991). Gardella and coworkers (1994) further analyzed the activities of $[Arg^2,Tyr^{34}]$PTH-(1–34)NH_2 in COS-7 cells transfected with rat or opossum PTHR1 or rat/opossum PTHR1 chimeras. They demonstrated that the differences in activity in ROS and OK cells are owing to differences in the interaction of the receptors (rat vs. opossum) with the amino terminus of the ligand and not to tissue-specific (bone vs. kidney) effects.

Cohen and coworkers (1991) reported that the highly conserved PTH and PTHrP residues, Ser^3 and Gln^6, make important contributions to the binding and activation of PTHR1. Substituting of Phe or Tyr for Ser^3, and Phe or Ser for Gln^6, generates partial agonists. Both $[Phe^3]$hPTH-(1−34) and $[Phe^6]$hPTH-(1–34) competitively inhibit bPTH-(1−34)- and PTHrP-(1–34)-stimulated adenylyl cyclase activity. Specific substitutions within the "activation domain" may therefore convert full agonists into partial antagonists. The study also suggests that structural perturbation of ligand−receptor bimolecular interactions at the N-terminus of PTH-(1–34) can interfere preferentially with the induction of conformational changes, and therefore inhibit intracellular signaling. Such conformational changes are required for the effective coupling of the ligand-occupied receptor to G proteins, but are not important for ligand recognition and binding.

Oldenburg *et al*. (1996) conducted an extensive study in which they introduced single, nonconservative point mutations in PTH-(1–34) and characterized them in UMR106, rat osteosarcoma cells. These mutations, which span the mid- and C-terminal regions, namely, the 11–34 sequence, generated several analogs more potent than the parent peptide. One of the more interesting analogs is $[Arg^{19,22,30},Lys^{29},Hse^{34}]$hPTH-(1–34), which is equipotent to bPTH (EC_{50} ∼0.9 and K_d ∼1.5 n*M*). The high potency of this analog is attributed to the presence and disposition of the seven positive charges in the C-terminal helix and

not to its amphiphilic nature. The positive charges may play a critical role in intramolecular, ligand−receptor or ligand − lipid interactions.

Similarly, Barbier *et al.* (2005) and Dean *et al.* (2006a) investigated the role of amino acid side-chains in region 17−31 of PTH-(1–31) in binding to PTHR1. In the first study, backbone methylation was found to disrupt the predicted amphiphilic C-terminal α-helix as reflected in a loss of activity. In particular, introduction of the respective N-methyl amino acids in positions Val^{21}, Leu^{24}, Arg^{25}, and Leu^{28} resulted in a pronounced loss of activity, suggesting that these residues play a critical role in interaction with the N-ECD. When testing the analogs with PTHR-delNt, a PTHR1 mutant lacking the N-ECD, a different set of positions (Ser^{17}, Trp^{23}, and Lys^{26}), located on the other side of the amphiphilic helix, was found to be particularly sensitive to methylation. The authors conclude that the C-terminal helix of PTH-(1–31) must bind to both the N-ECD as well as the extracellular loop regions of PTHR1 (Barbier *et al.*, 2005).

The second study by Dean *et al.* (2006a) reports that substitutions at residues from the hydrophobic face of the predicted amphiphilic C-terminal α-helix (Arg^{20}, Trp^{23}, Leu^{24}, and Leu^{28}) resulted in an approximate 200-fold reduced binding affinity to full-length PTHR1, compared to a 4-fold reduction in binding affinity to PTHR-delNt. In contrast, substitutions at the hydrophilic face of the helix (Arg^{25}, Lys^{26}, Lys^{27}) yielded 4 – 10-fold reduced activity for both receptors. The results are supportive of a role for the hydrophobic face of the C-terminal helix of PTH in contributing strongly to the binding interaction with the N-ECD of PTHR1.

In addition to C-terminal and N-terminal helices, flexible hinge regions around positions 12 and 19 of PTH-(1–34) were proposed to be involved in the bioactive conformation. Therefore, structure-activity relations of residues 11−13 of PTH-(1–34) were studied by introducing either β-amino acids (Peggion *et al.*, 2002) or α-amino isobutyric acid (Aib) (Peggion *et al.*, 2003). Analysis by CD spectroscopy, 2D-NMR and computer simulations stressed the importance of the conformational stability of the helical activation domain as well as the hydrophobic side-chain of Leu^{11} in PTH-(1–34). Introduction of β-amino acids around position 18 resulted in partial or complete loss of functionality in combination with minimal conformational differences in all analogs tested (Schievano *et al.*, 2003)

RECEPTOR SUBTYPE SPECIFICITY SWITCH

The finding that the N-truncated sequence, PTHrP-(7–34), can bind and weakly activate the PTHR2, which selectively binds PTH but not PTHrP (Behar *et al.*, 1996b; Usdin *et al.*, 1995), suggested to Behar *et al.* (1996a) that the N-terminal sequence 1–6 of PTHrP must contain a structural element that disrupts the PTHrP-(1–34) − PTHR2 interaction. The single-point hybrid ligands, $[His^5,Nle^{8,18},Tyr^{34}]$ bPTH-(1–34)NH_2 and $[Ile^5]$PTHrP-(1–34)NH_2, were generated by swapping the nonconserved residues in position 5 between PTH-(1–34), which binds and activates both PTHR1 and PTHR2, and PTHrP-(1–34) (Behar *et al.*, 1996a). Indeed, in HEK293 cells stably transfected with either hPTHR1 or hPTHR2, the receptor specificity of these point-hybrid ligands is reversed when compared with their parent compounds. Therefore, His^5, a single residue within the activation domain of the ligands, acts as a specificity "switch" between these two highly homologous receptor subtypes.

In parallel, a study conducted by Gardella and colleagues (1996a) in COS-7 cells transiently expressing PTHR1 and PTHR2 also identified position 5 in addition to position 23 to account for the different potencies of PTH and PTHrP for PTHR2. Residue 5 (Ile in PTH and His in PTHrP) determines signaling capability, whereas residue 23 (Trp in PTH and Phe in PTHrP) is a major determinant for binding affinity. $[Ile^5,Trp^{23},Tyr^{36}]$PTHrP-(1–36) is a full agonist and binds avidly to PTHR2, whereas swapping only position 23 yields $[Trp^{23},Tyr^{36}]$PTHrP-(1–36), an antagonist on PTHR2 but full agonist on PTHR1.

TIP39, A PUTATIVE ENDOGENOUS LIGAND OF PTHR2

Usdin *et al.* (1999b) have purified an endogenous ligand selective for PTHR2, a tuberoinfundibular peptide of 39 amino acids (bTIP39) from bovine hypothalamic extracts. A homology search reveals that 9 out of the 39 residues of bTIP39 are identical to bPTH (Fig. 1). TIP39 does not appreciably activate adenylyl cyclase in COS-7 cells transfected with either human or rat PTHR1, although it binds to the receptor with moderate affinity [IC_{50} = 59 n*M*, displacing ^{125}I-bPTH-(3–34)] (Hoare *et al.*, 2000). Jonsson *et al.* (2001) reported that TIP39 binds with weak affinity (~200 n*M*) to hPTHR1 stably expressed in $LLCPK_1$ cells (HKrk-B7 cells) and fails to stimulate adenylyl cyclase activity. The truncated peptides, TIP-(3–39) and TIP-(9–39), which display 3- and 5.5-fold higher affinity than the intact peptide, are similarly devoid of any adenylyl cyclase activity. Moreover, while TIP39 is a weak antagonist, both of the TIP39-derived N-terminally truncated peptides inhibit PTH-(1–34)-and PTHrP-(1–36)-stimulated adenylyl cyclase with efficiencies similar to a highly potent PTHR1 antagonist, $[Leu^{11},D\text{-}Trp^{12},Trp^{23},Tyr^{36}]$PTHrP-(7–36)$NH_2$.

Additional work with a hybrid PTHrP/TIP39 peptide and PTHR1/PTHR2 chimeras provides some insight into TIP39 − receptor interactions (Hoare *et al.*, 2000; Jonsson *et al.*, 2001). Jonsson and colleagues reported that the hybrid peptide PTHrP-(1− 20)-TIP39-(23 −39) binds effectively (IC_{50} = 8–11 n*M*) and stimulates cAMP efficaciously in

HKrk-B7 and SaOS-2 cells (EC_{50} = 1.4 and 0.38 n*M*, respectively). Hoare *et al.* (2000) reported that the juxtamembrane domains of the PTHR2, which include ECL's 1–3, determine binding and signaling selectivity of TIP39 for PTHR2 over PTHR1. This was established by studying TIP39 interactions with the reciprocal chimeric PTHR1/PTHR2, in which the N-ECD domains were exchanged. TIP39 fully activated [N-ECD]PTHR1/[JMD]PTHR2 (EC_{50} = 2 n*M*) and bound to it with an affinity equal to wild-type PTHR2 (IC_{50} = 2.3 and 2 n*M*, respectively). However, the reciprocal chimeric receptor, ([N-ECD]PTHR2/[JMD]PTHR1), is not activated by TIP39 and the binding affinity to TIP39 is similar to that of PTHR1. Truncation of the first six amino acid residues from the N-terminus of TIP39 results in a tenfold increase in binding affinity for PTHR1 (IC_{50} = 6 n*M*), making it a potent, selective antagonist of this receptor (Hoare *et al.*, 2000). At the same time, TIP39-(7–39) does not activate PTHR2 and has a seventy-fold lower affinity to it than the intact hormone (IC_{50} =370 and 5.2 n*M*, respectively). Jonsson *et al.* (2001) concluded from their studies with amino-terminal truncated TIP39 and PTHrP/TIP39 hybrid peptides that the carboxyl-terminal portion of TIP39 interacts with PTHR1 very similarly to the analogous domains in PTH-(1–34) and PTHrP-(1−36). At the same time, the amino-terminal portion has destabilizing interactions with this receptor that result in poor affinity and are therefore unproductive.

Taken together, these studies suggest that the dominant molecular determinants of the binding selectivity of TIP39 to PTHR2 are different from those identified for PTH and PTHrP binding to PTHR1. In the TIP39/PTHR2 system, binding specificity is assigned to the juxtamembrane domain of the receptor and the N-terminal domain of the ligand (Hoare *et al.*, 2000), the binding selectivity in the PTH/PTHrP − PTHR1 system is specified by the N-ECD in the receptor and the C-terminal portion of the ligands (Bergwitz *et al.*, 1996; Gardella *et al.*, 1994, 1996a; Rosenblatt *et al.*, 1978).

Although these findings are of major significance for understanding bimolecular ligand−receptor interactions, the physiological role of the TIP39/PTHR2 system still remains to be established (Usdin *et al.*, 2000).

SIGNALING-SELECTIVE LIGANDS

The activation of PTHR1 triggers at least two G protein-dependent signaling pathways, increasing both adenylyl cyclase/PKA via $G_s\alpha$ and PLC/IP_3-DAG/cytosolic transients of [Ca^{2+}]/PKC via G_q in homologous as well as heterologous receptor/cell systems (Abou-Samra *et al.*, 1992; Bringhurst *et al.*, 1993; Juppner *et al.*, 1991; Lee *et al.*, 1995b; McCuaig *et al.*, 1994; Pines *et al.*, 1994; Schneider *et al.*, 1993; Smith *et al.*, 1996). In addition, as is the case for several other GPCRs, G protein-independent activation of PTHR1 mediated through β-arrestins was recently demonstrated (Gesty-Palmer *et al.*, 2006). Currently, the relationship between these signaling pathways and the cellular and *in vivo* expression of PTH bioactivity is not fully established. Over the past years, much was learned about PTHR1 internalization and trafficking (Bisello *et al.*, 2002; Syme *et al.*, 2005; Rey *et al.*, 2006; Wheeler *et al.*, 2007, 2008; Wang *et al.*, 2007; Weinman *et al.*, 2007). However, many cellular processes in bone metabolism remain to be elucidated. One of the open questions in the development of PTH-based, anabolic anti-osteoporotic therapies focuses on understanding the mechanism responsible for catabolic versus anabolic actions of PTH induced by continuous versus intermittent administration of hormone, respectively. The direct linkage of one or several specific signaling pathways to Wnt signaling and the anabolic activity of PTH remains to be established with precision.

The design of signaling-selective PTH/PTHrP-derived agonists is of great significance for understanding the role of the different pathways in cellular metabolic processes. Studies carried out using osteoblastic cells and organ cultures suggest that PTH residues 1–7 form the cAMP/PKA activation domain (Fujimori *et al.*, 1991), whereas PTH residues 28–34 comprise the PKC activation domain (Jouishomme *et al.*, 1992, 1994). The latter encompasses the region also associated with PTH mitogenic activity in cultured osteoblast-like cells (residues 30–34) (Schluter *et al.*, 1989; Somjen *et al.*, 1990). Cyclic AMP appears to be involved in the bone formation (Rixon *et al.*, 1994) and resorption activities of PTH (Tregear *et al.*, 1973). Although PTH stimulation of bone resorption *in vitro* is mediated primarily through the cAMP-dependent activation of PKA (Kaji *et al.*, 1992), it may not be the sole second messenger pathway involved (Herrmann-Erlee *et al.*, 1988; Lerner *et al.*, 1991). At the same time, stimulation of TE-85 human osteosarcoma cell proliferation by PTH-(1−34) is not associated with an increase in intracellular cAMP (Finkelman *et al.*, 1992). Taken together, PTH analogs that stimulate increases in cAMP levels have been shown to either inhibit (Kano *et al.*, 1991; Reid *et al.*, 1988; Sabatini *et al.*, 1996) or stimulate (McDonald *et al.*, 1986; Sabatini *et al.*, 1996; Van der Plas *et al.*, 1985) osteoblastic cell proliferation, depending on species, cell models used, and experimental conditions.

The failure to demonstrate bone-forming activity *in vitro* and bone anabolic effects *in vivo* with PTH analogs in which the capacity to activate adenylyl cyclase is severely compromised or completely eliminated turned attention to adenylyl cyclase-selective analogs. The adenylyl cyclase-selective analog hPTH-(1–31)NH_2 (Ostabolin) is equipotent to PTH-(1–34) in stimulating cAMP production in ROS 17/2 (Jouishomme *et al.*, 1994; Neugebauer *et al.*, 1995) and a potent stimulator of cortical and trabecular bone growth in OVX rats (Armamento-Villareal *et al.*, 1997; Hilliker *et al.*, 1996; Rixon *et al.*, 1994; Whitfield *et al.*,

1996, 2000). By truncating the C terminus up to residue 31, Jouishomme *et al*. (1994) were able to compromise the putative PKC-signaling motif, Gln^{28}-His^{32}, and generate hPTH-(1–31)NH_2, a PKA-selective analog. Whitfield *et al*. (1997) developed *c*[Glu^{22},Lys^{26},Leu^{27}]hPTH-(1−31)NH_2, a second-generation PKA signaling-selective analog, in which the helical nature of the C-terminus is enhanced by formation of a side-chain to side-chain lactam ring and the introduction of a hydrophobic residue at position 27. The replacement of Lys^{27} with Leu improves the amphiphilicity of the C-terminal helical domain; the side-chain of Lys^{27} was shown to interact with L^{261} in ECL3 of PTHR1 (Greenberg *et al*., 2000; Piserchio *et al*., 2000a). This analog is only a 1.4- to 2-fold stronger stimulator of femoral trabecular bone formation than the linear parent analog. Both hPTH-(1–31)NH_2 and *c*[Glu^{22},Lys^{26},Leu^{27}]hPTH-(1–31)NH_2 have been reported to prevent loss of vertebral and trabecular bone and to raise vertebral and trabecular bone volume and thickness over those of control, vehicle-injected, sham-operated rats (Whitfield *et al*., 2000). The action of these analogs on vertebral bone was as effective as that of hPTH-(1–34)NH_2. However, unlike hPTH-(1−34)NH_2, their effect on pelvic BMD was equivocal.

Takasu *et al*. (1999a) offered an alternative view regarding the structural determinants associated with signaling pathway activation. Replacement of Glu^{19}→Arg, a receptor-binding and affinity-enhancing modification, generates [Arg^{19}]PTH-(1–28), which is a potent and full stimulator of adenylyl cyclase and PKC. Interestingly, substitution of Ala^1 for Gly generates [Gly^1,Arg^{19}]hPTH-(1–28), a PKA-selective agonist. This study concludes that the extreme N-terminus of hPTH constitutes a critical activation domain for coupling to PLC. The C-terminal region, especially hPTH-(28–31), contributes to PLC activation through receptor binding, but this domain is not required for full PLC activation. Therefore, they suggest that the N-terminal determinants for adenylyl cyclase and PLC activation in hPTH-(1–34) overlap but are not identical and that subtle modifications in this region may dissociate activation of these two effectors.

In the course of designing photoreactive PTHrP analogs for mapping the bimolecular ligand-receptor interface, Behar *et al*. (2000) generated [Bpa^1,Ile^5,$Arg^{11,13}$,Tyr^{36}]PTHrP-(1–36)NH_2. This analog binds and stimulates adenylyl cyclase equipotently to the parent analog [Ile^5,$Arg^{11,13}$,Tyr^{36}]PTHrP-(1–36)NH_2 in HEK293/C-21 cells overexpressing the recombinant human PTHR1 (~400,000 receptors/cell), but does not elicit intracellular calcium transients. Moreover, it does not stimulate the translocation of β-arrestin2-GFP fusion protein, an effect that is PKC dependent (Ferrari *et al*., 1999). Subsequently, the G_s/PKA signaling selectivity of [Bpa^1,Ile^5,$Arg^{11,13}$,Tyr^{36}]PTHrP-(1–36) and of PTHrP-(2–36) (position 1 modified or deleted, respectively) was correlated with the stabilization of an active, G protein-coupled receptor state, resulting in lack of β-arrestin2 recruitment to the cell membrane, sustained cAMP signaling, and absence of ligand−receptor complex internalization (Bisello *et al*., 2002). Utilizing molecular modeling, the authors generate a mechanistic explanation for the differences in conformational changes induced by agonist versus the two position 1-modified analogs that stresses a difference in the movement of ICL3.

Gesty-Palmer *et al*. (2006) recently presented another position 1-modified agonist, [Trp^1]PTHrP-(1−36), and likewise demonstrated its G_s/PKA pathway signaling selectivity and lack of β-arrestin recruitment. In this study, they dissociate activation of the mitogen-activated protein kinases (MAPK) ERK1/2 by PTH-(1−34) into two distinct signaling mechanisms: an early G protein-dependent pathway involving PKA and PKC, and a late G protein-independent pathway mediated through β-arrestins. [D-Trp^{12},Tyr^{34}]PTH-(7−34), previously presented as an inverse agonist for cAMP in cells expressing the constitutively active PTHR1 mutant H223R (Gardella *et al*., 1996c), selectively inhibits G_s/PKA activation while having no apparent activity in G_q/PKC stimulation. Despite its inability to activate G_s/PKA or G_q/PKC signaling pathways, the inverse agonist is able to activate MAP kinase. The study identifies that this happens through β-arrestin recruitment, and that this pathway corresponds to the late G protein-independent activation phase (Gesty-Palmer *et al*., 2006).

Such signaling-selective analogs are likely to help in the understanding of the molecular signaling mechanisms of PTH, as well as in the characterization of different active receptor conformations and ultimately in the development of novel therapeutics for the treatment of various bone pathologies.

TARGET-SPECIFIC LIGANDS

The wide distribution of PTHR1 in tissues other than bone and kidney (Urena *et al*., 1993), the classical target tissues for PTH, and its physiological activation by locally secreted PTHrP (Philbrick *et al*., 1996) raise concerns about potential side effects following parenteral administration of therapeutic doses of exogenous PTH. Bone-selective PTH/PTHrP-derived analogs may reduce the activation of PTHR1 in kidney and nonosseous tissues and provide better bone anabolic drugs.

To this end, Cohen and coworkers reported that [His^3]- and [Leu^3]hPTH-(1–34) are partial agonists of adenylyl cyclase in a kidney cell line (50% and 20%, respectively), but full agonists in UMR-106 rat osteosarcoma cells (Cohen *et al*., 1991; Lane *et al*., 1996). *In vivo,* however, both analogs were less potent than PTH in the induction of bone formation.

In summary, the development of an effective and safe therapeutic modality that would stimulate the formation of

new, mechanically competent bone and possibly reconstitute trabecular architecture in osteoporotic patients continues to be a worthy goal. This goal may be approached by analogs that interact with the PTHR1 in a signaling-selective manner or are targeted specifically to bone to achieve a more favorable therapeutic window.

PUTATIVE BIOACTIVE CONFORMATION

In the absence of a crystal structure of the PTH − PTHR1 complex, alternative approaches have been utilized to obtain insight into the three-dimensional structure of ligand while bound to PTHR1. Because GPCRs are embedded in the cell membrane, Schwyzer (1991, 1992, 1995) hypothesized that the initial conformations adapted by a ligand are induced by nonspecific interactions with the membrane. Only some of these membrane-induced conformations are recognized by the membrane-embedded GPCR. Therefore, the study of conformations in a membrane mimetic milieu, like the micellar environment, is probably the best available approximation of the natural state.

Secondary structure prediction methods suggest that the N-terminal 1–34 sequences of both PTH and PTHrP assume helical structures at their N- and C-terminal domains (Chorev *et al.,* 1990; Cohen *et al.,* 1991; Epand *et al.,* 1985). These helical sequences span residues 1–9 and 17–31 in PTH and 1–11 and 21–34 in PTHrP (Cohen *et al.,* 1991). A good correlation between receptor-binding affinity and the extent of helicity was established by circular dichroism (CD), a spectroscopic method that can assess the average conformation of a peptide (Neugebauer *et al.,* 1995). Assessment of helical content by CD estimated PTH-(1−34) to have on the average fewer than eight residues in helical conformation, which is lower than that estimated for PTHrP-(1−34) (Cohen *et al.,* 1991; Epand *et al.,* 1985; Neugebauer *et al.,* 1992; Willis and Szabo, 1992; Zull *et al.,* 1990). In the presence of 45% trifluoroethanol (TFE), a solvent that promotes secondary structure, the total helical content of both bPTH-(1−34) and hPTHrP-(1−34) is about 73% (Cohen *et al.,* 1991). Nevertheless, the relevance of the conformation in TFE to the bioactive conformation is still debated.

According to ^{1}H-NMR studies in water, the structure of PTH-(1−34) is mostly random, except for a short-ordered region encompassing residues 20–24 (Bundi *et al.,* 1976, 1978; Lee and Russell, 1989). Pellegrini *et al.* (1998b) reported that hPTH-(1−34) in water is highly flexible, with some evidence of transient helical loops spanning the sequences 21–26 and 7–8. This CD and NMR study was carried out in aqueous solution, with variable pHs and salt concentrations, and in the presence of dodecylphosphocholine (DPC) micelles. Distance geometry calculations generated conformations that were refined by molecular dynamic simulations explicitly incorporating solvent (H_2O). This study generated high-resolution conformational preferences of hPTH-(1−34), which were later used in the construction of an experimentally based model of the hormone−receptor complex. Both in aqueous solution and in the presence of DPC micelles, Pellegrini and coworkers observed fast conformational averaging on the NMR time scale. As anticipated, the two helical domains observed in aqueous solution − the N-terminal helix comprising residues 6–14, and the C-terminal helix comprising residues 19–23 − are extended (4–17 and 21–33, respectively) and stabilized in the presence of DPC micelles. A region of flexibility, which is centered around residues 15–16 in aqueous solution and around residues 18–19 in the micellar system, separates both helices (Fig. 2). Therefore, in solution, the two helical domains adopt a range of different spatial orientations, none of which corresponds to a tertiary structure in which helix − helix interactions can be observed (Pellegrini *et al.,* 1998b). This observation is in complete accord with conformational studies of lactam-containing PTHrP analogs (Mierke *et al.,* 1997), point-mutated and segment PTH-PTHrP hybrids (Peggion *et al.,* 1999; Schievano, 2000), and a model amphiphilic α-helix-containing PTHrP analog (Pellegrini *et al.,* 1997a).

Weidler *et al.* (1999) studied PTHrP-(1−34) by CD and NMR in what they define as near physiological solution (50 m*M* potassium phosphate, pH 5.1, 250 m*M* NaCl). According to their studies, PTHrP-(1−34) contains two helical domains, His^{5}-Leu^{8} and Glu^{16}-Leu^{27}, which are connected by a flexible linker. Similar to Pellegrini and coworkers (1998b), who studied PTH-(1−34), they also did not detect any tertiary structure in PTHrP-(1−34).

FIGURE 2 Ribbon diagram of two conformations of hPTH-(1–34) resulting from ensemble-based calculations. Averaging over these two-member ensembles fulfills all of the CD- and NMR-based experimental observations. The different locations and extents of the α-helices are highlighted in grey; the side-chain of Trp23, used to align the conformations, is shown as a ball-and-stick structure (Pellegrini *et al.*, 1998b).

The more hydrophobic and amphiphilic C-terminal sequence in PTHrP has a higher propensity for forming a helix than the N-terminal domain, as demonstrated by the higher percentage of TFE needed for nucleation of an N-terminal helix (Mierke *et al.*, 1997). Similar conclusions were reached by adding lipids (Epand *et al.*, 1985; Neugebauer *et al.*, 1992; Willis, 1994) or DPC micelles (Pellegrini *et al.*, 1997a, 1998b) to PTH- and PTHrP-derived sequences. Taken together, the conformational analyses yield a dynamic model for ligand−receptor binding. Binding is initiated by complementary hydrophobic interactions between the hydrophobic face of the amphiphilic C-terminal helical domain of the ligand, including the principal binding domain, and the hydrophobic membrane. This hydrophobic ligand − membrane interaction allows the propagation of the C-terminal helix and the formation of specific interactions with extracellular portions of the PTH receptor. In the membrane environment, nucleation of the N-terminal helix occurs either cooperatively with (in the antagonist) or independently of (in the agonist) the previously formed C-terminal helical domain. Consequently, in the case of PTH/PTHrP agonists, the flexibility around hinges 12–13 and 19–20 allows the membrane-induced "message domain" to be positioned correctly within the receptor. Specific message-receptor interactions leading to the conformational changes required for signal transduction can thus occur. In the case of PTH/PTHrP antagonists, which lack most of the "message" sequence, no conformational change in the receptor occurs and no signal transduction event is triggered. Absence of the critical hinge around positions 19–20, or a shift in register of the hinge region, results in reduced binding affinity and efficacy, as observed for the cyclic PTHrP analogs (Mierke *et al.*, 1997) and point-mutated PTH/PTHrP hybrids (Peggion *et al.*, 1999). This proposed dynamic model for ligand − membrane − receptor interaction has since been confirmed and extended by numerous studies (Gensure *et al.*, 2003; Castro *et al.*, 2005; Wittelsberger *et al.*, 2006a).

Piserchio and colleagues (2000b) studied bTIP39, the endogenous ligand for PTHR2, using both high-resolution NMR and CD in the presence of DPC micelles and computer simulation in a water/decane simulation cell. They reported a molecular architecture consisting of two stable α-helices, Ala^{5}-Leu^{20} and Leu^{27}-Val^{35}, separated by an unstructured region. This architecture is reminiscent of the structure of PTH-(1−34), with which TIP39 shares only limited sequence homology (Fig. 1). The N-terminal helix in TIP39, important for activation of PTHR2, has a spatial distribution of polar and hydrophobic amino acid residues almost identical to PTH, making it only moderately amphiphilic. Interestingly, in molecular modeling, Asp^{7} in TIP39 is homologous to Ile^{5} in PTH and His^{5} in PTHrP, both of which are crucial for ligand selectivity toward the PTHR2 (Behar *et al.*, 1996a; Gardella *et al.*, 1996a). Thus, the putative steric and repulsive interaction between His^{5} in PTHrP and H^{384} in the bottom of the narrow binding pocket of PTHR2, which is responsible for this receptor-ligand selectivity (Rolz *et al.*, 1999), is replaced by an attractive Coulombic interaction and smaller side-chain presented by Asp^{7} in TIP39. This complementarity may favorably accommodate the interaction between TIP39 and its cognate PTHR2. Compared to PTH, the N-terminal helix in TIP39 is longer by five residues (Leu^{16}-Leu-Ala-Ala-Leu^{20}), causing a shift in the relative location of the flexible region 21–26. The C-terminal helices in TIP39 and PTH-(1−34) are only slightly amphiphilic and share a lower degree of homology than the one observed for N-terminal helices. Some unique structural features related to the C-terminal portion of TIP39 may explain its weaker interaction with the N-ECD of PTHR2, and therefore its diminished role in recognition and binding (Hoare *et al.*, 2000). Compared to the C-terminal helix in PTH-(1−34), the amphiphilicity of the C-terminal helix of TIP39 is compromised by two factors: the presence of charged residues within the hydrophobic face and the location of Trp^{25} in the unordered region separating the N- and C-helices instead of within the C-terminal helix, as Trp^{23} is in PTH. These experimental and computational results reiterate the significance and relevance of studying structurally related, but functionally distinct, ligand−receptor systems to the PTH/PTHrP − PTHR1 system.

A much-debated issue is whether PTH and PTHrP fold into a tertiary structure, in which secondary structural elements interact specifically with each other to form a more stable and higher ordered structure. Cohen *et al.* (1991) suggested that in TFE, the amphiphilic helices located at the N and C termini of bPTH-(1−34) and hPTHrP-(1−34) interact to form a U-shaped tertiary structure, with the hydrophobic residues facing inward to form a hydrophobic core. As a result, the hydrophilic residues are oriented outward, exposing them to the polar solvent. However, in light of the lack of compelling spectroscopic evidence for long-range interactions between the two N- and C-terminal helices in both hPTH-(1−34) and PTHrP-(1−34) (Klaus *et al.*, 1991; Strickland *et al.*, 1993; Wray *et al.*, 1994), the notion of a U-shaped tertiary structure remains unsupported. Interestingly, Gronwald and coworkers (1996) reported that in aqueous TFE, the long-range proton-proton correlations (Val^{2}-to-Trp^{23} and Ile^{5}-to-Asn^{10}) between the two N-terminal helices (sequences 1–10 and 17–27) in the full-length, recombinant hPTH are dependent on interactions provided by residues in the middle and C-terminal portion of the molecule (sequences 30–37 and 57–62, respectively). They cautiously suggested that the molecule shows a tendency toward tertiary structure. It should be noted that in TFE, the low dielectric constant, which helps stabilize helices, is also supposed to shield the side-chains from hydrophobic interactions between the helices, and therefore, destabilizes alleged U-shaped tertiary structures.

Marx and coworkers (1995) suggested that hPTH-(1−37) assumes a U-shaped structure in aqueous solution containing a high salt concentration. However, their reported long-range, proton-proton correlations are limited to side-chains of Leu^{15} and Trp^{23} located close to the bend forming the putative U-shaped structure, leaving, therefore, too much flexibility to define a stable U-shaped structure. Others have also assigned a tertiary folded structure to PTH-(1−39), PTH-(1−34), and the osteogenic PTH sequence PTH-(1−31) (Chen *et al.*, 2000; Marx *et al.*, 2000). The same researchers identify a loop region around His^{14}-Ser^{17}, stabilized by hydrophobic interactions, and long-range proton-proton correlations between Leu^{15} and Trp^{23}, which are also found in hPTH-(1−37) and in N-truncated analogs hPTH-(2−37), -(3−47), and -(4−37) (Marx *et al.*, 1998).

Other studies of PTHrP analogs describe interactions between N- and C-terminal helical domains, in the presence of TFE, thus offering support for the U-shaped structure (Barden and Kemp, 1989, 1994, 1995, 1996; Barden *et al.*, 1997). Barden and Kemp mentioned the presence of a hinge at Arg^{19} − Arg^{20} in [Ala^9]PTHrP-(1−34)NH_2 and attributed to it a functional role in signal transduction. They also postulate long-range interactions between side-chains located on both sides of the turn, Gln^{16}-Arg^{19}, implicating the presence of a tertiary structure (Barden and Kemp, 1996). The question of tertiary structure in PTHrP-(1−34) was also addressed by Gronwald and coworkers (1997), who studied it in water and in 50% TFE. In the presence of TFE, they observed two stable α-helical regions spanning residues 3 to 12 and 17 to 33, which are connected by a flexible linker. Based on their CD and NMR study, Gronwald and colleagues concluded that there is no evidence of a stable tertiary structure in PTHrP-(1−34). Taken together, the current and prevailing view is that both PTH- and PTHrP-derived linear peptides in solution do not form an appreciable component of stable tertiary structure.

The lack of tertiary structure in PTHrP-(1−34) either in aqueous solutions or in the presence of TFE is not limited to the linear parent peptide (Barbier *et al.*, 2000; Maretto *et al.*, 1997; Mierke *et al.*, 1997). Similar conformational behavior was observed in a series of side-chain to side-chain-bridged mono- and bicyclic lactam-containing PTHrP analogs. These conformationally constrained analogs are obtained through cyclization of side-chain pairs, Asp^{13} to Lys^{17}, Asp^{22} to Lys^{26}, Lys^{25} (replacing Arg) to Glu^{29}, and Lys^{26} to Asp^{30}, located at the putative N- and C-terminal helical domains (Barbier *et al.*, 2000; Bisello *et al.*, 1997; Chorev *et al.*, 1991, 1993; Maretto *et al.*, 1997, 1998; Mierke *et al.*, 1997). This i- to -i + 4 side-chain to side-chain cyclization is known to stabilize helical structures in other peptide systems. Bioactivity in the agonist (1−34) and antagonist (7−34) series of lactam-containing analogs requires well-defined N- and C-helical domains that are linked by two flexible hinges located around residues 12–13 and 19–20 (Maretto *et al.*, 1997; Mierke *et al.*, 1997).

Two separate studies suggested that the bioactive conformation of PTH forms an extended helix (Condon *et al.*, 2000; Jin *et al.*, 2000). In a CD study, Condon and coworkers analyzed a series of lactam-containing PTH-(1−31) analogs that include the tricyclo ($Lys^{13}Asp^{17}$,$Lys^{18}Asp^{22}$, $Lys^{26}Asp^{30}$)-[Ala^1,Nle^8,Lys^{18},$Asp^{17,22}$,Leu^{27}]hPTH-(1−31)NH_2, a highly potent (EC_{50} = 0.14 n*M*) analog. This analog forms an extended helix − spanning residues 13–30 − in aqueous solution and is fully helical in 40% TFE. This tricyclic analog includes a lactam bridge, Lys^{18}-to-Asp^{22}, which engulfs Arg^{19}, a putative hinge site in the bioactive conformation. They concluded, therefore, that PTH binds to its cognate receptor in an extended helical conformation. A similar conclusion was reached by Jin and coworkers, who reported the crystal structure of hPTH-(1−34). The PTH crystallized in a slightly bent (residues 12–21), long helical antiparallel dimer (Fig. 3, see also color plate). In general, solid-phase structures of short peptides can be very much affected by the intermolecular packing forces stabilizing the crystal structure. In particular, formation of the dimer, as in the PTH crystal, can override other intramolecular interactions. In addition, there is no resemblance between the crystal environment and a membrane milieu in which the bimolecular ligand − GPCR interaction takes

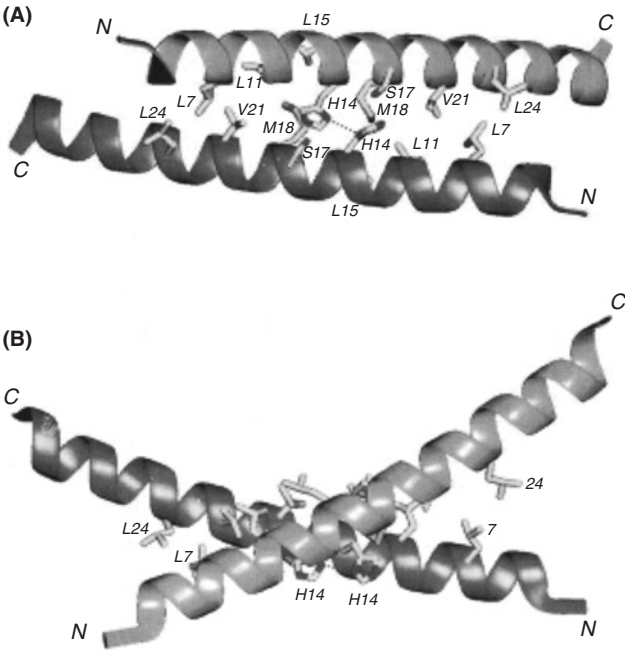

FIGURE 3 Overall structure of hPTH-(1–34) in the solid state. The monomeric chain is a slightly bent helix presented as green ribbons. At the crossing point of the amphiphilic helices in the dimer, His^{14} from each chain forms a hydrogen bond shown as a dotted line. The dimer interface is mainly hydrophobic. **(A)** and **(B)** are two different views of the dimer (Jin *et al.*, 2000).

place. We do not think that these studies contradict previous findings obtained with both PTH and PTHrP in solution, or with analogs more flexible than the tricyclic one. Conformations of the tricyclic analog of PTH in solution or PTH-(1−34) in the solid state may represent only a fraction of the ensemble of fast equilibrating conformations that can generate the bioactive conformation.

As we gain more knowledge about the complexity of receptor conformational states, the traditional search for the one bioactive ligand−receptor conformation must be reassessed. The new paradigm teaches that each ligand induces a specific series of conformational states that result in specific downstream signaling events. The "active state" for receptor triggering of β-arrestin-mediated signaling might be different from that for receptor activation of a G protein (Deupi *et al.*, 2007). Similarly, for receptors signaling through more than one G protein, as does PTHR1, the conformational switching involved in activation of one G protein (i.e., G_s) might be different from that activating another G protein (i.e., G_q) (Kenakin, 2003).

CONFORMATION-BASED DESIGN OF PTH/PTHrP ANALOGS

Restriction of conformational freedom of the ligand in a local or global manner may preclude a wide range of nonproductive conformations and will result in more potent analogs. Indeed, one of the goals of searching for the bioactive conformation of a ligand is to identify structural elements essential for its bioactivity and to devise ways to stabilize them. Furthermore, enhancement of complementary topological features in the ligand−receptor interface may also contribute to increased potency. For example, enhancement of the amphiphilicity of a helical segment may stabilize a favored bimolecular interaction and lead to a more productive receptor interaction. To this end, several studies have incorporated structural modifications that stabilize an element important in the putative bioactive conformation of several PTH analogs (Barbier *et al.*, 1997; Bisello *et al.*, 1997; Chorev *et al.*, 1991, 1993; Leaffer *et al.*, 1995; Mierke *et al.*, 1997; Surewicz *et al.*, 1999).

Much attention has been drawn to the amphiphilic nature of the C-terminal helix comprising residues 20–34 of hPTH-(1−34) and its role in receptor binding (Gardella *et al.*, 1993; Neugebauer *et al.*, 1992). A Lys27→Leu substitution in PTH-(1−34)NH_2 and PTH-(1−31)NH_2 improved the amphiphilic character of the C-terminal helical sequence and increased adenylyl cyclase activity over the corresponding nonsubstituted sequences (Barbier *et al.*, 1997; Surewicz *et al.*, 1999).

Vickery and coworkers (1996) reported a more extensive enhancement of the amphiphilicity of the C-terminal helix of PTHrP. Substitution in PTHrP-(1−34)NH_2 of the sequence 22–31 with a model amphipathic peptide (MAP; Glu[1]-Leu-Leu-Glu-Lys-Leu-Leu-Glu-Lys-Leu-Lys[10]), which is highly α-helical when incorporated into short peptides (Krstenansky *et al.*, 1989), generates [$(MAP_{1-10})^{22-31}$] hPTHrP-(1−34)NH_2 (RS-66271). In this analog, important structural features, such as Leu[24] and Leu[27], are maintained, and Ile[22] and Ile[31] are substituted conservatively by Leu. In aqueous buffer, RS-66271 displays eight- to ninefold higher helicity than the parent peptide. A detailed conformational analysis of RS-66271 in water, employing CD and ^{1}H NMR spectroscopy, confirmed the presence of an extensive helical structure encompassing residues 16–32 (Pellegrini *et al.*, 1997a). Nevertheless, the absence of a hinge element around Arg[19], considered to contribute to high biological activity, may explain the sixfold lower adenylyl cyclase activity and tenfold lower binding affinity in ROS17/2.8 cells of RS-66271, compared to the more flexible and less helical PTHrP-(1−34) (Krstenansky *et al.*, 1989, 1994). Importantly, the preservation of significant *in vitro* potency, despite the multitude of substitutions, validates the rationale behind the design of RS-66271.

It is generally accepted that PTH-(1−34) and PTHrP-(1−34) contain two helical domains spanning sequences 13–18 and 20–34 (Barden and Cuthbertson, 1993; Barden and Kemp, 1993; Strickland *et al.*, 1993; Wray *et al.*, 1994). Introduction of side-chain to side-chain cyclizations via lactam bond formation between residues that are four amino acids apart and located across a single helical pitch (residue i to residue i + 4) has been demonstrated to be an effective way to stabilize α-helical structure (Bouvier and Taylor, 1992; Danho *et al.*, 1991; Felix *et al.*, 1988a, 1988b; Madison *et al.*, 1990). Therefore, Chorev *et al.* (1991) undertook replacement of a potential ion pair participating in α-helical stabilization by a covalent lactam bridge in an attempt to further stabilize the helices in these regions. The initial application of this approach generated *c*[Lys[13]-Asp[17]]PTHrP-(7−34)NH_2, which was about tenfold more potent than the linear parent antagonist (K_b = 18 and 170 n*M*, K_i = 17 and 80 n*M*, respectively, in Saos2/B10 cells) (Chorev *et al.*, 1991). Rigidification of the C-terminal helix in *c*[Lys[26]-Asp[30]]PTHrP-(7−34)NH_2 did not improve antagonist potency (Bisello *et al.*, 1997), but a combination of two 20-membered lactam bridges, in both N- and C-terminal helices, generated *c*[Lys[13]-Asp[17],Lys[26]-Asp[30]]PTHrP-(7−34)NH_2, a potent (K_b = 95 n*M* and K_i = 130 n*M* in Saos2/B10 cells) (Bisello *et al.*, 1997), highly conformationally constrained, PTHrP-derived antagonist, and a valuable tool for conformational studies (Maretto *et al.*, 1997).

The same approach applied to the agonist PTHrP-(1−34)NH_2 yielded the mono- and bicyclic analogs *c*[Lys[13]-Asp[17]]PTHrP-(1−34)NH_2 and *c*[Lys[13]-Asp[17],Lys[26]-Asp[30]]PTHrP-(1−34)NH_2, which were equipotent to the linear parent compound (K_b = 3.2, 2.1, and 1 n*M*, K_m = 0.17, 0.22, and 0.57 n*M*, respectively, in Saos2/B10 cells) (Bisello *et al.*, 1997). A similar

approach was also applied to signaling-selective analogs, hPTH-(1−31)NH_2, and the more potent [Leu^{27}]hPTH-(1−31)NH_2. Both of these analogs stimulate the adenylyl cyclase, but not the PLC/PKC signaling pathway (Barbier *et al.*, 1997). Whereas i-to-i+4 lactam bridge formation between Glu^{22} and Lys^{26}, as in *c*[Glu^{22}-Lys^{26},Leu^{27}]hPTH-(1−31)NH_2, results in about a fourfold increase in adenylyl cyclase activity compared to the linear parent peptide (EC_{50} = 3.3 and 11.5 n*M*, respectively, in ROS 17/2 cells), similar cyclization between Lys^{26} and Asp^{30} or i-to-i+3 lactam bridge formation between Lys^{27} and Asp^{30} results in cyclic analogs less potent than the corresponding linear parent peptides (Barbier *et al.*, 1997).

Interestingly, the higher adenylyl cyclase activity *in vitro* observed for *c*[Glu^{22}-Lys^{26},Leu^{27}]hPTH-(1−31)NH_2 compared to the linear peptide results in a higher anabolic effect on trabecular bone growth in ovariectomized rats (Whitfield *et al.*, 1997) and more effective protection than hPTH-(1−34) affords against loss of femoral trabeculae in the same animal model (Whitfield *et al.*, 1998).

The retention of full PKC activity (in ROS 17/2 cells) by the extensively N-terminally truncated linear fragment [Lys^{27}]hPTH-(20−34)NH_2 and the structurally related lactam-bridged analog *c*[Lys^{26}-Asp^{30}]hPTH-(20−34)NH_2 was consistent with the stabilization of the amphiphilic helix at the C terminus and implicated the helix as an important functional motif for binding to the PTHR1 (Neugebauer *et al.*, 1994). Taken together, these studies provide important insights regarding the structural nature of the hormones PTH-(1−34) and PTHrP-(1−34) and help to better characterize conformational features important for PTH binding and bioactivity.

PTH MINIMIZATION: SHORT AMINO-TERMINAL ANALOGS

Although amino-terminal fragments of PTH and PTHrP shorter than 1–27 were previously reported devoid of biological activity (Azarani *et al.*, 1996; Kemp *et al.*, 1987; Rosenblatt, 1981; Tregear *et al.*, 1973), the efforts of Gardella and coworkers focused on the isolated activation domain represented by the amino terminus, PTH-(1−14) (Carter and Gardella, 1999; Luck *et al.*, 1999; Shimizu *et al.*, 1999). In the search for small peptide and nonpeptide PTH-mimicking molecules as potential therapies for bone metabolic disorders, the marginally active PTH-(1−14) was used as the starting point for structural manipulations in an effort to optimize its activity.

Luck and coworkers (1999) reported that PTH-(1−14) is equipotent in stimulating increased cAMP levels (EC_{50} 100 μM) via the intact rat (r) PTHR1 and the *N*-terminal truncated receptor (rΔNt) missing N-ECD residues 26–181, both transiently expressed in COS-7 cells. In contrast, PTH-(1−34) is two orders of magnitude less potent in stimulating adenylyl cyclase via the rΔNt than through the intact rPTHR1 (Luck *et al.*, 1999). In addition, the "Ala scan" of PTH-(1−14) revealed that the first nine of the N-terminal residues forming the critical activation domain are involved in ligand−receptor interaction, rather than in an intramolecular interaction with the C-terminal domain PTH-(15−34) as suggested earlier (Cohen *et al.*, 1991; Gardella *et al.*, 1995; Marx *et al.*, 1995). This study reinforced the paradigm that the N-terminus of PTH interacts with binding determinants within the ECLs and the juxtamembranal portions of the TMs of the PTHR1.

Shimizu and coworkers (1999) identified some substitutions in the 10–14 sequence of the hormone that are not only compatible with function, but also result in more potent peptides. The peptides [$Ala^{3,10,12}$,Arg^{11}]PTH-(1−14) and [$Ala^{3,10}$,Arg^{11}]PTH-(1−11) are, respectively, 100- and 500-fold more active than PTH-(1−14). In addition, insertion of His, a "Zn^{2+} switch," into some positions in the 10–13 sequence of PTH-(1−14) led to increases in ligand-stimulated cAMP levels in the presence of Zn^{2+} (Carter and Gardella, 1999). This result was interpreted by Carter and colleagues to suggest that the C-terminal portion of PTH-(1−14) contributes important interactions with the ECLs and TM domains. A particular ternary metal − ligand−receptor complex, in which the histidine residues in the ligand and the receptor participate in the coordination sphere around the Zn^{2+}, stabilizes these interactions. However, in the absence of demonstrable specific binding, it is unclear whether the extremely low levels of ligand-induced cAMP increases result from nonspecific interactions between PTH-(1−14) and PTHR1 or from interactions at sites different from the ones used by the 1–34 sequence.

Subsequently, introduction of homoarginine (Har) in position 11 of the (1−14) sequence was shown to increase potency by 40-fold (Shimizu *et al.*, 2001a). Next, the introduction of the sterically hindered and helix-promoting α-amino isobutyric acid (Aib) at positions 1 and 3 had an even larger impact (Shimizu *et al.*, 2001b): when introduced into the [$Ala^{3,12}$,Gln^{10},Arg^{11},Trp^{14}]PTH-(1−14) sequence ([M]PTH-(1−14)), potency increased by 100-fold. The resulting [$Aib^{1,3}$,M]PTH-(1−14), with an EC_{50} value of 1.1±0.1 nM, is ~100,000-fold more potent than native PTH-(1−14) and 2-fold more potent than PTH-(1−34). The shorter sequence [$Aib^{1,3}$,M]PTH-(1−11) displayed an EC_{50} value of 4±1 nM and is also fully efficacious. Finally, a study investigating the impact of other di-alkyl amino acids, 1-aminocycloalkane carboxylic acid (Ac_xc, x = 3, 5, or 6) or diethylglycine (Deg) yielded the most potent PTH-(1−14) and shorter length analogs to date: [Ac_5c^1,Aib^3,M]PTH-(1−X) (X = 14, 11, and 10; IC_{50}s = 80 nM, 260 nM, and 850 nM; EC50s = 1.7 nM, 3.1 nM, and 1.9 nM, respectively) (Shimizu *et al.*, 2004). A report by Barazza *et al.* (2005) confirmed that Ac_5c in either position 1 or 3 in combination with Aib at the respective other position further increases

potency in the [Glu[10],Arg[11]]hPTH-(1−11) sequence. Using circular dichroism (CD) spectroscopy and nuclear magnetic resonance (NMR) combined with computer simulation studies, helix contents of the analogs were evaluated. Consistent with Lim *et al.* (2004; Lee, 2004}, the study concludes that helix stability of the short PTH analogs is necessary but not sufficient for bioactivity, and side-chains also play a role (Barazza *et al.*, 2005).

Additional work in the search for potency-enhancing N-terminal modifications was based on the revelation by Mierke and coworkers that the side-chains of residues 6 (Asn) and 10 (Asn or Gln) of the signaling domain (1−14) of PTH are located on the same face of the putative α-helix (Tsomaia *et al.*, 2004). Mutation of either position 6 or 10 to Ala in N-terminal (1−11) and (1−14) PTH analogs (Shimizu *et al.*, 2003) demonstrated a loss of activity that was partially recovered by introduction of the double mutation. When a Lys in position 6 was covalently bridged by a lactam bond to a Glu in position 10, the activity of the resulting cyclic analog was found to be six-fold higher compared to the linear peptide. Ala mutations in positions 6 and 10 had no effect on binding or activity of PTH-(1−34) when tested with wild-type PTHR1. However, Ala[6] abolished PTH-(1−34) signaling via PTHR-delNt, an effect reversed by introduction of Ala[10]. High-resolution structures as determined by ^{1}H-NMR and NOE-restrained molecular dynamics simulations illustrate the structural differences between the linear and cyclic PTH-(1− 14) fragments, supporting the hypothesis that an α-helix is the preferred bioactive conformation of the N-terminal fragment of PTH (Tsomaia *et al.*, 2004).

