INTRODUCTION

Documentation of the skeletal abnormalities in mice that either overexpressed parathyroid-related protein (PTHrP) in their skeletons or had the genes for PTHrP and the PTH receptor ablated by the techniques of homologous recombination provided an exciting impetus for the rapid accumulation of knowledge regarding the mechanisms by which PTHrP regulates bone and cartilage development and physiology. These findings are reviewed in Chapters 13 and 15. Since the mid-1990s, increasing evidence has accumulated that PTHrP and the PTH/PTHrP receptor family also contribute to the development and functioning of several nonskeletal organs. Data regarding the action of PTHrP in the vascular system and the central nervous system are reviewed in Chapter 16. In this, the last of the series of chapters on the physiological actions of PTHrP, we review data regarding the function(s) of PTHrP in several other nonskeletal sites. We first consider the functions of PTHrP in skin. Next, we review its functions in the mammary gland, placenta, and other reproductive tissues. Finally, we examine its role in the endocrine pancreas.

SKIN

PTHrP and PTHrP Receptor Expression

Normal human keratinocytes were the first nonmalignant cells shown to produce PTHrP (Merendino *et al.,* 1986), and multiple studies have confirmed that rodent and human keratinocytes in tissue culture express the PTHrP gene and secrete bioactive PTHrP (reviewed in Phlbrick *et al.,* 1996). PTHrP expression has also been examined in skin *in vivo* by using both immunohistochemistry and *in situ* hybridization. During fetal development in rats and mice, PTHrP is expressed principally within the epithelial cells of developing hair follicles (Karmali *et al.,* 1992; Lee *et al.,* 1995). In mature skin, the PTHrP gene is also expressed most prominently within hair follicles, and mRNA levels appear to vary with the hair cycle. Cho and colleagues (2003) found that PTHrP expression increased within the outer root sheath and isthmus of late anagen hair follicles in mice. During catagen and telogen, PTHrP transcripts were abundant within the isthmus, but expression was downregulated during early anagen (Cho *et al.*, 2003). In addition to hair follicles, low levels of PTHrP expression may also be found throughout the interfollicular epidermis from the basal layer to the granular layer. Some studies have suggested that PTHrP is more highly expressed in the superbasal keratinocytes (Danks *et al.,* 1989; Hayman *et al.,* 1989), although not all studies have reported this pattern (Atillasoy *et al.,* 1991; Grone *et al.,* 1994). A variety of factors have been reported to regulate PTHrP production by cultured keratinocytes (see Philbrick *et al.,* 1996, for review). For example, glucocorticoids and 1,25-$(OH)_2$D have been shown to suppress PTHrP production, whereas fetal bovine serum, matrigel, and an as-yet-unidentified factor(s) secreted from cultured fibroblasts have been shown to enhance PTHrP production. The upregulation of PTHrP production by fibroblast-conditioned media is particularly interesting, as PTHrP, in turn, acts back on dermal fibroblasts, suggesting that it may function in a short regulatory loop

between keratinocytes and dermal fibroblasts (Shin *et al.,* 1997; Blomme *et al.,* 1999a). Finally, *in vivo,* PTHrP expression has been shown to be upregulated at the margins of healing wounds in guinea pigs (Blomme *et al.,* 1999b). Interestingly, in this study, PTHrP was also detected in myofibroblasts and macrophages, suggesting that keratinocytes may not be the only source of PTHrP in skin.

The general consensus has been that keratinocytes do not express the type I PTH/PTHrP receptor (PTH1R), but dermal fibroblasts do (Hanafin *et al.,* 1995; Orloff *et al.,* 1995). PTHrP has been shown to bind to skin fibroblasts and to elicit biochemical and biological responses in these cells (Shin *et al.,* 1997; Blomme *et al.,* 1999a; Wu *et al.,* 1987). In addition, studies utilizing *in situ* hybridization in fetal skin have demonstrated that PTH1R mRNA is absent from the epidermis, yet abundant in the dermis, especially in those cells adjacent to the keratinocytes (Karmali *et al.,* 1992; Lee *et al.,* 1995; Dunbar *et al.,* 1999a). There are fewer data concerning the expression patterns of the PTH1R in more mature skin, but, in mice, it appears that the relative amount of PTH1R mRNA in dermal fibroblasts is reduced in adult compared with fetal skin (Cho *et al*., 2003). As with PTHrP, there also appears to be a hair-cycle-dependent variation in expression of the PTH1R gene in the connective tissue adjacent to the isthmus of the hair follicles. However, unlike PTHrP mRNA, PTH1R mRNA appears to be most plentiful during early anagen (Cho *et al*., 2003). In addition to fibroblasts, recent studies using sensitive PCR-based detection methods have also reported expression of the PTH1R in keratinocytes, although these studies have used cultured cells (Errazahi *et al.,* 2003, 2004). Furthermore, studies have shown that cultured keratinocytes bind and respond to PTHrP by inducing calcium transients, suggesting the presence of PTHrP receptors, either the classical PTH1R or nonclassical, alternative PTHrP receptors (Orloff *et al.,* 1992, 1995). However, to date, no such alternative receptors have been isolated, so their existence remains uncertain. Furthermore, it is not clear whether the PTH1R is expressed on keratinocytes *in vivo*. Therefore, although the possibility of both paracrine and autocrine signaling exists, no functional studies address the relative importance of either pathway to the biology of PTHrP in skin.

Biochemistry of PTHrP

As described in Chapters 3 and 4, during transcription, the PTHrP gene undergoes alternative splicing to generate multiple mRNAs, which in human cells give rise to three main protein isoforms. In addition, each of these isoforms is subject to post-translational processing to generate a variety of peptides of varying length. Human keratinocytes have been shown to contain mRNA encoding for each of the three main isoforms, although, as in other systems, no clearly defined or unique role has yet emerged for any of the three individual isoforms (Philbrick *et al.,* 1996). Keratinocytes have also been shown to process full-length PTHrP into a variety of smaller peptides, including PTHrP(1–36) and a midregion fragment beginning at amino acid 38 (Soifer *et al.,* 1992). These cells have also been shown to secrete a large (≈10 kDa) amino-terminal form that is glycosylated (Wu *et al.,* 1991). There is currently no specific information regarding the secretion of COOH-terminal peptides of PTHrP in skin, but keratinocytes are also likely to produce these peptides.

Function of PTHrP

Several studies suggest that PTHrP is involved in the regulation of hair growth. As noted earlier, the PTHrP gene in embryonic skin is expressed most prominently in developing hair follicles, and overexpression of PTHrP in the basal keratinocytes of skin in transgenic mice leads to a severe inhibition of ventral hair follicle morphogenesis during fetal development (Wysolmerski *et al.,* 1994). This appears to be the result of an interaction between PTHrP and BMP signaling that normally is involved in the regulation of Msx2 expression, the patterning of the mammary mesenchyme and the lateral inhibition of hair follicle development around the nipple (Hens *et al*., 2007) (see "Mammary Gland"). However, it is unlikely that PTHrP is critical to hair follicle morphogenesis elsewhere because disruption of the PTHrP or PTH1R genes does not seem to affect hair follicle formation or patterning in mice except for the vicinity of the nipple (Karaplis *et al.,* 1994; Lansk *et al.,* 1996; Foley *et al.,* 1998).

It has also been suggested that PTHrP may participate in the regulation of the hair cycle. Systemic or topical administration of PTH1R antagonists to mice appears to perturb the hair cycle by prematurely terminating telogen, prolonging anagen growth, and inhibiting catagen (Schilli *et al.,* 1997; Safer *et al*., 2007). In a reciprocal fashion, mice overexpressing PTHrP in their skin (K14-PTHrP mice) demonstrate a delayed emergence of dorsal hair and have shorter hairs, and their hair follicles enter catagen approximately 2 days early (Cho *et al*., 2003; Diamond *et al.,* 2006). These findings were associated with a lower proliferation rate in the hair matrix and a less well-developed perifollicular vasculature during anagen. Together, these studies imply that PTHrP may regulate the anagen to catagen transition, acting to inhibit hair follicle growth by pushing growing hair follicles into the growth-arrested or catagen/telogen phase of the hair cycle. If this hypothesis were correct, one would expect PTHrP knockout mice to exhibit findings similar to PTH1R antagonist-treated mice. However, this does not appear to be the case. In mice that lack PTHrP in their skin, the hair cycle appears to be normal (Foley *et al.,* 1998). In fact, rather than a promotion of hair growth, these mice demonstrate a thinning of their coat over time. These conflicting results are difficult to rationalize at this point, but suggest that although PTHrP may contribute to the regulation

of the hair cycle, it is unlikely to be necessary for this process to unfold normally.

PTHrP has also been implicated in the regulation of keratinocyte proliferation and/or differentiation. Data from studies *in vitro* have suggested that PTHrP promotes the differentiation of keratinocytes (reviewed in Philbrick *et al.,* 1996), but studies *in vivo* have suggested that PTHrP inhibits keratinocyte differentiation (Foley *et al.,* 1998). A careful comparison of the histology of PTHrP-null and PTHrP-overexpressing skin demonstrated reciprocal changes. In the absence of PTHrP, it appeared that keratinocyte differentiation was accelerated, whereas in skin exposed to PTHrP overexpression, keratinocyte differentiation appeared to be retarded (Foley *et al.,* 1998). Therefore, in a physiological context, PTHrP appears to slow the rate of keratinocyte differentiation and to preserve the proliferative, basal compartment. Remarkably, these changes in the rate of keratinocyte differentiation are exactly analogous to those noted for chondrocyte differentiation in the growth plates of mice overexpressing PTHrP compared with PTHrP- and PTH1R-null mice (Philbrick *et al.,* 1996) (see Chapter 15). Again, at present, it is difficult to rationalize conflicting data regarding the effects of PTHrP on keratinocyte differentiation, but studies in genetically altered mice indicate that PTHrP participates in the complex regulation of these processes *in vivo.* Further research will be needed to understand its exact role.

As alluded to previously, an important but still unresolved question is whether the effects of PTHrP on keratinocyte proliferation, differentiation, and hair follicle growth are the result of its effects on keratinocytes directly or via its effects on dermal fibroblasts. At present there are more data to support the paracrine possibility. PTH1R is expressed on dermal fibroblasts *in vivo* and in culture (Lee *et al.,* 1995; Hanafin *et al.,* 1995). Dermal fibroblasts have been demonstrated to show biochemical and biological responses to PTHrP (Shin *et al.,* 1997; Blomme *et al.,* 1999a; Wu *et al.,* 1987, Thomson *et al.*, 2003). Furthermore, PTHrP has been shown to induce changes in growth factor and extracellular matrix production that could, in turn, lead to changes in keratinocyte proliferation and/or differentiation and hair follicle growth (Shin *et al.,* 1997; Blomme *et al.,* 1999a; Insogna *et al.,* 1989). Of course, the autocrine and paracrine signaling pathways are not mutually exclusive, but any direct autocrine effects of PTHrP on keratinocytes would require the presence of PTHrP receptors. An alternative possibility by which PTHrP might have cell autonomous effects on keratinocytes is via an intracrine pathway involving its translocation to the nucleus (Philbrick *et al.,* 1996). Clearly, much research is needed to define the receptors and signaling pathways by which PTHrP acts in skin. Only when this information is available will we be able to understand the mechanisms leading to the skin phenotypes that have been observed in the various transgenic models discussed earlier.

Pathophysiology of PTHrP

To date, PTHrP has not been clearly implicated in any diseases of the skin. It has been suggested that skin and skin appendage findings in the rescued PTHrP-null mice are reminiscent of a series of disorders collectively known as the ectodermal dysplasias (Foley *et al.,* 1998), but PTHrP has not been formally linked to any of these diseases. It has also been noted that psoriatic skin may downregulate PTHrP expression and a small trial of topically administered PTH suggested that stimulation of the PTH1R might improve the histological abnormalities in psoriatic plaques (Hollick *et al.*, 2003). However, these potentially exciting results will need to be verified in larger trials. Preliminary studies also suggest that topical application of PTH1R antagonists may be useful for stimulating hair growth, although there are no data to suggest that PTHrP is involved in the pathogenesis of alopecia(s) (Safer *et al.*, 2007). The most common tumors causing humoral hypercalcemia of malignancy (HHM) are those of squamous histology, but these tumors rarely arise from skin keratinocytes. In fact, the most common skin tumors, basal cell carcinomas, do not overexpress PTHrP and are not associated with hypercalcemia (Philbrick *et al.,* 1996). Although PTHrP appears to participate in the normal physiology of the skin, it is not clear at this juncture if it will be involved in skin pathophysiology.

MAMMARY GLAND

PTHrP was reported to be expressed in mammary tissue and to be secreted into milk very soon after its discovery (Thiede and Rodan, 1988; Budayr *et al.,* 1989). It is now appreciated that PTHrP is critically important for the proper development and functioning of the mammary gland throughout life. In addition, it has been implicated as an important modulator of the biological behavior of breast cancer. The mammary gland develops in several discrete stages and only reaches its fully differentiated state during pregnancy and lactation. PTHrP appears to serve different functions during these different stages of mammary development; therefore, we will organize our discussion around three principal stages of mammary development: embryonic development, adolescent growth, and pregnancy and lactation. For each stage, we will first outline the pertinent developmental events in rodents, as data regarding the function(s) of PTHrP largely come from studies in mice and rats. Next, we will discuss the localization of PTHrP and PTHrP receptors and the regulation of the expression of PTHrP and its receptors. Finally, we will address the function of PTHrP.

Embryonic Mammary Development

In mice, there are two phases of embryonic mammary development. The first involves the formation of five pairs

of mammary buds, each of which consists of a bulb-shaped collection of epithelial cells surrounded by several layers of fibroblasts known as the mammary mesenchyme (Sakakura, 1987). After the formation of these buds, mouse mammary development displays a characteristic pattern of sexual dimorphism. In male embryos, in response to androgens, the mammary mesenchyme destroys the epithelial bud and male mice are left without mammary glands or nipples (Sakakura, 1987). In female embryos, however, the mammary buds remain quiescent until embryonic day 16 (E16) when they undergo a transition into the second step of embryonic development, the formation of the rudimentary ductal tree. This process involves the elongation of the mammary bud, its penetration out of the dermis and into a specialized stromal compartment known as the mammary fat pad, and the initiation of ductal branching morphogenesis. At the time of birth, the gland consists of a simple epithelial ductal tree consisting of 15–20 branched tubes within a fatty stroma (Sakakura, 1987). This initial pattern persists until puberty at which time the mature virgin gland is formed through a second round of branching morphogenesis, regulated by circulating hormones (discussed later).

The PTHrP gene is expressed exclusively within epithelial cells of the mammary bud, soon after it begins to form. PTHrP mRNA continues to be localized to mammary epithelial cells during the initial round of branching morphogenesis, as the bud grows out into the presumptive mammary fat pad and begins to branch (Dunbar *et al.,* 1998, 1999a; Wysolmerski *et al.,* 1998). At some point after birth, PTHrP gene expression is downregulated, and in the adult virgin gland, PTHrP mRNA is found only within specific portions of the duct system (Dunbar *et al.,* 1998). In contrast to the PTHrP gene, the PTH1R gene appears to be expressed within the mesenchyme, but its expression is widespread and is not limited to the developing mammary structures. Transcripts for the PTH1R gene are found within the mammary mesenchyme but also throughout the developing dermis (Dunbar *et al.,* 1999a; Wysolmerski *et al.,* 1998). It is not clear when the receptor gene is first expressed within the subepidermal mesenchyme. However, it is already present when the mammary bud begins to form and it continues to be expressed within fibroblasts surrounding the mammary ducts as they begin to extend and branch (Wysolmerski *et al.,* 1998; Dunbar *et al.,* 1998).

Epithelial expression of PTHrP and mesenchymal expression of the PTH1R are not unique to the developing mammary gland, and this pattern has long led to speculation that PTHrP and its receptor might contribute to the regulation of epithelial–mesenchymal interactions during organogenesis. There is now solid evidence that this is the case during embryonic mammary development, where PTHrP acts as an epithelial signal that influences cell fate decisions within the developing mammary mesenchyme. Data supporting this notion come from studies in several genetically altered mouse models. First, in PTHrP or PTH1R knockout mice, there is a failure of the normal androgen-mediated destruction of the mammary bud owing to the failure of the mammary mesenchyme to differentiate properly and to express androgen receptors (Dunbar *et al.,* 1999a). Second, in PTHrP or PTH1R knockout mice, the mammary buds fail to grow out into the fat pad and initiate branching morphogenesis, again due to defects in the mammary mesenchyme (Wysolmerski *et al.,* 1998; Dunbar *et al.,* 1998). Finally, in keratin 14 (K14)-PTHrP transgenic mice that ectopically overexpress PTHrP within all the basal keratinocytes of the developing embryo, subepidermal mesenchymal cells, which should acquire a dermal fate, instead react to the excess PTHrP by becoming mammary mesenchyme (Dunbar *et al.,* 1999a).

As demonstrated by these studies, PTHrP signaling is essential for mammary gland formation in rodents. When the mammary gland begins to form, the PTH1R is expressed in all of the mesenchymal cells underneath the epidermis, but PTHrP is expressed only within the mammary epithelial buds and not within the epidermis itself (Karmali *et al.,* 1992; Thiede and Rodan, 1988; Wysolmerski *et al.,* 1998). As the mammary bud grows down into the mesenchyme, PTHrP, produced by mammary epithelial cells, interacts over short distances with the PTH1R on the immature mesenchymal cells closest to the epithelial bud and triggers these cells to differentiate into mammary mesenchyme. Recent studies have demonstrated that PTHrP accomplishes this, at least in part, by upregulating expression of BMP receptors on the mesenchymal cells and sensitizing them to respond in an autocrine fashion to BMP4 expressed in the ventral surface of the embryo (Hens *et al.*, 2007). In this way, PTHrP acts as a patterning molecule contributing to the formation of small patches of mammary-specific stroma around the mammary buds and within the surrounding sea of presumptive dermis (Fig. 1; Foley *et al.,* 2001). The process of differentiation set in motion by PTHrP signaling is critical to the ability of the mammary-specific stroma to direct further morphogenesis of the epithelium and to inhibit hair follicle development in the vicinity of the developing nipple. In the absence of this signaling, the mesenchyme can neither destroy the epithelial bud in response to androgens nor trigger the outgrowth of the bud and the initiation of branching morphogenesis (Dunbar *et al.,* 1998, 1999a; Wysolmerski *et al.,* 1998).

Although the model described earlier was developed from studies in mice, PTHrP is also critical to the formation of breast tissues in human fetuses. Blomstrand's chondrodysplasia is a fatal form of dwarfism caused by null mutations of the PTH1R gene (Jobert *et al.,* 1998) (see Chapter 44). Affected fetuses have skeletal abnormalities similar to those caused by deletion of the PTHrP and PTH1R genes in mice (see Chapter 15) and, in addition, lack breast tissue or nipples (Wysolmerski *et al.,* 1999). In normal human fetuses, the PTHrP gene is expressed within the mammary epithelial bud, and the PTH1R gene

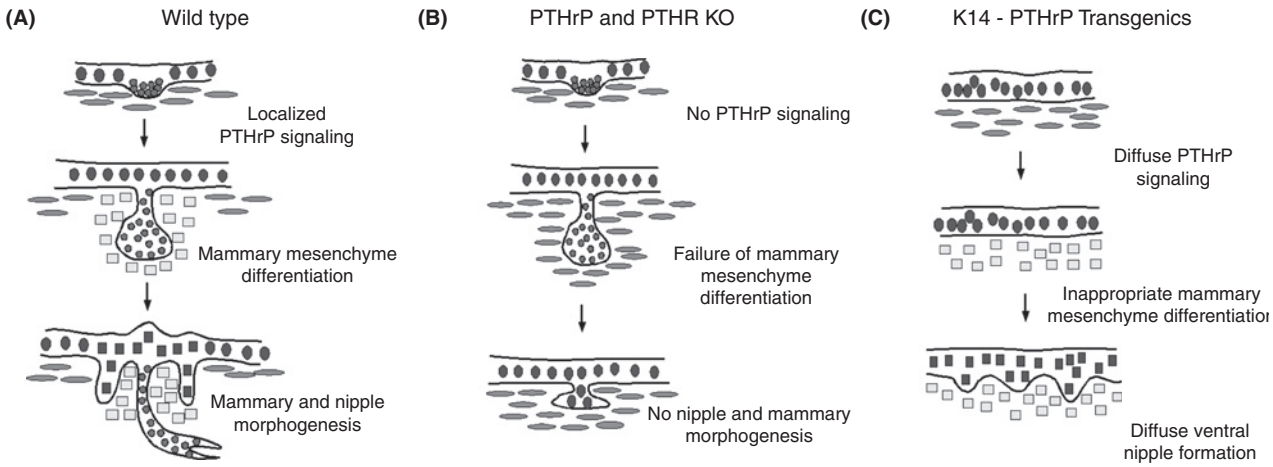

FIGURE 1 Model for the regulation of cell fate by PTHrP signaling during mammary gland and nipple development. **(A)** Normally, the mammary epithelial cells (small circles) express PTHrP after the bud starts to form. PTHrP signals to the dermal mesenchyme (ovals) near the developing bud and, as a result, these cells become mammary mesenchyme (light squares). The mammary mesenchyme maintains the mammary fate of the epithelial cells, triggers their morphogenesis, and induces the overlying epidermis (upright ovals) to become the nipple (dark squares). **(B)** In the absence of PTHrP signaling no mammary mesenchyme is formed. Therefore, the mammary epithelial cells revert to an epidermal fate, no morphogenesis occurs and the nipple does not form. **(C)** In the presence of diffuse PTHrP signaling, the entire ventral dermis becomes mammary mesenchyme and the ventral epidermis becomes nipple sheath. (Reproduced from Foley *et al.,* 2001, with permission.)

is expressed in surrounding mesenchyme (Wysolmerski *et al.,* 1999, Cormier *et al.*, 2003). Therefore, in humans, as in mice, epithelial-to-mesenchymal PTHrP to PTH1R signaling is essential to the formation of the embryonic mammary gland.

Adolescent Mammary Development

After birth, the murine mammary gland undergoes little development until the onset of puberty. At that point, in response to hormonal changes, the distal ends of the mammary ducts form specialized structures called terminal end buds. These structures serve as sites of cellular proliferation and differentiation during a period of active growth that gives rise to the typical branched duct system of the mature virgin gland (Daniel and Silberstein, 1987). Once formed, the ductal tree remains relatively unchanged until pregnancy when another round of hormonal stimulation induces the formation of the alveolar units that produce milk.

Similar to findings in the embryonic mammary gland, during puberty PTHrP is a product of mammary epithelial cells and the PTH1R is expressed in stromal cells (Dunbar *et al.,* 1998). However, the structure of the pubertal gland is more complex than that of the embryonic gland and, here, there are conflicting data regarding the localization of PTHrP and the PTH receptor. Although there is general agreement that PTHrP is expressed in epithelial cells in the postnatal gland, there is some disagreement regarding the specific epithelial compartments in which PTHrP is found. Studies employing *in situ* hybridization in mice have suggested that, after birth, the overall levels of PTHrP gene expression in mammary ducts are reduced except for in the terminal end buds during puberty (Dunbar *et al.,* 1998). In these structures, appreciable amounts of PTHrP mRNA were detected in the peripherally located cap cells. In other parts of the gland there was little, if any, specific hybridization for PTHrP. In contrast, studies looking at mature human and canine mammary glands using immunohistochemical techniques have suggested that PTHrP can be found in both luminal epithelial and myoepithelial cells throughout the ducts (Grone *et al.,* 1994; Liapis *et al.,* 1993). Furthermore, studies using cultured cells have suggested that PTHrP is produced by luminal and myoepithelial cells isolated from normal glands (Ferrari *et al.,* 1992; Seitz *et al.,* 1993; Wojcik *et al.,* 1999). There have been fewer reports looking at the localization of PTH1R expression in the postnatal mammary gland, but as in embryological development, it is expressed in the mammary stroma (Dunbar *et al.,* 1998). *In situ* hybridization studies have found the highest concentration of PTH1R mRNA in the stroma immediately surrounding terminal end buds during puberty (Dunbar *et al.,* 1998). This same study found lower levels of PTH1R mRNA distributed generally within the fat pad stroma, but very little expression in the dense stroma surrounding the more mature ducts. In addition, these investigators found no evidence of PTH1R mRNA in freshly isolated epithelial cells (Dunbar *et al.,* 1998). In contrast, other studies have suggested that PTH1R is expressed in cultured luminal epithelial and myoepithelial cells (Seitz *et al.,* 1993; Wojcik *et al.,* 1999), as well as in cultured breast cancer cell lines (Birch *et al.,* 1995). In summary, during puberty, PTHrP and its receptor are found predominantly within the terminal end buds, with PTHrP localized to the epithelium and PTH1R localized

in the stroma. It remains an open and interesting question whether, at some time during mammary ductal development, epithelial cells express low levels of PTH1R.

Studies in transgenic mice have suggested that PTHrP regulates mammary morphogenesis during puberty. Overexpression of PTHrP in mammary epithelial cells using the K14 promoter results in an impairment of ductal branching morphogenesis (Wysolmerski *et al.,* 1995). There are two aspects to the defect. First, the terminal end buds advance through the mammary fat pad at a significantly slower rate than normal. Second, there is a severe reduction in the branching complexity of the ductal tree. As seen in Fig. 2, this results in a spare and stunted epithelial duct system. Experiments altering the timing and duration of PTHrP overexpression in the mammary gland using a tetracycline-regulated K14-PTHrP transgene have demonstrated that the two aspects of this pubertal phenotype appear to represent separate functions of PTHrP. The branching (or patterning) defect results from embryonic overexpression of PTHrP, whereas the ductal elongation defect is a function of overexpression of PTHrP during puberty (Dunbar *et al.,* 2001). These effects on ductal patterning provide further evidence of the importance of PTHrP as a regulator of embryonic mammary development. In addition, the localization patterns for PTHrP and PTH1R during puberty, combined with the effects of pubertal overexpression of PTHrP on ductal growth, suggest that PTHrP also functions later in mammary development. During puberty it appears to modulate epithelial–mesenchymal interactions that govern ductal elongation.

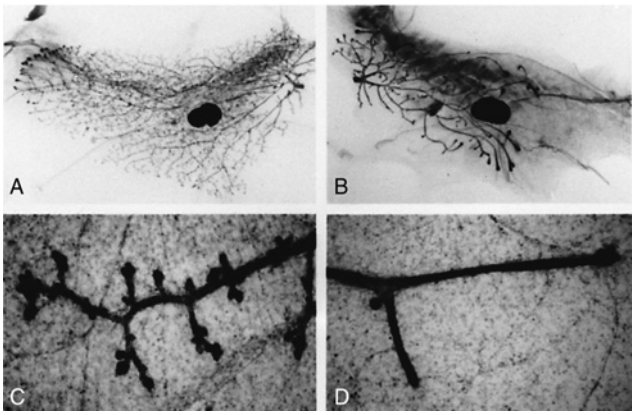

FIGURE 2 Overexpression of PTHrP in the mammary gland of K14-PTHrP transgenic mice antagonizes ductal elongation and branching morphogenesis during puberty. **A** and **B** represent typical whole-mount analyses of the fourth inguinal mammary glands from wild-type **(A)** and K14-PTHrP transgenic mice **(B)** at 6 weeks of age. The dark oval in the center of each gland is a lymph node. Growth of the ducts during puberty is directional and each gland is arranged so that the primary duct (the origin of the duct system) is toward the center of the figure. Note that overexpression of PTHrP results in an impairment of the elongation of the ducts through the fat pad as well as a dramatic reduction of the branching complexity of the ductal tree. **C** and **D** represent higher magnifications of a portion of the ducts from the wild-type **(C)** and transgenic **(D)** glands demonstrating the reduction in side branching caused by overexpression of PTHrP. (Modified from Wysolmerski *et al.,* 1995 with permission.)

Pregnancy and Lactation

Mammary epithelial cells only reach their fully differentiated state during lactation. Under hormonal stimulation during pregnancy, there is a massive wave of epithelial proliferation and morphogenesis that gives rise to multiple terminal ductules and alveolar units. During the later stages of pregnancy, the epithelial cells fully differentiate and then begin to secrete milk during lactation. By the time lactation commences, the fatty stroma of the mammary gland is almost completely replaced by actively secreting alveoli. Upon the completion of lactation, there is widespread apoptosis of the differentiated epithelial cells and the gland remodels itself into a duct system similar to that of the virgin animal (Daniel and Silberstein, 1987).

Localization studies in humans, rodents, and cows have all noted epithelial cells to be the source of PTHrP in the mammary gland during pregnancy and lactation (Liapis *et al.,* 1993; Wojcik *et al.,* 1998, 1999; Rakopoulos *et al.,* 1990). Based on the assessment of whole-gland RNA, PTHrP expression appears to be upregulated at the start of lactation under the control of both local and systemic factors (Philbrick *et al.,* 1996; Thiede and Rodan, 1988; Thiede, 1989; Thompson *et al.,* 1994; Buch *et al.,* 1992). Thiede and Rodan (1988) and Thiede (1989) originally reported that PTHrP expression in rats is dependent on suckling and on serum prolactin concentrations. However, prolactin must serve only as a permissive factor, for additional studies have shown that the suckling response is a local one and that PTHrP only rises in the milked gland (Thompson *et al.,* 1994). Furthermore, overall PTHrP expression increases gradually over the course of lactation, and in later stages, its expression becomes independent of serum prolactin levels (Bucht *et al.,* 1992). It is clear that much of the PTHrP made during lactation ends up in milk, in which levels of PTHrP are up to 10,000-fold higher than in the circulation of normal individuals and 1000-fold higher than in patients suffering from humoral hypercalcemia of malignancy (Philbrick *et al.,* 1996). PTHrP concentrations in milk have generally been found to mirror RNA levels in the gland, increasing over the duration of lactation and rising acutely with suckling (Thompson *et al.,* 1994; Yamamoto *et al.,* 1992a; Law *et al.,* 1991; Goff *et al.,* 1991). In addition, evidence shows that PTHrP levels may vary with the calcium content of milk (Yamamoto *et al.,* 1992a; Law *et al.,* 1991; Goff *et al.,* 1991; Vemura *et al.,* 1997; Kovacs and Kronenberg, 1997). In mice, the calcium-sensing receptor is expressed on the basolateral surface of mammary epithelial cells during lactation and regulates PTHrP production, such that increased delivery of calcium to the mammary gland decreases PTHrP production and secretion into milk

(VanHouten *et al.,* 2004; Ardeshirpour *et al.,* 2006). Finally, in mice, PTHrP mRNA levels are promptly downregulated during the early stages of involution and then increase to prelactation levels about a week into the remodeling process (M. Dunbar and J. J. Wysolmerski, unpublished data).

In contrast to PTHrP, there has been little study of the expression or regulation of PTHrP receptors during pregnancy and lactation. In early pregnancy, the PTH/PTHrP receptor is expressed at low levels in the stroma surrounding the developing alveolar units (Dunbar *et al.,* 1998). Studies using whole-gland RNA demonstrate a reciprocal relationship between PTH1R and PTHrP mRNA levels. That is, as PTHrP expression rises during lactation, PTH1R mRNA levels decrease, and as PTHrP mRNA levels fall during early involution, PTH1R expression increases to its former level (M. Dunbar and J. J. Wysolmerski, unpublished data). This may represent active downregulation of the receptor by PTHrP or may simply reflect the changing amount of stroma within the gland at these different stages. However, in a study of cells isolated from lactating rats, it was suggested that epithelial cells, as well as stromal cells, express this receptor (Wojcik *et al.,* 1999), so the regulation of PTH1R expression during pregnancy and lactation may be complex.

Initial reports of the presence of PTHrP in the mammary gland and in milk prompted a great deal of speculation regarding its functions in breast tissue during lactation. These proposals revolved around four general hypotheses: (1) PTHrP may be involved in maternal calcium homeostasis and the mobilization of calcium from the maternal skeleton; (2) PTHrP may be involved in regulating vascular and/or myoepithelial tone in the lactating mammary gland; (3) PTHrP may be involved in transepithelial calcium transport into milk; and/or (4) PTHrP may be involved in neonatal calcium homeostasis or neonatal gut physiology. The function of PTHrP in the lactating mammary gland in mice was addressed by disrupting the PTHrP gene solely in mammary epithelial cells during lactation (VanHouten *et al.*, 2003). This experiment has supplied evidence to support the role of PTHrP in regulating maternal and neonatal calcium and bone metabolism and has shown that PTHrP is not directly involved in mediating calcium transport into milk.

Milk production requires a great deal of calcium, and providing an adequate supply to the mammary gland stresses maternal bone and mineral metabolism (Kovacs and Kronenberg, 1997). Some of the calcium required for milk comes from the diet, as calcium intake is increased owing to the orexigenic effects of suckling (Smith and Grove, 2002). In addition, renal reabsorption of calcium is increased during lactation so that urinary losses are reduced. Finally, a significant proportion of the calcium transported into milk is derived from the maternal skeleton. Overall rates of bone turnover are elevated during lactation, but bone resorption outstrips bone formation so that bone mass declines rapidly. The average nursing woman loses between 5 and 10% of her bone mass over 6 months, whereas rodents lose up to one-third of their skeletal mass over 21 days of lactation (VanHouten and Wysolmerski, 2003). Mobilization of skeletal calcium during lactation does not rely on either of the established calcium-regulating hormones, PTH or $1,25(OH)_2D$ (Kovacs and Kronenberg, 1997). Recent experiments have shown that bone resorption is increased because of the combination of decreased systemic estradiol concentrations and elevated circulating PTHrP levels. Suckling directly inhibits hypothalamic GnRH secretion and induces hypogonadotropic hypogonadism (Smith and Grove, 2002). Bone loss correlates with the duration of amenorrhea in nursing women and rates of bone resorption correlate inversely with estradiol levels in lactating mice. Furthermore, estrogen replacement in lactating mice reduces bone loss by 60% (VanHouten and Wysolmerski, 2003). Many studies have now documented elevated circulating PTHrP levels in lactating humans and rodents (Kovacs and Kronenberg, 1997), and PTHrP levels correlate directly with biochemical markers of bone resorption and inversely with bone mass in lactating mice (VanHouten and Wysolmerski, 2003). In addition, circulating PTHrP levels have been shown to correlate with bone density changes in lactating humans (Sowers *et al.,* 1996). When the PTHrP gene was disrupted specifically in the lactating mammary gland in mice, circulating PTHrP levels declined, milk PTHrP became unmeasurable, rates of bone resorption decreased, and bone loss was reduced by 50% (VanHouten *et al*., 2003). Thus, it is now clear that the lactating mammary gland secretes PTHrP both into milk and into the circulation. Systemic PTHrP from the breast acts together with estrogen deficiency to stimulate bone resorption and cause bone loss during lactation. As noted previously, the production of PTHrP by the lactating breast is decreased by stimulation of the calcium-sensing receptor on mammary epithelial cells (VanHouten *et al*., 2004). Thus, as shown in Fig. 3, a classic endocrine feedback loop is created between bone and breast during lactation and, in effect, the mammary gland functions as an "accessory" parathyroid gland that uses PTHrP instead of PTH to ensure an adequate flow of calcium from the maternal skeleton to make milk. If calcium delivery to the gland falls, mammary epithelial cells produce more PTHrP, which stimulates increased bone resorption. The delivery of more calcium to the mammary gland from the skeleton then stimulates the CaR and decreases PTHrP production.

Genetic removal of PTHrP from the mammary gland does not alter milk calcium levels and PTHrP-null mammary epithelial cells are able to transport calcium *in vitro* at the same rate as wild-type mammary epithelial cells (VanHouten *et al*., 2003). Thus, unlike the placenta (see later), it does not appear that PTHrP contributes to the regulation of transepithelial calcium transport in the mammary gland. However, the function of PTHrP in milk remains an open question. There is a dose–responsive

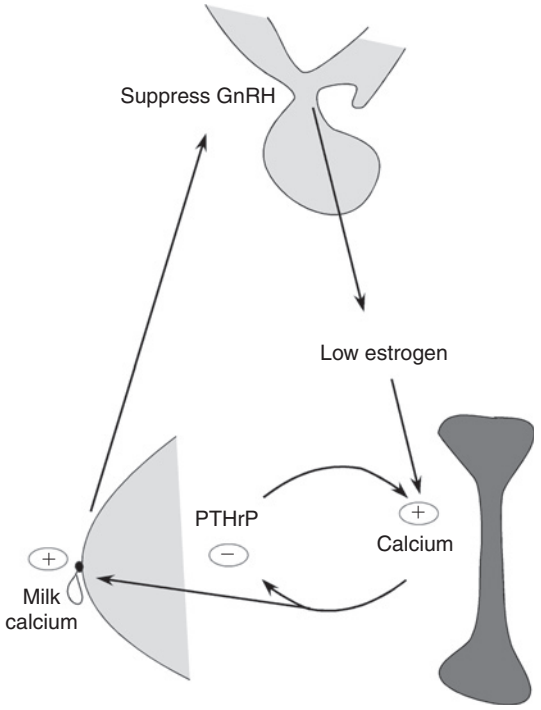

FIGURE 3 Interactions between breast, bone and brain during lactation. Suckling initiates neural reflexes that reduce GnRH secretion causing central hypogonadism. Low estrogen levels combine with PTHrP secreted from the breast to increase bone resorption. Calcium released from the skeleton feeds back to inhibit PTHrP secretion from breast cells.

nverse relationship between the milk PTHrP level and neonatal ash calcium content in mice (J. N. VanHouten and J. J. Wysolmerski, unpublished data). However, the mechanism(s) by which milk PTHrP modulates neonatal calcium and/or bone metabolism remains unexplored.

Another potential function of PTHrP during lactation is the regulation of vascular and/or myoepithelial cell tone. As discussed in Chapter 16, PTHrP has been shown to modulate smooth muscle cell tone in a variety of organs, including the vascular tree, where it acts as a vasodilator. Consistent with these effects, two studies have shown that PTHrP increases mammary blood flow during lactation (Davicco *et al.,* 1993; Thiede *et al.,* 1992). The injection of amino-terminal fragments of PTHrP into the mammary artery of dried ewes was shown to increase mammary blood flow and to override the vasoconstrictive effects of endothelin (Davicco *et al.,* 1993). Thiede and colleagues (1992) have demonstrated that the nutrient arteries of the inguinal mammary glands of rats secrete PTHrP and that its production is responsive to suckling and prolactin. Myoepithelial cells in the breast are similar, in some ways, to vascular smooth muscle cells and are thought to participate in the control of milk ejection by contracting in response to oxytocin (Daniel and Silberstein, 1987). Therefore, it is interesting that myoepithelial cells in culture have been shown to express PTH1R and to respond to PTHrP by elevating intracellular cAMP (Seitz *et al.,* 1993; Wojcik *et al.,* 1999). Furthermore, mirroring the effects of PTHrP on the endothelin-induced contraction of vascular smooth muscle, PTHrP has been shown to block the rise in intracellular calcium normally induced in response to oxytocin in myoepithelial cells (Seitz *et al.,* 1993).

Pathophysiology of PTHrP in the Mammary Gland

There are several instances in which PTHrP may contribute to pathophysiology in the human breast. First, as noted previously, fetuses afflicted with Blomstrand's chondrodystrophy lack nipples and breast tissue (Wysolmerski *et al.,* 1999). Second, some cases of lactational hypercalcemia have been reported to be associated with elevations in circulating levels of PTHrP (Khosla *et al.,* 1990; Reid *et al.,* 1992). One of these cases was caused by massive breast hyperplasia, and after reduction mammoplasty the patient's hypercalcemia and elevated PTHrP levels both resolved (Khosla *et al.,* 1990). Finally, the area with the greatest potential impact on human health is the relationship of PTHrP production to breast cancer. This is evolving into a complicated topic and will be addressed only briefly here. However, it will be reviewed in more depth in Chapter 43.

It is well documented that PTHrP is produced by a number of primary breast carcinomas and that this sometimes leads to classical humoral hypercalcemia of malignancy (Isales *et al.,* 1987). A potentially more widespread role may be the involvement of PTHrP in the osteotrophism of breast cancer (Guise *et al.,* 1996; Yin *et al.,* 1999). Animal models have suggested that PTHrP production by breast tumor cells is important to their ability to form skeletal metastases (Guise *et al.,* 1996; Yin *et al.,* 1999). However, there is conflicting evidence as to whether PTHrP production by a primary breast tumor is predictive of bone metastases in patients (Bundred *et al.,* 1996; Henderson *et al.,* 2001, 2006). The largest and most carefully controlled study suggested that PTHrP production by the primary tumor is actually a negative predictor, not a positive predictor, of skeletal metastases (Henderson *et al.,* 2006). It may be that PTHrP production does not enable a tumor cell to get into the skeleton, but once there, the ability of tumor cells to upregulate PTHrP production within the bone microenvironment becomes important to their ability to grow in the skeleton (Yin *et al.,* 1999). Several studies suggest that TGF-β released from the bone matrix during bone resorption may be particularly important in stimulating PTHrP production (Kakonen *et al*., 2002). More PTHrP would, in turn, be expected to increase osteoclast activity and release more TGF-β, setting up a potential feed-forward vicious cycle that may be important in the pathogenesis of bone destruction around the metastatic tumor.

There is a growing literature that suggests that PTHrP may also be important in controlling breast cancer cell proliferation, apoptosis, migration, and/or invasion. Although it is unclear if normal mammary epithelial cells express significant levels of the PTH1R, it appears that many breast cancer cell lines do so (Birch *et al.,* 1995). Some of the effects ascribed to PTHrP appear to be mediated by this receptor, but some appear to be mediated by midregion PTHrP fragments acting either through intracrine mechanisms or perhaps via a specific midregion PTHrP cell-surface receptor (Shen *et al*., 2004; Kumari *et al*., 2006; Shen and Falzon, 2006; Dittmer *et al.*, 2006; Sirchia *et al*., 2006). In either case, the effects of midregion PTHrP apparently require that this portion of the peptide enter the nucleus via a distinct bipartite nuclear localization signal. In particular, several studies have suggested that midregion PTHrP fragments may promote cell migration by regulating $\alpha 6\beta 4$ integrin expression through nuclear effects (Shen *et al*., 2003; Dittmer *et al*., 2006; Shen and Falzon, 2006). Despite these intriguing findings, at this point it is not clear if these effects are artifacts of cell lines or if they will prove to be clinically relevant. Most of the studies in cell lines suggest that PTHrP expression by a breast tumor would contribute to increased aggressiveness or to a tendency to metastasize. However, in the large clinical study of Henderson and colleagues mentioned previously (Henderson *et al*., 2006), PTHrP expression by a primary breast tumor was clearly a marker of a less aggressive course, correlating with estrogen and progesterone receptor positive status, better survival, lower rates of recurrence, and lower rates of all metastases, not just bone metastases. Similar results can be gleaned from gene expression surveys in breast cancer as well (www.oncomine.org; Rhodes *et al*., 2004). Thus, it is difficult to reconcile these two lines of evidence and clarification will need to await experiments manipulating PTHrP expression in animal models of breast cancer *in vivo*.

REPRODUCTIVE TISSUES

PTHrP and Placental Calcium Transport

Nearly all of the calcium, and a large proportion of the inorganic phosphate (85%) and magnesium (70%), transferred from the mother to the fetus is associated with development and mineralization of the fetal skeleton (Grace *et al.,* 1986). The bulk of placental calcium transfer occurs rapidly over a short interval late in gestation, such that 80% occurs in the third trimester in humans (Givens and Macy, 1933), whereas 96% occurs in the last 5 days of gestation in the rat (Comar, 1956). The concentrations of both total and ionized Ca in all mammalian fetuses studied during late gestation have been observed to be higher than maternal levels. As a result of studies in which the sheep was used extensively for the study of fetal calcium control, one of the first suggested physiological roles of PTHrP was that of regulating the transport of calcium from mother to fetus in the mammal, thereby making calcium available to the growing fetal skeleton (Rodda *et al.,* 1988).

Immunoreactive PTH levels were found to be low in fetal lambs, whereas PTH-like biological activity in serum was high (Care *et al.,* 1985), suggesting the presence of another PTH-like substance. Similar findings of low PTH and high PTHrP have been demonstrated in multiple studies of fetal mice and human cord blood (Kovacs, 2003). Parathyroidectomy in the fetal lamb resulted in loss of the calcium gradient that exists between mother and fetus, as well as impairment of bone mineralization, implicating parathyroids as the source of the regulatory agent. Crude, partially purified, or recombinant PTHrP, but neither PTH nor maternal parathyroid extract that contained no immunoreactive PTHrP, restored the gradient (Rodda *et al.,* 1988). Thus, PTHrP appeared to be the active component of the fetal parathyroid glands responsible for maintaining fetal calcium levels and suppressing fetal PTH levels. In support of this hypothesis, immunoreactive PTHrP was found to be readily detectable in sheep fetal parathyroids from the time they form (MacIsaac *et al.,* 1991) and was also found in early placenta, suggesting that the latter tissue may be a source of PTHrP for calcium transport early in gestation.