Fiori *et al.* (2007) introduced a rigid dipeptide mimetic unit at select positions into the PTH-(1−11) sequence. Comparing activities with structural data obtained from CD spectroscopy and 2D-NMR studies, the authors suggest that the relative spatial orientation of the side-chains of Val[2], Ile[5], and Met[8], together with an intact N-terminal α-helix, are important determinants for activity.

PTH RECEPTORS

The physiological and pathophysiological activities of PTH and PTHrP are mediated predominantly by PTHR1. PTHR1 is encoded by a single-copy gene expressed primarily in kidney, intestine, and bone, the target tissues for PTH, and the PTH − PTHR1 interaction is essential for maintaining mineral ion homeostasis (Schipani *et al.*, 1993). The discovery of receptors for PTH and PTHrP, their functional properties, and biological importance are summarized in some excellent reviews (Juppner, 1995, 1999; Mannstadt *et al.*, 1999).

The expanding pharmacological evidence for actions of PTH on targets other than bone and kidney and the divergence of signaling pathways suggest the presence of a distinct subfamily of cognate receptors for PTH, PTHrP, and other related peptides. Homology-based screen and the exploration of molecular evolution of PTH receptors in various species yielded cDNAs encoding three distinct PTH receptor subtypes (Fig. 4) (Rubin and Juppner, 1999; Usdin *et al.*, 1995). The designation of PTHR2 and PTHR3 as PTH receptor subtypes is based on their high level of sequence homology with PTHR1, their interaction with PTH- and/or PTHrP-derived peptides, and their capacity to stimulate both PKA- and PKC-dependent signaling pathways. However, this designation does not reflect any physiological or functional relationship to the PTH/PTHrP − PTHR1 system. In addition, evidence is currently accumulating for the existence of a carboxyl-terminal PTH receptor responding to C-terminal fragments of PTH-(1–84) (Divieti *et al.*, 2001).

Studying the structure-function relationship of the PTHR1 is an important indirect approach to gaining insight into the ligand−receptor bimolecular recognition process and the signal transduction mechanisms. This approach, however, focuses on only one component of the hormone − receptor complex, the receptor, and therefore it is "blind" to the structural information of the ligand. In addition, many of the point mutated, truncated, and hybrid receptors can be affected by long-range structural consequences that are removed from the site of modification,

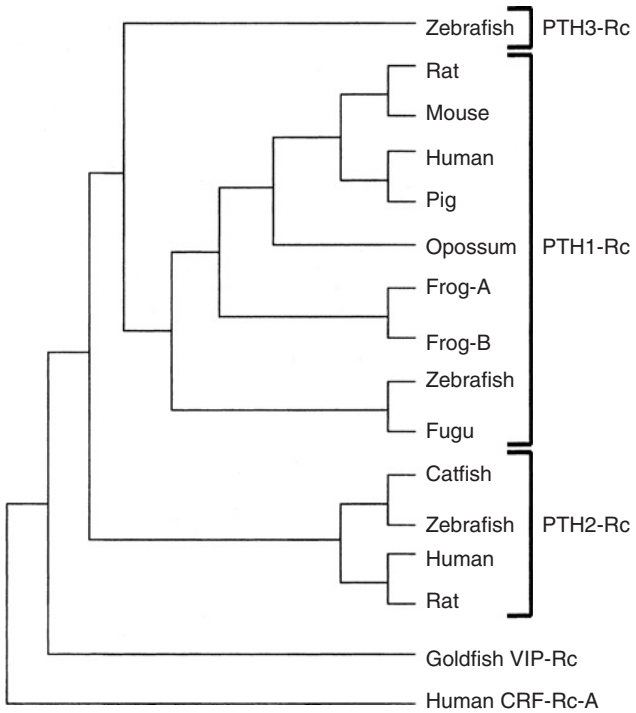

FIGURE 4 A phylogenic dendogram of PTH receptor subtypes. Analysis was reported by Rubin and Juppner (1999). VIP-Rc, vasoactive intestinal polypeptide receptor; CRF-Rc-A, corticotropin-releasing factor receptor A.

thus making the interpretation of structure-function relationships quite difficult.

PTH RECEPTOR TYPE 1

The ~87-kDa N-glycosylated PTHR1 is a member of the class II hepta-helical transmembrane domain G protein-coupled receptors. Class II comprises receptors recognizing peptide hormones ranging in size from 27 to 173 amino acid residues and it includes receptors for secretin, glucagon, calcitonin, growth hormone-releasing hormone, corticotropin-releasing hormone, vasoactive intestinal peptide, pituitary adenylyl cyclase-activating peptide, gastric inhibitory peptide, and glucagon-like peptide 1 (Juppner, 1994, 1995; Segre and Goldring, 1993). The putative hepta-helical structure, which defines the extracellular, TM, and cytoplasmic domains, was derived from structural homology studies (Abou-Samra *et al.*, 1992; Juppner *et al.*, 1991) and confirmed by epitope tag mapping of the extracellular and cytoplasmic domains (Xie and Abou-Samra, 1998). Class II GPCRs have no significant sequence identity (<12%) with other GPCRs. In addition, only 50 amino acid residues are strictly conserved, indicating their early emergence in evolution. The conserved residues are located predominantly in the N-ECD and the TM domains and must play an important structural and functional role.

The distinct features of the class II GPCRs include an N-ECD of ~160 residues, which is intermediate in length between those of the glycoprotein hormone (~400 residues) and aminergic receptors (~35 residues); a highly conserved pattern of 8 cysteines (6 in the N-ECD, 1 in the ECL1, and 1 in the ECL2); and multiple potential N-glycosylation sites located within the N-ECD.

PTHR1 homologues from different mammalian species, such as rat, opossum, pig, human, and mouse, are most divergent within the N-ECD, the ECL1, and the carboxyl-terminal intracellular domain (C-ICD) (Abou-Samra *et al.*, 1992; Juppner *et al.*, 1991; Kong *et al.*, 1994; Schipani *et al.*, 1993; Smith *et al.*, 1996). Evidently, the divergence in the response of different PTHR1 homologues to truncated sequences and analogs of PTH and PTHrP is instrumental in defining important functional domains within the PTHR1. For example, despite their 91% homology and similar apparent dissociation constant of ~10 n*M* for PTH-(1−34), rat and human PTHR1 have very different affinities for the antagonist PTH-(7−34) (K_d = 14 and 4385 n*M*, respectively) (Juppner *et al.*, 1994).

PTH RECEPTOR TYPE 2 AND TIP39

PTHR2, which has been cloned from rat and human cDNA libraries, selectively binds PTH, but not PTHrP (Usdin *et al.*, 1995, 1999a). *In situ* hybridization studies have identified a high level of expression of PTHR2 in brain and lower levels in the exocrine pancreas, epididymis, artrial and cardiac endothelium, vascular smooth muscle, lung, placenta, and vascular pole of renal glomeruli (Usdin *et al.*, 1995, 1999a). However, little is known about its physiological role in these tissues. While the tissue distribution, and particularly the lack of PTHR2 expression in kidney and bone, suggests a limited physiologic role in mineral metabolism, the distinct ligand specificity of PTHR2 has provided insight into the current model of PTH ligand−receptor interactions.

Usdin *et al.* (1999b) isolated a novel peptide from bovine hypothalamus, tuberofundibular peptide 39 (TIP39), whose binding affinity and stimulating activity for the PTHR2 are similar to those of PTH (Usdin *et al.*, 1995, 1999b). In contrast to PTH, TIP39 does not appreciably activate adenylyl cyclase in COS-7 cells transiently transfected with either human or rat PTHR1 (Usdin *et al.*, 1999b), but instead binds to them with moderate affinity (Hoare *et al.*, 2000). A homology search reveals that 9 out of the 39 residues of TIP39 are identical to bPTH, and most of them are located in the midregion of the molecule. The physiological role of the TIP39 − PTHR2 system remains to be established.

Several lines of evidence suggest that PTH is unlikely to be a physiologically important endogenous ligand for PTHR2. These include (1) different ligand rank order of intrinsic activity of a series of PTH analogs in the human and rat PTHR2, (2) considerably lower intrinsic activities and relative potencies of PTH-like ligands at the rPTHR2 than at the hPTHR2, (3) the partial agonist effect of PTH-based peptides when compared to bovine hypothalamic extracts (Hoare *et al.*, 1999a), and, last but not least, (4) the discovery that TIP39, a peptide distantly related to either PTH or PTHrP, is a potent and selective activator of the PTHR2 (Usdin *et al.*, 2000).

Although PTHR2 may not be the physiological target for PTH or PTHrP, its structural resemblance to PTHR1, its high-binding affinity, specific cross-linking, and effective coupling to PTH-induced intracellular signaling pathways make it an attractive target for exploring structure-function relations in the PTH/PTHrP-PTHR1 system. Analysis of the photoconjugates obtained upon cross-linking ^{125}I-Bpa^{1}-PTH and ^{125}I-Lys^{13}(pBz$_2$)-PTH to hPTHR2 stably expressed in HEK293 cells (HEK293/BP-16, ~160,000 Rc/cell) revealed that both hPTHR1 and hPTHR2 use analogous sites for interaction with positions 1 and 13 (Behar *et al.*, 1999).

PTH RECEPTOR TYPE 3

Two PTH receptor alleles, one highly homologous to human PTHR1 and the other a novel PTHR3, have been cloned by genomic PCR from zebrafish (z) DNA.

Although these receptors exhibited 69% similarity (61% identity) with each other, neither of them exhibited as great a degree of homology with zPTHR2 (Rubin *et al.*, 1999). Zebrafish PTHR1 and zPTHR3 showed 76 and 67% amino acid sequence similarity with hPTHR1, respectively, but similarity with hPTHR2 was 63 and only 59% for both teleost receptors (Rubin and Juppner, 1999). Recombinant zPTHR3, transiently expressed in COS-7 cells, exhibited more efficient adenylyl cyclase activity when stimulated by [Ala^{29},Glu^{30},Ala^{34},Glu^{35},Tyr^{36}]fugufishPTHrP-(1−36)NH_2 and [Tyr^{36}]hPTHrP-(1−36)NH_2 (EC_{50} = 0.47 and 0.45, respectively) than by [Tyr^{34}]hPTH-(1−34)NH_2 (EC_{50} = 9.95 n*M*).In addition, zPTHR3 showed higher affinity to the PTHrP analogs than to the PTH analog. Finally, zPTHR1 activated the inositol phosphate (IP) pathway but zPTHR3 did not (Rubin and Juppner, 1999).

When these results are taken together, compared to the nondiscriminatory interaction of PTHR1s with PTH and PTHrP and the selectivity of PTHR2 for PTH, zPTHR3 emerges as the preferential target for PTHrP-derived agonists. Interestingly, some compelling findings suggest the presence of a PTHrP-selective receptor in rat supraoptic nucleus, which is distinct from PTHR1, whose activation leads to the release of Arg-vasopressin (Yamamoto *et al.*, 1997, 1998). We may speculate that since PTHR1 from all known species appear to have similar structural and functional properties, it is likely that the mammalian homologue of zPTHR3, when identified, will interact preferentially with PTHrP.

Receptor Chimera

PTH receptor subtype chimeras, deletion mutation, and point mutations have been used to explore the functional domains in the receptor involved in ligand binding and signal transduction (Gardella *et al.*, 1994; Juppner *et al.*, 1994; Lee *et al.*, 1994). Rat/human and rat/opossum PTHR1 chimeras revealed that the N-ECD plays an important role in binding of the amino-truncated PTH-(1−34)-derived peptides, such as the antagonist PTH-(7− 34) (Juppner *et al.*, 1994). Chimeras with the N-ECD of hPTHR1 have considerably higher binding affinity for PTH-(7−34), PTH-(10 −34), and PTH-(15−34) than the reciprocal chimera where the N-ECD is from the rPTHR1. In addition, deletion of the sequence 61–105 (encoded by exon E2) from the N-ECD did not affect the binding of either PTH-(1−34) or PTH-(7−34) (Juppner *et al.*, 1994). Therefore, this region, which is much more variable among the human, rat, and opossum receptor species than the rest of the N-ECD, does not contribute to the difference in binding affinity of PTH-(7−34) in the rat and human PTHR1. Interestingly, the ectopic regions of TM5 (residues S^{370} and V^{371}) and TM6 (residue L^{427}), which provide important interactions with the extreme amino-terminal residues of PTH and PTHrP, have been found to participate in the binding and signaling of [Arg^2]PTH-(1−34) (Gardella *et al.*, 1994). This analog is a weak partial agonist for cAMP stimulation through rPTHR1 and full agonist for cAMP stimulation through the opossum PTHR1 (Gardella *et al.*, 1991). Reciprocal specific point mutations of residues in rPTHR1 with residues from oPTHR1 (S370A, V371I, and L427T) increased binding affinity to the mutated rPTHR1 to the level observed for the wild-type opossum receptor, yet without affecting the binding of PTH-(1−34). Only one of these mutations in the rPTHR1 (S370A) conferred agonist activity to [Arg^2]PTH-(1−34) (Gardella *et al.*, 1994). The tolerance for the deletion of residues 61–105, which are located in the N-ECD, was utilized to replace it with an epitope tag derived from *Haemophilus influenza* hemagglutinin (HA) without affecting receptor functions, thus generating a powerful tool for monitoring receptor expression levels (Lee *et al.*, 1994). However, deletions of residues 31–47 near the amino terminus and residues 431–440 in the ECL3 were both detrimental to the efficient binding of PTH-(1−34) (Lee *et al.*, 1994).

Luck and colleagues reported that the amino-terminal fragment PTH-(1−14), which encompasses the principal activation domain, is equally potent in stimulating adenylyl cyclase in rPTHR1 and in the N-ECD-truncated rPTHR1 (Carter *et al.*, 1999b; Luck *et al.*, 1999). In contrast, PTH-(1−34) was ~100-fold weaker in potency with N-ECD-truncated rPTHR1 than PTH-(1−14). An alanine scan identified R^{186} in the PTHR1 as critical for the cAMP response only in the case of PTH-(1−14) but not for PTH-(1−34) (Luck *et al.*, 1999). Lack of photocross-linking of fully biologically active ^{125}I-Lys^{13}(pBz_2)-PTH-(1−34) to [R186A/K]hPTHR1 mutants (Adams *et al.*, 1998) suggests that a contact site in the proximity of R^{186} contributes bimolecular interactions with PTH that are crucial for the signaling activity of PTH-(1−14). In addition, Carter and coworkers, carrying out Ala scan analysis and hydrophylic-to-hydrophobic substitutions in the 182–190 sequence of rPTHR1, identified by homolog-scanning mutagenesis strategy to be a candidate for a ligand-binding site (Lee *et al.*, 1995a), suggest that F^{184} and L^{187} are important deterninants of functional interaction with residues 3–14 in PTH (Carter *et al.*, 1999b).

Homolog-scanning mutagenesis (Cunningham *et al.*, 1989) is a powerful technique. It generates chimeric receptors by systematically replacing segments of the PTHR1 with homologous segments of other class II GPCRs and has the potential to maximize surface expression and minimize perturbation of receptor conformation. Exploring the extracellular domains of the rPTHR1 by substituting the corresponding segments of the homologous rat secretin receptor revealed that the ectopic end of TM1 and the carboxyl-terminal ends of ECL1, ECL2, and ECL3 are involved in ligand binding (Lee *et al.*, 1995a). In ECL3, two specific residues, W^{437} and Q^{440}, were identified as major contributors to agonist binding. Interestingly, these

two mutations did not affect the binding affinity of PTH-(3−34), suggesting that these residues are involved in the interaction with the critical amino terminus of the hormone (Lee *et al.*, 1995a). Two chimeric receptors in which the entire amino-terminal domains of corticotropin-releasing receptor 1 and hPTHR1 were exchanged bound analogs of their cognate receptors with a specificity determined by the N-ECD (Assil *et al.*, 2001).

Although calcitonin (CT) and PTH share little sequence homology, their functional domains have a similar organization. In both hormones the N-terminal portions function as activation domains, whereas the C-terminal portions contain the principal binding determinants. Although similar in structure, CTR and PTHR1 class II receptor glycoproteins have only 42% homology and are selectively activated only by their respective ligands. Bergwitz *et al.* (1996) created reciprocal CT-Rc/PTHR1 chimeras in which the N-ECD was exchanged between the two receptors. Similarly, chimeric ligands were synthesized in which the activation and binding domains of each ligand were exchanged to create CT/PTH hybrid peptides. Using a COS-7 mammalian expression system to assess ligand binding and cAMP accumulation, it was demonstrated that the reciprocal hybrid ligands [CT-(1− 11)/PTH-(15−34) and PTH-(1−13)/CT-(12−32)] do not activate normal CT- or PTHR1; they can, however, activate their respective N-ECD-PTHR1/CT-Rc and N-ECD-CT-Rc/PTHR1 chimeras. This interaction was dependent on the cognate receptor's N-ECD binding the hybrid with the cognate C-terminal portion. These chimeric receptors were then activated by the amino-terminal portion of the ligand interacting with the membrane-embedded domains of the receptor and the associated ECLs.

Vilardaga *et al.* (2001a) have created and evaluated the functionality of 27 PTHR1/secretin receptor chimeras. Their data demonstrate that substitution of the C-terminal half (residues 105−186) of the N-ECD of PTHR1 with a secretin receptor homologous segment did not reduce affinity for PTH, but did abolish signaling in response to PTH. Further analysis revealed that residues 146−186 in the N-ECD of PTHR1 are critically important for receptor activation. The data obtained suggest the existence of one distinct binding site in the receptor's far N-terminal region (residues 1−62, site 1) that participates in high-affinity PTH binding, in addition to a second distinct binding site in the C-terminal half of the N-ECD (residues 146−186, site 2) that provides critical contacts for receptor activation. In the absence of site 1, higher concentrations of hormone are required to activate the receptor, whereas the absence of site 2 results in loss of signal transduction without the loss of high-affinity PTH binding. In the same study, a fundamental role in receptor activation was assigned to TM helices 3 and 6 (Vilardaga *et al.*, 2001a).

Another series of experiments confirms the important role of PTHR1 TMs in ligand recognition and receptor structure. Mutation of a single amino acid (N192I) in the TM2 of the secretin receptor to the corresponding residue in the PTH receptor produced PTH binding and functional signaling by the secretin receptor (Turner *et al.*, 1996a). The reciprocal mutation in the PTHR1 (I234N) produced a PTHR1 that was responsive to secretin. Neither mutation significantly altered the response of the receptors to their own ligands. These results suggest a model of specificity wherein TM residues near the extracellular surface of the receptor function as a selectivity filter that blocks access of the wrong ligands to sites involved in receptor activation (Turner *et al.*, 1996a).

The discriminatory domains in PTHR2, which allow response to PTH but not PTHrP, were studied using PTHR1/PTHR2 chimeras with reciprocal exchanges among N-ECD, ECLs, and portions of the TMs (Bergwitz *et al.*, 1997; Turner *et al.*, 1998). The chimeric receptor N-ECD-PTHR1/PTHR2 responded similarly to PTH and PTHrP (EC_{50} = 1.1 and 1.3 n*M*, respectively). However, this chimera had 100-fold higher apparent affinity for PTH than for PTHrP (Turner *et al.*, 1998). These findings suggest that in addition to the discriminatory role of the N-ECD, which predominantly affects binding, other domains of the PTHR2 may contain sites that restrict activation by PTHrP. These sites were located by generating PTHR2 mutants in which single or multiple nonconserved TM domain residues were mutated to the corresponding PTHR1 residues. Mutations within TM3 and 7 of PTHR2 (I244L in TM3 and C397Y, L399M and F400L in TM7) resulted in only partial recovery of affinity toward PTHrP. Turner *et al.* (1998) therefore concluded that the extracellular juxtamembrane portions of the TMs function as a selectivity filter or barrier that discriminates between Ile^5 and His^5 in PTH and PTHrP (Behar *et al.*, 1996a; Gardella *et al.*, 1996a), respectively, by accommodating the first and causing destabilizing interactions with the latter.

Bergwitz *et al.* (1997) arrived at similar conclusions employing PTH/PTHrP point hybrids, [Trp^{23},Tyr^{36}]- and [Ile^5,Trp^{23},Tyr^{36}]PTHrP-(1−36)NH_2. Whereas both analogs were equipotent and had similar affinities to the PTHR1, only the former was an antagonist of PTHR2 (Gardella *et al.*, 1996a). Probing the pharmacological properties of these analogs with PTHR1/PTHR2 domain, cassette, and point-mutated chimeras revealed that I^{244} at the ectopic portion of TM3, as well as Y^{318} near the carboxyl end of ECL2, provide functional interactions with position 5 of the ligands that are involved in the PTH/PTHrP specificity switch (Bergwitz *et al.*, 1997).

Clark *et al.* (1998) studied PTHR1/PTHR2 chimeras in which the N-ECD and ECL3 of the two receptors were interchanged. They found that both domains in both receptors interact similarly with PTH and contribute to the differential interaction with PTHrP. Introduction of the ECL3 of PTHR2 into PTHR1 increased PTH- and PTHrP-stimulated adenylyl cyclase activity and maintained high binding

affinity to PTH but eliminated high-affinity PTHrP binding. Similarly, exchanging ECL3 in PTHR2 for the one from PTHR1 preserved high-affinity binding but reduced the response to PTH. Interestingly, Q^{440} in the ECL3 of PTHR1 is important for PTH-(1−34) binding (Lee *et al.*, 1995a) and is predicted to participate in the binding pocket that accommodates Val^2 in the ligand (Rolz *et al.*, 1999). The corresponding residue in PTHR2 is R^{394}. Introduction of the Q440R mutation in the ECL3 derived from PTHR1 and the R394Q mutation in the ECL3 derived from PTHR2 restored the function of ECL3 chimeric receptors. Moreover, simultaneous interchange of N-ECDs and ECL3s eliminated agonist activation but not binding for both receptors. Simultaneous elimination of the E2-coded sequence (residues 62–106) from the N-ECD of PTHR1 and introducing the Q440/R394 mutation into the ECL3 of the PTHR1 restored function in the PTHR2 chimera. Taken together, these results suggest that interaction between N-ECD and ECL3 in PTHR1 is important for PTHrP recognition. To achieve high-affinity binding of PTHrP to the mutated PTHR2, additional high-affinity interaction sites for PTHrP must be identified in PTHR1 and introduced to the PTHR2 (Clark *et al.*, 1998).

The reciprocal mutations of specific homologous domains and residues identify and delineate potential residues that are critical for local interactions with ligands of different pharmacological profiles and specificities and thus provide important insights into bimolecular ligand−receptor interactions. These studies have pointed to at least three critically important functioning domains on the extracellular surface of the PTHR1: (1) the N-ECD, which largely determines ligand-binding specificity by interactions with the C-terminus of PTH-(1−34), (2) the C-terminal region of the N-ECD, in particular residues 146−186, which plays a role in ligand orientation and subsequent receptor activation, and (3) the TM5/ECL3/TM6 region of the receptor, which interacts with the N-terminal activation domain in PTH. Taken together, receptor chimera-based studies indicate that class II GPCRs share a similar overall structure with multiple functionally important, ligand-specific domains. These domains are sufficiently different to permit synthetic hybrid ligands to bind and efficiently activate the complementary receptor chimeras.

Other Site-Directed Mutagenesis Studies

Mutagenesis has been instrumental in identifying polar residues within the hydrophobic TM domains of PTHR1 as important determinants of receptor function (Gardella *et al.*, 1996b; Turner *et al.*, 1996a). The polar residues R^{233} and Q^{451} located in TM2 and TM7, respectively, are highly conserved within class II GPCRs. Gardella *et al.* (1996b) found that mutating either R^{233} or Q^{451} resulted in reduced binding affinity and transmembrane signaling by the agonist but did not affect the binding of PTH-(3−34). These findings suggest that R^{233} and Q^{451} play important roles in receptor function by contributing to the interaction with the two critical N-terminal residues in PTH-(1−34) and thus affect affinity and signaling. Combining both mutations, as in R233Q/Q451K, restored the binding affinity of the agonist almost to the wild-type receptor level but was devoid of activation of PTH-mediated cAMP or inositol phosphate signaling pathways. These results strongly suggest that residues in TM domains 2 and 7 are linked functionally, are proximal to each other, as in the bacteriorodopsin, and are involved in agonist-induced conformational changes affecting coupling to G protein (Gardella *et al.*, 1996). Moreover, mutation of three residues (S^{227}, R^{230}, and S^{233}) predicted to be aligned on the same face of TM2 resulted in blunted PTH-(1−34)-stimulated adenylyl cyclase response and lower binding affinity for the agonist despite efficient cell surface expression (Turner *et al.*, 1996a). The same mutation at the corresponding sites in another member of the class II GPCRs, the secretin receptor, resulted in a similar reduction in adenylyl cyclase activity. Taken together, these studies led Turner and colleagues to propose that this ectopic region in TM2 participates in a signal transduction mechanism common to class II of GPCRs.

The Role of Cysteines in PTHR1

Cysteines are thought to play a critical role in the assembly and conformation of receptors. Cys→Ser mutations of any of the six cysteines in the N-ECD of PTHR1 severely impaired expression of the mutated receptor (Lee *et al.*, 1994). These six cysteines are highly conserved in class II GPCRs and therefore must contribute critically to receptor function. Mutations C281S or C351S, in the ECL1 and ECL2, respectively, resulted in a reduced level of cell surface expression and compromised binding affinity. The double mutant C281S/C351S, however, displayed significantly improved binding affinity, suggesting that these cysteines are involved in a disulfide bridge connecting the first and second ECLs as they are in rhodopsin and βAR (Lee *et al.*, 1994).

Elucidation of the distinct pattern of the three disulfide bridges formed by the six cysteines in the extracellular N-terminal domain of PTHR1 is a major accomplishment (Grauschopf *et al.*, 2000). Bacterial expression of the N-ECD in inclusion bodies was followed by oxidative refolding, which generated stable, soluble, monomeric, and functional protein (Grauschopf *et al.*, 2000). The N-ECD binds PTH-(1−34) with an apparent dissociation constant of 3–5 μM. Analysis of the disulfide bond pattern revealed the following pairwise arrangement: C^{131}-C^{170}, C^{108}-C^{148}, and C^{48}-C^{117} (Grauschopf *et al.*, 2000). This nonsequential pattern was validated by the structural elucidation of the N-ECD of the corticotropin-releasing factor receptor (CRFR), another member of the family B (class II) GPCRs, by Grace *et al.* (2004). They discovered a short consensus

repeat (SCR) fold as the major structural element of the N-ECD of CRFR; it involves the six Cys's as well as a salt bridge and several other critical residues, all of which are conserved among family B GPCRs. It is therefore likely that the SCR motif is relevant to the entire family B of GPCRs (Grace *et al*., 2004, 2007).

In addition to the six Cys's in the N-ECD and the two Cys's in ECLs 1 and 2, human PTHR1 has five more cysteines, distributed across the ICL1, ICL3, TM7, and the C-terminal intracellular domain (C-ICD). Their role in receptor structure and function was recently studied (Thomas *et al*., 2007). A series of PTHR1 mutants was created with the cysteines either substituted by leucine or alanine or removed by introduction of an enzyme cleavage site. Assessment of expression levels and the biological function of the mutant receptors demonstrated that one position in particular, namely C217 of the ICL1, is critically important for transport as well as function of PTHR1.

Mutated Receptor-Based Genetic Disorders

Jansen's Metaphyseal Chondrodysplasia

Jansen's metaphyseal chondrodysplasia (JMC) is a rare form of short limb dwarfism associated with abnormalities in endochondral skeletal development, hypercalcemia, and hypophosphatemia, despite normal levels of PTH and PTHrP. Three missense mutations in the PTHR1 coding region, H223R, T410P, and I458R, have been discovered in patients with the disease (Schipani *et al*., 1995, 1996, 1999). PTHR1 carrying any one of these mutations display constitutive, ligand-independent activation of the cAMP signaling pathway when tested *in vitro*.

The H223R, T410P, and I458R mutations are located at the cytoplasmic base of TM2, TM6, and TM7, respectively. In COS-7 cells transiently expressing the human I458R PTHR1, basal cAMP accumulation was approximately eight times higher than in cells expressing the recombinant normal receptor. Furthermore, the I458R mutant showed higher activation by PTH than the wild-type receptor in assays measuring the activity of downstream effectors, adenylyl cyclase, and PLC. Like the H223R and T410P mutants, the I458R mutant does not constitutively activate basal inositol phosphate accumulation. Interestingly, these mutations all occur at TM regions near the intracellular loops of PTHR1 that are hypothesized to interact with G proteins or other intracellular partners to trigger the subsequent signaling cascade.

These same mutations in PTHR1 have also been utilized to identify PTH and PTHrP analogs with inverse agonist activity. Two peptides, [Leu^{11},D-Trp^{12}]hPTHrP-(7 −34)NH_2 and [D-Trp^{12},Tyr^{34}]bPTH-(7−34)NH_2, which are highly potent antagonists for the wild-type PTHR1, exhibited inverse agonist activity in COS-7 cells expressing either mutant receptor (H223R or T410P) and reduced cAMP accumulation by 30–50% with an EC_{50} of approximately 50 n*M* (Gardella *et al*., 1996c). [D-Trp^{12},Tyr^{34}]bPTH-(7−34)NH2 was subsequently shown to selectively inhibit Gs/PKA activation while having no apparent activity for Gq/PKC stimulation (Gesty-Palmer *et al*., 2006). Such inverse agonist ligands may be useful tools for exploring the different conformational states of the receptor, as well as leading to new approaches for treating human diseases with an underlying etiology of receptor-activating mutations.

Blomstrand's Chondrodysplasia

Blomstrand's osteochondrodysplasia (BC) is a rare lethal skeletal dysplasia characterized by accelerated endochondral and intramembranous ossification (Blomstrand *et al*., 1985; Leroy *et al*., 1996; Loshkajian *et al*., 1997; Young *et al*., 1993). The phenotype of BC is strikingly similar to PTHR1 knockout mice, which display prominent pathology in the growth plate (Lanske *et al*., 1999). In both the human disease and the PTHR1-ablated mouse model, the growth plate is reduced in size because proliferating chondrocytes lack the normal columnar architecture as well as a greatly reduced zone of resting cartilage. This overall similarity of phenotype suggests that an inactivating mutation of PTHR1 is the underlying genetic defect in BC. To date, two types of inactivating mutations have been documented in BC patients (Karaplis *et al*., 1998; Zhang *et al*., 1998). The first is a single homozygous nucleotide exchange in exon E3 of the PTHR1 gene. This alteration introduces a P132L mutation in the N-ECD of the receptor (Zhang *et al*., 1998). Proline 132 is conserved in all mammalian class II GPCRs. COS-7 cells expressing a GFP-tagged mutant receptor do not accumulate cAMP in response to PTH or PTHrP and do not bind radiolabeled ligand, despite being expressed at levels comparable to GFP-tagged wild-type PTHR1. Thus, while full-length PTHR1 is being synthesized, it does not bind the ligand and it is functionally inactive.

Another mutation in PTHR1 detected in BC patients results in the synthesis of truncated receptor fragments (Karperien *et al*., 1999). Sequence analysis of all coding exons of the PTHR1 gene identified a homozygous point mutation in exon EL2 with one absent nucleotide (G at position 1122). This missense mutation produces a shift in the open reading frame, leading to a receptor truncated after amino acid 364 located in the ECL2. The mutant receptor, therefore, lacks TMs 5, 6, and 7.

Jobert *et al*. (1998) described a third point mutation in PTHR1 associated with BC. This mutation (G→A at nucleotide 1176) leads to the deletion of 11 amino acids (residues 373–383) in the TM5 of the receptor. The mutated receptor is well expressed in COS-7 cells, but does not bind PTH or PTHrP and fails to elevate cAMP and inositol phosphate in response to these ligands.

INTEGRATED STUDIES OF LIGAND–RECEPTOR INTERACTIONS

Two traditional and indirect approaches, one "ligand centered" and the other "receptor centered," have been pursued to further understand the ligand − PTHR interaction and each has made important contributions (see preceeding sections). The hormone-centered approach succeeded in mapping functional domains within the hormone that affect receptor binding and activation. In some cases, structural features responsible for biological properties have been identified down to the level of a single amino acid, which sometimes led to the development of important therapeutics. In the PTH/PTHrP field, the identification of the architecture of functional domains and the development of potent antagonists, partial agonists, and inverse agonists, signaling-selective analogs, and potent *in vivo* anabolic agents generate a very impressive list of accomplishments. However, this approach cannot be used to deduce the receptor domains that are in contact with the hormone across the interface. Furthermore, in some cases, modifying the primary structure of the hormone may result in altering the pattern of bimolecular interactions with the receptor. Some structural modifications of the hormone may directly alter its interaction with an important complementary structural feature of the receptor; others may affect bioactivity through either local or global conformational changes within the hormone that prevent formation of an optimal "bioactive conformation." In essence, the hormone-centered approach is "blind" to the structure of the receptor.

The "receptor-centered" approach has also succeeded in providing valuable insights. Point-mutated and chimeric PTHR − interspecies of PTHR1, such as rat with opossum receptor, or interhormone receptors, such as PTHR1 with calcitonin or secretin receptors − revealed the importance of specific receptor domains and single amino acids necessary for receptor function. However, analysis of the functional consequences that result from modifying the receptor structure alone cannot be used to identify unequivocally the interacting complementary structural elements in the hormone. Furthermore, one usually cannot distinguish R modifications that disrupt function as a result of local changes in an important "contact site" or a global conformational change. While local changes affect R interaction with a site in the hormone directly, global conformational changes lead to extensive modification of R topology, thereby altering interactions with the hormone indirectly. Hence, despite important contributions by both lines of investigation, conclusions drawn from the hormone-centered and receptor-centered approaches have inherent limitations and are inferential at best.

X-ray crystallography and nuclear magnetic resonance (NMR) spectroscopy are the tools of choice for analyzing the structure of bimolecular complexes. Unfortunately, membrane-embedded GPCRs are generally not amenable to either x-ray or NMR analysis because of their hydrophobic nature and conformational flexibility. Despite years of effort in several GPCR systems, to date only two GPCRs, the bovine retinal photoreceptor, rhodopsin (Palczewski *et al*., 2000), and the β_2-adrenergic receptor-2 (β_2AR) (Rasmussen *et al*., 2007; Cherezov *et al*., 2007) have been crystallized and subjected to high-resolution X-ray structural analysis. The crystal structure available for rhodopsin is in its resting state; hence, the mechanism of switching from the "ground" to "activated" state has not been directly revealed. In addition, rhodopsin is categorically different from other GPCRs. Its ligand, 11-*cis* retinal, is "pre-bound" covalently; hence, the dynamics of ligand association and dissociation do not pertain. In addition, conformational changes in rhodopsin are induced by light. Therefore, the nature of ligand−receptor interactions for rhodopsin are fundamentally different from other GPCRs.

The β_2AR was crystallized while binding an inverse agonist. Using different approaches, one group determined the structure at a 3.4 Å/3.7 Å level (Rasmussen *et al*., 2007); the other at 2.4 Å resolution (Cherezov *et al*., 2007). The cytoplasmic ends of the TMs and connecting loops are well resolved, but the structure of the extracellular regions (which play an important role in hormone binding in the PTH system) are either less resolved or could not be determined. The overall structure is closely similar to rhodopsin (which is used as a template in molecular modeling of many GPCRs, including PTHR). Of note is the observation that when β_2AR co-crystallizes with a ligand, the receptor remains in monomeric form; hence, receptor dimerization does not appear necessary for G protein activation.

Photoaffinity labeling has emerged as an effective methodology for studying interactions of biological macromolecules with their ligands (Chowdhry and Westheimer, 1979; Dorman and Prestwich, 1994; Hazum, 1983; Hibert-Kotzyba *et al*., 1995). The resultant photocross-linked conjugate can serve as a starting point for mapping "contact domains," and even "amino acid to-amino acid contact points" between a biologically active compound and an interacting macromolecule (Bitan *et al*., 1999; Blanton *et al*., 1994; Boyd *et al*., 1996; Girault *et al*., 1996; Hadac *et al*., 1999; Ji *et al*., 1997; Kage *et al*., 1996; Keutmann and Rubin, 1993; Kojr *et al*., 1993; Li *et al*., 1995; McNicoll *et al*., 1996; Phalipou *et al*., 1999; Williams and Shoelson, 1993).

A number of laboratories, including our own, have utilized photoaffinity scanning (PAS) to map the bimolecular interface between a peptide hormone and its cognate GPCR. The approach has numerous stringent requirements, the fulfillment of which is crucial for success. Bioactive, specific, cleavage-resistant, photoactivatable, and radiolabeled PTH analogs must be designed and synthesized. A rich and stable source of functional wild-type or mutant PTHR, overexpressed preferentially in a

homologous cellular background, must be developed and fully characterized pharmacologically. For purifying either the intact ligand−receptor conjugate or its ligand−receptor conjugated fragments, it may be advantageous to work with epitopetagged receptor. It may also be helpful to have antibodies to various receptor extracellular epitopes for use in purification and analysis. The PAS approach requires devising an analytic strategy with sequential chemical and enzymatic cleavages; theoretical digestion maps to allow unambiguous identification of hormone-binding sites within the PTHR; possibly the synthesis or expression of receptor domains that contain the identified contact sites for conformational studies; and the generation of site-directed mutated PTHRs, their expression and pharmacological characterization, and their use in the PAS technology to validate and/or delineate emerging results. Last but not least, this approach requires access to tools that will allow integrating cross-linking data with receptor mutagenesis data and eventually with conformational analysis and molecular modeling data to generate a unified, experimentally based model of the hormone−receptor complex.

In summary, PAS technology is a multidisciplinary, integrated, iterative, and labor-intensive approach. Nevertheless, it is currently the only direct method that yields the best approximation of the actual ligand−receptor complex. Because of the nature of this approach, however, it cannot yield molecular structures of the same resolution as those obtained by either x-ray crystallography or NMR analysis.

Photoreactive Analogs

Early efforts to generate a photoreactive, radiolabeled, and biologically active analog of PTH aimed to identify the receptor as a distinct molecular entity (Coltrera *et al.*, 1981; Draper *et al.*, 1982; Goldring *et al.*, 1984; Wright *et al.*, 1987). All of these studies used poorly characterized ligands containing nitroarylazide-based photophores and reported molecular masses ranging between 28 and 95 kDa for the hormone − receptor complex. Shigeno *et al.* (1988a, 1988b) carried out a careful synthesis and characterization of the nitroarylazide-based photoligand and identified it as [$Nle^{8,18}$,Lys^{13}(N^{ε}-(4-N_3-2NO_2-phenyl),Tyr^{34}]PTH-(1–34)NH_2, a fully active analog in ROS 17/2.8 cells. Using this photoaffinity ligand, they were able to identify in the same cells a plasma membrane glycoprotein corresponding to the PTH receptor that had the apparent molecular mass of 80 kDa.

Introduction of the arylketone-based photoaffinity scanning methodology (Adams *et al.*, 1995; Bisello *et al.*, 1999; Han *et al.*, 2000; Nakamoto *et al.*, 1995; Suva *et al.*, 1997) into the field of calciotropic hormones and their corresponding receptors enabled a series of investigations on contact points between ligand and PTHR1 (Adams *et al.*, 1998; Behar *et al.*, 1999, 2000; Bisello *et al.*, 1998; Greenberg *et al.*, 2000; Suva *et al.*, 1997; Zhou *et al.*, 1997; Gensure *et al.*, 2001; Gensure *et al.*, 2003; Wittelsberger *et al.*, 2006a). Advantages of the benzophenone moiety as a photophore over the aryl azide moiety are numerous. A partial list includes the high efficiency of cross-linking (only a small amount is lost to hydrolysis), and very little nonspecific cross-linking. Photoactivation is carried out at a wavelength greater than 330 nm, in which proteins are less susceptible to photodegradation. In addition, there is excellent compatibility with the solid-phase peptide synthesis methodology. Furthermore, synthesis, purification, and biological evaluation can be conducted in the laboratory under normal ambient light conditions.

Radioiodination is the tagging method of choice because of its high specific radioactivity translating into high sensitivity of detection of the radiolabeled conjugated ligand−receptor complex and the fragments derived from it. Therefore, successful PAS analysis requires maintaining the connectivity between the radiotag and the photophore throughout the controlled degradation of the conjugated ligand−receptor complex. Modifications in PTH-(1−34), which include $Met^{8\text{ and }18} \rightarrow Nle^{8\text{ and }18}$, $Lys^{13,26,\text{and }27} \rightarrow Arg^{13,26,\text{and }27}$, and $Trp^{23} \rightarrow$ 2-naphthylalanine^{23} (Nal), render the ligand resistant to the various chemical and enzymatic cleavage agents (i.e., CNBr, lysyl endopeptidase (Lys-C) and BNP-skatole, cleaving at the carboxyl side of Met, Lys, and Trp, respectively).

The fundamental requirement in any photoaffinity cross-linking study is that the photoreactive analogs have the same pharmacological profile as the parent peptide hormone. It will therefore be safe to assume that they share similar bioactive conformations and generate topochemically equivalent ligand−receptor complexes. The photoreactive benzophenone-containing analogs of PTH and PTHrP were designed specifically for PAS studies aimed at investigating the bimolecular interactions of the activation and binding domains of PTH and PTHrP with either PTHR1 or PTHR2 subtypes.

Identification of Contact Sites using Benzophenone-based Photoreactive Groups

Using the PAS methodology, contact sites have been identified for positions 1, 11, 13, 15, 18, 19, 21, and 27 in PTH and positions 1, 2, 19, 23, 27, 28, and 33 in PTHrP (Adams *et al.*, 1995; Behar *et al.*, 2000; Bisello *et al.*, 1998; Carter *et al.*, 1999a; Greenberg *et al.*, 2000; Zhou *et al.*, 1997; Wittelsberger *et al.*, 2006a; Gensure *et al.*, 2001; Gensure *et al.*, 2003). Two different photophores were used in different studies: *p*-benzoylphenylalanine (Bpa) (Behar *et al.*, 2000; Bisello *et al.*, 1998; Carter *et al.*, 1999a; Wittelsberger *et al.*, 2006a; Gensure *et al.*, 2001; Gensure *et al.*, 2003) and the Lys(N^{ε}-*p*-benzoylbenzoyl) [Lys(N^{ε}-*p*Bz_2]

(Adams *et al.*, 1995; Behar *et al.*, 2000; Greenberg *et al.*, 2000; Zhou *et al.*, 1997). The former has the benzophenone moiety attached to the peptide backbone through a β-carbon, whereas the latter is presented on a relatively long side-chain removed by six atoms from the backbone. These different modes of presentation of the benzophenone moiety may play a limited role in selecting cross-linking sites.

Photocross-linking of ^{125}I-[Bpa^{x},Nle^{8,18},Arg^{13,26,27},Nal^{23},Tyr^{34}]bPTH-(1−34)NH$_2$ (Bpa^{x}-PTH) to the human PTHR1 stably overexpressed (~400,000 Rc/cell) in human embryonic kidney cell line 293 (HEK293/C21) typically generates an 87-kDa photoconjugate (Bisello *et al.*, 1998; Wittelsberger *et al.*, 2006a). Chemical digestions by CNBr and BNPS-skatole, which cleave at the carboxyl end of Met and Trp, respectively, and enzymatic digestions by endopeptidases Lys-C, Glu-C, or Arg-C, in addition to endoglycosidase F/N-glycosidase F (Endo-F), which deglycosylates aspargines at consensus glycosylated sites, generate an array of fragments. These radioiodinated fragments are characterized by SDS-PAGE, and the apparent molecular weights obtained are compared with the theoretic digestion restriction map of the photoconjugated receptor. Although the resolving power of PAGE is limited, the combination of consecutive cleavages (e.g., Endo-F followed by Lys-C followed by CNBr) carried out in reversed order (e.g., Lys-C followed by BNPS-skatole and BNPS-skatole followed by Lys-C) is extremely powerful. It generates a reproducible pattern of fragments delimited by specific end residues and the presence or absence of glycosylation sites. Comparing the putative digestion map of the PTHR1 with experimentally obtained fragment sizes identifies the sequence of the smallest radiolabeled ^{125}I-Bpa^{x}-PTH—PTHR1-conjugated fragment.

Using this approach, two Met residues, 414 and 425, present at the midregion and the extracellular end of TM6, emerged as potential cross-linking sites for ^{125}I-Bpa^{1}-PTH. Contact between residue 1 in PTH and M^{414} requires the N terminus of PTH to protrude into the 7 helical and hydrophobic TMs bundle. In contrast, contact with M^{425} can be achieved while the N terminus is dipping only superficially into the TM bundle.

These biochemical methods are often supplemented by molecular biology to provide additional resolving power to the PAS method. In the case mentioned earlier, transient expression of two point-mutated hPTHR1, [M414L] and [M425L], generated fully active receptors in COS-7 cells (Bisello *et al.*, 1998). ^{125}I-Bpa^{1}-PTH lost its ability to photocross-link to [M425L] but not to [M414L], thus suggesting that M^{425} is the putative contact site for position 1 in PTH.

Behar *et al.* (2000) reported that radioiodinated PTHrP-based agonist [Bpa^{1},Ile^{5},Tyr^{36}]PTHrP-(1−36) NH$_2$ (^{125}I-Bpa^{1}-PTHrP), which carries a photophore at the same position as the photoreactive PTH analog ^{125}I-Bpa^{1}-PTH, forms a contact with M^{425} in hPTHR1. This exciting finding confirms that the functional and conformational similarity between PTH and PTHrP extends to a common contact site for the N-terminal residue in the ligand. The location of this site at M^{425} in the ectopic portion of TM6 supports the prevailing view that these two hormones interact very similarly, if not identically, with the PTHR1. Unlike Bpa^{1}-PTH and Bpa^{1}-PTHrP, which have a single cross-linking site (M425), the radiolabeled antagonist Bpa^{2}-PTHrP (^{125}I-[Bpa^{2},Ile^{5},Arg^{11,13},Tyr^{36}]PTHrP-(1−36)NH$_2$) cross-links to both M425 and a proximal site within receptor region [415−425] (Behar *et al.*, 2000). In contrast, Bpa^{2}-PTH, a full agonist, cross-links to M425 only. This investigation provides strong support for a fundamental difference in the binding mode of PTH agonists versus antagonists.

Using similar PAS techniques, the cross-linking site for radiolabeled [Nle^{8,18},Lys^{13}(N$^{\varepsilon}$-*p*(3-I-Bz)Bz),Nal^{23},Arg^{26,27},Tyr^{34}]bPTH-(1−34)NH$_2$ [Lys^{13}(*p*Bz$_2$)-PTH] was identified as Arg186 at the C-terminal end of the N-ECD (Adams *et al.*, 1998; Zhou *et al.*, 1997). Then, a site in the first extracellular loop (L261) was found to contain the contact site of [Lys^{27}(*p*Bz$_2$)-PTH (Greenberg *et al.*, 2000), suggesting that the extracellular loops contribute to the specificity of the PTH − PTHR1 interaction. A study by Gardella and coworkers using PTHrP analogs containing Bpa at positions 23, 27, 28, and 33 in the C-terminal half of PTHrP found all contact points to lie within the N-ECD, namely regions [33−63], [96−102], [64−95], and [151−172], respectively (Gensure *et al.*, 2001). The difference in contact point between Lys^{27}(*p*Bz$_2$)-PTH and Bpa^{27}-PTHrP is striking; however, the discrepancy may be attributed to differences in the hormone used, the photolabile moiety, or the receptor species used in the experiment.

A more recent study found that all contact points from the midregion of PTH lie within the C-terminal domain of the N-ECD: PTH analogs containing Bpa in positions 11, 15, 18, and 21 cross-linked to receptor regions [165−176], [183−189], [190−298], and [165−176], respectively (Wittelsberger *et al.*, 2006a). The contacts were used as distance restraints in molecular dynamics simulations and resulted in a substantial refinement of the PTH−PTHR1 model (Fig. 5). Specifically, (1) the overall receptor-bound conformation of the hormone is not extended, but bent; (2) helix [169−176] of the N-terminal extracellular domain (N-ECD) of the receptor is redirected toward the heptahelical bundle; and (3) the hormone traverses between the top of transmembrane (TM) helices 1 and 2, rather than between TM7 and TM1 (Fig. 5). The results point to a critical role of the midregion of PTH to fix, by extensive contacts within region [165−189] of the receptor, the entry of the hormone into the heptahelical bundle between TM1 and TM2. This anchorage orients the amino terminus into position to activate the receptor.

FIGURE 5 Experimentally derived model of the PTH–PTHR1 complex (Wittelsberger et al., 2006). Extracellular view of the receptor (green) illustrating interactions with PTH (orange), including PTH's N-terminal activation domain, midregion, and C-terminal binding domain. Side-chains at positions for which cross-linking sites were identified are displayed (yellow). The largest part of the N-ECD (residues 1–168), is shown for reference only (no structural features are implied).

REACHING THE RESOLUTION LIMIT OF Bpa-BASED PHOTOAFFINITY CROSS-LINKING

In the course of defining contact sites for Bpa^{11}-PTH and Bpa^{21}-PTH using engineered Met-containing mutants of PTHR1, Wittelsberger *et al.* (2006a) observed a low MW band in the CNBr-digestion pattern of cross-linked conjugates that corresponded in size to free ligand, suggesting that cross-linking to the methyl group of methionine occurred. It is known that insertion of a Bpa radical can occur at the ε − methyl of Met, and that subsequent CNBr treatment results in hydrolysis at that site, releasing a thiocyanomethyl derivative of the ligand (Kage *et al.*, 1996).

This finding instigated undertaking of a "Met scan" around position 176 of the receptor (Wittelsberger *et al.*, 2006b). Met was introduced individually at ten positions: 163, 168, 169, 171−176, and 183 of the N-ECD of PTHR1. Introduction of Met at 170 was not attempted because removal of the native Cys results in poor receptor expression (Lee *et al.*, 1994). The observations made after cross-linking of mutant receptors with both Bpa^{11}- and Bpa^{21}-PTH followed by CNBr treatment were striking: cross-linking occurs to M*et al*ong a wide range of the receptor domain, positions 163−173 (Fig. 6), a span of 11 amino acids. Importantly, when Met is incorporated at a site further away (e.g., position 183), cross-linking to Met does not occur. The range of "Met-reactivity" can be demarcated: Bpa^{21}-PTH cross-links to Met in positions 163 up to 173, but positions 174 and 175 are "out of reach." The study demonstrates a pronounced preferential reactivity of Bpa for Met over other amino acids. The region PTHR-(163−173) extends over 16 Å in the model (Fig. 6). The "Met-reactive" reach of positions 11 and 21 in PTH overlap considerably, despite being ten residues (13 Å) apart in the ligand (Fig. 6). The phenomenon is referred to as the "magnet effect" of Met (Wittelsberger *et al.*, 2006b). These data imply that when Met in the receptor is reported as the cross-linking site for a ligand, one needs to consider the possibility that such contact sites might be shifted or broader than actual owing to the presence of Met.

Another limitation of Bpa lies in its size and rotational freedom. The reactive radius of the benzophenone group was approximated as a sphere with a radius of 3.1 Å centered on the ketone oxygen (Dorman *et al.*, 1994). In Bpa, rotation around the $C\alpha - C\beta$ bond defined by angle χ_1 allows for significant increases in accessible distances (Fig. 7).

To define appropriate distance restraints for experimentally determined contact sites in molecular modeling, a model system was created (Wittelsberger *et al.*, 2008). The solution structure of PTH-(1−34) was used as determined by NMR (Pellegrini *et al.*, 1998b); Bpa was then introduced at a centrally located position replacing Arg^{20} (Fig. 8).

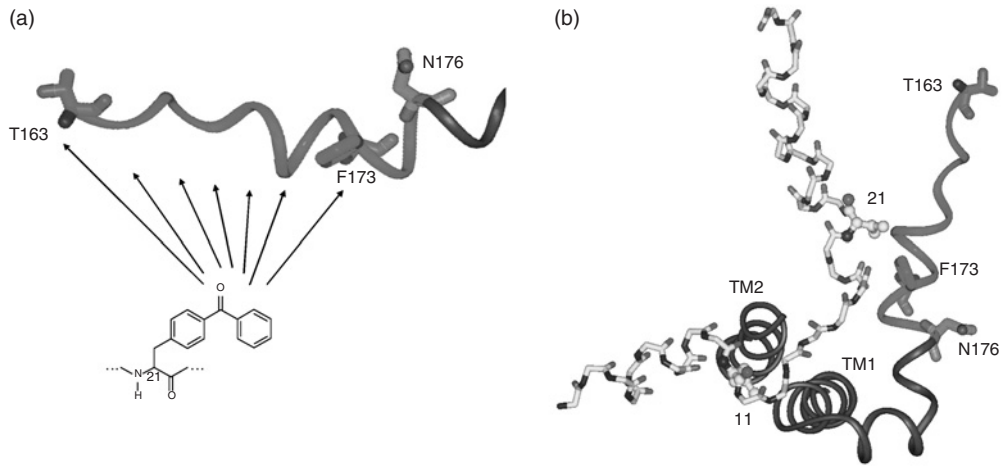

FIGURE 6 The "magnet effect" of Met. The "Met-reactive" region for Bpa^{11}-PTH and Bpa^{21}-PTH is colored light green. (A) The PTHR-(163–173) region has a 16 Å span. (B) Residues 11 and 21 in the ligand (yellow) are 13 Å apart, yet are "Met-reactive" within the same domain of PTHR (light green) (Wittelsberger et al., 2006b).

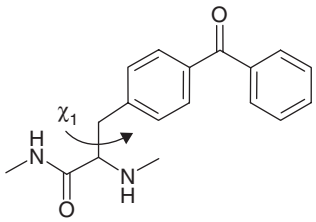

FIGURE 7 Structure of *p*-benzoylphenylalanine (Bpa) with the dihedral angle χ_1 denoted.

Next, the side-chain of Bpa^{20} was rotated from $\chi_1 = -60°$ to $\chi_1 = 60°$ to $\chi_1 = 180°$. For each of these three states, the distances from the reactive carbonyl group of Bpa to the side-chain of select residues toward the C-terminus (Lys^{27}) and toward the N-terminus (Asn^{10}) of the hormone were measured. As illustrated in Fig. 8, the distances between Bpa^{20} and K^{27} range from 7.0–15.5 Å; the distances between Bpa^{20} and Asn^{10} range from 8.1−17.2 Å. Similar conclusions can be drawn for the interactions between Bpa and the receptor. With the same exact ligand-binding mode, depending on the χ_1 rotational state of Bpa, a wide range of different amino acids of the receptor would be available for cross-linking; the distance variation from the reactive carbonyl in Bpa is approx. 10 Å. The study therefore concludes that it is imperative to use a distance constraint of at least 10 Å for experimentally determined contact points in MD simulations of ligand−receptor complexes, resulting in limited resolution.

Benzophenone-based photoaffinity scanning (PAS) was applied extensively in generating the model of PTH − PTHR1 because it provides direct information about sites of bimolecular contact. Although it lacks the resolution of x-ray crystallography, PAS provides "snapshots" of interactions by fixing contacts through covalent bond formation. An ensemble of contacts identified provides the set of constraints essential for molecular modeling. When PAS is combined with other approaches, an informative model of a hormone − Rc complex may emerge. In the PTH − PTHR system, however, we and others have taken the cross-linking methodology, based on Bpa photoactivation, toward its limit of resolution. Even new photolabile moieties, such as the trifluoromethyldiazirinphenylalanine-based Tdf group developed by Escher and colleagues (Fillion *et al.*, 2006), which lacks the Met selectivity of Bpa, still suffer from the inherent resolution limit of photoaffinity labeling, not to mention formidable challenges in synthesizing the photolabile moiety.

The Bpa-based technology does remain an excellent approach for the first rounds of investigations into a ligand−receptor system to obtain general landmarks and key contact regions.

Disulfide Capture

"Site-specific disulfide capture" or "Cys-trapping" is well suited to the PTH − PTHR system because it is most productively applied to systems in which a first-generation map of the ligand−receptor interface already has been generated. The approach applied to other GPCRs (Buck *et al.*, 2005a,b), is based on engineering a single Cys residue into a receptor domain postulated to be crucial for ligand-binding or activation. After demonstrating that the Cys-containing receptor mutant retains biological function, it can be used to capture Cys-containing peptide analogs of the cognate ligand for structural studies.

In this approach, one cysteine mutation is introduced into a specific site within the ligand and one in a region of the receptor predicted to interact with the specific mutated residue in the ligand. If these cysteines are in close proximity,

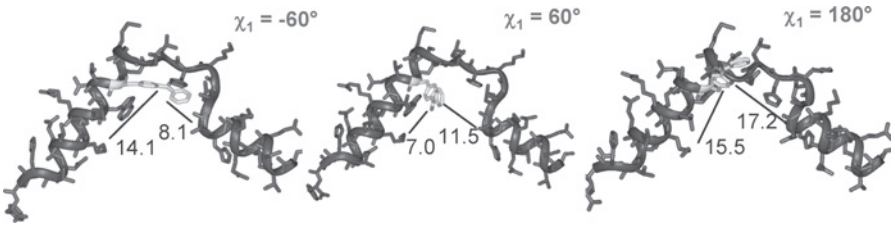

FIGURE 8 Model system based on the NMR structure of PTH-(1–34) (green). Distances (in Å) between the reactive carbonyl group of Bpa (yellow) and the side-chains of Asn^{10} and Lys^{27} are indicated in blue for the three staggered rotamers ($\chi_1 = -60°$, 60°, and 180°) (Wittelsberger *et al.*, 2008).

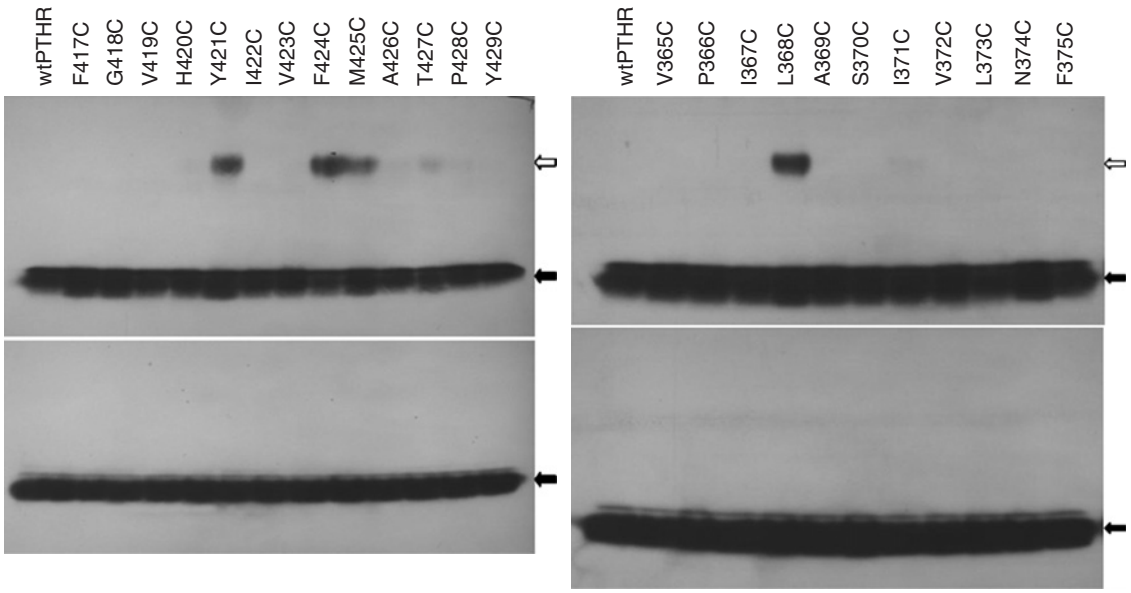

FIGURE 9 Disulfide-trapping of Cys^1-PTH to PTHR mutants with introduced cysteines in TM6 (left) and TM5 (right). Cells expressing the various mutant receptors were incubated with ^{125}I-labeled Cys^1-PTH and subsequently analyzed by SDS-PAGE in the absence (upper panel) or presence (lower panel) of reducing agent (β-mercaptoethanol). The white arrow indicates Cys^1-PTH cross-linked to receptors and the black arrow indicates the uncross-linked peptide.

upon ligand binding they form a disulfide bond. Because the geometry governing disulfide bond formation is more constrained than Bpa cross-linking, this novel approach can be employed to generate a more refined molecular model of the PTH − PTHR1 complex. Using a PTH analog containing a cysteine at position 1, Monaghan *et al.* (2008) probed a total of 24 positions in the top regions (toward the extracellular surface) of TM5 and TM6 of PTHR1: 11 positions in TM5 and 13 in TM6. Selection was based on the model of the PTH − PTHR1 complex (Wittelsberger *et al.*, 2006a). Four sites to which cross-linking occurred were identified (Fig. 9). Importantly, previous PAS studies, using a PTH analog with Bpa at position 1, only identified a single site of interaction.

SDS-PAGE analysis consistently showed that the Y421C, F424C, and L368C mutant receptors cross-link the peptide more effectively than the M425C PTHR1, as judged by the intensity of the cross-linked bands following autoradiography (Fig. 9). This suggests that in the natural binding state, position 1 of the ligand comes closer to Y421, F424, and L388 (or spends more time in their vicinity) than it does to M425. Although M425 remains a contact point, the predominance of Bpa^1-PTH interacting with M425, assumed in a previous report (Bisello *et al.*, 1998), no doubt reflects the preference of the Bpa moiety for methionine residues. When applied as constraints to the model of the PTH − PTHR1 complex, the new sites of cross-linking identified by the disulfide-trapping procedure allowed for a more detailed map of the receptor contacts of the N-terminus of PTH (Fig. 10).

In the case of the PTH − PTHR complex, the disulfide-trapping approach is heavily reliant on the previous successful application of Bpa PAS. For the platform built on the earlier method, it would not be possible to guide the placement of the Cys pairs. In addition,

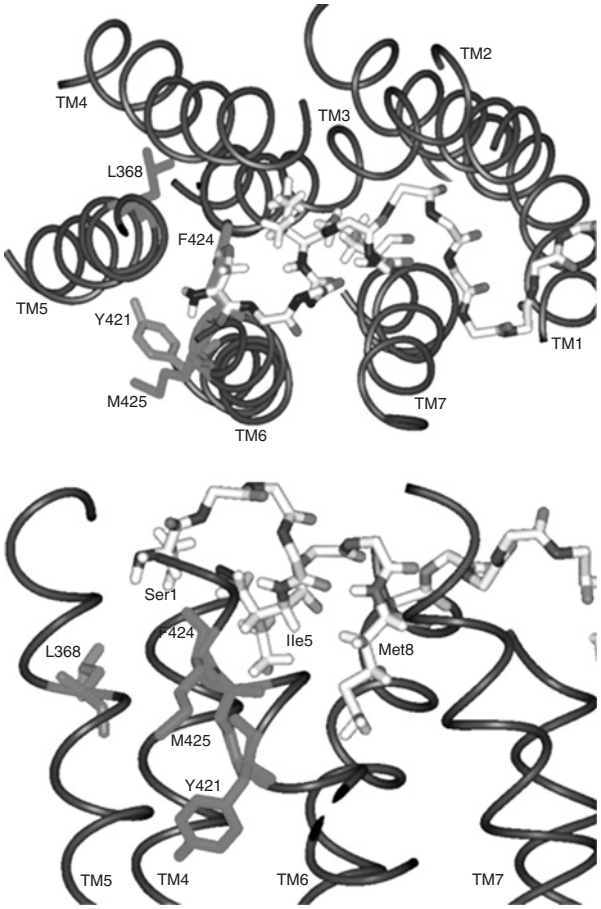

FIGURE 10 Model of the interaction of position 1 of PTH with PTHR obtained by Molecular Dynamic simulations. The four residues of PTHR that cross-linked to Cys^1-PTH are shown in green; the backbone of the ligand is shown in yellow (nitrogen = blue, oxygen = red). The side-chains of Ile^5 and Met^8 of the peptide are displayed for orientation. The top panel depicts a view from above the receptor; the lower panel depicts a side view.

prerequisite to application of the method is the availability of biologically active Cys-substituted hormone analogs and functional Cys-substituted receptor mutants.

One of the major advantages of the disulfide-trapping approach is that, unlike Bpa-mediated PAS, it allows for the simultaneous identification of numerous residues within the receptor that are in close proximity to a defined position in the ligand being investigated. Previous work with Bpa^1-PTH identified only a single residue, M425, of PTHR1 that was proximal to the N-terminus of the hormone (Bisello *et al.,* 1998): one ligand yields one contact. In contrast, the disulfide-trapping methodology amplifies the utility of each ligand probe: each probe can be used in a series of experiments to map the surface of interaction on the receptor. For example, in the investigation described earlier, 24 potential contact sites within TM5 and TM6 of PTHR1 were interrogated with a single PTH peptide, Cys^1-PTH. As a result of this scan, three additional points of interaction between position 1 of PTH and PTHR1 were defined. Based on the earlier-described demonstration, we are confident that disulfide-trapping can be applied successfully to other putative regions of PTH−PTHR interaction, and that a further refined model will emerge.

NMR Studies

Of course, there are clear advantages to obtaining data from direct structural studies of ligand−Rc interactions. The corticotropin-releasing factor (CRF) receptor (CRF-Rc) belongs to the same GPCR family B (class II) as PTHR1. An NMR study of the N-ECD of CRF-Rc identifies a short consensus repeat (SCR) motif as a characteristic structural determinant and suggests a hormone-binding site (Grace *et al.,* 2004). It also provides support for a two-step binding and activation sequence for the CRF-Rc. Recently, NMR analysis of the same protein in complex with the antagonist astressin reveals that the hydrophobic face of the amphipathic C-terminal segment of the ligand is in contact with the SCR motif, as well as the presence of characteristic intermolecular hydrogen bonds and a salt bridge (Grace *et al.,* 2007).

Mierke and coworkers analyzed the conformation of PTH while bound to the N-terminal extracellular domain (N-ECD) of PTHR1 (unpublished). A soluble form of the N-ECD of PTHR1 was previously expressed from insect cells using a baculovirus infection system (Monaghan, 2007). When PTH is added to the purified protein, transferred NOEs (trNOE) experiments demonstrate the formation of a C-terminal helix in the ligand during the interaction with protein. Saturation transfer difference (STD) experiments were carried out to determine the topological orientation of PTH-(1−34) while bound to the N-ECD. The data obtained identify the two aromatic residues, Trp-23 and Phe-34, to be buried deep in the N-ECD (unpublished).

Detection of Conformational Changes in the Receptor by Disulfide Cross-Linking

Photoaffinity cross-linking and other structural studies have provided valuable information about the nature of the ligand−receptor bimolecular complex. However, these approaches do not provide insights into the dynamics of receptor activation. The nature of the receptor "switch" from basal to activated state, triggered by binding of an agonist, is still not well understood for the vast majority of GPCRs, including PTHR1. The transmembrane helices (TMs) are likely to play a key role in conveying agonist-induced changes in conformation from the extracellular regions of the receptor to the cytoplasmic surface that interacts with G protein. TM3 and TM6 have been shown to play a role in PTHR1 activation (Vilardaga *et al.*, 2001a) and to be involved in conformational changes critical for

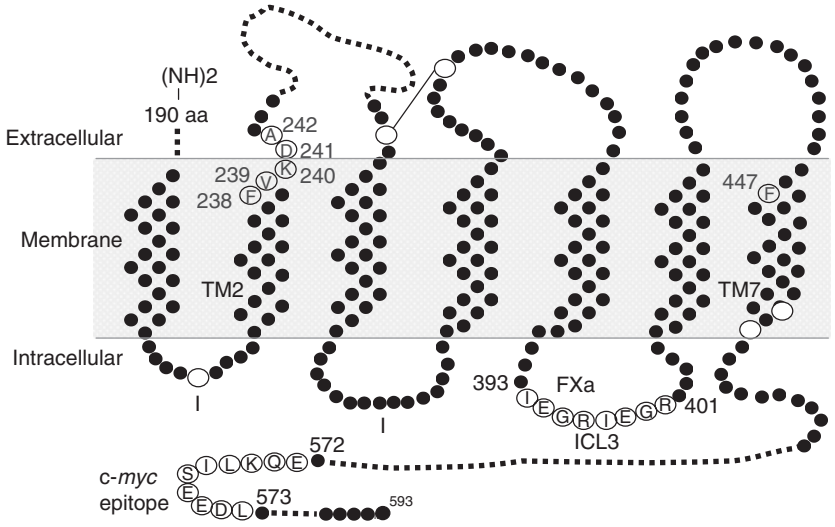

FIGURE 11 PTHR1 template and sites of mutation. Shown are amino acid residues A242, D241, K240, V239, F238 in TM2 and F447 in TM7 that were mutated to Cys (Thomas et al., 2008). Also shown is the location of two FXa cleavage sites in ICL3. For detection by Western blot, a c-myc tag was inserted between residues 572 and 573 of the C-ICD. The endogenous cysteines are shown as open circles (O).

G_s activation (Vilardaga *et al*., 2001b). The extracellular-facing region of TM2 of PTHR1 has been implicated in ligand binding (Gensure *et al*., 2003; Wittelsberger *et al*., 2006a), and TM7 has been suggested to interact with TM2 during the ligand binding and activation steps (Rölz *et al*., 1999; Gardella *et al*., 1996b).

The "*in situ* disulfide cross-linking strategy" (Ward *et al*., 2002; Zeng *et al*., 1999) is one approach to detect conformational changes in TM domains and was successfully applied to several GPCRs. A pair of cysteines is substituted into receptor regions (mostly TM regions) postulated to play a role in receptor activation (Han *et al*., 2005a, 2005b; Huang *et al*., 2005). Spontaneous formation of a disulfide bridge between TM helices indicates that the Cys's are positioned in proximity when the receptor is in its basal state. Agonist-dependent disulfide linkage indicates an agonist-induced conformational change that brings the two residues replaced by Cys's in close proximity. Likewise, formation of a disulfide bond in the ligand-free state that is reduced/abolished in the presence of agonist indicates a conformational change that brings the two respective positions further apart. In some instances, disulfide linkage generates a constitutively active Rc, indicating that a conformational change is promoted that "locks" the Rc in its active state. Of course, the system can be used to assay other ligands, such as antagonists or inverse agonists, and should allow for the detection of subtle differences in the conformational changes induced by different classes of ligands. For the muscarinic (M_3) acetylcholine Rc, a class I GPCR, agonist-dependent disulfide cross-linking has been demonstrated, indicating that Rc interaction with an agonist (but not an antagonist) changes the relative positions of two TM helices (TM3 and TM7), bringing them sufficiently close to form a linkage not possible in the "ground" state (Han *et al*., 2005b). Recently these investigations were extended to inverse agonists of the M_3 Rc; distinct conformational changes were detected compared to those associated with agonist docking (Li *et al*., 2007).

As a template for the design of several double Cys-containing mutants, Thomas *et al*. (2008) constructed PTHR1 with a c-myc epitope tag inserted at the C-terminal tail (between residues 572 and 573) and Factor Xa (FXa) cleavage-sites in ICL3. Ordinarily, cleavage by FXa generates two fragments of receptor. However, if an engineered disulfide bond forms, these fragments remain held together covalently despite FXa cleavage. In the first study, Cys was introduced along the extracellular facing region of TM2 (positions 238 − 242) and into one position toward the extracellular facing end of TM7 (position 447) (Fig. 12). Of five double-Cys mutants tested, A240C/F447C and A242C/F447C formed a disulfide bond after treatment with agonist, whereas in one case (mutant F238C/F447C), a disulfide linkage present in the ground state was disrupted by agonist. With mutant D241C/F447C, no disulfide bond formation was observed in both the presence and absence of agonist. The fifth mutant, (V239C/F447C), was inactive and therefore not tested.

The data nicely fit the model of the PTH−PTHR1 interaction (Wittelsberger *et al*., 2006a). The model predicts that the extracellular ends of TM2 and TM7 are in close proximity, with F447 projecting toward TM2 (Fig. 13). The

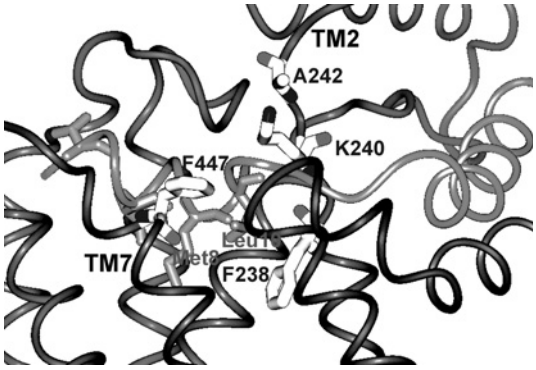

FIGURE 12 Expanded view of the PTH–PTHR1 complex illustrating the close proximity of the residues in TM2 (238, 240, 242) to TM7 (447) (yellow side-chains). Upon binding of PTH (light green), Met[8] and Leu[10] of the hormone interfere with the interaction between F447 and F238. In contrast, hormone binding does not disrupt, and may even enhance, the interaction between F447 and K240. D241 is not shown because it faces away from the reader in this figure.

distances between F447 and 238, 240, or 242 in the model are consistent with the experimental results that demonstrate that there is potential to form disulfide bonds. The model also suggests that the binding of PTH would interfere with the F447−F238 association; Met-[8] and Leu-[10] of PTH project down toward the receptor core, in between TM2 and TM7. K240 and A242 face the same direction (toward TM7), whereas D241 faces in the opposite direction. This explains why K240 and A242 are proximal enough to F447 to form disulfide bonds (<7 Å) when substituted with cysteine. The side-chain of position 241 is pointing away and therefore unable to form a disulfide bond with a cysteine at position 447 of TM7 (Thomas *et al.*, 2008).

The investigation reveals that hormone docking results in K240 and A242 moving toward F447, while F238 moves away from F447. According to the molecular model, K240, D241, and A242 are part of a loop just outside TM2 (Fig. 13), whereas F238 is still part of TM2. Association

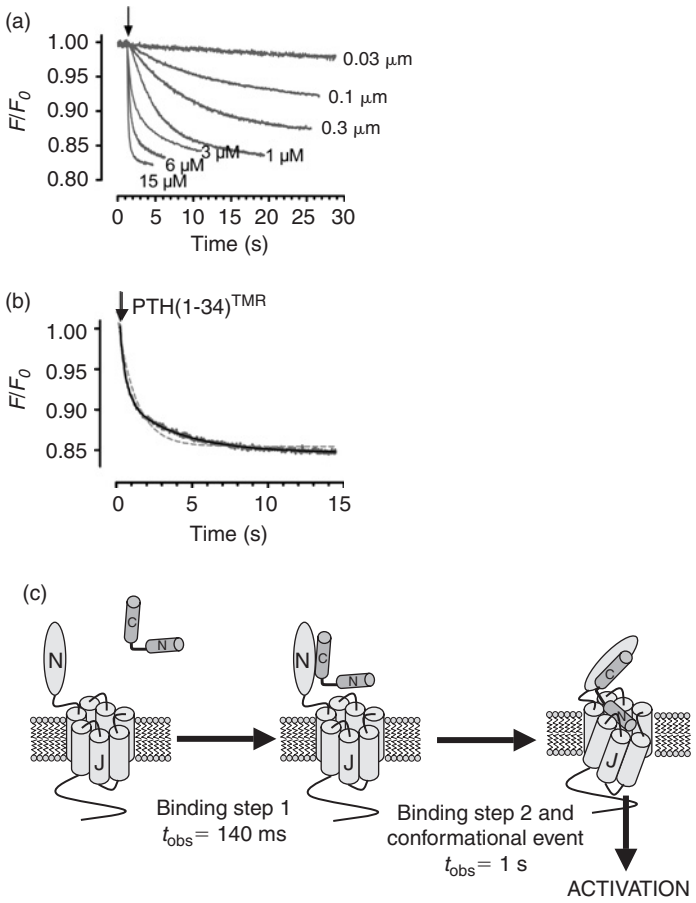

FIGURE 13 Association time courses of PTH(1–34)[TMR] with [GFP]N-PTHR. (A) Kinetics of PTH(1–34)TMR binding to [GFP]N-PTHR recorded by decreases in the fluorescence emission of the GFP moiety. Measurements were recorded in a single cell at 20 °C with various concentrations of PTH(1–34)[TMR]. (B) Comparing fits of one-component (dashed line) and two-component (solid line) model for the time course of binding of PTH(1–34)[TMR] (3 μM). The two-components model accurately describes the binding response. (C) Mechanistic model for PTHR activation. Upon PTH(1–34) binding there are two rates of association, a faster one that corresponds to agonist binding to the receptor N-domain and is strictly concentration-dependent, followed by a slower binding step to the receptor J-domain that is coupled to receptor activation (Castro, 2005).

between the cytoplasmic ends of TM2 and TM7 has been suggested to be responsible for the ligand-free activation of constitutively active receptors (Rolz *et al*., 1999). These data with the F238C/F447C mutant suggest that the opposite movement occurs at the other end of the helices, i.e., movement of TMs at the extracellular side of the receptor is away from each other.

The system will likely also enable the detection of differences in conformational changes induced by different classes of ligands (i.e., agonist vs. antagonists).

Fluorescence Resonance Energy Transfer (FRET) Studies

Vilardaga and coworkers devised a complementary approach utilizing Fluorescence Resonance Energy Transfer (FRET) to study the hormone–receptor interaction (Castro *et al*., 2005). By recording FRET between tetramethyl-rhodamine in PTH-(1−34) and GFP in the N-ECD of PTHR1, the binding event was measured in real time in living cells. The association time course between PTH-(1−34) and PTHR was fitted to a two-step binding process where the agonist initially binds the receptor with a fast time constant ($\tau \approx 140$ ms) and then with slower kinetics ($\tau \approx 1$ s). The fast and slow phases were assigned to hormone association to the receptor N-ECD and the J domain (comprising the 7 TM helices and the connecting extracellular loops), respectively. In addition, a PTHR sensor, PTHR-CFP_{IC3}/YFP_{CT}, was constructed by introducing enhanced cyan fluorescent protein into ICL3 and enhanced yellow fluorescent protein into the C-terminal tail of PTHR1 (Vilardaga *et al*., 2003). The sensor produces a FRET signal in the basal state that is reduced when agonist binds, presumably owing to conformational changes taking place during receptor activation. Data from both FRET systems indicate that the slow PTH-(1−34) binding step to the J-domain coincides with a conformational switch in the receptor (Castro *et al*., 2005).

Recently, these studies have been extended to PTHrP (Dean *et al*., 2008). Despite displaying a binding affinity comparable to PTH-(1−34), PTHrP-(1−36) was found to bind to PTHR1 more slowly and to dissociate more rapidly than PTH. Addition of hPTH-(1−34) to HEK293 cells expressing PTHR-CFP_{IC3}/YFP_{CT} induced a rapid ($t_{1/2} = 0.7$ sec) reduction (~13%) in the FRET signal that remained suppressed for quite awhile. In contrast, PTHrP-(1–36) induced a relatively slow FRET response ($t_{1/2} = 2$–5 sec), and the signal decayed immediately upon buffer exchange. Combined with data from a detailed pharmacological analysis, the authors suggest that the differences in the kinetics of PTH and PTHrP binding and dissociation derive from differences in the ability of the two hormones to bind to R°, a G protein-uncoupled state. These differences in the interaction with PTHR1 may explain important differences in the biological profile of the hormones, e.g., duration of action, differences in stimulation of bone resorption, and endocrine versus paracrine roles.

Experimentally Based Molecular Modeling

Over the years, an experimentally based model of the PTH–PTHR1 complex has steadily evolved as new bimolecular contact sites were identified and additional conformational data on receptor domains and hormone were generated (Bisello *et al*., 1998; Piserchio *et al*., 2000a; Rolz *et al*., 1999; Wittelsberger *et al*., 2006a) and unpublished work. Initially, the model was constructed combining hydrophobicity profile analysis with a search of the Brookhaven Protein Data Bank (PDB) employing the Basic Logic Alignment Search Tool (BLAST) to first identify and then refine the location of the TM helices (Altschul *et al*., 1990; Kyte and Doolittle, 1982). Identification of the TM domains of the PTHR1 is in good agreement with respect to those identified in peptides containing TM helical regions as determined by high-resolution NMR in micellar system (Mierke *et al*., 1996; Pellegrini *et al*., 1997b, 1998b). Arrangements of the TM heptahelical bundle in rhodopsin and bacteriorhodopsin (Grigorieff *et al*., 1996; Henderson *et al*., 1990; Pebay-Peyroula *et al*., 1997; Schertler *et al*., 1993; Schertler and Hargrave, 1995) were used as templates for the initial arrangement of the putative TM helical domains of the PTHR1 and optimized to account for hydrophobic moment toward the membrane environment, helix-helix, helix-core, and helix-membrane interactions (Pellegrini *et al*., 1997b).

Unlike the high structural similarity in the arrangement of the heptahelical TM domains bundle (Baldwin, 1993), the cytoplasmic and ectopic domains of GPCRs are extensively variable, and no *a priori* structural model is available. For family B GPCRs including PTHR1, a SCR motif might be the dominant structural element of the N-ECD (Grace *et al*., 2004, 2007). The extracellular and intracellular loops are constrained to some extent by the TM helical domains to which they are attached. Additional constraints are imposed by the three disulfide bridges at the extracellular N-terminus (Grauschopf *et al*., 2000) and the disulfide bridge connecting the first and second ECL. All of these cysteines are highly conserved in the family B (class II) GPCRs of which PTHR1 is a member.

A homology search with BLAST (Altschul *et al*., 1990) has identified the conformational preferences of the C-terminal portion of the N-ECD proximal to TM1 of PTHR1 and PTHR2 and ECL3 of PTHR1 (Bisello *et al*., 1998; Rolz *et al*., 1999). These homology searches suggest that the ECL3 adopts a helical conformation at T^{435}-Y^{443} (Rolz *et al*., 1999) and that the juxtamembrane portion of N-ECD in PTHR1 and PTHR2 contains amphipathic helices K^{172}-M^{189} and L^{129}-E^{139}, respectively (Bisello *et al*., 1998; Rolz *et al*., 1999). Unfortunately, such homology searches may

not always result in the assignment of a distinct secondary structure to a specific receptor sequence.

Mierke and Pellegrini (1999) modeled the receptor and receptor−ligand complex in a H_2O/decane/H_2O (40 Å each) simulation cell that mimics the membrane milieu. The molecular simulation is carried out in multiple steps in which the heptahelical bundle and/or the cytoplasmic and extracellular domains are allowed to move freely. PTH, in its membrane-associated conformation, is then added to the receptor model, applying the ligand−receptor distance constraints derived from the cross-linking experiments, and additional simulations are carried out. At this stage, additional constraints obtained via site-directed mutagenesis and chimera receptor studies can be incorporated to enhance the modeling procedure.

One way to identify conformational features of the cytoplasmic and ectopic domains of the GPCR is by synthesizing these receptor fragments and examining them by NMR in a membrane mimetic system. Adding small portions of the corresponding TM(s) to the otherwise flexible receptor-derived termini or loops provides an anchor(s) that partially reproduces the native orientation of the receptor domain relative to the membrane-mimicking milieu.

The conformational features of the following PTHR1 domains have been characterized: the third intracellular loop (ICL3), the C-terminal juxtamembrane portion of the N-ECD, and the ECL3 (Bisello *et al.*, 1998; Mierke *et al.*, 1996; Pellegrini *et al.*, 1997; Piserchio *et al.*, 2000a). These peptides were studied in a micellar system that mimics the cellular membrane and generates a micelle-water interface resembling the membrane-water interface. ICL3 was constructed as a 29 amino acid peptide with Cys residues in positions 1 and 28 (Pellegrini *et al.*, 1997b). Side-chains of the two cysteines were bridged by an octamethylene linker to maintain the putative ~12-Å distance between two consecutive TM domains (Schertler *et al.*, 1993; Schertler and Hargrave, 1995). Analysis of this constrained peptide revealed interesting conformational features that allow insight into ICL3 − G protein interactions (Pellegrini *et al.*, 1997b).

More relevant to the ligand−receptor bimolecular interactions are analyses of the two ectopic domains that photocross-link to Lys^{13} and Lys^{27} in PTH-(1−34) (Adams *et al.*, 1998; Bisello *et al.*, 1998; Greenberg *et al.*, 2000). The sequence PTHR1[172–189], which contains the contact sites for positions 13, 15, and possibly 11 and 21 of PTH (Adams *et al.*, 1998; Zhou *et al.*, 1997; Wittelsberger *et al.*, 2006a), was subjected to a combination of homology search and molecular dynamics calculations using a two-phase simulation cell consisting of H_2O and CCl_4 to mimic a membrane-water interface (Bisello *et al.*, 1998; Pellegrini *et al.*, 1998a). These analyses suggest that the segment R^{179}-E-R-E-V-F-D-R-L-G-M^{189} forms an amphipathic α-helix whose axis is parallel to the membrane surface and points away from the heptahelical bundle (Fig. 14, see also color plate) (Bisello *et al.*, 1998; Pellegrini *et al.*, 1998a). ^{1}H-NMR analysis of the synthetic peptide hPTHR1[168–198] in the presence of micelles was carried out in combination with distance geometry and a molecular dynamics simulation (Pellegrini *et al.*, 1998a). The analysis identifies three helical segments: 169–176, 180–188, and 190–196. The C-terminal helix, hPTHR1[190–196], corresponding to the ectopic portion of the first TM helix, is hydrophobic and embeds perpendicularly into the micelle. The other two α helices, [180–188] and [169–176], lie on the

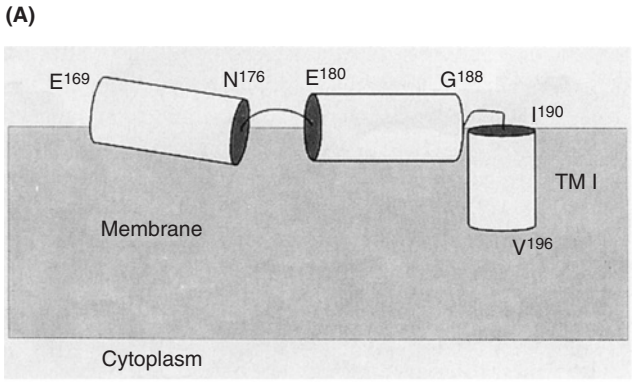

FIGURE 14 Structural features and topological orientation of PTHR1[168–198], which consists of the juxtamembrane portion of N-ECD and the ectopic portion of TM1 (Pellegrini *et al.*, 1998a). **(A)** Schematic presentation of the experimentally determined conformation, which consists of three α-helices, two of which have been determined to lie on the surface of the membrane; the third, at the top of TM1, is membrane-embedded. **(B)** Molecular simulation of this peptide in a water/decane simulation cell used to refine the structure obtained in the presence of dodecylphosphocholine (DPC) micelles used in the NMR study. Decane molecules are shown in green as CPK space-filling spheres. The peptide molecule is colored according to hydrophobicity (blue, polar, red, hydrophobic). (See also color plate.)

membrane surface (Fig. 14). Polar residues in the linker, E^{177} and R^{179}, and in the middle helix, R^{181}, E^{182}, D^{185}, and R^{186}, are exposed to the solvent, whereas the hydrophobic residues, $F^{173,}$ F^{184}, and L^{187}, project toward the hydrophobic membrane (Pellegrini *et al.,* 1998a). It is plausible that the positively charged Lys^{13} in PTH participates in stabilizing the Coulombic interaction with the negatively charged E^{182} and D^{185} located at the solvent-exposed hydrophilic phase of the receptor sequence. Nevertheless, this may not be an essential interaction, as analogs in which the ε-amino on Lys^{13} is blocked by acylation maintain high affinity and efficacy.

Combining the putative TM bundle obtained in the modeling studies with the experimentally derived conformation of the synthetic hPTHR1[168–198] establishes a partial PTHR1 model that can be used to dock hPTH-(1−34) in its experimentally derived putative bioactive conformation (Pellegrini *et al.,* 1998b). This "*in silico*" experiment resulted in the first generation of an experimentally based model of the PTH − hPTHR1 complex (Bisello *et al.,* 1998). Using contact sites identified by PAS studies for positions 1, 13, and 27 as a docking cue placed the C-terminal amphiphilic helix of the ligand parallel to the membrane-aligned portion of the receptor-derived peptide. This positioning allows the formation of complementary Coulombic interactions between the polar residues in the C-terminal helix, comprising the principal binding domain of the ligand and the polar residues E^{177}, R^{179}, R^{181}, E^{182}, D^{185}, and R^{186} in the receptor-derived peptide. Interestingly, this docking procedure brings only M^{425}, and not M^{414}, into sufficient proximity to permit cross-linking to position 1 in PTH. Therefore, these observations are in complete agreement with the results obtained through cross-linking studies (Bisello *et al.,* 1998).

Based on the contact site between position 27 in PTH and L^{261} in the ECL1 of PTHR1 (Greenberg *et al.,* 2000), the synthetic peptide hPTHR1[241–285], composed of ECL1 and a few residues from the ectopic portions of TM2 and TM3 at the N- and C-termini of the loop, respectively, was subjected to detailed conformational analysis. The studies included high-resolution NMR in the presence of dodecylphosphocholine micelles followed by distance geometry calculations and molecular dynamic simulations. The receptor fragment was found to contain three α-helical segments: [241–244], [256–264], and [275–284] (Fig. 15, see also color plate) (Piserchio *et al.,* 2000a). The first and last helices correspond to the ectopic portions of TM2 and TM3, respectively. Hydrophobic amino acids corresponding to the ectopic portion of the TMs are more strongly associated with the lipid micelle and may serve as membranal anchors. Moreover, all of the hydrophobic residues in the partially ordered central helical portion (terminated by the unique helix-breaking sequence P^{258}-P-P-P^{261}) project toward the lipid surface (Piserchio *et al.,* 2000a).

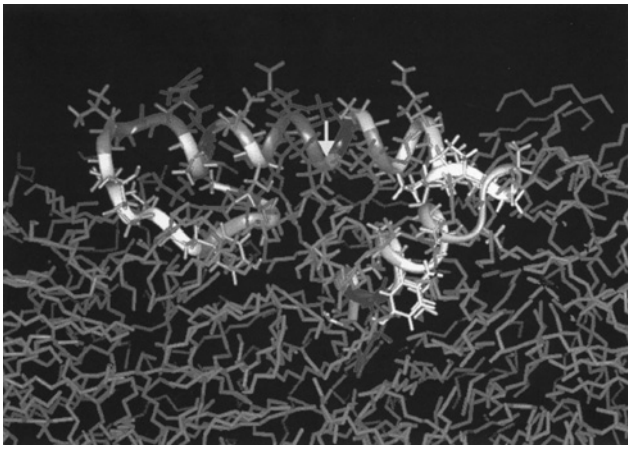

FIGURE 15 Structure of PTHR1-(241–285) (comprising the ECL1) from the molecular dynamics simulation in a water/decane simulation cell. Peptide residues are colored according to side-chain hydrophobicity (blue, polar; red, hydrophobic). Decane molecules are depicted in green; water molecules are not displayed for clarity. Residues belonging to TM2 and TM3 are embedded into the decane phase. The yellow arrow indicates the location of L^{261}, the cross-linking site to Lys^{27} in PTH-(1–34) (Piserchio et al., 2000a).

The emerging structure of ECL1 suggests an antiparallel organization of the two amphiphilic helices: the C-terminal helix in PTH, which includes Lys^{27}, and the [256–264] helical portion in ECL1, containing the contact site L^{261} (Pellegrini *et al.,* 1998b). The two helices are oriented with their hydrophobic faces interfacing the membrane and their polar faces exposed to the solvent and are capable of forming numerous intermolecular interactions. These additional findings were integrated into the PTH–PTHR1 model and placed the C-terminal helix of PTH in between the ECL1 helix and the C-terminal juxtamembrane helix of the N-ECD of hPTHR1 (Piserchio *et al.,* 2000a).

Finally, incorporation of the contact sites identified for midregion residues 11, 15, 18, and 21 (Wittelsberger *et al.,* 2006a) as distance restraints in MD simulations of the hormone–receptor interaction resulted in a significant refinement of the model of the PTH–PTHR1 complex compared to previous generations, as depicted in (Fig. 5). Most significantly, the hormone must adopt a loop structure in the midregion in order to bring both Leu^{11} and Val^{21} in close proximity to PTHR1[165−176]. The N-terminal α-helix of PTH (residues 2–10) is maintained during the simulation, as are the contacts between the N-terminus of the ligand (particularly Leu^{5} and Met^{8} of PTH) with the PTHR1 (Rolz, 1999). The contact point between Ser^{1} in PTH and Met425 of the receptor is also maintained. Another change involves the α-helical region [169−176] in the N-ECD of the PTHR1. During the MD simulations, this α-helix is found to fold underneath the C-terminal helix of the ligand. The driving force for this arrangement

FIGURE 16 Model of the PTH ligand–receptor complex obtained from MD simulations using experimentally determined contact points with tighter distance constraints of 8 Å (Wittelsberger et al., 2008). The ligand is shown in orange. The receptor region [165–176] containing the cross-linking site of Bpa^{11}-PTH is colored light green. The N-terminal helix of the hormone is distorted.

is a contact between this region of the receptor and residue 11 of PTH. These findings suggest a broad role for the N-ECD in determining ligand binding, involving interactions with not only the C-terminus of PTH, but also with the midregion of the ligand. During the MD simulations, an almost 90-degree bend of the two α-helices of PTH is observed (Fig. 5). This arrangement is the result of simultaneous contacts between the hormone midregion with the proximal N-ECD of the PTHR1, and position 27 of PTH with Leu-261 in the center of ECL-1 (Greenberg *et al.*, 2000).

A distance restraint of 14 Å is typically applied to the experimentally identified contact points during the simulation. Distance restraints are applied to the Cβ atom at the site of Bpa incorporation and to the side-chain of the appropriate residue across the interface in the receptor. This large distance seemed appropriate to allow some flexibility of Bpa fitting into the receptor during the cross-linking experiment, because native ligand is used in the refinement protocol, not the Bpa-containing analogs. To validate the choice of the distance restraint, we recently conducted a study comparing the outcome from MD simulations using 14 Å versus a tighter restraint of 8 Å for the 7 experimentally determined contact points between PTH and PTHR1. Using 14 Å, the structure obtained corresponds to the model depicted in Fig. 5, whereas the outcome of the 8 Å simulation can be summarized in Fig. 16. When the tight distance constraints are accommodated, the structural features of the ligand are distorted. The N-terminal α-helix, running from Val^2 to Gly^{10}, is reduced to a centrally located loop of helix, attempting to simultaneously fulfill the cross-linking points of Ser^1 to M425 (top of TM7) and Leu^{11} to L174 (proximal N-terminus, located in a second α-helix). In contrast, when using 14 Å constraints during the simulations (Fig. 5), the helical nature of the N-terminus of PTH is maintained throughout the entire Val^2 to Gly^{10} region.

As they emerged, the experimentally derived models of the complex between PTH/PTHrP ligands with both PTHR1 and PTHR2 were studied in detail (Adams *et al.*, 1998; Bisello *et al.*, 1998; Zhou *et al.*, 1997) to identify interresidue contacts within the heptahelical TMs (Rolz *et al.*, 1999). Some insights can explain ligand specificity (Behar *et al.*, 1996a; Gardella *et al.*, 1996a), the consequences of some site-directed mutations (Bergwitz *et al.*, 1997; Clark *et al.*, 1998; Gardella *et al.*, 1996b; Lee *et al.*, 1995a; Turner *et al.*, 1998), the constitutive activity of JCM-mutated receptors (Schipani *et al.*, 1995, 1997), the consequences of cross-linking studies (Bisello *et al.*, 1998), some structure–activity relations in the ligand (Cohen *et al.*, 1991; Rosenblatt *et al.*, 1976), first results on dynamics of TM movement during receptor activation (Thomas *et al.*, 2008), and some aspects of signal transduction. For example, there is a loss of affinity for PTH-(1−34) following mutations W437A/L/E or Q440A/L in PTHR1, an effect much reduced for PTH-(3−34) (Lee *et al.*, 1995a). The model positions both Q^{440} and W^{437} on the same face of ECL3, both projecting toward the center of the TM bundle (Rolz *et al.*, 1999). The side-chains of these residues participate in forming the hydrophobic pocket that accommodates Val^2 in the ligand, providing stabilizing interactions by shielding it from the extracellular aqueous environment. Mutating Q^{440} and/or W^{437} to any smaller or a more polar residue will compromise the binding pocket for Val^2 by exposing it to water. The model also attempts to explain position 5 in PTH and PTHrP as a receptor-subtype specificity switch (Behar *et al.*, 1996a; Gardella *et al.*, 1996a). It suggests that in PTHR1, the Ile^5 side-chain is accommodated by a hydrophobic pocket. The bottom of this pocket is composed of hydrophobic residues at the ectopic end of TM3 (A^{284} and V^{285}) and TM7 (F^{447}), and it is large enough to accommodate either Ile^5 or His^5 (Fig. 17). In PTHR2, owing to the presence of F386 and F401 located at the ectopic ends of TMs 6 and 7, respectively, the binding pocket for residue 5 is reduced in size compared to the same pocket in PTHR1. It therefore cannot accommodate His^5-containing PTHrP or hybrid ligands and discriminates against them (Fig. 17) (Rolz *et al.*, 1999). These authors also encourage the use of their model as a tool for predicting the pharmacological consequences of specific mutations such as receptor-subtype specificity-reversing mutations.

The quality of any model, namely its capacity to realistically represent ligand–receptor interactions and predict the nature of the interface, is based primarily on data and procedures used in its construction. It is important to avoid overinterpretation of any model and remember the assumptions and approximations used in its construction. Likewise, extrapolations derived from any model must be tested in order to validate the model's predictive potential.

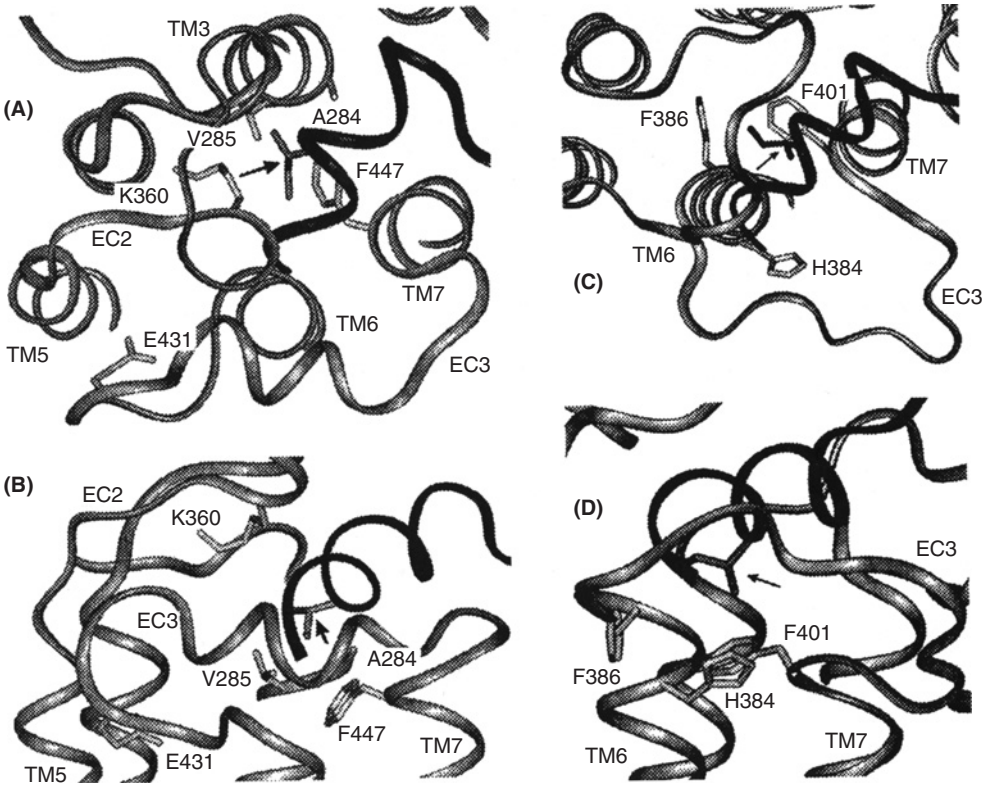

FIGURE 17 Illustration of the binding pocket for Ile^5 of PTH in PTH1- and PTHR2 (Rolz *et al.*, 1999). In PTHR1 Ile^5, the side-chain (indicated by black arrow) is accommodated in a hydrophobic pocket made up of the ectopic portions of TM3 (A284 and V285) and TM7 (F447). Top **(A)** and side **(B)** views of this pocket in PTHR1. The receptor and the ligand are depicted as ribbons in grey and black, respectively. In PTHR2, the binding pocket for residue 5 in the ligand is more limited in size compared to the same pocket in PTHR1 owing to the presence of F386 and F401 in the ectopic portions of TM6 and TM7, respectively. Top **(C)** and side **(D)** views of this pocket in PTHR2. In addition, in PTHR1 the presence of E432 in the ectopic portion of TM6, at the entrance to the binding pocket of His^5, can attract His^5 by favorable Coulombic interaction. However, in PTHR2 the presence of H384, at the bottom of the binding pocket for residue 5, will destabilize the interaction with an incoming side-chain of His^5-containing ligand.