The portion of PTHrP that appears to be responsible for regulating placental calcium transport lies between residues 67 and 86 (Care *et al.,* 1990), but the responsible receptor has not yet been identified. Although syncytiotrophoblasts are believed to be central in the transport of calcium to the fetus, cytotrophoblasts (which differentiate to form the syncytium) are believed to be the calcium-sensing cells, and raising the extracellular calcium concentration has been shown to inhibit PTHrP release from these cells (Hellman *et al.,* 1992). The calcium-sensing receptor (CaR) has been localized to cytotrophoblasts of human placenta (Bradbury *et al.,* 1997), and the work of Kovacs *et al.* (1998) has implicated it in placental calcium transport. Furthermore, a calreticulin-like, calcium-binding protein has been isolated from trophoblast cells and its expression is increased by treatment with PTHrP(67–84) but not with N-terminal PTHrP (Hershberger and Tuan, 1998).

Although these observations are strongly suggestive of involvement of PTHrP and the CaR, the mechanisms of placental calcium transport are still not fully understood. Support for the role of PTHrP also comes from the PTHrP gene knockout mouse in which placental calcium transport is severely impaired (Kovacs *et al.,* 1996). In mice homozygous for deletion of the PTHrP gene, fetal plasma calcium and maternal–fetal calcium gradient were significantly reduced. When fetuses were injected *in utero* with fragments of PTHrP or PTH, calcium transport was significantly restored only by treatment with a midmolecular region of

PTHrP that does not act via the PTH1R. Furthermore, in mice rendered null for the PTH1R gene, placental calcium transport was increased, and PTH1R null fetuses had plasma PTHrP levels more than 10 times higher than controls (Kovacs *et al.,* 2001). The circulating PTHrP in the fetal mice was found to be derived from several tissues, including liver and placenta, but the parathyroids were excluded as a source of PTHrP in this setting (Kovacs *et al.,* 2001). Additional studies confirmed that mice lacking parathyroid glands did not have an alteration in circulating PTHrP, nor was placental calcium transport reduced, although the absence of fetal PTH was associated with an even greater reversal of the maternal–fetal calcium gradient than that induced by loss of PTHrP (Kovacs *et al.,* 2001). These findings indicate that the fetal parathyroids may not be a source of circulating PTHrP, and are compatible with an earlier detailed examination of normal fetal rat parathyroids that found no detectable PTHrP by *in situ* hybridization, RT-PCR, and immunohistochemistry (Tucci *et al*., 1996).

Thus, conclusions from the murine studies are similar in many respects to those in the sheep, namely that PTHrP contributes to fetal skeleton calcium supply by controlling maternal–fetal calcium transport through actions mediated by a midmolecule portion of the PTHrP molecule. The murine and sheep studies differ in that the parathyroids do not appear to be a dominant source of PTHrP in rodents; the placenta may be the relevant source of PTHrP that controls placental calcium transfer and the fetal–placental gradient.

Uterus and Extraembryonic Tissues

The uterus, both pregnant and nonpregnant, is another of the many sites of production and action of PTHrP. The relaxing effect of PTH on uterine smooth muscle had been long recognized (Shew *et al.,* 1984), and it was not surprising that PTHrP had the same effect (Shew *et al.,* 1991). The finding that expression of mRNA for PTHrP in the myometrium during late gestation in the rat was controlled by intrauterine occupancy by the fetoplacental unit raised the possibility of a role for PTHrP in regulating uterine muscle tone (Thiede *et al.,* 1990).

In studies in rats with or without estrogen treatment, protein and mRNA for PTHrP were localized not only in the myometrium, as had been shown in pregnancy (Thiede *et al.,* 1990), but also in the epithelial cells lining the endometrium and endometrial glands. Indeed, the strongest PTHrP production appeared to be in these sites (Paspaliaris *et al.,* 1992), suggesting that the endometrium and endometrial glands might be the major uterine site of PTHrP production and that PTHrP might be a local regulator of endometrial function and myometrial contractility. Estrogen treatment enhanced uterine production of PTHrP, but most significantly, the relaxing effect of PTHrP on uterine contractility *in vitro* was enhanced greatly by the pretreatment of noncycling rats with estrogen. In keeping with this observation, uterine horns from cycling rats in proestrous and estrous phases of the cycle showed a greater responsiveness to PTHrP than those from noncycling rats. These findings are consistent with a role for PTHrP as an autocrine and/or paracrine regulator of uterine motility and function. Furthermore they suggest that PTHrP belongs to a class of other locally acting peptides, such as oxytocin, vasoactive intestinal peptide, and relaxin, for which pretreatment of animals with estrogen increases the response of the uterus (Ottesen *et al.,* 1985; Mercado-Simmen *et al.,* 1982; Fuchs *et al.,* 1982).

Further evidence for a specific and regulated role of PTHrP in the uterus during gestation comes from the observation of a temporal pattern in the relaxation response to PTHrP by longitudinal uterine muscle during pregnancy in the rat, with maximal responses at times when estrogen levels would be high. In contrast, the circular muscle did not respond at any stage during gestation (Williams *et al.,* 1994). The inability of PTHrP to relax uterine muscle in the last stages of gestation does not support a direct role in the onset of parturition. Treatment of pregnant rats with i.p. injections of human PTHrP 1–34 resulted in a significant decrease in the expression of connexin-43 (mRNA and protein) and the oxytocin receptor mRNA in the myometrium, but it did not affect the timing of delivery, progesterone in maternal plasma, or levels of c-fos, fra-2, or PTH1R mRNA on any gestational day. These findings are compatible with the hypothesis that PTHrP may act to keep the myometrium quiescent at a time when progesterone levels are falling, but that the effects of PTHrP signaling are overridden by other factors that dictate the onset of labor (Mitchell *et al*., 2003). This hypothesis is supported by the demonstration (Thiede *et al.,* 1990) that expression of mRNA was dependent on the presence of the fetus and that levels increased throughout pregnancy and decreased sharply after delivery. It seems likely, therefore, that the observed fall in PTHrP reflects the recontracted state of the uterine muscle, consistent with the observation in the bladder (Yamamoto *et al.,* 1992b), and that the level of expression is functionally related to contractility. The temporal expression of PTHrP in endometrial glands and blood vessels (Williams *et al.,* 1994) also supports roles in other regulated functions that might include uterine growth during pregnancy and the regulation of uterine and placental blood flow (Mandsager *et al.,* 1994).

Uterine growth restriction was induced in Wistar–Kyoto rats by ligating uterine vessels, and this resulted in a 15% decrease in fetal weight, a 21% decrease in fetal number, a 46% decrease in placental PTHrP content, but a 2.5-fold increase in uterine PTHrP content (Wlodek *et al.*, 2005). The increase in uterine PTHrP content may be compensatory to increase uteroplacental blood flow. Other studies have demonstrated that the vasodilatory effect of PTHrP on myometrial blood vessels is dependent upon

the presence of functional endothelium, and that the effect is likely mediated by nitric oxide (Meziani *et al.*, 2005). Conversely, treatment of pregnant rats with a PTHrP antagonist (PTHrP 7–34) resulted in evidence of growth restriction (reduced fetal weight and placental weight) and apoptosis within placentas (Thoten *et al.*, 2005). Thus, there is some functional evidence to suggest that PTHrP plays a role in regulating uterine blood flow and growth.

Placenta and Fetal Membranes

PTHrP mRNA and protein have been detected in rat and human placenta in various cell types (Hellman *et al.,* 1992; Germain *et al.,* 1992; Bowden *et al.,* 1994). In addition, neoplastic cells of placental origin secrete PTHrP, including hydatidiform moles and choriocarcinomas *in vitro* (Deftos *et al.,* 1994). The presence of PTH/PTHrP receptor mRNA has been demonstrated in rat (Urena *et al.,* 1993), mouse (Kovacs *et al.*, 2002), and human (Curtis *et al.,* 1998) placenta, and infusion of PTHrP(1–34) into isolated human placental lobules stimulates cyclic AMP production (Williams *et al.,* 1991). Three further sets of observations lend support to the hypothesis that PTHrP is involved in placental/uterine interactions and that its most likely role in the placenta and placental membranes is related to the growth and maintenance of the placenta itself during pregnancy. First, PTHrP production by cultured amniotic cells has been shown to be regulated by prolactin, human placental lactogen, transforming growth factor-β (TGF-β), insulin, insulin-like growth factor, and epidermal growth factor (Dvir *et al.,* 1995). Second, PTHrP has been shown to regulate epidermal growth factor receptor expression in cytotrophoblast cultures (Alsat *et al.,* 1993), an event associated with placental development. Third, studies of vascular reactivity in isolated human placental cotyledons preconstricted with a thromboxane A_2 mimetic showed PTHrP to be a very effective vasodilator (Macgill *et al.,* 1997). The narrow concentration range to which the tissue responded, together with the desensitization in response to repeated PTHrP infusions, was consistent with a paracrine and/or autocrine action of PTHrP in human gestational tissues. Adequacy of the fetoplacental circulation is essential for the nutritional demands of the growing fetus, and both humoral and local factors are likely to be important in its control. It is possible that alterations of the expression, localization, and/or action of PTHrP might contribute to the genesis of conditions such as preeclampsia and intrauterine growth retardation in which placental vascular resistance is increased (Gude *et al.,* 1996). Another related and potentially interacting influence is angiotensin II, known to be a powerful enhancer of PTHrP production in the vasculature and in human placental explants (Li *et al.,* 1998). The ability of angiotensin II to stimulate estradiol production in human placental explants through actions upon its AT_1 receptor (Kalenga *et al.,* 1995) provides a further link with PTHrP control.

PTHrP has also been shown to regulate the differentiation of cells explanted from the murine placenta. PTHrP treatment reduced proliferation, inhibited apoptosis, and promoted differentiation into trophoblast giant cells. As well, PTHrP treatment induced the expression of transcription factors known to stimulate giant cell formation (Stra13 and AP-2gamma), and inhibited the formation of other trophoblast cell types by suppressing trophoblast progenitors and spongiotrophoblast-promoting factors (Eomes, Mash-2, and mSNA) (El-Hashashetd *et al.*, 2005). Thus, PTHrP likely plays a role in the differentiation of cells during placentation.

The most likely source of increased amniotic fluid PTHrP concentrations during pregnancy is the amnion itself, because PTHrP mRNA expression is also highest at term and greater in the amnion than in choriodecidua or placenta (Bowden *et al.,* 1994; Ferguson *et al.,* 1992; Wlodek *et al.,* 1996). In tissue from women with full-term pregnancies and not in labor, the concentration of N-terminal PTHrP has been found to be higher in amnion covering the placenta than in the reflected amnion covering the decidua parietalis (Bowden *et al.,* 1994). Nevertheless, the concentration of N-terminal PTHrP in reflected amnion (the layer apposed to the uterus) was inversely related to the interval between rupture of the membranes and delivery. The observation that PTHrP levels in the amnion decrease after rupture of the fetal membranes has led to the proposal that PTHrP derived from the membranes may inhibit uterine contraction and that labor may occur following loss of this inhibition. Plasma levels of PTHrP increase during pregnancy and at 6 weeks postpartum (Gallacher *et al.,* 1994; Ardawi *et al.,* 1991) with the likely sources being placenta and breast, respectively. Human fetal membranes have been shown to inhibit contractions of the rat uterus *in vitro* (Collins *et al.,* 1993) so this tissue does appear to produce factors that can modulate uterine activity. Furthermore, primary cultures of human amniotic cells secrete PTHrP into the medium (Germain *et al.,* 1992). Thus, although the physiological function(s) of amnion-derived PTHrP is currently unknown, preliminary evidence suggests that it may play a role in regulation of the onset of labor. It is also possible that amniotic fluid is a source of PTHrP ingested by the fetus, and that it acts as a growth factor in lung and/or gut development. Consistent with this hypothesis, mice lacking PTHrP have immature lungs associated with arrested type II alveolar cell development and reduced surfactant production *in vivo* and *in vitro* (Rubin *et al.*, 2004).

In summary, although many functional studies remain to be completed, potential roles for PTHrP produced by fetal membranes and placenta include transport of calcium across the placenta, accommodation of stretch of membranes, growth and differentiation of fetal and/or maternal tissues, vasoregulation, and the regulation of labor.

Implantation and Early Pregnancy

Some physiological functions other than control of myometrial activity were suggested by findings of Beck *et al.* (1993), who identified PTHrP mRNA as being limited to epithelial cells of implantation sites. This pregnancy-related expression appeared at day 5.5 in the rat fetus in the antimesometrial uterine epithelium of implantation sites, raising the possibility of a further function of PTHrP, playing a part in the localization of implantation or initial decidualization. Decidual cells produced mRNA for PTHrP both in normal gestation and after the induction of deciduomata. Expression of the gene in these cells followed epithelial expression by 48 hours. It was concluded from this work that the location of PTHrP gene expression in the uterus, together with the time of its expression, suggests that it plays a part in implantation of the blastocyst. Further evidence for a function of PTHrP in the implantation process came from Nowak *et al.* (1999), who showed that PTHrP and TGF-β were potent stimulators of trophoblast outgrowth by mouse blastocysts cultured *in vitro*. The TGF-β effect appeared to be mediated by PTHrP, which itself was acting through a mechanism distinct from the PTHR1.

Thus, both the timing and the localization of PTHrP gene expression suggested that it might play a part in the implantation of the blastocyst (Beck *et al.,* 1993). Upon finding substantial levels of immunoreactive PTHrP in uterine luminal fluid of estrogen-treated immature rats, and because the PTH/PTHrP receptor was known to be expressed in rat uterus (Urena *et al.,* 1993), Williams *et al.* (1998) investigated the role of PTHrP acting through this receptor in influencing early pregnancy in the rat. Infusion of either a PTHrP antagonist peptide or a monoclonal anti-PTHrP antibody into the uterine lumen during pregnancy resulted in excessive decidualization. The latter appeared to be the result of a decrease in the number of apoptotic decidual cells in the antagonist-infused horn. In pseudopregnant rats, infusion of receptor antagonist into the uterine lumen resulted in increases in wet weight of the infused horn compared with the control side, indicating an effect on deciduoma formation.

These observations suggest that activation of the PTH/PTHrP receptor by locally produced PTHrP might be crucial for normal decidualization during pregnancy in rats, probably not by being involved in the initiation of the decidual reaction, but rather in the maintenance of the decidual cell mass.

Summary

The multiple roles of PTHrP in the reproductive tissues and cycle and in the placenta largely reflect its roles as a paracrine/autocrine/intracrine regulator. Of the many functions it exerts in these systems, probably the only endocrine one is that in which PTHrP in the fetal circulation regulates placental calcium transport. There remains much to be learned of the place of PTHrP in reproductive and placental physiology and pathology.

ENDOCRINE PANCREAS

PTHrP and Its Receptors

The presence of PTHrP in the pancreatic islet became apparent shortly after the identification of PTHrP in 1987. Asa *et al.* (1990) demonstrated that PTHrP was present in islet cells and demonstrated that it was present in all four cell types of the islet, including the α, β, δ, and PP cells. PTHrP mRNA was shown to be present in isolated islet RNA as well (Drucker *et al.,* 1989), demonstrating that the peptide could be produced within the islet. Gaich and collaborators (1993) confirmed these findings, demonstrating that PTHrP was indeed present in islet cells of all four types and that it was also present in pancreatic ductular epithelial cells. The peptide is not present in adult pancreatic exocrine cells. Plawner and colleagues (1995) demonstrated that PTHrP is present in individual beta cells in culture and showed that PTHrP colocalized with insulin in the Golgi apparatus, as well as in insulin secretory granules. Interestingly, in a perifusion system employing a beta-cell line, PTHrP was shown to be cosecreted with insulin from beta cells following depolarization of the cell (Plawner *et al.,* 1995). The secreted forms of PTHrP included amino-terminal, midregion, and carboxy-terminal forms of PTHrP (see later).

With regard to receptors for PTHrP on beta cells, little direct evidence has been provided for the presence of the PTH1R, although its presence has not been sought rigorously. However, there can be no question as to the presence of some type of PTHrP receptor on the pancreatic beta cell, as it is clear that PTHrP(1–36) elicits prompt and vigorous responses in intracellular calcium in cultured beta-cell lines. For example, Gaich *et al.* (1993) have demonstrated that PTHrP(1–36) in doses as low as 10^{-12} M stimulates calcium release from intracellular stores. Interestingly, unlike events observed in bone and renal cell types where PTHrP receptor activation is associated with activation of cAMP/PKA, as well as the PKC/intracellular calcium pathways, only the latter is observed in cultured beta cells in response to PTH or PTHrP(1–36) (Gaich *et al.,* 1993). Whether this reflects the presence of a different type of receptor on beta cells or differential coupling of the PTHR1 to subsets of specific G-proteins or catalytic subunits in beta cells compared with bone and renal cells has not been studied.

Regulation of PTHrP and PTHrP Receptors

There is little information describing how or to what degree PTHrP or the PTH receptor family is regulated in

the pancreatic islet. As will become clear from the sections that follow, there are physiological reasons why such regulation might occur under normal circumstances, but this area remains unexplored.

Biochemistry of PTHrP

PTHrP undergoes extensive post-translational processing as described in Chapters 3 and 4. Most of what is known or inferred regarding PTHrP processing is derived from studies in the rat insulinoma line, RIN-1038 (Soifer *et al.,* 1992; Yang *et al.,* 1994; Wu *et al.,* 1991). These cells have served as a model of PTHrP processing, because they have been shown to serve as a model for authentic processing of other human neuroendocrine peptides, such as insulin, proopiomelanocortin, glucagon, and calcitonin. Using a combination of untransfected RIN-1038 cells, RIN-1038 cells overexpressing hPTHrP(1–139), hPTHrP(1–141), or hPTHrP(1–173), and a panel of region-specific radioimmunoassays and immunoradiometric assays, RIN cells have been shown to secrete PTHrP(1–36), PTHrP(38–94), PTHrP(38–95), and PTHrP(38–101) (Soifer *et al.,* 1992; Yang *et al.,* 1994; Wu *et al.,* 1991). In addition, RIN 1038 cells have been shown to secrete a form of PTHrP that is recognized by a PTHrP (109–138) radioimmunoassay (Yang *et al.,* 1994), and another form that is recognized by a PTHrP(139–173) radioimmunoassay (Burtis *et al.,* 1992).

As described earlier, PTHrP(1–36) stimulates intracellular calcium increments in cultured beta cells (Gaich *et al.,* 1993). PTHrP(38–94) has also been shown to stimulate intracellular calcium release in these cells (Wu *et al.,* 1991). PTHrP(38–94) does not activate adenylyl cyclase in cultured beta cells, and other PTHrP species have not been explored in beta cells in functional terms.

Function of PTHrP

Pancreas development in rodents begins at approximately day E9–10, and by day E18–19, clusters of beta cells have begun to coalesce and form immature islets (Edlund, 1998). These islet cell clusters continue to increase in number, in size, and in density of beta cells in the week after delivery and then decline abruptly in number through a wave of beta-cell apoptosis (Finegood *et al.,* 1995).

The role of PTHrP in pancreatic cell development and function is poorly understood at present. The pancreas of PTHrP-null mice (Karaplis *et al.,* 1994) develops normally in anatomic terms (R. C. Vasavada and A. F. Stewart, unpublished observations), but nothing is known about the function of these islets. PTHrP-null mice die immediately after delivery, so nothing is known of islet function or development following birth in the absence of PTHrP. "Rescued" PTHrP mice do exist (Wysolmerski *et al.,* 1998) and they survive to adulthood. These mice have normal-appearing pancreata and islets (R. C. Vasavada and A. F. Stewart, unpublished observations), but they have dental abnormalities, are undernourished, and grow poorly. Therefore, it is difficult to characterize their islets in functional terms, as islet mass, proliferation, and function are heavily dependent on fuel availability. Streuker and Drucker (1991) have suggested that PTHrP may play a role in beta-cell differentiation, because it is upregulated in beta-cell lines in the presence of the islet-differentiating agent, butyrate.

In an effort to understand the role of PTHrP in the pancreatic islet, Vasavada and collaborators have developed transgenic mice that overexpress PTHrP under the control of the rat insulin-II promoter (RIP) (Vasavada *et al.,* 1996; Porter *et al.,* 1998). RIP-PTHrP mice display striking degrees of islet hyperplasia and an increase in islet number, as well as the size of individual islets. This increased islet mass is associated with increased function: RIP-PTHrP mice are hyperinsulinemic and hypoglycemic compared with their littermates (Vasavada *et al.,* 1996; Porter *et al.,* 1998). They become profoundly and symptomatically hypoglycemic with fasting. Interestingly, RIP-PTHrP mice are also resistant to the diabetogenic effects of the beta-cell toxin, streptozotocin. Following the administration of streptozotocin, normal mice readily develop diabetes, but RIP-PTHrP mice either fail to become diabetic or develop only mild hyperglycemia (Porter *et al.,* 1998).

The mechanism(s) responsible for the increase in islet mass in the RIP-PTHrP mouse remains undefined. There are two levels at which this question can be addressed: identification of the source of the cells responsible for the increase in islet mass and the signaling mechanisms that are responsible for the increase. With respect to the first, islet mass can, in theory, be increased by three pathways: (a) the recruitment of new islets from the pancreatic duct or its branches distributed throughout the exocrine pancreas, in a process referred to as "islet neogenesis"; (b) induction of proliferation of existing beta cells within islets; and/or (c) prolongation of the life span of existing beta cells. Of these options, there is evidence that PTHrP can drive beta-cell replication (Villanueva *et al.,* 1999; Fujinaka *et al.,* 2004) suggesting that beta-cell proliferation may account for at least part of the phenotype. The RIP promoter is restricted to expression in beta cells, and therefore unable to influence pancreatic cells prior to their differentiation into beta cells, suggesting that the neogenesis of beta cells from ductal or other precursors is not a likely contributor (Vasavada *et al.,* 1996). Finally, the bulk of evidence would support a dominant role for PTHrP in enhancing beta-cell survival, as occurs in other cell types (Cebrian *et al,* 2002).

At the signaling level, little is known regarding the mechanism of action of PTHrP on beta cells. Although it is known that PTHrP can stimulate intracellular calcium in cultured beta-cell lines (Gaich *et al.,* 1993; Wu *et al.,* 1991), it is not known whether this occurs *in vivo* in normal, nontransformed beta cells within intact islets. Nor is it

known whether PTHrP stimulates adenylyl cyclase in normal beta cells *in vivo* or whether it participates in nuclear or intracrine signaling in beta cells as it appears to in chondrocytes, osteoblasts, vascular smooth muscle cells, or other cell types (Aarts *et al.,* 1999; Massfelder *et al.,* 1997; Lam *et al.,* 1999) (see Chapter 6). These processes, too, are under study.

Finally, and importantly, the results of overexpression studies do not demonstrate that PTHrP enhances beta-cell mass *in vivo* under normal circumstances. In the absence of meaningful data from knockout or rescued knockout mice, it is difficult to be sure if PTHrP is important in normal islet biology. This question, too, will need to await further studies such as the conditional or islet-specific deletion of the PTHrP gene.

Pathophysiology of PTHrP

From the discussion given earlier, it is clear that the normal physiological role of PTHrP in the pancreatic islet remains undefined. In contrast, PTHrP plays clear pathophysiological roles in at least some pancreatic islet neoplasms. PTHrP overexpression with resultant development of humoral hypercalcemia of malignancy has been demonstrated on multiple occasions in multiple investigators' hands (Asa *et al.,* 1990; Stewart *et al.,* 1986; Wu *et al.,* 1997; Skrabanek *et al.,* 1980). In the only large series of malignancy-associated hypercalcemia in which tumors have been fully subdivided based on histology (Skrabanek *et al.,* 1980), islet cell carcinomas, which are not particularly common, produce humoral hypercalcemia of malignancy fully as often as pancreatic adenocarcinomas, a very common neoplasm. Historically, islet tumors were among the first in which PTHrP bioactivity was identified (Stewart *et al.,* 1986; Wu *et al.,* 1997). Furthermore, patients with islet carcinomas regularly demonstrate increases in circulating PTHrP as determined by radioimmunoassay or immunoradiometric assays (Lansk *et al.,* 1996). When assessed by immunohistochemistry, these tumors also demonstrate increased staining for PTHrP (Asa *et al.,* 1990; Drucker *et al.,* 1989).

The significance of these findings for islet tumor oncogenesis is not known. Is this simply a random derepression of the PTHrP gene or is it a specific upregulation of the PTHrP gene? Is there a pathological role for PTHrP in the development of pancreatic islet tumors, corresponding to the mass enhancing effects of PTHrP in the islets of the RIP-PTHrP mouse? These questions remain interesting but unanswered at present.

CONCLUSION

Advances in mouse genetics and in transgenic technology have been a boon to the study of physiology. This has certainly been the case for the PTHrP field, where studies in genetically altered mice have provided a starting place for the study of the physiology of a protein that was discovered outside its natural context. This chapter outlined the current state of knowledge regarding the physiological roles of PTHrP in skin, the mammary gland, placenta, uterus, and pancreas. Much of this information (although not all) has come from studies performed in a variety of transgenic mice. These studies have shown that PTHrP is important to both the development and the physiological functioning of these organs. However, at this point, we continue to have as many questions as answers. There are many experiments to be done before we comprehend all the nuances of the functions of PTHrP at these sites. The next several years promise to see continued progress in the investigation of the nonskeletal effects of this remarkable molecule.

ACKNOWLEDGMENTS

The authors thank Dr. John Foley for valuable discussions. This work was supported by the National Institutes of Health (DK55501, CA94175, and DK069542 to J.J.W.) and by the Canadian Institutes of Health Research (FR15439), the Dairy Farmers of Canada, the Natural Sciences and Engineering Research Council, and the Government of Newfoundland and Labrador (to C.S.K.).

VASCULAR AND CARDIOVASCULAR ACTIONS

Historical Perspectives

The origins of parathyroid hormone (PTH) as a putative cardiovascular regulatory factor date to the early 1900s when the calcemic properties of the hormone were first identified. In classic studies, Collip and Clark (1925) demonstrated that systemic injection of extracts of parathyroid glands lowered systemic blood pressure in dogs (Fig. 1). The first formal characterization of the cardiovascular activity of PTH was conducted by Charbon (1968a,b, 1969) in the early 1960s. This investigator quantified the vasodilatory effects of a purified parathyroid extract in the rabbit and cat and demonstrated that a synthetic N-terminal fragment displayed similar actions in the dog. Relaxant activity was not blocked by pharmacological antagonists of other known vasoactive agents, suggesting a direct action of the hormone. Numerous studies have now unequivocally established the hypotensive/vasodilatory and cardiac effects of PTH (Mok *et al.,* 1989) that can be broadly summarized as follows: First, the hypotensive and vasorelaxant actions of PTH occur in the absence of a change in blood calcium and are mediated by PTH activation of the type 1 PTH/PTH-related protein (rP) receptor (PTH1R) expressed in the smooth muscle layer of the vessel wall. Second, although all vascular beds are relaxed by PTH, resistance vessels appear to be more responsive than conduit vessels. Third, PTH can reduce the pressor effects of other vasoactive agents that exert their action through different mechanisms. Finally, PTH exerts both ionotropic and chronotropic effects on the heart (Ogino *et al.,* 1995).

Although the cardiovascular effects of PTH are undisputed, their physiological significance has been frequently debated. This is in part because the concentrations of PTH required to produce vasodilation (10−100nM) are substantially greater than normal circulating levels (low pM). Consequently, it has been difficult to conceptualize how physiological levels of this systemic hormone, which is synthesized only in the parathyroid gland, could function in the local control of vascular tone. Also enigmatic is the fact that patients with primary hyperparathyroidism and elevated circulating PTH levels often have high (not low) blood pressure that sometimes returns to normal after parathyroidectomy. A plausible explanation for the seemingly enigmatic regulatory effects of PTH on the cardiovascular system emerged with the discovery of PTHrP in 1987.

As discussed in Chapter 33, PTHrP was identified as the factor responsible for the paraneoplastic syndrome termed humoral hypercalcemia of malignancy. Almost immediately after its cloning, expression of PTHrP was detected in many normal fetal and adult tissues but was undetectable in the circulation, suggesting that the protein functioned in an autocrine/paracrine mode. Although many functions have been ascribed for PTHrP, three main

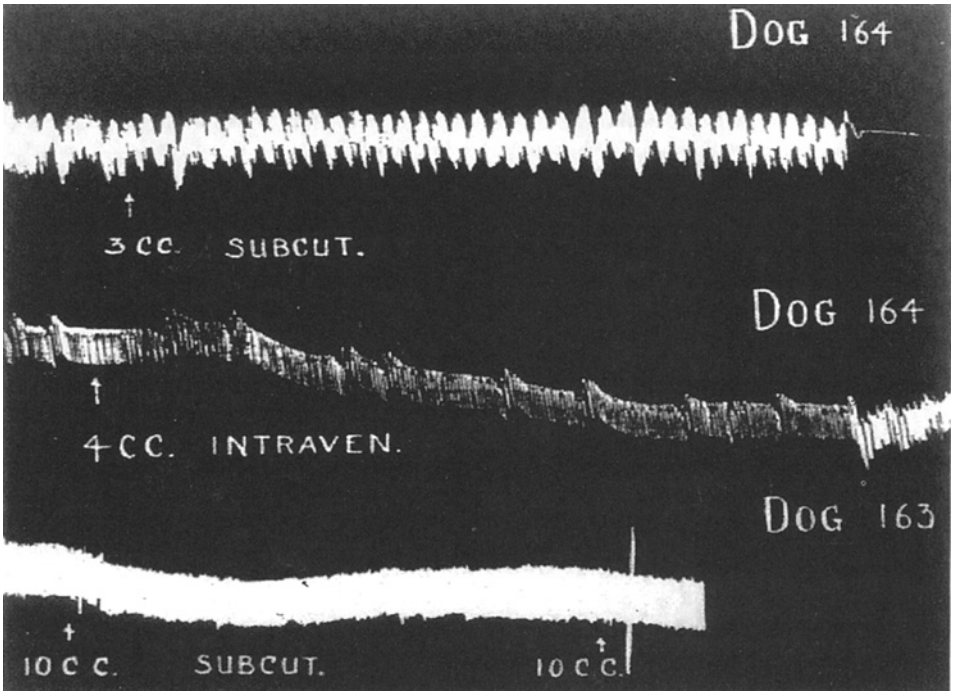

FIGURE 1 Effects of extracts of parathyroid glands on blood pressure in thyroparathyroidectomized dogs. From Collip and Clark (1925), with permission.

physiological themes have emerged. Observations in gene knockout mice have demonstrated that PTHrP is required for the development of cartilage, morphogenesis of the mammary gland, and tooth eruption (reviewed in Philbrick *et al.,* 1996; Lanske and Kronenberg, 1998; and elsewhere in this volume). PTHrP also appears to participate in maternofetal calcium transfer across the placenta. The third physiological role for PTHrP is in smooth muscle in which the protein functions to regulate contractility and proliferation. Although this chapter focuses on the physiology of PTHrP in *vascular* smooth muscle, it is relevant to begin with a brief review of its physiological effects in other smooth muscle-containing tissues.

In all smooth muscle cell beds studied to date, induction of PTHrP expression occurs in close association with normal physiological stimuli. In the smooth muscle layer of the chicken oviduct, induction of PTHrP expression coincides temporally with egg movement and its arrival in the shell gland (Thiede *et al.,* 1991). In the rat uterus, PTHrP expression is localized to the myometrium and is markedly upregulated by fetal occupancy (Thiede *et al.,* 1990) or by mechanical distention of the uterine horn with a balloon catheter (Daifotis *et al.,* 1992). PTHrP expression is increased in prelabor human amnion and abruptly falls with the onset of labor and rupture of the amniotic sac (Ferguson *et al.,* 1992). In the urinary bladder, induction of PTHrP mRNA occurs during filling in proportion to bladder distension (Yamamoto *et al.,* 1992). Finally, as discussed in detail later, PTHrP is also expressed in vascular smooth muscle, in which it is induced by vasoconstrictor agents and mechanical stimuli. In each of these smooth muscle beds, application of PTHrP to precontracted smooth muscle preparations induces relaxant activity, precisely mimicking the actions described previously for PTH. It would therefore appear that PTHrP rather than PTH represents the physiologically important regulator of smooth muscle tone. Consequently, the remainder of this chapter focuses primarily on the physiology of PTHrP in the cardiovascular system.

PTHrP in the Vasculature

Vascular Anatomy and Contractile Mechanisms

Blood vessels are composed of three principal cell types: the intima, which consists of a single epithelial cell layer; the muscularis layer, made up of vascular smooth muscle cells embedded in a connective tissue matrix; and an outer adventitial layer, which receives input from the cholinergic and adrenergic nervous system. The relative composition and contribution of each of these cell types to vascular growth and tone varies during development and among different vascular beds. For example, during development, blood vessels initially form as simple tubular structures consisting entirely of endothelial cells into which smooth muscle cells migrate to form the vascular wall. In the mature mammal, the large conduit vessels (e.g., aorta) are highly elastic to accommodate high-capacity blood flow, whereas resistance vascular beds (e.g., mesentery) typically contain more

smooth muscle cells and are densely innervated. Changes in the cellular and connective tissue constituents within the vasculature occur with normal aging and in particular during pathological conditions such as atherosclerosis. The regulation of vascular growth, remodeling, and smooth muscle cell tone is achieved through a coordinated network of both systemic and local factors, as well as input from adrenergic, cholinergic, peptidergic, and sensory neurons.

Mechanisms regulating vascular smooth muscle cell contractility have been studied in detail (reviewed in Somlyo *et al.,* 1999). The intracellular-free-calcium concentration is the major determinant of vascular tone. Depolarization of vascular smooth muscle cells enables calcium to enter the cell via L-type voltage-sensitive calcium channels (L-VSCCs). These events trigger the release of much larger quantities of calcium from the sarcoplasmic reticulum. Alternatively, pharmacological or ligand activation of G protein receptors (e.g., angiotensin II) activate phospholipase (PLC), which catalyzes phosphoinositol hydrolysis and causes calcium release from intracellular stores. The increases in cytoplasmic calcium achieved by either of these mechanisms activate myosin light chain kinase through the calcium–calmodulin complex and phosphorylation of the 20-kDa regulatory light chain of myosin, with subsequent cross-bridge cycling and force development. The mechanisms of vascular smooth muscle cell relaxation are less well understood. In the simplest scheme, a reduction of cytoplasmic calcium with a fall in myosin light chain kinase activity would suffice to account for dephosphorylation of the regulatory light chain and relaxation. However, other mechanisms have been implicated in cyclic nucleotide-dependent relaxation in vascular and other smooth muscle tissues (McDaniel *et al.,* 1994).

The demonstration of a calcium-sensing receptor in vascular smooth muscle with pharmacological properties similar to those of the parathyroid calcium-sensing receptor (discussed in Chapter 26) has prompted speculation that it might also participate in the regulation of contractile events (Bukoski *et al.,* 1995). Alterations of extracellular calcium over the physiological concentration range depress contractility of precontracted vascular smooth muscle. This effect of extracellular calcium has been shown to be mediated by activation of a calcium-dependent potassium channel and is associated with alterations in myofilament calcium sensitivity. These activities were mimicked by gadolinium, neomycin, and lanthanum, all factors that activate the calcium-sensing receptor. However, the structure of this putative calcium-sensing receptor is unknown and it remains unclear whether it bears homology to the renal or parathyroid or kidney calcium-sensing receptor.

Expression and Regulation of PTHrP

PTHrP is expressed in blood vessels in essentially all vascular beds from a broad range of species, including rodent and human fetal blood vessels (Moniz *et al.,* 1990), adult rat aorta (Burton *et al.,* 1994; Pirola *et al.,* 1994), vena cava (Burton *et al.,* 1994), kidney afferent arterioles, artery, and microvasculature (Nickols *et al.,* 1990), the arterial and venous supply of the mammary gland (Thiede, 1994), the serosal arterioles in avian egg shell gland (Thiede *et al.,* 1991), and blood vessels of the rat penis (Lang *et al.,* 1999). The protein appears to be expressed predominantly in the smooth muscle layer of the vessel, although its expression has also been reported in cultured endothelial cells (Rian *et al.,* 1994; Ishikawa *et al.,* 1994a). The regulation of PTHrP mRNA expression has been studied in detail by using cultured vascular smooth muscle cells. In primary rat aortic vascular smooth muscle cells, expression of PTHrP is induced rapidly (2−4 hours) but transiently by exposure of quiescent cells to serum (Hongo *et al.,* 1991) (Fig. 2). This mode of tight regulation is reminiscent of the behavior of cytokine mRNAs and would appear to constitute a mechanism that would restrict the activity of PTHrP to a narrow window of time. Among the most potent inducers of PTHrP are vasoconstrictors, including angiotensin II, seritonin, endothelin, norepinephrine, bradykinin, and thrombin, each of which induces PTHrP mRNA and protein levels over the same time course as that observed for serum (Pirola *et al.,* 1993). The induction of PTHrP mRNA by angiotensin II depends on protein kinase C activation and is mediated by both transcriptional and post-transcriptional mechanisms (Pirola *et al.,* 1993). Prior addition of saralaysin and captopril, which inhibit angiotensin II action or generation, respectively, inhibit the serum-induced increase in PTHrP

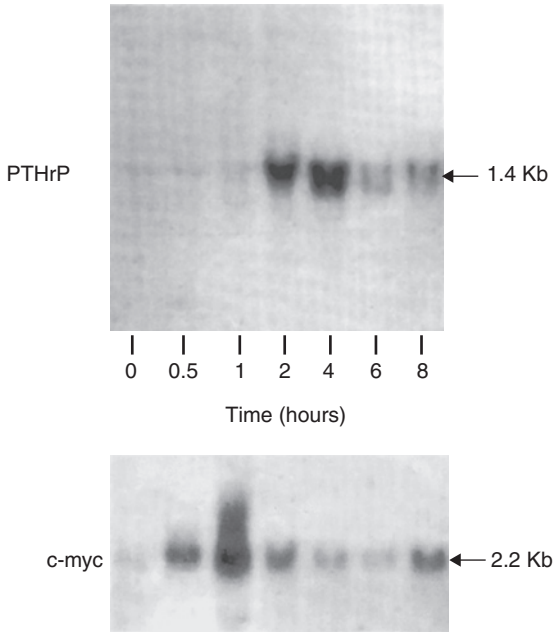

FIGURE 2 Time course of serum induction of PTHrP mRNA in aortic vascular smooth muscle cells. From Hongo *et al.* (1991), with permission.

in vascular smooth muscle cells. This finding suggests that the angiotensin II present in serum represents a significant component of the serum induction of PTHrP.

PTHrP is also induced in vascular smooth muscle in response to mechanical stimuli. PTHrP mRNA is increased transiently in rat aorta following distension with a balloon catheter (Pirola *et al.,* 1994). Fluid flow-induced mechanical events induced by rocking or rotation of monolayer cultures of rat aortic vascular smooth muscle cells result in increased PTHrP mRNA expression (Pírola *et al.,* 1994; Noda *et al.,* 1994). The inductive effects of mechanical stretch and angiotensin II on PTHrP mRNA appear to be synergistic, suggesting that they occur through distinct mechanisms (Noda *et al.,* 1994). PTHrP mRNA is also produced in capillaries of slow-twitch soleus and fast-twitch skeletal muscle, and its expression is increased in response to low-frequency stimulation (Schneider *et al.,* 1999). This maneuver was associated with enhanced capillarization of the muscle, indicating that PTHrP might function to promote new capillary growth in response to increased contractile activity.

Vascular Actions of PTHrP

Shortly after the identification of PTHrP, a number of studies demonstrated that synthetic N-terminal fragments of the peptide replicated many of the vascular actions of PTH, including its vasorelaxant actions in the aorta (Crass and Scarpace, 1993), portal vein (Shan *et al.,* 1994), coronary artery (Nickols *et al.,* 1989), renal artery (Wingulst *et al.,* 1987; Musso *et al.,* 1989), placenta (Macgill *et al.,* 1997; Mandsager *et al.,* 1994), and mammary gland (Prosser *et al.,* 1994). In general, the vasodilatory potency of PTHrP is comparable to that of PTH when examined in organ bath systems. In contrast, in mouse portal vein preparations, PTHrP(1–34) was shown to be a more potent vasorelaxant than PTH(1–34) (Shan *et al.,* 1994). In perfused rabbit kidney (Musso *et al.,* 1989) and in rat aorta (Nickols *et al.,* 1989) the vasorelaxant effects of PTHrP do not appear to require the presence of an intact endothelium. However, in mouse aortic rings, endothelium denudation attenuates the relaxant activity of PTHrP markedly (Sutliff *et al.,* 1999), possibly reflecting a species difference.

In addition to its effects on vascular tone, PTHrP also modulates vascular smooth muscle cell proliferation. The peptide decreases serum- and platelet-derived growth factor (PDGF)-activated DNA synthesis in primary arterial vascular smooth muscle cells (Hongo *et al.,* 1991; Jiang *et al.,* 1995) and in A10 vascular smooth muscle cells stably expressing the PTH1R receptor (Maeda *et al.,* 1996). In both of these cell types, antimitogenic effects require the PTH-like N-terminal portion of the molecule and are mimicked by dibutyryl cAMP or forskolin. The mechanism for the antiproliferative effect of PTHrP involves the induction of the cyclin-dependent kinase inhibitor, $p27^{kip1}$, and impairment of phosphorylation of the retinoblastoma gene product (Rb), which results in cell cycle arrest in mid-G_1 phase (Maeda *et al.,* 1997). However, Massfelder *et al.* (1997) reported that overexpression of PTHrP in A10 vascular smooth muscle cells was associated with an increase in DNA synthesis. This apparent discrepancy likely results from the presence of an alternate CUG translation initiation site downstream of PTHrPs secretion signal sequence. PTHrP translated from this second site is transported via β1-importin to the nucleus where it stimulates the proteasomal degradation of $p27^{kip1}$ and hyperphosphorylation of Rb (Fiaschi-Taesch *et al*., 2004, 2006). Similar nuclear trafficking has also been described in chondrocytes, whereby nuclear PTHrP enhances chondrocyte survival (Henderson *et al.,* 1995). It is important to note that, in these studies, exogenous application of PTHrP inhibited A10 cell growth in agreement with the studies cited earlier. Therefore, the ability of PTHrP to influence the proliferation of vascular smooth muscle cells either positively or negatively appears to depend on where the protein is trafficked in the cell. Cellular levels of PTHrP fluctuate during the cell cycle and reach their highest levels in G_2/M (Okano *et al.,* 1995). It is possible that the protein is directed to the nucleus in the later stages of the cell cycle to participate in mitotic events. The mechanism regulating differential usage of translation initiation sites remains undefined.

PTHrP also inhibits PDGF-directed migration of vascular smooth muscle cells *in vitro* (Ishikawa *et al.,* 1998). The antimigratory effects of PTHrP are mediated through a cAMP-dependent mechanism that leads to diminished PDGF signaling through the PI3 kinase cascade.

The effects on vascular smooth muscle cell growth and migration *in vitro* are likely to be physiologically relevant to conditions under which vascular smooth muscle cell (VSMC) growth and migratory behavior is altered *in vivo.* For example, Ozeki *et al.* (1996) have reported that PTHrP protein and mRNA expression were upregulated markedly in neointimal smooth muscle in rat carotid arteries following experimental balloon injury. Moreover, immunoreactive PTHrP is increased in human arterial tissue removed from patients undergoing angioplasty. In light of the possibility of opposing effects of PTHrP on vascular smooth muscle cell growth cited earlier, these observations can be viewed in one of two ways: either upregulation of PTHrP is a primary stimulus for growth under these conditions or, alternatively, it represents an antiproliferative signal. Consistent with the latter possibility, the local administration of PTHrP(1−34) dose-dependently inhibits cuff-induced neointimal formation in the rat femoral artery (Ishikawa *et al.,* 2000), whereas 3′,5′-cyclic AMP or the phosphodiesterase inhibitors aminophylline or amrinone have similar effects following experimental balloon injury of rat carotid arteries (Indolfi *et al.,* 1997). Moreover, other studies using a similar model of arterial injury showed high levels of $p27^{kip1}$ expression in media within 2 weeks of angioplasty (Tanner *et al.,* 1998).