In summary, the model of the PTH–PTHR1 complex should be regarded as a steadily evolving "working" platform that might help explain new experimental findings and that will be modified and/or refined as new experimental results are incorporated.

Ligand-Tethered hPTHR1

Shimizu *et al.* (2000a) reported what seems to be the absolute integration of ligand and receptor entities. Borrowing from the protease-activated thrombine receptor system (Kawabata and Kuroda, 2000), they generated constitutively active, ligand-tethered hPTHR1s. The receptors were constructed by truncating the N-ECD from E^{182} to the N terminus (yielding ΔN-ECD-PTHR1), adding a Gly_4 spacer (Gly_4-ΔN-ECD-PTHR1), and linking it to N-terminal fragments of PTH (varying in size from 9 to 11 residues). Transient expression of the ligand-tethered receptor PTH-(1− 9)-G_4-ΔN-ECD-hPTHR1 in COS-7 cells resulted in tenfold higher basal cAMP levels compared to the wild-type hPTHR1 control. Tethering the extended and more potent [Arg^{11}]PTH-(1−11) resulted in 50-fold higher basal cAMP levels than those seen with the wild-type hPTHR1. Interestingly, like in PTH-(1−14) (Luck *et al.*, 1999), where Val^2, Ile^5, and Met^8 are the most critical residues for activation, these residues were also the most critical ones for the constitutive activity of the [Arg^{11}]PTH-(1−11)-G_4-ΔN-ECD-hPTHR1 (Shimizu *et al.*, 2000a).

The elegance of this study lies in devising a unique way to specifically "immobilize" the principal activation domain of the ligand in the proximity of the contact sites critical for receptor activation. The high effective molarity of the tethered ligand minimizes the role of binding affinity in bimolecular interactions compared to free ligand, thus allowing the identification of residues within the tethered ligand essential for induction of activity. However, the accessibility to the ligand tethered receptor system requires the employment of molecular biology and therefore it is most applicable to tethered ligands composed of coded amino acids. In addition, stringent requirements for the efficient expression of tethered ligand−receptors in a relevant cellular background may turn out to be major obstacles in practicing and extending this approach in the

future. It remains to be demonstrated whether the tethered ligand−receptor system is a source for identifying structural constraints that can contribute to the refinement of the experimentally based ligand−receptor model and to rational drug design. The elimination of most of the entropic component from the ligand−receptor interaction may generate contact interactions and produce activation mechanisms that differ from those involved in the interaction with a diffusible ligand.

The autoactivation mechanism of ligand-tethered PTHR1 was validated by molecular modeling (Monticelli *et al.*, 2002). The model found the N-terminal α-helix of tethered PTH-(1−11) to interact with ECL3, specifically with the side-chains of the hydrophobic residues Leu^5 and Met^8 buried deep into well-defined pockets in the central core of the TM helical bundle, consistent with the requirement for these amino acids to be involved in receptor activation. The authors postulate that the improved signaling properties of [Arg^{11}]PTH-(1−11) over wild-type PTH-(1−11) is owing to a stable hydrogen bond between Arg^{11} and E444, at the beginning of TM7.

MULTIPLE CONFORMATIONAL RECEPTOR STATES: AN EMERGING PARADIGM

Like several other class II GPCRs (Beyermann *et al.*, 2000; Holtmann *et al.*, 1995; Juarranz *et al.*, 1999; Stroop *et al.*, 1995), PTHR1 can be devided into two functional domains. One consists of the large N-ECD (N domain) that has been proposed to provide most of the principal binding interactions with the ligand (Bergwitz *et al.*, 1996; Juppner *et al.*, 1994). The rest of the receptor, which includes the ECLs, TMs, and the ICLs designated as the juxtamembrane domain (J domain), is involved in ligand interactions that lead to activation and signal transduction (Bergwitz *et al.*, 1996; Gardella *et al.*, 1994; Juppner *et al.*, 1994; Turner *et al.*, 1996). A similar two functional domain architecture is found in the ligands, PTH and PTHrP; the 15–34 sequence includes the principal binding domain (Caulfield *et al.*, 1990; Rosenblatt *et al.*, 1980), and the 1–14 sequence includes the activation domain for intracellular signaling (Bergwitz *et al.*, 1996; Gardella *et al.*, 1991; Luck *et al.*, 1999; Shimizu *et al.*, 2000a, 2000b; Takasu *et al.*, 1999a).

It is now generally accepted that the interaction between hormone and PTHR1 proceeds in at least two sequential steps (Bisello *et al.*, 1998; Juppner *et al.*, 1994; Luck *et al.*, 1999; Mannstadt *et al.*, 1999; Castro *et al.*, 2005): A first step is an interaction between the C-terminal segment of PTH-(1−34) and the N-ECD (and possibly extracellular loops) that contributes mainly to binding affinity. The second step is the activating interaction between the N-terminal segment of the hormone with sites within the heptahelical bundle. Recently, a third functional interaction was suggested

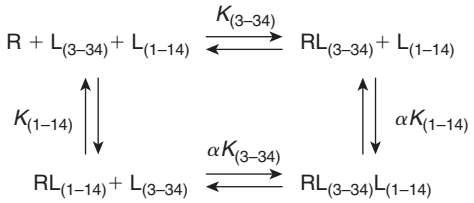

FIGURE 18 Model for simultaneous binding of ^{125}I-PTH-(3–34) and PTH-(1–14) to PTHR1, where R is the receptor; L(3–34) is ^{125}I-PTH-(3–34); K(3–34) is the equilibrium association constant for ^{125}I-PTH-(3–34); K(1–14) is the equilibrium association constant for PTH-(1–14); and α is the cooperativity factor defining the effect of L(1–14) occupancy on the receptor-binding affinity of L(3–34) and reciprocally the effect of L(3–34) occupancy on the receptor-binding affinity of L(1–14) (Hoare *et al.*, 2001).

to represent a critical middle step in the PTH–PTHR1 interaction: residues from the midregion of PTH-(1−34) form extensive contacts with sites at the C-terminal end of the N-ECD that guide the N-terminus of PTH into the binding groove of the TM bundle (Wittelsberger *et al.*, 2006a).

In the course of studying the pharmacology of [$(MAP_{1-10})^{22-31}$] hPTHrP-(1−34)NH_2 (RS-66271), a PTHrP analog in which sequence 22−31 was replaced by a model amphipathic peptide, the discrepancy between its low binding affinity compared to that of PTH-(1−34), and its PTH-(1−34)-like *in vivo* and *in vitro* activities (Frolik *et al.*, 1999; Krstenansky *et al.*, 1994; Vickery *et al.*, 1996), was explained by differential binding affinity to G protein-coupled and uncoupled receptor states. According to Usdin and coworkers, RS-66271 binds with high affinity (IC_{50} = 16 p*M*) to the G protein-coupled PTHR1, but with much lower affinity (IC_{50} > 100 n*M*) to the uncoupled receptor (Hoare and Usdin, 1999). Therefore, if the PTHR1 population in the intact cell is predominantly uncoupled from G protein, the binding affinity of RS-66271 will be markedly low (Hoare *et al.*, 1999b; Hoare and Usdin, 1999, 2000). hPTH-(1−34), on the other hand, was shown to bind with high affinity (IC_{50} < 10 n*M*) to the PTHR1, whether or not it is coupled to G protein (Hoare *et al.*, 1999b). Interestingly, His^5 in RS-66271, which has been implicated previously in specifying the signaling and binding of PTHrP to PTHR1 but not to PTHR2 (Behar *et al.*, 1996a; Gardella *et al.*, 1996a), is also implicated as a determinant in G protein-coupled versus -uncoupled PTHR1 selectivity (Hoare *et al.*, 2001). Replacement of His^5 in RS-66271 with Ile reduced selectivity toward the high-affinity G protein-coupled PTHR1 by 17-fold and increased the affinity to the uncoupled receptor by 160-fold. The ability of [Ile^5]RS-66271 to restore adenylyl cyclase activation in N-ECD-truncated PTHR1, in which RS-66271 failed to stimulate cAMP production, suggests that the residue in position 5 affects receptor selectivity through interactions with the ECLs and the ectopic portions of the TMs (Hoare *et al.*, 2001).

Hoare and coworkers (2001) reported that [Ala^{3,10,12},Arg^{11}]rPTH-(1−14)NH$_2$ [PTH-(1−14)] and PTH-(3−34) show allosteric binding behavior on PTHR1 (Fig. 18). The former binds predominantly through the J domain, partially inhibits ^{125}I-PTH-(3−34) binding, and the interaction is stabilized by G protein coupling. The latter interacts almost exclusively with the N domain, only partially inhibits PTH-(1−14)-stimulated adenylyl cyclase activity, and the interaction is GTPγS insensitive. The higher binding affinity of agonist ligands to RG versus the R state of the receptor implies different conformations of the receptor in both states. At the uncoupled state, PTH-(1−14) and the PTH-(3−34) bind almost independently of each other. The negative cooperativity between the binding of ^{125}I-PTH-(3−34) and PTH-(1−14) is significantly greater in the RG state than in the uncoupled one. Moreover, agonist binding to the RG state is pseudo-irreversible. PTH-(3−34) inhibits PTH-(1−14)-stimulated cAMP accumulation, increases EC_{50} by 18-fold, and reduces E_{max} in a noncompetitive manner.

The study suggests that the receptor is in an "open" conformation in the uncoupled state, permitting simultaneous binding of both PTH-(3−34), the N domain-interacting ligand, and PTH-(1−14), the J domain-interacting ligand. At the coupled state, for which agonist has higher affinity than for the uncoupled state, the receptor is in a more "closed" conformation, preventing simultaneous access of both ligands to their preferred binding sites and trapping the ligand within the coupled receptor. Consistent with these results, the modified N-terminal fragment ^{125}I-[Aib^{1,3},Nle^{8},Gln^{10},homoarginine^{11},Ala^{12},Trp^{14},Tyr^{15}]rPTH-(1–15)NH$_2$, ^{125}I-[Aib^{1,3},M]PTH-(1–15), a PTH analog interacting with the receptor predominantly through the J domain, was also found to selectively bind to a G protein-coupled, active-state PTHR1 conformation (Dean *et al.*, 2006b).

The finding that agonists bind with higher affinity to the RG complex than to the uncoupled receptor, whereas antagonists bind with similar affinities to the two states (Hoare *et al.*, 2001; Teitelbaum *et al.*, 1982), is in agreement with studies of type I GPCRs (Lefkowitz *et al.*, 1993). It suggests that agonists enhance G protein activation by stabilizing the RG state.

Bisello *et al.* (2002) showed that PTHrP analogs modified at position 1 induced selective stabilization of an active G protein-coupled receptor conformation that resulted in lack of β-arrestin recruitment to the cell membrane, sustained cAMP signaling, and absence of ligand–receptor complex internalization. Molecular modeling comparing the conformational states induced by agonist versus the position 1-modified analogs showed a significant difference in the location of ICL3.

Likewise, Bisello *et al.* (2004) showed that PTHR2 activity is regulated in an agonist-specific manner. When comparing PTH-(1−34) and TIP39-induced PTHR2 desensitization and internalization, they find that TIP39 induces β-arrestin and protein kinase C mobilization and receptor internalization, whereas PTH-(1−34) does not. Furthermore, PTH-(1−34) stimulation of cAMP activity was brief and resensitization occurred rapidly, whereas cAMP stimulation by TIP39 was sustained and partly desensitized for a prolonged period. Specific PTHR2 − ligand interactions therefore mediate distinct post-activation processes.

Dean *et al.* (2008) recently reported differences in the binding/activation mechanism between PTH and PTHrP. They find that despite displaying a binding affinity comparable to PTH-(1−34), PTHrP-(1−36) was found to bind to PTHR1 more slowly and to dissociate more rapidly than PTH. PTH-(1−34) produces greater cumulative cAMP signaling than PTHrP. The cAMP signaling response capacity of PTHrP-(1−36) in cells decayed more rapidly than did that of PTH-(1−34) ($t_{1/2}$ = ∼1 vs. ∼2 h). These differences were suggested to derive from differences in the ability of the two hormones to bind to R°, a G protein-uncoupled state (defined as a receptor conformation that can bind ligand with high affinity in the presence of GTPγS). The R° conformation is a putative preactive state for RG, the conformation primed to couple with a G protein. Such conformational flexibility may explain important differences in the biological profile of the hormones, e.g., duration of action, differences in stimulation of bone resorption, and endocrine versus paracrine roles (Dean *et al.*, 2008).

Furthermore, it was recently shown that PTHR1, like some other GPCRs (Azzi *et al.*, 2003; Charest *et al.*, 2007; Seta *et al.*, 2002; Shenoy *et al.*, 2006; Wei *et al.*, 2003), can be activated in a G protein-independent manner (which gives rise to the suggestion to change their name to 7TM receptors). Gesty-Palmer *et al.* (2006) show that PTH can stimulate the mitogen-activated protein kinase ERK1/2 through distinct signal transduction pathways: an early G protein-dependent pathway involving PKA and PKC, as well as a late G protein-independent pathway mediated through β-arrestins. These findings imply the existence of distinct active conformations of the hPTHR1 responsible for the two pathways, which can be stimulated by unique ligands. The signaling selective analogs [Bpa^{1},Ile^{5},Arg^{11,13},Tyr^{36}]PTHrP-(1−36), PTHrP-(2−36), and [Trp^{1}]PTHrP-(1−36) (Bisello *et al.*, 2002; Gesty-Palmer *et al.*, 2006) stabilize a receptor conformation that selectively activates Gs/PKA, but is unable to recruit β-arrestin. The receptor conformation induced by [D-Trp^{12},Tyr^{34}]PTH-(7−34)NH$_2$ is unable to activate G proteins, but is able to recruit β-arrestin (Gesty-Palmer *et al.*, 2006).

As proposed for most GPCRs in general (Kenakin, 2003; Kobilka *et al.*, 2007), the evolving paradigm contends that different stages during receptor activation stabilize different receptor conformations and that unique ligand-specific receptor conformations are differentially activating distinct signaling pathways.

SUMMARY AND OUTLOOK

With PTH-(1−34) as the first truly bone anabolic agent approved to treat osteoporosis, understanding the interactions between hormone and PTHR1 as well as mechanisms of receptor activation has become ever more important. Much information was gathered over the past decade from photoaffinity cross-linking experiments, structure-functional studies, and molecular modeling, and the currently available model of the PTH–PTHR1 complex provides significant detail on both ligand and receptor structure.

At the same time, the understanding that the receptor exists in multiple conformational states, depending on ligand, allosteric effector, or even signaling pathway, adds a new level of challenge (and opportunity) to investigations of the PTH system and GPCR research in general. The biggest impact in the future might come from techniques such as cysteine cross-linking and time-resolved single cell fluorescence approaches that can be used to examine the dynamics of triggering receptor activation. The detection of ligand-specific differences in the stabilization of specific conformations and therefore activation of distinct signaling pathways is crucial. The elucidation of the structural detail of conformational changes is still in the early stages.

The field of GPCR research is advancing quickly, with a second (in addition to rhodopsin) GPCR recently crystallized, with structural information on the N-ECD of class II GPCRs available, with new activation pathways discovered, and discoveries from other GPCR systems. PTH ligand–receptor interactions are therefore likely to remain a fertile research field in the next decades.

Chapter 30

Cellular Actions of Parathyroid Hormone

Stavroula Kousteni
Department of Medicine, College of Physicians and Surgeons, Columbia University, New York

John P. Bilezikian*
Departments of Medicine and Pharmacology, College of Physicians and Surgeons, Columbia University, New York

Parathyroid hormone (PTH) is essential for the maintenance of calcium homeostasis through direct actions on its principal target organs, bone and kidney, and through indirect actions on the gastrointestinal tract. PTH acts directly on the skeleton to promote calcium release from bone and on the kidney to enhance calcium reabsorption. The indirect effects of PTH on the gastrointestinal tract lead to greater calcium absorption through its actions to facilitate the conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D. Actions of PTH at these three sites (the kidney, the skeleton, and the gastrointestinal tract) result in restoration of the extracellular calcium concentration. When the hypocalcemic signal for parathyroid hormone release returns to normal, calcium ion continues to regulate the release of PTH. In the setting of a hypercalcemic signal, not because of abnormal secretion of PTH (i.e., primary hyperparathyroidism): parathyroid hormone secretion is inhibited. The resulting physiological events associated with reduced concentrations of PTHlead to reduced calcium mobilization from bone, a reduction in renal tubular reabsorption of calcium, and, by virtue of reducing the conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D, to reduced absorption of dietary calcium. Hence, in hypercalcemic states, control of parathyroid hormone secretion by calcium reduces serum calcium levels.

PTH helps to regulate phosphorus metabolism. An increase in phosphorus leads to a reduction in the circulating calcium concentration. The resultant increase in PTHleads to phosphaturia, a classical physiological effect of the hormone and restoration of the serum phosphorus concentration (Chapter 20).

Cellular responsiveness to PTH occurs via receptor-mediated activation of intracellular events and several major biochemical pathways. Details of the initial steps by which a change in extracellular calcium is sensed by the parathyroid cell and the mechanisms by which PTH binds to its receptor, as well as the induction of several different messenger systems, are covered in other chapters. This chapter focuses on the cellular effects of PTH on the skeleton.

CELLULAR ACTIONS OF PARATHYROID HORMONE ON BONE

The emergence of mouse genetics during the last 18 years, in combination with a plethora of *in vitro* studies, has generated a wealth of knowledge regarding the effects and mechanisms of actions of parathyroid hormone (PTH) on bone cells. This information has helped to enhance our understanding of the pharmacologic and physiologic actions of PTH.

BRIEF HISTORICAL TRAIL

Anabolic actions of parathyroid gland extract were first described in young rats, guinea pigs, kittens, and rabbits as early as the 1930s (Pugsley and Selye, 1933; Burrows, 1938; Jaffe, 1933; Parsons, 1972). At the time, the responses were thought to reproduce some of the pathologic processes associated with primary hyperparathyroidism in which an early destructive phase was followed by a reparative phase of bone formation, secondary to parathyroidectomy (Heath, 1996). When hPTH(1–34) was first synthesized in the early 1970s (Potts *et al.*, 1995), the early studies suggesting an anabolic potential for bone were revisited. Small clinical trials in the 1970s and early 1980s were impressive and suggested that PTH did have potential as a bone-forming agent (Cosman and Lindsay, 1998a; Dempster *et al.*, 1993). The common thinking at the time was that PTH was primarily a catabolic hormone as seen classically in the disorder of PTH excess, primary hyperparathyroidism. It was not surprising then that these early studies suggesting an

Principles of Bone Biology, 3rd Edition

opposite metabolic effect induced by the same hormone would be viewed with considerable skepticism. The apparent paradox that contained in one molecule both anabolic and catabolic actions was resolved over the ensuing several decades. The key to insight was appreciation of the fact that continuous versus intermittent and high dose versus low dose would dictate the predominant response to PTH. It is now recognized that continuous exposure to high levels of PTH is associated with catabolic effects whereas exposure to low doses of PTH intermittently is associated with anabolic effects. It has been extensively demonstrated that intermittent exposure of the skeleton to PTH is anabolic in mice and rats. This form of delivery gives a pulse of PTH that is cleared from the circulation within 2–3 hours (Frolik *et al.*, 2003; Bellido *et al.*, 2005; Lindsay *et al.*, 1993). This anabolic response of the skeleton to repeated cycles of systemic PTH elevation is associated with increased bone formation on the three surfaces of bone (cancellous, endocortical, and periosteal) and of both the appendicular (peripheral) and axial (central) skeleton. PTH as an anabolic agent for osteoporosis represents a new therapeutic class for osteoporosis. Clinical trials with the foreshortened aminoterminal form, namely PTH(1–34) have demonstrated efficacy to reduce vertebral and nonvertebral fractures in postmenopausal women. How PTH serves this anabolic role is now thought to be because of actions on all three bone cell types: the osteoblast, osteoclast, and osteocyte.

PTH Regulation of Osteoblasts and their Osteoprogenitors

Stimulation of bone formation at endocortical surfaces is a universal species-independent hallmark of the anabolic effect of PTH (Cosman and Lindsay, 1998b; Dempster *et al.*, 1993; Whitfield *et al.*, 1998; Oxlund *et al.*, 1993). Intermittent PTH rapidly increases mineralizing surface and mineral apposition rate in cancellous bone of animals and human subjects indicating stimulatory actions on osteoblast number or function. Because increases in mineral apposition rate are larger than changes in mineralizing surfaces and, at least in rodents, correlate with increased osteoblast numbers, it has been proposed that increased osteoblast numbers account for the bone-forming properties of the hormone (Jilka, 2007). The ability of PTH to affect cell numbers by regulating proliferation, differentiation, and survival of osteoblasts and osteoblast progenitors has been, and still is, a major view of PTH's actions on this cell type.

Effects of PTH on the Proliferation of Osteoblast Progenitors

The impact of PTH on the proliferation of osteoblast progenitors has been studied *in vivo* in rodents. In young rats, in which proliferating cells are abundantly available adjacent to the growth plates and in cortical endosteum of the metaphyses and the periosteal diaphyseal surfaces (Kimmel and Jee, 1980; Kember, 1960): PTH targets cells in the G_1/S phase of the cell cycle (Onyia *et al.*, 1995; Young, 1962; Young, 1964; Roberts, 1975). Similarly, short-term exposure to PTH suppresses proliferation of osteoblastic cells derived from the primary spongiosa of growing rats (Qin *et al.*, 2005; Onyia *et al.*, 1997b). The effects of PTH in young rats suggest possible roles in skeletal development, accretion of peak bone mass, and increased bone formation. In PTH-treated adult rats exposure to [^{3}H-] thymidine, which labels dividing cells, indicated that the percentage of labeled osteoblasts derived from labeled osteoblast progenitors is not affected. However, unlabeled, nonproliferative bone surface cells are activated (Dobnig and Turner, 1995). Daily administration of PTH to adult or aged mice does not affect the number of mesenchymal stem cells as measured by the number of colony-forming unit-osteoblasts (CFU-OB) present in femoral marrow isolates (Jilka *et al.*, 1999; Sakai *et al.*, 1999; Knopp *et al.*, 2005). SAMP6 mice, a strain with low CFU-OB number, gives an anabolic response to PTH that is equivalent to that of control mice (Jilka *et al.*, 1999). Collectively, these lines of evidence suggest that in cancellous bone, PTH does not affect the replication of uncommitted osteoblast progenitors but suppresses proliferation of committed osteoprogenitors.

In vitro studies further support the hypothesis that the actions of intermittent PTH on the osteoblast cell cycle are specific to the differentiation/developmental stage. Anti-proliferative effects have been reported in osteoblastic cell lines or cultures of primary cells. At the cellular level, several mechanisms of inhibition of proliferation by PTH occur. Topoisomerase IIα, a marker of proliferation (Feister *et al.*, 2000): decreased expression of the cell cycle marker H4, increased expression of the cell cycle inhibitors $p27^{Kip1}$ and $p21^{Cip1}$ (Onyia *et al.*, 1995; Qin *et al.*, 2005) and caused a lack of stimulation of thymidine incorporation (Young, 1962; Young, 1964; Onyia *et al.*, 1995; Onyia *et al.*, 1997a). Concomitant with the increase in cell cycle inhibitors, PTH also attenuates the expression of cyclin D1, which is required for cell cycle progression (Qin *et al.*, 2005; Datta *et al.*, 2005). In UMR-106 cells, PTH blocked entry of cells into S phase of the cell cycle, thereby increasing the number of cells in G_1; and cell proliferation was inhibited as a consequence of an increase in $p27^{Kip1}$ (Onishi and Hruska, 1997). The effect of PTH on osteoblast proliferation was also examined in pre-confluent cultures of calvaria cells derived from transgenic mice expressing green fluorescent protein (GFP) under the control of a collagen promoter. In these mice, the emergence of a GFP signal marks the transition of osteoprogenitors into preosteoblasts. Transient exposure of pre-confluent cultures to PTH reduced the proportion of S-phase cells but increased the proportion of cells in Go/G_1 and G_2 + M phases (Wang, Liu, and Rowe, 2007). Thus, although transient exposure to PTH has no effects on the replication of

uncommitted progenitors, it appears to enhance their commitment to an osteogenic fate. In agreement with this observation, histomorphometric studies have consistently shown early increases in bone-forming surfaces, consistent with the stimulation of differentiation of osteoprogenitors, rather than proliferation of osteoblasts (Cosman and Lindsay, 1998a; Dempster *et al.*, 1993; Onyia *et al.*, 1997b; Leaffer *et al.*, 1995; Hodsman and Steer, 1993; Meng *et al.*, 1996).

In contrast to the anti-mitotic effects of transient PTH exposure, proliferative effects of the hormone have also been reported. PTH promotes proliferation in bone marrow or calvaria-derived osteoblastic cultures (Swarthout *et al.*, 2001; Cole, 1999; Cornish *et al.*, 1999; Miao *et al.*, 2001; Ishizuya *et al.*, 1997; MacDonald, Gallagher, and Russell, 1986): in periosteal cells (Scutt *et al.*, 1994) and in an *in vivo* model of ectopic bone formation from bone-marrow-derived stromal cells (Datta *et al.*, 2007). In periosteal cells, cyclic exposure to PTH has a biphasic effect to enhance then suppress proliferation of osteoblast progenitors (Ogita *et al.*, 2007). With the exception of the *in vivo* model and the experiments on periosteal osteoblasts, all *in vitro* studies were performed under prolonged (6 to 24 hours) treatment with PTH; and as such they may represent the consequences of continuous rather than intermittent administration of the hormone. Low doses of PTH also promoted proliferation of osteoblasts in a PKC-dependent manner (Swarthout *et al.*, 2001). Alternatively, proliferation of differentiating osteoblasts may be differentially affected by PTH: proliferation is enhanced in early but suppressed in later stages of osteoblast differentiation. Finally, proliferative actions of PTH may be specific to bone compartments (as in the periosteum) or required in other settings as intermittent PTH promotes mesenchymal cell proliferation in the early stages of fracture repair in rodents (Nakazawa *et al.*, 2005).

Effects on PTH on Osteoblast Differentiation

It is generally accepted that differentiation and proliferation are inversely associated. Differentiation requires exit from the cell cycle and, as a result, proliferation is attenuated as differentiation proceeds. Consistent with its lack of an effect on the replication of uncommitted progenitors and its anti-mitotic actions on differentiating osteoblasts, PTH may first induce the commitment of cells to the osteoblastic lineage and then promote their differentiation by inducing an exit from cell cycle. The ability of PTH to promote commitment to osteoblast differentiation was initially demonstrated using a fibroblast osteoprogenitor colony-forming assay (CFU-f) with bone marrow stromal cells of neonatal or young rats (Ishizuya *et al.*, 1997; Nishida *et al.*, 1994). Bone-marrow-derived osteoblastic cultures established from ovariectomized rats treated with intermittent PTH showed increased ability to form mineralized nodules (Valenta *et al.*, 2005). In general, evidence from *in vitro* studies suggests that under conditions that simulate administration of PTH in an intermittent fashion, the hormone stimulates osteogenic cell proliferation and osteoblastic lineage commitment in bone-marrow-derived as well as in periosteal cells (Dempster *et al.*, 1993; Miao *et al.*, 2001; Locklin *et al.*, 2003; Midura *et al.*, 2003). Moreover, PTH upregulates the expression of several Wnt family members and Wnt signaling, suppresses the Wnt antagonist DKK1 in osteoblast progenitors and mature osteoblasts, and requires the Wnt receptor secreted frizzled related protein 1 (SFRP1) for its bone anabolic actions (Bikle *et al.*, 2002; Kulkarni *et al.*, 2005; Bodine *et al.*, 2004; Guo *et al.*, 2005; Barnes *et al.*, 2005). PTH also rapidly and transiently stimulates the expression and activity of the osteoblast-specific transcription factor Runx2 as well as the expression of alkaline phosphatase and type I procollagen in cultured bone marrow or calvaria cells (Locklin *et al.*, 2003; Ishizuya *et al.*, 1997). *In vivo*, a single injection of PTH upregulates the expression of collagen I within 6 hours and increases bone matrix synthesis within 24 hours in young growing rats (Onyia *et al.*, 1995; Onyia *et al.*, 2000). Consistent with a PTH-induced increase in the number of differentiating osteoblasts, intermittent PTH enhances ossicle development from bone-marrow-derived stromal cells implanted into immunocompromised mice (Pettway *et al.*, 2005).

In vitro, prolonged exposure to PTH appears to exert an attenuating effect on osteoblast differentiation: It inhibits the expression and synthesis of matrix proteins, including collagen I, osteocalcin, and alkaline phosphatase activity, regardless of whether exposure is for a few hours or several days in differentiated osteoblasts (Tetradis *et al.*, 1998; Bogdanovic *et al.*, 2000; Clohisy *et al.*, 1992; Howard *et al.*, 1981; Dietrich *et al.*, 1976; Kream *et al.*, 1993b; Raisz and Kream, 1983b; Raisz and Kream, 1983a; Tetradis *et al.*, 1997; Tetradis *et al.*, 1996). It is well established that PTH regulates gene expression of osteoblasts, supporting synthesis of matrix proteins required for new bone formation (Parfitt, 1976a) and proteins associated with matrix degradation and turnover (Parfitt, 1976b). Prolonged exposure to PTH in cultured bone cells altered several nuclear matrix proteins (Bidwell *et al.*, 1998). Some of these appear to be architectural transcription factors and some, such as NMP4 (a nuclear matrix protein) and NP (a soluble nuclear protein): bind directly to the regulatory region of the rat type I collagen α(I) promoter in the presence of PTH (Bidwell *et al.*, 1998; Alvarez *et al.*, 1998). The expression of matrix metalloproteinase-13 (MMP-13): which is responsible for degrading components of extracellular matrix, is stimulated by PTH through a PKA-dependent pathway that leads to removal of histone deacetylase 4 (HDAC4) from the MMP-13 promoter (Shimizu *et al.*, 2007). These experiments suggest that the profile of gene expression, protein activity, and pro-differentiating actions of PTH are subject to the duration of the exposure. *In vitro* data may predict *in vivo* data

associated with continuous exposure to PTH. Following continuous infusion of PTH in adult rats, osteoblasts are associated with fibrosis rather than new bone matrix (Dobnig and Turner, 1997; Kitazawa *et al.*, 1991). The transcriptional signature of intermittent versus continuous PTH administration was examined *in vivo* in the rat. In the intermittent treatment, many genes encoding signaling mediators, transcription factors, cytokines, and proteases/protease inhibitors were regulated rapidly and cyclically with each PTH injection. Genes associated with skeletal development showed a slowly accruing pattern of expression. With continuous treatment, the expression of some genes was sustained while others showed a biphasic response, decreased then increased expression (Li *et al.*, 2007a).

An interesting observation in studies of the anabolic effects of PTH has been the consistent finding that PTH upregulates expression of both matrix-degrading proteins, such as matrix metalloproteinases and ADAMTS-1, and cytokines associated with regulating matrix degradation and turnover, such as interleukin (IL)-6 and IL-11 (Onyia *et al.*, 1995; Onyia *et al.*, 1997a; Clohisy *et al.*, 1992; Greenfield *et al.*, 1995; Greenfield, Horowitz, and Lavish, 1996; Huang *et al.*, 1998; McClelland *et al.*, 1998; Winchester *et al.*, 1999; Elias, Tang, and Horowitz, 1995; Miles *et al.*, 2002). In response to PTH, ADAMTS-1 increases the three-dimensional growth of human primary osteoblasts through type I collagen processing (Rehn *et al.*, 2007). This action involves inhibiting migration of cells on a planar substrate but enhancing growth in a collagen scaffold.

Intermittent PTH may promote osteoblastogenesis by a recently identified mechanism that involves downregulation of the expression of the transcription factor PPARγ. PPARγ exerts a tonic, suppressive effect on osteoblast differentiation by promoting commitment of mesenchymal cells to the adipocytic lineage at the expense of the osteoblastic lineage. *In vitro*, short and transient exposure of human mesenchymal stem cells to PTH, inhibited adipocyte formation by an insulin and troglitazone-containing medium shown to induce adipocytic differentiation (Chan *et al.*, 2001). *In vivo*, the anabolic effect of intermittent PTH was associated with decreased number of adipocytes in the bone marrow. Similar to the expression profiling of genes related to osteoblast differentiation, PTH-induced inhibition of adipogenesis may depend on the duration of treatment. The anti-adipogenic effects of PTH were not seen in cells exposed to a continuous PTH treatment (Rickard *et al.*, 2006).

Effects on Osteoblast Survival

Dose response studies indicate that intermittent PTH administration to adult mice decrease the prevalence of osteoblast apoptosis in the secondary spongiosa of distal femur. The decrease in osteoblast apoptosis was positively correlated with increased bone mineral density in both the spine and hind limbs (Jilka *et al.*, 1999; Bellido *et al.*, 2003). In the same report, osteoblast apoptosis was not affected by six days of continuous PTH infusion or by two days of hormone elevation caused by a calcium-deficient diet. Expression of a constitutive active PTH1 receptor (PTHR1) in cells of the osteoblastic lineage decreased osteoblast apoptosis concomitantly with increasing the number of proliferating osteoblasts (Calvi *et al.*, 2001). In contrast to these studies, an increase in osteoblast apoptosis in the primary spongiosa was observed following intermittent PTH administration to mice (Stanislaus *et al.*, 2000). However, this increase was transient and paradoxically associated with decreased activity of caspases 2, 3, and 7 measured in the femoral metaphysis; a site including both primary and secondary spongiosa. A transient increase in apoptosis in proliferating cells and osteocytes of young rat metaphyses was recorded during the initial response to PTH (Stanislaus, Devanarayan, and Hock, 2000). Intermittent PTH was also reported to increase osteoblast apoptosis in cancellous bone of transiliac biopsies obtained from postmenopausal women (Lindsay *et al.*, 2007). The number of apoptotic osteoblasts was positively correlated with increases in bone formation rate. Such conflicting observations may result from differences in the skeletal site used to measure apoptosis, or in the susceptibility of osteoblast subsets to the hormone. A subset of osteoblasts may be highly susceptible to apoptosis. Additionally, in some instances a pro-apoptotic action of PTH on osteoblasts may be secondary to its matrix-degrading properties. Parathyroid hormone may induce upregulation of matrix metalloproteinases (McClelland *et al.*, 1998; Zhao *et al.*, 1999b) leading to matrix degradation and osteoblast retraction through a calpain-dependent, proteolytic modification of the osteoblast cytoskeleton (Murray *et al.*, 1997). The consequence of cell retraction and detachment because of matrix degradation is apoptosis of cells that are unable to reattach. Even so, the transient increase in osteoblast apoptosis and upregulation of matrix metalloproteinases can still be consistent with mechanisms activating bone turnover. One consequence of matrix-activation-degrading enzymes may be that reconditioned bone surface can serve as an attractant for newly differentiating osteoblasts to increase bone-forming surfaces (anabolic action) or as an attractant for differentiating osteoclasts to continue resorption of old surfaces (catabolic action). Reattachment of detached osteoblasts may delay or inhibit their apoptosis.

The majority of *in vitro* studies suggest that short-term exposure to PTH protects rat, murine, and human osteoblastic cells from a variety of pro-apoptotic stimuli (Bellido *et al.*, 2003; Jilka *et al.*, 1998; Chen *et al.*, 2002). In contrast, long-term exposure to PTH stimulates apoptosis of the multi-potential C3H10T1/2 osteoblastic cell line (Chen *et al.*, 2002). Mechanistic studies using cultured osteoblastic cells indicate that the anti-apoptotic action of PTH is initiated by rapid cAMP-mediated activation of PKA. Downstream of PKA the anti-apoptotic pathway was two-pronged: it involved activation of survival proteins in

the cytoplasm and survival genes in the nucleus (Bellido *et al.*, 2003). In the cytoplasm, PKA phosphorylated and inactivated the pro-apoptotic protein Bad. In the nucleus it increased transcription the survival gene Bcl-2, cAMP response element-binding protein (CREB); and Runx2. The upregulation of Runx2 expression was short-lived as the transcription factor was targeted for proteasomal degradation by the Smurf1 E3 ligase (ubiquitin-protein isopeptide ligase): and, also accounted for the short-lived anti-apoptotic effect of PTH in cultured osteoblastic cells. On the other hand, continuous PTH caused sustained reduction in Runx2 levels. Factors that control Runx2 expression in response to PTH may also be involved in the anti-apoptotic actions of the hormone. $p21^{Cip1}$ expression increased with PTH treatment and contributed to the increase in Runx2. In addition, $p21^{Cip1}$ may have a separate, Runx2-independent pro-survival effect as it can prevent activation of caspases and block the pro-apoptotic effects of apoptosis signal-regulating kinase 1 (Gartel and Tyner, 2002) or promote survival of osteoblastic cells (Bellido *et al.*, 1998).

Differential regulation of Runx2 expression and degradation by intermittent versus continuous PTH administration influences both the survival and pro-differentiating actions of the hormone and as such is at least one of the mechanisms that may explain its anabolic versus catabolic profile. Differences in the profile of responses to intermittent versus continuous exposure to PTH in cells of the osteoblastic lineage are still being identified and have yet to be completely clarified. Recently, regulation of gene expression by PTH was used as a basis for investigating the molecular mechanism of its dual actions in bone: anabolic with intermittent versus catabolic with continuous administration of the hormone (Onyia *et al.*, 2005; Li *et al.*, 2007a). Gene array approaches indicate two gene expression patterns that can be placed in two groups according to the dynamics of their changes. Under the influence of intermittent treatment, many genes encoding signaling mediators, transcription factors, cytokines, and proteases/protease inhibitors are regulated rapidly and cyclically with each PTH injection (Li *et al.*, 2007a). With continuous treatment, some genes are regulated within six hours and their levels are sustained while others show a biphasic response: a decrease then increase later.

Independent of the phenomena that determine osteoblast fate in response to PTH, be that proliferation, differentiation, function, or apoptosis, or combinations of them all, the signaling cascades and their interaction with pathways elicited by autocrine and paracrine factors are clearly under dynamic controls.

PTH REGULATION OF OSTEOCYTES

It is now appreciated that osteocytes, the most abundant cells in bone, are principal target cells for PTH. The PTH1 receptor (PTH1R) has been detected in osteocytes *in vivo* (Lee *et al.*, 1993; Langub *et al.*, 2001). Receptor sites that appear to have specificity for carboxyl-terminal regions of PTH(1–84) and other circulating PTH fragments were present in osteocytic cells derived from clonal, conditionally transformed, calvaria cells (Divieti *et al.*, 2001). The response of osteocytes to mechanical stress *in vivo* is enhanced by PTH(1–33) and may even require circulating PTH. When PTH is rendered absent (i.e., after total parathyroidectomy): such effects are no longer demonstrable (Plas *et al.*, 1994; Chow *et al.*, 1998). An anabolic dose of intermittent PTH(1–34) administered to mice, or short-term exposure to PTH, prolonged osteocyte survival (Jilka *et al.*, 1999; Bellido *et al.*, 2003). This effect together with the anti-apoptotic actions of the hormone was, at a minimum, a critical contributor to the PTH-induced increase in bone mass. In contrast to the anti-apoptotic actions of PTH(1–34): PTH(1–18): and carboxyl-terminal fragments of PTH [PTH(34–84)], promoted apoptosis *in vitro*, in osteocytic cells lacking a functional PTH1R. Carboxyl-terminal fragments of PTH are secreted from the parathyroid glands or produced by proteolytic cleavage of PTH(1–84) in peripheral tissues. It is therefore possible that PTH1R and receptors for carboxyl-terminal fragments of PTH exert opposite effects on osteocyte survival. Osteocytes may be able to integrate signals between these two types of PTH receptors in response to changes in circulating levels of intact PTH and carboxyl-terminal fragments of PTH. In addition, carboxyl-terminal fragments of PTH upregulate the expression of connexin 43, a gap-junction protein important in mediating intercellular communication in osteocytes (Ziambaras *et al.*, 1998). The functional significance of this observation is not known. Perhaps carboxyl-terminal fragments of PTH produced by the parathyroids during hypercalcemia promote communication of osteocytes to other bone cells to limit osteoclast recruitment and thereby exert negative feedback on bone resorption. Such speculations on actions of carboxyl terminal fragments of PTH although interesting have to be regarded with caution because a bona fide receptor for this portion of the PTH molecule has not yet been cloned, despite several decades of intense effort by several laboratories.

More recently, PTH has been found to regulate the expression of sclerostin (SOST), which antagonizes the pro-osteoblastogenic actions of bone morphogenetic proteins (BMPs) and LRP5 and 6 (Poole *et al.*, 2005; Van Bezooijen *et al.*, 2004; Semenov, Tamai, and He, 2005; Ellies *et al.*, 2006). SOST may not act as a classical BMP antagonist predominantly blocking Smad phosphorylation, but use alternative signaling pathways or interfere with unknown BMP-induced factors, cofactors, or other pathways. SOST was identified as a potent osteocyte product that negatively regulates bone formation *in vitro*. In murine models and in patients with the bone overgrowth disorders sclerosteosis and van Buchem disease, the *Sost* gene is inactive, thus relieving the anabolic pathway

of tonic inhibition by SOST (Winkler *et al.*, 2003; Van Bezooijen *et al.*, 2004; Wergedal *et al.*, 2003; Brunkow *et al.*, 2001). Continuous infusion of PTH to mice for four days decreased the mRNA and protein expression of SOST 80–90% in vertebral bone and in osteocytes, respectively (Bellido *et al.*, 2005). In contrast, a single injection of PTH caused a transient 50% reduction in Sost mRNA at two hours, but four daily injections had no effect on Sost mRNA or protein. Similarly, in a short-term mouse calvaria model of local bone formation five days of intermittent PTH application stimulated bone formation and Sost expression. On the other hand, local bone formation was robustly decreased four hours after the last local PTH administration, whereas it was unchanged from control levels after the follow-up period, suggesting a tight control of Sost expression by PTH. Interestingly, the profile of PTH-induced changes in Sost expression was different from PTH-induced regulation of the osteocalcin gene (Keller and Kneissel, 2005). A decrease of Sost mRNA levels was observed in the cortical bone of skeletally mature rats within six hours after the single systemic subcutaneous injection of PTH(1–34): confirming rapid regulation of SOST by PTH (Keller and Kneissel, 2005). Suppression of Sost by PTH represents a novel mechanism for hormonal control of osteoblastogenesis mediated by osteocytes. PTH may promote osteoblastogenesis directly by stimulating Wnt and BMP signaling in osteoblast progenitors or indirectly by controlling SOST production in osteocytes. In support of this idea, overexpression of a constitutively active PTHR1 receptor gene specifically in osteocytes, suppressed Sost expression, and increased bone mass in transgenic mice (O'Brien *et al.*, 2006).

Hence, the increased production of osteoblasts needed for increased bone turnover in primary hyperparathyroidism may result from such an indirect effect of PTH on early stages of osteoblastogenesis. Mechanisms underlying a potential sustained SOST inhibition after long-term intermittent PTH treatment, as opposed to transient inhibition following single application, remain to be determined.

PTH REGULATION OF LINING CELLS

By electron microscopy, PTH has been shown to rapidly stimulate differentiation of nonproliferating osteoprogenitors lining quiescent bone surfaces (Roberts, 1975). Intermittent PTH administration to rats increased the number of osteoblasts lining the surface of cancellous bone (Leaffer *et al.*, 1995). This increase was accompanied by a reciprocal reduction in the number of lining cells that covered the surface of quiescent bone. Following cessation of hormone administration, osteoblast number declined while lining cells increased. Based on this evidence, it was proposed that intermittent PTH caused lining cells to revert to their osteoblast phenotype, thus providing a potential explanation for the rapid appearance of osteoblasts on previously quiescent bone surfaces in response to PTH. However, the extent to which the few lining cells contribute to generate the number of osteoblasts required to produce the increased osteocyte number and density observed in mice receiving daily PTH injections remains to be explored (Jilka *et al.*, 1999). Moreover, the reciprocal changes in osteoblast and lining cell number could also be explained if lining cells were replaced by osteoblasts that overfill the resorption cavity and migrate onto adjacent quiescent surfaces as suggested by evidence from studies in humans (Lindsay *et al.*, 2006; Ma *et al.*, 2006). Lining cell activation has also been proposed to explain the PTH-induced increase in osteoblasts when remodeling is low or absent, such as in the periosteal surface. A better understanding of the biosynthetic properties of lining cells, and their response to PTH, is needed before the role of these cells as mediators of PTH can be accounted.

PTH Regulation of Osteoclasts and their Osteoprogenitors

Barnicott (1948) first recognized the resorptive properties of PTH. In this study, remnants of parathyroid glands were laid on the inverted underside of calvaria and reimplanted under the skulls of mice. Significant bone resorption in the calvaria resulted. This work laid the foundation for *in vitro* assays utilizing rat and mouse bones in which resorption was induced routinely by PTH (Raisz, 1963; Raisz, 1965). PTH indirectly enhances bone resorption and release of calcium from bone surfaces by activating osteoclasts. This is despite lack of evidence for direct binding of ^{125}I-bovine PTH(1–84) to avian osteoclasts (Teti, Rizzoli, and Zallone, 1991) and for activation of resorption via a direct effect on the osteoclast (Mears, 1971; Murrills *et al.*, 1990). In bone, PTH receptors are found primarily on osteoblasts (Luben, Wong, and Cohn, 1976; Partridge *et al.*, 1981; Majeska and Rodan, 1982): and apparently osteoclasts do not possess PTH receptors (Suda *et al.*, 1996). Thus, the effect of PTH on osteoclasts is most likely indirect. *In vivo*, PTH induced a transient increase in apoptosis of osteoblasts (Stanislaus, Devanarayan, and Hock, 2000) and upregulation of osteoblast matrix metalloproteinases (McClelland *et al.*, 1998; Zhao *et al.*, 1999a). This is consistent with PTH-mediated mechanisms activating bone turnover in which protein synthesized by osteoblasts activates osteoclasts. Evidence that bisphosphonates attenuate the anabolic effect of intermittent PTH in animal models and humans is consistent with the involvement of osteoclasts (Black *et al.*, 2003; Finkelstein *et al.*, 2003; Ettinger *et al.*, 2004; Delmas *et al.*, 1995; Wronski *et al.*, 1993): but such inhibition was not seen in other studies (Liu *et al.*, 2007; Cosman *et al.*, 1998; Cosman *et al.*, 2005; Ma *et al.*, 2003). Indeed, both OPG and alendronate prolonged the duration of the anabolic

effect in ovariectomized mice, apparently by preventing the increased bone resorption that occurs in the later stages of treatment (Samadfam, Xia, and Goltzman, 2007).

In genetically modified mice in which collagenase is unable to cleave collagen I, daily PTH injections over the skull did not induce osteoclast-mediated resorption but did occur in control animals (Zhao *et al.*, 1999a). *In vitro*, osteoclast-like cells in culture failed to respond to PTH unless cocultured with stromal or osteoblast-like cells (Kanzawa *et al.*, 2000; Suda *et al.*, 1999; Horwood *et al.*, 1998; McSheehy and Chambers, 1986; Fuller, Owens, and Chambers, 1998; Fuller *et al.*, 1998).

Stromal cells and osteoblastic lineage cells regulate osteoclast differentiation through cell–cell contact by controlling the synthesis of osteoprotegerin (OPG/OCIS) and the ligand for the receptor activator of NF-*k*B (RANKL/ODF/TRANCE/OPGL) (Kanzawa *et al.*, 2000; Suda *et al.*, 1999; Horwood *et al.*, 1998). These two secreted proteins compete for binding to the osteoclast progenitor receptor activator NF-*k*B(RANK): a TNF receptor family member (Suda *et al.*, 1999). If RANKL binding to RANK predominates, as seen following PTH treatment of cultured osteoblast-like osteosarcoma cells transfected with the PTH1 receptor, osteoclast progenitors differentiate into osteoclasts in the presence of M-CSF (Suda *et al.*, 1999; Fuller, Owens, and Chambers, 1998; Fuller *et al.*, 1998). Intermittent PTH provoked a transient increase in RANKL (Ma *et al.*, 2001) that may result in a transient increase in osteoclastic resorptive activity. In addition, PTH downregulated OPG expression in a variety of bone cell lines (Kanzawa *et al.*, 2000; Lee and Lorenzo, 1999). PTH stimulated osteoclast formation in part by increasing the RANKL/OPG ratio in osteoblasts (Khosla, 2001; Ma *et al.*, 2001; Buxton, Yao, and Lane, 2004). Activation of the cAMP/PKA–CREB pathway was required for the effects of PTH on RANKL and OPG (Fu *et al.*, 2002; Lee and Lorenzo, 2002; Kondo, Guo, and Bringhurst, 2002). Reciprocal regulation of OPG and RANKL expression by PTH preceded its effects on osteoclast formation by 18–23 hours. These effects were more pronounced in primary bone marrow cells than in calvaria bone organ cultures or MC3T3-E1 cells (Lee and Lorenzo, 1999). Recently, evidence for a direct role of PTH on RANKL expression and osteoclastogenesis *in vivo* was obtained using mice lacking a distant transcriptional enhancer of the RANKL gene that confers responsiveness to PTH (Fu, Manolagas, and O'Brien, 2006). Elevation of PTH levels in these animals, induced by a calcium-deficient diet, failed to upregulate RANKL expression in bone. Moreover, PTH was unable to stimulate osteoclast formation in primary cultures of bone marrow cells derived from these mutant mice.

In vivo studies of young rats treated once daily with hPTH(1–34) for three days showed an altered ratio of mRNA for osteoprotegerin and RANKL (Onyia *et al.*, 2000): but it is not known if the magnitude of these changes translates into relevant function. Changes in resorption associated with once-daily treatment of PTH are rarely detected in rat models *in vivo*. In humans and animals with osteonal bone skeletons, increased resorption in response to PTH in cortical bone occurs, but only after the increase in surface bone formation, which occurs during the first remodeling period (sigma) (Cosman and Lindsay, 1998a; Hodsman and Steer, 1993; Mashiba *et al.*, 2001; Hirano *et al.*, 1999; Hirano *et al.*, 2000; Burr *et al.*, 2001). This increase in new bone-forming surfaces appears to offset the increase in resorption that precedes new osteonal formation in intracortical bone.