PTHrP may also function in the calcification of vascular tissue. The overexpression of the molecule in atherosclerotic lesions increases the expression of MCP-1 and enhances the migration of circulating monocytes (Martin-Ventura *et al.,* 2003). The accumulation of inflammatory cytokines within the plaque likely leads to the expression of osteoinductive molecules and ultimately calcification (reviewed by Whitfield, 2005). However, i*n vitro* studies suggest that PTHrP inhibits the calcification of bovine vascular smooth muscle cells. PTHrP secretion decreases as vascular smooth muscle cells produce a calcified matrix following treatment with a source of inorganic phosphate, and the addition of the molecule inhibits calcification of VSMC via the activation of both phosphokinase A (PKA) and phosphokinase (PKC) (Jono *et al.,* 1997). Thus, the exact role of PTHrP in the calcification of vascular tissue remains elusive.

The ability of PTHrP to modulate vascular smooth muscle cell growth suggests that the protein might function during the development of the cardiovascular system. Although the cardiovascular system appears to develop normally in the PTHrP knockout mouse, homologous deletion of the PTH1R receptor results in a higher incidence of early fetal death at approximately embryonic day 9–10, coincident with development of the heart and major blood vessels (Lanske *et al.,* 1996). Furthermore, transgenic mice expressing high levels of PTHrP and its receptor in vascular smooth muscle, created by crossing the ligand- and receptor-overexpressing mice, die at day E9.5 with severe thinning of the ventricle and disruption of ventricular trabeculae (Qian *et al.,* 1999) (Fig. 3; see also color plate). Additional anecdotal evidence for a role of PTHrP in heart and vascular development is evident from the abnormalities seen in patients with the rare fatal condition known as Blomstrand chondrodysplasia caused by an inactivating mutation of PTH1R receptor (Karaplis *et al.,* 1998). These patients die prenatally with coarctation of the aorta and hydrops fetalis, the latter condition typically caused by high-output heart failure.

PTHrP and Angiogenesis

As suggested earlier, PTHrP might function in the development of new blood vessels. The overexpression of the peptide by many tumor cell types and the observation that PTHrP enhances the angiogenic behavior of endothelial cells *in vitro* led to the hypothesis that PTHrP is a proangiogenic factor (Akino *et al.,* 2000). Indeed, PTHrP may be able to influence angiogenesis by modulating the expression of interleukin-8 (Guijal *et al.,* 2001). However, two recent studies suggest that PTHrP is a negative regulator of angiogenesis. Adenoviral-mediated overexpression of PTHrP or treatment with N-terminal fragments of the peptide disrupts angiogeneis in chick chorioallantoic membranes (Bakre *et al.,* 2002). Whereas PTHrP acts on VSMCs to produce its vasodilatory effects, i*n vitro* studies suggest that PTHrP inhibits endothelial cell migration to affect angiogenesis. The activation of PKA inhibits Rac activity and thus cell migration (Bakre *et al.,* 2002). Consistent with these findings, the fetal skin of mice lacking either PTHrP or the PTH1R receptor exhibits increased blood vessel diameter and length, whereas overexpression of PTHrP produced reciprocal changes (Diamond *et al.*, 2006).

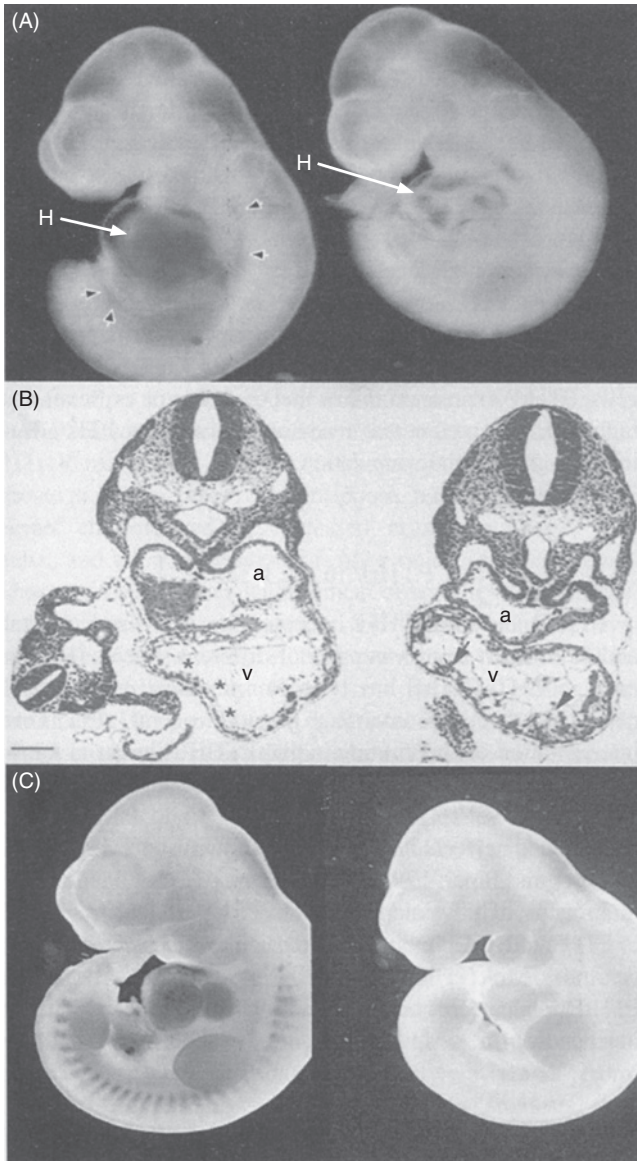

FIGURE 3 Overexpression of PTHrP and PTH1R disrupts heart development. **(A)** Whole mounts at E9.5 of double transgenic (*left*) and wild-type (*right*) embryos. The double transgenic embryo exhibits a greatly enlarged heart with pericardial effusion and vascular pooling (*arrows*). **(B)** Histological sections of double transgenic (*left*) and wild-type (right) embryos at E9.5. Trabeculae within the ventricular cavity (v) of the wild-type embryo are prominent (*large arrows*), whereas in the double transgenic embryo, trabeculae are reduced severely or absent (*asterisks*). Prominent gaps are also evident between the cardiomyocytes in the double transgenic hearts (*small arrowheads*), a, atria. Bar: 100 μm. (**C**, left). Mode of Action/Receptor Interactions

PTHrP exerts its vasodilatory actions by activating the PTH1R. This receptor is expressed in rat vascular smooth muscle beds (Urena *et al.,* 1993), and relaxation of aortic preparations is accompanied by an increased accumulation of cAMP (Ishikawa *et al.,* 1994b). Cultured rat aortic smooth muscle cells also express the PTH1R and respond to N-terminal PTHrP peptide fragments with an increase in cAMP formation (Wu *et al.,* 1993). Moreover, relaxation responses to PTH in aortic strip preparations are potentiated by phosphodiesterase inhibitors and forskolin (Nickels and Cline, 1987). Although the PTH1R receptor appears to be primarily coupled to adenylate cyclase, linkage to calcium-phosphoinositol pathways is suggested by studies by Nyby *et al.* (1995), who demonstrated a transient increase in cytosolic calcium and cAMP in response to PTHrP(1−34) in primary arterial rat vascular smooth muscle cells. However, other studies using similar preparations of primary rat aortic smooth muscle cells showed that PTHrP consistently stimulated cAMP accumulation but had no effect on intracellular calcium (Wu *et al.,* 1993). Furthermore, in A10 embryonic aortic vascular smooth muscle cells stably expressing recombinant PTH1R receptors, PTHrP induced large increases in cAMP accumulation but did not increase cytoplasmic calcium (Maeda *et al.,* 1996) despite the presence of detectable levels of expression of G_q, known to be required for functional coupling of the receptor to the PLC-phosphoinositide calcium pathway. However, when G_q was overexpressed in these cells, PTHrP evoked a calcium transient. It therefore appears that under most conditions the PTH1R receptor couples preferentially to G_s and adenylate cyclase to raise intracellular cAMP, which would be consistent with the established vasodilatory properties of this cyclic nucleotide. This does not, however, preclude the possibility that under certain physiological conditions (or in specific vascular smooth muscle cell beds), PTHrP might also activate PLC, which could mediate other as yet unidentified activities of the protein.

Vasorelaxation induced by cyclic nucleotides in arterial smooth muscle has also been reported to be associated with a reduction in intracellular calcium. In addition, in rat tail artery, PTH relaxes KCl-induced contraction; this effect is inhibited by nifedipine, suggesting an inhibition of the L-VSCC (Wang *et al.,* 1991a). Subsequent patch-clamp experiments (Wang *et al.,* 1991b) confirmed a decrease in L-type voltage-dependent calcium currents in vascular smooth muscle cells in response to PTH. Although not yet formally tested, it is likely that PTHrP also inhibits the L-VSCC activity in vascular smooth muscle, as is the case in cultured neuroblastoma cells.

As discussed in detail elsewhere in this volume (see Chapter 33), PTHrP is subject to post-translational processing to produce both N-terminal peptides, midregion PTHrP fragments, and possibly also C-terminal forms. PTHrP peptides that lack the PTH-like N-terminal region likely activate receptors distinct from the PTH1R and would be expected to exhibit a biological profile different from N-terminal PTHrP peptides. To date, however, there is no evidence that these midregion or C-terminal forms of PTHrP are biologically active either in cultured vascular smooth muscle cells (Wu *et al.,* 1993) or in intact vessel preparations (Sutliff *et al.,* 1999).

Although PTHrP is capable of relaxing vascular preparations devoid of endothelium, studies in mouse aortic preparations suggest that the endothelial layer may serve to amplify relaxant effects of PTHrP and PTH (Sutliff *et al.,* 1999). The mechanism accounting for the endothelium-dependent relaxant effects of PTH and PTHrP remains unclear, but does not appear to require nitric oxide formation. The recent demonstration of expression of a novel PTH-2 receptor (PTH2R; see later) in endothelial and smooth muscle cells in blood vessels and heart (Usdin *et al.,* 1996) suggests an additional pathway through which PTH-related peptides could alter vascular reactivity.

As with other G-coupled receptors, prolonged exposure of vessel preparations (Nyby *et al.,* 1995) or cultured aortic smooth muscle cells (Okano *et al.,* 1994) to PTHrP is associated with desensitization. Angiotensin II, which induces PTHrP expression in cultured aortic vascular smooth muscle cells, also rapidly desensitizes cells to PTHrP and downregulates the PTH1R receptor mRNA expression (Okano *et al.,* 1994), indicating crosstalk in the signaling circuitry among these vasoactive peptides.

From the studies just summarized, it is possible to construct a simple model for the mode of PTHrP action in vascular smooth muscle (Fig. 4; see also color plate). In response to mitogenic, vasoconstrictor, or mechanical signals, PTHrP is released and acts locally via a short feedback loop to activate the PTH1R receptor and stimulate adenylate cyclase in adjacent cells. Effector pathways downstream of cAMP impact specific sets of genes, which function to oppose the pressor (contraction coupling) and mitogenic (cell cycle) events. As mentioned earlier, induction of $p27^{kip1}$ with consequent inhibition of Rb phosphorylation would represent one such target for cAMP-induced cell cycle arrest. With regard to relaxant activity, stimulation of cAMP-dependent PKA is associated with a reduction in cytoplasmic calcium and attenuated myosin light chain kinase activity (McDaniel *et al.,* 1994).

Because PTH and PTHrP activate the same receptor, how does the smooth muscle PTH1R receptor distinguish between these two ligands? A likely possibility is that the sensitivity of a given tissue to PTH or PTHrP is governed by the relative abundance of each ligand and the number of PTH1R receptors. For example, in tissues such as vascular smooth muscle, which express high levels of PTHrP but relatively low numbers of the PTH1R receptor, the fraction of receptor occupancy must be high in order to achieve a

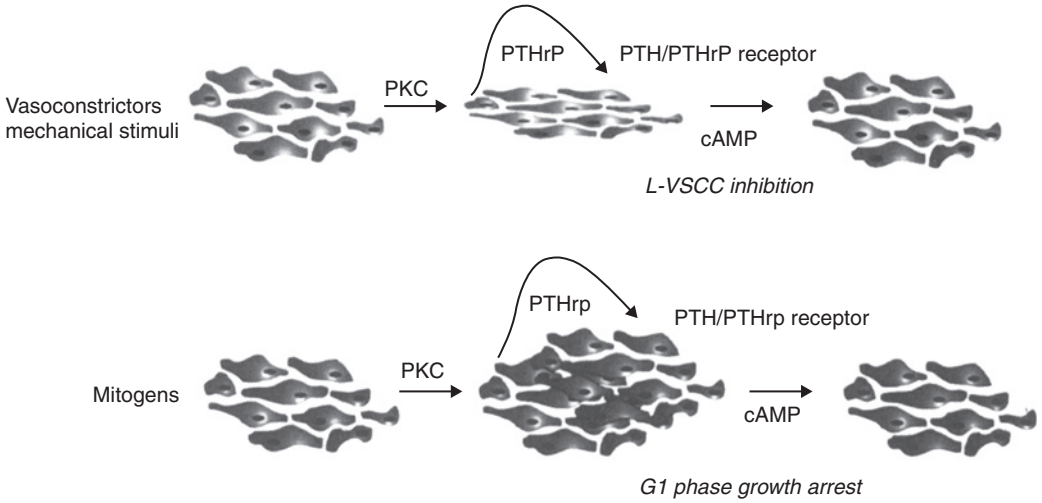

FIGURE 4 Model for PTHrP production and action in vascular smooth muscle cells (see text for description).

response, thus favoring the local (PTHrP) regulator. In contrast, in bone cells, PTHrP expression is low and the receptor expression is high, enabling preferential receptor activation by PTH arriving from the systemic circulation.

PTHrP in the Heart

PTHrP and the PTH1R receptor are expressed in fetal and adult heart from a number of different species (Burton *et al.*, 1994). PTHrP has been immunolocalized to atrial natriuretic peptide-containing granules of rat atria. One interpretation of this finding is that PTHrP, like atrial natriuretic peptide, is released in response to stretch, but this concept has yet to be tested. Both PTH and PTHrP exert pronounced effects on cardiac function (reviewed in Schluter and Piper, 1998).

Infusion of physiological levels of N-terminal fragments of PTH and PTHrP induce hypotension and tachycardia in intact rats (*Mok et al.,* 1989). In isolated perfused hearts, PTHrP induces chronotropic and ionotropic effects that are independent of perfusion pressure (Nickols *et al.,* 1989). Additionally, it has been established that the ionotropic activity of PTHrP occurs indirectly in response to increased coronary blood flow (Ogino *et al.,* 1995). The mechanisms responsible for the chronotropic effects of PTH and PTHrP have been examined in cultured cardiomyocytes (reviewed in Schluter and Piper, 1998). In neonatal cardiomyocytes, PTH increases beating frequency through a cAMP-dependent pathway. These effects are associated with increased L-type calcium currents, precisely the opposite of what is observed in vascular smooth muscle cells. In contrast, in adult rat cardiac myocytes, both PTH(1−34) and PTHrP(1–34) increase the rate of spontaneous contraction, but only PTHrP was found to stimulate cAMP accumulation. The reason for this difference is unclear but may relate to the coupling of the PTH1R receptor to different G proteins. PTH has also been shown to elicit a hypertrophic response in adult rat cardiomyocytes characterized by increased protein synthesis, cell mass, and the reexpression of embryonic cardiac proteins. These effects, together with clinical observations of patients with elevated PTH and increased left ventricular mass, have been interpreted as evidence for a pathogenic role of PTH in ventricular hypertrophy. Finally, as discussed earlier, the timing (E9–10) of embryonic death occurring in PTH/PTHrP receptor-null mice suggests that PTHrP functions during heart development. Consistent with this hypothesis, disruption of the receptor is associated with cardiomyocyte death likely as a result of calcium dysregulation (Qian *et al.*, 2003).

Insight into the global actions of PTHrP in the cardiovascular system has come from studies in genetically manipulated mice. Transgenic mice overexpressing either PTHrP or PTH1R in smooth muscle have reduced systemic blood pressure consistent with the prediction that PTHrP acts as a local vasodilator (Qian *et al.,* 1999). In aortic ring preparations from PTHrP-overexpressing mice, the relaxant effects of both PTHrP and acetylcholine seen in nontransgenic mice were attenuated markedly in aortas from PTHrP-overexpressing mice. This finding suggests that local overexpression of PTHrP not only desensitizes the vasculature to PTHrP, but also dampens relaxation to acetylcholine and perhaps other vasorelaxants. Thus, it appears that prolonged stimulation of the PTH1R and the consequent increase in cAMP converge on signaling circuitry used by acetylcholine.

PTH-Related Proteins and Hypertensive States

Several lines of circumstantial evidence suggest that PTH and PTHrP alter vascular tone in hypertensive humans and animals. For example, primary hyperparathyroidism is commonly associated with hypertension that may be corrected upon removal of the parathyroid lesion (Young

et al., 1988). However, because alterations in circulating PTH also influence other regulators of vascular tone (e.g., ionized calcium), it is probable that the hypertension seen in long-term hyperparathyroidism is a secondary event. Alternatively, prolonged exposure to elevated PTH concentrations in these patients could desensitize vascular tissue to PTH or PTHrP, thereby increasing vascular tone (Nyby *et al.,* 1995). A similar scenario appears to occur in two rat models of hypertension. For example, removal of the parathyroid glands in the spontaneously hypertensive rat (SHR) and the desoxycorticosterone acetate (DOCA) salt hypertensive rat attenuates the development of hypertension (Schleiffer, 1992). Moreover, the PTH-induced changes in urinary cAMP, magnesium, calcium, and phosphorus responses are blunted in the SH rats, again suggesting a desensitization of the PTH1R receptor. The apparent resistance to PTH and PTHrP in humans and rats with hypertension described earlier prompted Pang and coworkers (1991) to propose the existence of an additional "hypertensive" factor made in the parathyroid gland. However, despite more than a decade of work on this putative hypertensive factor, its precise structure is still unknown.

NEUROLOGICAL ACTIONS

Introduction

As noted earlier, interest in potential regulation of excitable cells by PTH/PTHrP began with Collip and Clark's demonstration in 1925 that parathyroid extracts had hypotensive effects in the dog. For the next 60 years, PTH was the focus of work in both vascular and nonvascular smooth muscle and in neurons. In smooth muscle, it now seems quite clear that the physiological regulator is actually PTHrP, acting on the PTH1R. The best functional evidence suggests that very similar trends are apparent in the central nervous system (CNS), in that PTHrP acts on the PTH1R. Additionally, the pivotal target of PTH/PTHrP regulation is the L-VSCC, because PTH and/or PTHrP appear to be capable of either inhibiting of stimulating L-VSCC-mediated Ca^{2+} influx, depending on the cell/tissue in question (Wang *et al.,* 1991a). However, in the CNS PTH may influence pituitary function, and the recently described TIP39 acting on the PTH2R may prove to be an important CNS regulatory system.

PTH/PTHrP Gene Family Expression in the CNS

The CNS was one of the first sites to be examined in detail for PTHrP gene expression, and the gene was found to be widely expressed in neurons of the cerebral cortex, hippocampus, and cerebellum (Weir *et al.,* 1990) (Fig. 5). This work was extended by a second survey, which included the PTH1R as well as PTHrP (Weaver *et al.,* 1995). Both were found to be widely expressed, and they colocalized in a number of sites. It was noted at the time that the hot spots for PTHrP gene expression are neuronal populations that have a number of features in common, including high-density L-VSCC expression as well as high-density

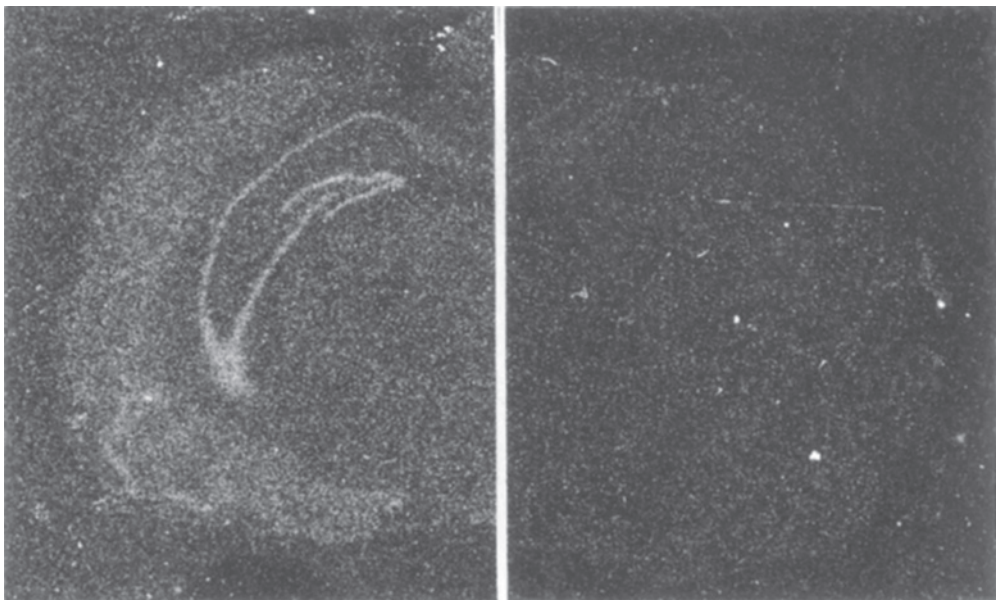

FIGURE 5 In situ hybridization histochemistry of PTHrP mRNA in the CNS of the rat using antisense (AS) and sense (S) oligonucleotides. The dentate gyrus and CA fields of the hippocampus are strongly positive. There are also many PTHrP-positive neurons scattered throughout the cerebral cortex. From Weir *et al.* (1990), with permission.

expression of excitatory amino acid receptors and a known susceptibility to excitotoxicity. The implications of these common features will become clear later in this chapter.

Although early histochemical studies suggested that PTH might be present in a number of neuronal populations, the most careful and reproducible work has localized PTH to nuclei on the hypothalamus with projections into the portal system (Pang *et al.,* 1988; Harvey and Fraser, 1993). The implication is that PTH may regulate pituitary function, specifically including prolactin secretion (Harvey and Fraser, 1993).

Usdin and colleagues identified the PTH2R in a cerebral cortical cDNA library by homology screening in 1995. This receptor is sensitive to PTH(1−34) (EC_{50} about 1 nM) but is unresponsive to PTHrP(1–36). The PTH2R is expressed most abundantly in several basal forebrain nuclei and hypothalamic nuclei (Usdin *et al.,* 1996). This group has succeeded in purifying the natural ligand for this receptor by using a staggering 50 lbs of bovine hypothalamus as starting material (Usdin *et al.,* 1999). This ligand is a small unmodified peptide of 39 amino acids referred to as tuberoinfundibular peptide 39 (TIP39), and it bears only 9 of 39 amino acids that are identical to those of bovine PTH. Only limited structure–function work has been done, but TIP39 is at least as potent as PTH(1–34) at the PTH2R and may be one or two orders of magnitude more potent than PTH, depending on the species of origin of the PTH2R (Usdin *et al.,* 1999). The sites of PTH2R expression imply potential TIP39 function in regulating the pituitary and in modulating pain sensitivity.

An additional neuroendocrine role for PTHrP has been proposed in osmoregulation. PTHrP is localized to the paraventricular (PVN) and supraoptic nuclei (SON), the population of neurons that synthesize arginine vasopressin (AVP) (Weaver *et al*., 1995; Tokunaga *et al*., 1997; Yamamoto *et al*., 2002). Axonal projections from the PVN and SON terminate in the posterior pituitary where AVP is released in response to changes in plasma osmolality and volume. In response to these changes, AVP stimulates renal tubular water reabsorption and exerts vasoconstrictive effects.

The central administration of PTHrP results in the secretion and expression of AVP from the PVN and SON (Yamamoto *et al.*, 1998). AVP and PTHrP expression are also mutually regulated in dissociated SON neuronal cultures. PTHrP stimulates the intracellular accumulation of cAMP in SON neurons and the secretion of AVP in a PKA-dependent manner. However, the inability of PTH(1−34) to exert any effect on AVP secretion suggests that PTHrP acts via a novel adenylyl cyclase-coupled receptor subtype in SON neurons. In contrast, stimulation of PTHrP by AVP is PKC-dependent and is mediated via the type 1 AVP receptor (V1a and V1b), which couple to phospholipase signaling and the generation of inositol 1,4,5-triphosphate and diacylglycerol (Yamamoto *et al*., 2002).

Thus, three ligands and at least two receptors of the PTH/PTHrP gene family are expressed in the CNS. Two of the ligands (PTH and TIP39) are expressed in highly discrete locations, whereas PTHrP is widely expressed in neuronal populations throughout the brain.

Calcium Channels, Neuromodulation, and Signaling Microdomains

Calcium Channels

Calcium channels are heteromeric associations of four or five subunits (Walker and de Waard, 1998). The α_1 subunit is the pore-forming structure that is responsible for permeation as well as gating function of the channel. There are a half-dozen classes of calcium channels, each defined by a specific α_1 gene. Given the number of different genes for each subunit and alternate splicing of these gene products, the combinatorial possibilities are enormous (perhaps 1000).

In brief, calcium channels are either L-type or non-L-type (e.g., N, P/Q, T, and R channels) (Walker and de Waard, 1998). L-type channels mediate large and long-lasting Ca^{2+} fluxes (therefore "L") and are composed of three subclasses, defined by their α_1 subunits, as well as by the locations in which they were initially identified. These are S ("skeletal," α_1s), C ("cardiac," α_1c), and D (neuroendocrine, α_1d). L channels are dihydropyridine sensitive, and there are a number of classes of these widely used drugs (e.g., nifedipine, diltiazem).

Virtually every class of calcium channel is expressed in the CNS (Walker and de Waard, 1998). N and P/Q channels are expressed in both pre- and postsynaptic locations and are involved in the regulation of synaptic transmission. L channels are widely expressed in neurons throughout the brain and are found only in postsynaptic locations, specifically on cell bodies and proximal dendrites (Hell *et al.,* 1993). This localization is crucial to L channel function. These channels appear to regulate cytosolic Ca^{2+} levels in the soma and proximal dendrites of neurons as a function of the integrated excitatory synaptic input into these locations (Hell *et al.,* 1993). Given the location and gating of these channels, it is quite clear that their Ca^{2+} currents are not involved in neurotransmission, but rather with fundamental aspects of neuronal cell biology such as regulation of cellular signaling pathways and regulation of gene expression.

Neuromodulation

The clustering of L-VSCCs on neuronal cell bodies is also characteristic of the location of neuropeptide/growth factor receptors. This clustering of receptors is strategically convenient to the nucleus as well as to the regulation of channels of all sorts and the capacity of peptides and growth factors to crosstalk with each other (Hökfelt, 1991). This

kind of short-range autocrine/paracrine signaling to the soma and proximal processes of neurons is referred to as "neuromodulation" to emphasize that the regulation and signaling involved are very different from neurotransmission (Hökfelt, 1991).

Signaling Microdomains

Even a generation ago, it was clear that signal transduction corresponded to more than cells simply serving as bags of rising and falling tides of cyclic nucleotides and Ca^{2+}, but the biochemical details that account for the exquisite specificity of signal transduction have become clear only in the past decade. The work of Ghosh and Greenberg (1995) has provided insight into the specificity of neuronal Ca^{2+} signaling. Depending on the specific route of entry into a neuron, Ca^{2+} has highly specific and differential effects on a wide variety of neuronal processes, such as gene expression, learning and memory, modulation of synaptic strength, and Ca^{2+}-mediated cell death (Ghosh and Greenberg, 1995). For example, Ca^{2+} entry via L-VSCCs elicits an entirely different response in terms of gene expression than Ca^{2+} entry mediated via *N*-methyl D-aspartate (NMDA) receptors (Ghosh and Greenberg, 1995). Clearly, every calcium ion entering the cytosol of a neuron is not perceived in the same way. Similarly, cAMP generated in a neuron by a voltage-sensitive adenylate cyclase as opposed to a G protein coupled to a hormone receptor is not perceived by the cell in the same way.

A major advance in understanding the specificity of signaling has come from the recognition that microdomains exist at the cell surface that cluster together the receptor/channel in question, the PKA and/or PKC transducers, and the target to be modified. The key players that account for this clustering of specific signaling components are the A kinase anchoring proteins (AKAPs) and the receptors for activated C kinase (RACKs) (Mochly-Rosen, 1995). In certain cases, a single AKAP is capable of binding both PKA and PKC, thus serving as a scaffold that brings together all of the early components of a complex regulatory system. The net result of this tethering of signaling receptor, transducer, and target into a microdomain is a tremendous resolution in terms of specificity and speed.

PTHrP Is Neuroprotective

PTHrP Gene Expression in Neurons Is Regulated by L-VSCC Ca^{2+} Influx

It is now apparent that the regulation of PTHrP gene expression in cerebellar granule cells is a classic example of the kind of specificity of Ca^{2+} signaling described in the previous section. Cerebellar granule cells are a hot spot of PTHrP and PTH1R expression *in vivo* (Weir *et al.,* 1990; Weaver *et al.,* 1995), and cultured cerebellar granule cells are a commonly used neuronal model system *in vitro.* PTHrP gene expression in these cells is a direct function of depolarization, which triggers L-VSCC Ca^{2+} influx that tracks to the PTHrP gene via the calmodulin-CaM kinase cascade (Holt *et al.,* 1996; Ono *et al.,* 1997). Ca^{2+} entry into granule cells by any other means (e.g., veratridine treatment) has no influence whatsoever on the PTHrP gene. In granule cells, as in most other cells that express the PTHrP gene, PTHrP is a constitutive secretory product, so that the quantity of PTHrP secreted by the cell is a linear function of the level of PTHrP mRNA expression. PTHrP immunolocalizes principally to the granule cell soma (Holt *et al.,* 1996) so that it is presumably secreted by the cell bodies themselves, acting in the autocrine/paracrine fashion typical of a neuromodulatory peptide.

PTHrP Inhibits L-VSCC Ca^{2+} Influx, Defining a Protective Feedback Loop

Overstimulation can lead to neuronal injury or death, a process referred to as excitotoxicity, which may be brought about in two conditions. High concentrations of the excitatory amino acid glutamate cause a generalized influx of cations and a collapse in mitochondrial function leading to almost immediate necrosis (Ankarcrona *et al.,* 1995). Lower concentrations of glutamate or exposure to other excitotoxins, such as kainic acid, trigger Ca^{2+} entry via L-VSCCs, which leads to excitotoxicity characterized by a long latency (6–24 hours to cell death) (Ankarcrona *et al.,* 1995; Weiss *et al.,* 1990).

The granule cell system is subject to both immediate and latent forms of excitotoxicity. A low concentration of kainic acid produces about 50% granule cell death at 24 hours, and the calcium channel blocker nitrendipine is capable of fully protecting these cells, thereby defining the central importance of L-VSCC Ca^{2+} influx in long-latency excitotoxicity (Brines *et al.,* 1999). It will be recalled that PTH has been shown to inhibit L-VSCCs in smooth muscle and neuroblastoma cells (Wang *et al.,* 1991; Pang *et al.,* 1990). This led to the working hypothesis that PTHrP might be capable of inhibiting L-VSCC Ca^{2+} influx in cerebellar granular cells, which proved to be the case. PTHrP was found to be fully neuroprotective in kainic acid-treated granule cells (Fig. 6) and was as effective as nitrendipine in reducing kainic acid-induced L-VSCC Ca^{2+} influx (Brines *et al.,* 1999). Pang *et al.* (1990) used whole-cell patch-clamp techniques to demonstrate that PTH is capable of inhibiting L-VSCC Ca^{2+} influx in mouse neuroblastoma cells and one of us (AEB) has used patch-clamp techniques to demonstrate the same findings with PTHrP in these cells. This effect is mediated by the PTH1R, but nothing is yet known of the mechanism by which the channel is actually regulated.

Although the PTHrP knockout mouse dies at birth as a result of systemic chondrodystrophy, a genetic strategy

has been used to generate a mouse that is PTHrP sufficient in chondrocytes but PTHrP null in all other sites (Wysolmerski *et al.,* 1998). There are no CNS abnormalities per se in the rescued mouse, but it displays a sixfold increase in sensitivity to kainic acid. Thus, as might be predicted from the findings in cultured cerebellar granule cells described earlier, PTHrP appears to be provided with a defense against excitotoxicity that is operative *in vivo* (Chatterjee *et al.,* 2002).

Taken together, these findings indicate that PTHrP serves as an endogenous L-VSCC regulator that functions in a neuroprotective feedback loop of the sort depicted in Fig. 7. As shown, the L-VSCC itself is the fulcrum of this loop, and the rheostat is L-VSCC Ca^{2+} entry. This loop would provide neuroprotection to individual (autocrine) and neighboring (paracrine) neurons.

Other Potential Calcium Channel Effects

PTHrP increases L-VSCC activity and thereby enhances dopamine secretion in PC-12 cells (Brines and Broadus, 1999). Additionally, PTH and/or PTHrP has been reported to increase calcium channel-like activity in snail neurons (Kostyuk *et al.,* 1992) and in rat hippocampal neurons (Hirasawa *et al.,* 1998; Fukayama *et al.,* 1995), but these effects are slow and perhaps involve channels other than the classic L-VSCC. UMR-106 osteoblast-like cells contain L-VSCCs that are stimulated by PTH treatment (Barry *et al.,* 1995). L-VSCCs are also widely expressed in a great many other excitable and nonexcitable cells that have thus far not been examined with respect to PTHrP regulation.

PTHrP in the Peripheral Nervous System

PTHrP as a Regulator of Schwann Cell Differentiation

One of the most well characterized functions of PTHrP is its role in regulating the differentiation state of chondrocytes during endochondrial bone development and growth. The growth plate is an exceptional example of a tissue that provides a "snapshot" of cells progressing through its own developmental program. An increase in PTHrP production by growth plate chondrocytes delays the differentiation and maturation of these cells, maintaining a proliferative phenotype and slowing chondrocyte differentiation so that premature ossification of bone does not occur during development (Kronenberg, 2006).

Although the development of tissues such as bone may seem a world away from the peripheral nervous system (PNS), the potential biological significance of PTHrP as a regulator of Schwann cell differentiation following nerve injury has recently been described (Macica *et al.*, 2006). Neurons of the PNS are able to regenerate after nerve injury, resulting in recovery of sensory and motor function (Ide, 1996). Just as the maintenance of an immature pool of chondrocytes is important during periods of bone growth, the dedifferentiation of Schwann cells to an immature phenotype in response to nerve injury is paramount to successful nerve regeneration.

Schwann cells, which are quiescent in normal myelinated and unmyelinated nerves, dedifferentiate and expand into phenotypically immature Schwann cells in response to nerve injury (Hall, 1999). Whereas myelin genes are downregulated upon denervation, a number of genes associated

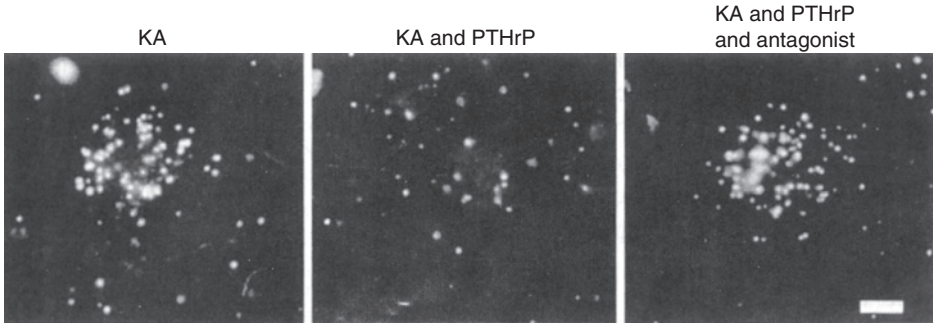

FIGURE 6 Cell death assessed by propidium iodide staining. Propidium iodide can bind to nuclear DNA only when the cell membrane is not intact; each bright dot therefore represents the nucleus of a dead cell. Kainic acid (KA) alone (*left*), KA plus PTHrP (*center*), and KA together with PTHrP and a 10-fold molar excess of a competitive antagonist of PTHrP binding (*right*). Percentage kill (±SEM) under these three conditions was 23 ± 3% ($n = 10$), 2 ± 2% ($n = 11$, $P < 0.001$ with respect to KA alone), and 23±2% ($n = 10$), respectively. Scale bar: 25 μm. From Brines *et al.* (1999), with permission.

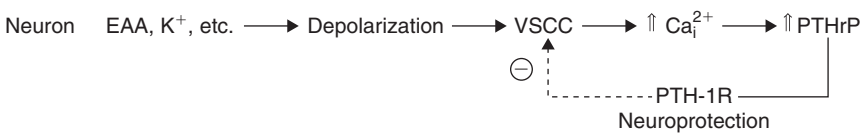

FIGURE 7 Schema of autofeedback loop in which PTHrP, triggered by L-VCSS Ca^{2+} influx, feeds back via the PTH1R to dampen L-VCSS Ca^{2+} currents.

with the immature nonmyelinating Schwann cells are upregulated including a change in the profile of adhesion molecules, growth factors, and growth factor receptors (Ide, 1996; Wanner, 2002). PTHrP expression strongly correlates with the immature Schwann cell phenotype and suggests that PTHrP may regulate the Schwann cell differentiation program following injury (Macica *et al.*, 2006).

PTHrP is localized to the PNS and is upregulated following sympathetic ganglion axotomy (Weaver *et al.*, 1995; Boeshore *et al.*, 2004). PTHrP mRNA is also upregulated *in vivo* following sciatic nerve injury and is a constitutively secreted product of dedifferentiated Schwann cells. Furthermore, consistent with reports that nuclear c-jun in Schwann cells is induced in injured sciatic nerve, c-jun was highly upregulated in nuclei of PTHrP-positive Schwann cells in crushed sciatic nerve (Shy *et al.*, 1996; Soares *et al.*, 2001; Macica *et al.*, 2006). These data suggest that loss of axonal contact may be a stimulus for Schwann cell-derived PTHrP mRNA upregulation. Indeed, by using purified Schwann cell cultures, PTHrP is a constitutively secreted product of immature Schwann cells. Conversely, when grown under conditions that stimulate Schwann cell differentiation and quiescence, PTHrP secretion is inhibited (Macica *et al.*, 2006).

PTHrP also potentiates the migration of Schwann cells in dorsal root ganglion (DRG) explants. Dedifferentiated Schwann cells retain the ability to migrate, a role that fulfills two functions important for successful regeneration. First, they migrate along regrowing axons from the proximal stump and segregate axons into groups of clustered fibers (Bunge, 1987). They ultimately form a one-to-one relationship with an axon, followed by myelin ensheathment and basal lamina deposition. Schwann cells also ensheath and segregate small, unmyelinated axons into separate troughs. Further, Schwann cells from both the proximal and distal stump form columns of cells along the basal lamina (bands of Büngner) that provide both a physical conduit and growth-promoting factors to regrowing axons (Ide, 1996). PTHrP can dramatically modulate the migration of Schwann cells along regrowing axons in DRG explants, a model of both nerve regeneration and Schwann cell migration that retains the physiological relationship between DRG axons and Schwann cells within an extracellular matrix (Macica *et al.*, 2006; Tonge *et al.*, 1997; Salzer and Bunge, 1980).

PTHrP also affects axonal bundling by Schwann cells. During development and following injury, immature Schwann cells migrate along outgrowing axons where they segregate axons into groups of clustered fibers (Bunge, 1987). Bundling of axons by migrating Schwann cells likewise occurs in DRG explants. DRG explants treated with exogenous PTHrP reveal a striking potentiation of axonal bundling by migrating Schwann cells. In contrast, explant cultures immunoneutralized with PTHrP antibody show significantly smaller axonal bundles and are only rarely associated with Schwann cells owing to the relative decrease in Schwann cell migration (Macica *et al.*, 2006).

Thus, PTHrP may play a pivotal role in Schwann cell dedifferentiation, one of the earliest events following loss of axonal contact and one that precedes Schwann cell proliferation. PTHrP may therefore promote Schwann cell dedifferentiation by downregulating genes or gene products that are typical of differentiated Schwann cells.

$1\alpha,25(OH)_2$ Vitamin D_3

Vitamin D Nuclear Receptor (VDR) and Plasma Vitamin D-Binding Protein (DBP) Structures and Ligand Shape Preferences for Genomic and Rapid Biological Responses

Anthony W. Norman*

Department of Biochemistry and Division of Biomedical Sciences, University of California, Riverside, California

INTRODUCTION TO VITAMIN D AND $1\alpha,25(OH)_2D_3$

Structure

The term vitamin D designates a group of closely related secosteroids (Fig. 1). The two most prominent members of this group are cholecalciferol (vitamin D_3) and ergocalciferol (vitamin D_2) (Norman *et al.*, 2006). Cholecalciferol is produced from 7-dehydrocholesterol that is present in skin of humans and most animals; it is the natural form of vitamin D that since the 1950s has been widely employed for food fortification (Norman 2003; Norman *et al.*, 2007) and as a vitamin supplement (Norman *et al.*, 2006). Ergocalciferol is derived from a common plant steroid, ergosterol, and is the form that was employed for vitamin D fortification of foods in the United States from the 1940s to 1960s.

The chemical structures of vitamin D and its daughter metabolites are closely related structurally to their provitamin forms as well as to the four-ring nucleus of other classical steroids that are derived from the cyclopentanoperhydrophenanthrene ring system (see Fig. 1). The official nomenclature proposed for vitamin D by the International Union of Pure and Applied Chemistry (IUPAC) relates it to the steroid nucleus, which is numbered as shown in Figure 1 for provitamins (The Commission on the Nomenclature of Biological Chemistry, 1960). The carbons in vitamin D retain the same number as designated in the provitamins. No vitamin D biological activity becomes apparent until ring B of the provitamins is opened. Thus, vitamin D and its metabolites are simply steroids with a broken B ring as a consequence of rupture of the carbon–carbon bond between C-9 and C-10. The presence of the nonintact B ring in the steroid nucleus is officially designated by the use of the term "seco." The formal chemical name of vitamin D_3 is 9,10-secocholesta-5,7,10,(19)-trien-3β-ol and of $1\alpha,25(OH)_2D_3$ is 9,10-secocholesta-5,7,10,(19)-trien-1α,3β,25-triol. Vitamin D_3 is the form of vitamin D obtained when radiant energy from the sun strikes the skin and converts the precursor 7-dehydrocholesterol into vitamin D_3. Because the body is capable of producing cholecalciferol, vitamin D technically does not meet the classical definition of a vitamin, i.e., a substance required by the body, but which can not be made by the body. A more accurate description of vitamin D is that it is a prohormone. It has been shown that vitamin D is metabolized to a biologically active form, $1\alpha,25(OH)_2$vitamin D_3 [$1\alpha,25(OH)_2D_3$] that functions as a steroid hormone (Haussler *et al.*, 1968; Myrtle *et al.*, 1970; Norman *et al.*, 1971; Brickman *et al.*, 1972). However, because the parent vitamin D was first recognized as an essential nutrient, it continues to be classified among the fat-soluble vitamins. Indeed, even in the first decade of the twenty-first century there are classical examples of vitamin D deficiency in many countries as documented by low serum concentrations of $25(OH)D_3$ (e.g., DeLucia *et al.*, 2003; Rejnmark *et al.*, 2004; Hanley *et al.*, 2005; Hirani *et al.*, 2005; Tareen *et al.*, 2005).

Conformational Flexibility

Vitamin D_3 and all its daughter metabolites, including $1\alpha,25(OH)_2D_3$, are unusually conformationally flexible (Fig. 2). The structure of $1\alpha,25(OH)_2D_3$ is shown in Figure 2A.Three key aspects of the $1\alpha,25(OH)_2D_3$ molecule confer a unique range of conformational mobility on this molecule.