As suggested by *in vitro* data (Kanzawa *et al.*, 2000; Suda *et al.*, 1999; Horwood *et al.*, 1998): increased resorption plays a key role in the mechanisms activated when PTH is given by continuous infusion and occurs within the first three days of infusion in young rats. In humans and dogs, continuous infusion of PTH was associated with histomorphometric and biochemical data consistent with the early induction of resorption and increased bone turnover (Malluche *et al.*, 1982; Cosman *et al.*, 1991; Cosman and Lindsay, 1998a). In rats, resorption results in loss of bone mass despite a small increase in bone-forming surfaces (Watson *et al.*, 1999; Hock and Gera, 1992; Tam *et al.*, 1982). In a pathologic condition of continuously elevated PTH levels, primary hyperparathyroidism (PHPT): catabolic actions associated with the osteoclastogenic properties of PTH have been linked to its ability to regulate the expression of RANKL and OPG and to increase the RANKL/OPG ratio *in vitro* and *in vivo* (Lee and Lorenzo, 1999; Khosla, 2001; Buxton, Yao, and Lane, 2004; Huang *et al.*, 2004; Ma *et al.*, 2001; Onyia *et al.*, 2000). Early data in human subjects also argue for RANKL as a key intermediate in the catabolic actions of PTH. In subjects with PHPT who underwent successful parathyroid surgery, Stilgren *et al.* analyzed mRNA in transiliac bone biopsies. They showed a positive correlation between RANKL levels and both bone formation and resorption markers (Stilgren *et al.*, 2004). Moreover, the ratio of RANKL to OPG declined after surgery. Concomitant with the decrease in RANKL/OPG expression was an increase in bone mass. In cross-sectional studies, PTH and serum OPG levels were shown to be negatively correlated with each other (Szulc *et al.*, 2001). A similar negative correlation was observed in a study of osteoporotic women treated with PTH and in women with early breast cancer (Seck *et al.*, 2001). These observations in human subjects suggest that PTH exerts its catabolic effect on bone by stimulating RANKL-mediated bone resorption.

Upregulation of RANKL and osteoclastic activity are also noted during the anabolic actions of intermittent PTH. Gene array analysis in bone from rats indicated a fivefold increase and cyclic stimulation of RANKL expression in the anabolic (intermittent) regime (Li *et al.*, 2007a; Onyia *et al.*, 2005). A moderate but sustained stimulation was

associated with continuous infusion of the hormone. OPG levels also increased with the intermittent PTH regime, but the increases lagged considerably behind the increases in RANKL resulting in a transient stimulation of the RANKL/OPG ratio. In contrast, in the continuous treatment, OPG levels decreased with time maintaining an elevated RANKL/OPG ratio. In addition to its effects on osteoblasts, a cyclic upregulation of bone resorption, versus a moderate but sustained elevation of RANKL/OPG, may contribute to the anabolic actions of intermittent PTH. RANKL may also stimulate the secretion of an osteoblastogenic factor from osteoclasts (Martin and Sims, 2005). Osteoclast activation following continuous infusion of PTH may also be related to the shift in matrix protein synthesis by osteoblasts to a more fibroblast-like profile (Dobnig and Turner, 1997): which would result in an extracellular matrix (ECM) feedback signal to activate increased bone turnover.

PTH rapidly and dramatically stimulated the expression of monocyte chemoattractant protein-1 (MCP-1) in femurs of rats receiving daily injections of the hormone or in primary osteoblastic cells (Li *et al.*, 2007b). Studies with the mouse monocyte cell line RAW 264.7 and mouse bone marrow indicated that osteoblastic MCP-1 can recruit osteoclast monocyte precursors and facilitate RANKL-induced osteoclastogenesis and fusion. Thus, in addition to stimulation of RANKL production, upregulation of MCP-1 levels may contribute to the osteoclastic/bone remodeling activity that accompanies the anabolic effects of PTH.

When hPTH(1–34) was infused at 40 μg/kg/day in young rats and compared to a PTH injection of 40 μg/kg/day, there was upregulation of c-fos and IL-6 mRNA expression following injection and equivalent upregulation of c-fos but no alteration of IL-6 mRNA levels following infusion (Liang *et al.*, 1999). These responses were detected in the femur metaphysis, which is enriched for osteoblasts, but not in the cortical diaphysis, which contains predominantly hematopoietic and stromal cells. In primary cultures of bone marrow stromal cells from either metaphysis or diaphysis of rat femurs, PTH increased both c-fos and IL-6 expression suggesting that, *in vivo*, there are site-specific regulatory factors controlling the profile of genetic responses, in addition to those associated with different treatment regimens. Confounding their interpretation is a study in which serum IL-6 was increased in mice infused with PTH or rats in which PTH was locally injected over calvaria to mimic a resorption model. Blocking IL-6 release was associated with a decrease in resorption markers, with no change in biochemical markers of formation (Grey *et al.*, 1999; Pollock *et al.*, 1996). There were no measures of bone mass to ascertain if this altered profile was associated with a catabolic or anabolic effect, and no comparison was made to intermittent, once-daily administration of PTH.

Another potential osteoclastogenic mechanism of PTH may involve recently recognized effects of the hormone on Wnt signaling; as well as unappreciated actions of β-catenin on osteoclastogenesis. It was recently shown that mice harboring a gain-of-function mutation of β-catenin in osteoblasts exhibited decreased bone resorption resulting from stimulation of OPG and suppression of RANKL expression (Glass *et al.*, 2005). Additionally, Wnt/β-catenin signaling in osteoblasts upregulated RANKL expression and inhibits osteoclastogenesis *in vitro* (Spencer *et al.*, 2006). As PTH has been shown to interact with Wnt signaling components (reviewed later in this chapter): it is possible that it promotes osteoclastogenesis by opposing the effects of endogenous Wnt/β-catenin-mediated transcription on RANKL and/or OPG. More studies along this line will be needed to elucidate a potential role of PTH–Wnt interactions in osteoclastogenesis.

One limitation of these gene-profiling studies has been our lack of knowledge of how the balance of increased activation frequency may favor formation (anabolic effect of intermittent PTH) or resorption (catabolic effect of continuous PTH). A mathematical model that assumes a longer delay in osteoclast activation (because of a requirement for signals from the osteoblast to osteoclast progenitors) than the delay required for osteoblast differentiation argues that osteoblast function will predominate with intermittent PTH, whereas resorption will be greater with continuous PTH (Kroll, 2000). The importance of interval duration of PTH administration emphasized in this theoretical model has some support from preliminary data. In rats treated with PTH, six injections in one hour once daily, or infusion for one hour once daily, induced an equivalent bone gain to that of one injection/day, whereas six injections over eight hours or continuous infusion for longer than one hour/day resulted in bone loss (Dobnig and Turner, 1997; Turner *et al.*, 1998). Studies in humans have previously shown in PHPT the ability of PTH to act both as a catabolic and as an anabolic hormone. Moreover, as mentioned earlier in this chapter, both intermittent and continuous PTH infusion activates the Wnt signaling pathway to stimulate the recruitment of osteoblast progenitors. The catabolic and anabolic cell signaling properties of PTH appear to be independent as illustrated further in studies by Kalinowski *et al.* in which the skeletal anabolic response to intermittent PTH exposure was maintained in mice with defective osteoclast formation because of transplantation with RANKL-deficient hematopoietic cells (Lorenzo *et al.*, 2006).

The current concept thus is that PTH utilizes both catabolic (OPG-RANKL) and anabolic (Wnt and BMP) pathways. Chronically elevated levels of PTH are more likely to lead to RANKL-associated processes while intermittent administration of PTH is more likely to lead to LRP5-independent Wnt-associated processes. However, it is also clear that chronically elevated levels of PTH (e.g., PHPT) or intermittent exposure to PTH (e.g., treatment for osteoporosis) is also associated with evidence for counterbalancing actions. It follows then that under physiologic conditions, PTH will provide dual anabolic and catabolic skeletal actions that are

nicely balanced. On the other hand, the stimulatory effect of PTH on bone resorption may represent a two-edged sword in the setting of anabolic therapy. Intermittent PTH may increase release of osteogenic growth factors from the bone matrix or from osteoclasts, but this effect may be counterbalanced by increased resorption, particularly in later stages of the therapy. The negative impact of increased resorption may be overcome by administering PTH for short periods of time in a cyclic fashion to maximize the bone-forming effects and minimize the pro-resorptive effects (Cosman *et al.*, 2005; Iida-Klein *et al.*, 2007). Such approaches have theoretical appeal but remain to be conclusively demonstrated.

MOLECULAR MECHANISMS AND MEDIATORS OF PTH ACTION: SIGNALING CASCADES TRANSCRIPTION FACTORS, GROWTH FACTORS, AND HORMONES

General Aspects

The actions of PTH (and PTHrP) are mediated by binding of the hormone to its G protein coupled receptor, referrer to as PTH receptor 1 (PTHR1) (Potts, 2005). Activated PTHR1 stimulates G_{as}-mediated activation of adenyl cyclase, which in turn promotes cyclic AMP (cAMP) production and subsequent activation of protein kinase A (PKA). Alternatively, PTHR1 stimulates G*aq*-mediated activation of protein kinase C (PKC). Finally, PTH also activates β-arrestin with a dual outcome: a) subsequent activation of extracellular regulated kinases (ERKs): and b) a negative feedback mechanism involving desensitization of PTHR1-induced cAMP signaling (Gesty-Palmer *et al.*, 2006; Gensure, Gardella, and Juppner, 2005).

Cytoplasmic Signaling: The cAMP/PKA and PKC Pathways

In vitro studies have suggested that cAMP is a key signaling pathway activated by PTH; although its relative importance *in vivo* is not well understood. cAMP binds to the regulatory subunit of PKA, which releases the active catalytic subunits of the enzyme. The catalytic form of PKA phosphorylates proteins on serine residues in the specific recognition sequence R-X-X-S, which often causes changes in the target proteins' structure and function. PTH also activates phospholipase Cβ by Gα_q leading to the formation of diacylglycerol (DAG): which activates protein kinase C (PKC) and 1,4,5-inositol triphosphate (IP3) (Civitelli *et al.*, 1988; Babich *et al.*, 1991): resulting in increased intracellular free Ca^{2+} (Reid *et al.*, 1987). Activation of calcium and protein kinase C (PKC) signal transduction pathways require higher doses of PTH *in vitro* than those required to activate the cAMP-PKA pathways. Thus, it has been proposed that cAMP is the key pathway by which the anabolic responses of PTH are effected (Whitfield *et al.*, 1998; Civitelli *et al.*, 1990; Li *et al.*, 2007a; Potts, 1995). Proving this suggestion, gene expression profiling of intermittent versus continuous PTH administration to rats' bone suggested that in both regimes the PKC pathway played a limited role in mediating PTH's dual effects while the PKA pathway appeared to predominate (Frisch, 2000; Howe and Juliano, 2000). Several PTH-induced genes that are primary response genes regulating signaling or transcription in osteoblasts are cAMP dependent. Those include c-fos (Clohisy *et al.*, 1992): collagenase (Civitelli *et al.*, 1989; Scott *et al.*, 1992): IL-6 (Greenfield *et al.*, 1995): type I collagen (Kream *et al.*, 1993a): Nurrl (Tetradis, Bezouglaia, and Tsingotjidou, 2001): Nur77 (Tetradis *et al.*, 2001): NOR-1 (Pirih *et al.*, 2003): E4bp4 (Ozkurt, Pirih, and Tetradis, 2004): RGS-2 (Tsingotjidou *et al.*, 2002): and ICER (Tetradis *et al.*, 1998; Pirih *et al.*, 2003). More recently, the cAMP-inducible coactivator PPARγ coactivator-1α (PGC-1α) was shown to synergize with the orphan nuclear receptor Nurr1 to induce target gene transcription in osteoblasts in response to PTH (Nervina *et al.*, 2006). Additionally, RAMP3 (Receptor Activity Modulating Protein-3): which modifies calcitonin receptor function, is also a cAMP-dependent target of PTH in osteoblasts (Phelps *et al.*, 2005).

In fibroblasts, cAMP signaling activates PKA-controlled cell growth by abrogating signaling required for detachment of cells, inhibiting both progression through the cell cycle and apoptosis (Bretschneider, Vasiev, and Weijer, 1997; Hofer *et al.*, 2000; Thomas, 2000). If valid for osteoprogenitors, this could provide mechanisms by which PTH promotes differentiation but not proliferation of bone cells. However, regarding the mechanistic basis for the differential effects of intermittent versus continuous PTH treatment on bone, the magnitude of changes in cAMP and the PKA pathway cannot explain the paradoxical actions of PTH to inhibit and stimulate bone formation and to spare or stimulate osteoclast-mediated resorption. Concepts on how waves of differing amplitude and frequency of cAMP and Ca^{+2} signaling traverse a cell and may be amplified in neighboring cells by activation of intracellular calcium-sensing receptors are examined for the relevance to signal transduction in bone cells in response to PTH (Steddon and Cunningham, 2005). Compounds that increase (calcimimetics) or decrease (calcilytics) the sensitivity of the G-protein-coupled calcium-sensing receptor to calcium are currently being explored as means for regulating the response of bone (and other cell types) to endogenous serum levels of PTH (Stanislaus, Devanarayan, and Hock, 2000; Liang *et al.*, 1999).

c-fos and c-jun AP-1 Family Members

As one of the cAMP-dependent mechanisms, the upregulation of c-fos and the role of the immediate early gene comprising the AP-1 fos and jun family members have been widely studied. *In vivo*, PTH [as either hPTH(1–84) or hPTH(1–34)] rapidly and transiently increased c-fos,

fra-2, junB, and c-jun significantly above baseline levels in the metaphyses and whole tibia of young and adult mice at doses as low as 1 μg/kg (Sabatakos *et al.*, 2000). Although other AP-1 members, δfosB (Jochum *et al.*, 2000) and fra-1 (Stanislaus, Devanarayan, and Hock, 2000): regulate bone formation, PTH did not regulate their expression in young rats (Stanislaus, Devanarayan, and Hock, 2000). The regulation of c-fos in bone has the greatest magnitude of change of the PTH-regulated AP-1 family members and is time- and cell-dependent (Kano *et al.*, 1994; McCauley *et al.*, 1997; Clohisy *et al.*, 1992). *In situ* hybridization of young rat bone showed that bone-lining cells expressed an increased amount of c-fos within 15 to 60 minutes of exposure to hPTH(1–84) (0.2 mg/kg): followed by stromal cell and osteoclast expression after 1 to 2 hours. *In vitro*, constant exposure to PTH (1–34) and PTHrP(1–34) induced c-fos gene expression rapidly in bone cell lines (Fiol *et al.*, 1994; Tyson *et al.*, 2002). The effect of PTH on c-*fos* expression is mediated predominantly by the actions of cAMP acting through the major cAMP response element (CRE) within the c-*fos* promoter. The major CRE is bound by CREB and CREB is phosphorylated at serine 133 in response to PTH treatment. Most likely, a second phosphorylation event, at serine 129 by GSK-3 (Clohisy *et al.*, 1992): is required before full transcriptional activity in response to PTH can occur. In addition to c-fos, PTH increases expression of c-*jun* in osteoblasts both rapidly and transiently as is typical of immediate-early genes (Civitelli *et al.*, 1989; Scott *et al.*, 1992). Heterodimerization of Fos with its partner Jun can lead to increased expression of many genes possessing an AP-1 site within their promoters. The presence of AP-1 binding sites in the collagenase-3 promoter and the fact that the AP-1 element is required for the PTH induction of collagenase-3 expression (Johnson, Spiegelman, and Papaioannou, 1992; Wang *et al.*, 1992; Grigoriadis *et al.*, 1994) suggest that Fos/Jun heterodimers may play an important role in mediating the effects of osteogenic stimuli. Knocking down of c-fos expression antagonized the PTH- (or PTHrP-) induced inhibition of proliferation in osteoblastic cells, as well as induction of osteoclast differentiation in the presence of these cells (Kano *et al.*, 1994). However, deletion of the c-*fos* gene in mice does not have any apparent effects on osteoblasts, perhaps because its osteoblastic function is substituted by a related c-fos family member, but, dramatically inhibits osteoclastogenesis (Li *et al.*, 2007a). Thus, c-*fos* is required for osteoclast differentiation, but the role of c-fos in osteoblasts is still not completely determined. c-fos has also been implicated in the process of programmed cell death in other cells, and the PTH-induced increases in c-fos may be relevant to the inhibition of apoptosis in bone cells.

Wnt Signaling and Sclerostin

There is plenty of evidence to suggest that intermittent administration of the PTH can induce osteoblastic lineage commitment and differentiation by stimulating Wnt and BMP-2 signaling in osteoblast progenitors. PTH mediated early stem cell recruitment during fracture repair, in part, by upregulating the expression of Wnt4 and Wnt5b. In an expression profiling of intermittent versus continuous PTH to rats, Wnt4 and the Wnt receptor antagonist secreted frizzled related protein 4 (SFRP4) were upregulated whereas SFRP2 was downregulated by both regiments in bone (Kulkarni *et al.*, 2005). Continuous exposure to PTH (1–38) both *in vivo* and *in vitro* upregulated the expression of LRP6 and the Wnt receptor Frizzled 1 (FZD-1): and decreased LRP5 and Dkk-1. These effects in UMR 106 cells were associated with an increase in β-catenin protein levels and resulted in functional activation (three- to six-fold) of a downstream Wnt responsive TBE6-luciferase (TCF/LEF-binding element) reporter gene. The effect of PTH on the canonical Wnt signaling pathway occurred, at least in part, via the cAMP-PKA pathway through the differential regulation of the receptor complex proteins (FZD-1/LRP5 or LRP6) and the antagonist Dkk-1 (Tobimatsu *et al.*, 2006). PTH stimulated osteoblast β-catenin levels via Smad3 in mouse MC3T3-E1 osteoblastic cells, and both the PKA and PKC pathways were involved (Kakar *et al.*, 2007). Smad3-dependent upregulation of β-catenin levels by PTH may be involved in the anti-apoptotic actions of the hormone in osteoblasts. In osteoblast progenitors derived from the periosteal surface, cyclic PTH treatment to simulate an intermittent mode of administration, upregulated the expression of the Wnt target Axin2; and this effect correlated with a pro-differentiating action of the hormone on periosteal osteoblast progenitors (Ogita *et al.*, 2007).

In vivo, the ability of PTH to enhance the earliest stages of endochondral bone repair correlated with increased level of Wnt-signaling at multiple time points across the time course of fracture repair, indicating that such responses are at least in part mediated through Wnt signaling (Bodine *et al.*, 2007). PTH suppressed the expression of the LRP5 and LRP6 antagonist Dkk1 but activated Wnt signaling in transgenic mice overexpressing Dkk1 in osteoblasts under the control of the α1(I)collagen promoter, indicating that LRP5-independent Wnt signaling may be required for the anabolic actions of PTH. In support of this idea, intermittent PTH administration for four or six weeks increased osteoblast number and cancellous and cortical bone formation in an LRP5-deficient female mice (Sawakami *et al.*, 2006; Iwaniec *et al.*, 2007). In contrast to these findings, a blunting of the anabolic effects of PTH was observed in male LRP5-null mice of the same studies and in the femoral trabecular bone of LRP5 knockout mice receiving up to tenfold higher dose (300 ng/g) of the anabolic dose of daily PTH (Kato *et al.*, 2002). In agreement with the lack of an effect of LRP5 deletion to the anabolic effects of PTH, at least in murine cortical bone of both sexes and in cancellous bone of females, intermittent PTH further increased bone formation in mice transgenic for the G171V LRP5 high bone mass mutation. These observations may not be

unexpected because LRP5 and PTH differentially affect the fate of osteoprogenitors. LRP5 increases bone formation by enhancing the proliferation of osteoblast progenitors and without affecting osteoblast differentiation and survival (Bodine *et al.*, 2007). On the contrary, as summarized throughout this chapter, PTH exerts both pro-differentiating and anti-apoptotic effects in murine osteoblast or their osteoprogenitors and exerts mainly an anti-proliferative effect in the same cells. Thus, if Wnt signaling were involved as a mediator of the anabolic effects of PTH, it would be the osteoblastogenic or prosurvival actions of the hormone that it would mediate. In support of this contention, the anabolic effects of intermittent PTH were blunted by deletion of SFRP1 in mice (Poole *et al.*, 2005). Thus, overlapping mechanisms of action may mediate the increased bone mass resulting from administration of the hormone or the activation of endogenous Wnt signaling that follows deletion of the Wnt antagonist SFRP1.

The influence of, specifically, continuous PTH on the Wnt signaling pathway appears to be related to its actions to inhibit the expression of the osteocyte product and Wnt antagonist, sclerostin (Sost). SOST is strongly expressed in osteocytes within bone (Winkler *et al.*, 2003; Van Bezooijen *et al.*, 2004; Wergedal *et al.*, 2003; Brunkow *et al.*, 2001). SOST loss-of-function mutations in humans are the cause of the autosomal recessive bone dysplasias sclerosteosis and van Buchem disease, which are characterized by massive bone overgrowth throughout life and increased bone strength and serum markers of bone formation (Bellido *et al.*, 2005; Keller and Kneissel, 2005). PTH has been shown to suppress Sost expression in osteocytes by a mechanism that is mainly mediated via the cAMP/PKA pathway (Loots *et al.*, 2005). Sost inhibition by PTH was not blocked by the protein synthesis inhibitor cycloheximide, indicating direct regulation, and PTH did not influence Sost mRNA degradation, implying transcriptional regulation. A distant enhancer within the 52 kb Van Buchem disease deletion downstream of the Sost gene was found to be essential for its expression in adult bone (Leupin *et al.*, 2007). Myocyte enhancer factor 2 (MEF2) transcription factors control this enhancer and mediate inhibition of sclerostin expression by PTH (Schmid *et al.*, 1994). Thus, continuous administration of PTH may also have a beneficiary effect on the induction of osteoblast lineage commitment and differentiation by a sustained decrease in the expression of Sost. In support of this contention, overexpression of a constitutive active PTHR1 specifically in osteocytes, suppressed Sost expression and increased bone mass in transgenic mice (O'Brien *et al.*, 2006).

Growth Hormone and IGF-1

Growth hormone (GH) has been evaluated either as a direct regulator of bone cell biology or as a stimulator of IGF-1, which was known to stimulate osteoblast proliferation and differentiation *in vitro* (Canalis, Hock, and Raisz, 1994; Hock and Fonseca, 1990). A study of young male hypophysectomized rats showed that GH was required for PTH to increase bone mass equivalent to the increment seen in treated, intact controls (Schmidt, Dobnig, and Turner, 1995). As the effects of GH on bone can be mediated by IGF-1, it was inferred that IGF-1 might be required for the anabolic effect of PTH, at least during skeletal development when growth plates are still active. The addition of PTH to older, mature hypophysectomized female rats resulted in increased osteoblast number and trabecular bone volume, even in the absence of GH (Gunness and Orwoll, 1995; Mosekilde *et al.*, 2000). Other studies of PTH in combination with either GH alone or combined with IGF-1 in intact old female rats showed a substantial additional effect of either GH or IGF-1 (Mosekilde *et al.*, 2000). It has been suggested that GH in older animals may enhance the effect of PTH by stimulating periosteal formation to change the geometry of the bones, making them more resistant to fracture in biomechanical tests (Canalis *et al.*, 1989): data to prove this additive effect of GH are limited. Collectively, these data suggest that GH is required for the anabolic effect of PTH during the "adolescent" phase of skeletal growth in rats, but is not necessary after skeletal maturation in rats.

IGF-1 acts as both a pro-differentiating and a pro-survival factor in osteoblasts (Conover, 2000). One elegant study showed that a neutralizing IGF-1 antibody blocked the effects of PTH on collagen synthesis in cultured fetal rat calvaria and implicated IGF-1 as a key mediator of PTH effects on osteoblasts (McCauley *et al.*, 1997). In calvarial bone cells isolated from two-day rats and treated with hPTH(1–34) for six hours, osteoblast commitment to differentiation was blocked by the IGF-1 antibody (Grey *et al.*, 2003). These data suggested that IGF-1 may be one of the mediators of PTH effects on skeletal growth and maturation. Indeed, long-term exposure to PTH stimulated IGF-1 synthesis in a cAMP-dependent mechanism in osteoblasts in culture (Locklin *et al.*, 2003). Short-term treatment with the hormone had no effect on osteoblastic cells (Watson *et al.*, 1995). However, intermittent PTH administration to ovariectomized rats for four weeks increased IGF-1 transcripts as determined by *in situ* hybridization (Bikle *et al.*, 2002). The increase in IGF-1 levels in this study could be because of accumulative effects of repeated exposure to PTH. Nevertheless, the role of IGF-1 as a mediator of the anabolic actions of PTH has been established in studies in animal models. Daily PTH administration to IGF-1-deficient mice for up to 14 days failed to stimulated periosteal bone formation and cortical thickness (Miyakoshi *et al.*, 2001) or to increase bone mass in the distal femoral metaphysis. Anabolic actions of PTH at all three sites were observed in wild-type animals (Yamaguchi *et al.*, 2005). Deletion of the insulin receptor substrate adapting molecule-1, which transmits IGF-I

receptor signaling, in mice blunted the anabolic response to four weeks of intermittent PTH administration (Yakar *et al.*, 2006). Finally, inactivation of IGF-1 in the liver had no effect on the anabolic actions of PTH in cancellous bone, but attenuated its effects on cortical bone (Wang *et al.*, 2007). These studies suggest that local IGF-1 production mediate PTH-induced anabolism in the cancellous site but liver-derived IGF-1 is involved in the PTH-induced increase in cortical thickness.

Consistent with the involvement of IGF-1 in the anabolic effects of PTH, osteoblast-specific deletion of IGF-1 receptor in mice attenuated PTH-stimulated endosteal bone formation but had no effect on the increase in cortical thickness in the proximal tibia (Schmid *et al.*, 1989; LaTour *et al.*, 1990; McCarthy *et al.*, 1994; Moriwake *et al.*, 1992). IGF-1 receptor inactivation affected the ability of PTH to stimulate osteoprogenitor cell proliferation and differentiation as administration of PTH increased the number of alkaline phosphatase expressing colonies and mineralized nodules in bone marrow-derived stromal cells from control mice, but not from IGF-1 receptor-deficient mice.

As skeletal cells secrete the six known IGF-binding proteins (IGFBPs) and two of the four known IGFBP-related proteins (IGFBP-rP): there may be several levels of regulation if IGF-1 mediates the action of PTH *in vivo* (Pereira and Canalis, 1999; Qin *et al.*, 1998). IGFBPs may prolong the half-life of IGF-1 and compete with its receptors for binding. IGF-BP4 may inhibit osteoblast function *in vitro*, whereas IGF-BP5 enhances the stimulatory effects of IGF-1 (Pereira and Canalis, 1999; Pereira, Durant, and Canalis, 2000). PTH induces IGFBP-rP-1 and IGFBP-rP-2 in osteoblasts by transcriptional control (Hurley *et al.*, 1999). A potential role of IGF-1-binding proteins to the actions of PTH has not yet been elucidated.

FGF-2

FGF-2 exerts both proliferative and anti-apoptotic effects in osteoblasts. In cultured mouse cells and bone organ culture, hPTH-(1–34) increased expression of FGF-2 and FGF receptors 1 and 2 within 30 minutes (Hurley *et al.*, 2006). FGF-2 may contribute to the anabolic effect of intermittent PTH as evidenced by the failure of the hormone to increase cancellous bone volume in growing or adult FGF-2 deficient mice (Okada *et al.*, 2003). PTH-stimulated osteoclast formation in bone marrow cultures or cocultures of osteoblast-spleen cells from FGF-2 deficient mice was also significantly impaired (Lane *et al.*, 2003). Daily injections of FGF-2 and PTH both increased trabecular bone mass in osteopenic rats but had different effects on trabecular bone architecture. Whereas intermittent PTH increased trabecular thickness, FGF-2 increased trabecular number and connectivity. Because the effect of intermittent FGF-2 on trabecular architecture did not mimic the effect of intermittent PTH, either the increase in FGF-2 induced by intermittent PTH was not enough to increase trabecular number and connectivity, or the cellular response of osteoblast progenitors was modified by the anti-proliferative effect of PTH.

INTRODUCTION

Although not originally conceived as a vasoactive substance, it is now generally appreciated that parathyroid hormone has important effects on the regulation of vascular tone. Parathyroid hormone-induced relaxation of vascular smooth muscle (Mok *et al.,* 1989) is a mechanism for the classical hypotensive property that was first demonstrated by Collip and Clark (1925). In spite of this finding, parathyroid hormone (PTH) has been implicated in multiple aspects of coronary heart disease including hypertension.

Hypercalcemia has been associated with cardiovascular diseases including hypertension, arrhythmias, left ventricular hypertrophy, and vascular and valvular calcification. The effect of PTH on the cardiovascular system has also been explored, because PTH has known positive chronotropic and inotropic effects on the heart. This chapter will review possible mechanisms by which PTH may influence the cardiovascular system including affects of blood pressure and left ventricular function, and examine the studies that address the question of cardiovascular involvement in primary hyperparathyroidism (PHPT).

PRIMARY HYPERPARATHYROIDISM AND THE CARDIOVASCULAR SYSTEM

Any review of this literature must be mindful of the evolution in the clinical profile and severity of PHPT over the past 40 years. In the past, PHPT was characterized by marked hypercalcemia and very elevated levels of PTH. This profile remains typical in some areas of the world. However, in the United States and other developed countries today, PHPT is more commonly characterized by very mild hypercalcemia and PTH levels that are often only minimally elevated. If the cardiovascular manifestations of PHPT are dependent upon the extent to which these biochemical hallmarks are abnormal, one might anticipate a spectrum rather than a single profile of involvement.

Cardiovascular mortality has been assessed in several studies in patients with PHPT (Lunghall *et al.,* 1991; Hedback and *et al.*, 1991; Palmer *et al.,* 1987). In some studies, the increase in the cardiovascular death rates persisted even after curative surgery of the PHPT, although other studies suggest that the risk of cardiovascular death returns to normal after parathyroidectomy. One study demonstrated a decrease in cancer and coronary heart disease (CHD)-related deaths in patients with PHPT. Wermers *et al.* reported mortality figures in patients with PHPT who were diagnosed between 1965 and 1992 (Wermers *et al.,* 1998). Despite the overall finding that overall survival was not adversely affected among patients with PHPT, higher maximal serum calcium levels were shown to be an independent predictor of mortality. This was particularly the case in subjects who were in the highest quartile of serum calcium levels (11.2 to 16.0 mg/dL). It should be noted that the mean serum calcium levels in the cohort of Wermers *et al.* were lower than in the studies that reported increased mortality.

After parathyroid surgery, data are available in the context of subjects whose PHPT was cured and those in whom elevated calcium and PTH levels persisted. In the latter setting, a retrospective review of medical records was performed in 23 of 124 patients who after parathyroid surgery had persistent elevations of serum calcium and PTH levels (Vestergaard and Kristensen, 2002). Follow-up information was available for comparison after 12 months in 14 of these 23 subjects with persistent PHPT and in 38 subjects whose PHPT was cured. In patients with persistently

*Corresonding author: Lorraine A. Fitzpatrick, Research and Development, Musculoskeletal Diseases, GlaxoSmithKline, King of Prussia, Pennsylvania

elevated levels of PTH, the frequency of ischemic heart disease and hypertension was higher as compared to those whose PHPT was cured. Another case-control study of Danish individuals gleaned from that country's national hospital registry from 1977–1993 found that the diagnosis of PHPT carried with it an increased risk of premature death (Ogard *et al.,* 2004). The overall cardiovascular mortality in the PHPT cohort was elevated compared to the background population. The standard mortality ratios due to ischemic heart disease for women and men with PHPT were 1.9 (95% CI, 1.4–2.4) and 1.5 (95% CI, 0.9–2.3), respectively. It is notable that this study did not address subjects with mild PHPT because it is unlikely that they would have been hospitalized and thus captured in the national registry.

Nilsson *et al.* (2004) suggested that PHPT due to multiglandular disease had an increased risk of death. The patients in this study were identified through a national registry of hospitalized patients in Sweden from 1964–1999, and appear to be restricted to subjects with multiglandular parathyroid disease. There was an increase in standard mortality ratio (1.44; 95% CI, 1.37–1.52) beyond the first postoperative year. Cardiovascular disorders were the predominate cause of death in both genders.

There are limited data on the effect of hyperparathyroidism and hypercalcemia, the hallmarks of PHPT, on cardiovascular disease. Serum PTH levels predicted the presence of coronary heart disease in a study of 3,570 subjects in Tromso (Kamycheva *et al.,* 2004). Linear regression was used to determine associations and a logistic regression model was utilized to find independent predictors of coronary heart disease. Data were obtained by measuring PTH levels and relating them to information obtained from a questionnaire about angina pectoris and myocardial infarction. When stratified for age, the rate of CHD was higher in subjects with elevated serum PTH than in those with normal or low serum PTH levels (relative risk 1.67; 95% CI, 1.26–2.23 in men and 1.78; 95% CI, 1.22–2.57 in women). A positive association was evident after adjustment for body mass index, systolic blood pressure, and total serum calcium and serum cholesterol levels. Other parameters of bone metabolism, such as 25-hydroxyvitamin D levels were not captured. These subjects had serum calcium levels within the reference range, implicating PTH as an associated factor for CHD. However, it is not clear whether the subjects with highest PTH values had primary or secondary hyperparathyroidism. Because the serum calcium levels were normal, it is likely that at least some of these patients had secondary hyperparathyroidism. In those individuals with renal impairment causing hyperparathyroidism there may well be alternative explanations for the increased finding of CHD.

There are also data supporting an association of hypercalcemia itself with cardiovascular disease. In a large prospective, epidemiologic study of Swedish men, hypercalcemia was found to be a risk factor for myocardial infarction (Lind *et al.,* 1997; Jorde *et al.,* 1999). Furthermore, higher serum calcium levels within the normal range are reported to be associated with increased cardiovascular mortality (Leifsson and Ahren, 1996). More recently, a study from Rubin *et al.* documented an association between serum calcium levels and carotid plaque, which is a strong predictor of clinical coronary and cerebrovascular events (Rubin *et al.,* 2007). In this study of 1,194 multi-ethnic subjects from New York City, the interaction of age and serum calcium was the most significant predictor of carotid plaque thickness when traditional cardiovascular risk factors were considered. Unfortunately, PTH levels were not available in this cohort, so it is impossible to determine the relative associations of this finding with calcium and calciotropic hormones.

The mechanism by which coronary heart disease might be associated with PHPT is also not well understood. Several studies have evaluated specific biomarkers of CHD, but a comprehensive assessment of CHD and these biomarkers have not been performed in the same cohort. Markers of inflammation and N-terminal pro-B-type natriuretic peptide that are associated with CHD were elevated in a study of hypertensive PHPT patients (Ogard *et al.,* 2005). In this study, 45 patients with PHPT and 40 matched controls were evaluated. Plasma N-terminal pro-B-type natriuretic peptide (NT-proBNP), high-sensitivity C-reactive protein, and tumor necrosis factor alpha, but not interleukin-6, were higher in patients with PHPT than in controls. NT-proBNP levels were correlated with systolic blood pressure, left-ventricular end-diastolic volume, and peak oxygen uptake (determined on a bicycle exercise test). No decrease in NT-proBNP, markers of inflammation or blood pressure was observed after parathyroidectomy with follow-up evaluations performed at 7 and 18 months. The investigators suggested that hypertension could explain the increased risk of inflammatory markers and NT-proBNP levels that could, in turn, increase cardiovascular mortality rates in this group of patients. Other studies have implicated increased levels of adipokines that are associated with the development of atherosclerosis and cardiovascular disease such as leptin in patients with PHPT and these levels correlated with body mass index (Delfini *et al.,* 2007). Although the connection between leptin and PHPT is not clear, leptin possess direct and indirect effects on bone cells, and the changes in bone remodeling that occur with PHPT may be responsible for the increased leptin levels.

One issue that is difficult to assess is whether patients with mild PHPT without hypertension would be at risk for cardiovascular disease. In a small study, selected patients with PHPT without any evidence of renal or cardiovascular complications were evaluated for heart disease (Barletta *et al.,* 2000). In these subjects, echocardiography of the heart revealed no structural abnormalities. In comparison to normal subjects, the left ventricular isovolumetric relaxation time was normal, but significantly shorter than for control subjects suggesting an increased sympathetic stimulation. The authors suggested that in mild PHPT,

cardiovascular function is essentially normal in those patients who are normotensive. These data have not been confirmed in a larger cohort of patients with PHPT.

There is a paucity of data regarding mortality of subjects with normocalcemic PHPT, but one study evaluated lipid levels in a small number of subjects with this disorder (Hagstrom *et al.*, 2006). In this study, individuals with normal serum calcium and an inappropriately high serum PTH were followed over a five-year period. At study entry, these subjects had higher serum levels of calcium, PTH, glucose, low-density lipoprotein/high density lipoprotein-cholesterol ratio (due to a lower HDL-cholesterol level), very low-density lipoprotein-cholesterol, and total triglycerides and a higher body mass index compared to controls. Subjects who underwent parathyroidectomy had a return of their serum calcium and proatherosclerotic lipoprotein levels to more favorable concentrations that were similar to levels of control subjects.

Genetic causes for an increase in cardiovascular risk have been explored for a specific polymorphism of the calcium-sensing receptor. The calcium-sensing receptor is a G-protein-coupled receptor that senses extracellular calcium levels and alters PTH release from the parathyroid gland. One of the more common polymorphisms in the calcium-sensing receptor is an alanine to serine change of amino acid 986. In healthy women, carriers of the S-allele results in asymptomatic, mild increases in calcium concentrations in (Cole *et al.,* 2001). Marz and colleagues evaluated subjects with this polymorphism for coronary heart disease, myocardial infarction, and cardiovascular mortality (Marz, 2007). Compared to AA homozygotes, the prevalence of CHD (odds ratio 1.25; 95% CI, 1.02–1.54) and myocardial infarction (odds ratio 1.33; 95% CI, 1.06–1.68) was increased in carriers of at least one S-allele. The prevalence of CHD and myocardial infarction increased with each S-allele. These associations were independent of cardiovascular risk factors, and calcium and phosphate levels. The S-allele impairs the sensitivity of the renal tubule to ambient calcium, reduces renal calcium elimination, and enhances the excretion of phosphate. The S-allele is likely to increase the set point of the parathyroid gland for calcium ions and increase PTH concentrations. These data indicate that a common genetic polymorphism of the calcium-sensing receptor was associated with angiographic CHD, previous myocardial infarction, and cardiovascular mortality, and that these associations were independent of well-established cardiovascular risk factors.

EVIDENCE FOR HYPERTENSION IN PATIENTS WITH HYPERPARATHYROIDISM

Several studies have addressed the clinical relevance of the association between parathyroid hormone levels and blood pressure measurements, despite a higher prevalence of hypertension in patients with PHPT than in the general population. In a population health survey, serum PTH levels were measured in a large number of subjects ages 39 to 79. In a follow-up study in 1998, 72 subjects had elevated levels of PTH and 100 subjects had normal serum PTH levels. After excluding patients with PHPT, measurements of serum calcium, serum vitamin D, bone mineral density, and systolic and diastolic blood pressure were obtained. Subjects with elevated PTH levels had significantly lower serum calcium levels and intakes of dietary calcium than those with normal PTH levels. Differences in vitamin D intake or serum levels did not differ between the two groups. Subjects with elevated levels of parathyroid hormone had significantly lower bone mineral density in the lumbar spine than those with normal PTH levels. Females with elevated serum PTH levels had significantly higher systolic and diastolic blood pressures, but this was not true for male subjects (Jorde *et al.,* 2000). A second study looked at the association between serum parathyroid hormone levels in normotensive elderly subjects undergoing 24-hour ambulatory blood pressure monitoring. In this group of 123 subjects ages 63 to 88, serum PTH levels correlated to nocturnal systolic blood pressure, nocturnal diastolic blood pressure, daytime systolic blood pressure, and mean 24-hour systolic blood pressure on univariate and multivariate analyses. Nocturnal, daytime, and mean 24-hour blood pressures were not correlated to serum calcium levels, 25(OH) concentrations, age, body mass index, or alcohol consumption. In this study, gender differences were also assessed and men were found to have higher diastolic blood pressure than women. The authors concluded that serum PTH levels were strongly related to blood pressure, particularly nocturnal blood pressure in elderly subjects (Morfis *et al.,* 1997).

To further explore the relationship between blood pressure and levels of PTH, interventional studies have been performed in human subjects. The acute administration of parathyroid hormone was utilized to mimic the role of secondary hyperparathyroidism in the pathogenesis of hypertension in patients with renal failure. Because uremia is characterized by insulin resistance and hyperinsulinemia, administration of physiologic doses of hPTH (1–34) was performed under conditions of a euglycemic clamp technique in 10 healthy male subjects. The study was a double-blind, crossover design using a sham infusion or 200 units of hPTH (1–34). The infusion of hPTH (1–34) resulted in a significant increase in mean arterial pressure compared to sham infusions. Changes in intracellular calcium concentration determined in platelets were significantly correlated with changes in mean arterial pressure, but insulin sensitivity was not affected by PTH infusion. Thus, subacute administration of physiologic doses of parathyroid hormone under hyperinsulinemic conditions alters intracellular calcium and blood pressure in healthy subjects (Fliser *et al.,* 1997).

Several hypotheses have been proposed for the mechanism of hypertension in patients with PHPT and include increased serum calcium levels, increased PTH levels (with attendant changes in cytokines and hormones), raised renin activity and hypomagnesemia. Hypercalcemia created by infusion of calcium to normal volunteers resulted in an increase in systolic and diastolic blood pressure. This may be mediated by a dose-related impairment of endothelial vasodilation (Nilsson, *et al.,* 2001). PTH infusion results in hypercalcemia and hypertension in normal subjects (Hulter *et al.,* 1986). Additional studies have suggested that PTH causes an increase in renin levels (Gennari *et al.,* 1995). In a cohort of subjects with PHPT, there were no differences in calcium or PTH levels between those with hypertension and normotensive individuals. However, plasma renin activity and plasma aldosterone levels were higher in the hypertensive patients. After surgery, blood pressure, renin and aldosterone levels became normal in 8 of the 10 hypertensive patients. Another study supports the hypothesis that hypomagnesemia and hypertension are related (Sangal *et al.,* 1989). In this retrospective analysis, magnesium levels were significantly lower in hypertensive PHPT patients compared to normotensive subjects. The mechanism by which magnesium may cause a change in blood pressure is thought to be due to the role of magnesium in altering vascular tone.

The effects of parathyroid hormone on the vasculature extends to potential actions on vascular reactivity as well as on the blood pressure per se. Nilsson *et al.* (1999) have shown that in primary hyperparathyroidism, there is an abnormal vasodilatory response to the local infusion of metacholine and nitroprusside. Parathyroid hormone modulates the secretion of endothelin-1, whereas endothelin-1, in turn, may influence parathyroid hormone secretion. Endothelin levels have been shown to be elevated in the plasma of patients with primary and secondary hyperparathyroidism (Lakatos *et al.,* 1996).

The most clinically relevant question is whether improvement of blood pressure will occur in patients following normalization of elevated levels of PTH. Several studies have evaluated blood pressure measurements before and after parathyroidectomy (Schleiffer, 1992). In most cases, hypertension persists after removal of the abnormal parathyroid gland(s) and restoration of PTH to normal levels (Sancho *et al.,* 1992). In one study of hypertensive patients on maintenance dialysis, 19 patients were evaluated one month before total parathyroidectomy, the first month after surgery, and also after 16 months. There was neither a clinically relevant nor a statistically significant change in either systolic or diastolic blood pressure over time (Ifudu *et al.,* 1998). Although most studies do not support this, there are limited data suggesting that hypertension may be reversible after surgery for PHPT (Nilsson *et al.,* 2005).

A recent study by Hedback and Oden compared the risk of death after surgery for PHPT in patients with and without hypertension. A series of 845 patients with PHPT was followed for a mean of 10.2 years after surgery. The risk of death was 50% higher in PHPT patients with hypertension than in those who were normotensive. However, the decline in risk of death following surgical cure was twice as great in those with hypertension as compared with those who were normotensive (Hedback and Oden, 2002).

OTHER CARDIOVASCULAR PROPERTIES IN PATIENTS WITH HYPERPARATHYROIDISM

In addition to the effects on blood pressure and cardiovascular mortality, parathyroid hormone has major effects in influencing cardiac function (Dipette *et al.,* 1992; Schluter and Piper, 1998). These actions include increases in heart rate, coronary blood flow, and contractility. PTH is active in the absence of changes in autonomic reflexes (Bogin *et al.,* 1981; Dipette *et al.,* 1992; Roca-Cusachs *et al.,* 1991; Tenner *et al.,* 1983). In isolated perfused hearts, parathyroid hormone is a positive inotropic agent (Nickols *et al.,* 1989).

To determine whether parathyroid hormone and parathyroid hormone related peptide (PTHrP) can directly stimulate cardiac contractility, the isolated, perfused rat heart was studied under conditions where the individual contributions of heart rate, coronary blood flow, and contractility could be assessed independently (Ogino *et al.,* 1995). In this model, both parathyroid hormone and PTHrP stimulated heart rate, coronary blood flow, and contractility in a dose-dependent manner. When heart rate was fixed by pacing, the effect on coronary blood flow and contractility was still appreciated. However, when heart rate and coronary blood flow were rendered constant pacing and by maximal dilatation maintained by treatment with nitroprusside, neither parathyroid hormone nor PTHrP could directly increase inotropy. These studies provide evidence that the cardiac actions of parathyroid hormone and PTHrP are mediated by effects on heart rate and coronary blood flow as compared with direct actions on contractility per se. More recent studies have suggested that the actions of parathyroid hormone and PTHrP on heart rate may be due to increases in the pacemaker current, I_f of the sinoatrial node (Hara *et al.,* 1995; Hara *et al.,* 1997). These observations provide an electrophysiological basis (Shimoyama *et al.,* 1998a) and, more recently, a biochemical basis (Shimoyama *et al.,* 1998b) for the actions of parathyroid hormone and PTHrP to directly alter automaticity of the heart.

On the clinical side, Smith *et al.* (2000) have shown that in mild PHPT, certain indices of vascular stiffness were higher than in control subjects. The augmentation index is a measure of arterial stiffness that is a strong independent marker for premature coronary artery disease. Rubin *et al.* (2005) evaluated this index in mild PHPT and adjusted for confounding factors such as age, gender, heart rate, height, blood pressure, diabetes mellitus, smoking, and hyperlipidemia. Thirty-nine patients with mild PHPT were

compared to 134 healthy controls. The patients with mild HPT had an increased augmentation index, an early measure of arterial stiffness. Another measure of cardiovascular function, flow-mediated dilation, is an early marker of atherosclerotic degeneration and correlates with coronary endothelial dysfunction. In a prospective study, endothelium-dependent, flow-mediated dilation was impaired in patients with PTH compared to controls (Baykan *et al.,* 2007). Other authors have found that successful parathyroidectomy will improve this parameter of endothelial dysfunction (Kosch *et al.,* 2000).

Other parameters of cardiovascular function that have been evaluated in PHPT include measures of the autonomic nervous system. In PHPT, the diurnal variation in parathyroid hormone secretion is attenuated, which might result in an increased risk for CHD. Nilsson *et al.* (2003) evaluated heart rate variability and circadian rhythm in patients with PHPT compared to control subjects. PHPT patients had lower maximal heart rates than controls, but the finding was not statistically significant. Other findings were consistent with an imbalance in cardiac autonomic regulation in hyperparathyroidism with a diminished responsiveness to autonomic input. Another study found no differences in blood pressure profiles, heart rate, or left ventricular mass in a small number of patients and controls, but noted a statistically significant greater increase in carotid intimal-medial thickness, with a trend to more frequent atherosclerotic plaques (Nuzzo *et al.,* 2002). Because this study was limited to patients with marked hypercalcemia, one cannot know what the results would have been if those with mild PHPT had also been studied.

Other markers of endothelium dysfunction have been explored in a small study by Fallo and colleagues (Fallo *et al.,* 2006). Twenty patients with PHPT had measurements of endothelial activation: plasma thrombomodulin, soluble E-selectin, and von Willebrand factor, before and one year after parathyroidectomy. The patients were divided into two groups depending on the absence (n = 8) or presence (n = 12) of one or more cardiovascular risk factors. Baseline thrombomodulin levels were similar in the two groups and similar to a group of control, normocalcemic subjects. Soluble E-selectin and von Willebrand factors were higher in patients with PHPT with risk factors compared to PHPT patients without cardiovascular risk factors and controls. After surgery, neither thrombomodulin nor soluble E-selectin changed, but plasma von Willebrand factor decreased in patients without risk factors and persisted at elevated levels in those patients with cardiovascular risk factors.

Left Ventricular Dysfunction

Some studies have implicated that patients with a history of PHPT have an increase in congestive heart failure. The reasons for this effect on the cardiovascular system are likely to be multifactorial. Evaluation of left ventricular mass index in patients with PHPT was performed in a group of patients that underwent surgery and compared to a second group that was observed for one year. Left ventricular mass index was larger in the group of patients with PHPT that were observed for one year and the measure correlated with serum concentrations of PTH, but not serum calcium levels (Almqvist *et al.,* 2002). Subclinical changes included a reduction in left ventricular ejection fraction. Several studies have suggested that intervention can reverse these findings, although in some studies, reversible changes were documented only in hypertensive patients (Stefenelli *et al.,* 1997; Piovesan *et al.,* 1999; Nilsson *et al.,* 2000, Nilsson *et al.,* 2005). Nilsson and colleagues, reporting on a cohort with more severe hypercalcemia than is common in the United States, suggested that these findings were coupled with evidence for higher systolic blood pressure, an increase in the number of extrasystolic beats and an increase in ST-segment depression during exercise, all of which were reversible by parathyroidectomy (Nilsson *et al.,* 2000). In another study, myocardial perfusion defects and left ventricular ejection fracture was evaluated in a small sample of patients with PHPT (Ogard *et al.,* 2005). Only patients without a history of myocardial infarction, angina pectoris, or diabetes participated in the study. Using ^{99m}Tc-sestamibi scanning, 5 of 22 subjects had myocardial perfusion defects above 15% at rest. The patients with the perfusion defects had significantly higher levels of PTH than those without a perfusion defect. There were no differences in plasma ionized calcium levels. Patients with the perfusion defects also had a decreased left ventricular ejection fraction. This was a small, uncontrolled study, which suggests that larger evaluation of these findings is warranted. The reversibility of left ventricular dysfunction was assessed by Piovesan *et al.* (1999). Evaluation of left ventricular hypertrophy in patients with PHPT who underwent surgery indicated that the abnormal findings on echocardiography were reversible six months after surgery.

Reversibility of cardiovascular dysfunction after parathyroidectomy was evaluated in 30 consecutive patients with PHPT (mean baseline serum calcium 11.8 mg/dl) who were followed for one and five years postsurgery. Thirty matched controls and the PHPT patients underwent echocardiography and a bicycle exercise test (Nilsson *et al.,* 2005). Serum calcium levels were normal in all patients and normal subjects at five years. Although the maximal blood pressure during exercise was higher before parathyroidectomy, it was not different five years after surgery. ST-segment depression diminished after surgery and the number of ventricular extrasystolic beats at exercise testing before parathyroidectomy was higher in the patient group than in the control group. The authors concluded that successful surgery for PHPT can induce improvements in the regulation of blood pressure, left ventricular diastolic function, and cardiac irritability, which may have implications for cardiac mortality for patients with PHPT.

SUMMARY

Cardiovascular disease and mortality have been associated with PHPT. Various mechanisms have been implicated such as endothelial dysfunction, decreased vascular compliance, autonomic dysfunction, left ventricular hypertrophy, and hypertension. Most studies have had a relatively small number of subjects, have been retrospective in design, and have measured a limited number of variables. It is possible that the seemingly contradictory results of some studies on the cardiovascular manifestations of PHPT may be explained by the evolution of the clinical picture of PHPT. What was once a disease characterized by marked hypercalcemia, and PTH levels that were also very elevated, is now, more commonly a disorder in which hypercalcemia is not extreme (indeed, serum calcium levels are often within 1 mg/dl of the upper end of the normal range) and PTH elevations are similarly moderate. Thus the cardiovascular manifestations of PHPT may well present along a continuum, related to the extent of elevation in PTH, calcium, or both. Longer and larger prospective studies of well-defined populations are needed to understand these relationships more completely.

Chapter 32

PTH and PTHrP Actions on Kidney and Bone

Alessandro Bisello and Peter A. Friedman*
Department of Pharmacology, University of Pittsburgh School of Medicine, Pittsburgh, PA

INTRODUCTION

This chapter reviews accepted concepts and considers controversial or unsettled elements of parathyroid hormone (PTH) and PTH-related protein (PTHrP) actions. Recent advances in our understanding of the mechanisms and regulatory actions of PTH and PTHrP on kidney and bone are introduced. Mineral ion homeostasis is regulated primarily by the kidneys, largely through the actions of PTH. PTHrP exerts actions on the kidney that are associated with controlling renal vascular tone, though its physiological role is unsettled (Mundy and Edwards, 2008). In bone, PTHrP is a major hormonal regulator of bone formation, whereas PTH contributes to postnatal skeletal integrity. Bone and kidney form a storage and regulatory axis that ensures normal growth, development, and multiple tissue and cellular functions that intimately depend on stringent control of intra- and extracellular mineral ion concentrations. This regulation is accomplished principally in the kidneys. Therefore, the renal effects of PTH and PTHrP action will be discussed first to provide a framework for understanding their actions on bone.

PTH ACTIONS ON KIDNEY

By regulating renal tubular absorption of calcium and phosphate and the synthesis of $1,25(OH)_2D_3$, PTH controls urinary excretion and intestinal absorption of these mineral ions. Renal tubular responses to PTH deficiency, PTH or PTHrP excess, or defects in function of the type 1 PTH/PTHrP receptor (PTH1R) lead to alterations in blood calcium, phosphate, or dihydroxyvitamin D_3 [$1,25(OH)_2D_3$] that are the hallmarks of numerous clinical disorders, described later in this volume. This chapter reviews the mechanisms of PTH and PTHrP control of renal tubular calcium and phosphate absorption. The discussion focuses principally on PTH because distinct or unique PTHrP actions on tubular ion transport are not well delineated. Because the amino termini of both ligands are similarly recognized by the PTH1R, it is likely that PTHrP shares the effects of PTH. Expression and specific renal actions of PTHrP are associated with regulation of renovascular hemodynamics and may have important effects on hypertension (Massfelder *et al.*, 1998; Massfelder and Helwig, 1999).

Although magnesium is an important mineral ion, its serum levels do not appear to be significantly regulated by PTH and, therefore, will not be discussed further here. Reviews of renal magnesium transport can be found elsewhere (Konrad *et al.*, 2004) and in previous editions of this chapter (Bringhurst and Strewler, 2002).

CALCIUM AND PHOSPHATE HOMEOSTASIS

Serum Calcium

Plasma calcium concentrations in adults average 2.5 mmol/L (or, 5mEq/L, 10 mg/dL[1]). Calcium in plasma is present to varying extents in protein-bound, complexed, and ionized forms. Approximately 45% of the serum calcium is bound to plasma proteins, mostly to albumin. Smaller amounts are bound to globulins. Only a negligible amount of calcium is bound to fibrin. Therefore, serum and plasma calcium concentrations are generally indistinguishable (Miles *et al.*, 2004). Another 45% of serum calcium is ionized (or "free"). The remaining 10% of serum calcium is associated with small polyvalent anions such as bicarbonate, phosphate, and sulfate. Such ion pairs, e.g., calcium bicarbonate, which form by electrostatic forces, are called to as "calcium complexes." Together, ionized and complexed calcium are referred to as "diffusible" because only

[1]Concentrations of calcium and phosphate are expressed here in SI units (mmol/L). Although more traditional units remain in use, they are confusing for multivalent ions and, in the case of P_i, are ambiguous because the concentration of the different forms is dependent upon pH.

Principles of Bone Biology, 3rd Edition

diffusible calcium is filtered at the glomerulus and is able to cross cell membranes.

Ultrafilterable and ionized fractions of calcium are affected by changes in the total serum calcium concentration, blood pH, plasma protein concentration, and the concentration of complexing anions. Increases in the total serum calcium concentrations are usually accompanied by concomitant elevations of ultrafilterable calcium to a total concentration of about 4 mM (Edwards *et al.*, 1974; Le Grimellec *et al.*, 1974). This upper limit in calcium ultrafiltration with hypercalcemia has been postulated to result from the formation of insoluble $Ca_3(PO_4)$–protein complexes. This idea is supported by the finding that the ultrafilterable phosphate concentration also declines (Cuche *et al.*, 1976). Conversely, hypocalcemia is generally associated with a decline of calcium ultrafiltration (Terepka *et al.*, 1957).

Changes in the concentration of serum proteins are usually accompanied by parallel alterations of total serum calcium concentration such that the ultrafilterable fraction remains constant (Loeb, 1926; Marshall, 1976; Peterson *et al.*, 1961). In severe hypoproteinemia, however, the ultrafilterable fraction increases (Hopkins *et al.*, 1952; Terepka *et al.*, 1957).

Ionized Ca^{2+} varies inversely with blood pH. Acidemia increases ionized Ca^{2+}, whereas alkalosis decreases Ca^{2+} (Hopkins *et al.*, 1952; Loeb, 1926; Peterson *et al.*, 1961). Ionized Ca^{2+} concentrations also change inversely with variations of serum anions. For instance, elevation of phosphate, citrate, sulfate, or bicarbonate increases the serum-free Ca^{2+} secondary to augmented formation of calcium complexes (Walser, 1973).

Symptoms of hypocalcemia vary in relation to the ionized serum calcium concentration. Mild reductions of plasma calcium are associated with paresthesia and muscle cramps; more severe decreases of calcium may induce seizures. Hypercalcemia, on the other hand, has been implicated in the attenuation of the renal effects of PTH, the antidiuretic action of vasopressin, and reduced renal concentrating capacity (Gill and Bartter, 1961; Takaichi and Kurokawa, 1986). The calcium concentration in the extracellular fluid represents a dynamic balance between intestinal absorption, renal reabsorption, and osseous resorption. The parameters affecting calcium balance for an adult are schematically shown in Figure 1. Bidirectional calcium movement from intestine, kidney, and bone are shown and representative magnitudes are provided. Assuming a daily dietary calcium intake of 1000 mg, net intestinal absorption amounts to about 200 mg, with the remaining 800 mg excreted in the feces. When in balance, net intestinal absorption is matched by urinary excretion, whereas calcium accretion and loss from bone are equal. Thus, approximately 200 mg of calcium are excreted daily. In adults, net calcium balance is effectively zero, suggesting that, in the absence of a calcium challenge such as lactation, the kidneys represent the dominant regulatory site of calcium metabolism (Peacock *et al.*, 1969).

Phosphate Chemistry

Terrestrial mammals are characterized by their avidity for calcium and equally keen mechanisms to eliminate phosphorous. Elemental phosphorous (P) exists in both organic and inorganic (P_i) forms. Organic forms include phospholipids and various organic esters. The bulk of phosphate in extracellular fluid exists as the inorganic forms, NaH_2PO_4 and Na_2HPO_4. The Henderson relation determines the ratio of the two:

The dissociation constant, pKa, for phosphate is 6.8. Thus, at pH 7.4, the ratio is essentially 4:1 and the plasma phosphate has an intermediate valence of 1.8.[2]

Serum Phosphate

As in the case of calcium, not all serum P_i is ultrafilterable (see later). Small amounts are bound to plasma proteins. However, some 90%, whether ionized or complexed with Ca, Mg, or Na, is filtered at the glomerulus. Ultrafilterable P_i decreases with elevation of Ca or P_i, presumably because of formation of high-molecular-weight protein complexes.

Although it is commonly stated that P_i is freely and completely filtered at the glomerulus, this is incorrect. Ten percent of the plasma P_i is bound to protein and is not filtered. However, the reduction in ultrafilterable P_i is counterbalanced by an opposite Gibbs–Donnan effect that raises

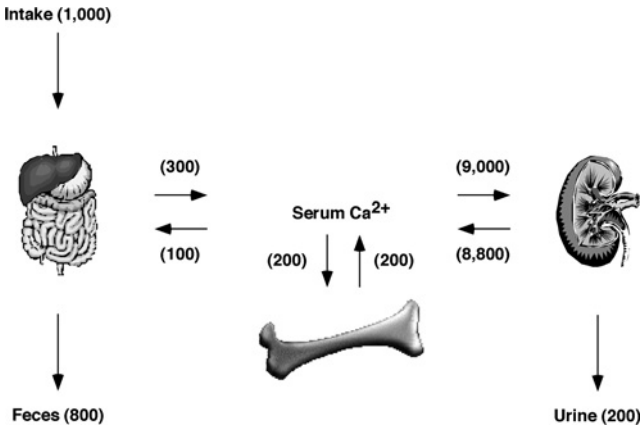

FIGURE 1 Extracellular calcium balance in the adult human. Numeric values for calcium intake, excretion, and fluxes are in mg/day for a 70-kg individual. Original data are from Wilkinson (1976). The recommended adult American daily diet includes 1000 mg of calcium though actual diets generally contain less elemental calcium (Heaney *et al.*, 1975; Mundy, 1990). Using an assumed intake of 1000 mg, 800 mg are excreted in feces and 200 mg in urine.

[2]The net valence is calculated from the total number of negative charges, $2 \times 4 + 1$, divided by the number of molecules, $4 + 1$, as determined by the Henderson relation, viz., $9/5 = 1.8$. Thus, at pH 7.4, 1 mmol of phosphorous = 1.8 mEq.

the P_i concentration in the ultrafiltrate. Correcting the volume occupied by plasma proteins (7%) raises the ultrafiltrate P_i concentration by an additional 7.5% mitigating the reduction of protein-bound P_i. Indeed, both *in vivo* and *in vitro* measurements show that the ratio of ultrafilterable P_i to total plasma P_i is close to unity (Harris *et al.*, 1974).

PTH Actions on Mineral Ion Homeostasis

By regulating renal tubular absorption of calcium and phosphate and the synthesis of $1,25(OH)_2D_3$, PTH controls urinary excretion and intestinal absorption and of these mineral ions. Renal tubular responses to PTH deficiency, PTH or PTHrP excess, or defects in function of the PTH1R, lead to alterations in blood calcium, phosphate, or $1,25(OH)_2D_3$ that are the hallmarks of numerous clinical disorders, described later in this volume. This chapter reviews current understanding of the mechanisms whereby PTH (and PTHrP) controls renal tubular epithelial function. Because PTH and PTHrP actions in kidney and bone are mediated by the PTH1R, its expression, signaling, and trafficking are presented first as a foundation for understanding hormone actions. Although PTH or PTHrP receptors distinct from the PTH1R have been described (see Chapter 24), their role, if any, in normal renal physiology is unknown. Although not unequivocally proven in each case, it is likely that the effects of PTH and PTHrP described here are mediated by the PTH1R.

PTH1R EXPRESSION, SIGNALING, AND REGULATION IN THE KIDNEY

The PTH1R is expressed both on renal tubular epithelial cells and vascular endothelial cells. The response to PTH1R activation observed in individual renal cells depends on the number and location of PTH1Rs; the expression of cell-specific adapter proteins that modify PTH1R signaling; the array of PTH1R-inducible genes; effector proteins including enzymes, ion channels, and transporters; the local concentration of PTH or PTHrP; exposure to other agents that heterologously regulate PTH1R function; and the history of recent exposure to PTH or PTHrP, which affect the state of receptor desensitization.

PTH1R Expression within the Kidney

Renal localization of the PTH1R was deduced initially from the physiological effects of infused PTH extracts on phosphate and calcium absorption (Lambert *et al.*, 1964; Widrow and Levinsky, 1962). These and similar studies pointed to prominent actions on proximal and distal tubules, respectively. Subsequent investigation amply confirmed the actions of PTH to block P_i absorption by proximal tubules (Agus *et al.*, 1971) and to stimulate calcium absorption by distal nephron segments (Sutton and Dirks, 1975). Later examination of the nephron sites at which PTH promoted cAMP formation (Table I) was generally

TABLE I Stimulation of Adenylyl Cyclase Activity by PTH in Nephron Segments

consistent with the pattern of PTH effects. Some distinct species differences also emerge from this analysis. After the PTH1R was cloned, RT-PCR and *in situ* hybridization techniques were used to define the nephron sites of mRNA expression (Lee *et al.*, 1996; Riccardi *et al.*, 1996; Yang *et al.*, 1997). General consensus pointed to conspicuous PTH1R expression in the glomerulus, proximal convoluted and proximal straight tubules, cortical ascending limbs and distal convoluted tubules. Some differences may also be noteworthy. Riccardi and Hebert additionally reported PTH1R expression in rat cortical collecting ducts (Riccardi *et al.*, 1996), a finding not confirmed by Yang *et al.* (1997). Functional examination of PTH actions on Ca absorption by rabbit cortical collecting duct failed to disclose detectable effects (Shareghi and Stoner, 1978; Shimizu *et al.*, 1990b), a nephron site where evidence for cellular calcium transport could not be found (Bourdeau and Hellstrom-Stein, 1982). Of course, PTH1Rs in cortical collecting duct could mediate other regulatory events such as modulating proton secretion and acid–base balance.

More precise PTH1R localization was undertaken by immunoelectron microscopy and immunofluorescence localization. As expected, PTH1R protein was detected on basolateral membranes of proximal convoluted tubule cells (Amizuka *et al.*, 1997). Unexpectedly, and, to a lesser extent, immunoreactivity was found also on the luminal surface. Endothelial cells of the cortical capillaries expressed at high levels of PTH1R. Vascular staining was detected on the surface of glomerular podocytes but not in glomerular vascular endothelial cells. Moderate immunoreactivity was detected in medullary collecting ducts. Other studies employing immunofluorescence detection likewise found both luminal and basolateral PTH1R expression in proximal tubules (Ba *et al.*, 2003). Considerably stronger staining was present in thick ascending limbs of Henle's loop, where both apical and basolateral receptors were detected. By contrast, PTH1R expression in distal convoluted tubules is distributed only on basolateral surfaces. Possible roles of apical membrane PTH1Rs are discussed later.

Considerable evidence points to the bilateral presence of PTH1Rs on apical and basolateral surfaces of proximal tubules. However, PTH actions are asymmetrical (Quamme *et al.*, 1989; Reshkin *et al.*, 1990, 1991). This suggests differential PTH1R coupling to G proteins on apical and basolateral membranes, the presence of adapter proteins such as NHERF1 or AKAPs that modify or specify second messenger signaling, or that the receptor has different functions when present on apical cell membranes. The former possibility seems unlikely because G_s is amply expressed in brush-border membrane vesicles (Brunskill *et al.*, 1991; Stow *et al.*, 1991; Zhou *et al.*, 1990). Interestingly, inhibitory G_i isoforms are found only on apical and not basolateral proximal tubule cells (Stow *et al.*, 1991).

Radioligand-binding studies indicate that PTH1Rs are expressed on glomeruli, apical and basolateral membranes of proximal tubules, cortical thick ascending limbs of Henle's loop, and distal convoluted tubules (Kaufmann *et al.*, 1994; Rouleau *et al.*, 1986). Although the apical expression of PTH1Rs was unexpected, it can be reconciled with the fact that circulating PTH peptides are presumably filtered at the glomerulus and appear in the urine (Bethune and Turpin, 1968). However, apical membrane receptors appear not to be coupled tightly, if at all, to adenylyl cyclase (Kaufmann *et al.*, 1994; Shlatz *et al.*, 1975). Moreover, a high-capacity apical peptide-uptake mechanism, mediated by the multifunctional endocytic clearance receptor megalin (Hilpert *et al.*, 1999) limits the access of filtered bioactive PTH peptides to these receptors. Downstream cortical ascending limbs and distal convoluted tubule sites would be unlikely to encounter biologically meaningful amounts of PTH.

An entirely different function for apical PTH receptors can be envisioned, whereby they serve as clearance receptors. Such a view is supported by studies that examined the disposition of radioiodinated PTH by isolated perfused kidneys. In these studies, the accumulation, extraction, and catabolism of PTH was primarily accomplished from the luminal surface (Kau and Maack, 1977). Such a mechanism, especially when complemented by megalin, would explain the virtual absence of PTH from urine (Hilpert *et al.*, 1999).

As described in more detail in Chapter 24, the PTH1R gene incorporates multiple promoters and 5′-untranslated exons and therefore can generate various transcripts by alternative promoter usage and different patterns of RNA splicing (Amizuka *et al.*, 1997; Bettoun *et al.*, 1998; Jobert *et al.*, 1996; Joun *et al.*, 1997; McCuaig *et al.*, 1995). P1 and P3 promoters in mouse and human, respectively, seem to be used exclusively in kidney cells, whereas the P2 promoter is employed to generate PTH1R mRNAs that are widely expressed in extrarenal tissues and organs (Amizuka *et al.*, 1997; Bettoun *et al.*, 1998; Joun *et al.*, 1997). It is presently unknown whether these differences simply reflect opportunities for tissue-specific gene regulation or lead to expression of structurally different forms of the PTH1R (Jobert *et al.*, 1996; Joun *et al.*, 1997).

PTH1R Signal Transduction in Renal Cells

The PTH1R exerts its biological actions by activating various signaling pathways. Activation is mediated by G_s, $G_{q/11}$, G_i, and G_{12}/G_{13} heterotrimeric G proteins (Abou-Samra *et al.*, 1992; Offermanns *et al.*, 1996; Schwindinger *et al.*, 1998; Singh *et al.*, 2005) (see also Chapters 27 and 67). In most cells and tissues, the PTH1R signals by activating G_s or $G_{q/11}$ (Abou-Samra *et al.*, 1992; Bringhurst *et al.*, 1993). In some instances the PTH1R couples with both G_s and $G_{q/11}$ resulting in activation of adenylyl cyclase and phospholipase C (PLC). In certain instances, however, the PTH1R couples only to a single pathway and does so in

a cell-specific manner. For example, in vascular smooth muscle cells, PTH stimulates adenylyl cyclase but not PLC (Maeda *et al.*, 1996; Wu *et al.*, 1993), whereas in keratinocytes (Orloff *et al.*, 1992, 1995; Whitfield *et al.*, 1992), cardiac myocytes (Rampe *et al.*, 1991; Schlüter *et al.*, 1995), and lymphocytes (Atkinson *et al.*, 1987; Klinger *et al.*, 1990; Whitfield *et al.*, 1971), PLC but not adenylyl cyclase is activated. The particular coupling mechanism depends on the cell type in a manner that remains incompletely understood.

PTH administration leads to the rapid excretion of cAMP in the urine, which is referred to as nephrogenous cAMP (Chase and Aurbach, 1967). This effect has been employed as a clinical test to distinguish between primary and secondary hyperparathyroidism (Broadus, 1979). Practically speaking, nephrogenous cAMP is formed exclusively in proximal tubules because of the relative mass of proximal tubules compared with other nephron segments that express PTH1Rs. Further, although PTH-induced nephrogenous cAMP is a robust index of the phosphaturic action of PTH, it fails to disclose the effects of PTH on calcium absorption by distal tubules. Several reasons may account for this including the profusion of proximal tubules compared with distal tubules, receptor abundance on the two cell types, the presence of modifying proteins that alter the coupling of the PTH1R to G proteins, and the signaling array employed.

Considerable evidence indicates that in kidney epithelial or vascular cells PTH can stimulate adenylyl cyclase with attendant formation of cAMP and activation of protein kinase A (PKA); PLC with consequent generation of inositol phosphates + diacylglycerol, release of intracellular calcium, and activation of PKCs, as well as phospholipase A_2 (PLA_2) (Derrickson and Mandel, 1997; Ribeiro *et al.*, 1994; Ribeiro and Mandel, 1992) and phospholipase D (PLD) (Friedman *et al.*, 1996, 1999). Other signaling mechanisms may participate in mediating PTH1R actions in renal cells. For example, PTH-induced activation of mitogen-activated protein kinases in renal epithelial cells may proceed by activation of nonreceptor tyrosine kinases, transactivation of EGF receptors, with subsequent assembly of active Ras/Raf-1/MEK complexes (Cole, 1999; Lederer *et al.*, 2000; Sneddon *et al.*, 2000, 2007).

PTH1R signaling appears to differ depending on the nephron segment where it is expressed. For example, PTH provokes rapid and transient elevations ("spikes") of Ca_i^{2+} in proximal tubules and cells derived from them (Filburn and Harrison, 1990; Friedman *et al.*, 1999; Hruska *et al.*, 1986, 1987; Tanaka *et al.*, 1995). This response is characteristic of PLC activation, as opposed to calcium influx, and results from the formation of inositol trisphosphate and its action to provoke calcium release from endoplasmic reticulum. Distal tubule cells, in contrast, exhibit a delayed and sustained Ca_i^{2+} response to PTH. This effect is because of apical membrane Ca^{2+} entry (Bacskai and Friedman, 1990) and is inhibitable by dihydropyridine-type calcium channel blockers (Gesek and Friedman, 1992b). Furthermore, although PTH-stimulated elevation of Ca_i^{2+} in distal tubule cells involves PLC-independent protein kinase C (PKC) activation (Friedman *et al.*, 1996), PTH-induced PKC activation in distal tubule cells is mediated by PLD (Friedman *et al.*, 1999).

PTHrP, though not as exhaustively characterized, exerts effects on Ca_i^{2+} that are similar to those seen with PTH (Abou-Samra *et al.*, 1992; Bringhurst *et al.*, 1993; Yamamoto *et al.*, 1989). Recent clinical studies revealing a larger calcemic action of PTH compared with PTHrP owing to greater renal $1,25(OH)_2$ vitamin D production (Horwitz *et al.*, 2005) will surely provoke further examination of the mechanistic details by which PTH and PTHrP bind and activate the PTH1R (Dean *et al.*, 2008).

Regulation of PTH1R Signaling in Renal Cells

The magnitude of physiological responses mediated by the PTH1R is tightly linked to the balance between signal generation and signal termination. Rapid termination of PTH1R signaling is mediated by receptor desensitization and internalization, whereas prolonged reduction in responsiveness is caused by downregulation and diminished receptor biosynthesis. Desensitization and internalization of the PTH1R, as with other G protein-coupled receptors is generally thought to be regulated by intracellular proteins, termed arrestins, and by G protein-coupled receptor kinases (GRKs). Hormone-induced receptor phosphorylation facilitates binding between the receptor and arrestin. Phosphorylation may be mediated by both second messenger-dependent protein kinases, e.g., PKA and PKC, and by GRKs. Just as receptor desensitization provides a mechanism to protect cells against excessive stimulation, resensitization guards cells against prolonged inactivity and hormone resistance. As in other PTH/PTHrP target cells, the responsiveness of renal epithelial cells to PTH or PTHrP may be regulated both by previous or chronic exposure to the homologous ligand and by other agonists that do not interact directly with the PTH1R. Desensitization of renal cellular responsiveness during continuous exposure to high concentrations of PTH or PTHrP has been well documented and studied extensively. Chronic hyperparathyroidism, either primary or secondary to calcium or vitamin D deficiency, as well as acute infusion of PTH, leads to PTH resistance in humans or animals, which is manifested by impaired cAMP and phosphaturic responses (Bellorin-Font *et al.*, 1995; Carnes *et al.*, 1980; Forte *et al.*, 1976; Tomlinson *et al.*, 1976; Tucci *et al.*, 1979). The nephrogenous cAMP reaction to PTH in humans desensitizes more readily than the phosphaturic response at low doses of hormone (Law and Heath, 1983).

Similar desensitization is observed in cultured renal epithelial cells (Fujimori *et al.*, 1993; Guo *et al.*, 1997; Henry *et al.*, 1983; Pernalete *et al.*, 1990; Ureña *et al.*, 1994).

GPCR activation is generally followed by a loss of responsiveness, termed desensitization. Receptor desensitization protects cells against excessive stimulation and may be rapid or develop only slowly. Although receptor desensitization is caused by phosphorylation of the PTH1R by GRKs and arrestin-mediating uncoupling with the cognate G proteins that mediate effector activation, hormone resistance may also arise by receptor downregulation, i.e., reduced expression of cell surface PTH1Rs. Receptor downregulation can arise from diminished receptor synthesis, increased receptor degradation, or a combination of the two. The relative roles of receptor desensitization or downregulation in causing PTH1R refractoriness appear to vary with the specific situation and experimental system (Carnes *et al.*, 1978; Forte *et al.*, 1976; Mahoney and Nissenson, 1983; Mitchell *et al.*, 1988; Tamayo *et al.*, 1982; Turner *et al.*, 1995).

GPCR desensitization occurs as a consequence of uncoupling the receptor from its cognate G protein in response to phosphorylation of Ser or Thr residues within the intracellular tail. Upon ligand binding to the PTH1R, the receptor is phosphorylated both by G protein receptor kinases (GRKs) and by second messenger-dependent protein kinases, PKA and PKC (Blind *et al.*, 1996; Dicker *et al.*, 1999; Flannery and Spurney, 2001). Phosphorylation of Ser residues in the PTH1R is mediated by G protein-coupled receptor kinase-2 (GRK2) (Dicker *et al.*, 1999; Malecz *et al.*, 1998), and to a lesser extent by PKC (Castro *et al.*, 2002). GRK2 preferentially phosphorylates the distal sites of the intracellular PTH1R tail, whereas PKC phosphorylates more upstream residues (Blind *et al.*, 1996). Nonetheless, PTH1R phosphorylation is not required for the interaction of the PTH1R with β-arrestin and receptor internalization (Dicker *et al.*, 1999; Ferrari *et al.*, 1999; Malecz *et al.*, 1998; Sneddon *et al.*, 2002).

The particular signals mediating PTH1R desensitization in renal epithelial cells is complex and may be cell-type specific. It was suggested that homologous desensitization of the PTH1R in opossum kidney (OK) proximal tubule-like cells is mediated by PKC (Pernalete *et al.*, 1990). However, further and more detailed analysis revealed that neither PKC nor PKA mediated PTH-induced PTH1R desensitization because blockade of PKA with H-89 or of PKC with bisindolylmaleimide-1 did not inhibit phosphorylation (Blind *et al.*, 1995). These results suggest that agonist-stimulated PTH1R phosphorylation and desensitization involves GRKs. Indeed, GRK2 was shown specifically to mediate PTH(1–34)-induced receptor phosphorylation (Malecz *et al.*, 1998). Mutagenesis of serine residues 483, 485, 486, 489, 495, and 498 within the carboxy-terminal tail of the PTH1R abolished GRK2-mediated phosphorylation. However, the rate and extent of PTH-stimulated internalization of the phospho-deficient PTH1R was indistinguishable from that of the wild-type PTH receptor. Nonetheless, inhibition of PTH1R desensitization by GRKs was seen in the absence of receptor phosphorylation, suggesting that inhibition is effected prior to phosphorylation and that GRK binding to the PTH1R may by itself impair receptor signaling (Dicker *et al.*, 1999). Subsequent β-arrestin binding may stabilize this inhibition and initiate receptor internalization.

As noted earlier, the PTH1R signals facultatively through adenylyl cyclase and PLC. In LLC-PK_1 kidney cells stably overexpressing the PTH1R, PTH increases cAMP and inositol phosphate accumulation (Guo *et al.*, 1995). Continuous exposure to PTH causes desensitization of both adenylyl cyclase and PLC (Guo *et al.*, 1997). Desensitization may be pathway specific. Treatment with forskolin reduced subsequent cAMP formation but not inositol phosphate formation in response to a challenge with PTH. Conversely, exogenous PLC activation with a phorbol ester produced desensitization, albeit modest, of inositol phosphate formation but not of cAMP accumulation (Guo *et al.*, 1997). Remarkably, receptor desensitization proceeded without concomitant downregulation of cell surface receptor expression, an exception to the normal pattern of coupled desensitization and PTH1R downregulation (Mitchell and Goltzman, 1990; Teitelbaum *et al.*, 1986).

PTH1R abundance may modulate the signaling pathway employed, as well as the relative and absolute intensities of signaling. Guo and Bringhurst generated LLC-PK_1 cells stably expressing PTH1R at densities of 20,000 to 400,000 receptors per cell (Guo *et al.*, 1995). Receptor density had a negligible effect on PTH-stimulated adenylyl cyclase insofar as cAMP accumulation was essentially maximal even at the lowest levels of receptor number. Half-maximal stimulation occurred at a PTH(1–34) concentration of 2 n*M*. In contrast, activation of PLC by PTH(1–34) was strongly dependent on PTH1R density, increasing exponentially as a function of receptor copy. Maximal stimulation was achieved only at receptor numbers of 400,000 per cell. The EC_{50} for stimulation was 25 n*M*. These findings are consistent with the view that the PTH1R couples more efficiently with G_s than with $G_{q/11}$. If these observations can be extended to other cells and to intact tissue, they suggest that receptor density has little effect on the potency of adenylyl cyclase stimulation. The results also provide a mechanism for the differential modulation of PTH1R signaling responses in a given renal cell.

Rapid internalization of PTH1Rs following ligand occupancy also contributes to abrogating further activation and signaling by reducing cell surface receptor expression (Bisello *et al.*, 2002; Malecz *et al.*, 1998; Sneddon *et al.*, 2003; Wang *et al.*, 2007). Recent work disclosed that PTH1R internalization, like activation, occurs in a ligand- and renal cell-specific manner. It was well established that full PTH1R agonists such as PTH(1–34) or PTHrP elicited prompt receptor internalization (Bounoutas *et al.*, 2006; Huang *et al.*, 1995, 1999; Sneddon and Friedman, 2007; Sneddon *et al.*, 2003; Tawfeek *et al.*,

2001; Teitelbaum *et al.*, 1986; Wheeler and Sneddon, 2006). Although the PTH1R lacks a canonical NPXXY internalization motif, other endocytotic signals have been identified within the carboxy terminus. Detailed analysis of the intracellular tail of the PTH1R revealed bipartite sequences that negatively or positively regulate receptor endocytosis (Huang *et al.*, 1995). An endocytic signal was detected within residues 475 to 494 of the opossum kidney PTH1R (corresponding to D482 to S501 of the human PTH1R). Mutations or deletions within this region result in diminished PTH-induced receptor endocytosis (Huang *et al.*, 1995; Sugai *et al.*, 2003). A smaller sequence (EVQ), which is present in other Family B receptors, is a negative regulator of endocytosis and, when removed, results in enhanced receptor internalization (Huang *et al.*, 1995; Vazquez *et al.*, 2005).

Expression of PTH1Rs on the surface of kidney cells is also controlled by the rate of PTH1R gene transcription, although current understanding of this process is incomplete. Hypoparathyroidism, induced by either parathyroidectomy or dietary phosphate depletion, upregulates PTH1R mRNA levels in rat renal cortex (Kilav *et al.*, 1995). However, high concentrations of PTH have no detectable effect on PTH1R mRNA (Kilav *et al.*, 1995; Ureña *et al.*, 1994). Renal PTH1R mRNA expression is reduced in rats with renal failure, but this apparently is caused by some aspect of uremia or renal disease (Disthabanchong *et al.*, 2004) other than secondary hyperparathyroidism *per se*, because it is not prevented by a parathyroidectomy (Largo *et al.*, 1999; Urena *et al.*, 1994, 1995). In rats with secondary hyperparathyroidism owing to vitamin D deficiency, renal cortical PTH1R mRNA levels were found to be twice as high as normal and could not be corrected by normalizing serum calcium (Turner *et al.*, 1995). These results suggest that vitamin D impairs PTH1R gene transcription in proximal tubules. However, in immortalized distal convoluted tubule cells PTH1R expression was upregulated severalfold by $1,25(OH)_2D_3$ (Sneddon *et al.*, 1998). In OK cells, TGFβ1 diminished PTH1R mRNA expression (Law *et al.*, 1994). The physiological significance of this effect has not been clarified. PTH1R mRNA expression was not affected by the mild secondary hypoparathyroidism induced by ovariectomy in rats nor by subsequent estrogen treatment (Cros *et al.*, 1998).

A critical insight to PTH1R regulation was achieved with the discovery that the receptor interacts with the cytoplasmic Na/H Exchanger Regulatory Factors NHERF1 and NHERF2 (NHERF1/2), which govern certain aspects of the signaling and trafficking (Mahon *et al.*, 2002). NHERF1/2 are cytoplasmic proteins consisting of two tandem PSD95/Discs Large/ZO-1 (PDZ) domains and a merlin/ezrin/radixin/moesin (MERM). The PTH1R binds to these domains through a recognition sequence at its carboxy terminus. This Glu-Thr-Val-Met (ETVM) sequence corresponds to a canonical PDZ domain of D/E-S/T-X-Φ, where X is any amino acid and Φ is a hydrophobic residue, generally L/I/V but it can also be M (Songyang *et al.*, 1997; Wang *et al.*, 1998). Mutation of any residue of the PDZ sequence of the PTH1R, other than the permissive position, abrogates interaction with NHERF1/2 (Mahon *et al.*, 2002; Sneddon *et al.*, 2003). In seminal work, Mahon and Segre found that NHERF1/2 switched PTH1R signaling from adenylyl cyclase to PLC. NHERF1 also regulates mitogen-activated Erk signaling (Wang *et al.*, 2008). NHERF1 is abundantly expressed on proximal tubule apical membranes (Wade *et al.*, 2001). Mouse proximal tubules express both NHERF1 and NHERF2 (Wade *et al.*, 2003). NHERF1 is strongly expressed in microvilli, whereas NHERF2 is detected only weakly in microvilli. However, it is expressed predominantly at the base of the microvilli in the vesicle-rich domain. Notably, neither NHERF1 nor NHERF2 is found is distal tubules. Human and mouse kidneys exhibit comparable NHERF1 localization (Shenolikar *et al.*, 2002; Wade *et al.*, 2003; Wade *et al.*, 2001; Weinman *et al.*, 2002). As will be discussed in greater detail later, NHERF1 is expressed in the proximal nephron, where it importantly regulates PTH-dependent phosphate absorption.

In addition to governing PTH1R signaling, NHERF1 also is significantly involved in determining receptor endocytosis. Disrupting the interaction of NHERF1 with the PTH1R by mutating the PDZ-binding domain, by mutating NHERF1, or by depolymerizing the actin cytoskeleton cause important alterations in PTH1R endocytosis. Notably, in the absence of NHERF1, both PTH(1–34) and PTH(7–34) (along with their corresponding full-length peptides) promoted efficient PTH1R sequestration. In the presence of NHERF1, PTH(1–34)-induced receptor internalization was unaffected, whereas PTH(7–34)-initiated endocytosis was largely inhibited (Sneddon *et al.*, 2003). PDZ core-binding domains and the NHERF1 MERM domain are required for inhibition of endocytosis (Wang *et al.*, 2007). NHERF1 does not alter PTH1R recycling and in this regard differs from β_2-adrenergic and κ-opioid receptors, where NHERF1 promotes rapid recycling to the plasma membrane (Cao *et al.*, 1999; Li *et al.*, 2002).

The PTH1R interacts with other adapter proteins including Tctex and 4.1G. Tctex1, which forms part of the dynein motor complex, interacts with the carboxy terminus of the receptor (Sugai *et al.*, 2003). Tctex1 binds to G protein-coupled receptors through an R/K-R/K-X-X-R/K motif (Mok *et al.*, 2001). A KRKAR sequence is found at positions Lys^{484}–Arg^{488} of the hPTH1R. This region was previously defined by Nissenson to contain a positive receptor endocytic signal (Huang *et al.*, 1995).

4.1G is a multifunctional cytoskeletal protein involved in cell morphology and membrane stability. It contains a 4.1/ezrin/radixin/moesin domain in common with NHERF1/2. 4.1G binds to the intracellular tail of the PTH1R within the Gln^{467}–Gly^{490} region. This portion of the PTH1R is involved in β-arrestin and AP-2 binding. When heterologously expressed in COS-7 cells, 4.1G increased membrane

targeting of the PTH1R (Saito *et al.*, 2005). Although 4.1G is not expressed in kidney, 4.1R is expressed in thick ascending limbs; 4.1N is found in thin limbs of Henle's loop, distal convoluted tubules, and all regions of the collecting ducts; and 4.1B is restricted to Bowman's capsule and proximal convoluted tubules (Ramez *et al.*, 2003). Homologous recombination of 4.1R resulted in mild hemolytic anemia but no conspicuous mineral ion phenotype (Shi *et al.*, 1999). The colocalization of certain 4.1 splice variants with the PTH1R opens the possibility for a role in governing receptor trafficking, signaling, and function.

CALCIUM ABSORPTION AND EXCRETION

The kidneys are responsible for controlling extracellular calcium balance. Renal calcium regulation occurs by a series of sequential events as the urine passes through the nephron. As described later in some detail, the bulk of the filtered calcium is absorbed by proximal tubules, with progressively smaller fractions recovered as the insipient urine passes through downstream tubule segments. The majority of the calcium absorption is not subject to hormone regulation. Hormonal, and pharmacological, regulation of calcium absorption is achieved by its action in modifying the fine control of calcium transport that occurs in distal segments.

Participation of PTH in the maintenance of the extracellular calcium concentration was described soon after the discovery of the parathyroid glands. Early observations in animals or in patients with hypo- or hyperparathyroidism clearly implicated renal calcium handling in PTH abnormalities (Carney, 1996; Gley, 1893; Hackett and Kauffman, 2004; Sandström, 1879–1880).

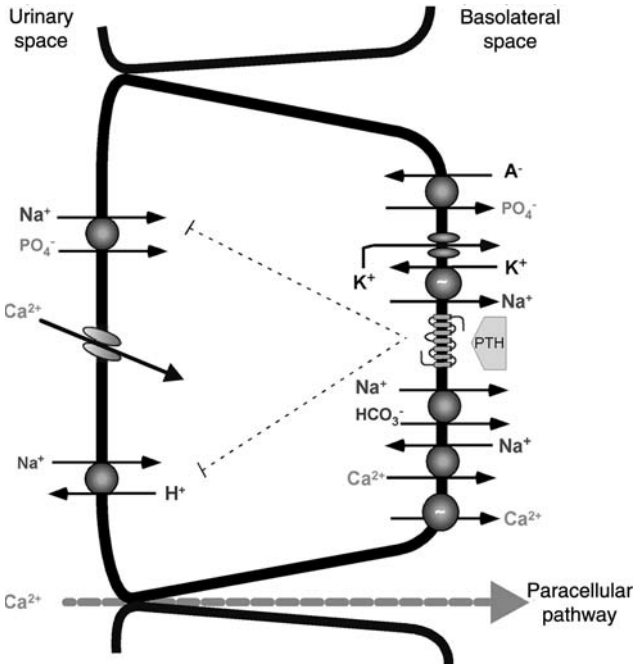

FIGURE 2 Ion transport in proximal tubules. Proximal tubule Na-P_i cotransport is mediated principally by apical membrane Npt2a. Apical brush-border membranes also express the NHE3 Na^+/H^+ exchanger. Both transporters are inhibited by PTH as described in the accompanying text. The mechanism of basolateral PO_4 extrusion is uncertain and is illustrated here as proceeding by a nonspecified anion (A^-) exchange. Notably, calcium absorption by proximal tubules is largely, if not entirely, a passive process that proceeds through the paracellular pathway of the lateral intercellular spaces (dashed line). Evidence for apical membrane Ca^{2+} entry and basolateral efflux has been described, but whether these single processes contribute to transcellular calcium absorption is controversial. For simplicity, the PTH1R is shown only on basolateral cell membranes, though it is present also on luminal, brush-border membranes and signals differentially from basolateral PTH1R to inhibit Na-Pi cotransport.

Renal Calcium Absorption

PTH reduces renal calcium excretion. Although calcium is absorbed throughout the nephron, the calcium-sparing action of PTH occurs primarily in distal tubules (Friedman, 2007; Sutton and Dirks, 1975). The sites of renal calcium absorption and mechanism of PTH action are discussed in the following paragraphs.

Approximately 60% of filtered calcium is reabsorbed by the proximal tubules (Frick *et al.*, 1965; Lassiter *et al.*, 1963). Absorption is mostly passive, driven by the favorable electrochemical gradient generated by the progressive absorption of chloride and water (Berry and Rector, 1978; Bomsztyk *et al.*, 1984; Ng *et al.*, 1984), and proceeding through the lateral intercellular spaces that define the paracellular pathway (Fig. 2). A small fraction of active calcium absorption could be detected in euparathyroid rats under conditions where passive calcium movement was eliminated (Ullrich *et al.*, 1976). It should be borne in mind that, although small by comparison with paracellular calcium absorption, active cellular absorption by proximal tubules amounts to some 20 μmol/min (Ullrich *et al.*, 1976), which, in fact, is approximately twice that of the distal nephron, where calcium absorption is entirely cellular. Thus, even a small fraction of active calcium absorption would be substantial compared with that occurring in more distal nephron segments.

Conflicting evidence precludes a definitive statement regarding PTH effects on apical membrane calcium uptake by proximal tubules. Calcium entry has been reported to increase (Khalifa *et al.*, 1983), decrease (Agus *et al.*, 1973; Dolson *et al.*, 1985), or not to change (Frick *et al.*, 1965; Lajeunesse *et al.*, 1994) in response to PTH. Neither PTH, the calcium channel blockers nitrendipine or nisoldipine, nor the calcium channel agonist Bay K 8644 affect Ca^{2+} entry in apical membrane vesicles prepared from proximal tubules (Lajeunesse *et al.*, 1994) or ^{45}Ca efflux from perfused rat tubules (Kauker *et al.*, 1997). PTH has been reported to stimulate Na^+/Ca^{2+} exchange-mediated calcium efflux by basolateral membrane vesicles obtained from the

cortex of rat and canine kidneys (Jayakumar *et al.*, 1984; Scoble *et al.*, 1985). It is not known whether this effect occurs directly or it involves an electrogenic action of PTH. PTH stimulates Ca^{2+}-ATPase activity in basolateral membranes from proximal tubules of the rat and the dog (Levy *et al.*, 1986; Tsukamoto *et al.*, 1992) but not in the rabbit (Bouhtiauy *et al.*, 1991). It should be borne in mind that because virtually all cells require calcium for various regulatory activities, the presence of calcium uptake and calcium efflux mechanisms, *per se*, even if regulated by PTH, should not be construed as evidence for the presence of transcellular or transepithelial calcium absorption. Indeed, PTH exerts an inhibitory effect on proximal tubule calcium absorption (Agus *et al.*, 1973, 1971; Amiel *et al.*, 1970). This modest inhibitory action of PTH is attributable to reduced Na^+ absorption secondary to inhibition by PTH of Na-P_i cotransport, Na^+/H^+ exchange, and Na^+-K^+-ATPase activity. However, it should be underscored that the overall effect of PTH on the kidney is to increase calcium absorption. Indeed, because calcium absorption by distal nephron segments is load dependent (Costanzo and Windhager, 1978; Greger *et al.*, 1978), it is likely that calcium rejected by proximal tubules in response to PTH is recovered in a compensatory manner by distal nephron segments.

Thin descending and thin ascending limbs of Henle's loop exhibit low calcium permeability (Rocha *et al.*, 1977; Rouse *et al.*, 1980), consistent with limited calcium transport. Moreover, neither segment expresses the PTH1R and, thus, are not sites where PTH stimulates or regulates calcium absorption.

Thick ascending limbs of Henle's loop, in contrast, are sites of appreciable calcium absorption. Approximately 20% to 25% of the filtered calcium is absorbed by thick ascending limbs, which consist of medullary and cortical portions. Calcium is absorbed by both medullary and cortical portions of thick ascending limbs, though to differing degrees (Friedman, 2007). In contrast to proximal tubules, where calcium absorption is virtually all passive and proceeds through the paracellular pathway, calcium movement in thick ascending limbs is characterized by parallel active transcellular movement and passive calcium transport (Fig. 3). Passive calcium absorption is driven by the favorable lumen-positive transepithelial voltage, which provides the driving force for movement through the calcium-permeable tight junctions. In this setting, the rate and magnitude of calcium transport are parallel and proportional to those of sodium. Physiological responses or interventions that enhance sodium absorption increase the voltage and thereby augment calcium absorption. Conversely, maneuvers that decrease sodium absorption also reduce calcium absorption. Such maneuvers commonly involve the use of diuretics such as furosemide or bumetanide that inhibit sodium absorption by thick ascending limbs and increase calcium excretion. Less commonly, mutations of the Na-K-2Cl cotransporter (Slc12a1), or the ROMK apical K^+ channel

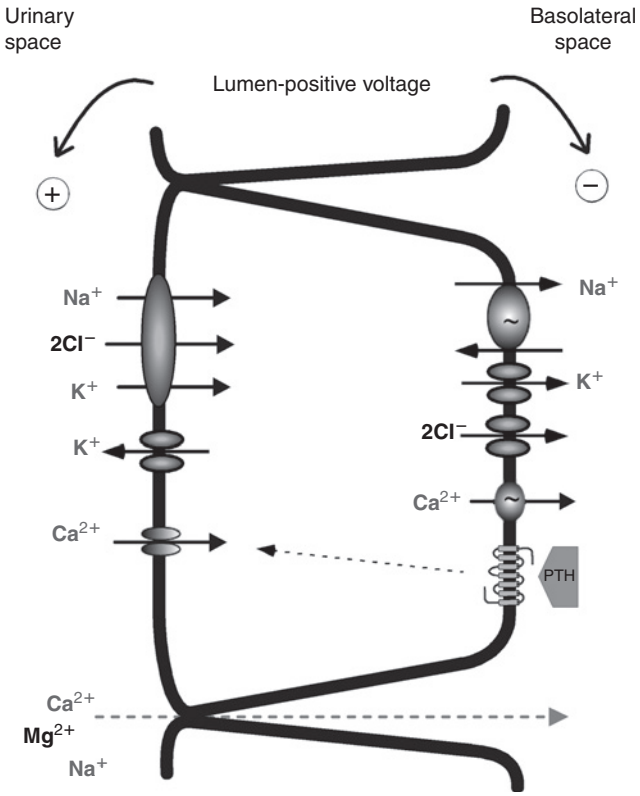

FIGURE 3 Parallel calcium transport pathways in thick ascending limbs. Calcium absorption in cortical and medullary thick ascending limbs of Henle's loop proceeds through an active, transcellular pathway and a parallel passive mechanism that traverses the paracellular pathway. Basal calcium absorption is passive and is driven by the ambient electrochemical gradient. PTH stimulates active, cellar calcium absorption by cortical thick ascending limbs as detailed in the accompanying text. Calcitonin exerts a similar effect on medullary thick limbs (Suki and Rouse, 1981) (data not shown). Other hormones, such as vasopressin, which stimulate sodium absorption by the Na-K-2Cl cotransporter, cause parallel elevations of calcium absorption by increasing the transepithelial voltage and the driving force for passive calcium absorption. Conversely, loop diuretics such as bumetanide and furosemide, by inhibiting Na-K-2Cl cotransport, decrease the transepithelial voltage and diminish passive calcium absorption with an attendant increase in calcium excretion.

(*KCNJ1*) or basolateral ClC-K2 basolateral Cl^- channel (*CLCNKB*) associated with the different forms of Bartter's Syndrome, are accompanied by hypercalciuria, underscoring the parallel nature of sodium and calcium absorption by thick ascending limbs (Hebert, 2003).

Experimental evidence exists for active, transcellular calcium absorption by medullary and cortical thick ascending limbs (Rocha *et al.*, 1977; Suki *et al.*, 1980). Calcitonin stimulates active calcium absorption by medullary thick limbs, whereas PTH promotes active calcium absorption by cortical thick limbs (Suki and Rouse, 1981). Active calcium absorption is regulated by PTH as discussed later.

Initial reports failed to identify an effect of PTH on calcium transport by thick ascending limbs (Shareghi and Stoner, 1978). However, utilizing protocols to abolish passive

calcium flux revealed that PTH stimulated transepithelial calcium transport (Bourdeau and Burg, 1980; Di Stefano *et al.*, 1990; Friedman, 1988; Suki and Rouse, 1981; Suki *et al.*, 1980). The stimulatory action of PTH on calcium absorption by thick ascending limbs is limited to the cortical segment; PTH does not affect calcium transport by medullary thick ascending limbs (Di Stefano *et al.*, 1990; Friedman, 1988; Suki and Rouse, 1981; Suki *et al.*, 1980). PTH augments net calcium absorption by cortical thick ascending limbs in the absence of changes of the transepithelial voltage (Bourdeau and Burg, 1980). Bourdeau and Burg interpreted these findings as being compatible with either active calcium absorption or with single file diffusion. When the effects of PTH were analyzed in mouse cortical thick ascending limbs in the absence of transepithelial electrochemical driving forces for calcium (Friedman, 1988), PTH clearly stimulated active, transcellular calcium absorption. These findings notwithstanding, the extent to which such hormone-dependent calcium transport contributes to overall renal calcium economy is uncertain. The reason for this is that substantial passive calcium movement is present under virtually all conditions and this fraction likely dominates net calcium absorption by thick ascending limbs.

The calcium-sensing receptor (CaSR) is expressed on basolateral membranes of thick ascending limbs of Henle's loop, especially of cortical thick ascending limbs (Riccardi *et al.*, 1998). CaSR activation selectively inhibits passive calcium but not sodium transport, and also inhibits PTH-dependent active calcium absorption (see later) (Motoyama and Friedman, 2002).