Principles of Bone Biology, 3rd Edition

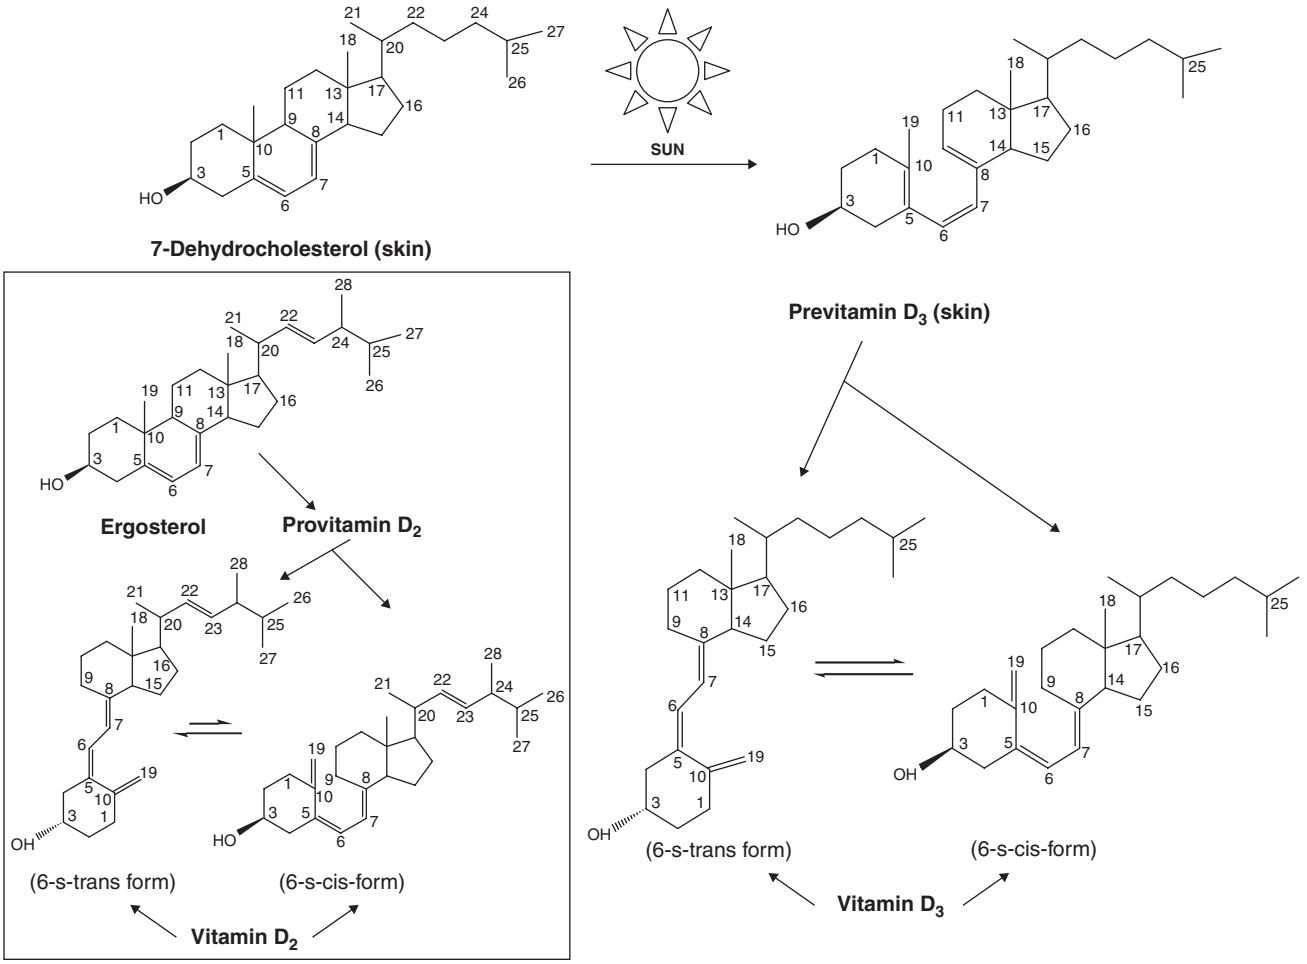

FIGURE 1 Chemistry and irradiation pathway for production of vitamin D3 (a natural process) and vitamin D_2 (a commercial process). In each instance, the provitamin, which is characterized by the presence in the B ring of a Δ5, Δ7-conjugated double-bond system, is converted to the seco-B previtamin steroid, where the 9,10 carbon–carbon bond has been broken. Then the previtamin D, in a process independent of ultraviolet light, thermally isomerizes to the vitamin form, which is characterized by a Δ5,6, Δ7,8, Δ10,19-conjugated triple bond system. In solution (and in biological systems) vitamin D is capable of assuming a large number of conformational shapes because of rotation about the 6,7 carbon–carbon single bond of the B ring.

(1) The intact 8-carbon side chain of vitamin D and related secosteroids can easily assume numerous shapes and positions in three-dimensional space by virtue of rotation about its five carbon–carbon single bonds (see Fig. 2B). A discussion of the consequences of the side-chain conformational mobility has been previously presented (Okamura *et al.*, 1992; Midland *et al.*, 1993). (2) The cyclohexane-like A ring is free to rapidly interchange (many thousands of times per second) between a pair of chair–chair conformers (see Fig. 2C); this has the consequence of changing the orientation of the key 1α− and 3β-hydroxyls between either an equatorial or an axial orientation (Wing *et al.*, 1974). (3) Rotational freedom about the 6–7 carbon–carbon bond of the seco-B ring allows conformations ranging from the more steroidlike 6-s-*cis* conformation to the open and extended 6-s-*trans* form of the hormone (see Fig.2D) (Norman *et al.*, 1993b). In general, it is accepted that this conformational mobility of vitamin D secosteroids is displayed by the molecules in both an organic solvent as well as an aqueous environment similar to that encountered in biological systems. Thus, receptors for $1\alpha,25(OH)_2D_3$ have had to accommodate to the reality of binding a highly conformationally flexible ligand.

VITAMIN D ENDOCRINE SYSTEM

The concept of the existence of the vitamin D endocrine system is firmly established (Reichel *et al.*, 1989; Bouillon *et al.*, 1995) (Fig. 3). The key organ in this endocrine system is the kidney where the renal proximal tubule is responsible for producing the hormonal $1\alpha,25(OH)_2D_3$ that circulates in the blood in accordance with strict physiological signals (Henry, 2000). The parent vitamin D_3 is metabolized to $25(OH)D_3$ (by the liver) and then to $1\alpha,25(OH)_2D_3$ and $24R,25(OH)_2D_3$ (by the endocrine gland and the kidney) as well as to at least 34

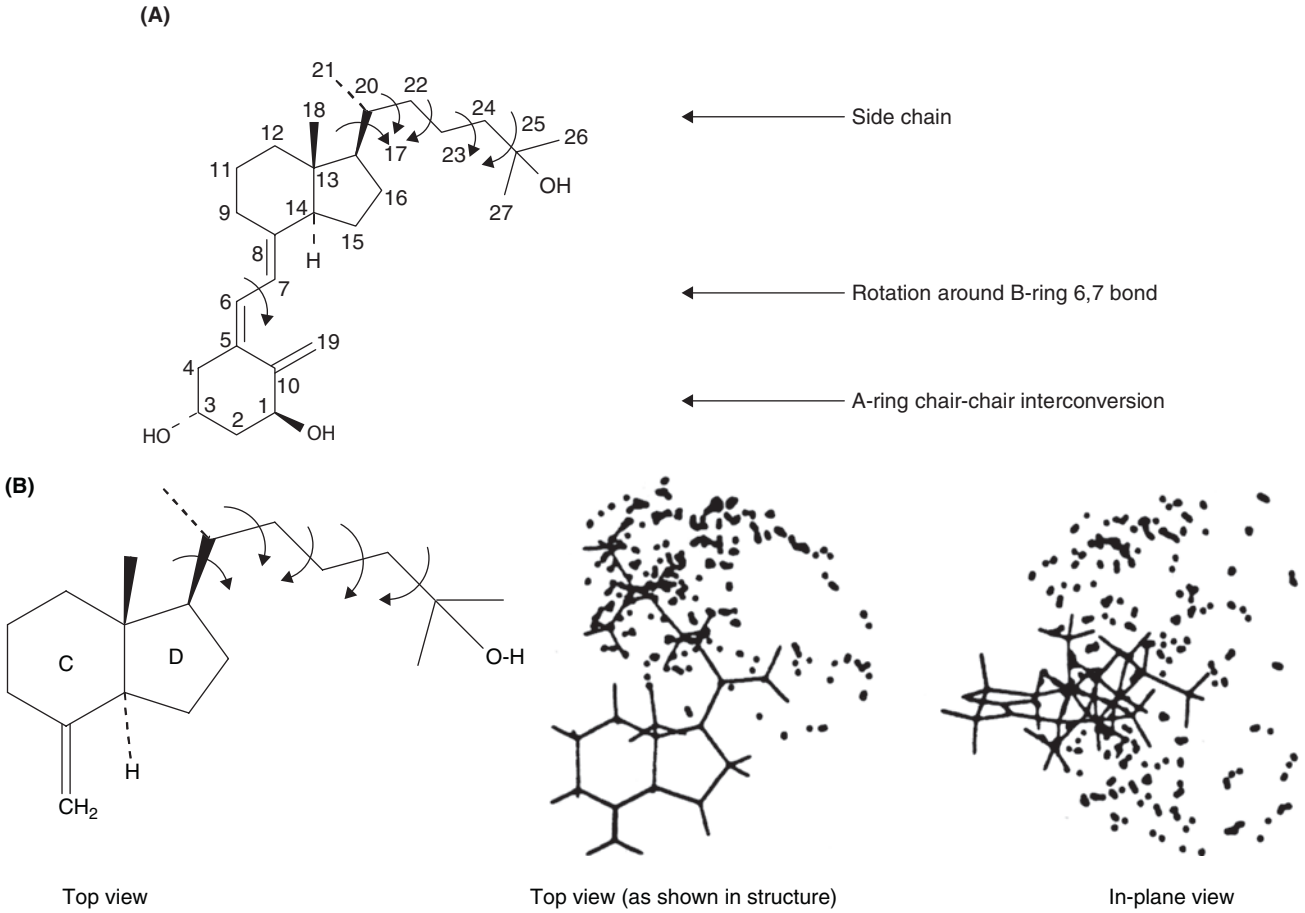

FIGURE 2 Structure of 1α,25(OH)$_2$D$_3$ illustrating the three structural aspects of vitamin D secosteroids that contribute to the conformational flexibility of these molecules. **(A)** Structure of 1α,25(OH)^{2}D^3 with indication of the three structural features of the molecule that confer conformational flexibility on this molecule. **(B)** The dynamic rotation of the cholesterol-like side chain of 1α,25(OH)$_2$D$_3$ with 360° rotations about the five single carbon–carbon bonds indicated by the curved arrows. The dots indicate the position in three-dimensional space of the 25-hydroxyl group for some 394 readily identifiable side-chain conformations. A discussion of the consequences of the side-chain conformational mobility has been presented (Okamura *et al*., 1992; Midland *et al*., 1993; Okamura *et al*., 1994). **(C)** The rapid (millions of times per second) chair–chair interconversion of the cyclohexane-like A ring of the secosteroid between chair conformer A and chair conformer B; this effectively equilibrates the 1α- and 3β-hydroxyls between the axial and equatorial orientations. **(D)** Rotational freedom about the 6–7 carbon–carbon single bond of the seco-B ring allows conformations ranging from the open and extended 6-s-*trans* conformation, utilized by the VDR for genomic responses, to the more steroid-like 6-s-*cis* form of the hormone believed to be used by the VDR for RR. **(E)** Structure of 1α,25(OH)$_2$-lumisterol (JN) that is chemically locked in a permanent 6-s-*cis* shape and has potency equivalent to 1α,25(OH)$_2$D$_3$ in mediating RR (see text). Space-filling **(F)** and stick representations **(G)** illustrating the clear differences in their shapes of the three optimal ligands for the nuclear localized VDR (left), the membrane-caveolae-localized VDR (*center*), and the plasma vitamin D-binding protein (*right*). The nuclear VDR ligand [1α,25(OH)$_2$D$_3$] is in a bowl-shaped, twisted 6-s-*trans* conformation with the A ring and side chain both 300 above the plane of the C/D ring. The relatively planar 6-s-*cis* locked [1α,25(OH)$_2$-lumisterol] is an optimal ligand for the membrane VDR. The DBP ligand [25(OH)D$_3$] is in a twisted 6-s-*trans* orientation with the A ring C10-C19 exocyclic alkene 300 below the plane of the C/D ring and the side chain almost 900 below the C/D ring plane. Each of the illustrated molecules has its 25-OH pointed to the "right" and the A ring to the "left." The shapes of the nuclear VDR (Rochel *et al*., 2000) and DBP (Verboven *et al*., 2002) ligands were learned from the separate determination of the x-ray structure of each protein, whereas the shape of the membrane VDR ligand was determined by computer modeling.

FIGURE 2 (*Continued*)

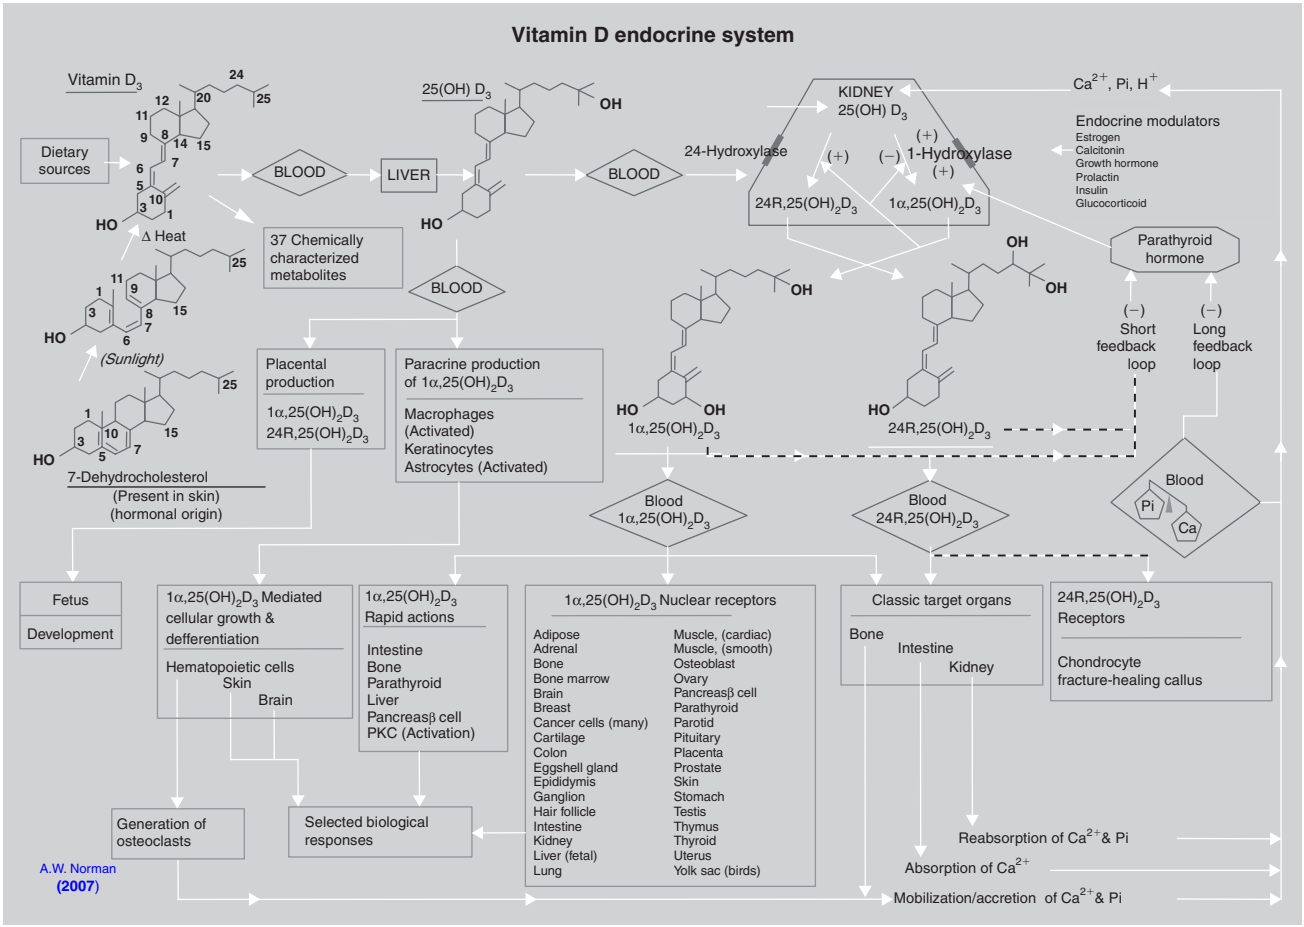

FIGURE 3 Overview of the vitamin D endocrine system. The figure lists 34 target organs and cells types that are known to contain the nuclear vitamin D receptor (VDR_{nuc}). When the VDR_{nuc} is occupied by its cognate ligand, the naturally occurring steroid hormone 1α,25(OH)$_2$D$_3$, this receptor-ligand complex is able to modulate genomic events (Hannah *et al.*, 1994; Carlberg, 2003; MacDonald *et al.*, 2004; Whitfield *et al.*, 2005; Norman, 2006). In addition 1α,25(OH)$_2$D$_3$ generates biological effects via rapid response pathways; these sites are listed in Table 2 and are discussed in the following references: Norman (1997), Norman *et al.* (2004), and Norman (2006) . There is also emerging evidence that 24R,25(OH)$_2$D$_3$ may also have important biological effects (Seo *et al.*, 1997a; Boyan *et al.*, 2001).

other metabolites (Bouillon *et al.*, 1995). The secosteroid 1α,25(OH)$_2$D$_3$ has been shown to initiate biological responses via regulation both of gene transcription as well as via a membrane-receptor that initiates rapid responses. As will be discussed later, the vitamin D nuclear receptor (VDR), which is present in the nucleus and responsible for regulation of gene transcription, is also known to be localized to membrane caveolae where it can initiate in rapid responses (Norman *et al.*, 2002b; Huhtakangas *et al.*, 2004). The rapid responses can, for example, involve opening of voltage-gated Ca^{2+} channels (Caffrey *et al.*, 1989) or the rapid stimulation of intestinal Ca^{2+} absorption known as transcaltachia (Nemere *et al.*, 1984b) (Fig. 4).

An additional key participant in the operation of the vitamin D endocrine system is the plasma vitamin D-binding protein (DBP), which carries vitamin D$_3$ and all its metabolites to their various target organs. The DBP is known to have a specific ligand-binding domain for vitamin D-related ligands that is different in specificity from the ligand-binding domain of the nuclear vitamin D receptor (Bishop *et al.*, 1994). The structure of these two key proteins of the vitamin D endocrine system, the VDR and DBP, is presented later in this chapter.

SIGNAL TRANSDUCTION PATHWAYS UTILIZED BY 1α,25(OH)$_2$D$_3$ TO GENERATE BIOLOGICAL RESPONSES

Figure 3 summarizes the 33 target organs that are known to possess the VDR_{nuc} and in which there is an impressive amount of detail concerning regulation of gene transcription (Hannah *et al.*, 1994; Sutton *et al.*, 2003; Carlberg, 2004; Pike *et al.*, 2005; Carlberg *et al.*, 2006).

Figure 4 presents a schematic model that postulates that the various biological responses generated by

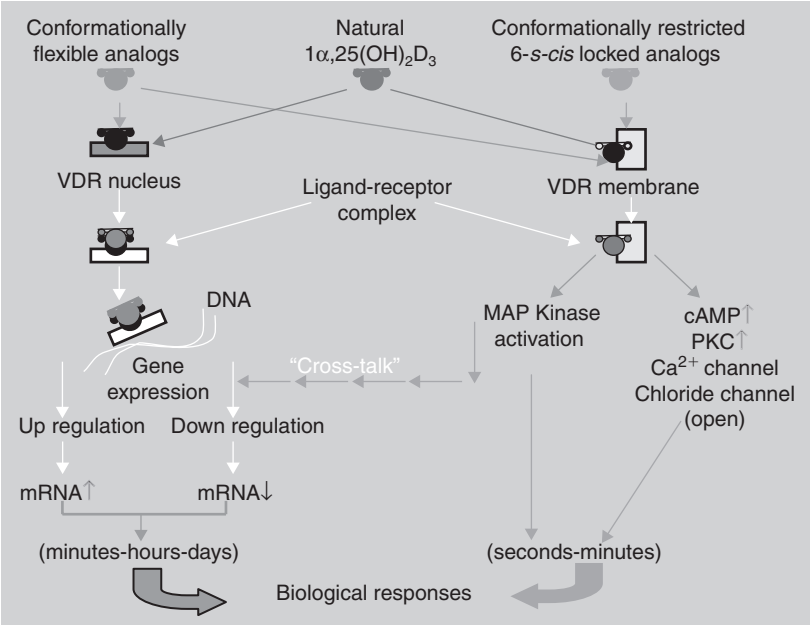

FIGURE 4 Proposed signal transduction pathways utilized by $1\alpha,25(OH)_2D_3$ (hat icon) and analogs of $1\alpha,25(OH)_2D_3$ to generate biological responses. Different shapes of $1\alpha,25(OH)_2D_3$ and its conformationally flexible analogs (spiked hat icon) may interact with either the VDR_{nuc} or the VDR_{mem} to initiate different signal transduction pathways that result in genomic responses or rapid responses. In contrast, the conformationally restricted 6-s-*cis* analogs restricted (half hat icon) (see Figure 1; JM, JN) only can interact with VDR_{mem}. In the genomic pathway (*left side*), occupancy of the nuclear receptor for $1\alpha,25(OH)_2D_3$ (VDR_{nuc}) by a ligand leads to an up- or downregulation of genes subject to hormone regulation. More than 50 proteins are known to be transcriptionally regulated by $1\alpha,25(OH)_2D_3$ [see Table I and Hannah *et al.*, 1994]. In the membrane-initiated pathway (*right side*), occupancy of a putative membrane receptor for $1\alpha,25(OH)_2D_3$ by a ligand is believed to rapidly lead to activation of a number of signal transduction pathways, including adenylate cyclase, phospholipase C, protein kinase C (PKC), mitogen-activated protein kinase (MAP kinase), and/or opening of voltage-gated L-type Ca^{2+} channels, which are either individually or collectively coupled to generation of the biological response(s).

$1\alpha,25(OH)_2D_3$ depend on two types of receptors. These are the classic nuclear receptor for $1\alpha,25(OH)_2D_3$ (designated as VDR_{nuc}) and a membrane receptor (designated as VDR_{mem}). It has been postulated that the conformationally flexible steroid hormone $1\alpha,25(OH)_2D_3$ generates biological responses using different shapes so as to selectively activate the two general signal transduction pathways (Norman, 1997; Norman *et al.*, 2002a; Norman, 2005). (1) One shape of $1\alpha,25(OH)_2D_3$ interacts with the VDR_{nuc} to form a competent receptor–ligand complex that interacts with other nuclear proteins to create a functional gene transcription complex to increase or decrease mRNA coding for selected proteins (see Fig. 4, left). (2) A different shape of $1\alpha,25(OH)_2D_3$ interacts with the VDR_{mem} that promptly stimulates signal transduction events that activate the rapid appearance of biological responses (see Fig. 4, right). Also see Fig.2E, to see the structure of the 6-s-*cis*-locked $1\alpha,25(OH)_2$-lumisterol (analog JN) that is a full agonist for rapid responses. Figure 2E and F compares the shapes of the optimal ligands for genomic responses (VDR) and rapid responses and for binding to the DBP.

A wide array of rapid responses stimulated by $1\alpha,25(OH)_2D_3$ have been reported over the past 15 years; a summary is given in Table I. Recent additions to the list include demonstrations that $1\alpha,25(OH)_2D_3$ can stimulate opening of chloride channels (Zanello *et al.*, 1996, 2006) and activation of mitogen-activated protein (MAP) kinase (Buitrago *et al.*, 2006; Song, 1998). MAP kinase belongs to the family of serine/threonine protein kinases and can be activated by phosphorylation on a tyrosine residue induced by mitogens or cytodifferentiating agents (Pelech *et al.*, 1992). MAP kinase integrates multiple intracellular signals transmitted by various second messengers and regulates many cellular functions by phosphorylation of a number of cytoplasmic kinases and nuclear transcription factors including the epidermal growth factor (EGF) receptor, c-Myc, and c-Jun (Lange-Carter *et al.*, 1993). These rapid actions of $1\alpha,25(OH)_2D_3$ have been postulated to regulate cell biological function and potentially to interact with other membrane-mediated kinase cascades or to crosstalk with the cell nucleus to control genomic responses associated with cell differentiation and proliferation (Berry *et al.*, 1996) and modulation of osteoblast function (Vertino *et al.*, 2005).

NUCLEAR RECEPTOR (VDR) FOR $1\alpha,25(OH)_2D_3$

The $1\alpha,25(OH)_2D_3$ receptor was originally discovered in the intestine of vitamin D-deficient chicks (Haussler *et al.*, 1969; Tsai *et al.*, 1972). A timeline summarizing the important developments in our understanding of the

TABLE I Distribution of Rapid Responses to $1\alpha,25(OH)_2D_3$

Organ/cell/system	Response studied	Reference
Intestine	Rapid transport of intestinal Ca^2 (transcaltachia)	Nemere *et al.* (1984b); De Boland ***et al.*** (1990a, 1990b)

The reader should compare the information in this table with the concepts illustrated in Figures 4 and 7 which summarize the vitamin D endocrine system and signal transduction pathways utilized by $1\alpha,25(OH)_2D_3$ for generation of biological responses.

vitamin D receptor (VDR) and its historical involvement in genomic responses and now, more recently, its proposed involvement in rapid responses is presented in Table II. The interval from its discovery in 1969 to 1984 established that the cell nucleus-localized VDR, like those for the classical ligand-occupied steroid hormone receptors (the estrogen, progesterone, androgen, glucocorticoid, and mineralocorticoid receptors) is intimately involved with selective gene transcription appropriate to the biology of each system. The VDR is known to be present in more than 30 target tissues in humans (Reichel *et al.*, 1989; Bouillon *et al.*, 1995; Norman, 2001; Norman *et al.*, 2006) (see Figure 3). Given the long-standing understanding that vitamin D acting via $1\alpha,25(OH)_2D_3$ is principally responsible for calcium homeostasis via actions in the intestine, bone, and kidney; the other additional VDR-containing target organs collectively reflect "new" genomic response assignments for $1\alpha,25(OH)_2D_3$ and its VDR. Some of the new genomic frontiers include the immune system's B and T lymphocytes, the hair follicle, muscle, adipose tissue, bone marrow, and cancer cells.

The VDR has been extensively characterized and the cDNA for the nuclear receptor has been cloned and sequenced (McDonnell *et al.*, 1987; Baker *et al.*, 1988). To date only a single form of the receptor has been identified. The $1\alpha,25(OH)_2D_3$ receptor is a DNA-binding protein with a molecular mass of about 50,000 Da. It binds $1\alpha,25(OH)_2D_3$ with high affinity with a K_D in the range

TABLE II Vitamin D Receptor Timeline: A Historical Past (Genomic Responses) and New Assignments for the Future (Rapid Responses)

Year	Comment	Reference
1968–1971	Discovery of $1\alpha,25(OH)_2D_3$ as a new steroid hormone and its chemical characterization	Haussler *et al.* (1968); Myrtle *et al.* (1970); Norman *et al.* (1971)
1969	Discovery of the nuclear receptor for $1\alpha,25(OH)_2D_3$	Haussler *et al.* (1969); Tsai *et al.* (1973b)
1973	Actinomycin D, an inhibitor of DNA-directed RNA synthesis, blocks the biological actions of both vitamin D_3 and $1\alpha,25(OH)_2D_3$	Norman (1965); Tsai *et al.* (1973a)
1982	The $1\alpha,25(OH)_2D_3$ unoccupied receptor is partitioned between the cytosol and nucleus of the cell	Walters *et al.* (1980)
1985–1995	Appreciation that $1\alpha,25(OH)_2D_3$ is a very conformationally flexible molecule/receptor ligand as a consequence of its eight-carbon side chain, 360° rotation about its 6,7 single carbon and A-ring chair–chair interconversion	Okamura *et al.* (1974); Wing *et al.* (1974)
1984	Discovery of $1\alpha,25(OH)_2D_3$ rapid response of transcaltachia	Nemere *et al.* (1984a)
1984	Appreciation that the VDR is present in more than 30 target tissues of humans, including classical (intestine, kidney, cartilage, and bone) as well as nonclassical (pancreas β-cell, hair follicle, many cancer cells, and activated B and T lymphocytes) target organs of vitamin D through its daughter steroid hormone, $1\alpha,25(OH)_2D_3$	Norman *et al.* (1982b); Reichel *et al.* (1989)
1994	Postulate of a membrane receptor for $1\alpha,25(OH)_2D_3$ involved in rapid responses	Nemere *et al.* (1994)
1997	Demonstration for $1\alpha,25(OH)_2D_3$ that a 6-s-*cis* shape is the rapid responses agonist, whereas a 6-s-*trans* shape is the genomic responses agonist	Norman *et al.* (1997)
2000	The first x-ray structure of the VDR ligand-binding domain is reported.	Rochel *et al.* (2000)
2003	Evidence that annexin II is not a membrane receptor for $1\alpha,25(OH)_2D_3$	Mizwicki *et al.* (2003a)
2003	Discovery of a [^{3}H] $1\alpha,25(OH)_2D_3$-binding protein in caveolae membrane fractions of chick intestinal cells	Norman *et al.* (2002b)
2004	The vitamin D receptor is present in caveolae-enriched plasma membranes and binds $1\alpha,25(OH)_2$-vitamin D_3 *in vivo* and *in vitro*	Huhtakangas *et al.* (2004)
2004	A putative $1\alpha,25(OH)_2D_3$ membrane-binding protein (1,25D-MARRS or membrane-associated, rapid-response steroid-binding), linked to intestinal phosphate transport is found to be identical to the protein ERp57	Nemere *et al.* (2004)
2004	The rapid response effects of $1\alpha,25(OH)_2D_3$ requires a functional VDR	Nguyen *et al.* (2004)
2004	Identification of an alternative ligand-binding pocket in the VDR and its functional importance in $1\alpha,25(OH)_2D_3$ signaling emphasizes the importance of a VDR receptor ensemble model	Norman *et al.* (2004); Mizwicki *et al.* (2004)
2004	Rapid modulation of osteoblast ion channel rapid responses is abrogated in VDR knockout mice emphasizing that $1\alpha,25(OH)_2D_3$-mediated rapid responses require the presence of a functional VDR	Zanello *et al.* (2004)
2005	Presence of a truncated form of the VDR in a strain of VDR KO mice	Bula *et al.* (2005)

of 1–50 $\times$ 10^{-10} M (Wecksler *et al.*, 1980a, 1980b). The exquisite ligand specificity of the nuclear $1\alpha,25(OH)_2D_3$ receptor is illustrated in Table III. This table tabulates the Relative Competitive Index (RCI) of eight key analogs of the reference compound, namely $1\alpha,25(OH)_2D_3$; the RCI of $1\alpha,25(OH)_2D_3$ is set to 100%. Thus, changing the 3β-hydroxyl to a 3α-hydroxyl reduces the RCI to 24%, whereas removal of the 25-hydroxyl or 1α-hydroxyl reduces the RCI to 0.15%. The parent vitamin D_3 with a RCI of 0.0001% has no capability to bind to the VDR.

The impact of $1\alpha,25(OH)_2D_3$-mediated rapid response (RR) on the VDR from 1994 to the present are summarized in Table I. The concept of the existence of a membrane receptor for $1\alpha,25(OH)_2D_3$ has its origins in the study of the

TABLE III Ligand Specificity of the Nuclear $1\alpha,25(OH)_2D_3$ Receptor

Ligand	Structural modification	RCI[a] (%)
$1\alpha,25(OH)_2D_3$		100
$1\alpha,25(OH)_2$-24-nor-D_3	Shorten side chain by 1 carbon	67
$1\alpha,25(OH)_2$-3-epi-D_3	Orientation of 3β-OH altered	24
$1\alpha,25(OH)_2$-24a-dihomo-D_3	Lengthen side chain by 2 carbons	24
$1\beta,25(OH)_2D_3$	Orientation of 1α-OH changed	0.8
$1\alpha(OH)D_3$	Lacks 25-OH	0.15
$25(OH)D_3$	Lacks 1α-OH	0.15
$1\alpha,25(OH)_2$-7-dehydrocholesterol	Lacks a broken B ring; is not a secosteroid	0.10
Vitamin D_3	Lacks 1α- and 25-OH	0.0001

[a]*The Relative Competitive Index* (RCI) *is a measure of the ability of a nonradioactive ligand to compete, under* in vitro *conditions, with radioactive* $1\alpha,25(OH)_2D_3$ *for binding to the nuclear* $1\alpha,25(OH)_2D_3$ *receptor* (VDR).

Source: From Bouillon *et al.* (1995).

process of $1\alpha,25(OH)_2D_3$-mediated response of transcaltachia, or the rapid hormonal stimulation of intestinal Ca^{2+} absorption in the perfused chick intestine (Nemere *et al.*, 1984b). The most potent agonist is the natural hormone $1\alpha,25(OH)_2D_3$, which can stimulate the transport of calcium across the intestine within 4–5 minutes of its injection in the celiac artery that perfuses the duodenum (Nemere *et al.*, 1984b). It now appears that the classical VDR normally associated with the cell nucleus and gene transcription can also be resident near to or associated with caveolae present in the plasma membrane (Norman *et al.*, 2002b; Huhtakangas *et al.*, 2004; Bula *et al.*, 2005). Caveolae are flask-shaped membrane invaginations that are enriched in sphingolipids and cholesterol, which are commonly found in both caveolae and/or lipid rafts (Razani *et al.*, 2002). It has also been reported that the estrogen receptor (ER), androgen receptor (AR), and aldosterone receptor are associated with caveolae of (Norman *et al.*, 2004).

There are several recent reviews describing the properties of the VDR. See the following: Sutton *et al.* (2003); MacDonald *et al.* (2004); Kato *et al.* (2004); Norman (2005); Pike *et al.* (2005); and Carlberg *et al.* (2006).

The protein superfamily to which the VDR belongs includes receptors for glucocorticoids (GR); progesterone (PR); estrogens (ER); aldosterone; androgens; thyroid hormone (T3R); hormonal forms of vitamin A (RAR, RXR); the insect hormone, ecdysone; the peroxisome proliferator–activator receptor, PPAR; and several orphan receptors including the estrogen-related receptor, ERR, and the cholic acid lipid-sensing receptor, LXR (Evans 1988; Mangelsdorf *et al.*, 1995; Carlberg, 1996).To date, biochemical evidence has been obtained for the existence of about 24 small molecule/steroid receptors. Based on evaluation of the human genome database, it is believed that there are a total of 48 members of the steroid receptor superfamily (Mangelsdorf *et al.*, 1995). Figure 5 describes the hypothesized evolutionary relationship of the superfamily of nuclear receptors.

Figure 6 presents a schematic model of the domains of the VDR in comparison with the domains of the vitamin D-binding protein (DBP); both of these proteins bind $1\alpha,25(OH)_2D_3$ specifically and with high affinity, but they have a vastly different protein structure and biological functions. A discussion of the ligand-binding domain of DBP and its protein structure, compared with that of the VDR, is presented somewhat later.

The DNA-binding domain C is the most conserved domain throughout the family of all the nuclear receptors. About 70 amino acids fold into two zinc finger-like motifs in which conserved cysteines coordinate a zinc ion in a tetrahedral arrangement. The first finger, which contains four cysteines and several hydrophobic amino acids, determines the hormone response element (HRE) specificity; an HRE is a specific nucleotide sequence located in the promoter region of the gene to be regulated by the receptor and cognate ligand (Beato, 1989; McKenna *et al.*, 2002a; McKenna *et al.*, 2002b). The second zinc finger, which contains five cysteines and many basic amino acids, is also necessary for DNA binding and is involved in receptor dimerization (Green *et al.*, 1988; Rastinejad *et al.*, 1995). The zinc fingers identify the receptor cognate HRE and physically interact with the HRE to form a receptor + ligand + HRE–DNA complex.

The next most conserved region for the nuclear receptors is paradoxically the steroid-binding domain (region E). This region contains a hydrophobic pocket for ligand binding and also contains signals for several other functions including dimerization (Bourguet *et al.*, 1995; Renaud *et al.*, 1995), nuclear translocation, and hormone-dependent transcriptional activation (Weatherman *et al.*, 1999). Given the wide diversity in the chemistry and structure of all the steroid, thyroid, and retinoid ligands, it would not have been predicted that the same fundamental amino acid sequence of domain E would specifically and exquisitely define the strict high-affinity binding of each specific ligand only with its cognate receptor. Thus, the conserved amino acid residues of the E domain create the three-dimensional framework of the ligand-binding domain, whereas the nonconserved amino acid residues confer upon the ligand-binding domain (LBD) its ability for sharp discrimination in favor of its cognate steroid hormone.

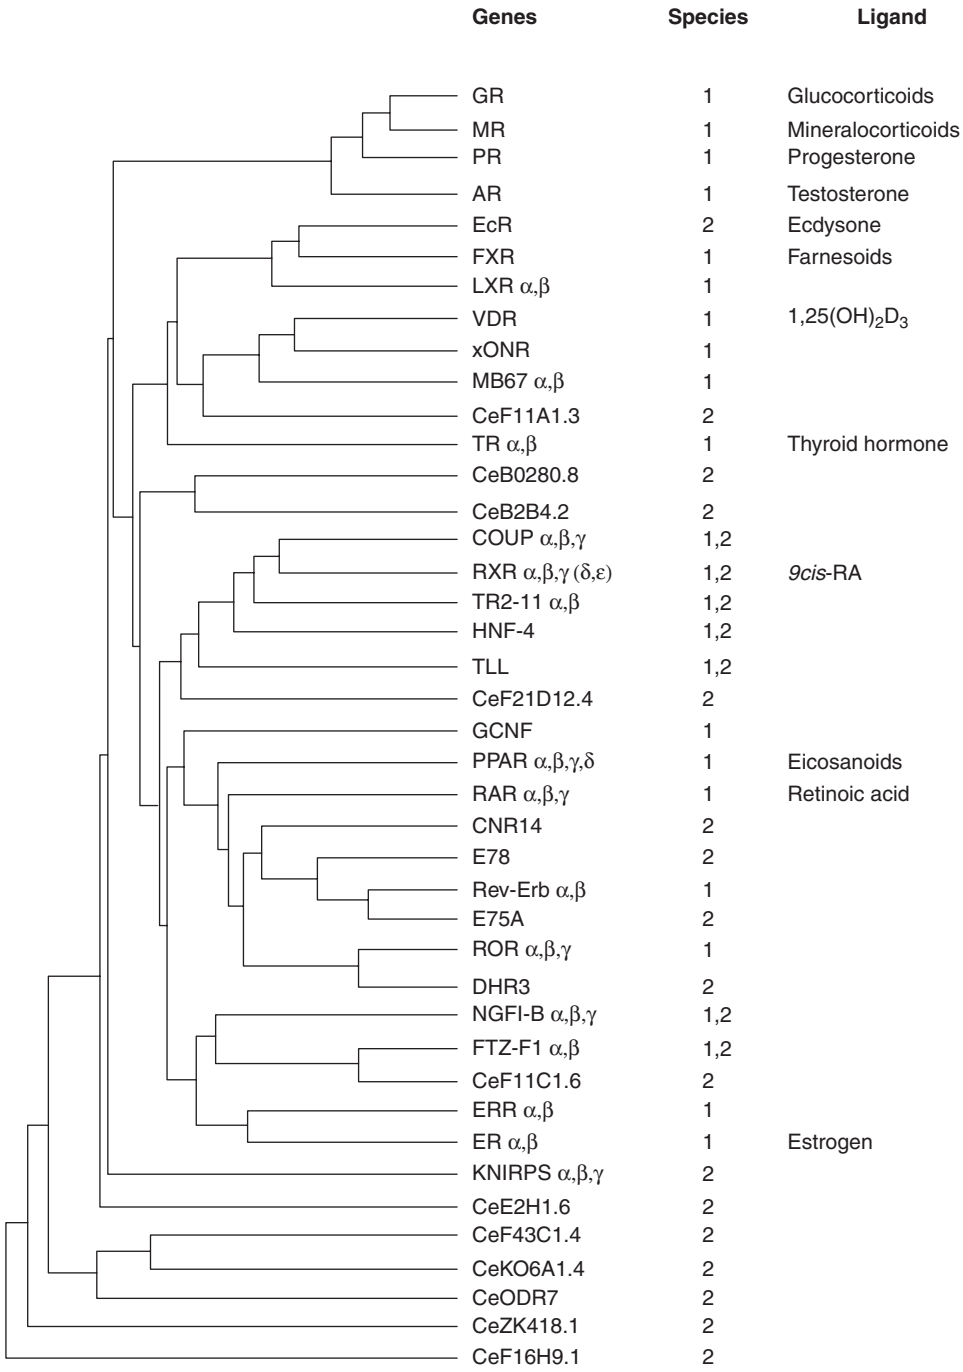

FIGURE 5 Nuclear receptor superfamily. The figure summarizes the hypothesized evolutionary relationships for the extended family of known nuclear receptors and related orphan receptors based on the extent of homology for the nucleotide sequence of the cDNA of the individual protein. This figure was modified from that presented by Mangelsdorf *et al.* (1995).

The A/B (transactivation) domain, which is quite small in the VDR (25 amino acids), is poorly conserved across the nuclear receptor superfamily and its function has not yet been clearly defined. An independent transcriptional activation function is located within the A/B region (Green *et al.*, 1988; Weatherman *et al.*, 1999) which is constitutive in receptor constructs lacking the ligand-binding domain (region E). The relative importance of the transcriptional activation by this domain depends on the receptor, the context of the target gene promoter, and the target cell-type (Weatherman *et al.*, 1999).

Domain D of the nuclear receptors is the hinge region between the DNA-binding domain and the ligand-binding domain. The hinge domain must be conformationally

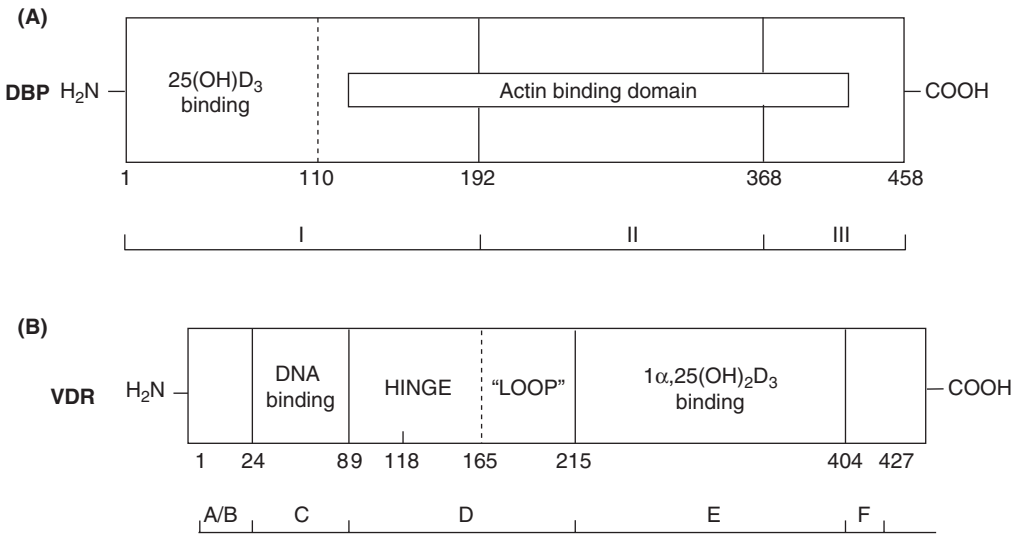

FIGURE 6 Schematic models of the vitamin D-binding protein (DBP) **(A)** and the vitamin D receptor (VDR) **(b)**. **(a)** The DBP consists of 458 amino acid residues and is divided into three domains (I, II, and III). The numbers below the DBP indicate the amino acid residue boundaries for the various domains. The domains I, II, and III have been postulated to have evolved from a progenitor that arose from the triple repeat of a 192-amino-acid sequence (Gibbs *et al*., 1987a). However, domain III is significantly truncated at the C terminus. The 25(OH)D_3 binding cleft is associated with the first six α-helices or residues 1–110 of domain I. The actin-binding property of DBP is associated with a portion of domains I and III that clamp the actin while it rests on domain II (Verboven et al., 2003). **(B)** The VDR comprises 427 amino acid residues that are divided into six domains (A–F). The numbers below the VDR indicate the amino acid residue boundaries for the various domains. The VDR belongs to a superfamily of nuclear receptors all of which have the same general A–F domain organization. The C domain, the most highly conserved, which contains the DNA-binding domain, defines the superfamily; it contains two zinc finger motifs. The E domain or ligand-binding domain (LBD) is less conserved and is responsible for binding 1α,25(OH)$_2$D$_3$ or its analogs and transcriptional activation. The A/B domain of the VDR is much smaller than other members of the superfamily. The portion of the intact VDR that was crystallized and subjected to x-ray crystallographic analysis included residues 118–427 but with deletion of the "loop" region of the hinge domain D, residues 165–215 (Rochel *et al*., 2000; Tocchini-Valentini *et al*., 2001, 2004).

flexible because it allows the DNA-binding domains and ligand-binding domain some flexibility for their proper interactions with DNA and ligand, respectively. The VDR hinge region contains 65 amino acids and has immunogenic properties.

Receptor Dimerization

The superfamily of nuclear receptors has been classified into subgroups based on their dimerization properties, DNA-binding site preferences, and cellular localization. Group I includes the receptors for glucocorticoids, estrogen, mineralocorticoids, progesterone, and androgens. These receptors bind as homodimers to palindromic DNA response elements. Group II includes the receptors for VDR, T3R, RAR, RXR, ecdysone, and several orphan receptors. These receptors bind as homodimers or heterodimers to direct repeats, palindromic, and inverted palindromic DNA response elements. Group III includes the orphan receptors for reverb A, ROR, SF-1, and NGFI-B. No ligands have yet been identified for these receptors and they bind DNA response elements as monomers or heterodimers.

As a class, the group II receptors bind nonsteroid conformationally flexible ligands (where vitamin D is classified as a secosteroid, rather than as a steroid). The group II receptors have more flexibility in the types of DNA response elements they can recognize and in the types of dimeric interactions they participate in than the group I receptors. All of the group II receptors can form heterodimers with RXR (Yu *et al.*, 1991; Kliewer *et al.*, 1992), and other heterodimeric interactions have also been reported (Carlberg, 1993). The VDR_{nuc} can bind to DNA response elements as homodimers and as heterodimers with RAR, RXR, and T3R (Schräder *et al.*, 1993; Carlberg, 1993). The ability to form heterodimers with other receptors allows for enhanced affinity for distinct DNA targets, generating a diverse range of physiological effects as shown in Figure 7.

The first zinc finger determines the sequence specificity of the DNA element. The second zinc finger is aligned by the binding of the first finger to the DNA and is involved in the protein–protein contacts responsible for the cooperativity of binding. The spacing of nucleotides between the two half-sites is important for the DNA-binding specificity because of the asymmetric dimer interface formed by the DNA-binding domains of a heterodimer pair. Ligand binding may function to modulate receptor dimerization. In fact, VDR_{nuc} has been shown to exist as a monomer in solution either in the presence or absence of ligand. When DNA is present, in the absence of ligand,

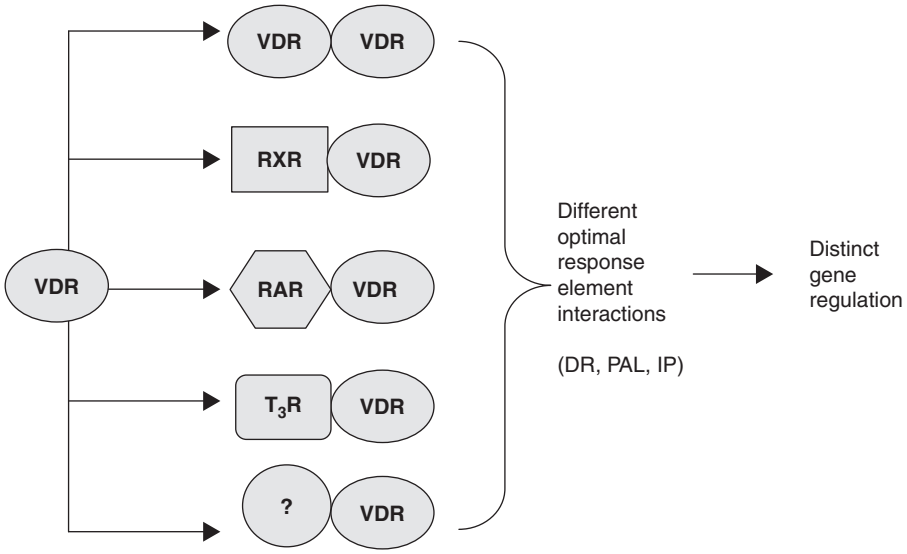

FIGURE 7 Schematic of possible dimeric interactions of VDR_{nuc} with other receptor members of the superfamily (see Fig. 5). VDR_{nuc} can bind to DNA as a homodimer or as a heterodimer with a variety of other group II receptors, i.e., RXR (retinoid X receptor), RAR (retinoid A receptor), T3R (thyroid receptor), and perhaps other receptors or factors not yet identified. Each dimer pair has an enhanced affinity for distinct DNA targets allowing a small family of receptors to generate a diverse range of physiological effects.

the VDR_{nuc} binds to the DNA both as monomers and homodimers. The addition of ligand stabilizes the bound monomer, which favors the formation of VDR_{nuc}-RXR (or other) heterodimers. The presence of the ligand decreases the rate of monomer-to-homodimer conversion. The presence of the RXR ligand, 9-*cis*-retinoic acid, has the opposite affect on heterodimerization formation; it enhances the binding of RXR homodimers to DR + 1 elements (Cheskis *et al.*, 1994). Ligand bound to VDR_{nuc} enhances the binding of RXR-VDR_{nuc} heterodimers to DR + 3 elements. There are also other possible protein–protein interactions that can involve VDR_{nuc} including association with AP-1, EE1A/TFIID, TFIIB, and coactivator proteins (Zhang *et al*,. 2003; MacDonald *et al.*, 2004). These protein–protein interactions can be determined by the concentration of the protein partner and/or by the concentration of ligand or both as well as by the nature of the DNA target site itself.

Hormone Response Elements

Each zinc finger appears to be encoded by separate exons as shown by the genomic structure of the ER (Ponglikitmongkol *et al.*, 1988), PR (Huckaby *et al.*, 1987), and the VDR_{nuc} (Freedman 1992). Most of the knowledge of how zinc fingers interact with DNA response elements has been gained by studies of GR and ER. The palindromic nature of GR and ER response elements suggested that these hormone receptors would bind to DNA as symmetrical dimers. Subsequent studies have confirmed that both GR and ER bind as homodimers to their response elements (Schwabe *et al.*, 1990; Picard *et al.*, 1990). The principal ER dimerization domain is in its ligand-binding domain (Kumar *et al.*, 1988). Both the ER and GR contain additional residues in the DNA-binding domain that are also important for dimerization. When the GR and ER DNA-binding domain are translated, they cannot dimerize alone but, in the presence of the correct palindromic response element, they bind to DNA as a dimer in a cooperative manner (Hard *et al.*, 1990). The five-amino-acid stretch between the first two coordinating cysteines of the second zinc finger is designated the "D" box (Umesono *et al.*, 1988) and mediates spacing requirements critical for cooperative dimer binding to palindromic HREs probably through a dimer interface involving these residues in each monomer (Jonat *et al.*, 1990; Schule *et al.*, 1990; Diamond *et al.*, 1990).

Using the GR and ER as models of receptor–DNA interactions, the binding of VDR_{nuc} to DNA has also been examined. Because VDR_{nuc} can bind to DNA as a heterodimer, often with RXR, VDR_{nuc} and other group II receptors seem to display more variety in how they bind to their response elements (Forman *et al.*, 1989; Jones, 1990; Freedman, 1992). The primary response element for the group II receptors is a direct repeat instead of an inverted palindrome; the protein–protein contacts are nonequivalent. There is an asymmetrical dimerization interface. Amino acid residues, designated the T/A box in the hinge region (domain D) just adjacent to the DNA-binding domain, are involved. The T/A-box residues form an α-helix making backbone and minor groove interactions that are involved in intramolecular packing against residues in the tip of the first zinc finger and determine the spacing requirements for the heterodimer pair.

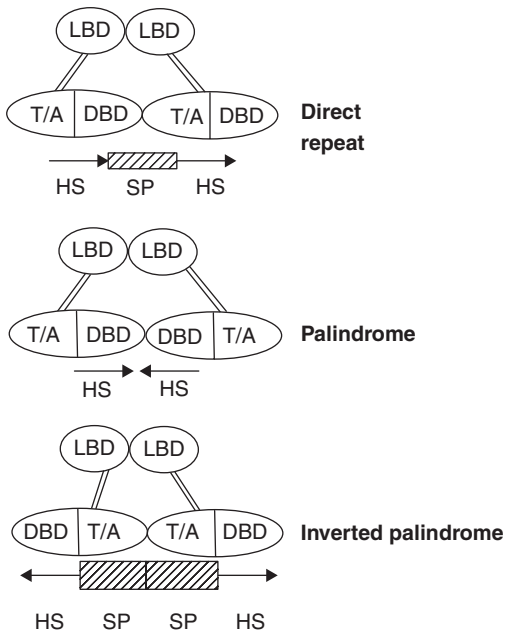

FIGURE 8 Mechanism of steroid nuclear receptor superfamily dimers binding to DNA response elements. Group II receptors can bind to three types of response elements: direct repeats, palindromes, and inverted palindromes. The spacing (SP), number of base pairs between half-sites (HS), is determined by steric constraints of the T/A box. The orientation of the DNA half-sites is shown with arrows. The flexible hinge domain allows the formation of the same dimerization interface between ligand-binding domains (LBD) regardless of the orientation of the DNA half-sites.

Eventually it is to be anticipated that a x-ray crystallographic structure of a full-length nuclear receptor bound to its cognate DNA promoter with all the associated transcription factors and coactivator proteins necessary for a functional transcriptional complex will be elucidated. There are two recent papers available that provide the first steps in this arena (Taatjes *et al.*, 2004a; Taatjes *et al.*, 2004b).

Table IV summarizes examples of hormone response elements for VDR_{nuc} and Figure 8 illustrates how receptor dimers can bind to the DNA hormone response elements. The natural response elements for the group II receptors appear to consist of a direct repeat of the hexamer AGGTCA. The spacing of the direct repeat determines the receptor preference: VDR_{nuc} prefers a three base-pair space, T3R prefers four base pairs, and RAR prefers five base pairs (Umesono *et al.*, 1991). The RXR, RAR, T3R, and VDR_{nuc} spacing optimum on a palindrome is no nucleotides between the half-sites. Spacing on inverted palindromes depends on the overhang of the dimeric partners: 11 for VDR_{nuc}-RAR; 7 to 8 is predicted for VDR_{nuc}-RXR, but actually is 9; RXR appears to use a slightly different contact interface when it heterodimerizes with VDR_{nuc} than with other receptors (Schräder *et al.*, 1994). Free rotation around the hinge (domain D) enables the same interaction of the ligand-binding domains of both receptors on each response element. The steric requirements of the T/A boxes gives the receptor its asymmetry when binding to direct repeats and inverted palindromes and determines the optimal spacing (see Fig. 8).

Ligand-Binding Domain

The ligand-binding domain of group II receptors as exemplified by the VDR has been further dissected (see Fig. 6). Subdomains ligand1 and ligand2 are nearly identical. Surprisingly, there is greater homology between the ligand-binding subdomains of RAR (α, β, γ) and T3R (α, β) than there is between RAR and RXR. The τi subdomain is highly conserved among all nuclear hormone receptors and is a putative transcriptional inactivating domain. Inactivation of this domain is relieved by ligand binding.

The dimerization domain consists of eight to nine heptad repeats of hydrophobic amino acids. The heptads contain leucine or other hydrophobic residues such as Ile, Val, Met, or Phe at positions 1 and 8 or charged amino acids with hydrophobic side chains such as Arg or Gln in position 5. In an ideal coiled-coil α-helix, these amino acids would form a hydrophobic surface along one face of the helix that would act as a dimerization interface R (Fawell *et al.*, 1990). Deletion/mutation analysis of the VDR_{nuc} ligand-binding domain has shown that Asp-258 and Ile-248 are involved in heterodimerization with RXR. Leu-254 and -262 are critical for heterodimerization. A mutant that is truncated at amino acid 190 becomes constituitively transcriptionally active.

Other amino acids identified as being important for heterodimerization are 325–332, 383–390, and 244–263. Residues 403–427 are particularly important for ligand side-chain binding [$1\alpha,25(OH)_2D_3$] (Nakajima *et al.*, 1994).

Figure 9 presents a schematic model of the VDR_{nuc} interaction with its heterodimer partner and their subsequent interaction with the promoter of genes selected for modulation, as well with other proteins (coactivators, TATA-binding protein, etc.) so as to generate a competent transcriptional complex. Over the past decade there has been a continuing evolution of understanding and complexity concerning the details of what constitutes a "competent transcriptional complex." Additional viewpoints and information can be found in several recent articles (Weatherman *et al.*, 1999; Glass *et al.*, 2000; Pathrose *et al.*, 2002; Pike *et al.*, 2005; Kim *et al.*, 2005) .

VDR Receptor Structure

A dramatic advance in understanding the three-dimensional structure of the LBD of steroid receptors occurred from 1995 to 1999 when the x-ray crystallographic structure determination of the LBD of five hormone nuclear receptors was achieved. These include the LBDs of the thyroid hormone (TR), retinoic acid (RAR), estrogen (ER), progesterone (PR), and the PPARγ [see the review by Weatherman *et al.* (1999)]. Also an x-ray structure is available for the LBD of the unoccupied 9-*cis*-retinoic acid receptor RXR (Bourguet *et al.*, 1995). Further, ER LBD x-ray structures are known for a ligand (raloxifene) that can act as an antagonist of the transcriptional activation function (Brzozowski *et al.*, 1997; Shiau *et al.*, 1998).

The crystal structure of an engineered version of the ligand-binding domain of the nuclear receptor for vitamin D, bound to $1\alpha,25(OH)_2D_3$, was determined in 2000 at a 1.8-Å resolution (Rochel *et al.*, 2000). A follow-up x-ray crystallographic report compared the VDR LBD and bound ligand for $1\alpha,25(OH)_2D_3$ with that of four superagonist analogs of $1\alpha,25(OH)_2D_3$ (Tocchini-Valentini *et al.*, 2001). Other x-ray structures of the VDR, which are all very similar to the original report, have appeared in the following: Tocchini-Valentini *et al.* (2001), Shaffer *et al.* (2002), Sicinska *et al.* (2004), Ciesielski *et al.* (2004), Vanhooke *et al.* (2004), and Tocchini-Valentini *et al.* (2004).

Figure 10 compares the three-dimensional structure of the vitamin D receptor (VDR) with bound $1\alpha,25(OH)_2D_3$ (see Fig. 10A and B) with the three-dimensional structure of the vitamin D-binding protein (DBP) with bound $25(OH)D_3$ (see Fig 10C and D).

The x-ray structure of the LBD of the human VDR_{nuc} spans amino acid residues 143–427 (COOH terminus), but without residues 165–215, which were in an "undefined" loop in the hinge region of domain D (see Fig. 10A

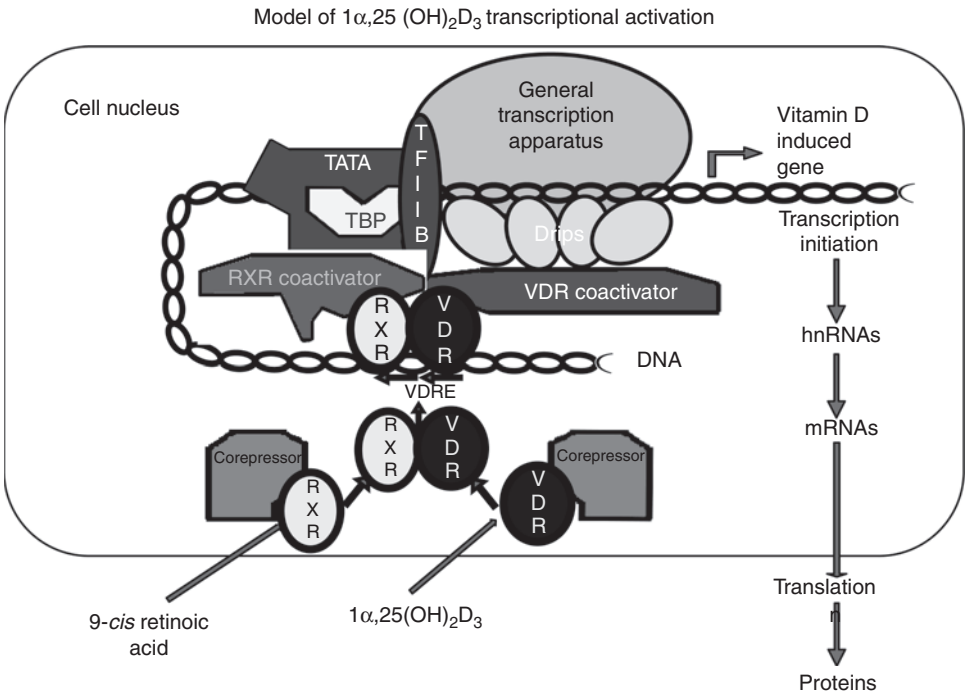

FIGURE 9 Model of $1\alpha,25(OH)$ and VDR_{nuc} activation of transcription. The VDR, after binding its cognate ligand $1\alpha,25(OH)_2D_3$, forms a heterodimer with RXR. This heterodimer complex then interacts with the appropriate VDRE on the promoter of genes (in specific target cells), which are destined to be up- or downregulated. The heterodimer–DNA complex then recruits necessary coactivator proteins, TATA, TBP, and TFIIB, and other proteins to generate a competent transcriptional complex capable of modulating mRNA production.

and B). The removal of the flexible insertion domain in the VDR LBD produced a more soluble protein that was more amenable to crystallization. The VDR LBD protein structure is very similar to the LBD of the five other x-ray crystallographic nuclear receptor structures that had been determined before VDR in 2000 (Weatherman *et al.*, 1999). All nuclear steroid hormone receptors consist of a three-stranded β-sheet and 12 α-helices that are arranged to create a three-layer sandwich that completely encompasses the ligand [1α,25(OH)$_2$D$_3$ in the case of the VDR] in a hydrophobic core (see Fig. 10). The x-ray structures of all six nuclear hormone receptors are so similar that their ribbon diagrams are virtually superimposable, indicating a remarkable spatial conservation of the secondary and tertiary structures (Weatherman *et al.*, 1999). In addition, the AF-2 domain of the C-terminal helix 12 (domain F; residues 404–427), contributes to the hormone-binding pocket .

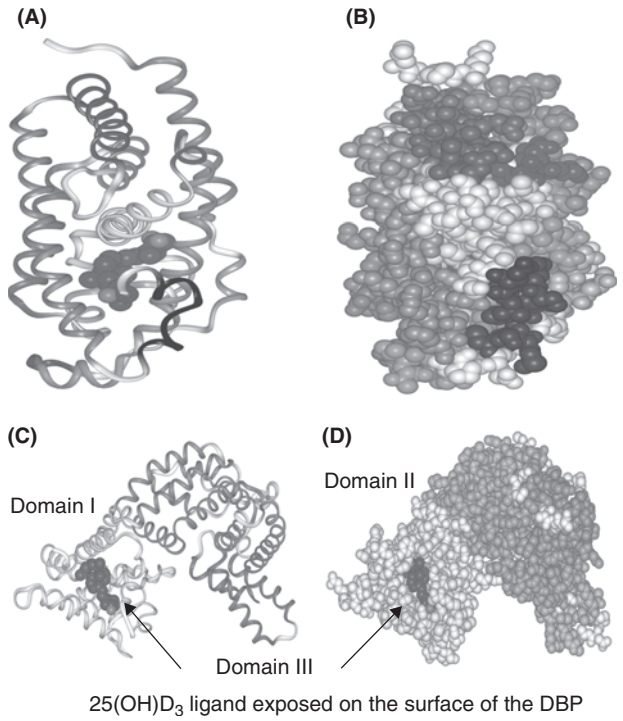

FIGURE 10 Comparison of the three dimensional structure of the vitamin D receptor (VDR) for the steroid hormone, 1α,25(OH)$_2$D$_3$ (**A** and **B**) with the three-dimensional structure of the vitamin D-binding protein (DBP) for 25(OH)D$_3$ (**C** and **D**). (**A**) Three-dimensional ribbon structure of the VDR ligand-binding domain for amino acid residues 118–425 (Δ165–215) as determined via x-ray crystallography (Rochel *et al*., 2000). Also the presence of the bound ligand, 1α,25(OH)$_2$D$_3$, is shown; its structure and shape are presented in more detail in Fig 2F. The white regions represent loops and other flexible regions of the molecule. The ligand, 1α,25(OH)$_2$D$_3$, has its atoms indicated. (**B**) Illustration of the Corey–Pauling–Koltun (CPK) space-filling model of the VDR LBD. The position of helix-12 in the "closed" position effectively sequesters the ligand from the external environment of the protein, indicated by the absence of visible carbon and oxygen atoms from 1α,25(OH)$_2$D$_3$ in this view. (**C**) Three-dimensional structure of DBP for residues 1–458 as determined via x-ray crystallography (Verboven *et al*., 2002). Illustration of the three domains (I, II, and III,) of the DBP in a ribbon structure representation. The atoms of the ligand, 25(OH)D$_3$ are black. The x-ray structure of DBP was determined separately with two different ligands. These ligands were 25(OH)D$_3$ and 22-(*m*-hydroxyphenyl)-23,24,25,26,27-pentanor vitamin D$_3$ (analog JY); both x-ray structures contained the same conformer shape of the bound ligands. The structure and shape of 25(OH)D$_3$ is presented in more detail in Figure 8C. (**D**) The ligand-binding domain of the DBP is a crevice located on the surface of domain I. The figure illustrates the CPK space-filling structure of DBP, with white regions indicating flexible regions of the molecule. Virtually the entire top face of the 25(OH) is exposed to the external environment.

Vitamin D-Binding Protein (DBP)

The vitamin D-binding protein (DBP), also historically referred to as group-specific component of serum or Gc-globulin, was initially identified by its polymorphic migration pattern on serum electrophoresis. Although its function was quite unknown, its polymorphic properties allowed DBP (Gc) to play a significant role in human population genetics. In 1975 human Gc protein was found to specifically bind radioactive vitamin D$_3$ and 25(OH)-vitamin D$_3$ thus identifying one of its biological functions (Daiger *et al.*, 1975, 1977; Constans *et al.*, 1983).

The vitamin D-binding protein (DBP) is the serum protein that serves as the transporter and reservoir for the principal vitamin D metabolites throughout the vitamin D endocrine system.(Bouillon *et al.*, 1981a; Haddad, 1995). These include 25(OH)D$_3$, the major circulating metabolite (K_D ~ 6 × 10^{-9} M) (Haddad *et al.*, 1976; Song *et al.*, 1999) and the steroid hormone 1α,25(OH)2D$_3$ (K_D ~ 6 × 10^{-8} M). DBP is similar in function to the corticosteroid-binding globulin (CBG), which carries glucocorticoids, and the steroid hormone-binding globulin (SHBG), which transports estrogens or androgen.

DBP is a slightly acidic (pI = 5.2) monomeric glycoprotein of 53 kDa that is synthesized and secreted by the liver as a major plasma constituent. DBP can be up to 5% glycosolated and is known to be one of the most polymorphic proteins, with three common allelic variants and more than 124 rare variants known (Song *et al.*, 1999). DBP's plasma concentration (4–8 μM) is approximately 20-fold higher than that of the total circulating vitamin D metabolites (~10^{-7} M). DBP binds 88% of the total serum 25(OH)D$_3$ and 85% of serum 1,25(OH)$_2$D$_3$, yet only 5% of the total circulating DBP actually carries vitamin D metabolites (Bouillon *et al.*, 1977). The concentration of the "free" hormone may be important in determining the biological activity of the 1α,25(OH)$_2$D$_3$ steroid hormone (Bouillon *et al.*, 1981b; Bikle *et al.*, 1985; Greenberg *et al.*, 1986). In addition to the vitamin D metabolite-binding properties of DBP, the protein has been shown to function as a high-affinity plasma actin–monomer scavenger functioning in concert with the protein gelsolin to prevent arterial congestion (Haddad *et al.*, 1990). There are stoichiometric, 1:1, molar

amounts of DBP and actin in their high-affinity heterodimer; the actin/DBP K_D was determined in 2002 (Swamy *et al.*, 2002; Otterbein *et al.*, 2002). This information is not considered in detail in this presentation.

DBP has been proposed to be involved in the transport of fatty acids (Bouillon *et al.*, 1992); the DBP K_D for binding fatty acids is ~10^{-6} M. Also, DBP has been implicated in playing a role in complement C5a-mediated chemotaxis (DiMartino *et al.*, 2001)and has been found to be associated with immunoglobulin surface receptors on lymphocytes, monocytes, and neutrophils (DiMartino *et al.*, 1999).

DBP (~53 kDa) is a member of the albumin multigene family of proteins that also contains albumin (human serum albumin or HSA), α-fetoprotein (AFP), and afamin (AFM) (Gibbs *et al.*, 1987a, 1987b; Nishio *et al.*, 1996). AFP (~70 kDa) has an analogous function to albumin in the fetus and is measured clinically to diagnose or monitor fetal distress or fetal abnormalities, some liver disorders, and some cancers; however, AFP has no known function in adults. Albumin is the major protein component in human plasma and binds a number of relatively water-insoluble endogenous compounds, including fatty acids, bilirubin, and bile acids. DBP originally was referred to as the group-specific component (Gc), which was initially studied electrophoretically as a polymorphic marker in the α-globulin region of human serum. See the reviews in Haddad (1995).

The x-ray crystal structure of DBP has been determined; see Figure 10C and D (Verboven *et al.*, 2002, 2003).

The known multifunctionality of DBP (both vitamin D metabolite and actin binding) separates it from the other members of its family and other steroid transport proteins like retinal-binding protein (RBP) and thyroid-binding globulin (TBG). However, two proteins that bind and transport sterols, sex hormone-binding globulin (SHBG) and uteroglobulin (UG), have been implicated in physiological functions other than steroid transport. SHBG, which binds sex steroids in blood, triggers cAMP-dependent signaling through binding to specific cell surface receptors in prostate (Nakhla *et al.*, 1994) and breast cancer cells (Porto *et al.*, 1995).

The three-domain schematic plan of DBP is shown in Figure 6B where it is compared with the domain structure of the VDR (see Fig. 6A). Domains I, II, and III have been postulated to have evolved from a progenitor that arose from the triple repeat of a 192-amino-acid sequence (Gibbs *et al.*, 1987a); however, domain III is significantly truncated at the C terminus. The position of the vitamin D metabolite and actin-binding domains are specified in domains I and portions of domains I, II, and III, respectively.

The x-ray crystallographic structures of the human DBP with a bound ligand of 25(OH)-D_3 has been recently determined (Verboven *et al.*, 2002) (see Fig. 10C and D). The N-terminal region of DBP, helix 1 to helix 6 of domain I, forms the ligand-binding domain (LBD) where 25(OH)D_3 and other vitamin D metabolites bind. When bound to DBP, vitamin D sterols, including 1α,25$(OH)_2D_3$, remain highly exposed to the external environment, which is not the case for internally sequestered ligands bound to the other plasma transport proteins, e.g., steroid hormone-binding globulin (SHBG), retinol-binding protein (RBP), uteroglobulin (UG), and thyroid-binding globulin (TBG) and as well as the VDR (see Fig. 10A and B). Virtually the whole α-face, top view, of the 25(OH)D_3 molecule is exposed to the external environment when bound to the DBP, but the protein's affinity for 25(OH)D_3 still remains high (~6×10^{-9} M) presumably because of the relative strength of the protein–ligand interactions on the α-face of 25(OH)D_3.

Table V summarizes the important similarities and differences in the structure of the two key proteins of the vitamin D endocrine system, the VDR LBD and DBP. Even though there is no amino acid or structural similarity between the two proteins, each has independently evolved to create a unique but highly effective ligand-binding domain that can tightly bind its optimal vitamin D secosteroid ligand: for DBP, 25(OH)D_3, $K_D \sim 6 \times 10^{-9}$ M; and for the VDR, 1α,25$(OH)_2D_3$, $K_D \sim 1 \times 10^{-9}$ M. However, the location of the two ligand-binding domains is vastly different for the two proteins; for the VDR the ligand is sequestered inside the protein (see Fig. 10A and B), whereas for DBP the ligand is held in a surface crevice (see Fig. 10C and D) such that one face of the ligand is exposed to the solvent environment. Thus, there is a much greater freedom of ligand structure tolerated by the DBP ligand compared with the VDR; compare optimal DBP ligands with VDR ligand.

Genetics and the Vitamin D Endocrine System

Mutations in the VDR_{nuc}

Table VI summarizes the 6 natural and 26 experimental mutations in the LBD of the VDR_{nuc} that have identified amino acids critical for normal LBD function. There are also at least 14 other natural mutations in the zinc finger DNA-binding domain C of the VDR_{nuc} [data not presented but reviewed in Haussler *et al.* (1997b)].

Hereditary vitamin D-resistant rickets (HVDRR), also known as vitamin D-dependent rickets, type II (VDDRII) is a rare genetic disease. Genetic analysis has shown that it is autosomal recessive. Less than 30 kindreds have been reported. The combination of symptoms, i.e., defective bone mineralization, decreased intestinal calcium absorption, hypocalcemia, and increased serum levels of 1α,25$(OH)_2D_3$, suggest end-organ resistance to the action of 1α,25$(OH)_2D_3$. Patients do not respond to doses of vitamin D, 25(OH)D_3, or 1α,25$(OH)_2D_3$.

The unresponsiveness to 1α,25$(OH)_2D_3$ associated with the HVDRR has been demonstrated to arise from

TABLE V Comparison of DBP and VDR Protein Crystal Structures and the Ligands for Genomic and Rapid Responses and for DBP

Property	DBP	VDR_{nuc}	VDR_{mem}
Molecular mass (kDa)	58	51	51
Number of amino acid residues of protein	458	427	427
Number of of residues in x-ray structure	458	158	NA
Location of LBD on the protein	Surface cleft	Interior pocket	Interior pocket
Ligand–protein contacts	Unique[a]	Unique[a]	Unique
Ligand A-ring conformation	α-chair	β-chair	β-chair
1α-OH	–	Equatorial	Equatorial or axial
3β-OH	Equatorial	Axial	Axial or equatorial
C5–C6–C7–C8 torsion angle	+149°	+211°	
General ligand shape	Twisted 6-s-*trans*	Bowl-shaped 6-s-*trans* with A-ring 30° above the plane of the CD ring	Planar 6-s-*cis* for $1\alpha,25(OH)_2$-lumisterol
A-ring position	31° below C/D ring	30° above C/D ring	Planar
C17–C20–C22–C23 torsion angle	−70°	−156°	Not defined
Side-chain orientation	"Curled down"	Extended	Probably extended
Distance from C-19 to oxygen on C-25	3.8Å	6.9Å	
Overall ligand shape	Hook	Bowl	Relatively planar
Optimal ligand(s)	$25(OH)D_3$	6-s-*trans*-$1\alpha,25(OH)_2D_3$	6-s-*cis*-$1\alpha,25(OH)_2D_3$ $1\alpha,25(OH)_2$-lumisterol
K_D for $1\alpha,25(OH)_2D_3$	5×10^{-7} M	$1–5 \times 10^{-9}$ M	$1–5 \times 10^{-9}$ M

defects in the gene coding for the VDR_{nuc}. Two types of abnormalities have been defined by binding studies: receptor-negative and receptor-positive phenotypes (see Table VI). The nucleotide sequence change identified in the receptor-negative phenotype is involved a mutation that introduces a premature stop codon in the message. The resulting truncated protein is not able to bind ligand. The receptor-positive phenotype arises from one of several missense mutations localized within the zinc finger domains of the DNA-binding domain. Several of these mutant receptors have been demonstrated to be defective in their ability to bind to DNA-cellulose and to be unable to mediate $1\alpha,25(OH)_2D_3$-stimulated gene transcription *in vitro* (Sone *et al.*, 1989; Ritchie *et al.*, 1989; Kristjansson *et al.*, 1993; Rut *et al.*, 1994).

Knockout of the VDR_{nuc}

Two different groups independently (Yoshizawa *et al.*, 1997; Li *et al.*, 1997) engineered an animal model of hereditary vitamin D-resistant rickets (HVDRR) by targeted disruption of DNA encoding the first and the second zinc finger of the DNA-binding domain of the VDR, respectively. The resultant animals were phenotypically normal at birth. No defects in development and growth were observed before weaning, irrespective of reduced

expression of vitamin D target genes. After weaning (3 weeks after birth), however, the VDR null mutant mice showed marked growth retardation. No overt abnormalities, however, were found in the heterozygotes even at 6 months. Unexpectedly, all of the VDR null mutant mice developed alopecia (absence of hair) and had few whiskers by 7 weeks. Further, the serum levels of calcium and phosphate were reduced at 4 weeks, with markedly elevated serum alkaline phosphatase activity present in the null mutant mice, whereas in older VDR-deficient mice, these abnormalities became more prominent. These observations in the VDR null mutant mice are similar to those in a human vitamin D-dependant rickets type II disease, in which mutations in the VDR gene have been identified in several families, although this disease is not lethal.

In the VDR null mutant mice at 3 weeks, the serum levels of $1\alpha,25(OH)_2D_3$, $24R,25(OH)_2D_3$, and $25(OH)D_3$ were the same as those in the heterozygous and wild-type mice. However, a marked 10-fold increase in serum $1\alpha,25(OH)_2D_3$ and a clear reduction (to almost undetectable levels) in serum $24R,25(OH)_2D_3$ developed in the VDR null mutant mice at 4 weeks and persisted at 7 weeks. Immunoreactive PTH levels were also raised sharply after weaning and the size of the parathyroid glands in the 70-day-old VDR-ablated mice was increased more than 10-fold. These observations establish that the VDR is essential for regulation of the 1α- and 24R-hydroxylases by $1\alpha,25(OH)_2D_3$ after weaning, again supporting the idea that VDR plays a critical role only after weaning.

Severe bone malformation was induced by the inactivation of the VDR after weaning. Radiographic analysis of VDR null mutant mice at 7 weeks revealed growth retardation with loss of bone density. A 40% reduction in bone mineral density was observed in the homozygote mutant mice. In gross appearance and on x-ray analysis of tibia and fibula, typical features of advanced rickets were

observed, including widening of epiphyseal growth plates, thinning of the cortex, fraying, cupping, and widening of the metaphysis. In marked contrast, in the VDR-ablated mice in whom normal mineral ion homeostasis had been preserved by feeding of a high-calcium, high-lactose diet, none of these bone parameters were significantly different from those in wild-type litter mates raised under identical conditions. In particular, the morphology and width of the growth plate were indistinguishable from those in wild-type controls, demonstrating that a calcium/phosphorus/lactose-enriched diet started at 16 days of age in the VDR null mice permits the development of both normal morphology in the growth cartilage and adjacent metaphysis and normal biomechanical competence of cortical bone. Thus, the remarkable conclusion is that there is no clear contribution of the VDR to normal bone development, skeletal growth, maturation, and remodeling. The major calcium homeostatic contribution of the VDR$_{nuc}$ is its role in intestinal calcium absorption.

The male and female VDR null mutant mice were infertile. Uterine hypoplasia and impaired folliculogenesis were observed in the female, and decreased sperm count and motility with histological abnormality of the testis were observed in the male. The aromatase activities in these mice were low in the ovary, testis, and epididymis. These results indicated that vitamin D is essential for full gonadal function in both sexes (Kinuta *et al.*, 2000).

Knockout of the 25(OH)D$_3$-24-hydroxylase

24R,25(OH)$_2$D$_3$ is the second major dihydroxylated metabolite of vitamin D$_3$ that is found in significant concentrations in the serum of humans (Nguyen *et al.*, 1979; Jongen *et al.*, 1989; Castro-Errecaborde *et al.*, 1991), rats (Jarnagin *et al.*, 1985), and chicks (Goff *et al.*, 1995). Although the production of 24R,25(OH)$_2$D$_3$ by the kidney is tightly regulated (Henry *et al.*, 1984), the biological importance of this compound is still the subject of uncertainty and question (Norman *et al.* 1982a, 1982b). Although several possible biological roles and sites of action have been suggested for 24R,25(OH)$_2$D$_3$, including regulation of parathyroid hormone release from the parathyroid gland (Canterbury *et al.*, 1978; Norman *et al.,* 1982a), most studies concerning this vitamin D metabolite have focused on its possible actions on bone biology (Nakamura *et al.*, 1992; Norman *et al*., 1993a; Seo *et al.*, 1997a). The possible existence of a nuclear or cytosolic binding protein for 24R,25(OH)$_2$D$_3$ was reported in the chick parathyroid gland (Merke *et al.*, 1981), the long bone of rat epiphysis (Corvol *et al.*, 1980), and chick tibial fracture-healing callus (Seo *et al.*, 1996a). However, there has been no general confirmation of these early findings. Also, several more recent reports have described specific actions and accumulation of 24R,25(OH)$_2$D$_3$ in cartilage (Corvol *et al.*, 1980; Seo *et al.*, 1996b), and the bone fracture-healing callus tissue (Lidor *et al.*, 1987; Seo *et al.* 1997a, 1997b).

A strain of mice deficient for the 25(OH)D-24-hydroxylase enzyme have been generated (St.Arnaud *et al.*, 1997) through homologous recombination in embryonic stem cells in order to address the physiological functions of 24R,25(OH)$_2$D$_3$. The targeted mutation effectively deleted the heme-binding domain of the cytochrome P450 enzyme, ensuring that the mutated allele could not produce a functional protein. The analysis of the phenotype of the knockout animals revealed fascinating and previously unrecognized roles for 24R,25(OH)$_2$D$_3$. About half of the mutant homozygote mice born from heterozygote females died before weaning. Bone development of those survivors was abnormal in homozygous mutants born of homozygous females. Histological analyses of the bones from these mice revealed an accumulation of unmineralized matrix at sites of intramembranous ossification, in particular, the calvaria and exocortical surface of long bones. However, the growth plates from these mutant animals appeared normal, suggesting that 24R,25(OH)$_2$D$_3$ is not a major regulator of chondrocyte maturation *in vivo*.

EVIDENCE FOR A MEMBRANE RECEPTOR (VDR$_{MEM}$) FOR 1α,25(OH)$_2$D$_3$

The impact of 1α,25(OH)$_2$D$_3$-mediated RR on the VDR from 1994 to the present have been summarized in Table II. The concept of the existence of a membrane receptor for 1α,25(OH)$_2$D$_3$ has its origins in the study of the process of 1α,25(OH)$_2$D$_3$-mediated response of transcaltachia, or the rapid hormonal stimulation of intestinal Ca^{2+} absorption in the perfused chick intestine (Nemere *et al.*, 1984b) The most potent agonist is the natural hormone 1α,25(OH)$_2$D$_3$, which can stimulate the transport of calcium across the intestine within 4–5 minutes of its injection in the celiac artery that perfuses the duodenum (Nemere *et al.*, 1984b).

Some have questioned what is the true physiological relevance of 1α,25(OH)$_2$D$_3$-mediated rapid response because no phenotype or disease has yet been described. One hypothesis advanced by Gniadecki (1998b) is that 1α,25(OH)$_2$D$_3$-initiated rapid responses generate signal transduction pathways, which has the end result of altering gene transcription. Certainly the ability of the VDR$_{nuc}$ operating in the nucleus to activate/suppress gene transcription of appropriate genes is well established. However the process of genomic signaling lacks two important characteristics. (1) Rapidity—It can take several hours to achieve the transition to a new transcriptional steady state, which requires the integrated change at the transcription level of a gene followed by translational generation of the product protein in adequate amounts and, if necessary, post-translational modifications of the protein. When the production of multiple proteins is required for the desired

biological response, the time may be increased even further. (2) Modulation—The fine tuning and expansion of the initiating signal to change gene transcription. Although the primary stimulus for a biological response is principally dependent upon the number of activated liganded VDR_{nuc} heterodimer + coactivator complex bound to the promoter, it may be possible for other signal transduction pathways (MAP kinase activation) to modulate the final outcome. One report clearly demonstrates, via gene array analysis, how activation of MAP kinase altered the expression of 383 genes (Roberts *et al.*, 2000).

The current view of this laboratory is that transcalcitachia and many other $1\alpha,25(OH)_2D_3$-mediated RR are initiated by a membrane-localized receptor that binds $1\alpha,25(OH)_2D_3$ (Huhtakangas *et al.*, 2004) Recent work in our laboratory has focused on isolation of the intestinal, kidney, or lung membrane fractions which contain caveolae. Caveolae are flask-shaped membrane invaginations that are enriched in sphingolipids and cholesterol that are commonly found in both caveolae and/or lipid rafts (Razani *et al.*, 2002; Lucius *et al.*, 2003; Liscovitch *et al.*, 2004). The caveolae-enriched membrane fraction (CMF) is isolated from chick or rat intestine, kidney, or lung tissue by Percoll buoyant density centrifugation. We find that under both *in vivo* and *in vitro* conditions there is a saturable binding of high-specific-activity tritiated $1\alpha,25(OH)_2D_3$ in the CMF. This binding activity is steroid specific for 1α-hydroxylated analogs, and for $1\alpha,25(OH)_2D_3$, it has a K_D equal to 1.4 nM (see Table V) which is identical to the nuclear VDR K_D for $1\alpha,25(OH)_2D_3$ (Huhtakangas *et al.*, 2004) . Further, by confocal microscopy we showed that green fluorescent labeled antibodies to the classical nuclear VDR colocalized with red fluorescent labeled antibodies to caveolin-1 in caveolae present in the plasma membrane of ROS-17.2,8 osteoblast cells (Huhtakangas *et al.* 2004). Both my laboratory (Huhtakangas *et al.*, 2004) and that of Lieberherr and Garabedian (Nguyen *et al.*, 2004) have separately concluded that the rapid response effects of $1\alpha,25(OH)_2D_3$ require a functional VDR. We found that in VDR knockout mice (VDR KO) that $1\alpha,25(OH)_2D_3$ was unable to stimulate the opening of voltage-gated Ca^{2+} and Cl^- channels (Huhtakangas *et al.*, 2004; Bula *et al.*, 2005) and that there was a loss of 70–90% in the ability of $[^3H]$-$1\alpha,25(OH)_2D_3$ to bind to isolated caveolae membrane fractions obtained from VDR KO intestine, lung, and kidney tissues (Huhtakangas *et al.*, 2004). The residual binding of $[^3H]$-$1\alpha,25(OH)_2D_3$ present in VDR KO tissues was found to be attributable to the presence of a truncated form of the VDR present in the strain of VDR KO mice employed in our studies (Bula *et al.*, 2005). Lieberherr and Garabedian found that, in fibroblasts obtained from a patient with the genetic disease of vitamin D-resistant rickets (VDRR), which results from a single-point mutation in the VDR (Lys45Glu), there was a loss of $1\alpha,25(OH)_2D_3$ RR (Nguyen *et al.*, 2004).

Thus, this laboratory's view is that the classical VDR normally associated with the cell nucleus and gene transcription can also be resident near to or associated with caveolae present in the plasma membrane. It has also been reported that the estrogen receptor (ER) (Pedram *et al.*, 2006a, 2006b) and androgen receptor (AR) are associated with caveolae. For the nuclear estrogen, androgen, and progesterone receptors, recent evidence implicates that palmitoylation of nuclear receptor allows them to associate and become attached the plasma membrane caveolae (Guo *et al.*, 2006).

It is apparent that for the VDR there is a perceived problem, because a 6-s-*trans* shape of $1\alpha,25(OH)_2D_3$ is obligatory for genomic responses, whereas a 6-s-*cis* shape is required for RR. This then poses the conundrum as to how a receptor with one ligand-binding domain (LBD) can bind ligands of quite different shapes to generate two quite different biological outcomes? Yet, the x-ray structure of the VDR only revealed one ligand-binding domain, that which bound the 6-s-*trans* shape (see Fig. 10A).

One possible solution to the conundrum was obtained from molecular modeling of the VDR (Mizwicki *et al.*, 2004). Using the atomic coordinates of the x-ray structures of the VDR and computer modeling, we have been able to identify the presence of a putative alternative LBD in the VDR that can accommodate via computer "docking" either the appropriate natural hormone or analogs that are known to be agonists only for RR (see Fig. 11A) (Mizwicki *et al.*, 2004). Figure 11A illustrates for the VDR the classical nuclear ligand pocket (red) and the proposed alternative ligand pocket (blue). Each ligand pocket is envisioned to have separate portals. The entrance to the nuclear pocket depends on helix-12 being in an "open" configuration so that the hormone/ligand can enter into the LBD pocket and gain access to integral H-bonding residues, thereby fully occupying the genomic pocket. Next, helix-12 moves to "close" the portal. One surprising discovery is that the alternative pocket and the genomic pocket partially overlap. Each of these pockets uses the same hydrogen-bonding partners of the VDR to stabilize the A rings of the bound ligands; however, the remaining interactions of the C/D ring and side chain of the ligand in the genomic or alternative pockets are entirely unique.