Distal convoluted tubules reabsorb 5% to 10% of the filtered calcium. Here, calcium absorption is entirely transcellular, proceeding against a steep adverse electrochemical gradient (Fig. 4) (Costanzo and Windhager, 1978; Lau and Bourdeau, 1995; Shareghi and Stoner, 1978). Transcellular calcium movement is a two-step process, wherein calcium enters the cell across apical membranes and, following diffusion across the cell, is extruded across basolateral membranes. Calcium entry is mediated by calcium ion channels (Lau *et al.*, 1991; Matsunaga *et al.*, 1994; Poncet *et al.*, 1992; Saunders and Isaacson, 1990) and extrusion is accomplished by the plasma membrane Ca^{2+}-ATPase and Na^+/Ca^{2+} exchange (Bacskai and Friedman, 1990; Matsunaga *et al.*, 1994; Poncet *et al.*, 1992).

Calcium entry is now thought to be mediated by TrpV5 (ECaC1, CAT2) (Hoenderop *et al.*, 1999, Vennekens *et al.*, 2000). TrpV5-null mice exhibit renal calcium wasting, thus establishing its participation in some aspects of calcium homeostasis in rodents (Hoenderop *et al.*, 2003). TrpV5 is a homotetramer that is constitutively active, which is difficult to reconcile with a regulated, negative feedback process (Nilius *et al.*, 2000). Indeed, TrpV5 is insensitive to PTH or to thiazide diuretics, two well characterized agents that stimulate calcium absorption by distal convolutedtubules. In contrast, an oligomeric calcium channel that is activated by PTH and by thiazide diuretics has been described (Bacskai and Friedman, 1990; Barry *et al.*, 1998; Matsunaga *et al.*, 1994), though its molecular identity is unknown.

Notably, whereas calcium and sodium transport proceed in parallel in proximal tubules and in thick ascending limbs, their movement is inversely related in distal convoluted tubules and this is a hallmark of calcium absorption by this nephron segment. Evidence for the inverse relationship comes from the pharmacological effects of thiazide diuretics, which increase sodium excretion but diminish that of calcium, as well as from patients with Gitelman's syndrome. This inherited disorder is caused by inactivating

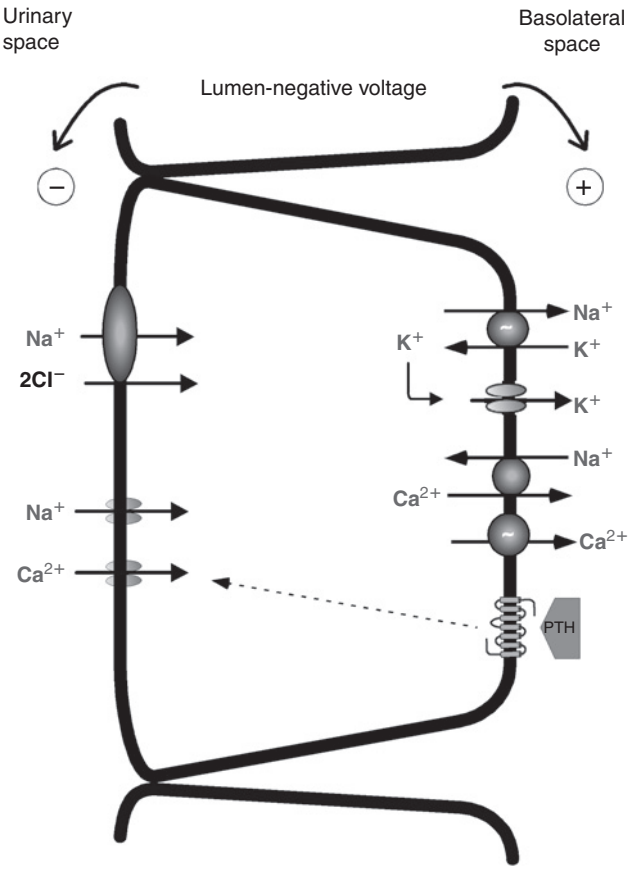

FIGURE 4 Calcium absorption by distal convoluted tubules. Two features distinguish distal tubule calcium absorption. First, calcium transport proceeds exclusively through a cellular pathway. Because of the substantial adverse electrochemical barrier, calcium movement is negligible in the absence of PTH (Costanzo and Windhager, 1980). Second, calcium and sodium movement in distal convoluted tubules are inversely related. Thus, thiazide diuretics, which block sodium transport, augment calcium absorption (Gesek and Friedman, 1992a). The cell model shows two apical membrane sodium entry mechanisms, the thiazide-diuretic-inhibitable Na-Cl cotransporter and the amiloride-blockable, epithelial Na channel, ENaC. Amiloride also stimulates calcium transport by distal tubule cells (Friedman and Gesek, 1995). Calcium enters the cell across apical membranes through dihydropyridine-sensitive calcium channels (Bacskai and Friedman, 1990). Basolateral calcium efflux is mediated by the plasma membrane Ca^{2+}–ATPase (PMCA) and the Na^+/Ca^{2+} exchanger as discussed in detail in the text and elsewhere (Friedman, 1998).

mutations of the Na-Cl cotransporter (NCC; *Slc12a3*) that mediates sodium absorption in distal convoluted tubules. Patients (Bettinelli *et al.*, 1992; Gitelman *et al.*, 1966) and experimental animals (Schultheis *et al.*, 1998) with Na-Cl cotransporter mutations exhibit characteristic hypocalciuria.

PTH stimulation of calcium absorption by distal tubules involves hyperpolarization of the membrane voltage (Gesek and Friedman, 1992b). Shimizu *et al.* (1990a) found that PTH induced biphasic changes of transepithelial voltage in single rabbit connecting tubules, the functional analogue of distal tubules in the rabbit. In other studies, however, alterations of voltage in response to PTH were not found (Imai, 1981; Suki *et al.*, 1980). Membrane hyperpolarization increases calcium entry in mouse distal convoluted tubule cells (Bacskai and Friedman, 1990; Matsunaga *et al.*, 1994) and in rabbit connecting tubules (Tan and Lau, 1993). This effect is caused by increases in the open probability of apical membrane Ca^{2+} channels and by an elevation of the driving force for calcium entry (Matsunaga *et al.*, 1994). PTH-induced hyperpolarization also enhances the driving force for basolateral calcium extrusion mediated by Na^+/Ca^{2+} exchange (Bouhtiauy *et al.*, 1991; Friedman, 1998; White *et al.*, 1996, 1998).

It has been proposed recently that α-klotho modulates renal calcium homeostasis by acting on distal tubules (Imura *et al.*, 2007). Homologous recombination of α-klotho results in a phenotype that includes osteoporosis and renal calcium wasting. (Kuro-o *et al.*, 1997; Tsuruoka *et al.*, 2006). The proposed mechanism for this effect involves enhanced Ca^{2+} entry secondary to augmentation of the Na^+ gradient following recruitment by α-klotho of the Na^+,K^+-ATPase to basolateral cell membranes. This action, in cooperation with TRPV5, calbindin$_{28k}$, and the NCX1 Na^+/Ca^{2+} calcium exchanger, it was suggested, enhances calcium absorption. Although there is little doubt that α-klotho participates in renal calcium economy, we believe it unlikely that the mechanism proposed by Imura accounts for this action because it would result in parallel increases of Ca^{2+} and Na^+ transport, whereas the signature of distal tubule calcium absorption is the well-established inverse relation between Ca^{2+} and Na^+ flux. Alternatively, the finding that α-klotho activates TRPV5 by hydrolyzing extracellular sugar residues provides a more compelling mechanism (Chang *et al.*, 2005). α-Klotho effects on PTH-dependent renal calcium absorption in intact animals may involve indirect actions on PTH secretion (Imura *et al.*, 2007) in combination with rather than direct effects on distal nephron calcium movement. A comprehensive picture of the mechanism of PTH action on renal calcium homeostasis requires further examination.

The contribution of cortical collecting tubules to renal calcium conservation is modest at best and uncertain. A small absorptive flux of calcium has been noted as has an equally small secretory transport (Bourdeau and Hellstrom-Stein, 1982; Imai, 1981; Shareghi and Stoner, 1978; Shimizu *et al.*, 1990b). Net calcium transport in isolated perfused rabbit cortical collecting ducts varied with the magnitude and direction of the transepithelial voltage (Bourdeau and Hellstrom-Stein, 1982). A small net secretory calcium flux was observed under ambient conditions. The Ca^{2+} permeability was very low compared with that of thick ascending limbs and proximal tubules. It is conceivable that secretory calcium transport could play a role in regulating calcium excretion when long-term changes of transepithelial voltage occur, for instance, as an adaptive response to changes in mineralocorticoid status (O'Neil, 1990). A model of calcium transport by collecting tubules is shown in Fig. 5. PTH exerts no detectable action on calcium movement by collecting ducts (Shimizu *et al.*, 1990b), and, as described earlier, the presence of the PTH1R at this nephron site is uncertain.

PHOSPHATE EXCRETION

Extracellular phosphate homeostasis is regulated primarily by controlling its transport in the kidneys, where it is

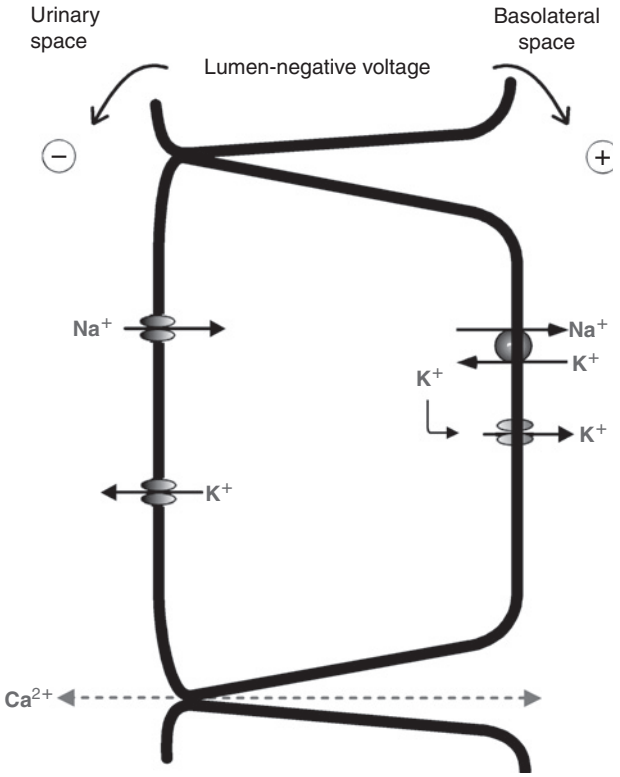

FIGURE 5 Calcium transport by collecting ducts. Collecting ducts are not a primary site of net calcium transport. Studies suggest that calcium movement is small in magnitude and thermodynamically passive (Bourdeau and Hellstrom-Stein, 1982). Transport may be absorptive or secretory, driven by the lumen-negative transepithelial voltage, and proceeds through the paracellular pathway (dashed line). PTH1Rs may or may not be expressed but PTH does not affect the rate of calcium absorption (Shareghi and Stoner, 1978).

absorbed mostly by proximal tubules. The prompt phosphaturia caused by PTH was one of the earliest recognized and best studied actions of PTH (Albright *et al.*, 1929; Greenwald and Gross, 1925). Early confusion about other purported actions can be attributed to the substantial contamination of the primitive extracts employed. With the availability of purified PTH, the direct phosphaturic action of PTH on the kidney was firmly established (Levinsky and Davidson, 1957; Pullman *et al.*, 1960).

Classical renal clearance studies established that more than 90% of the plasma phosphate is freely filtered at the glomerulus and 80% is actively reabsorbed. Ensuing investigations applying micropuncture and microperfusion techniques delineated the sites and cellular mechanisms of renal phosphate transport and its hormonal regulation. Based on those findings it is now well accepted that 60% to 70% of the filtered P_i is absorbed by late proximal convoluted tubules (Amiel *et al.*, 1970; Brunette *et al.*, 1973; Le Grimellec *et al.*, 1974; Staum *et al.*, 1972; Strickler *et al.*, 1964; Wen, 1974). P_i absorption was nearly three times greater in isolated perfused rabbit proximal convoluted tubules than in proximal straight tubules (Dennis *et al.*, 1976). The existence of distal P_i absorption is uncertain. Evidence from micropuncture experiments suggests that distal tubules absorb up to 10% of the filtered P_i (Pastoriza-Munoz *et al.*, 1978). Other studies failed to uncover evidence for distal P_i transport (Lang *et al.*, 1977). P_i transport by terminal nephron segments has also been suggested by studies showing a higher fraction of filtered P_i remaining in late distal tubules than that appearing in the final urine (de Rouffignac *et al.*, 1973; Lang *et al.*, 1977; Pastoriza-Munoz *et al.*, 1978). Collecting tubules may absorb 2% to 3% of the filtered P_i (Dennis *et al.*, 1977; Peraino and Suki, 1980). Phosphate transport by inner medullary collecting ducts was absent in control rats but was stimulated after acute thyroparathyroidectomy and was reversed by PTH administration (Bengele *et al.*, 1979). However, insofar as PTH receptors are not expressed in terminal nephron segments, the origin of this effect and its interpretation are uncertain. In summary, proximal convoluted and straight tubules are the major sites of P_i absorption. The extent of P_i absorption by distal and terminal nephrons is uncertain.

Addition of calcium to the lumen of perfused proximal tubules increased P_i absorption (Rouse and Suki, 1985). It was postulated that calcium modulates the anion affinity of the Na-P_i cotransporter. However, the identification of CaSRs at the luminal surface of proximal tubules (Riccardi *et al.*, 1998) suggests that the stimulatory effect of calcium might arise from a regulatory action exerted by the CaSR. The role of the CaSR in modulating basal and PTH-dependent proximal P_i transport was directly examined (Ba *et al.*, 2003). Activation of the CaSR by addition of luminal Ca^{2+} or Ba^{3+} specifically reduced PTH-inhibitable P_i transport without affecting basal P_i absorption.

Mechanisms of Proximal Tubular Phosphate Absorption

Clarification of the cellular mechanisms of proximal tubular phosphate absorption was largely derived from experiments utilizing renal membranes and membrane vesicles (Murer *et al.*, 2008, 2000). Apical P_i entry is rate-limiting for cellular P_i absorption and is the major site of its regulation. P_i enters the cell across apical brush-border membranes against a steep electrochemical gradient established primarily by the strongly negative intracellular voltage. This electrochemical barrier is overcome by Na^+/P_i cotransporters that couple P_i influx to the favorable dissipative entry of Na^+ (see Fig. 2).

Three classes (types I, II, and III) of Na-P_i ("NaP_i") cotransporters have been identified by molecular cloning techniques. The nomenclature, general features, and GenBank accession numbers for the human forms are summarized in Table II. The presence of three types of Na-P_i cotransporters underscores the complexity of the cell and molecular mechanisms and regulation of renal P_i absorption. Comprehensive reviews of the background, biochemistry, and expression patterns of NaP_i cotransporters can be found in previous editions of this chapter (Bringhurst and Strewler, 2002) and elsewhere (Murer *et al.*, 2001, 2003, 2008; Tenenhouse, 2007; Virkki *et al.*, 2007). Our attention here focuses on the present understanding of the mechanisms of renal P_i homeostasis and its regulation by PTH. Other hormonal or cytokine control of P_i handling by FGF23 and klotho has been reviewed recently (Kuro-o, 2006; Prie *et al.*, 2005; Stubbs *et al.*, 2007; Torres *et al.*, 2007).

Type I and type IIa NaP_i cotransporters are localized on apical brush-border membranes of proximal convoluted tubule cells. Type II cotransporters are structurally and genetically distinct from type I transporters, sharing only 20% identity. Type IIb transporters, an isoform of type IIa, are expressed exclusively in intestine and not in kidney (Hilfiker *et al.*, 1998). Type III NaP_i cotransporters, originally identified as cell surface virus receptors Glvr-1 and Ram-1 are widely expressed, both within and outside the kidney (Kavanaugh and Kabat, 1996). Type III cotransporters, which are expressed on basolateral cell membranes, are regulated by extracellular P_i deprivation and PTH (Ohkido *et al.*, 2003; Segawa *et al.*, 2007). Type II cotransporters are also expressed by distal convoluted tubule cells and may thus be involved in phosphate absorption by both proximal and distal nephrons (Collins *et al.*, 2004; Tenenhouse *et al.*, 1998). Targeted mutagenesis of Npt2 suggests that type IIa cotransporters account for 70% of renal P_i absorption (Beck *et al.*, 1998). Interestingly, despite an earlier account to the contrary (Hoag *et al.*, 1999), Npt2c protein abundance increased in Npt2a-null mutant mice suggesting that it may provide some compensatory response for Npt2a deficiency (Tenenhouse *et al.*,

TABLE II Sodium Phosphate Transporter Family

2003). Type II cotransporters are 80- to 90-kDa glycoproteins that are predicted to span the membrane eight times, with both their amino and carboxyl termini in the cytoplasm (Murer and Biber, 1997). Recent work shows two variant transcripts of the mouse Npt2a gene, Npt2a-v1 and Npt2a-v2 (Yamamoto *et al.*, 2005). These are characterized by the presence of alternative first exons (either exon 1 A or exon 1B). Npt2a-v2 is important for $1,25(OH)_2D_3$-dependent renal cell-specific activation. Type IIa cotransporters are electrogenic and transport Na^+ and $H_2PO_4^-$ at a molar ratio of 3:1 (Murer and Biber, 1997). Expression and activity of type IIa NaP_i cotransporters ("NaP_i2," in rat; "NaP_i3" or "NPT2" in human) are strongly regulated by both parathyroid status and dietary phosphate (Keusch *et al.*, 1998; Lotscher *et al.*, 1999; Murer *et al.*, 1996; Pfister *et al.*, 1997; Ritthaler *et al.*, 1999; Takahashi *et al.*, 1998). PTH regulation of serum P_i and tubular NaP_i absorption is lost in mice lacking type IIa cotransporters (Zhao and Tenenhouse, 2000). Thus, regulation of Npt2 activity is the principal mechanism whereby PTH controls phosphate absorption in proximal convoluted tubules.

The type IIc transporter (Npt2c) has been identified in rat and human kidneys (Ohkido *et al.*, 2003). Npt2c accounts for approximately 30% of Na/P_i cotransport in kidneys of P_i-deprived adult mice (Ohkido *et al.*, 2003). The contribution of Npt2c to overall renal P_i reabsorption is uncertain. Recent work showed upregulation of renal Npt2c but not Npt1 expression in Npt2a-null mice (Tenenhouse *et al.*, 2003). This compensatory response occurred in the absence of a corresponding upregulation of mRNA transcription or stability. Further, Npt2c protein abundance was not further increased by dietary P_i restriction. These findings are consistent with maximum upregulation of Npt2c protein in Npt2a-null mice fed P_i-replete diets. These findings were interpreted to suggest that hypophosphatemia is insufficient for upregulation of Npt2c gene expression and that Npt2c is responsible for residual $Na\text{-}P_i$ cotransport in Npt2a-null mice. The precise contribution of Npt2c to overall P_i economy and homeostasis in intact animals is, nonetheless, uncertain.

PTH Regulation of Renal Phosphate Absorption

PTH exerts a prompt phosphaturic action that early biochemical studies demonstrated involved reduction of the maximal rate of $Na\text{-}P_i$ cotransport and that recovery from this effect required microtubules and new protein synthesis (Dousa *et al.*, 1976; Malmström and Murer, 1987). Based on classical transport mechanisms and their regulation, it had been widely assumed that PTH inhibited $Na\text{-}P_i$ cotransport through phosphorylation or other actions that would control the kinetics or driving force. In fact, functional and immunohistochemical analyses of Npt2 in intact kidneys or in cultured cells revealed that PTH induces rapid (15 min) removal of Npt2 from the apical membrane, into the subapical endocytic apparatus, followed by microtubule-dependent delivery to lysosomes and proteolytic degradation (Fig. 6) (Bacic *et al.*, 2006; Kempson *et al.*, 1995; Keusch *et al.*, 1998; Lötscher *et al.*, 1999; Pfister *et al.*, 1997; Zhang *et al.*, 1999). The inhibitory action of PTH on proximal tubular Pi absorption correlates with the abundance of brush-border membrane Npt2 cotransporters (Lötscher *et al.*, 1996, 1999). PTH-induced retrieval of Npt2 from apical membranes requires the presence of a specific Lys^{503}–Arg^{504} dibasic amino acid motif in the proximal carboxyl-terminal cytosolic loop of Npt2 (Karim-Jimenez *et al.*, 2000). In chronic kidney disease, elevated phosphaturia is maintained by parallel reductions of Npt2a mRNA and protein abundance. In contrast, decreased phosphate excretion associated with parathyroidectomy or a low-P_i diet is mediated by increased Npt2a protein

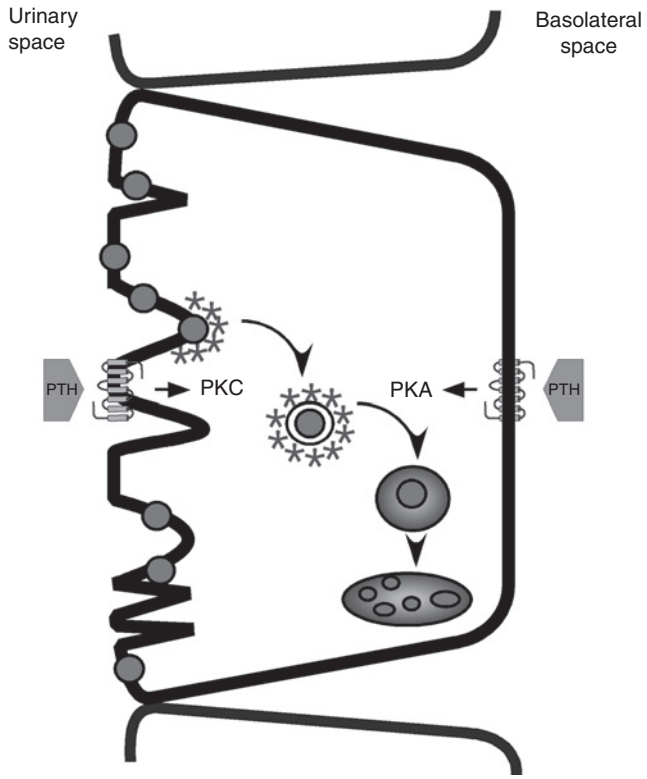

FIGURE 6 Simplified model of proximal tubule Na-Pi cotransport by endocytosis and downregulation by PTH. Stimulation of apical membrane PTH1Rs activate PKA, whereas basolateral membrane PTH1R predominantly activate PKC. PKA and PKC induce rapid retrieval of apical Npt2 transporters. Apical targeting of Npt2 requires the adapter protein NHERF1 (data not shown), as does PKC activation and efficient Npt2 internalization. Npt2 is translocated to clathrin-coated pits, which are pinched off to form vesicles. The clathrin-coated vesicles containing Npt2 is transported to endosomes and then to lysosomes, where it is degraded, causing downregulation.

without a change in mRNA expression, suggesting differential post-transcriptional regulation of Npt2a (Elhalel *et al.*, 2004).

Hypoparathyroidism and hypophosphatemia increase both PTH1R and NaP_i mRNA and protein showing that there is coordinate regulation of the proteins mediating PTH effects on renal P_i transport (Kilav *et al.*, 1995). PTH does not acutely reduce Npt2 mRNA expression, although parathyroidectomy does lead to severalfold increases of both apical Npt2 protein and mRNA (Kilav *et al.*, 1995; Saxena *et al.*, 1995; Takahashi *et al.*, 1998).

PTH1R Signal Transduction in the Regulation of Calcium and Phosphate Excretion

As described earlier, and discussed in Chapter 27, the PTH1R mediates its actions through multiple signaling pathways. Signaling is both ligand- and cell-specific. PTH exerts physiologically distinct and spatially separated effects on the kidney. In proximal tubules, PTH inhibits Na-P_i cotransport and Na/H exchange, increases Na^+/Ca^{2+} exchange (see Fig. 2), activates 25-hydroxyvitamin D_3-1α-hydroxylase, while suppressing Na^+, K^+-ATPase activity, and stimulates gluconeogenesis and ammoniagenesis. Complex, but precise, individual control over these multiple physiological activities ensures that all are not simultaneously engaged in response to elevations or reductions of PTH. Just how this is accomplished is far from understood. However, important insight has been gained in to PTH-dependent regulation of renal calcium and phosphate transport by the identification of cytoplasmic scaffolding proteins that specifically modulate individual PTH actions. Moreover, emerging evidence supports a role of these cytoplasmic adapter proteins in accounting for this remarkable specificity(Biber *et al.*, 2005).

PTH Signaling of Renal Calcium Transport

PTH stimulates calcium absorption in distal tubules. The specific subsegment where this occurs differs somewhat between species. In humans, and in the rat, the mouse, and the dog, distal convoluted tubules are the primary site of PTH-dependent calcium absorption. This has been demonstrated directly or is inferred from the localization of the PTH1R or the presence of PTH-stimulated adenylyl cyclase activity (Chabardès *et al.*, 1980; Friedman and Gesek, 1993). Connecting tubules are the site of PTH-stimulated calcium transport in the rabbit (Shimizu *et al.*, 1990b).

The initial entry of Ca^{2+} across apical cell membranes in murine distal convoluted tubule cells requires activation of both PKA and PKC (Friedman *et al.*, 1996, 1999; Hilal *et al.*, 1997). Considerable evidence suggested that PTH action on calcium absorption was mediated exclusively through activation of PKA. That is, stimulation of adenylyl cyclase was thought to be necessary and sufficient for induction of calcium transport. The most compelling evidence for this conclusion was that addition of exogenous cAMP analogues or forskolin, which directly activates adenylyl cyclase, or phosphodiesterase inhibitors stimulated calcium absorption in different tubule preparations (Bindels *et al.*, 1991; Bourdeau and Burg, 1980; Bourdeau *et al.*, 1990; Bourdeau and Lau, 1992; Costanzo and Windhager, 1980; Friedman, 1988; Imai, 1981; Lau and Bourdeau, 1989; Shimizu *et al.*, 1990b; Suki and Rouse, 1981). PTH stimulates cAMP formation and increases calcium uptake by murine distal convoluted tubule cells. However, isoproterenol, vasopressin, and glucagon stimulated cAMP formation to levels comparable to or greater than those evoked by PTH but had no significant effect on calcium uptake (Friedman and Gesek, 1993). These findings were consistent with the idea that activation of both PKA and PKC is required to stimulate calcium uptake. Forskolin, however, induced the greatest cAMP accumulation and

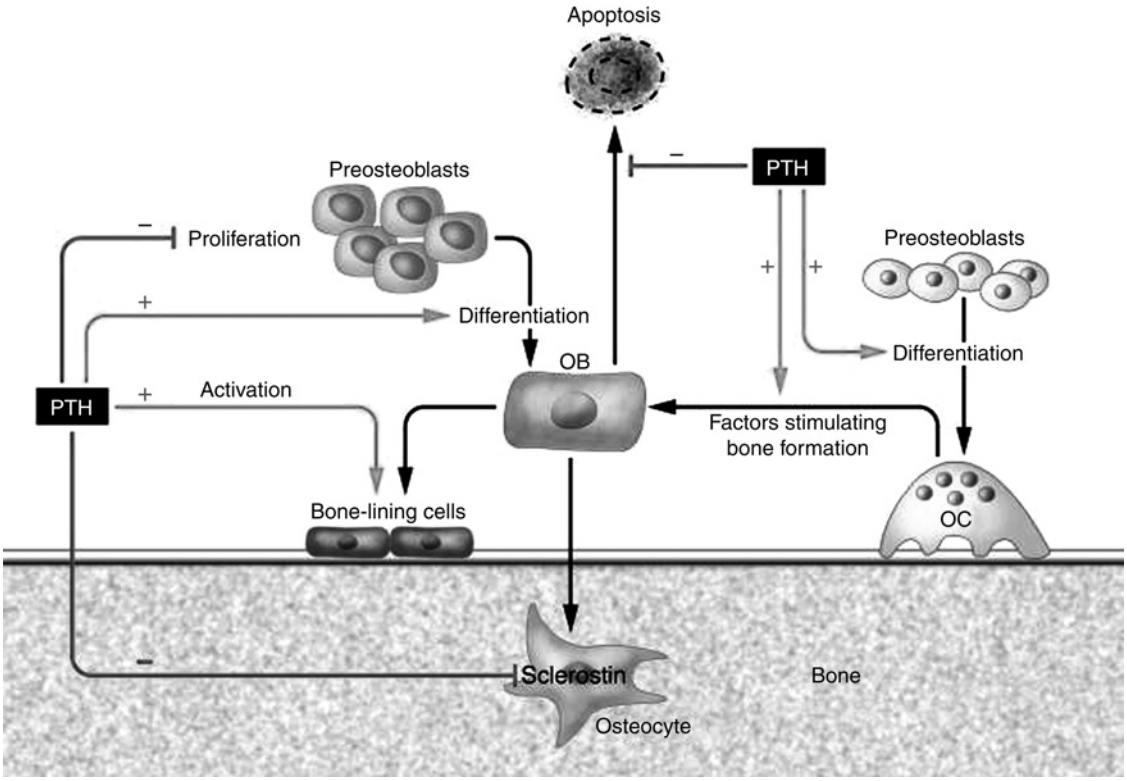

FIGURE 7 Cellular effects of PTH on bone. Bone resorption. PTH stimulates differentiation and activation of osteoclasts by increasing RANKL, and possibly decreasing OPG, production by stromal cells and osteoblasts. Bone formation. PTH decreases proliferation of preosteoblasts and stimulates their differentiation. PTH decreases osteoblast apoptosis and can activate bone lining cells into functioning osteoblasts. These combined actions result increased numbers of osteoblast. Moreover, PTH suppresses the production of the Wnt inhibitor sclerostin by osteocytes, thereby increasing β-catenin signaling in osteoblasts. From Khosla *et al*. (2008).

also augmented calcium uptake, but only to a fraction of that observed with PTH. When the concentration of forskolin was adjusted to one eliciting comparable stimulation of cAMP formation as that maximally induced by PTH, forskolin no longer enhanced calcium uptake. However, simultaneous addition of forskolin and a phorbol ester, which had no effect of its own, to stimulate PKC, resulted in calcium uptake that was similar in magnitude to that elicited by PTH. These results support the view that activation of both PKA and PKC pathways are necessary for stimulation of calcium uptake by mouse distal convoluted tubule cells. The findings also indicate that relatively high concentrations of forskolin (= 1 μM) may induce nonspecific crossover activation of PKC (Anderson and Breckon, 1991; Jiang *et al.*, 1992; MacNicol and Schulman, 1992; Shabb *et al*., 1991).

PKC is typically stimulated secondary to mobilization of $G_{q/11}$ with subsequent activation of PLC, hydrolysis of phosphatidylinositol to form inositol phosphates and diacylglycerol, which, in the presence of elevated Ca^{2+}, activates PKC. Further evidence implicated a Ca^{2+}-independent ("atypical") PKC as a mediator of PTH effects (Hoenderop *et al.*, 1999). Surprisingly, however, although PTH activates PKC in distal tubule cells, and stimulation of calcium transport requires such activation, stimulation of PLC was undetectable (Friedman *et al.*, 1999). This raised the question as to the mechanism by which PTH activates PKC independent of PLC. Subsequent investigation explored an alternative pathway, in which PTH stimulates PLD. PLD hydrolyzes phosphatidylcholine or phosphatidylethanolamine with attendant formation of phosphatidic acid, conversion to diacylglycerol, and activation of PKC. The PTH1R uses this G_q- and PLC-independent mechanism in a cell-specific manner to activate PKC (Friedman *et al.*, 1999; Singh *et al.*, 1999). Notably, the PTH1R employs this pathway despite the fact that bradykinin and α_2-adrenergic receptors in distal convoluted tubule cells exhibit conventional PKC and calcium signaling through PLC. An important question remaining from these findings is how the PTH1R activates PLD. PTH1R activation of $G\alpha_{12}/G\alpha_{13}$ mediates PTH activation of PLD in UMR-106 cells (Singh *et al.*, 2005). Other pathways involving EPAC (exchange protein activated by cAMP) (Lopez De Jesus *et al.*, 2006) or the sorting motif, NPXXY (Johnson *et al.*, 2006), have been described.

Cellular efflux of calcium is mediated by Na^+/Ca^{2+} exchange and the plasma membrane Ca^{2+}-ATPase, both

of which are expressed on distal tubule cell membranes (Magyar *et al.*, 2002; White *et al.*, 1997). Although opinions differ regarding the relative contribution of each process, we think it likely that Ca^{2+}-ATPase mediates basal Ca^{2+} efflux because the electrochemical driving force for Ca^{2+} extrusion by Na^+/Ca^{2+} exchange is insufficient (Friedman, 1998). After stimulation by PTH, distal tubule cells hyperpolarize (Gesek and Friedman, 1992b; Shimizu *et al.*, 1990a), thereby augmenting the driving force for Na^+/Ca^{2+} exchange. In this setting, Na^+/Ca^{2+} exchange likely is responsible for the elevated Ca^{2+} efflux that accompanies transcellular calcium absorption. Regardless of its relative importance, PTH stimulates Na^+/Ca^{2+} exchange (Bouhtiauy *et al.*, 1991; Hanai *et al.*, 1986).

Ca^{2+}-ATPase activity is also stimulated by PTH (Itoh *et al.*, 1988; Levy *et al.*, 1986). However, this effect was demonstrated in proximal tubule basolateral membranes, where PTH inhibits transcellular phosphate absorption. The effect on Ca^{2+}-ATPase may be associated with a homocellular action of PTH or represent an epiphenomenon. Indeed, PTH fails to alter Ca^{2+}-ATPase activity in membranes prepared from distal tubule cells (Bouhtiauy *et al.*, 1991).

Considering that PTH may orchestrate a series of coordinated single events including membrane hyperpolarization, insertion or activation of apical membrane Ca^{2+} channels, calbindin-D_{28K} expression, increased Na^+/Ca^{2+} exchange, and, perhaps, increased Ca^{2+}-ATPase activity to achieve distal tubular Ca^{2+} absorption, it is not surprising that some uncertainty attends the precise roles of PKA, PKC, or mitogen-activated protein kinases (Sneddon *et al.*, 2000) (or other PTH1R-activated effectors) in controlling distal tubular Ca^{2+} transport. Apparent requirements for multiple effectors may reflect a convergence of several signals on a single mechanism; independent actions of different effectors on one or more of the elemental cellular responses that contribute to the overall Ca^{2+}-reabsorptive response, or both.

PTH Signaling of Renal Phosphate Transport

Early experiments *in vivo* or with isolated renal membranes indicated that regulation of P_i absorption was mediated by cAMP. The evidence marshaled in support of this conclusion was based, *inter alia*, on the observation that cAMP analogues or phosphodiesterase inhibitors mimicked the phosphaturic action of PTH (Agus *et al.*, 1973; Coulson and Scheinman, 1989; Gmaj and Murer, 1986; Hammerman, 1986). Indeed, the excretion of urinary cAMP in response to PTH administration, so-called nephrogenic cAMP, reflects virtually exclusively the action of PTH on proximal tubule P_i absorption (and not distal tubule Ca absorption), and is a direct index of PTH1R sensitivity or refractoriness (Besarab and Swanson, 1984). Although these conclusions are solid, the mechanisms by which PTH inhibits renal P_i transport are complex and incompletely resolved. The intricacy stems from the recognition that the PTH1R activates multiple signaling paths. The possibility that differentially expressed PTH1R types (Pun *et al.*, 1988) or isoforms account for the heterogeneity of action can be excluded. The first studies profiling the effect of PTH on inositol phosphate and Ca^{2+} signaling, in fact, preceded the cloning of the PTH1R (Bidot-López *et al.*, 1981; Meltzer *et al.*, 1982). PTH stimulation of inositol phosphate and diacylglycerol accumulation is independent of cAMP formation (Hruska *et al.*, 1987) and occurs in parallel (Friedman *et al.*, 1996).

The involvement of specific PTH1R-generated signals in the regulation Na-P_i cotransport has been pursued extensively *in vitro* using immortalized opossum kidney (OK) cells, which exhibit a proximal tubule-like phenotype that includes expression of the Npt2a NaP_i cotransporter and the PTH1R (Jüppner *et al.*, 1991; Rabito, 1986). Considerable evidence supports cAMP/PKA-mediated signaling, but other observations point to an important contribution of inositol phosphates/PKC. The extensive body of work on this subject has been reviewed elsewhere (Muff *et al.*, 1992; Murer *et al.*, 2000; Pfister *et al.*, 1999) and described in the previous edition this text (Bringhurst and Strewler, 2002). Recent incisive work and the discovery of cytoplasmic binding partners for the PTH1R and Npt2a have largely reconciled the apparently disparate views. The salient features of PTH1R signaling of proximal tubule P_i transport can be summarized as follows.

PTH1Rs, as noted earlier, are expressed on both apical and basolateral membranes of proximal tubule cells (Amizuka *et al.*, 1997; Ba *et al.*, 2003; Traebert *et al.*, 2000). Studies selectively applying PTH(1–34) or PTH(3–34) to apical or basolateral surfaces of perfused murine proximal tubules indicate that PTH1Rs present at both membrane domains induce rapid retrieval of apical NaP_i proteins (Traebert *et al.*, 2000). Notably, this occurs exclusively by a PKC-dependent mechanism that entails activation of apical PTH1Rs. In contrast, basolateral PTH1Rs induce cotransporter endocytosis by PKA-dependent signaling. More recent studies uncovered the molecular basis for the sidedness of PTH action and the dependence on PKC or PKA. The likely explanation for the asymmetric actions and signaling stem from the localized expression of the adapter protein, NHERF1. NHERF1 is a PDZ protein that binds both to the PTH1R and to Npt2a (Hernando *et al.*, 2002; Mahon *et al.*, 2002; Wade *et al.*, 2003). In the absence of NHERF1, mice exhibit a phosphate-wasting phenotype (Shenolikar *et al.*, 2002). NHERF1 is abundantly expressed at proximal tubule brush-border membranes in the rat, and is also detected in the cytoplasm and on basolateral membranes (Wade *et al.*, 2001). In mice, NHERF1 is found exclusively on proximal tubule brush-border microvilli (Wade *et al.*, 2003). In OK/H cells, which lack NHERF1, PTH fails to inhibit Na-P_i cotransport and this defect can be surmounted by overexpressing NHERF1 (Mahon *et al.*, 2003).

According to the presently accepted understanding, PTH1R signals through PKA in the absence of NHERF1 and by means of PKC in its presence (Mahon *et al.*, 2002). Thus, at basolateral membranes, where there is little NHERF1, PTH would be expected to signal through adenylyl cyclase and PKA. At apical (i.e., luminal) cell membranes, signaling would be predicted to be mediated by PLC and PKC because of the coupling between the PTH1R and PLC (Mahon and Segre, 2004). These predictions are compatible with the observations that PTH(1–34) evoked Npt2a sequestration when added to either cell surface, whereas PTH(3–34), which activates PKC but not PKA, induced Npt2a internalization only when applied to the luminal surface (Traebert *et al.*, 2000). Consistent with this scheme, more recent studies reveal that PTH(3–34) was unable to promote Npt2a internalization from proximal tubule brush-border membranes prepared from NHERF1-null mice (Capuano *et al.*, 2006). Activation of PLC by PTH was impaired. Bypassing this defect by directly activating PKC with a diacylglycerol analogue caused Npt2a internalization in proximal tubules of both wild-type and NHERF1-null mice. Although these are elegant and compelling observations, their relevance to regulation of phosphate transport under physiological or pathophysiological conditions is unsettled. As described earlier, Na-P_i cotransport is regulated by cAMP and PKA. Metabolism of cAMP involves nucleotide degradation to adenosine by brush-border membrane ectoenzymes such as ecto-5′-nucleotidase. PTH(1–34) augmented ecto-5′-nucleotidase activity in apical membranes of OK cells (Siegfried *et al.*, 1995). This effect was mimicked by PTH(3–34) but not by forskolin. Both PTH fragments increased cytoplasmic Ca^{2+} and stimulated PKC activity. Conversely, stimulation of ecto-5′-nucleotidase activity was blocked by inhibitors of PKC. Thus, PKC-mediatedstimulation of 5′-nucleotidase thereby bolster the effects transduced by PKA.

PTH1Rs present on proximal tubule luminal membranes presumably may be activated by PTH peptides that are filtered through the glomerulus and appear in the luminal fluid. It is unlikely that these peptides or smaller fragments escape in the final urine, because they are absorbed (Kau and Maack, 1977), internalized (Hilpert *et al.*, 1999), and metabolized (Brown *et al.*, 1991; Daugaard *et al.*, 1994; Yamaguchi *et al.*, 1994) during their passage through the nephron. However, given the increased generation and accumulation of amino-truncated PTH peptides during kidney disease and other pathological settings, it is likely that significant amounts reach luminal brush-border membranes and would be expected to promote Npt2a/NPT2a internalization with concomitant renal phosphate wasting. Such an action might represent an adaptive response to the elevation of plasma phosphate in chronic kidney disease. By contrast, in distal tubules, which lack NHERF1, no such effect would be anticipated.

Activation by PTH fragments of PKA and PKC may lead to temporally and qualitatively distinct changes in Npt2 expression and activity (Cole *et al.*, 1987; Lederer *et al.*, 1998; Pfister *et al.*, 1999). Each can separately inhibit Npt2 activity by internalizing the cotransporter; only the PKA pathway, however, leads to Npt2 downregulation. Stimulation of both kinases may be necessary for maximal PTH action, and PTH1Rs located on opposite membrane surfaces of proximal tubule cells may be coupled to different effectors of Npt2a regulation.

SODIUM AND HYDROGEN EXCRETION

PTH exerts three principal and direct renal effects on ion homeostasis: increasing P_i excretion, and decreasing calcium and proton (H^+) excretion. Acute (Ellsworth and Nicholson, 1935; Hellman *et al.*, 1965; Kleeman and Cooke, 1951; Nordin, 1960) or chronic (Hulter and Peterson, 1985) PTH exerts an acute alkalotic action attended by elevated bicarbonate excretion. Primary hyperparathyroidism, however, is generally not attended by consistent or remarkable changes of serum pH and is largely asymptomatic (Bilezikian and Silverberg, 2004). This occurs despite marked hyperchloremia because of compensating metabolic acidosis (Wills, 1971). Similar metabolic changes have been described in chronic kidney disease (Liborio *et al.*, 2007).

Elimination of the daily metabolic acid load by the kidneys involves the secretion of H^+ by proximal tubules. This is accomplished by a plasma membrane H^+-ATPase and by Na^+/H^+ exchange. PTH inhibits acidification by suppressing Na^+/H^+ exchange. As described later, this involves activation of adenylyl cyclase, NHERF1, which serves as a scaffold to assemble PKA and NHE3, the Na^+/H^+ exchanger isoform expressed on proximal tubule brush-border membranes, followed by phosphorylation and inhibition of NHE3 (Moe *et al.*, 1995; Weinman *et al.*, 1998, 2005). Notably, the inhibitory effect of PTH on proximal tubule bicarbonate absorption due to blockade of Na^+/H^+ exchange does not necessarily result in increased bicarbonate excretion (Bank and Aynedjian, 1976; Puschett *et al.*, 1976) and is not accompanied by appreciable reductions in serum bicarbonate (Hulter, 1985). These results suggest that the presence of distal compensatory bicarbonate absorption (Bichara *et al.*, 1986) and acidification by downstream tubule segments in response to PTH (Paillard and Bichara, 1989). Secondary actions of PTH to mobilize bicarbonate from bone also contribute to the absence of an effect on systemic pH (Hulter and Peterson, 1985). More important than its modest effects on net bicarbonate balance or pH homeostasis, however, is the permissive action of bicarbonate to facilitate PTH-dependent distal tubule calcium absorption (Marone *et al.*, 1983; Mori *et al.*, 1992; Sutton *et al.*, 1979), a primary function of PTH.

Much of the transcellular sodium absorption in proximal convoluted tubules is mediated by Na^+/H^+ exchange.

As a corollary of the inhibitory action of PTH on Na^+/H^+ exchange, proximal sodium absorption is diminished. However, PTH has a negligible effect on sodium excretion because of compensatory absorption by downstream tubule segments (Harris *et al.*, 1979). Natriuretic actions of PTH, however, have been described in experimental animals (Bichara *et al.*, 1986; Hellman *et al.*, 1965) and in humans (Jespersen *et al.*, 1997).

The fundamental mechanism whereby PTH inhibits Na^+/H^+ exchange differs from its action on Na-P_i cotransport. As described earlier, PTH decreases Na-P_i cotransport by retrieving the protein from brush-border membranes. In contrast, PTH acutely regulates Na^+/H^+ exchange by *in situ* phosphorylation of NHE3 that is mediated by PKA (Hamm *et al.*, 2008). The immediate decrease of NHE3 activity is followed several hours later by decreased brush-border membrane abundance of NHE3 protein (Fan *et al.*, 1999). Details of this process and the involvement of NHERF1 are detailed in the next section.

Na^+/H^+ exchange is a dissipative, i.e., secondary active, transport process that depends on the continuous extrusion of Na across basolateral cell membranes. This is accomplished by the ATP-dependent Na^+,K^+-ATPase. Data showing that PTH inhibits the Na^+,K^+-ATPase have been published (Ribeiro and Mandel, 1992; Zhang *et al.*, 1999). An inhibitory action of PTH on Na^+,K^+-ATPase would certainly contribute to, or explain, reduced Na^+/H^+ exchange. However, such an action would be expected to have profound effects on proximal tubule ion transport and all Na-coupled transport process such as those mediating glucose (Na-glucose) and amino acid (Na-amino acid) cotransport, and perhaps Na-P_i cotransport. Moreover, the inhibitory action of PTH should extend to virtually all cells expressing PTH1R including the distal tubule. In this setting, blockade of the Na^+,K^+-ATPase would be expected to reduce Na^+/Ca^{2+} exchange and decrease net calcium absorption when, in fact, just the opposite occurs. The described actions of PTH seem remarkably specific for the proximal tubule Na^+,K^+-ATPase and for Na^+/H^+ exchange. A rationale explication of these findings awaits further clarification.

PTH Regulation of Proximal Tubular Sodium and Hydrogen Excretion

Efficient bicarbonate absorption by proximal tubules requires NHERF1. Targeted disruption of NHERF1 virtually eliminates PTH- or forskolin-inhibited Na^+/H^+ exchange in proximal tubule cells (Cunningham *et al.*, 2004). This defect could be restored by infecting the cells with an adenovirus containing NHERF1. Interestingly, cAMP generation and PKC activation were equivalent in proximal tubule cells from wild-type mice or NHERF1-null animals. This result seemingly contrasts with the paradigm of the PTH "signaling switch" advanced by Mahon and Segre (Mahon *et al.*, 2002), where PTH1R signaling proceeds through cAMP in the presence of NHERF1 but by PKC in its absence. However, mouse proximal tubules express both NHERF1 and NHERF2, and NHERF2 expression is normal in NHERF1-null mice (Cunningham *et al.*, 2008; Shenolikar *et al.*, 2002). Thus, it is entirely possible that NHERF2 compensates for the absence of NHERF1, binds the PTH receptor, and directs appropriate signaling and cell functions. Notably, OK cells express NHERF1 but not NHERF2 (Wade *et al.*, 2001).[3] Thus, the results of studies conducted with OK cells demonstrating an absolute role of NHERF1 in PTH1R mediated inhibition of Na-P_i cotransport (Mahon *et al.*, 2003) may have fortuitously benefited from the absence of NHERF2.

The majority of PTH effects appear to be mediated by PKA and, to a lesser extent, by PKC. However, recent evidence uncovered an alternative pathway that involves cAMP but utilizes EPAC (exchange protein directly activated by cAMP) rather than PKA as an effector (Fujita *et al.*, 2002). Studies employing proximal tubule cells derived from wild-type or NHERF1-null mice revealed a role for EPAC in mediating Na^+/H^+ exchange (Murtazina *et al.*, 2007).

Following the secretion of H^+ (in exchange for one Na^+ ion by the apical cell membrane Na^+/H^+ exchanger) OH^- is generated within the cell. This is converted to $HCO_3^-$and CO_3^-, which are then extruded across basolateral cell membranes. This is accomplished by Na^+-dependent HCO_3^- (NBC) cotransporters (Boron, 2006; Romero *et al.*, 2004; Soleimani and Burnham, 2001). The possibility that PTH inhibits bicarbonate absorption by an action on basolateral HCO_3^- exit was a matter of uncertainty (Pastoriza-Munoz *et al.*, 1992; Sasaki and Marumo, 1991), and this action was attributed by some to an effect on the Na^+,K^+-ATPase as discussed earlier. More recent studies reveal direct effects of cAMP on NBC activity. This action requires NHERF1 (Bernardo *et al.*, 1999; Weinman *et al.*, 2001). PTH presumably exerts comparable actions but this has not been explicitly determined.

PTH1R Signal Transduction in the Regulation of Sodium and Hydrogen Excretion

The mechanisms by which the PTH1R regulates Na^+/H^+ exchange are both complex and incompletely resolved. NHE3 is rapidly phosphorylated and inactivated following *in vivo* PTH exposure, after which it is internalized (Fan *et al.*, 1999; Hensley *et al.*, 1989; Zhang *et al.*, 1999). NHE3 is a target for PKA-mediated phosphorylation (Zhao

[3]Rats too express only NHERF1 on proximal tubule brush-border membranes. Thus, OK cells are more of a model for the rat proximal tubule than for that of humans or mice, where both NHERF1 and NHERF2 are expressed.

et al., 1999). Considerably greater uncertainty attends the question of whether NHE3 is also phosphorylated by PKC. Indirect evidence derived from the application of PTH fragments that largely, but not entirely, activate signaling-selective protein kinases is consistent with the view that PKC activation is insufficient to promote NHE3 internalization *in vivo* (Zhang *et al.*, 1999). Comparable results were obtained in a cell culture system (Maeda *et al.*, 1998). PTH induces phosphorylation of multiple serine residues within the cytoplasmic tail of NHE3 (Collazo *et al.*, 2000). Evidence developed using kinase inhibitors and signal-selective PTH analogues supports the involvement of both PKA- and PKC-dependent pathways in NHE3 regulation (Azarani *et al.*, 1995, 1996; Helmle-Kolb *et al.*, 1990; Kahn *et al.*, 1985). Phosphorylation is maximal within 5 minutes and is associated with a reduction in NHE3 activity but not surface expression. NHE3 phosphorylation requires NHERF1 (Weinman *et al.*, 1993, 2005). Following the initial inactivation of NHE3, the exchanger is retrieved from the cell membrane by dynamin-dependent endocytosis (Chow *et al.*, 1999; Collazo *et al.*, 2000).