My laboratory believes that the resolution of the conundrum stated earlier is to propose a receptor ensemble model that can describe how a classic steroid (nuclear) receptor could accommodate differently shaped ligands so as to result in the initiation of either rapid or genomic responses (Fig. 11B). This model posits that unbound receptor macromolecules exist in the cytoplasm as multiple, equilibrating receptor conformations that follow the laws associated with standard statistical distributions (Mizwicki *et al.*, 2004). Thus, a steroid hormone would sample the existing population of receptor conformations available and form a receptor–hormone complex with the receptor species that formed the best complementary fit between the two molecules; this

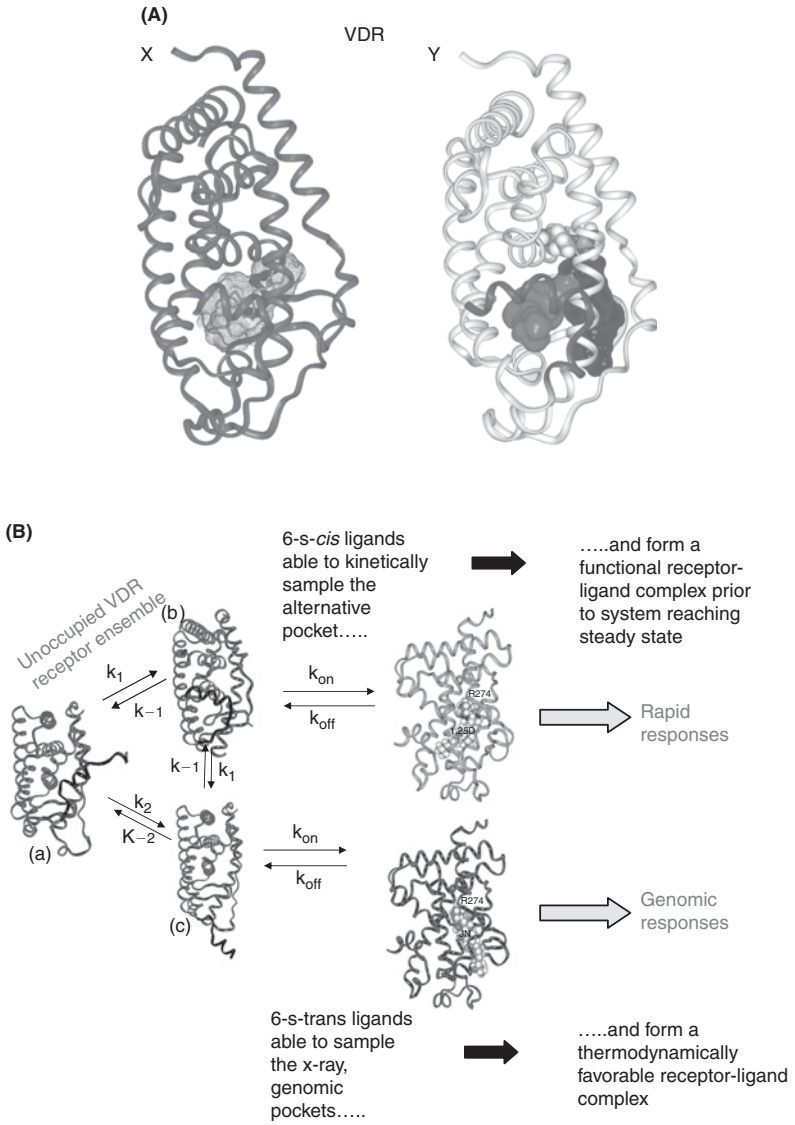

FIGURE 11 Structural details of the VDR that support a conformational ensemble model. **(A)** Details of the ligand-binding domain(s) in the ribbon structures of the nuclear VDR. (*X*) Differences in the volume and shape of the interior of the VDR ligand-binding domain (light blue) with the structure of the $1\alpha,25(OH)_2D_3$ shown in wire frame as revealed by x-ray crystallography of the protein + ligand. (*Y*) Illustration for the VDR of the location of the classic genomic pocket (red: $1,25(OH)_2$-vitamin D_3; a genomic agonist) and a putative alternative pocket (blue: $1,25(OH)_2$-lumisterol; a nongenomic 6-s-*cis*-locked agonist) as studied by molecular modeling; helix-12 (H12) is brown and shown in the closed conformation. The proposed alternative pocket portal lies between the C terminus of H1 and N terminus of H3. An intriguing aspect of the two ligand binding pocket model, is that the A ring of ligands bound to either the genomic pocket or alternative pocket use the same hydrogen-bonding partners (R274, S237, S278) to stabilize their 1α- and 3β-hydroxyls; The conserved helix 5 R274 is shown in CPK; thus the VDR can not bind two ligands simultaneously. Details of the modeling are provided in (Norman *et al*., 2004; Mizwicki *et al*., 2004). **(B)** Schematic model of a receptor ensemble model to describe how a classic steroid receptor could accommodate differently shaped ligands that result in the initiation of either rapid responses or genomic responses. The ensemble model proposes that there is a population of three different unoccupied receptor species (*a*, *b*, and *c*) illustrated by different positions of helix-12 (H12;-brown) that are in rapid equilibrium with one another; each receptor conformer species may preferentially bind differently shaped ligands (Bursavich *et al*., 2002). In this example, transient occupancy of the alternative pocket by a ligand could/would lead to initiation of RR whereas occupancy of the classical pocket by a ligand would lead to activation of genomic responses; both of these pockets are illustrated for the VDR in Figure 2A. The alternative pocket is accessible in all three H12 conformers (*a*, *b*, and *c*). Occupancy of this alternative pocket is only favored prior to achieving the steady-state equilibrium for the receptor's natural ligands given the increased accessibility coupled with weaker van der Waals interactions compared with genomic pocket occupancy. Receptor conformer (*c*) is the only conformer able to accept ligands that can bind to the classical ligand-binding site leading to genomic responses because, in conformers a and b, H12 blocks ligand accessibility to the conserved H5 Arg residue located at the innermost part of the classic ligand-binding pocket. An interesting consequence of the receptor ensemble concept may be that association of the nuclear receptor with caveolae or cell membranes may change the ligand-binding preferences to favor the alternative pocket. Ligand occupancy of this genomic pocket is favored under steady-state conditions because of the increase in thermodynamic stability derived from hydrophobic interactions. It is possible that drug analogs, especially those related to the natural hormone(s), may have differential fractional occupancies of the two pockets, thus affecting the efficiency of the cellular signaling pathways mediated by either pocket.

would shift the equilibrium among the receptor species so as to favor the energetically most stable hormone-bound receptor conformation. It should be noted that $1\alpha,25(OH)_2D_3$ is able to change its conformation much more quickly than the receptor protein, so essentially the whole ensemble of $1\alpha,25(OH)_2D_3$ conformations can sample each of the individual protein ensemble conformations. Implicit in this model is that the receptor "sampling" by the ligand involves gaining entrance and exploring the interior surface of the LBD to determine whether a complementary "fit" can be achieved. A related model to describe ligand/receptor-induced separation of rapid from genomic responses was included in the comprehensive analysis of nongenotropic, sex-nonspecific signaling by the ER and AR (Kousteni *et al.*, 2001). Although this model has not yet been fully validated, it is possible to identify experiments involving site-directed mutagenesis of the VDR that may give further insight.

SUMMARY

In contrast to classical steroid hormones, like estradiol, which have only one shape, it is apparent that $1\alpha,25(OH)_2D_3$ can generate at least three functionally different shapes that effectively accommodate the ligand-binding domain requirements of the VDR_{nuc}, the caveolae-associated VDR_{mem}, and DBP proteins. These different shapes are described in Figure 2E to G and in Table V.

Figure 12 is a summary figure that integrates the signal transduction pathways that are used by the nuclear VDR and the membrane-associated VDR with $1\alpha,25(OH)_2D_3$ functioning as a conformationally flexible agonist. This model emphasizes the complexity of overlapping and interconnecting signal transduction pathways. Although there is a solid and secure foundation describing $1\alpha,25(OH)_2D_3$-mediated genomic actions, $1\alpha,25(OH)_2D_3$-mediated RRs are still in their developmental phase. One important challenge will be to identify and fully biochemically characterize the membrane-associated VDR. An equally daunting task will be to define in the various cell systems that display RR, the identification of the specific signal transduction pathways that contribute to mediation of a specific rapid biological response. A further important question is to determine whether the membrane VDR can communicate with the nucleus of the cell to modulate gene transcription. In data not shown, but summarized in Figure 11, there are

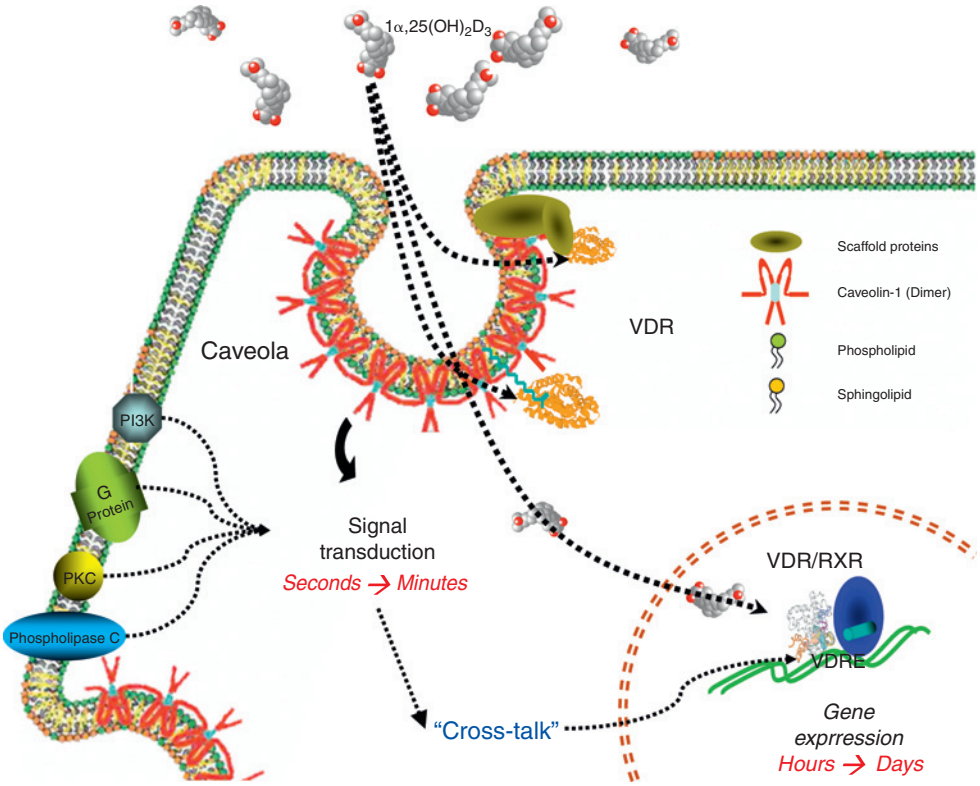

FIGURE 12 Schematic model describing how the conformationally flexible $1\alpha,25(OH)_2D_3$ can interact with the VDR localized in the cell nucleus to generate genomic responses or in caveolae of the plasma membrane to generate RR. Binding of $1\alpha,25(OH)_2D_3$ to the caveolae-associated VDR may result in the activation of one or more second messenger systems, including phospholipase C, protein kinase C, G protein-coupled receptors, or phosphatidylinositol-3′-kinase (PI3K). There are a number of possible outcomes including opening of the voltage-gated calcium or chloride channels or generation of the indicated second messengers. Some of these second messengers, in particular, RAF/MAP kinase, may engage in "crosstalk" with the nuclear VDR to modulate gene expression (Norman *et al.*, 2000). (See plate section)

at least five different systems (pancreas β-cell, adipocytes, vascular smooth muscle, intestine, and osteoblasts) where molecular biological evidence has been obtained for the process of crosstalk from 1α,25(OH)$_2$D$_3$ rapid responses to changes in gene expression in the cell nucleus. In these studies, 6-s-*cis*-locked analogs have been shown to modulate genomic responses at relatively early time intervals (2–4 hours). This supports the generality of 1α,25(OH)$_2$D$_3$-mediated rapid responses in a wide variety of physiological systems. It adds further impetus to the need to continue studies at the molecular level to define and characterize the molecular physiology of 1α,25(OH)$_2$D$_3$-mediated responses.

ACKNOWLEDGMENTS

I thank Ms. Susan Haesuk Kim for patient, hard work in preparing this manuscript. Work for the my laboratory was supported by National Institutes of Health Grant DK-09012–39.

Chapter 36

Vitamin D Gene Regulation

Sylvia Christakos

Department of Biochemistry and Molecular Biology, University of Medicine and Dentistry of New Jersey, New Jersey Medical School, Newark, New Jersey

VITAMIN D METABOLISM

Vitamin D is a principal factor required for the development and maintenance of bone as well as for maintaining normal calcium and phosphorus homeostasis. In addition, evidence has indicated the involvement of vitamin D in a number of diverse cellular processes, including effects on differentiation and cell proliferation, on hormone secretion, and on the immune system (DeLuca, 2004; Christakos *et al*., 2003). For vitamin D to affect mineral metabolism as well as numerous other systems, it must first be metabolized to its active form. Vitamin D, which is taken in the diet or is synthesized in the skin from 7-dehydrocholesterol in a reaction catalyzed by ultraviolet irradiation, is transported in the blood by the vitamin D-binding protein to the liver. In the liver, vitamin D is hydroxylated at C-25, resulting in the formation of 25-hydroxyvitamin D_3 [25(OH)D_3]. 25-Hydroxyvitamin D proceeds to the kidney via the serum vitamin D-binding protein. Megalin, a member of the LDL receptor superfamily, plays an essential role in the renal uptake of 25(OH)D_3 (Nykjaer *et al.,* 1999). In the proximal convoluted and straight tubules of the kidney nephron, 25(OH)D_3 is hydroxylated at the position of carbon 1 of the A ring, resulting in the formation of the hormonally active form of vitamin D, 1,25-dihydroxyvitamin D_3 [1,25(OH)$_2$$D_3$]. The kidney can also produce 24,25-dihydroxyvitamin D_3 [24,25(OH)$_2$$D_3$]. 24-Hydroxylase [24 (OH)ase] has been reported to be capable of hydroxylating the 24 position of both 25(OH)D_3 and 1,25(OH)$_2$$D_3$ (Omdahl *et al*., 2003) (see Fig. 1). Because the K_m value of 24(OH)ase for 1,25(OH)$_2$$D_3$ is 1/5 to 1/30 of the K_m value for 25(OH)D_3 (Tomon *et al.,* 1990), it has been suggested that the preferred substrate for 24(OH)ase *in vivo* may be 1,25(OH)$_2$$D_3$ rather than 25(OH)D_3 (Shinki *et al.,* 1992). Studies using mice with a targeted inactivating mutation of the 24(OH)ase gene [24(OH)ase null-mutant mice] have provided the first direct *in vivo* evidence for a role for 24(OH)ase in the catabolism of 1,25(OH)$_2$$D_3$ (St-Arnaud *et al.,* 2000). Both chronic and acute treatment with 1,25(OH)$_2$$D_3$ resulted in an inability of 24(OH)ase-deficient mice to clear 1,25(OH)$_2$$D_3$ from their bloodstream. Impaired bone formation at specific sites (calvaria, mandible, clavicle, and periosteum of long bones) was also noted in the deficient mice. 24,25-Dihydroxyvitamin D_3 supplementation failed to correct most of the bone abnormalities. Because crossing 24(OH)ase-deficient mice to vitamin D receptor (VDR)-ablated mice totally rescued the bone phenotype, the authors suggested that elevated 1,25(OH)$_2$$D_3$ levels acting through VDR at specific sites and not the absence of 24,25(OH)$_2$$D_3$, were responsible for the abnormalities observed in bone development. Whether 24,25(OH)$_2$$D_3$ is an active metabolite has been a matter of debate. However, most studies indicate that 24,25(OH)$_2$$D_3$ appears to be relatively inactive when compared with 1,25(OH)$_2$$D_3$.

The production of 1,25(OH)$_2$$D_3$ and 24,25(OH)$_2$$D_3$ is under stringent control. Calcium and phosphorus deprivation

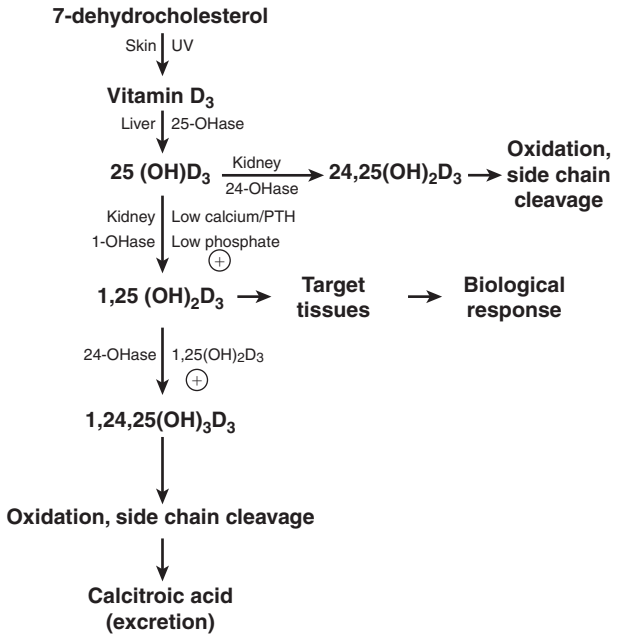

FIGURE 1 The metabolic pathway for vitamin D.

Principles of Bone Biology, 3rd Edition

results in enhanced production of $1,25(OH)_2D_3$ (Omdahl *et al.*, 2003). Elevated PTH resulting from calcium deprivation may be the primary signal mediating the calcium regulation of $1,25(OH)_2D_3$ synthesis (Boyle *et al.,* 1971; Henry, 1985; Murayama *et al.,* 1999). PTH has been reported to stimulate 25-hydroxyvitaminD_3 1α hydroxylase (1α (OH)ase) by acting on the promoter of the 1α (OH)ase gene (Brenza *et al.*, 1998). 1,25-dihydroxyvitamin D_3 also regulates its own production by inhibiting 1-hydroxylase (Brenza and DeLuca, 2000; Murayama *et al.*, 1999; Murayama *et al.*, 2004). The synthesis of $24,25(OH)_2D_3$ has been reported to be reciprocally regulated when compared with the synthesis of $1,25(OH)_2D_3$ [stimulated by $1,25(OH)_2D_3$, and inhibited by low calcium and PTH] (Omdahl *et al.,* 2003). In addition to PTH, phosphorus, calcium, and $1,25(OH)_2D_3$, it has been reported that sex hormones can influence production of the renal vitamin D hydroxylases. Estrogens alone or when combined with androgens have been reported to stimulate $1,25(OH)_2D_3$ production, and estradiol has been reported to suppress $24,25(OH)_2D_3$ synthesis in avian species (Pike *et al.,* 1978; Tanaka *et al.,* 1976). It is not clear, however, whether a similar relationship exists between sex steroids and vitamin D hydroxylases in mammalian species (Baski and Kenny, 1978). It is of interest that calcitonin has been reported to stimulate the expression of 1α (OH)ase under normocalcemic conditions (Shinki *et al.,* 1999). Because calcitonin is elevated in the serum of the fetus, it has been suggested that calcitonin may have a role (in addition to its known role in shrinking osteoclasts under high calcium conditions) in regulating 1α (OH)ase during development. FGF23, a recently discovered phosphaturic factor, has also been identified as a physiological regulator of vitamin D metabolism, which reduces 1α (OH)ase mRNA (Shimada *et al.*, 2004). Low dietary phosphate intake results in decreased FGF23 levels and a corresponding increase in 1α (OH)ase activity (Perwad *et al.,* 2005). It has been reported that FGF23 requires the klotho protein (a multifunctional protein involved in phosphate and calcium homeostasis and in aging that binds to FGF receptors) to activate FGF signaling (Kuro-o, 2006). Further studies are needed to determine the exact mechanisms by which FGF23 acts to affect vitamin D metabolism. Although the proximal tubule of the kidney, placenta, and macrophages are sites of synthesis of 1α (OH)ase, it has been suggested that 1α (OH)ase is present in other cell types and that local production of $1,25(OH)_2D_3$ could have a role in the function of extra renal tissues. 1α (OH)ase null mutant mice have recently been generated (Panda *et al.*, 2001). It is of interest that besides a phenotype identical to the human vitamin D-dependent rickets type I phenotype, immune and reproductive dysfunction has been noted in these mice (Panda *et al.*, 2001). Further studies are needed to test the hypothesis of a physiological role of 1α (OH)ase in extra renal tissues that has been a matter of debate.

Serum $1,25(OH)_2D_3$ levels and the capacity of the kidney to hydroxylate $25(OH)D_3$ to $1,25(OH)_2D_3$ have been reported to decline with age (Armbrecht *et al.,* 1980). In addition, an increase in renal 24-hydroxylase gene expression and an increase in the clearance of $1,25(OH)_2D_3$ with aging have been reported (Matkovits and Christakos, 1995; Wada *et al.,* 1992). These findings have implications concerning the etiology of osteoporosis and suggest that the combined effect of a decline in the ability of the kidney to synthesize $1,25(OH)_2D_3$ and an increase in the renal metabolism of $1,25(OH)_2D_3$ may contribute to age-related bone loss. Whether there is an interrelationship between the decline of sex steroids with age and age-related changes in the 1- and 24-hydroxylase enzymes remains to be determined.

ROLE OF $1,25(OH)_2D_3$ IN CLASSICAL TARGET TISSUES

Bone

Exactly how $1,25(OH)_2D_3$ affects mineral homeostasis is a subject of continuing investigation. It has been suggested that the antirachitic action of $1,25(OH)_2D_3$ is indirect and the result of increased intestinal absorption of calcium and phosphorus by $1,25(OH)_2D_3$, thus resulting in their increased availability for incorporation into bone (Underwood and DeLuca, 1984; Weinstein *et al.,* 1984). Studies using VDR-ablated mice (VDR knockout mice) also suggest that a principal role of the vitamin D receptor in skeletal homeostasis is its role in intestinal calcium absorption (Li *et al.,* 1997; Yoshizawa *et al.,* 1997; Amling *et al.,* 1999). VDR knockout mice were found to be phenotypically normal at birth, but developed hypocalcemia, hyperparathyroidism, and alopecia within the first month of life. Rickets and osteomalacia were seen by day 35. When VDR knockout mice were fed a calcium/phosphorus/lactose-enriched diet, serum-ionized calcium levels were normalized, the development of hyperparathyroidism was prevented, and the animals did not develop rickets or osteomalacia, although alopecia was still observed. Thus, it was suggested that skeletal consequences of VDR ablation are due primarily to impaired intestinal calcium absorption. *In vitro* studies, however, have shown that $1,25(OH)_2D_3$ can resorb bone (Raisz *et al.,* 1972). Although $1,25(OH)_2D_3$ stimulates the formation of bone-resorbing osteoclasts, receptors for $1,25(OH)_2D_3$ are not present in osteoclasts but rather in osteoprogenitor cells, osteoblast precursors, and mature osteoblasts. Stimulation of osteoclast formation by $1,25(OH)_2D_3$ requires cell-to-cell contact between osteoblastic cells and osteoclast precursors and involves upregulation by $1,25(OH)_2D_3$ in osteoblastic cells of osteoprotegerin ligand or RANKL (osteoclast differentiating factor; Takeda *et al.,* 1999; Yasuda *et al.,* 1998a, 1998b). RANKL is induced by $1,25(OH)_2D_3$ (Kim *et al.*, 2007) as well as by PTH, interleukin 11, and prostaglandin E_2 in osteoblasts/stromal cells. RANKL is a member of the membrane-associated tumor necrosis factor ligand family that enhances osteoclast formation by mediating direct

interactions between osteoblast/stromal cells and osteoclast precursor cells. Osteoclastogenesis inhibitory factor/osteoprotegerin, a member of the tumor necrosis factor receptor family, is a soluble decoy receptor for RANKL that antagonizes RANKL function, thus blocking osteoclastogenesis. Osteoprotegerin is downregulated by $1,25(OH)_2D_3$ (Yasuda *et al.,* 1998a).

In addition to increasing the availability of calcium and phosphorus for incorporation into bone and stimulating osteoclast formation, $1,25(OH)_2D_3$ also has a direct effect on osteoblast-related functions. For example, $1,25(OH)_2D_3$ has been reported to stimulate the production of osteocalcin (OC) (Price and Baukol, 1980) and osteopontin (OPN) (Prince and Butler, 1987) in osteoblastic cells. The exact function of osteocalcin, a noncollagenous protein associated with the mineralized matrix, is not known. However, increased synthesis of osteocalcin has been positively correlated with new bone formation. Concerning osteopontin, also a major noncollagenous bone protein, it has been suggested that this secreted, glycosylated phosphoprotein is important for resorption of the bone matrix (the OPN-$\alpha_v\beta_3$ integrin interaction has been reported to be important for the adherence of the osteoclast to bone), as well as for mineralization (Denhardt and Guo, 1993). OPN-deficient mice are resistant to mineral loss and bone resorption upon estrogen deprivation and have impaired activation of osteoclasts, suggesting the requirement for OPN in bone resorption (Asou *et al*., 2001; Yoshitake *et al*., 1999). Runx2, identified as a transcriptional regulator of osteoblast differentiation, is involved in regulation of the expression of OPN and OC and has also been reported to be regulated by $1,25(OH)_2D_3$ (Javed *et al.,* 1999; Shen and Christakos, 2005; Centrella *et al*., 2004). In addition, analogs of $1,25(OH)_2D_3$ have been developed that exhibit selective anabolic actions in osteoblasts and result in enhanced bone formation (Shevde *et al*., 2002), suggesting that selective bone analogs of $1,25(OH)_2D_3$ may be therapeutically beneficial for the treatment of bone loss disorders. Studies using transgenic mice overexpressing VDR in osteoblastic cells have noted increased bone formation, further indicating direct effects of $1,25(OH)_2D_3$ on bone (Gardiner *et al*., 2000). Besides analogs of $1,25(OH)_2D_3$ that have direct effects on bone and enhance bone formation, it has also been suggested that vitamin D may reduce falls and therefore fractures by improving neuromuscular function (Dhesi *et al*., 2004). However, further studies are needed to determine whether the vitamin D endocrine system has direct effects on neuromuscular function or whether the observed effects are secondary to a primary effect on maintenance of calcium homeostasis.

Intestine

In addition to its effect on bone, another extensively studied action of $1,25(OH)_2D_3$ is the stimulation of intestinal calcium absorption (Wasserman and Fullmer, 1995). Although the exact mechanisms involved in this process have still not been defined, it has been suggested that $1,25(OH)_2D_3$ affects intracellular calcium diffusion by inducing the calcium-binding protein, known as calbindin. One of the most pronounced effects of $1,25(OH)_2D_3$ is increased synthesis of calbindin (for reviews see Christakos, 1995, and Christakos *et al.,* 1989). Two major subclasses of calbindin have been described: a protein of a molecular weight of ~9,000 (calbindin-D_{9k}) and a protein with a molecular weight of ~28,000 (calbindin-D_{28k}). Calbindin-D_{9k} has two calcium-binding domains, has been observed only in mammals, and is present in highest concentration in mammalian intestine. Calbindin-D_{28k}, unlike calbindin-D_{9k}, is highly conserved in evolution and has four functional high-affinity, calcium-binding sites. Calbindin-D_{28k} is present in highest concentrations in avian intestine and in avian and mammalian kidney, brain, and pancreas. There is no amino acid sequence homology between calbindin-D_{9k} and calbindin-D_{28k}. In VDR-ablated mice, which demonstrate impaired intestinal calcium absorption, calbindin-D_{9k} mRNA is reduced dramatically (Li *et al.,* 1998). However, studies using analogs of $1,25(OH)_2D_3$ suggest that there need not be a direct correlation between calbindin induction and stimulation of intestinal calcium transport. Intestinal calbindin-D_{9k} mRNA but not intestinal calcium transport has been reported to be induced by $1,25(OH)_2D_3$ 24-homologues (Krisinger *et al.,*1991). In addition, 1,25,28-trihydroxyvitamin D_2 has been found to have no effect on intestinal calcium absorption but to result in a significant induction in rat intestinal calbindin-D_{9k} mRNA and protein (Wang *et al.,* 1993). These findings, as well as recent studies that indicated normal serum calcium levels in calbindin-D_{9k} null mutant mice regardless of age or gender (Kutazova *et al*., 2006; Benn *et al.*, 2008), provide evidence that calbindin alone is not responsible for the $1,25(OH)_2D_3$-mediated intestinal transport of calcium. Besides acting as a facilitator of intestinal calcium diffusion, it is also possible that calbindin in the intestine may act as an intracellular buffer to prevent toxic levels of calcium from accumulating in the intestinal cell during $1,25(OH)_2D_3$-dependent transcellular calcium transport (Christakos *et al.,* 1989).

$1,25(OH)_2D_3$ also affects calcium extrusion from the intestinal cell, which involves calcium transport against a concentration gradient. The intestinal plasma membrane calcium pump (PMCA-1) and PMCA-1 mRNA are stimulated by $1,25(OH)_2D_3$, suggesting that the intestinal calcium absorptive process may involve a direct effect of $1,25(OH)_2D_3$ on calcium pump expression (Cai *et al.,* 1993; Wasserman *et al.,* 1992; Zelinski *et al.,* 1991).

In addition to the role of $1,25(OH)_2D_3$ on transcellular movement of calcium and on the extrusion of calcium from the intestinal cell, it has been known that calcium transfer into the intestinal cell can be increased by $1,25(OH)_2D_3$. However, the existence of a calcium channel responsible for this process had been controversial. In 1999 a calcium

selective channel, which is potentially important in the control of intestinal calcium absorption, TRPV6, was cloned from rat duodenum (Peng *et al.,* 1999). Calmodulin binds to TRPV6 and regulates its activity and the association of S100A10-annexin 2 complex has been reported to be required for the targeting and retention of TRPV6 to the plasma membrane (Lambers *et al.,* 2004; van de Graaf *et al*., 2003). TRPV6 is induced by $1,25(OH)_2D_3$ in intestine and in VDR knockout mice TRPV6 was found to be more markedly decreased than calbindin-D_{9k} (Song *et al*., 2003; Van Cromphaut *et al*., 2001). It has been suggested that TRPV6 may play a key role in vitamin D-dependent calcium entry into the enterocyte and that TRPV6 may be the rate-limiting step in vitamin D-dependent intestinal calcium absorption (Van Cromphaut *et al*., 2001). TRPV6 null mutant mice have recently been generated (Bianco *et al*., 2007). Although these mice have normal serum calcium levels, they have increased serum PTH and $1,25(OH)_2D_3$ levels as well as a 9.3% decrease in femoral bone density, suggesting a disturbance in calcium homeostasis (Bianco *et al*., 2007). Further studies using these mice as well as TRPV6/calbindin-D_{9k} double knockout mice should result in new insight in our understanding of the process of vitamin D-dependent intestinal calcium absorption.

Kidney

In addition to bone and intestine, a third target tissue involved in the regulation by $1,25(OH)_2D_3$ of mineral homeostasis is the kidney. Micropuncture data, as well as studies using a mouse distal convoluted tubule cell line, have indicated that vitamin D metabolites can enhance the stimulatory effect of PTH on calcium transport in the distal nephron (Friedman and Gesek, 1993; Winaver *et al.,* 1980). $1,25(OH)_2D_3$ has been reported to increase PTH receptor mRNA and binding activity in distal tubule cells, providing a mechanism whereby $1,25(OH)_2D_3$ enhances the action of PTH (Sneddon *et al.,* 1998). In the mouse, both vitamin D-dependent calcium-binding proteins (calbindin-D_{9k} and calbindin-D_{28k}) have been reported to be localized in the distal nephron (distal convoluted tubule, connecting tubule, and cortical collecting tubule) (Rhoten *et al.,* 1985). Kinetic analysis has suggested that the two proteins affect renal calcium reabsorption by different mechanisms. Calbindin-D_{28k} stimulates the high-affinity system in the distal luminal membrane (Bouhtiauy *et al.,* 1994a), whereas calbindin-D_{9k} was found to enhance the ATP-dependent calcium transport of the basolateral membrane (Bouhtiauy *et al.,* 1994b). These findings provide evidence for a role for calbindins in vitamin D-dependent calcium transport processes in the kidney. Similar to studies in intestine, an apical calcium channel, TRPV5, was also identified in the distal convoluted tubule and distal connecting tubules (Hoenderop *et al.,* 1999; Vennekens *et al.,* 2000). TRPV5 shows 73.4% sequence homology with TRPV6 and is also induced by $1,25(OH)_2D_3$ (Song *et al.,* 2003). The S100A10-annexin 2 complex was found to play a role in routing TRPV5 to the plasma membrane as well as TRPV6 (van de Graaf *et al*., 2003). The klotho protein activates TRPV5 by hydrolyzing TRPV5 N-linked oligosaccharides (Chang *et al.,* 2005). In addition, calbindin-D_{28k} was reported to associate directly with TRPV5 and to control TRPV5-mediated calcium influx (Lambers *et al*., 2006). Mice lacking TRPV5 display diminished calcium reabsorption in the distal tubule, hypercalciuria, and disturbances in bone structure, supporting the suggested role for TRPV5 in renal calcium handling (Hoenderop *et al.,* 2003). Thus, $1,25(OH)_2D_3$ may affect calcium transport in the distal tubule by enhancing the action of PTH and by inducing TRPV5 and the calbindins. In addition to the calbindins and TRPV5, the plasma membrane calcium pump has also been localized immunocytochemically exclusively to the distal tubule and to the collecting duct (Borke *et al.,* 1988). However, the interrelationship between the renal calcium pump and $1,25(OH)_2D_3$ is not clear at this time. In addition to the suggested role of $1,25(OH)_2D_3$ in the tubular reabsorption of calcium, another important effect of $1,25(OH)_2D_3$ in the kidney is inhibition of the $25(OH)D_3$ 1α-hydroxylase enzyme and stimulation of the 24-hydroxylase enzyme. Both the 1α-hydroxylase and 24(OH)ase genes have been cloned, and studies indicate that they are regulated through liganded VDR (Takeyama *et al.,* 1997; Shinki *et al.,* 1997; Murayama *et al.,* 1999; Murayama *et al*., 2004; Kerry *et al.,* 1996; Zierold *et al.,* 1995). In addition to effects on calcium transport in the distal nephron and modulation of the $25(OH)D_3$ hydroxylases, effects of $1,25(OH)_2D_3$ on phosphate reabsorption in the proximal tubule have also been suggested. Vitamin D has been reported to increase or decrease renal phosphate reabsorption depending on the parathyroid status and on experimental conditions. Mutations in the PHEX gene, a phosphate-regulating gene, are responsible for X-linked hypophosphatemia. $1,25(OH)_2D_3$ has been reported to downregulate PHEX gene expression, suggesting a role for $1,25(OH)_2D_3$ in renal phosphate transport (Hines *et al.,* 2004). Although progress has been made, further studies are needed to provide new insight concerning the renal effects of $1,25(OH)_2D_3$ that have not been well understood.

Parathyroid Glands

In the regulation of mineral homeostasis, the parathyroid glands are also an important target of $1,25(OH)_2D_3$ action. 1,25-Dihydroxyvitamin D_3 inhibits the secretion and synthesis of PTH. A direct action of $1,25(OH)_2D_3$ on the preproparathyroid hormone gene has been reported (Demay *et al.,* 1992; Mackey *et al.,* 1996). $1,25(OH)_2D_3$ also functions to prevent the proliferation of the parathyroid gland and thus helps to maintain normal parathyroid status (Martin and Gonzalez, 2004).

NONCLASSICAL ACTIONS OF $1,25(OH)_2D_3$

Effects of $1,25(OH)_2D_3$ on Differentiation and Proliferation

In addition to affecting tissues involved in mineral homeostasis, $1,25(OH)_2D_3$ has been reported to affect numerous other systems. Because $1,25(OH)_2D_3$ receptors have been identified in tissues not involved in calcium homeostasis, it has been suggested that the actions of $1,25(OH)_2D_3$ in these nonclassical target tissues are mediated, at least in part, by genomic mechanisms. One of the best characterized actions of $1,25(OH)_2D_3$ in a number of different normal and malignant cells is the ability of $1,25(OH)_2D_3$ to inhibit proliferation and to stimulate differentiation. The effect of $1,25(OH)_2D_3$ on the inhibition of proliferation and the stimulation of differentiation is of interest because it has been related to the treatment of skin lesions found in psoriasis with $1,25(OH)_2D_3$ or analogs of $1,25(OH)_2D_3$. In addition to keratinocytes, $1,25(OH)_2D_3$ has been reported to inhibit the proliferation and induce the differentiation of leukemia cells (Suda, 1989) and to inhibit the proliferation of a number of malignant cells, including colon, breast, and prostate cancer cells (Gonzalez-Sancho *et al*., 2006; Lowe *et al.,* 2003; Krishnan *et al.,* 2003; Wang *et al.,* 2000). $1,25(OH)_2D_3$ is known to induce expression of p21 and p27, proteins that play an important role in regulation of growth (Inoue *et al.,* 1999; Liu *et al*., 1996). A very active area of current investigation is the development of analogs of $1,25(OH)_2D_3$, which can inhibit cell growth and promote differentiation but do not affect serum calcium and the testing of their therapeutic potential in the treatment of leukemia and other malignancies.

Effects of $1,25(OH)_2D_3$ on Hormone Secretion

Studies using VDR knockout mice have indicated that vitamin D is essential for full gonadal function in both sexes (Kinuta *et al.,* 2000). Although vitamin D plays a role in estrogen biosynthesis partially by maintaining calcium homeostasis, direct regulation by $1,25(OH)_2D_3$ of the aromatase gene was suggested (Kinuta *et al.,* 2000). 1,25-Dihydroxyvitamin D_3 treatment can also enhance the secretion of insulin from the pancreas (Chertow *et al.,* 1983; Clark *et al.,* 1981; Norman *et al.,* 1980), the first nonclassical target tissue in which $1,25(OH)_2D_3$ receptors were identified (Christakos and Norman, 1979). Although normalization of insulin secretion by vitamin D has been observed in vitamin-deficient rats, it has been argued that this effect of vitamin D may be secondary to a primary effect of vitamin D on serum calcium or to other beneficial effects of vitamin D on growth and nutrition. However, this is still a matter of debate. It is indeed possible that $1,25(OH)_2D_3$ may act together with calcium to control insulin secretion. One of the earliest indications that the β cell may be a target for $1,25(OH)_2D_3$ came from immunocytochemical studies that localized calbindin-D_{28k} to the islet (Morrissey *et al.,* 1975). Studies using pancreatic islets from calbindin-D_{28k} null-mutant mice and β cell lines stably transfected and overexpressing calbindin have provided evidence for a role for calbindin in the modulation of depolarization-stimulated insulin release and suggest that calbindin can control the rate of insulin release by regulating intracellular calcium and by modulating calcium influx via L type calcium channels (Sooy *et al.,* 1999; Lee *et al.,* 2006).

Effects of $1,25(OH)_2D_3$ on the Immune System

$1,25(OH)_2D_3$ has been reported to inhibit IFN-γ, IL-2, granulocyte/macrophage colony-stimulating factor (GM-CSF) and TNF-α. For IL-2, IFN-γ, and GM-CSF the mechanism of $1,25(OH)_2D_3$ mediated inhibition involves VDR-mediated inhibition of gene transcription (Alroy *et al*., 1995; Cippitelli and Santoni, 1998; Towers *et al*., 1999). $1,25(OH)_2D_3$ has also been reported to upregulate IL-4 (Cantorna *et al.,* 1998). Studies have indicated that $1,25(OH)_2D_3$ can also inhibit the differentiation and survival of dendritic cells, resulting in impaired alloreactive T-cell activation (Penna and Adorini, 2000; Griffin *et al*., 2001). Due to its immunosuppressive actions, it has been suggested that $1,25(OH)_2D_3$ or analogs of $1,25(OH)_2D_3$ may prevent the induction of certain autoimmune disorders and may have beneficial effects when given in combination with immunosuppressive drugs such as cyclosporin A.

Very recent studies have indicated that $1,25(OH)_2D_3$ is a direct inducer of antimicrobial peptide gene expression, resulting in killing of *Mycobacterium* tuberculosis. These findings indicate a novel action of $1,25(OH)_2D_3$ in the regulation of innate immunity and suggest that decreased ability to produce $1,25(OH)_2D_3$ may contribute to increased tuberculosis susceptibility (Liu *et al.,* 2006).

TRANSCRIPTIONAL REGULATION BY $1,25(OH)_2D_3$

Vitamin D-Regulated Genes

$1,25(OH)_2D_3$, similar to other steroid hormones, is known to act by binding stereospecifically to a high-affinity, low-capacity nuclear receptor (VDR) resulting in the concentration of the $1,25(OH)_2D_3$ receptor complex in the nucleus and the activation or repression of target genes. To date, more than 50 vitamin D-dependent genes have been identified in different target tissues in a number of species (see Segaert and Bouillon, 1998, for lists of vitamin D-dependent genes). However, only a limited number of vitamin D responsive elements (VDREs) have been defined. In general, the

VDRE consensus consists of two direct imperfect repeats of the hexanucleotide sequence GGGTGA separated by three nucleotide pairs (Table I).

Calbindin-D_{9K}, Calbindin-D_{28K}

As mentioned previously, one of the most pronounced effects of $1,25(OH)_2D_3$ is increased synthesis of calbindin. Although sequence elements in the mouse calbindin-D_{28k} promoter (–200/–169) and in the rat calbindin-D_{9k} promoter (–489/–445) that respond to $1,25(OH)_2D_3$ have been identified, the response observed using the calbindin-D_{9k} or the calbindin-D_{28k} responsive sequences is modest (Darwish and DeLuca, 1992; Gill and Christakos, 1993). This modest response reflects previous *in vivo* findings that indicated that $1,25(OH)_2D_3$ induces the expression of the calbindin-D_{9k} or the calbindin-D_{28k} gene by a small, rapid transcriptional stimulation followed by a large accumulation of calbindin mRNA long after $1,25(OH)_2D_3$ treatment (Christakos *et al.,* 1989). These findings suggest that the large induction of calbindin mRNA by $1,25(OH)_2D_3$ may be due primarily to post-transcriptional mechanisms. More recent studies noted the requirement of the homeodomain protein Cdx2, a transcription factor active only in intestinal epithelium, for calbindin-D_{9k} expression and that cooperation between the proximal calbindin-D_{9k} promoter and a distal element located in an open chromatin structure (–3600/–3400) is needed for vitamin D responsiveness (Colnot *et al.,* 1998). These studies suggest that the mechanism of action of $1,25(OH)_2D_3$ on calbindin regulation is more complicated than the conventional hormone-receptor transcriptional activation model. Calbindin-D_{9k} and calbindin-D_{28k} are regulated by a number of hormones in addition to $1,25(OH)_2D_3$. Calbindin-D_{9k} in rat uterus and calbindin-D_{28k} in mouse uterus, oviduct, and ovary have been reported to be regulated by estradiol (see Christakos, 1995, and Christakos *et al.,* 1989, for review). 1,25-Dihydroxyvitamin D_3 has no effect on calbindins in these female reproductive tissues. Regulation of calbindin-D_{28k} by retinoic acid has also been reported (Wang and Christakos, 1995). In addition, neurotrophin 3, brain-derived neurotrophic factor, fibroblast growth factor, and tumor necrosis factor have all been observed to increase the expression of calbindin-D_{28k} in the brain, suggesting regulation of calbindin by signal transduction, as well as by steroids (see Christakos, 1995, for review). Thus, it has become evident that calbindin is no longer considered a calcium-binding protein whose synthesis is dependent solely on vitamin D. Calbindin is present in a number of different tissues, may have multiple functions, and can be regulated by different ligands as well as by signal transduction.

TABLE I Vitamin D Responsive Elements Present in Vitamin-Regulated Genes

Rat 24-hydroxylase	AGGTGA gtg AGGGCG (–151/–137)
	CGCACC cgc TGAACC (–259/–245)
Human 24-hydroxylase	AGGTGA gcg AGGGCG (–171/–143)
	ACTTCA ccg GGTGTG (–293/–273)
Mouse osteopontin	GGTTCA cga GGTTCA (–757/–743)
Human osteocalcin	GGGTGA acg GGGGCA (–499/–485)
Rat osteocalcin	GGGTGA atg AGGACA (–455/–441)
Mouse calbindin-D_{28k}	GGGGAT gtg AGGAGA (–198/–182)
Mouse calbindin-D_{9k}	GGGTGT cgg AAGCCC (–488/–474)
Human TRPV 6	AGGTCT tgg GGTTCA (–2,170/–2,156)
	GGGGTA gtg AGGTCA (–4,287/–4,273)

Osteocalcin, Osteopontin

Studies concerning the regulation by vitamin D of two other calcium-binding proteins, osteocalcin (OC) and osteopontin (OP), which are secreted by the osteoblasts, have been important to our understanding of transcriptional activation by $1,25(OH)_2D_3$. VDREs in both the human and the rat OC promoter (Demay *et al.,* 1990; Kerner *et al.,* 1989) and in the mouse OP promoter (Noda *et al.,* 1990; Shen and Christakos, 2005) have been well characterized. Runx2 is important for basal and vitamin D responsive transcription of the OC gene (Javed *et al.,*1999; Lian *et al.,* 2001). Recent studies indicated cooperative effects among Runx2, VDR, and Hes-1 (a downstream factor in the notch signaling pathway) in the transcriptional regulation of OPN (Shen and Christakos, 2005).

24-Hydroxylase

Vitamin D responsive elements have also been identified in the rat 24-hydroxylase [24(OH)ase] gene (Kerry *et al.,* 1996; Ohyama *et al.,* 1996; Zierold *et al.,*1995). The 24(OH)ase gene is the first vitamin D-dependent gene reported to be controlled by two independent VDREs (at –259/–245 and at –151/–137). It has been suggested that the proximal VDRE is more responsive to $1,25(OH)_2D_3$ than the distal VDRE (Ohyama *et al.,* 1996). The most pronounced effects of $1,25(OH)_2D_3$ in intestine and kidney are increased synthesis of 24(OH)ase and calbindin (Matkovits and Christakos, 1995). However, unlike calbindin, which is only modestly transcriptionally responsive to $1,25(OH)_2D_3$, 24(OH)ase is strongly responsive to $1,25(OH)_2D_3$ at the level of transcription.

PARATHYROID HORMONE AND 1α HYDROXYLASE

The first demonstration of a negative VDRE was by Demay *et al.* (1992), who indicated that sequences in the human

parathyroid hormone (PTH) gene (–125/–101) mediate transcriptional repression by $1,25(OH)_2D_3$. Only a single copy motif (AGGTCA) is identified within this region, and vitamin D receptor binding to this element does not require the retinoid X receptor (RXR) (Mackey *et al.,* 1996). The response is tissue specific because the 25-bp oligonucleotide was reported to mediate transcriptional repression in GH4C1 cells but not in ROS 17/2.8 cells.

A negative VDRE has also been demonstrated in the human 1α(OH)ase promoter (–537/–514). No direct binding of VDR or VDR/RXR was detected. A helix-loop-helix factor designated as vitamin D interacting repressor (VDIR) was identified as a direct sequence-specific activator of the 1α(OH)ase negative VDRE (Murayama *et al.,* 2004).

Interleukin-2 and Granulocyte/Macrophage Colony-Stimulating Factor

Mechanisms involved in mediating the effects of $1,25(OH)_2D_3$ in systems other than those involved in maintaining mineral homeostasis have only recently begun to be explored. A decrease in the proliferation of T lymphocytes in the presence of $1,25(OH)_2D_3$ is correlated with a decrease in interleukin-2 (IL-2) mRNA and GM-CSF mRNA. Transcriptional repression of these genes contributes to the overall immunosuppressive effects of $1,25(OH)_2D_3$ (Alroy *et al.,* 1995; Towers *et al.,* 1999). Mechanisms involved in the repression by $1,25(OH)_2D_3$ of IL-2 and GM-CSF have been provided (Alroy *et al.,* 1995; Towers *et al.,* 1999). VDR can block the positive transcription factors NFATp and Jun/Fos, which bind to a composite site containing a consensus NFAT1-binding site. These findings provide novel insight concerning how $1,25(OH)_2D_3$ can act as an immunosuppressive agent and may provide a general mechanistic basis for how steroid receptors elicit immunosuppressive responses.

Transient Receptor Potential Vanilloid Type 6

Transient receptor potential vanilloid type 6 (TPRV6), the calcium channel in intestinal epithelial cell membranes, is regulated at the transcriptional level by $1,25(OH)_2D_3$ (Meyer *et al.,* 2006). The human TPRV6 promoter was found to contain multiple VDR/RXR binding sites (at –1.2, –2.1, –3.5, –4.3, and –5.5 kb). Only the elements at –2.1 and –4.3 kb were $1,25(OH)_2D_3$ responsive (Table 1). The unexpected feature of this study is the unusual distant location of the VDREs relative to the transcription start site, revealing new insight into how $1,25(OH)_2D_3$ acts and suggesting a chromatin looping mechanism whereby these regulatory regions can be brought into close proximity with the gene's natural promoter.

FACTORS INVOLVED IN VITAMIN D-MEDIATED TRANSCRIPTIONAL REGULATION

Vitamin D Receptor (VDR)

VDR Regulation

Due to the importance of VDR in the molecular mechanism of vitamin D action, the regulation of VDR has been a focus of a number of studies. Upregulation of VDR by $1,25(OH)_2D_3$ (known as homologous upregulation) has been shown in several different systems, including pig kidney LLCPK-1 cells (Costa *et al.,* 1985), HL-60 leukemia cells (Lee *et al.,* 1989), osteoblastic cells (Arbour *et al.,* 1993), calvarial tissue (Zella *et al.,* 2006), parathyroid gland (Naveh-Many *et al.,* 1990), and kidney (Healy *et al.,* 2003, 2005a). In kidney the induction of VDR and VDR mRNA by $1,25(OH)_2D_3$ is entirely dependent on levels of dietary calcium sufficient to maintain normal serum calcium (Healy *et al.,* 2003, 2005a). *In vivo* studies have shown that neither calcium nor $1,25(OH)_2D_3$ have any significant effect on intestinal VDR or VDR mRNA expression, indicating tissue-specific regulation of VDR (Huang *et al.,* 1989; Healy *et al.,* 2005a). Although homologous upregulation of the VDR has been reported to be due to increased stability of the occupied receptor (Lee *et al.,* 1989; Wiese *et al.,* 1992; Arbour *et al.,* 1993), recent studies showed that $1,25(OH)_2D_3$ can induce VDR, at least in bone, by an induction in transcriptional activity mediated by enhancers located within two introns of the mouse VDR gene (Zella *et al.,* 2006). VDR has also been reported to be regulated by a number of other factors, including PTH, activation of protein kinase A and protein kinase C. *In vivo* PTH decreases renal VDR expression, suggesting that PTH may be the trigger responsible for the hypocalcemia-mediated suppression of renal VDR (Healy *et al.,* 2005b). Treatment of NIHT3 mouse fibroblasts with forskolin (Krishnan and Feldman, 1992) and treatment of mouse osteoblasts (MC3T3-E1 cells) or rat osteosarcoma cells (UMR-106–01) with forskolin or PTH (Krishnan *et al.,* 1995) result in an induction in VDR abundance. Treatment of these cells with the phorbol ester, phorbol myristate acetate (PMA), whose actions are mediated by protein kinase C, results in a downregulation of VDR (Krishnan and Feldman, 1991; Krishnan *et al.,* 1995). Up- or downregulation of VDR in NIHT3 cells by forskolin or PMA, respectively, results in a corresponding induction or attenuation of reporter activity in cells transfected with the human OC VDRE fused to a reporter gene (Krishnan and Feldman, 1992). Treatment of UMR cells with PTH enhances the $1,25(OH)_2D_3$-mediated induction of 24(OH)ase mRNA (Krishnan *et al.,* 1995; Huening *et al.,* 2002). Thus the functional response corresponds to the change in VDR. However, opposite findings concerning the effect of activation of protein kinase A or protein kinase C on VDR have been reported by others

(Reinhardt and Horst, 1990, 1994; Barletta *et al.,* 2004), suggesting that proliferation state, cell type, and stage of differentiation affect the interaction between $1,25(OH)_2D_3$ and signal transduction pathways. In general, these studies suggest cooperativity between signal transduction pathways and $1,25(OH)_2D_3$. Effects of second messenger systems may be on the VDR. However, effects on the promoter of the target gene or on other transcription factors that may be interacting with the VDR also need to be considered (increased interaction between VDR and coactivators such as DRIP205 has been suggested as an additional mechanism that can couple extracellular signals to vitamin D action [Barletta *et al*., 2002; Liu *et al*., 2005]. Studies related to the regulation of VDR will be facilitated by further analysis of the hVDR gene that spans more than 60 kb, consists of at least 14 exons, and is directed by at least 2 distinct promoters (Miyamoto *et al.,* 1997).

Phosphorylation of the VDR

Although the VDR, similar to other steroid receptors, is phosphorylated, the exact functional role of phosphorylation of the VDR remains to be further elucidated. It has been suggested that phosphorylation may play a role in the binding of the receptor to DNA or in the interaction of VDR with other transcription factors. Phosphorylation of VDR was shown to involve serine residues. Serine-208 in the ligand-binding domain has been identified as a site of phosphorylation that accounts for at least 60% of the phosphorylation of the receptor (Hilliard *et al.,* 1994; Jurutka *et al.,* 1993). Casein kinase II has been reported to mediate VDR phosphorylation at serine-208 (Jurutka *et al.,* 1996). Although transcriptional activation by $1,25(OH)_2D_3$ is not dependent on serine-208 phosphorylation, studies have shown that VDR phosphorylation by casein kinase II at serine-208 can potentiate transcriptional activation (Jurutka *et al.,* 1996).

VDR Receptor Homodimerization vs. Heterodimerization

VDR functions as a heterodimer with RXR for activation of gene transcription. However, a few studies indicated that purified VDR can bind as a homodimer to certain VDREs but that RXR was required for binding to other VDREs (Freedman *et al.,* 1994; Nishikawa *et al.,* 1994). The physiological relevance of VDR homodimers has been questioned. Cheskis and Freedman (1994) reported that VDR exists as a monomer in solution and homodimerization occurs upon binding to the OPN VDRE. 1,25-Dihydroxyvitamin D_3 was reported to destabilize homodimerization, resulting in VDR/RXR heterodimer formation. Thompson *et al.* (1998) also reported that formation of the VDRE-complexed VDR-RXR heterodimer is strikingly dependent on the presence of $1,25(OH)_2D_3$. These studies suggest that although the VDR homodimer can exist in solution, the heterodimer is the functional transactivating species. 9-*cis*-Retinoic acid has been reported to decrease heterodimer formation by driving the equilibrium from the VDR heterodimer to the RXR homodimer or to the interaction of RXR with other receptors (Cheskis and Freedman, 1994; MacDonald *et al.,* 1993). Further studies using VDR mutants also suggest the importance of heterodimerization, as none of the mutants without the capability to form heterodimers showed $1,25(OH)_2D_3$-dependent transcriptional activation (Nakajima *et al.,* 1994).

Regions of VDR within the ligand-binding domain (LBD) that may be crucial for heterodimerization have been suggested. Mutagenesis studies have indicated that the regions in the C-terminal between amino acids 317 and 395 and between amino acids 244 and 263 corresponding to portions of helices 7–10 and 3–4, respectively, are important for ligand dependent heterodimerization (Nakajima *et al.,* 1994; Jin *et al.,* 1996; Rosen *et al.,* 1993; Whitfield *et al.,* 1995). The LBD of VDR also has been shown to be involved in protein-protein interaction of VDR with other cofactors. A more complete understanding of the three-dimensional contacts between VDR and RXR and between VDR and other accessory factors will be obtained now that the crystal structure of the VDR ligand domain bound to its ligand has been published (Rochel *et al.,* 2000).

Interaction of VDR with Transcription Machinery

The mechanisms involved in VDR-mediated transcription following binding of the VDR-RXR heterodimer to DNA are only now beginning to be defined. Initiation of basal transcription involves binding of TFIID, which is composed of the TATA box-binding protein and associated TAFs, to the TATA element. After the binding of TFIID to the TATA element, other factors, including TFIIA, TFIIB, RNA polymerase II, TFIIE, TFIIF, and TFIIH, are recruited and associated with the complex. Studies have suggested that VDR can interact physically and functionally with TFIIB (Blanco *et al.,* 1995; Masuyama *et al.,* 1997). The interaction of TFIIB is with unliganded VDR, and the $1,25(OH)_2D_3$ ligand disrupts the VDR-TFIIB complex (Masuyama *et al.,* 1997). These findings suggest that VDR prerecruits TFIIB and, in the presence of ligand, TFIIB is released for assembly into the preinitiation complex to facilitate activated transcription.

Several TAFs have been suggested to be involved in VDR-mediated transcriptional activity. The TFIID subunit $TAF_{II}135$ potentiates the transcriptional activity of VDR (Mengus *et al.,* 1997) and $TAF_{II}28$ (Mengus *et al.,* 2000) and $TAF_{II}55$ (Lavigne *et al.,* 1999) interact with VDR at α helices H3 to H5 and at α helix 8. Determinants for interaction with $TAF_{II}28$ or $TAF_{II}135$ are not identical. A mutation in the H3-H5 region that determines interaction with $TAF_{II}28$ was reported to abolish VDR-mediated transactivation (Mengus *et al.,* 2000).

SRC/p160 Coactivators

Over the past few years a number of proteins known as p160 coactivators (based on one of the first identified members, the 160-kDa protein, steroid receptor coactivator-1; SRC-1) that bind to steroid receptors and enhance their activity have been identified. Three related family members, based on homologies, include SRC-1(NcoA1 or p160), GRIP-1(TIF-2, NcoA-2, or SRC-2) and ACTR (pCIP, RAC3, or SRC-3) (for reviews, see McKenna *et al.,* 1999; Smith and O'Malley, 2004; Fig. 2). They interact with the AF2 domain of steroid receptors, including VDR (C-terminal helix 12 contains the core AF2) in a ligand-dependent manner. Studies indicate that helix 3 of the VDR is also important for interaction with p160 coactivators (Jimenez-Lara and Aranda 1999; Kraichely *et al.,* 1999). These coactivators share a series of LxxLL (or NR box) motifs and possess histone acetylase (HAT) activity. This modification of histones is thought to destabilize the interaction between DNA and the histone core, liberating DNA for transcription. These coactivators can also form complexes with CBP (CREB-binding protein). CBP also has HAT activity. Thus the SRC/p160 family of coactivators can recruit CBP to the nuclear receptor, resulting in a multisubunit complex.

Vitamin D Receptor Interacting Proteins (DRIP) Complex

VDR-mediated transcription is also mediated by a coactivator complex, DRIP (Rachez *et al.,* 1998, 1999; Fig. 2). These proteins are also called TRAP and ARC, depending on the transcription factor initially identified as the target (TR or androgen receptor, respectively), but are now thought to have broader target specificity due to their close identity. This complex does not have HAT activity but rather functions, at least in part, through recruitment of RNA polymerase II (Rachez *et al.,* 1999). Results of chromatin immunoprecipitation assays have indicated that the CBP/SRC coactivator complex may be needed first for chromatin remodeling followed by the recruitment of the transcription machinery by the DRIP/TRAP/ARC complex (sequential model).

OTHER FACTORS MODULATING VDR-MEDIATED TRANSCRIPTION

Various additional factors have been reported to modulate VDR-mediated transcription. A binding site for the

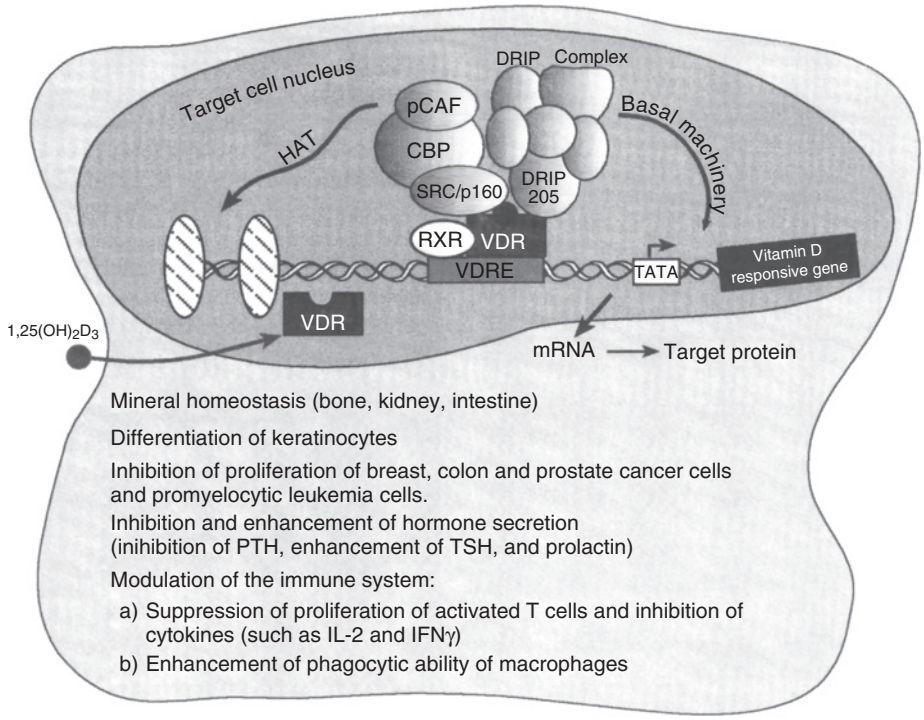

FIGURE 2 Genomic mechanism of action of $1,25(OH)_2D_3$ in target cells. 1,25-Dihydroxyvitamin enters the target cell and interacts with the nuclear VDR, which heterodimerizes with RXR. After interaction with the VDRE, transcriptional activation or repression proceeds through the interaction of VDR with coactivators and with the transcription machinery. Two models for the genomic action of $1,25(OH)_2D_3$ are shown. The histone acetyltransferase (HAT) activity-containing complex of SRC/p160 and CBP may be recruited first by VDR in response to the ligand. This would lead to DNA accessibility that would allow as a second step the binding of the DRIP complex (DRIP 205 subunit binds directly to VDR) and recruitment of RNA polymerase II (sequential model). Alternatively, there could be simultaneous chromatin remodeling and basal machinery recruitment (cooperative model). 1,25-Dihydroxyvitamin D_3 is known to affect mineral homeostasis, to differentiate keratinocytes, to inhibit the proliferation of cancer cells, to affect hormone secretion, and to modulate the immune system. Adapted with permission from Christakos *et al.* (1996).

Ras-activated Ets transcription factor was identified downstream from the proximal VDRE in the rat 24(OH)ase promoter, and this site was found to be critical for $1,25(OH)_2D_3$ mediated 24(OH)ase transcription (Dwivedi *et al.,* 2000). The multifunctional transcriptional regulator YY1 represses $1,25(OH)_2D_3$-induced transcription of 24(OH)ase and OC (Raval-Pandya *et al*., 2001; Guo *et al*., 1997). CCAAT enhancer binding protein (C/EBP) β and δ are induced by $1,25(OH)_2D_3$ in osteoblasts and can enhance 24(OH)ase and OC transcription (Dhawan *et al.,* 2005; Gutierrez *et al.,* 2002). In the regulation of OC transcription there is synergism between C/EBP β and Runx2 mediated by the interaction between Runx2 and C/EBP β (Gutierrez *et al.,* 2002). C/EBP β has also been reported to be involved in the immune-mediated regulation of 1α-hydroxylase in monocytes and macrophages (Esteban *et al.,* 2004; Stoffels *et al.,* 2007).

SWI/SNF, complexes that remodel chromatin using the energy of ATP hydrolysis, are also involved in VDR-mediated transcription. Functional cooperation between C/EBP β and SWI/SNF has been reported in the regulation of $1,25(OH)_2D_3$-induced 24(OH)ase and OC transcription (Christakos *et al.,* 2006; Villagra *et al.,* 2006).

Preliminary results have indicated that cooperativity between histone methyltransferases and p160 coactivators may also play a fundamental role in VDR-mediated transcriptional activation (Christakos *et al.*, 2007).

FUTURE DIRECTIONS

New target genes, novel vitamin D responsive elements, and new factors involved in vitamin D-mediated transcription will undoubtedly be identified in numerous different systems, which are currently known to be affected by $1,25(OH)_2D_3$. Sequences divergent from the current consensus VDRE or at distant locations from the transcriptional start site may be observed, which should expand our understanding of $1,25(OH)_2D_3$-mediated genomic responses. In addition to transcriptional regulation, it is likely that post-transcriptional mechanisms will be an important mechanism of control of a number of newly identified target genes. In addition to studies concerning the mechanisms involved in mediating the genomic actions of $1,25(OH)_2D_3$, further studies related to the physiological significance of target proteins using null mutant mice are needed in the future. Finally, in the next few years, with the elucidation of the crystal structure of VDR, we will obtain an increased understanding of the structure of VDR in the presence and absence of ligand and/or protein partners. Based on the structural information, synthetic analogs of $1,25(OH)_2D_3$ may be designed that would selectively modulate specific $1,25(OH)_2D_3$ responses. Thus, new insight into the multiple roles of $1,25(OH)_2D_3$ will be obtained and selective modulation of $1,25(OH)_2D_3$ responses in bone and other target tissues may indeed be possible.

Chapter 37

Photobiology and Noncalcemic Actions of Vitamin D

Michael F. Holick
Boston University School of Medicine, Boston, Massachusetts

PHOTOBIOLOGY OF VITAMIN D

Photosynthesis of Provitamin D_3 and Its Conversion to Vitamin D_3

When human skin is exposed to sunlight, a photo-chemical process occurs that is essential for the maintenance of calcium homeostasis and a healthy skeleton. During exposure to sunlight, the ultraviolet B (UV-B; 290–315 nm) portion of the solar spectrum is responsible for photolyzing 7-dehydrocholesterol (the precursor cholesterol; provitamin D_3) to previtamin D_3(Holick, 1994). Once formed, previtamin D_3 undergoes an internal isomerization of its three double bonds to form a more thermodynamically stable, 5,6-cis-triene and is transformed in vitamin D_3 (Fig. 1). For warm-blooded animals, such as humans, this process would, under normal circumstances, take approximately 24 hr for 50% of previtamin D_3 to convert to vitamin D_3. However, in cold-blooded animals, this process could take several days (Holick *et al.,* 1980). It has now been found that there is membrane enhancement for the conversion of previtamin D_3 to vitamin D_3 in both cold-blooded and warm-blooded animals, including humans (Holick *et al.,* 1995). 7-Dehydrocholesterol is found principally in the cell membrane. Within the membrane, the hydrophobic side chain of 7-dehydrocholesterol is aligned with the hydrophobic chains of the fatty acids and cholesterol, thereby restraining the confirmation of previtamin D_3 when it is formed (Tian *et al.*, 1993) (Fig. 2). Thus, when 7-dehydrocholesterol is exposed to sunlight, 7-dehydrocholesterol is photolyzed to the s-*cis,* s-*cis* conformer of previtamin D_3. In an organic solvent, the s-cis, s-*cis*-previtamin D_3 conformer is thermodynamically unstable and immediately isomerizes to the s-*cis,* s-*trans* form. Because only the s-*cis,* s-*cis* conformer is able to isomerize to vitamin D_3, the entrapment of previtamin D_3 in its s-*cis,* s-*cis* form within the plasma membrane promotes a more than 10-fold increase in its rate of isomerization to vitamin D_3 when compared to the same reaction in an organic solvent (Tian *et al.,* 1994; Holick *et al.,* 1995). This process guarantees that the precious previtamin D_3 that is made in the skin is converted efficiently to vitamin D_3. In addition, as vitamin D_3 is being formed from previtamin D_3, its conformational change probably permits it to selectively exit from the membrane into the extracellular space.

Factors That Regulate Photosynthesis of Previtamin D_3 in Skin

Sunlight-Mediated Photolysis

It is well known that intense prolonged exposure to sunlight will not cause vitamin D intoxication. The reason for this is that during the initial exposure to sunlight, 7-dehydrocholesterol is converted to previtamin D_3. However, because previtamin D_3 is photolabile, when exposed to sunlight it is converted to lumisterol and tachysterol, which are thought to be biologically inert on calcium metabolism (Holick *et al.,* 1981) (Fig. 1). Once previtamin D_3 is isomerized to vitamin D_3, vitamin D_3 is also extremely photosensitive and is isomerized rapidly by sunlight to supersterol 1, suprasterol 2, and 5,6-transvitamin D_3 (Fig. 1), which are also thought to be either biologically inert or have less activity on calcium metabolism than vitamin D_3 (Webb *et al.,* 1989).

Melanin, Sunscreens, Clothing, Glass, and Plastics

Melanin is a natural sunscreen that effectively absorbs ultraviolet B radiation, thereby competing with 7-dehydrocholesterol for these photons. As a result, increased skin pigmentation requires longer exposure to sunlight to produce the same amount of previtamin D_3 as in a lighter-skinned individual (Clemens *et al.,* 1982).

Sunscreen use is highly recommended, especially for individuals who are prone to sunburning. Sunscreens like

Principles of Bone Biology, 3rd Edition

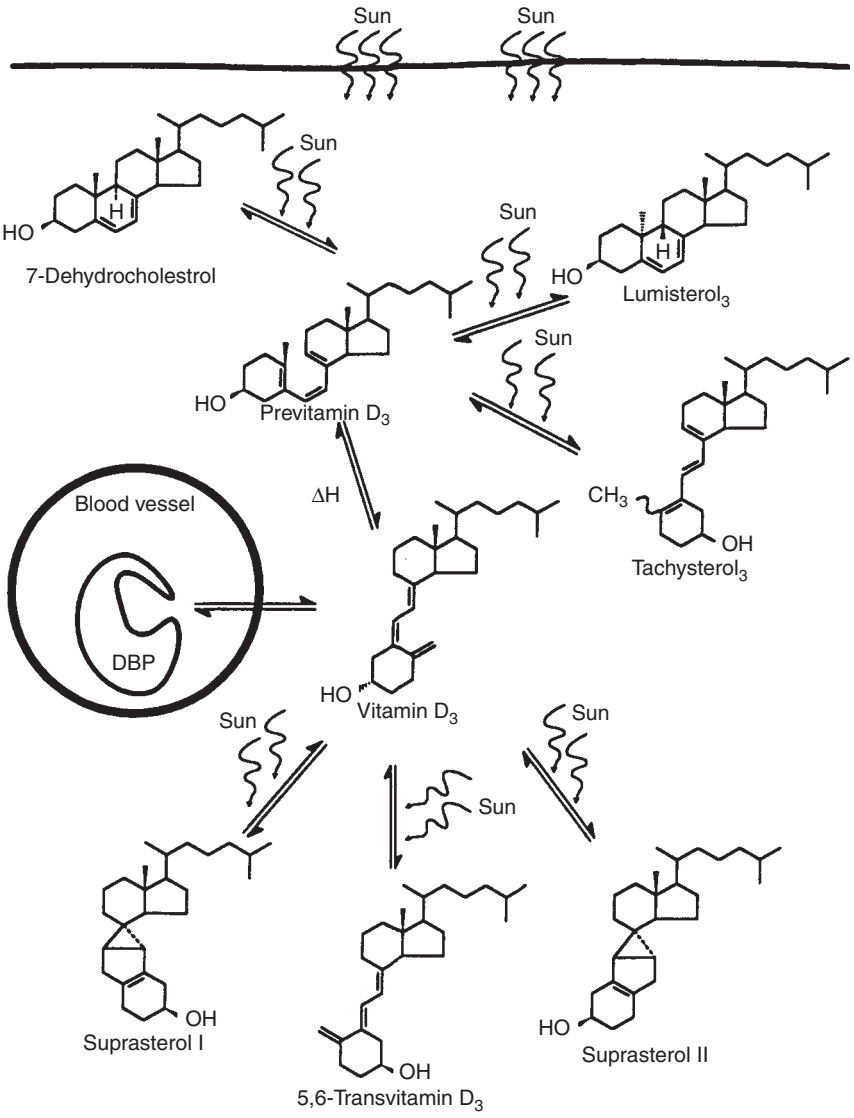

FIGURE 1 Photochemical events in the skin that lead to the production of vitamin D_3 and the regulation of vitamin D_3 in the skin. Reproduced with permission from Holick (1994).

melanin absorb ultraviolet B radiation. Therefore, the topical application of a sunscreen will substantially diminish or completely prevent the cutaneous production of previtamin D_3. When young adults were covered with a sunscreen preparation with a sun protection factor of 8 (SPF 8) followed by a whole body exposure to one minimal erythemal dose of simulated sunlight, they were unable to elevate their circulating concentrations of vitamin D above baseline values (Matsuoka *et al.,* 1987) (Fig. 3). Similarly, clothing absorbs most ultraviolet radiation and therefore prevents the cutaneous production of vitamin D_3 (Matsuoka *et al.,* 1994). Chronic use of a sunscreen will diminish circulating concentrations of 25-hydroxyvitamin D_3 as a measure of vitamin D status (Matsuoka *et al.,* 1998). In addition to sunscreens, exposure of the skin to sunlight that has passed through windowpane glass or Plexiglas will not permit any significant synthesis of vitamin D_3 in the skin because most glass and plastics absorb ultraviolet B radiation efficiently (Holick, 1994).

Aging

Aging influences a variety of metabolic processes. Therefore, it is not surprising that aging also markedly decreases the free concentrations of 7-dehydrocholesterol in the epidermis (MacLaughlin and Holick, 1985). When healthy young and elderly volunteers were exposed to the same amount of simulated sunlight, the circulating concentrations of vitamin D in the young volunteers (aged 22–30 years) increased to a maximum of 30 ng/ml within 24 hr after exposure, whereas

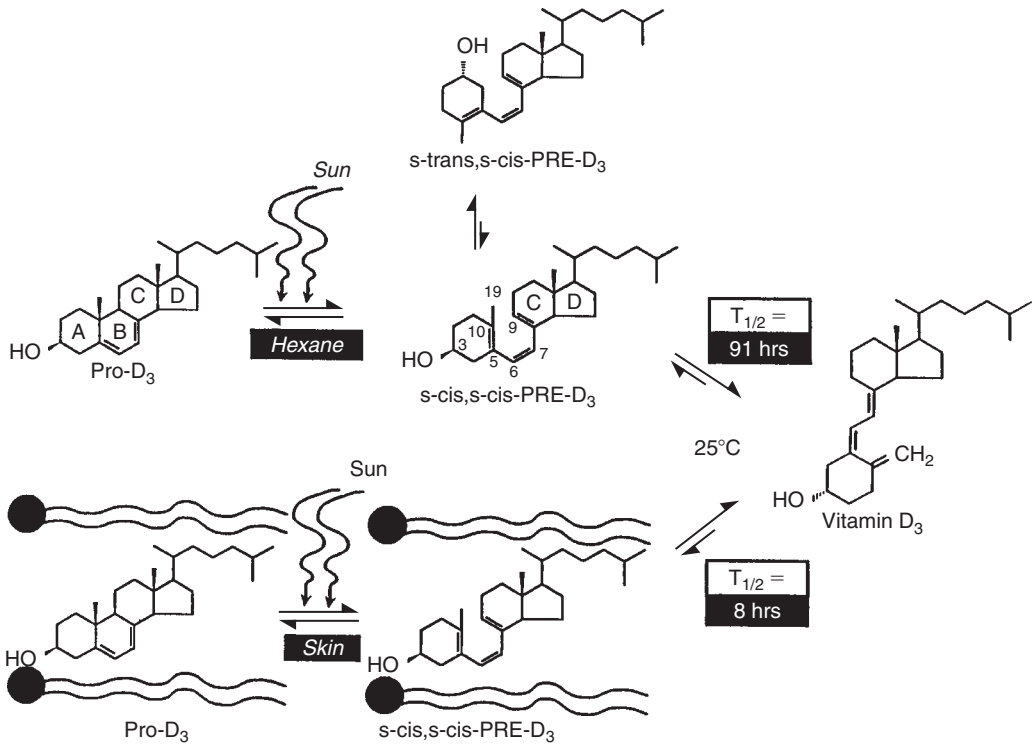

FIGURE 2 Photolysis of provitamin D_3 (pro-D_3) into previtamin D_3 (pre-D_3) and its thermal isomerization to vitamin D_3 in hexane and in skin. In hexane, pro-D_3 is photolyzed to s-*cis*,s-*cis*-pre-D_3. Once formed, this energetically unstable conformation undergoes a conformational change to the s-*trans*,s-*cis*-pre-D_3. Only the s-*cis*,s-*cis*-pre-D_3 can undergo thermal isomerization to vitamin D_3. The s-*cis*,s-*cis* conformer of pre-D_3 is stabilized in the phospholipid bilayer by hydrophilic interactions between the 3β–hydroxyl group and the polar head of the lipids, as well as by van der Waals' interactions between the steroid ring and side chain structure and the hydrophobic tail of the membrane lipids. This "entrapment" significantly decreases its conversion to the s-*trans*,s-*cis* conformer, thereby facilitating the thermal isomerization of s-*cis*,s-*cis*-pre-D_3 to vitamin D_3. Reproduced with permission from Holick *et al.* (1995).

Adapted from Matsuoka *et al.*, 1987. Reproduced with permission from Holick (1994).

the older subjects (aged 62–80 years) were only able to achieve a maximum concentration of 8 ng/ml (Holick *et al.*, 1989) (Fig. 4).

Season, Latitude, and Time of Day

Season, latitude, and time of day can greatly influence the cutaneous production of vitamin D_3. As the zenith angle of the sun becomes more oblique, the ultraviolet B photons have to pass through the stratospheric ozone layer at a more oblique angle. This results in the ozone layer absorbing an increasing number of ultraviolet B photons. This can have a dramatic effect on the cutaneous production of previtamin D_3 (Webb *et al.*, 1988) (Fig. 5). In Boston, exposure to sunlight between the months of March and October is capable of producing previtamin D_3 in the skin. However, between the months of November and February, little if any cutaneous vitamin D_3 production can occur no matter how long one stays outdoors. The time of day also

FIGURE 4 Circulating concentrations of vitamin D in response to a whole body exposure to one minimal erythemal dose in healthy young and elderly subjects. Adapted from Holick *et al.* (1989). Reproduced with permission from Holick (1994).

greatly influences the cutaneous production of vitamin D_3 (Fig. 6). During the summer in Boston, exposure of the skin to sunlight from 07:00 to as late as 17:00 hr eastern standard time (EST) resulted in previtamin D_3 production in human skin. However, in the spring and autumn, previtamin D_3 synthesis began at approximately 09:00 EST and ceased at approximately 15:00 EST.

PERSPECTIVE ON UTILIZATION OF SUNLIGHT FOR VITAMIN D

It is not well appreciated that casual exposure to sunlight provides most of us with our vitamin D requirement. With the exception of cod liver oil, fatty fish, and other fish liver oils, there are very few foods that have naturally occurring vitamin D. Although some foods are fortified with vitamin D, most notably milk, a recent survey of the vitamin D content in milk suggests that more than 50% of milk samples in the United States contained less than 80% of the vitamin D content stated on the label and approximately 15% contained no detectable vitamin D (Tanner *et al.,* 1988; Holick *et al.,* 1992; Chen *et al.,* 1993). Some orange juices are fortified with 100 IU of vitamin D_3 along with 300 mg calcium/8 oz.

The alarming increase in the incidence of skin cancer that has been directly related to an increased exposure to sunlight has prompted widespread use of sunscreening agents for preventing the damaging effects of sunlight on the skin. Because children and young adults will not routinely cover all sun-exposed areas with a sunscreen all of the time, there is no need for concern about the topical use of sunscreens in causing vitamin D deficiency in this population. However, elderly people, who have decreased capacity to produce vitamin D_3 in their skin, are concerned about developing wrinkles and skin cancer and will religiously topically apply a sunscreen on all sun-exposed areas before going outdoors. This can result in vitamin D insufficiency

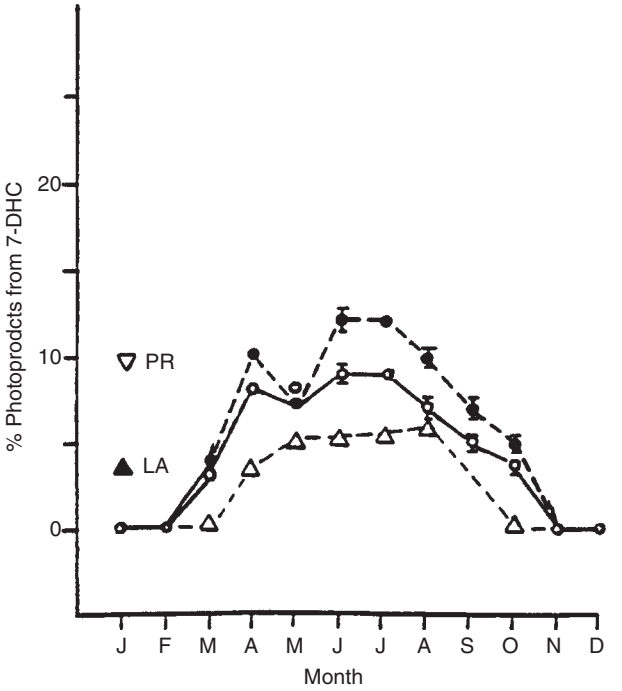

FIGURE 5 Photosynthesis of previtamin D_3 lumisterol, and tachysterol (photoproducts) after exposure of 7-dehydrocholesterol to sunlight in Boston (42° N) for 1 (○) and 3 (●) hours, Edmonton, Canada (52°N) after 1 hour (△) each month for 1 year, Los Angeles (34°N) (▲) and Puerto Rico (18°) in January (▽). Adapted from Webb *et al.* (1988).

or overt vitamin D deficiency (Matsuoka *et al.,* 1988). People over 65 years of age who are not taking a vitamin D supplement can satisfy their bodies' vitamin D requirement by exposing their hands, arms, and face to suberythemal doses of sunlight (usually 5 to 15 min, depending on location and time of day) two to three times a week. For

those who wish to stay outdoors for longer than the initial suberythemal exposure, it is recommended that they apply a sunscreen with a sun protection factor of equal to or greater than 15 to sun-exposed areas. Therefore, the intelligent use of sunlight to promote the cutaneous synthesis of vitamin D_3 and the topical use of sunscreening agents after the initial exposure prevent the damaging effects due to excessive chronic exposure to sunlight while providing it beneficial effect: vitamin D_3 (Holick, 1994).

VITAMIN D METABOLISM

Once vitamin D is made in the skin or ingested in the diet, it is bound to the vitamin D-binding protein (DBP). It travels to the liver where it is metabolized to 25-hydroxyvitamin D [25(OH)D]. Once formed, it leaves the liver bound to the DBP and is filtered in the gomerulus into the ultrafiltrate. 25(OH)D-DBP is reabsorbed from the ultrafiltrate by the tubules by the endocytitic receptor megalin (Nykjaer *et al.,* 1999). This endocytotic process is required to preserve 25(OH)D and to deliver it to the renal tubular cells for cytochrome P_{450} 25(OH)D-1 α-hydroxylase (1α-OHase). This mitochondrial enzyme hydroxylates 25(OH)D on carbon 1 to form the biologically active form of vitamin D: 1,25-dihydroxyvitamin D [1,25$(OH)_2$D](Holick, 1999; Holick 2007) (Fig. 7).

Originally, it was believed that the kidney was the sole source of 1α-OHase. This was based on the observation that anephric rats could not metabolize 25$(OH)D_3$ to 1,25$(OH)_2D_3$ (DeLuca, 1988; Holick, 1989b). This was also confirmed by many observations that low and undetectable concentrations of 1,25$(OH)_2D_3$ are present in patients who have no kidneys or no kidney function (Holick, 1989b). There is, however, compelling evidence that a wide variety of tissues also possess 1α-OHase activity. The first tissue demonstrated to have 1α-OHase was the skin (Bikle *et al.,* 1986). It has now been demonstrated that normal prostate and prostate cancer cells express 1α-OHase activity (Schwartz *et al.,* 1998). Using *in situ* hybridization and antibodies to 1α-OHase, it was found that 1α-OHase was present in the basal keratinocytes, hair follicles, lymph nodes, parasympathetic ganglion, pancreas, islet cells, adrenal medulla, brain (cerebellum and cerebral cortex), and placenta (Zehnder *et al.,* 2001).

Although the exact function of the extrarenal 1α-OHase is not well understood, it appears that this enzyme may be important for producing 1,25$(OH)_2D_3$ locally to act as a cellular growth modulator (Holick, 2007) (Fig. 8). To determine the effect of this enzyme on cellular growth and differentiation, we made a plasmid construct containing the 1α-OHase gene that was tagged with the green fluorescent protein gene (Flanagan *et al.,* 1999). A prostate cell line LnCaP that has a vitamin D receptor (VDR) but no 1α-OHase activity was transfected with the 1α-OHase plasmid. It was observed that cells expressed in their mitochondria a protein that had green fluorescence. These cells also had the capability of converting 25$(OH)D_3$ to 1,25$(OH)_2D_3$, whereas cells transfected with on empty vector were unable to produce any 1,25$(OH)_2D_3$. Cells transfected with the 1α-OHase construct were exposed to 25$(OH)D_3$, as were cells transfected with the empty vector construct. Cells transfected with 1α-OHase gene had decreased proliferative activity in the presence of 10^{-8} and 10^{-7} *M* 25$(OH)D_3$ whereas there was no effect in cells transfected with the empty vector (Flanagan *et al.,* 1999; Whitlatch *et al.,* 2002). These results suggest that 1,25$(OH)_2D_3$ may be produced locally in a wide variety of cells and that the function of 1,25$(OH)_2D_3$ is to regulate cell growth (Holick, 2001). Indeed, there have been numerous reports of the expression and activity of 1-OHase in normal and maligant human colon tissue (Tangpricha 2002), (Cross *et al.*, 2001), lung (Mawrer *et al.*, 1994), pancrease among other tissues (Chen and Holick, 2003; Holick 2007). This could be the explanation for why people who live at higher latitudes, and therefore make less vitamin D_3, are more likely to die of colon, breast, prostate, and ovarian cancer (Garland *et al.,* 1989, 1991; Ahonen *et al.,* 2000; Schwartz *et al.,* 1998; Gorham *et al.*, 2005; Grant and Garland 2005). It may be that higher circulating concentrations of 25(OH)D are required in order for the extrarenal 1α-OHase to maximally function to produce 1,25$(OH)_2D_3$ locally to regulate cell growth and prevent metastatic activity of cells that become cancerous (Holick, 1999; Holick 2001; Holick 2006; Holick 2007).

NONCALCEMIC ACTIONS OF 1,25-DIHYDROXYVITAMIN D_3

Nuclear Localization of ^{3}H-1,25$(OH)_2D_3$ in Noncalcemic Tissues

In 1979, Stumpf and colleagues reported that autoradiographic analysis of frozen sections of tissues from vitamin D-deficient rats that received an intravenous injection of [^{3}H-]1,25$(OH)_2D_3$ showed nuclear localization of [^{3}H-]1,25$(OH)_2D_3$ in a multitude of tissues that were not associated with calcium metabolism, including pituitary gland, thymus, gonads, stomach, breast, pancreas, and skin. Since this initial observation, a variety of investigators have reported that these tissues, as well as transformed cells and cancer cells, possess a vitamin D receptor (VDR) (Table I) (Eisman *et al.,* 1981; Colston *et al.,* 1981; Abe *et al.,* 1981; Tanaka *et al.,* 1982; Simpson *et al.,* 1985; Holick, 1995).