By way of summary, PTH regulates Na^+/H^+ exchange primarily by an immediate inhibitory action that depends on phosphorylation and requires the presence of NHERF1. Phosphorylation is thought generally to be mediated by PKA, though a regulatory influence of PKC can not be excluded. Following the initial inhibition of membrane-associated NHE3, the protein is withdrawn from the membrane. However, it does not appear to be degraded, which would lead to downregulation. Though its fate is uncertain, it seems plausible that after dephosphorylation the transporter is recycled to the plasma membrane, as are the PTH1R and other G protein-coupled receptors.

PTH Regulation of Sodium and Hydrogen Excretion beyond the Proximal Tubule

The effect and physiological significance of downstream PTH actions on sodium and proton transport are poorly defined. Studies, particularly *in vivo* experiments, published before the molecular cloning and tubular localization of the PTH1R should be considered suspect. Actions attributed to PTH evidently must have involved indirect actions insofar as present consideration would argue that no detectable receptors are present at the presumed site of action. Such an interpretation is especially relevant because it is now appreciated that phosphaturia induced by PTH contributes to net acid secretion (Mercier *et al.*, 1986), and PTH can increase net renal acid secretion during metabolic acidosis (Bichara *et al.*, 1990).

VITAMIN D METABOLISM

The biologically active form of vitamin D, $1,25(OH)_2D_3$, is synthesized by a cascade of multiorgan processes, the penultimate step of which is 1-alpha hydroxylation that proceeds in proximal renal tubules and is regulated by PTH and the CaSR (DeLuca, 2004; Dusso *et al.*, 2005; Holick, 2007; Maiti and Beckman, 2007).

Parathyroidectomy reduces $1,25(OH)_2D_3$ synthesis and PTH administration increases renal 1α-hydroxylase activity (Armbrecht *et al.*, 2003; Fraser and Kodicek, 1973; Walker *et al.*, 1990). Increased synthesis of the $25(OH)D_3$ 1α-hydroxylase gene results from regulated expression in proximal tubular cells, where the promoter is rapidly induced in response to PTH (Fukase *et al.*, 1982; Kremer and Goltzman, 1982). This *in vitro* effect of PTH can be overridden *in vivo* by the direct suppressive action of hypercalcemia on 1α-hydroxylase expression (Weisinger *et al.*, 1989). Induction of 1α-hydroxylase mRNA by PTH is transcriptional; additive to that of calcitonin; occurs in the absence of the vitamin D receptor; and is antagonized by coadministration of $1,25(OH)_2D_3$, which directly inhibits its expression when administered alone (Murayama *et al.*, 1999). Positive actions of PTH on 1α-hydroxylase expression and $1,25(OH)_2D_3$ biosynthesis are counter-regulated by the CaSR (Maiti and Beckman, 2007; Maiti *et al.*, 2008).

PTH not only promotes $1,25(OH)_2D_3$ synthesis, but also regulates its degradation. 24-Hydroxylation of $1,25(OH)_2D_3$ is the first step in the catabolic inactivation of $1,25(OH)_2D_3$. It was long held that only proximal renal tubules expressed 24-hydroxylase (Iida *et al.*, 1993; Kawashima *et al.*, 1981). Distal tubules, however, take up $1,25(OH)_2D_3$ (Stumpf *et al.*, 1980), express the vitamin D receptor (VDR) (Kumar *et al.*, 1994), and possess vitamin D-dependent calcium-binding proteins (Christakos *et al.*, 1981). 24-Hydroxylase message, protein, and activity have been demonstrated in murine distal tubule cells (Yang *et al.*, 1999), human distal tubules (Kumar *et al.*, 1994), and collecting duct cells (Bland *et al.*, 2001). Whereas PTH reduces 24-hydroxylase activity in proximal tubule cells (Barletta *et al.*, 2004; Matsumoto *et al.*, 1985), PTH and cAMP augment 24-hydroxylase activity in murine distal tubule cells (Yang *et al.*, 1999). Oppositely oriented actions of PTH on 24-hydroxylase activity suggest differential regulation of 24-hydroxylase expression in proximal and distal tubules.

The signaling pathways employed by the PTH1R to increase $1,25(OH)_2D_3$ synthesis have been examined extensively *in vivo* and *in vitro*. Involvement of cAMP is suggested by the fact that the PTH effect can be mimicked by cAMP analogues, forskolin, or phosphodiesterase inhibitors (Armbrecht *et al.*, 1984; Henry, 1985; Horiuchi *et al.*, 1977; Korkor *et al.*, 1987; Larkins *et al.*, 1974; Rost *et al.*, 1981; Shigematsu *et al.*, 1986). PTH- or forskolin-stimulated transcriptional induction of 1α-hydroxylase occurred and was blocked by the PKA inhibitor H89 (Murayama *et al.*, 1999). A role for PKC in regulating 1α-hydroxylation has been identified from studies of the effects of PTH on

isolated proximal tubules (Janulis *et al.*, 1992, 1993). PKC activation produced rapid (30 to 60 minute) increases of $1,25(OH)_2D_3$ synthesis [PKC and $1,25(OH)_2D_3$ synthesis correlated with PTH concentrations 100- to 1000-fold lower than required for activation of PKA]. Moreover, inhibition of PKC blocked $1,25(OH)_2D_3$ synthesis, and amino-truncated PTH fragments that stimulate PKC but not PKA likewise enhanced $1,25(OH)_2D_3$ formation. Taken together, the results suggest a predominant effect of PKA on transcriptional regulation of 1α-hydroxylase gene expression and a more rapid, post-transcriptional action of PKC on 1α-hydroxylase enzymatic activity.

OTHER RENAL EFFECTS OF PTH

PTH exerts a variety of additional described, but far less well understood, effects on ion transport, such as activation of apical Cl^- channels (Suzuki *et al.*, 1991), and metabolism.

The kidney contributes significantly to systemic gluconeogenesis (Friedman and Torretti, 1978; Schoolwerth *et al.*, 1988), although this is not normally apparent because of balancing by renal medullary glycolysis. PTH-dependent renal gluconeogenesis is attended by segmental and internephron heterogeneity. PTH increases gluconeogenesis (Chobanian and Hammerman, 1988), ammoniagenesis (Wang and Kurokawa, 1984), and phosphoenolpyruvate carboxykinase (PEPCK) (Watford and Mapes, 1990) mRNA expression in proximal tubules. PTH primarily stimulates gluconeogenesis in cortical S1 and S2 proximal tubules (Wang and Kurokawa, 1984). Although juxtamedullary S1 proximal tubules exhibit the highest rate of gluconeogenesis, they are unaffected by PTH.

Gluconeogenesis is linked to ammoniagenesis because both are stimulated by acidosis and by PTH. Moreover, L-glutamine, which is the major gluconeogenic precursor, is also a substrate for ammoniagenesis. Thus, there may be some metabolic interdependence of PTH actions on gluconeogenesis and ammoniagenesis.

PTH also exerts conspicuous morphological effects causing rapid microvillus shortening (Goligorsky *et al.*, 1986). This action appears to be specific for proximal tubule cells. Emerging observations suggest that this cell-specific effect may be caused by the prominent brush-border expression of NHERF1 in proximal tubule cells and its absence from distal tubule cells.

Whether proximal tubule PTH regulation of $Na\text{-}P_i$ cotransport, Na^+/H^+ exchange, or Na^+/Ca^{2+} exchange, or its metabolic actions on the 25-hydroxyvitamin D-1α-hydroxylase, gluconeogenesis, or ammoniagenesis involves more complicated second messenger signaling is unknown. It should be mentioned that emerging evidence points to the ability of PTH receptors to activate additional signaling pathways involving phospholipase A_2 (Mandel and Derrickson, 1997; Ribeiro *et al.*, 1994), PLD (Friedman *et al.*, 1996; Somermeyer *et al.*, 1983), and MAP kinase (Quamme *et al.*, 1994; Swarthout *et al.*, 1997; Verheijen and Defize, 1997).

RENAL EXPRESSION AND ACTIONS OF PTHrP

PTHrP is expressed by glomeruli, distal tubules, and collecting ducts of fetal kidneys and by proximal convoluted tubules, distal convoluted tubules, and glomeruli of adult kidneys (Aya *et al.*, 1999; Philbrick *et al.*, 1996). In rat kidneys, PTHrP mRNA is found in glomeruli, proximal convoluted tubules, and macula densa but not in cortical ascending limbs, medullary ascending limbs, distal convoluted tubules, or collecting ducts (Yang *et al.*, 1997), where as other studies reported PTHrP transcripts in glomerular mesangial cells, proximal and distal tubules (Soifer *et al.*, 1993). Although PTHrP is critical for normal cardiovascular and bone development, the kidneys of PTHrP-null mice appear histologically normal (Karmali *et al.*, 1992) and a physiological role for PTHrP on the kidney is uncertain (Mundy and Edwards, 2008).

Amino-terminal fragments of PTHrP exhibit renal actions, including stimulation of cAMP production, regulation of $Na\text{-}P_i$ cotransport, and calcium excretion, that are largely indistinguishable from those of PTH (Everhart-Caye *et al.*, 1996; Horiuchi *et al.*, 1987; Horwitz *et al.*, 2003; Pizurki *et al.*, 1988; Scheinman *et al.*, 1990; Yates *et al.*, 1988). Some differences may be discerned. In distal tubule cells, for instance, PTHrP(1–34) and PTHrP(1–74) were more potent than equimolar concentrations of PTH(1–34) and PTH(1–84) in stimulating adenylyl cyclase (Friedman *et al.*, 1989). In contrast, PTHrP(1–36) has a markedly lower effect to raise serum $1,25(OH)_2D_3$ levels (a consequence of its action on proximal tubules) in human volunteers than does comparable administration of PTH(1–34) (Horwitz *et al.*, 2003).

PTHrP possesses mid- and carboxy-terminal regions that have distinct biological actions (Clemens *et al.*, 2001; Philbrick *et al.*, 1996). Longer PTHrP fragments may exhibit unique renal properties. For example, excretion in perfused rat kidneys was enhanced equivalently by PTHrP(1–34) and PTH(1–34), whereas PTHrP(1–84), PTHrP(1–108), and PTHrP(1–141) were each less active than PTH(1–34) (Ellis *et al.*, 1990). As discussed in Chapter 25, the PTHrP gene can generate multiple transcripts and protein products, some of which may undergo unique nuclear localization. It is possible, therefore, that locally expressed PTHrP exerts actions in the kidney that are not shared with PTH.

A possible role for locally produced PTHrP in the renal response to ischemia has been suggested by findings that PTHrP expression is induced by ischemia or after recovery

from ATP depletion (García-Ocaña *et al.*, 1999; Largo *et al.*, 1999; Soifer *et al.*, 1993). PTHrP is expressed in the intima and media of human renal microvessels and in the macula densa (Massfelder *et al.*, 1996). PTHrP (like PTH) increases renin release from the juxtaglomerular apparatus and also stimulates cAMP in renal afferent and efferent arterioles, leading to vasodilation and enhanced renal blood flow (Endlich *et al.*, 1995; Helwig *et al.*, 1991; Musso *et al.*, 1989; Saussine *et al.*, 1993). Both cAMP and nitric oxide have been implicated in PTHrP-induced *in vitro* vasorelaxation (Massfelder *et al.*, 1996). Thus, enhanced local PTHrP production induced by inadequate renal perfusion or ischemia may be involved in both local and systemic autoregulatory mechanisms. According to this view, direct local vasodilatory actions are supplemented by the systemic activation of angiotensinogen, which increases arterial pressure and further sustains renal blood flow.

PTHrP promotes fibrogenesis and is upregulated in experimental nephropathy (Funk, 2001; Ortega *et al.*, 2006; Ortega *et al.*, 2005). Locally produced PTHrP may contribute to the pro-inflammatory effect by activating NF-κB and extracellular signaling-related kinases (ERK) (Ramila *et al.*, 2008). The incidence of renal hypertrophy is greater in diabetic mice overexpressing PTHrP than in control animals, suggesting that constitutive PTHrP overexpression may elicit adaptive responses such as nitric oxide production to mitigate against renal damage (Izquierdo *et al.*, 2006).

PTHRP AND RECEPTORS FOR PTH AND PTHrP IN BONE

Receptors and Second Messenger Systems for PTH and PTHrP in Bone

Most PTH and PTHrP effects in bone are mediated by the type 1 PTH/PTHrP receptor (PTH1R) (Abou-Samra *et al.*, 1992; Jüppner *et al.*, 1991). As discussed in detail in Chapter 24, this is a G protein-coupled receptor that recognizes both PTH and PTHrP, as well as their biologically active N-terminal peptides PTH(1–34) and (1–36) and PTHrP(1–36). The PTH1R binds PTH and PTHrP with equal affinity (although some differences in the affinity for G protein-coupled and uncoupled states have recently been reported) (Dean *et al.*, 2008) and, in response to these ligands, signals through various cellular effector systems. The best characterized are the adenylyl cyclase/cAMP/PKA pathway via activation of Gs proteins and the PLC/PKC pathway via activation of Gq proteins (see Chapters 24 and 26) (Abou-Samra *et al.*, 1992; Civitelli *et al.*, 1989; Jüppner *et al.*, 1991; Pines *et al.*, 1996; Syme *et al.*, 2005). In addition, important effects of the PTH1R on mitogen-activated protein kinases (MAPK), especially ERK1 and ERK2, have been described (Cole, 1999; Miao *et al.*, 2001; Sneddon0 *et al.*,2000, 2003; Swarthout *et al.*, 2001; Syme *et al.*, 2005).

The PTH1R is expressed widely in cells of the osteoblast lineage. Receptor expression is greater in more differentiated cells such as mature osteoblasts on the trabecular, endosteal, and periosteal surfaces (Fermor and Skerry, 1995; Lee *et al.*, 1993) and osteocytes (Fermor and Skerry, 1995; van der Plas *et al.*, 1994). PTH1R are also expressed in marrow stromal cells near the bone surface (Amizuka *et al.*, 1996), a putatively preosteoblast cell population that had been shown previously to bind radiolabeled PTH (Rouleau *et al.*, 1988, 1990). However, PTH1R is virtually absent in STRO-1+ positive, alkaline phosphatase negative marrow stromal cells (Gronthos *et al.*, 1999; Stewart *et al.*, 1999), which are thought to represent relatively early osteoblast precursors. Indeed, PTH1R expression can be induced by the differentiation of stromal cells, MC3T3 cells, or C3H10T1/2 cells with dexamethasone, ascorbic acid, or bone morphogenetic proteins (Feuerbach *et al.*, 1997; Hicok *et al.*, 1998; Liang *et al.*, 1999; Stewart *et al.*, 1999; Wang *et al.*, 1999; Yamaguchi *et al.*, 1987). Other data suggest that PTH receptors are limited to a relatively mature population of osteoprogenitor cells that express the osteocalcin gene (Bos *et al.*, 1996).

Whether receptors for PTH or PTHrP are expressed on the osteoclast is controversial. Initial studies using receptor radioautography failed to demonstrate them (Rouleau *et al.*, 1990; Silve *et al.*, 1982), and other studies have not identified PTH1R mRNA or protein on mature osteoclasts (Amizuka *et al.*, 1996; Lee *et al.*, 1993, 1995). However, PTH1R are reportedly present on normal human osteoclasts (Dempster *et al.*, 2005) and from patients with renal failure (Langub *et al.*, 2001) and relatively low-affinity binding of radiolabeled PTH peptides to osteoclasts or preosteoclasts has been reported (Teti *et al.*, 1991). The functional importance of such putative receptors is unclear.

Both PTH and PTHrP have additional receptors besides the PTH1R. The PTH2R is a G protein-coupled receptor closely related to the PTH1R (Usdin *et al.*, 1995), which recognizes the amino-terminal domain of PTH but not of PTHrP (see Chapter 24). The endogenous ligand for the PTH2R is likely to be tuberoinfundibular peptide of 39 amino acids (TIP39). The PTH2R and TIP39 are expressed predominantly in brain, vasculature, and pancreas (Dobolyi *et al.*, 2003; Eichinger *et al.*, 2002; Usdin *et al.*, 1996., 1999) but have yet to be demonstrated in adult bone, and at present no evidence is available for a direct role of PTH2R and TIP39 on bone metabolism.

A large body of evidence exists for the presence of specific receptor(s) for carboxyl-terminal PTH peptides on osteoblasts (Divieti *et al.*, 2005; Inomata *et al.*, 1995; Nguyen-Yamamoto *et al.*, 2001) and osteocytes (Divieti *et al.*, 2001) and evidence for actions of carboxyl-terminal PTH peptides on bone has been presented (Murray *et al.*, 1989, 1991; Nakamoto *et al.*, 1993; Sutherland *et al.*, 1994).

PTHrP is expressed and secreted by osteoblast-like osteosarcoma cells (Rodan *et al.*, 1989; Suda *et al.*, 1996)

and by rat long-bone explants *in vitro* (Bergmann *et al.*, 1990). Messenger RNA for PTHrP is detected in periosteal cells of fetal rat bones (Karmali *et al.*, 1992). *In situ* hybridization and immunohistochemistry localized PTHrP mRNA and protein to mature osteoblasts on the bone surface of fetal and adult bones from mice and rats (Amizuka *et al.*, 1996; Lee *et al.*, 1995) and to flattened bone lining cells and some superficial osteocytes (Amizuka *et al.*, 1996) in postnatal mice. In addition, the PTHrP gene is expressed in preosteoblast cells in culture, and in some studies its expression is reduced as preosteoblasts undergo differentiation (Kartsogiannis *et al.*, 1997; Oyajobi *et al.*, 1999; Suda *et al.*, 1996).

As discussed in Chapter 25, PTHrP is cleaved to produce a set of peptides: those that contain the amino terminus [such as PTHrP(1–36)] activate the PTH1R, and additional peptides representing the midregion and carboxyl terminus of PTHrP appear to have distinct biological actions mediated by their own receptors (Philbrick *et al.*, 1996; Wysolmerski and Stewart, 1998). Receptors that are specific for amino-terminal PTHrP and do not recognize PTH have been identified in brain (Yamamoto *et al.*, 1997) and other tissues (Gaich *et al.*, 1993; Orloff *et al.*, 1992; Valin *et al.*, 2001), and midregion peptides of PTHrP have actions on placental calcium transport that imply a distinct receptor (Care *et al.*, 1990; Kovacs *et al.*, 1996), but there is presently no evidence for either receptor in bone. Carboxyl-terminal PTHrP fragments [e.g., PTHrP(107–139)] are reported to inhibit bone resorption (Cornish *et al.*,1997; Fenton *et al.*, 1991a, 1991b, 1993) and stimulate (Goltzman and Mitchell, 1985) or inhibit (Martinez *et al.*, 1997) the growth of osteoblasts and their function (Esbrit *et al.*, 2000; Grey *et al.*, 1999), and it is thus likely that a specific receptor for this peptide is present on osteoblasts, and conceivably also on osteoclasts.

EFFECTS OF PTH AND PTHrP ON BONE CELLS

Molecular mechanisms of action in osteoblasts

Transcription Factors

A major effect of PTH and PTHrP in osteoblasts is directed to modulating the expression and/or function of a number of transcription factors known to be important in bone metabolism. Among these, the most prominent are the cAMP response element-binding protein CREB (Brindle and Montminy, 1992; Papavassiliou, 1994), the immediate early gene of the activator protein-1 (AP-1) family *c-fos* (c-fos, fra-1, fra-2) and *c-jun* (c-jun, junD) (Clohisy *et al.*, 1992; Lee *et al.*, 1994; McCauley *et al.*, 1997., 2001; Stanislaus *et al.*, 2000), and Runx2 (Komori, 2002).

PTH induces *c-fos* transcription in a fashion that does not require protein synthesis and is mediated by the transcription factor CREB. Binding and phosphorylation of CREB to cAMP responsive elements (CRE) within the c-fos promoter (Evans *et al.*, 1996; Pearman *et al.*, 1996; Tyson *et al.*, 1999) are required to activate transcription. These events are stimulated by PTH through its ability to activate PKA, whereas the PKC signaling pathway is not involved in this response (Evans *et al.*, 1996; McCauley *et al.*, 1997). Activation of AP-1 transcription factors is important for osteoblast function because the *collagenase-3* (MMP-13) promoter contains AP-1 binding sites (Pendas *et al.*, 1997; Selvamurugan *et al.*, 1998).

One member of the runt-domain transcription factor family, namely Runx2 (also called cbfa1 and OSF2), is a specific osteoblast transcriptional activator and is required for determination of the osteoblast phenotype (Ducy *et al.*, 1997; Komori, 2002). Runx2 stimulates transcription of a number of key osteoblastic genes such as osteocalcin, osteopontin, collagenase-3, and collagen α1 and α2 (Banerjee *et al.*,2001; Porte *et al.*, 1999; Selvamurugan *et al.*, 1998). The importance of Runx2 for osteoblast formation and bone metabolism has been established in a number of *in vitro* and *in vivo* models (Ducy *et al.*, 1997, 1999; Komori *et al.*, 1997; Otto *et al.*, 1997). Short PTH treatment stimulates rapid and transient increases in Runx2 mRNA and protein both in osteoblastic cell cultures and in mice (Krishnan *et al.*,2003). In addition, PTH, likely via cAMP/PKA activation, stimulates Runx2 activity (Selvamurugan *et al.*, 2000; Winchester *et al.*, 2000). In contrast, long-term treatment with PTH reduces Runx2 levels (Bellido *et al.*, 2003). The dual effect of PTH on Runx2 levels and activity is particularly interesting. As will be discussed later, PTH promotes osteoblast survival in part by increasing Runx2 activity and, consequently, inducing expression of the survival gene *Bcl2*. However, PTH also induces proteasomal degradation of Runx2 though a mechanisms involving Smurf2. Therefore, the ability of PTH either to increase or decrease Runx2 levels in osteoblasts in a fashion dependent on the administration schedule may provide one of the possible (and likely many) mechanisms to explain the complex effect of PTH on bone formation and resorption.

Osterix is a zinc finger domain transcription factor expressed specifically in osteoblasts (Nakashima *et al.*, 2002). Its function is necessary for full osteoblastic differentiation and maturation (Nakashima *et al.*, 2002), and studies in cells (Nishio *et al.*, 2006) and genetically modified mice (Nakashima *et al.*, 2002) established that osterix lies downstream of Runx2. Similar to Runx2, PTH rapidly stimulates expression of osterix both in cell cultures (Wang *et al.*, 2006) and *in vivo* (Tanaka *et al.*, 2004).

Finally, PTH injection stimulates rapid and transient increases in the expression of at least three members of the nerve growth factor-inducible factor B (NR4A; NGFI-B) family of orphan nuclear receptors: Nurr1, Nur77, and NOR-1 (Pirih *et al.*, 2005). Although the functional significance of these molecules is largely undetermined, Nurr1

mediates PTH-stimulated activation of the *osteopontin* (Lammi *et al.*, 2004) and *osteocalcin* (Nervina *et al.*, 2006; Pirih *et al.*, 2004) promoters.

Growth Factors and Cytokines

Insulin-like Growth Factors

PTH stimulates synthesis and secretion of insulin-like growth factors (IGF), IGF-I and IGF-II, in bone. Both IGF-I and IGF-II are expressed in rat (McCarthy *et al.*, 1989) and mice (Linkhart and Mohan, 1989; Watson *et al.*, 1995). The PTH-dependent increase of IGF requires activation of the cAMP/PKA pathway because its effects are mimicked by cAMP analogues or agents that increase cAMP, but not by stimulation of calcium signals or PKC (McCarthy et al., 1990).

IGF-I exerts both proliferative and antiapoptotic actions in osteoblasts (Grey *et al.*, 2003) and a number of observations support the requirement of IGF-I as a mediator of the anabolic action of PTH. First, treatment of intact rats with PTH under conditions where it has an anabolic effect on bone leads to an increase in IGF-I mRNA (Watson *et al.*, 1995) and the bone matrix content of IGF-I. Second, daily PTH injection failed to stimulate bone formation in mice lacking IGF-I (Bikle *et al.*, 2002). Third, a similar absence of an anabolic effect by PTH was observed in mice null for the insulin receptor substrate-1 (IRS-1) (Yamaguchi *et al.*, 2005), the key intracellular mediator of IGF-I receptor signaling.

Additionally, both PTH and PTHrP affect the secretion of IGF-binding proteins (IGFBP), in particular, IGFBP-4 (LaTour *et al.*, 1990) and IGFBP-5 (Conover *et al.*, 1993) in bone. The role of IGFBP on IGF function is complex, because it can exert both inhibitory (IGFBP-4) and stimulatory (IGFBP-5) effects on IGF action in a cell- and context-specific manner. Moreover, some IGFBP have been proposed to have effects independent of IGF (Conover, 2008). Thus, the role of IGFBP on PTH action remains mostly to be defined.

Fibroblast Growth Factor-2 (FGF-2)

Like IGF-I, FGF-2 is a potent mitogen (Ling *et al.*, 2006), induces differentiation (Woei Ng et al., 2007) and exerts antiapoptotic effects on osteoblasts (Chaudhary and Hruska, 2001; Debiais *et al.*, 2004). PTH rapidly increases FGF-2 and FGF receptors in both primary and clonal osteoblastic cells (Hurley *et al.*, 1999). Stimulation of bone formation by PTH is impaired in mice null for FGF-2 (Hurley *et al.*, 2006) and bone marrow cultures from these mice produce fewer osteoclasts in response to PTH (Okada *et al.*, 2003). Collectively, these observations provide evidence that FGF-2 participates in the skeletal actions of PTH in vivo.

Amphiregulin

Recent studies demonstrated an important role for amphiregulin (AR), a member of the epidermal growth factor (EGF) family, as a mediator of PTH action. PTH stimulates AR expression in osteoblastic cells in a cAMP/PKA-dependent manner (Qin and Partridge, 2005). The increase in AR mRNA is mediated by phosphorylation of CREB and binding to a conserved CRE site in the AR promoter. AR appears to be important for bone metabolism because mice lacking AR have decreased trabecular bone (Qin *et al.*, 2005). In addition, AR stimulates rapid increases in *c-fos* and *c-jun* expression (Qin *et al.*, 2005). Treatment of primary calvarial cultures in vitro with AR stimulated cell proliferation and concomitant inhibition of osteoblastic differentiation, suggesting a role for AR on preosteoblastic mesenchymal stem cells (Qin and Partridge, 2005; Qin *et al.*, 2005). It is also notable that PTH stimulates the release heparin-bound EGF, which belongs to the same family of membrane bound and releasable EGF receptor agonists as AR, by activation of ADAM proteins in osteoblasts (Ahmed *et al.*, 2003). This process leads to the activation of EGF receptor in an auto- and paracrine fashion. It is therefore likely that PTH may not only induce expression of AR in osteoblasts but also its release via a similar mechanism.

Transforming Growth Factor-β

All three TGF-β isoforms are detected in bone, with TGF-β1 being the most abundant (Hering *et al.*, 2001; Seyedin *et al.*, 1985). TGF-β1 is secreted in by bone cells and is stored in the extracellular matrix. TGF-β is a potent mitogen for osteoprogenitors (Hock *et al.*, 1990) and has varied effects on differentiation and mineralization. Intermittent PTH treatment of rats increases the bone matrix content of TGF-β1 (Pfeilschifter *et al.*, 1995; Watson *et al.*, 1995) and the expression of TGF-β in osteoblasts (Oursler *et al.*, 1991; Pfeilschifter and Mundy, 1987; Wu and Kumar, 2000). Moreover, PTH and PTHrP increase the secretion of TGF-β by osteoblast-like bone cells (Wu and Kumar, 2000), TGF-β1 activity (Pfeilschifter and Mundy, 1987; Sowa *et al.*, 2003), and the release of TGF-β from bone matrix. Collectively, these observations suggest the possibility that TGF-β may contribute to the anabolic effects of intermittent PTH administration.

RANK Ligand and Osteoprotegerin

The regulation of these molecules by PTH and PTHrP is now recognized as the most prominent mechanism linking PTH1R-mediated actions in osteoblasts (and possibly stromal cells) and osteoclastogenesis. RANK ligand (RANKL)[4] is a member of the TNF family of cytokines that is expressed on the osteoblast and stromal cell surface. Its receptor, called receptor activator of NFkB (RANK), is expressed in osteoclast precursors and mature osteoclasts, and its activation by RANKL stimulates osteoclast

[4]It is also called osteoprotegerin ligand (OPGL), osteoclast differentiation factor (ODF), and TNF-related activation-induced cytokine (TRANCE).

formation, activity, and survival (Burgess *et al*., 1999; Fuller *et al*., 1998; Hofbauer *et al*., 2000; Lacey *et al*., 1998). A second component of this system, expressed and secreted by osteoblasts, is osteoprotegerin (OPG) (Simonet *et al*., 1997; Yasuda *et al*., 1998), a released protein that binds RANKL and prevents its actions on RANK. Therefore, it is the balance between RANKL and OPG (in other words, the ratio RANKL:OPG) that ultimately determines the extent of osteoclast formation and function.

Both PTH and PTHrP regulate the expression of RANKL and OPG. It is interesting to note that the frequency of administration of PTH affects the ratio RANKL:OPG differently. Thus, prolonged exposure to PTH in rats causes sustained stimulation of RANKL expression while inhibiting OPG expression (Huang *et al.*, 2004; Kondo *et al.*, 2002; Lee and Lorenzo, 1999; Ma *et al.*, 2001)—with the final effect being an overall stimulation of osteoclast number and resorptive capacity. In contrast, intermittent PTH treatment affected RANKL and OPG only transiently (Ma *et al.*, 2001). Exposure to PTH increases the expression of RANKL in murine bone marrow cultures, cultured osteoblasts, and mouse calvariae (Hofbauer *et al.*, 2000; Lee and Lorenzo, 1999; Tsukii *et al.*, 1998), and simultaneously decreases the expression of OPG (Lee and Lorenzo, 1999). In addition, studies using primary cultures indicate that the effect of PTH on RANKL expression is more pronounced in differentiated osteoblasts, whereas the inhibition of OPG occurs at all differentiation stages (Huang *et al.*, 2004). Notably, the stimulation of osteoclastic differentiation by RANKL requires the presence of macrophage-colony-stimulating factor (M-CSF), which is also upregulated by PTH (Horowitz *et al.*, 1989; Weir *et al.*, 1989).

Strong evidence supports the key role of the RANK/RANKL/OPG system in the activation of bone resorption upon prolonged exposure to PTH and PTHrP. Stimulation of osteoclastogenesis by PTH is blocked by antibodies to RANKL (Tsukii *et al.*, 1998) or by OPG (Lacey *et al.*, 1998; Yasuda *et al.*, 1998) and OPG inhibits the hypercalcemic response to PTH or PTHrP (Morony *et al.*, 1999; Oyajobi *et al.*, 2001).

Wnt/β-catenin/sclerostin

The Wnt/β-catenin signaling pathway is recognized as an important regulator of bone mass. This is a complex signaling system that comprises a number of members. Canonical Wnt signaling is mediated by a receptor complex formed by a Frizzled (a seven transmembrane domain receptor) and a coreceptor lipoprotein-receptor-related proteins 5 or 6 (LRP5/6). Upon engagement by Wnt, this complex activates the cytoplasmic protein dishevelled (Dsh), followed by the accumulation of unphosphorylated β-catenin. As a result, β-catenin translocates to the nucleus and regulates gene transcription. Moreover, cells secrete proteins (such as DKK-1) that interact with the coreceptors LRP5/6 and inhibit Wnt signaling (Baron and Rawadi, 2007). All the key elements of this pathway are expressed in bone cells and in osteoblastic cultures and are regulated by PTH (Kulkarni *et al*., 2005). Treatment of rats with PTH increased Frizzled-1 and β-catenin levels and decreased DKK-1, with a resultant activation of Wnt responses (Kulkarni *et al*., 2005). Sclerostin, the product of the Sost gene, is also a secreted Wnt inhibitor and binds LRP5 and LRP6 (Li *et al*., 2005; Semenov *et al*., 2005), and its level in osteocytes is dramatically reduced by continuous PTH treatment (Bellido, 2006; Bellido *et al*., 2005). It is interesting that sclerostin appears to inhibit osteoblast differentiation (van Bezooijen *et al*., 2004, 2007), thereby providing a functional link between osteocytes and osteoblasts. The profound effects of the Wnt signaling complex on bone metabolism are well described by a number of genetic studies, both in human and in animal models (Baron and Rawadi, 2007), and the observation that PTH engages this pathway in bone cells is indeed of great interest.

Adaptor Proteins

G protein-Coupled Receptor Kinase 2 and β-Arrestins

These two ubiquitously expressed proteins play important roles in the regulation of several G protein-coupled receptors, including the PTH1R. It is not surprising that alterations in their expression or activity impact the function of osteoblasts and their responsiveness to PTH. G protein-coupled receptor kinase 2 (GRK2) phosphorylates agonist-occupied PTH1R and promotes the binding of β-arrestins (Dicker *et al*., 1999; Ferrari *et al.*, 1999; Flannery and Spurney, 2001; Vilardaga *et al*., 2001). These combined actions result in decreased signaling and receptor desensitization (Bisello *et al*., 2002; Dicker *et al*., 1999; Ferrari and Bisello, 2001). Targeted overexpression of GRK-2 in osteoblasts promotes bone loss (Wang *et al*., 2005). In contrast, inhibition of GRK2 activity by expression of a dominant negative mutant increases PTH-stimulated cAMP, and mice overexpressing this molecule have increased bone remodeling with a net gain in bone content (Spurney *et al*., 2002). Similarly, intermittent PTH increased the number of osteoblasts in mice null for β-arrestin2 (Ferrari *et al.,* 2005). However, no net increase in bone mass was observed, likely because of the intense stimulation of osteoclastogenesis. Another regulator of G protein-coupled receptor signaling, the regulator of G protein signaling-2 (RGS2), which increases the rate of hydrolysis of GTP bound to G proteins, thereby terminating signaling, has also been implicated in PTH1R actions in bone cells. RGS2 mRNA is rapidly and transiently increased by PTH in rat bones, as well as in osteoblast cultures (Miles *et al*., 2000) and its expression in bone cells decreased PTH-stimulated cAMP production (Thirunavukkarasu *et al*., 2002). Interestingly, RGS2 upregulation was also observed in cells overexpressing

Runx2 (Thirunavukkarasu *et al.*, 2002), suggesting the possibility that mechanisms limiting PTH1R signaling by G proteins may be activated upon differentiation of cells along the osteoblastic lineage.

Effects on Gap Junctions

PTH increases intercellular communication of bone cells by increasing connexin-43 gene expression (Schiller *et al.*, 1992) and opening gap junctions (Donahue *et al.*, 1995; Schiller *et al.*, 1992). The reduction of connexin-43 levels by transfection of antisense cDNA markedly inhibited the cAMP response to PTH (Vander Molen *et al.*, 1996) and blocked the effect of PTH on mineralization by osteoblast-like cells (Schiller *et al.*, 2001). These effects appear to be significant to the anabolic action of PTH because increases in bone mineral content in response to intermittent PTH administration were significantly decreased in mice with targeted deletion of connexin-43 in osteoblasts (Chung *et al.*, 2006).

Effects on Bone Matrix Proteins and Alkaline Phosphatase

PTH regulates the expression of a number of bone matrix proteins, including type I collagen, osteocalcin, osteopontin, bone sialoprotein, osteonectin, and alkaline phosphatase. In most cases, these genes (with the exception of osteocalcin) are downregulated by continuous exposure to PTH (Wang *et al.*, 2005), whereas intermittent administration of PTH has inhibitory or stimulatory effects in different genes.

Type I collagen is the most abundant bone matrix protein. PTH and PTHrP acutely inhibit collagen synthesis *in vitro* (Kream *et al.*, 1980, 1986; Partridge *et al.*, 1989; Pines *et al.*, 1990). Similar inhibition is observed upon infusion of PTH in humans (Simon *et al.*, 1988). However, anabolic PTH treatment can stimulate type I collagen expression (Canalis *et al.*, 1990; Opas *et al.*, 2000), an effect that is likely mediated by increases in IGF-I (Canalis *et al.*, 1989). Intermittent treatment of mouse bone marrow cells with PTH modestly increased collagen expression (Locklin *et al.*, 2003). Similarly, PTH treatment inhibits osteopontin (Noda *et al.*, 1988) and osteonectin (Termine *et al.*, 1981) expression.

The osteocalcin gene is also importantly regulated by PTH (Noda *et al.*, 1988; Towler and Rodan, 1995; Yu and Chandrasekhar, 1997). However, in contrast to the effect on type I collagen, expression of osteocalcin is stimulated by chronic administration of PTH or PTHrP, whereas the acute effect of these hormones is inhibitory (Gundberg *et al.*, 1995).

Finally, the effect of PTH on the expression of bone sialoprotein can be either stimulatory (Ogata *et al.*, 2000; Yang and Gerstenfeld, 1997) or inhibitory (Ma *et al.*, 2001; Wang *et al.*, 2000).

The reported effects of PTH on the expression of alkaline phosphatase are inconsistent. PTH can either stimulate or inhibit secretion of alkaline phosphatase from bone cells (Jongen *et al.*, 1993; Kano *et al.*, 1994; Majeska and Rodan, 1982; McPartlin *et al.*, 1978; Yee, 1985) and may not be particularly indicative of PTH-specific actions. Indeed, although anabolic therapy with PTH generally increases the circulating levels of alkaline phosphatase (Finkelstein *et al.*, 1998), this effect is likely caused by an increase in osteoblast number rather than an increase in protein expression.

Effects on Bone Proteases

PTH stimulates the secretion of a number of matrix metalloproteases (MMPs) in bone cells (see Chapter 16) that are involved in bone remodeling. These include collagenase-3 (MMP-13) (Partridge *et al.*, 1987; Quinn *et al.*, 1990; Scott *et al.*, 1992; Winchester *et al.*, 1999 , 2000), stromelysin-1 (MMP-3) (Meikle *et al.*, 1992), gelatinase B (Meikle *et al.*, 1992), and the disintegrin and metalloprotease with thrombospondin repeats ADAMTS-1 (Miles *et al.*, 2000). Bone proteases, in particular collagenase-3 and gelatinase B, partially mediate the stimulation of bone resorption by PTH (Witty *et al.*, 1996). As described earlier, stimulation of the collagenase-3 promoter by PTH requires the combined action of AP-1 transcription factors and Runx2, effects that are mediated by cAMP-dependent activation of CREB (Porte *et al.*, 1999; Selvamurugan *et al.*, 1998, 2000). All of these events are stimulated by PTH. PTH treatment also increases secretion of the tissue inhibitor of matrix metalloproteins TIMP-1 by osteoblasts (Meikle *et al.*, 1992). This is relevant to the action of PTH because mice overexpressing TIMP-1 in osteoblasts responded to intermittent PTH with increases in bone mineral density higher than those in normal mice (Merciris *et al.*, 2007). This was also accompanied by decreased osteoclastic differentiation (Geoffroy *et al.*, 2004; Merciris *et al.*, 2007).

Effects of PTH and PTHrP on Bone Cell Proliferation

Continuous exposure to relatively high concentrations of PTH(1–34) or PTHrP(1–34) inhibits proliferation of virtually every osteoblastic cell line, including UMR 106-01, MC3T3-E1, SaOS-2, and calvarial primary cultures (Civitelli *et al.*, 1990; Kano *et al.*, 1991; Onishi and Hruska, 1997; Qin *et al.*, 2005). This effect is mediated by changes in the expression levels of several components of the cell cycle, ultimately resulting in arresting cells in the G_1 phase. PTH treatment decreases expression of cyclin D1, while increasing the levels of $p21^{Cip1}$ and $p27^{Kipl}$ (Onishi and Hruska, 1997; Qin *et al.*, 2005), with evident cell cycle arrest.

In contrast, some *in vitro* studies demonstrated that in certain circumstances PTH stimulates the proliferation of osteoblastic cells (Finkelman *et al.*, 1992; Onishi *et al.*, 1997; Somjen *et al.*, 1990). In particular, very low concentrations of PTH (Swarthout *et al.*, 2001) and brief exposure to PTH (Scutt *et al.*, 1994) resulted in increased cell proliferation. In the preosteoblast cell line TE-85, PTH stimulated proliferation by increasing expression of the cyclin-dependent kinase cdc2 (Onishi *et al.*, 1997).

The effects of PTH and PTHrP on the cell cycle in osteoblastic cells have important consequences *in vivo*. Several studies indicate that intermittent injections of PTH increase the number of osteoblasts (Kostenuik *et al.*, 1999; Nishida *et al.*, 1994) and this contributes to the stimulation of bone formation. However, this effect does not appear to be related to a direct stimulation of osteoblast mitogenesis. Indeed, although intermittent PTH administration in rats greatly increased osteoblast number and function, osteoblast proliferation was not detected (Dobnig and Turner, 1995; Onyia *et al.*, 1995, 1997). It is possible that the increase in osteoblast number produced by intermittent treatment with PTH is caused by the activation of bone lining cells to osteoblasts (Dobnig and Turner, 1995), a process that does not require mitosis. These data are compatible with the conclusion that PTH inhibits cell cycle progression of committed osteoprogenitors, thereby permitting their maturation.

Effects of PTH and PTHrP on Bone Cell Differentiation

PTH and PTHrP have a profound influence on the differentiation program of bone marrow cells to form osteoblasts. Several studies indicate that anabolic administration of PTH stimulates rapid changes in histomorphometry and gene expression, which have been interpreted as resulting from cell differentiation (Hodsman and Steer, 1993; Onyia *et al.*, 1995). The effects of PTH and PTHrP on cell differentiation in culture are also well documented and appear to depend on both the duration and frequency of PTH exposure. Early, transient PTH treatment enhances the commitment of progenitor cells and increases osteoblast differentiation (Wang *et al.*, 2007). *In vitro*, primary osteoblasts briefly (1 hour every 48 hours) exposed to PTH showed inhibited expression of alkaline phosphatase activity and bone nodule formation (Ishizuya *et al.*, 1997). In contrast, intermittent PTH treatment for 6 hours every 2 days stimulated osteoblastic differentiation and formation of mineralized nodules (Ishizuya *et al.*, 1997). Similarly, transient PTH treatment of calvarial osteoblasts inhibited the initial osteoblast differentiation but ultimately resulted in increased mineralized nodules and osteoblastic differentiation (Wang *et al.*, 2007). In cultured murine marrow cells, intermittent PTH treatment increases the expression of osteoblast differentiation markers (such as Runx2, alkaline phosphatase, and type I collagen) (Locklin *et al.*, 2003). In all cases, however, continuous exposure to PTH strongly inhibits osteoblast differentiation (Ishizuya *et al.*, 1997; Wang *et al.*, 2007). In this respect, it is interesting to note that in humoral hypercalcemia of malignancy (HHM), PTHrP is continuously secreted by tumors and results in the virtual absence of mature osteoblasts (Stewart *et al.*, 1982). In contrast, elevated PTH levels observed in hyperparathyroidism do not have the same effect: indeed, hyperparathyroidism is characterized by increased bone remodeling (i.e., higher formation and resorption) with complex effects on bone (Stewart *et al.*, 1982). Although the mechanisms of this difference remain to be fully elucidated, one possible underlying basis is the pulsatile secretion of PTH by the parathyroids in hyperparathyroidism versus the continuous, unregulated secretion of PTHrP in HHM.

Effects of PTH and PTHrP on Bone Cells: Survival

Cell culture studies show that PTH rapidly stimulates transcription of the prosurvival gene *Bcl-2*, while increasing the inactivation of the apoptotic protein Bad (Bellido *et al.*, 2003; Jilka *et al.*, 1998), suggesting that activation of the PTH1R in osteoblasts may inhibit apoptosis. Indeed, various studies showed that PTH reduces the apoptotic effects of etoposide, dexamethasone, and serum deprivation in osteoblastic cultures (Bellido *et al.*, 2003; Chen *et al.*, 2002; Jilka *et al.*, 1998). The effect of PTH on the expression of survival proteins appears to require the action of CREB and Runx2 (Bellido *et al.*, 2003). Considering the disparate effects of PTH on Runx2 stability discussed previously, it is therefore possible that the timing and frequency of PTH stimulation may be a key determinant for its prosurvival action. Thus, although some studies in mice demonstrated a significant decrease in apoptotic osteoblasts following daily PTH administration (Bellido *et al.*, 2003; Jilka *et al.*, 1999), a study in rats reported an actual increase in apoptotic osteoblasts by intermittent PTH (Stanislaus *et al.*, 2000). An additional complexity results from the observation that daily administration of PTH in postmenopausal women resulted in increased osteoblast apoptosis (Lindsay *et al.*, 2007). Finally, it should be noted that differences have been observed in the effect of PTH on osteoblast apoptosis at different skeletal sites (cortical and trabecular) and possibly between primary and secondary spongiosa (Jilka *et al.*, 1999; Stanislaus *et al.*, 2000).

EFFECTS OF PTH AND PTHrP ON BONE

Bone Resorption

Cellular Basis of PTH Action

PTH and PTHrP increase bone resorption by stimulating both osteoclastogenesis and activating the mature osteoclast. These effects require the participation of classical PTH target cells, including stromal cells and osteoblasts (Akatsu *et al.*, 1989; McSheehy and Chambers, 1986). Moreover,

as described earlier, osteoclasts do not express high-affinity PTH1R (Amizuka *et al.*, 1996; Rouleau *et al.*, 1990; Silve *et al.*, 1982). The identification of the central role of the RANK/RANKL system in osteoclast formation and function, and the appreciation that PTH and PTHrP affect the expression of RANKL and OPG in stromal cells and osteoblasts, provides a molecular basis for understanding PTH-stimulated bone resorption. The precise target cell in the osteoblast lineage responsible for mediating the bone-resorbing effects of PTH and PTHrP, if any, has not been identified, but various marrow stromal cell lines suffice *in vitro* (Aubin and Bonnelye, 2000) and bone resorption is still active when mature osteoblasts have been ablated (Corral *et al.*, 1998). By binding to its cognate receptor, RANK, on osteoclast precursors and mature osteoclasts, RANKL stimulates both osteoclastogenesis and the activity of mature osteoclasts. Therefore, the increased expression of RANKL mediated both the acute and chronic actions of PTH on bone resorption. The major difference in the two effects is likely related to the stronger suppression of the decoy receptor OPG upon prolonged exposure to PTH (Huang *et al.*, 2004). Osteoclast activation by RANKL is apparently responsible for both bone resorption at the cellular level and for hypercalcemia, because both are blocked by the decoy receptor OPG (Morony *et al.*, 1999; Yamamoto *et al.*, 1998).

The bone-resorbing effects of amino-terminal PTH and PTHrP are essentially indistinguishable when studied using isolated osteoclasts (Evely *et al.*, 1991; Murrills *et al.*, 1990), bone explant systems (Raisz *et al.*, 1990; Yates *et al.*, 1988), or infusion into the intact animal (Kitazawa *et al.*, 1991; Thompson *et al.*, 1988). In contrast, PTHrP is considerably less potent than PTH in inducing hypercalcemia in humans (Horwitz *et al.*, 2006). This difference is most likely because of lower induction of renal $1,25(OH)_2D_3$ by PTHrP compared with PTH (Horwitz *et al.*, 2003). Notably, studies in humans showed that intermittent administration of PTHrP(1–36) over 3 months stimulated bone formation without attendant increases in markers of bone resorption (Horwitz *et al.*, 2003).

As discussed in Chapter 3, PTHrP is a polyhormone, the precursor of multiple biologically active peptides. Carboxy-terminal peptides that are predicted to arise from cleavage of PTHrP in the polybasic region PTHrP(102–106) have been synthesized and shown to inhibit bone resorption in several explant systems (Fenton *et al.*, 1991b, 1993) and *in vivo* (Cornish *et al.*, 1997). On this basis, the minimal peptide that inhibits bone resorption, PTHrP(107–111), has been identified and called osteostatin.

EFFECTS OF PTH AND PTHrP ON BONE

Bone Formation

The mechanisms by which PTH increases bone formation are complex. As described previously, PTH and PTH exert a variety of effects on osteoblasts. The increase in bone formation in response to intermittent administration of PTH and PTHrP correlates with marked increases in the number of active osteoblasts (Boyce *et al.*, 1996; Dempster *et al.*, 1999; Shen *et al.*, 1993).

It is evident from the preceding discussion that every aspect of the osteoblast existence is affected by PTH, and all of these cellular actions may contribute to the increase in osteoblast number observed in the stimulation of bone formation. First, activation of the PTH1R produces various actions on the cell cycle of both the osteoblasts and their precursors. It is clear that in most circumstances PTH and PTHrP cause cell cycle arrest in osteoblasts and preosteoblasts and this may be a prerequisite to induce further differentiation and activation. Most *in vivo* evidence does not support a direct proliferative effect of PTH on mature osteoblasts (Dobnig and Turner, 1995; Onyia *et al.*, 1995, 1997). However, PTH and PTHrP increase expression and release of a number of potent mitogens (such as IGF-I, TGFβ, and amphiregulin), which may act in a paracrine fashion to expand the pool of osteoprogenitors (Grey *et al.*, 2003; Hock *et al.*, 1990; Qin *et al.*, 2005). Second, intermittent PTH administration stimulates transcription factors, such as Runx2 and osterix, which in turn stimulate differentiation. This effect is accompanied by increases in osteoblastic differentiation markers (Hodsman and Steer, 1993; Onyia *et al.*, 1995; Wang *et al.*, 2007). Third, some of the rapid hystomorphometric changes observed upon anabolic administration of PTH may derive from activation of bone lining cells to become active osteoblasts (Dobnig and Turner, 1995). Fourth, intermittent PTH administration exerts antiapoptotic actions in osteoblasts and osteocytes (Bellido *et al.*, 2003; Jilka *et al.*, 1999). Obviously, prolonging the life span of osteoblasts would contribute to increasing the number of mature osteoblasts. It is interesting to observe that Runx2, a key molecule mediating PTH effects on osteoblast survival, is also involved in the stimulation of osteoblastic differentiation.

The relative contribution of each of these mechanisms to the anabolic action of PTH has not been completely established. It seems likely that the remarkable increases in bone formation in response to intermittent administration of PTH and PTHrP arise from a combination of these effects. Moreover, it is possible that PTH and PTHrP may not have the same effect under all circumstances and in the presence of other treatments affecting bone metabolism.

Finally, it has long been thought that the anabolic effects of PTH and PTHrP are substantially equivalent because most of their cellular effects *in vitro* and activities in animal models are quite similar. However, it has recently become apparent that some basic differences exist in the action of these two hormones in humans. Intermittent administration of PTHrP(1–36) for 2 weeks (Plotkin *et al.*, 1998) and 3 months (Horwitz *et al.*, 2003), for instance, leads to increases in biochemical markers of bone formation without changing markers of bone resorption, suggesting that PTHrP(1–36) may uncouple bone formation and resorption.