Noncalcemic Functions of 1,25-Dihydroxyvitamin D_3

Cancer Cells

Initially, when normal tissues and cells such as the skin and immune cells were found to have receptors for 1,25$(OH)_2D$, it was thought that this was either an artifact or was of little

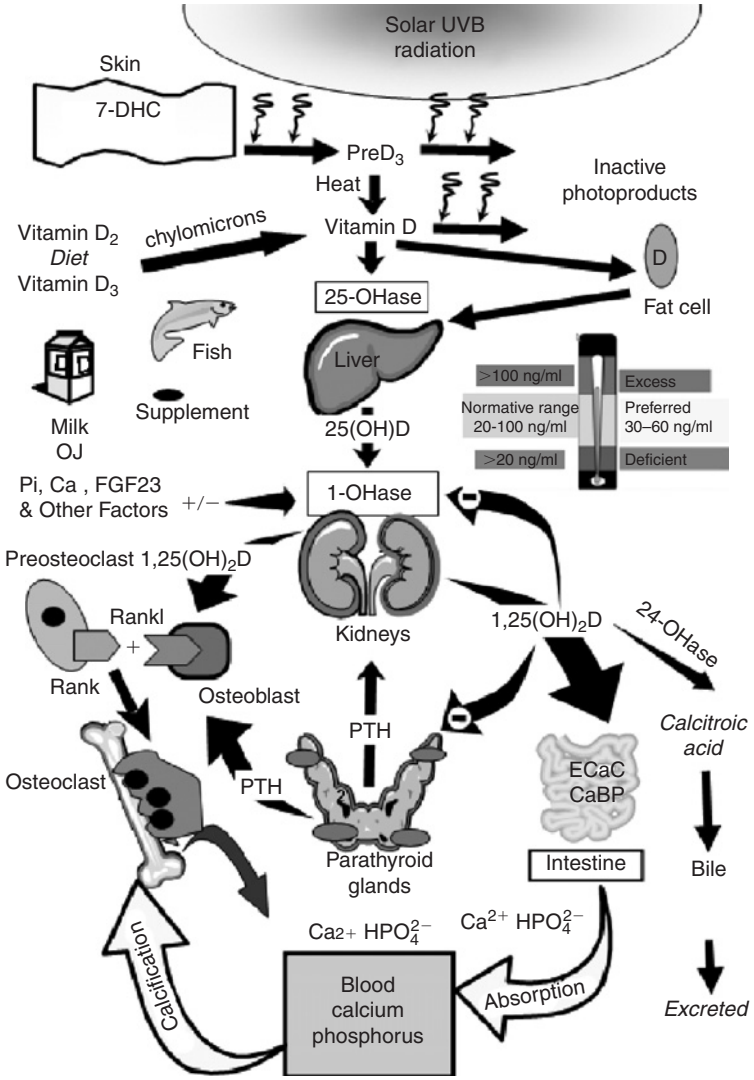

FIGURE 7 Schematic representation of the synthesis and metabolism of vitamin D for regulating calcium, phosphorus, and bone metabolism. During exposure to sunlight 7-dehydrocholesterol (7-DHC) in the skin is converted to previtamin D_3 (preD_3). PreD_3 immediately converts by a heat-dependent process to vitamin D_3. Excessive exposure to sunlight degrades previtamin D_3 and vitamin D_3 into inactive photoproducts. Vitamin D_2 and vitamin D_3 from dietary sources are incorporated into chylomicrons, transported by the lymphatic system into the venous circulation. Vitamin D (D represents D_2 or D_3) made in the skin or ingested in the diet can be stored in and then released from fat cells. Vitamin D in the circulation is bound to the vitamin D binding protein that transports it to the liver where vitamin D is converted by the vitamin D-25-hydroxylase (25-OHase) to 25-hydroxyvitamin D [25(OH)D]. This is the major circulating form of vitamin D that is used by clinicians to measure vitamin D status (although most reference laboratories report the normal range to be 20–100 ng/ml, the preferred healthful range is 30–60 ng/ml). 25(OH)D is biologically inactive and must be converted in the kidneys by the 25-hydroxyvitamin D-1α-hydroxylase (1-OHase) to its biologically active form 1,25-dihydroxyvitamin D [1,25$(OH)_2$D]. Serum phosphorus, calcium, fibroblast growth factor (FGF-23) and other factors can either increase (+) or decrease (−) the renal production of 1,25$(OH)_2$D. 1,25$(OH)_2$D feedback regulates its own synthesis and decreases the synthesis and secretion of parathyroid hormone (PTH) in the parathyroid glands. 1,25$(OH)_2$D increases the expression of the 25-hydroxyvitamin D-24-hydroxylase (24-OHase) to catabolize 1,25$(OH)_2$D and 25(OH)D to the water soluble biologically inactive calcitroic acid that is excreted in the bile. 1,25$(OH)_2$D enhances intestinal calcium absorption in the small intestine by stimulating the expression of the epithelial calcium channel (ECaC; also known as transient receptor potential cation channel subfamily V member 6; TRPV6) and the calbindin 9 K (calcium-binding protein; CaBP). 1,25$(OH)_2$D is recognized by its receptor in osteoblasts causing an increase in the expression of receptor activator of NFκB ligand (RANKL). Its receptor RANK on the preosteoclast binds RANKL, which induces the preosteoclast to become a mature osteoclast. The mature osteoclast removes calcium and phosphorus from the bone to maintain blood calcium and phosphorus levels. Adequate calcium and phosphorus levels promote the mineralization of the skeleton and maintain neuromuscular function. Holick copyright 2007, with permission.

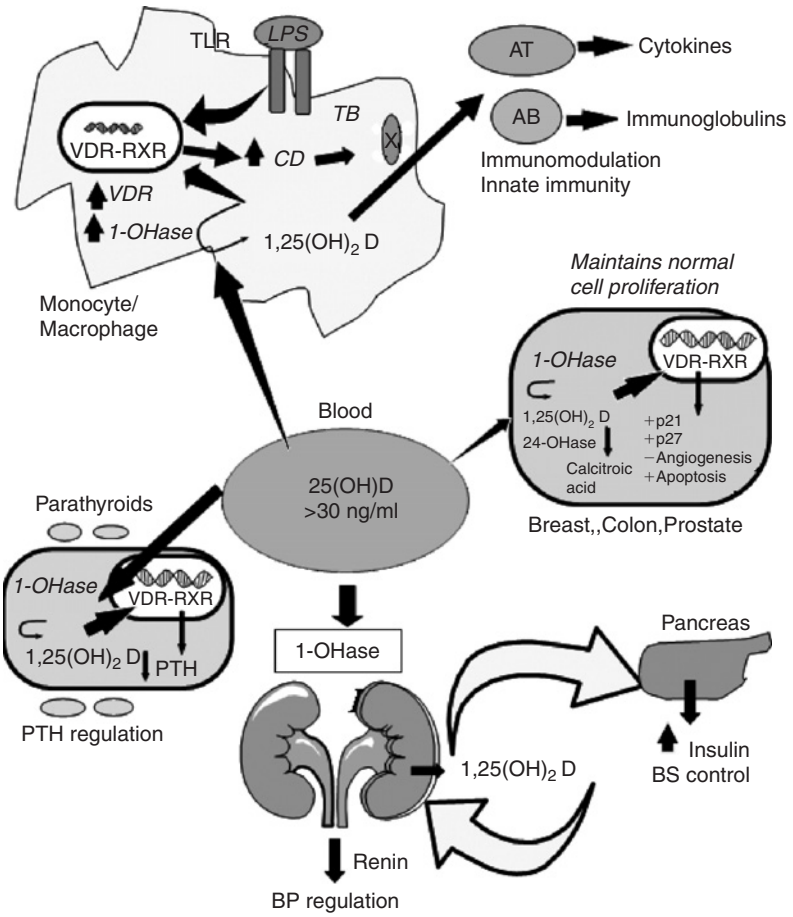

FIGURE 8 Metabolism of 25-hydroxyvitamin D [25(OH)D] to 1,25 dihydroxyvitamin D $1,25(OH)_2D$ for nonskeletal functions. When a monocyte/macrophage is stimulated through its toll-like receptor 2/1 (TLR2/1) by an infective agent such as Mycobacterium tuberculosis (TB) or its lipopolysaccharide (LPS), the signal upregulates the expression of vitamin D receptor (VDR) and the 25-hydroxyvitamin D-1-hydroxylase (1-OHase). 25(OH)D levels >30 ng/ml provides adequate substrate for the 1-OHase to convert it to 1,25(OH)2D. $1,25(OH)_2D$ returns to the nucleus where it increases the expression of cathelicidin (CD), which is a peptide capable of promoting innate immunity and inducing the destruction of infective agents such as TB. It is also likely that the $1,25(OH)_2D$ produced in the monocytes/macrophage is released to act locally on activated T (AT) and activated B (AB) lymphocytes, which regulate cytokine and immunoglobulin synthesis, respectively. When 25(OH)D levels are ≈30 ng/ml, it reduces risk of many common cancers. It is believed that the local production of $1,25(OH)_2D$ in the breast, colon, prostate, and other cells regulates a variety of genes that control proliferation including p21 and p27 as well as genes that inhibit angiogenesis and induced apoptosis. Once $1,25(OH)_2D$ completes the task of maintaining normal cellular proliferation and differentiation, it induces the 25-hydroxyvitamin D-24-hydroxylase (24-OHase). The 24-OHase enhances the metabolism of $1,25(OH)_2D$ to calcitroic acid, which is biologically inert. Thus, the local production of $1,25(OH)_2D$ does not enter the circulation and has no influence on calcium metabolism. The parathyroid glands have 1-OHase activity and the local production of $1,25(OH)_2D$ inhibits the expression and synthesis of PTH. The production of $1,25(OH)_2D$ in the kidney enters the circulation and is able to downregulate renin production in the kidney and to stimulate insulin secretion in the β-islet cells of the pancreas. Holick copyright 2007, with permission.

physiologic significance. In 1981, Eisman and co-workers reported that 80% of 54 breast cancer tissues possessed VDR activity. During the same year, Abe *et al.* (1981) and Feldman *et al.* (1982) reported that a mouse myeloid leukemic cell line (M-1) and melanoma cells, respectively, possessed a VDR (VDR+). Abe *et al.* (1981) showed a dose-dependent induction of differentiation of these myeloid leukemic cells by $1,25(OH)_2D_3$, and Colston *et al.* (1981) found that $1,25(OH)_2D_3$ inhibited melanoma cell proliferation. Cultured human promyleocytic leukemic cells (HL-60), which were VDR+ , responded in a similar fashion (Tanaka *et al.,* 1982; Suda *et al.,* 1984). $1,25(OH)_2D_3$ was found to decrease cellular proliferative activity, reduce c-myc-mRNA, and induce the expression of monocyte-specific cell surface antigen 63D3 (Tanaka *et al.,* 1982). Of great interest was the *in vivo* observation that when M-1 leukemic mice were treated with $1,25(OH)_2D_3$ or 1α-hydroxyvitamin D_3 ($1\alpha(OH)D_3$), their survival was enhanced substantially compared to the control group (Honma *et al.,* 1982). This suggested the possibility of using $1,25(OH)_2D_3$ or one of its analogs as an antiproliferative agent for the treatment of some leukemias and other malignant disorders.

Stomach	Cardiac muscle
Placenta	Brain

Immune System

In the early 1980s, with the revelation that many tissues possessed a VDR, it was of great interest to determine whether cells of the immune system also possessed a VDR. Initial studies showed that resting T lymphocytes from the circulation did not possess VDR activity. However, upon stimulation with phytohemoglutinin or concanavalin A (Con A), these cells were induced to produce a VDR (Bhalla *et al.,* 1983; Tsoukas *et al.,* 1984). Once activated T lymphocytes developed VDR activity, they responded to $1,25(OH)_2D_3$ in a variety of ways, including decreased interleukin (IL)-2, interferon-γ, and GM-CSF production (Tsoukas *et al.,* 1984; Bhalla *et al.,* 1986; Binderup, 1992; Vanhan *et al*., 1989). Like resting T lymphocytes, resting B lymphocytes do not possess a VDR. When B cells were stimulated, a VDR was induced, which resulted in decreased DNA synthesis and immunoglobulin production in response to $1,25(OH)_2D_3$ (Lemire *et al.,* 1984; Provvedini *et al.,* 1986b). (Moller *et al.,* 1991) Circulating monocytes also possessed a VDR. In transformed and normal monocytes, $1,25(OH)_2D_3$ induced phagocytic activity in a time-and dose-dependent manner, increased OKII binding, augmented IL-1 production, enhanced lysosomal activity, and increased expression of cell surface antigens, including Fc and C_3 (Gray and Cohen, 1985; Amento, 1987; Suda *et al.,* 1984). When normal human monocytes were incubated with $1,25(OH)_2D_3$, cells developed morphologic and enzymatic changes consistent with their differentiation into macrophages (Provvedini *et al.,* 1986a).

Therefore, it would appear that the immune system is potentially very sensitive to the modulating activities of $1,25(OH)_2D_3$. However, the exact physiological role of $1,25(OH)_2D_3$ on regulating the immune system is not well understood. An insight into the potential physiologic action of $1,25(OH)_2D_3$ on the immune system can best be seen in animals and patients with vitamin D deficiency and in patients with an inborn error in the metabolism of 25-OH-D to $1,25(OH)_2D$ or a defective VDR. Patients with vitamin D-deficient rickets have been noted to have recurrent infections, mainly of the respiratory tract (Lorente *et al.,* 1976). Vitamin D-deficient patients also have a depressed inflammatory and phagocytic response that is corrected by vitamin D replacement (Lorente *et al.,* 1976). A more subtle defect in the immune system is seen in patients with vitamin D receptor defects [vitamin D-dependent rickets type II (DDR II)]. Circulating mononuclear cells from these patients that had been stimulated previously with Con A did not respond to the same degree as normal monocytic cells to the antiproliferative activity of $1,25(OH)_2D_3$ (Koren *et al.,* 1985). Furthermore, $1,25(OH)_2D_3$ and 1α-OH-D_3 treatment restored deficient macrophage and lymphocyte activities in vitamin D-deficient rats, in patients with vitamin D resistance, and in renal failure patients (Weintraub *et al.,* 1989; Binderup, 1992; Kitajima, 1989; Tabata *et al.,* 1988).

As early as 1849, it was appreciated that cod liver oil was effective in treating tuberculosis. In the early 1900's, patients with TB were routinely sent to sunny areas or at higher altitudes to help in their treatment. How sunlight and vitamin D played a role in the prevention and treatment of TB was unclear until Liu *et al.*, 2006 reported that the local production of $1,25(OH)_2D_3$ plays a critical role in innate immunity. Exposure of monocytes/macrophages to either lipopolysaccharide or mycobacterium tuberculosis induced the toll-like receptors which in turn enhanced the nuclear expression of the VDR and the 1-OHase (Fig. 8). Further investigation revealed that the local increase of $1,25(OH)_2D_3$ in these monocytes/macrophage increased the expression of the bacteriocidal protein cathelicidin. To make certain that the observation was clinically relevant, they took serum from African-Americans who typically have a circulating level of 25(OH)D of < 20 ng/ml and infected monocytes with TB. The monocytes/macrophages were unable to significantly increase the production of cathelicidin. When the African-American serum was supplemented with $25(OH)D_3$ to a concentration that is typical for a Caucasian, i.e. $\sim$26 ng/ml, the monocytes/macrophages enhance cathelicidin expression by 5 fold and they destroyed the TB. Based on this observation, it was suggested that raising blood levels of 25(OH)D to > 26 ng/ml is clinically important for innate immunity, and may help explain why African-Americans who are more prone to vitamin D deficiency are also more likely to be infected with TB and have more aggressive illness.

$1,25(OH)_2D_3$ has a variety of *in vitro* and *in vivo* effects on the immune system. However, the *in vitro* observations do not necessarily predict *in vivo* outcomes. This may be due to the multitude of effects $1,25(OH)_2D$ has on T and B

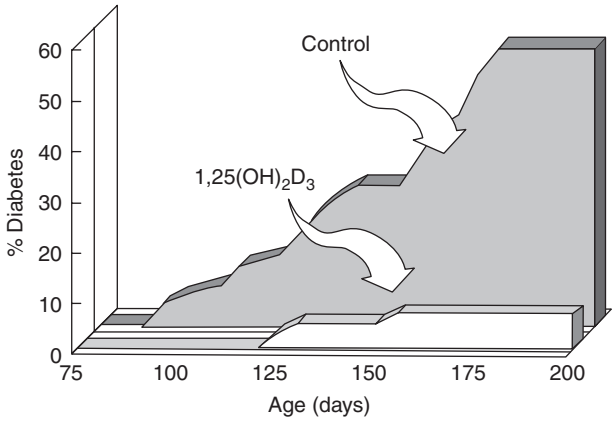

FIGURE 9 The effect of $1,25(OH)_2D_3$ on reducing the incidence of diabetes mellitus type I in NOD mice. Adapted from Mathieu *et al.* (1994).

lymphocytes and monocytes. *In vivo,* the combination of these effects manifest themselves in numerous ways. In mice, $1,25(OH)_2D_3$ substantially reduces the development of autoimmune thyroiditis (Fournier *et al.,* 1990), encephalomyelitis (Lemire and Archer, 1991), and multiple sclerosis (Hayes *et al.,* 1997). $1,25(OH)_2D_3$ prolongs the survival of transplanted skin allografts in mice (Chiocchia *et al.,* 1991) and prevents the incidence of autoimmune diabetes in nonobese diabetic (NOD) mice (Mathieu *et al.,* 1994; Mathieu *et al.,* 1998) (Fig. 9). Whereas *in vitro* $1,25(OH)_2D_3$ decreases immunoglobulin synthesis in B lymphocytes, *in vivo,* its precursor analog, $1\alpha(OH)D_3$, leads to an increase in primary antibody response (Komori *et al.,* 1985).

Many of these *in vivo* animal studies have been corroborated by retrospective and prospective epidemiologic studies. A birth cohort study involving 10,366 children conducted in Finland showed that during the first year of life, children who took the recommended supplemental dose of 2,000 IU/d of vitamin D had a rate ratio of 0.022 (range, 0.05–0.89) for type I diabetes mellitus compared to those who regularly received <2000 IU/d (Hypponen *et al.,* 2001). Stene *et al.*, 2003 reported a lower risk of type I diabetes in children of mothers who took cod liver oil during pregnancy. Vitamin D deficiency has been implicated in several other diseases including rheumatoid arthritis, inflammatory bowel disease, systemic lupus erythematosus, osteoarthritis and periodontal disease (Holick, 2006, 2007). Vitamin D intake was reported to be inversely associated with rheumatoid arthritis (Merlino *et al.*, 2004), and Munger *et al.*, 2004, found that higher intake of vitamin D > 400 IU/d was associated with a lower risk of developing multiple sclerosis.

Skin

The original observation that $[^3H]1,25(OH)_2D_3$ localized in the nuclei of cells in the basal layer of the epidermis has now been extended to include nuclei of cells in the outer root sheath of the hair follicle and in the stratum granulosum and stratum spinosum of the epidermis (Stumpf *et al.,* 1979, 1984). The presence of and amounts of VDR in keratinocytes appear to be related to the proliferative and differentiation activity of the cells; more VDR activity is observed in preconfluent proliferating cells than in postconfluent cells (Pillai *et al.,* 1987). VDR immunoreactivity has been detected in nuclei of dermal papilla cells and outer root sheath keratinocytes of the hair follicle. During hair follicle proliferation, the VDR immunoreactivity was enhanced significantly in both cell types, suggesting a potential role of $1,25(OH)_2D_3$ in regulating the hair cycle (Reichrath *et al.,* 1994). Although the physiologic function of $1,25(OH)_2D_3$ in these skin cells is not well understood, in cultured human and murine keratinocytes, $1,25(OH)_2D_3$ inhibited their proliferation in a dose-dependent fashion and caused them to terminally differentiate (Fig. 10) (Hosomi *et al.,* 1983; Smith *et al.,* 1986; Pillai *et al.,* 1987). Human skin fibroblasts also have VDR and respond to the hormone in a similar manner (Feldman *et al.,* 1982; Clemens *et al.,* 1983; Holick, 1995).

When cultured melanoma cells with VDR+ were incubated with $1,25(OH)_2D_3$, this hormone inhibited their proliferation and induced them to differentiate (Colston *et al.,* 1981). These data suggest that melanocytes may also be a target cell for $1,25(OH)_2D_3$. There is also immunohistochemical evidence for the presence of VDR in melanocytes from skin biopsies of patients with psoriasis (Milde *et al.,* 1991). However, there is no direct evidence that normal human melanocytes either possess a VDR or respond to $1,25(OH)_2D_3$ (Mansur *et al.,* 1988).

Other Tissues

A wide variety of other cells and tissues from the brain to the gonads possess VDR (Clemens *et al.,* 1988). Cultured chick embryo skeletal myoblasts have receptor binding for $1,25(OH)_2D_3$ (Boland *et al.,* 1985). Furthermore, when cultured VDR+ myoblast cells (G-8 and H9c2) were incubated with $1,25(OH)_2D_3$, there was a dose-dependent decrease in cell proliferation and induction of terminal differentiation. When the cells became fused microtubules, VDR activity decreased (Simpson *et al.,* 1985). VDR is also present in rodent heart tissue, and when isolated cardiac muscle cells were exposed to $1,25(OH)_2D_3$, the hormone increased calcium uptake in a time-and dose-dependent fashion (Weishaar and Simpson, 1989).

Ovaries and testes have VDR activity. Sertoli cells in culture increase rapid uptake of calcium when exposed to $1,25(OH)_2D_3$ (Akerstrom and Walters, 1992). Of great interest was the observation that primary cultured prostate cells derived from normal, benign prostatic hyperplasia and prostate cancer tissues possess VDR (Skowronski *et al.,* 1995). Prostate cancer cell lines and primary cultures of stromal and epithelial cells derived from normal and

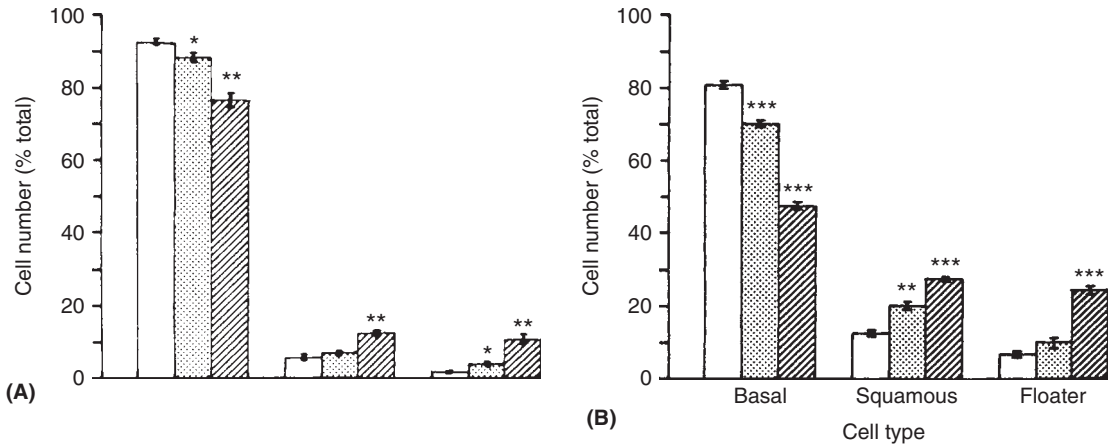

FIGURE 10 Effect of $1\alpha,25(OH)_2D_3$ on the morphologic differentiation of cultured human keratinocytes. The proportion of different keratinocyte cell types after 1 (**A**) or 2 (**B**) weeks of incubation with vehicle alone (open bar), $1\alpha,25(OH)_2D_3$ at 10^{-10} M (dotted bar), or $1\alpha,25(OH)_2D_3$ at 10^{-8} M (striped bar). Each bar represents the mean of triplicate determinations ± SEM. Student's *t* test was used to assess the level of significance (*$p < 0.05$; **$p < 0.001$). Reproduced with permission from Smith *et al.* (1986).

malignant prostate tissues respond in a dose-dependent fashion to the antiproliferative activity of $1,25(OH)_2D_3$.

β islet cells of the pancreas possess a VDR. There is some evidence that $1,25(OH)_2D$ may alter insulin secretion (Cade and Norman, 1986). Pittas *et al.*, 2006, reported a 33% reduction in risk of developing type 2 diabetes when 1200 mg of calcium and 800 IU vitamin D were taken daily. The parathyroid glands possess VDR, and there is strong evidence that $1,25(OH)_2D_3$ suppresses preproparathyroid hormone mRNA levels (Naveh-Many and Silver, 1990; Dusso *et al.*, 2005).

RELEVANCE OF VDR AND $1,25(OH)_2D_3$ IN NONCALCEMIC CELLS AND TISSUES

Physiologic Actions

It is remarkable that most cells and tissues in the human body possess VDR and are therefore potential target tissues for $1,25(OH)_2D_3$ (Table I). Although there is very strong evidence *in vitro* and *in vivo* that $1,25(OH)_2D_3$ can have a wide range of noncalcemic activities that have an impact on the function of the immune system, skin, gonads, prostate gland, brain, skeletal and smooth muscle, and pancreas, the true physiologic function of $1,25(OH)_2D_3$ is not well understood. To put this into perspective, patients who are vitamin D deficient or patients who suffer from DDR II and are therefore totally resistant to the action of $1,25(OH)_2D_3$ do not seem to have major deficits in the physiologic function of most of the tissues described. There is evidence that vitamin D deficiency causes muscle weakness (Bishoff-Ferrari *et al.*, 2005) and alters the immune system to make these patients more prone to some infections, and in the case of DDR II, the patients often suffer from alopecia (Demay, 1995; Holick, 1995). They, however, do not have a higher incidence of cancer such as leukemia, they do not suffer from diabetes mellitus, and their skin appears to be normal with no evidence of hyperproliferation, such as psoriasis or pigmentation disorders.

Pharmacologic Actions

The recognition in the early 1980s that $1,25(OH)_2D_3$ inhibited proliferation and induced differentiation of normal and tumor cells that possessed VDR was greeted with great excitement. The observation that mice with an M-1 cell leukemia had a marked prolongation in their survival when they received $1\alpha(OH)D_3$ or $1,25(OH)_2D_3$ suggested that the antiproliferative activity of $1,25(OH)_2D_3$ and its analogs could be used to treat a variety of cancers (Honma *et al.*, 1982). Eighteen patients with myelodysplasia (preleukemia) were treated with 2μg of $1,25(OH)_2D_3$ for 12 weeks. A majority of the patients initially had a significant increase in their granulocyte, monocyte, and platelet counts, suggesting that $1,25(OH)_2D_3$ was inhibiting the proliferation and inducing terminal differentiation of the myelodysplastic cells. After 12 weeks of the study, however, there was no significant difference in the blood count for granulocytes, monocytes, and platelets compared to baseline and most patients progressed to acute myelocytic leukemia. In addition, most of the patients had developed hypercalcemia, limiting the amount of drug that could be used (Koeffler *et al.*, 1985). Three patients with myelofibrosis who received $1,25(OH)_2D_3$ (0.5 μg daily) had some improvement in their blood count indices after therapy (Arlet *et al.*, 1984).

Definition of vitamin D deficiency

There is no general consensus as to what the levels of 25(OH)D need to be to satisfy the body's vitamin D

requirement. However, many experts believe that a 25(OH)D of >20 ng/ml is important to help maximally suppress PTH levels. Chapuy et al reported that PTH levels reach their nadir when 25(OH)D levels approach 30–40 ng/ml. This observation has been confirmed by both Thomas *et al.*, 1998 and Holick *et al.*, 2005. In addition, Heaney *et al.*, 2003 reported that women who had on average a serum 25(OH)D of 20 ng/ml and then raised their blood level to above 32 ng/ml were able to increase their efficiency of intestinal calcium absorption by 45–65%. Thus, based on this new information, most experts now agree that a preferred 25(OH)D level should be > 30 ng/ml. (Fig. 7)

The adequate intake recommendation by the Institute of Medicine in 1997 for vitamin D intake (Standing Committee, 1999) is now considered to totally inadequate for both children and adults. Most experts agree that 1,000 IU of vitamin D/d is necessary in the absence of any sun exposure to maintain 25(OH)D levels >30 ng/ml (Vieth *et al.*, 2007). Patients, especially the elderly who are vitamin D deficient, don't necessarily have elevated PTH levels which has been perplexing. However, it is now recognized that many of these patients are magnesium deficient, and since magnesium is important in the synthesis and secretion of PTH, this is the likely explanation for the lack of expected secondary hyperparathyroidism associated with a 25(OH)D level < 20 ng/ml.

Vitamin D deficiency is now routinely treated by giving adults 50,000 IU of vitamin D_2/week for 8 weeks (Holick 2007). To maintain a 25(OH)D > 30 ng/ml, 50,000 IU of vitamin D every two weeks is effective. Vitamin D_2 is as effective as vitamin D_3 in maintaining serum 25(OH)D levels and giving 50,000 IU of vitamin D_2 every two weeks will maintain 25(OH)D levels > 30 ng/ml (Holick 2007).

There is great fear in the medical community regarding the use of 50,000 IU of vitamin D_2 because of concern for vitamin D toxicity. However, Vieth *et al.*, 2004 reported that healthy males receiving 10,000 IU of vitamin D_3/d for up to five months demonstrated no untoward toxicity. Vitamin D intoxication is extremely rare and often occurs because of inadvertent or intentional ingestion of upwards of 50,000 IU of vitamin D/d for several months. Typically vitamin D intoxication is observed when 25(OH)D are >150 ng/ml. (Holick 2007).

This collective information has now been translated by reference laboratories who perform 25(OH)D levels either by a radioimmuno assay (RIA) or by liquid chromatography – tandem mass spectroscopy (LC-MS) to report levels of 25(OH)D of 20–100 ng/ml as the normative range. It should be noted that LC-MS assay is able to separate 25(OH)D_2 from 25(OH)D_3, and, thus, are reported separately. It is the total 25(OH)D that is the measure of vitamin D status and levels above 30 ng/ml by both RIA and LC-MS assay is what is now considered to be healthyl (Holick 2007).

CLINICAL UTILITY OF NONCALCEMIC ACTIONS OF 1,25(OH)$_2$D$_3$ AND ITS ANALOGS

Use of 1,25(OH)$_2$D$_3$ and Its Analogs for Treatment of Skin Diseases

Rationale for Their Use

In the mid-1980s, there was mounting evidence that epidermal skin cells were very sensitive to the antiproliferative activity of 1,25(OH)$_2$D$_3$ (Hosomi *et al.*, 1983; Smith *et al.*, 1988). Because psoriasis is a nonmalignant hyperproliferative disorder of the epidermis, it was reasoned that if psoriatic skin cells possessed a VDR, then it might be possible to use 1,25(OH)$_2$D$_3$ or one of its analogs to decrease psoriatic keratinocyte proliferation, thereby treating this disorder. Before initiating a clinical trial to evaluate the therapeutic efficacy of 1,25(OH)$_2$D$_3$, MacLaughlin *et al.* (1985) obtained skin biopsies from six patients with psoriasis to determine whether cultured psoriatic fibroblasts responded to the antiproliferative activity of 1,25(OH)$_2$D$_3$. It was found that psoriatic fibroblasts had a partial resistance to the antiproliferative activity of 1,25(OH)$_2$D$_3$, and it was concluded that pharmacologic rather than physiologic amounts of 1,25(OH)$_2$D$_3$ and its analogs could be used for the treatment of psoriasis (MacLaughlin *et al.*, 1985). At the same time, Morimoto *et al.* (1986) treated an osteoporosis patient with 1α-OH-D and observed that this patient, who also suffered from psoriasis, had significant improvement in her disease while on therapy. There are now numerous reports that topical 1,25(OH)$_2$D$_3$, (Fig. 11) as well as topical application of analogs of 1,25(OH)$_2$D$_3$, including 1,24-dihydroxyvitamin D_3 and calcipotriene (Dovonex; Bristol-Meyers Squibb, Buffalo, NY), is safe and effective for the treatment of psoriasis (Kato *et al.*, 1986; van de Kerkhof *et al.*, 1989; Kragballe *et al.*, 1989; Kragballe *et al.*, 1991; Staberg *et al.*, 1989; Langner *et al.*, 1992; Bourke *et al.*, 1993; Langner *et al.*, 1993; Holick, 1993; Bruce *et al.*, 1994; Perez *et al.*, 1996a, 2001).

There has been great concern that in light of the earlier studies using 1,25(OH)$_2$D$_3$ for treating preleukemia that caused severe hypercalcemia (Koeffler *et al.*, 1985) that 1,25(OH)$_2$D$_3$ would not be a safe medication for treating psoriasis. However, for the most part, these concerns have not proven to be correct (Holick, 1993; Perez, *et al.*, 1996a,b).

Several other analogs have been developed for the treatment of psoriasis. The most commonly used analog is calcipotriene (Dovonex). The strategy for developing this analog was to alter the side chain so that it would be metabolized rapidly and, therefore, less prone to developing hypercalciuria and hypercalcemia (Binderup and Bramm, 1988; Kragballe *et al.*, 1989; Kragballe, 1991). Indeed,

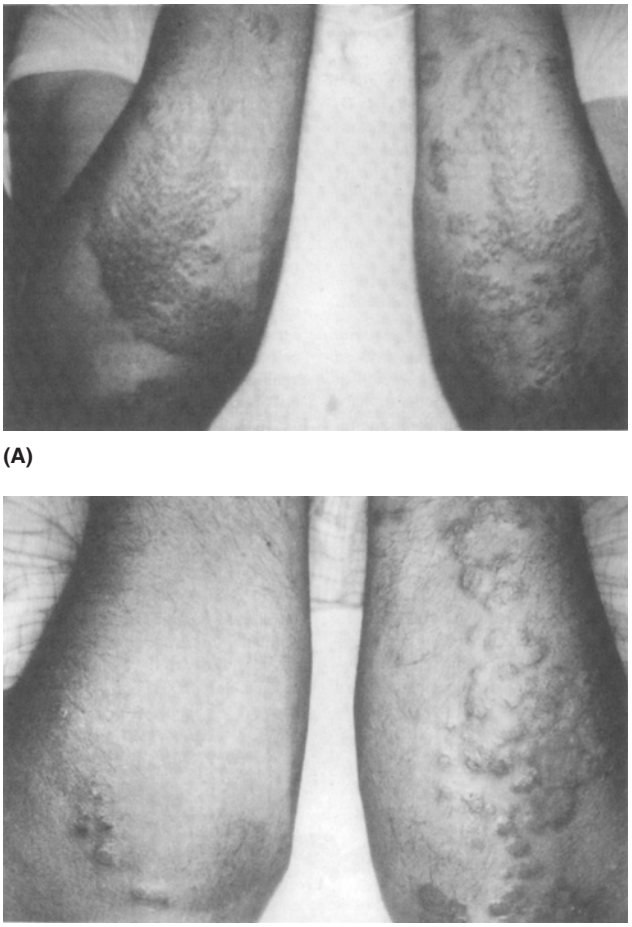

FIGURE 11 (**A**) Arms of a patient with a long history of plaque psoriasis before treatment with the topical form of 1,25-dihydroxyvitamin D_3. (**B**) The same patient who applied only petroleum jelly on the left forearm (at right) and petroleum jelly containing 15 μg/g of $1,25(OH)_2D_3$ on the right forearm (at left) for 3 months. Reproduced with permission from Holick (1994).

calcipotriene is metabolized and degraded rapidly (Binderup *et al.,* 1988; Sorensen *et al.,* 1990). Calcipotriene at 50 μg/g of ointment or cream is used worldwide for the treatment of psoriasis. Other analogs, including 1,24-hydroxyvitamin D_3 (Kato *et al.,* 1986) and hexafluoro-1,25-dihydroxyvitamin D_3 (Durakovic *et al.,* 2001), have been shown to be effective for treating psoriasis. However, calcipotriene can cause a dermatitis that occurs on very sensitive skin areas, such as the face and genital regions (Yip *et al.,* 1991), and very rarely hypercalcemia (Hoeck *et al.,* 1994).

Treatment of Psoriatic Arthritis with $1,25(OH)_2D_3$

It has been estimated that approximately 10% of patients with psoriasis suffer from psoriatic arthritis. In an open-label trial, we found that 10 patients with active psoriatic arthritis who received up to 2.5 μg of oral $1,25(OH)_2D_3$ each night had a statistically significant improvement in mean tender joint count and physician global assessment (Huckins *et al.,* 1990). Forty percent of patients had greater than 50% improvement in their disease and an additional 30% had greater than 25% improvement.

CONCLUSION

Casual exposure to sunlight provides most humans with their vitamin D requirement. Because vitamin D plays an essential role in the maintenance of a healthy skeleton, it is important that all vertebrates, including humans, have a steady supply of vitamin D. The skin is not only the site for the synthesis of this important calciotropic hormone, but is also a major target tissue for $1,25(OH)_2D_3$. The skin may also be a site for the metabolism of 25(OH)D to $1,25(OH)_2D$ (Bikle *et al.,* 1986). It is remarkable that $1,25(OH)_2D_3$ has so many potential biologic actions for health (Holick 1998; Holick 2007) (Fig. 12). As a result, $1,25(OH)_2D_3$ and its analogs have been developed for the treatment of a wide variety of clinical disorders. $1,25(OH)_2D_3$ and its analogs have been very effective in the treatment of hypocalcemic disorders and for the treatment of metabolic bone diseases associated with acquired and inherited disorders of 25(OH)D metabolism and VDR defects (Demay, 1995; Holick, 1999). $1,25(OH)_2D_3$ and its analogs have also been shown to be of value for the treatment of osteoporosis (Tilyard *et al.,* 1992). What has been most intriguing about $1,25(OH)_2D_3$ is its potent antiproliferative properties. One might assume that because $1,25(OH)_2D_3$ is such a potent antiproliferative agent that its chronic use for the treatment of a hyperproliferative disorder would ultimately result in an atrophy of the treated tissues. For example, for the treatment of psoriasis, would the chronic use of $1,25(OH)_2D_3$ and its analogs cause senescence of the skin similar to topical steroids? All of the experience has suggested that $1,25(OH)_2D_3$ will not cause any thinning of the skin, unlike topical steroids. This suggests that $1,25(OH)_2D_3$ is able to sense abnormal proliferative activity and return the activity of the cell to normal. It is for this reason that $1,25(OH)_2D_3$ and its analogs hold such promise for the treatment of a wide variety of proliferative disorders, most notably some cancers.

The observations that many nonrenal tissues, including the skin, colon, and prostate, have 1α-OHase activity opens a new chapter in the vitamin D story (Holick, 2007). Why $1,25(OH)_2D$ would be produced locally in the skin, prostate, colon, and so on remains unknown but may be important in the regulation of cell growth and cancer prevention (Fig. 8). The observation that the product of the Wilm's tumor gene modulates cellular proliferative activity of renal and hemopoetic cells and also regulates the expression of the VDR provides insight into the complexity of the function of $1,25(OH)_2D$ in cell growth (Mawer *et al.,* 2001).

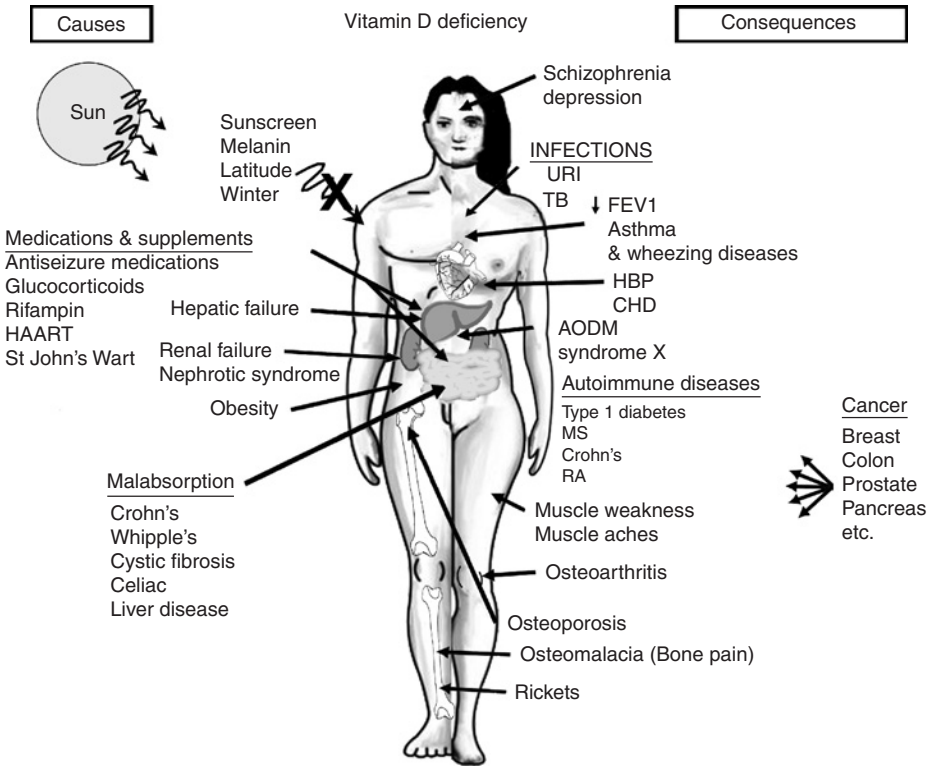

FIGURE 12 A schematic representation of the major causes for vitamin D deficiency and potential health consequences. Holick copyright 2007, with permission.

$1,25(OH)_2D_3$ and its analog $1\alpha(OH)D_3$ have been used successfully during the past two decades for treating a variety of acquired and inborn errors in the metabolism of 25(OH)D to $1,25(OH)_2D$, as well as other hypocalcemic disorders (Demay, 1995; Holick, 1995). The revelation that $1,25(OH)_2D_3$ has noncalcemic activities, including regulating proliferation and differentiation of cells and altering the immune function, sparked great interest in developing selective analogs of $1,25(OH)_2D$ that had the desirable noncalcemic actions of $1,25(OH)_2D$ without the potential toxic side effect on calcium metabolism. There are a very large number of analogs that have been synthesized and well reviewed by Bouillon *et al.* (1995). At the present time, there are very few analogs of $1,25(OH)_2D_3$ that are available commercially and have limited calcemic activity.

Chapter 38

Calcitonin Gene Family of Peptides

Mimi I. Hu and Robert F. Gagel*

Department of Endocrine Neoplasia and Hormonal Disorders, Division of Internal Medicine, The University of Texas M. D. Anderson Cancer Center, Houston, Texas

INTRODUCTION

In 1961, Copp observed that protein extract derived from the ultimobranchial body of salmon had a hypocalcemic effect when administered to rodents (Copp and Cameron 1961; Copp *et al*., 1962). He named this substance calcitonin (CT). In mammalian species, this activity was subsequently localized to the thyroid gland (Hirsch *et al*., 1963). This hormone was then shown to be produced by parafollicular cells, called C cells (calcitonin-producing cells), of the thyroid gland (Hirsch *et al*., 1963; Foster *et al*., 1964). The active principle subsequently was shown to be a 32-amino-acid peptide, released in response to an increase in the plasma calcium concentration.

What these discoverers could not have envisioned was that they had identified the first of a complex series of ligands, receptors, and coreceptors that regulate a broad spectrum of physiological functions that include skeletal remodeling, blood pressure control, neural transmission in both the central and peripheral nervous system, cardiovascular development, and development of the lymphatic system. Although, in this chapter, we will focus primarily on the role of the calcitonin and calcitonin gene-related family of peptides in bone, we will also provide an overview of current progress associated with the entire family. As one assesses the whole of this family of peptides, receptors, and receptor-activity-modifying proteins, one comes to the inescapable conclusion that this receptor family has served as the "pinch hitter" of signaling systems throughout evolutionary history. This system, modified by evolutionary pressure, is present in a broad spectrum of species that encompasses the whole of life. It is expressed very early in development and has important roles in normal mammalian development. At the same time, current evidence suggests that it functions in a secondary role in a variety of developmental systems. This ligand–receptor system is rarely the primary driver in developmental biology, but it frequently plays a crucial role as a secondary driver of differentiation. Thus, deletion or overexpression of the components of this gene family in animal models is more likely to produce complex and nuanced phenotypes rather than the startling phenotypes associated with gene's development. We will attempt to highlight some examples in this chapter.

CALCITONIN GENE FAMILY

The nomenclature for the calcitonin gene family has evolved largely from work performed in humans and rodents. Although the human and rodent gene families have considerable homology, each has evolved with a different nomenclature. In this chapter we will focus on these two mammalian species, but it is important to recognize that this family of genes is present in some of the simplest forms of life where it has evolved very differently. For example, there are substantial differences between mammalian, fish, and bird gene families. Because the focus on this chapter is on bone biology, we will limit our discussion to human and rodent models that have been studied most intensively.

The human calcitonin/calcitonin gene-related peptide (CGRP) gene family, based on their nucleotide sequence homologies, is composed of five separate genes: calcitonin-I (CALC-I), -II, -III, -IV, and -V (Table I). With the exception of CALC-IV, which is on chromosome 12, all of these genes are located on chromosome 11. CALC-I gene consists of six exons, of which tissue-specific alternative RNA splicing yields CT (designated calcitonin gene-related peptide-alpha, CGRP-alpha, in rodents). CALC-II, considered to have arisen from gene duplication, encodes CGRP-beta (or CGRP-II); it is unclear which gene, CALC-I or CALC-II, appeared first (Wimalawansa, 1996). The CALC-III gene is not transcribed and is considered a pseudogene. CALC-IV and -V encode amylin (AMY) and the vasodilator peptide, adrenomedullin (AM), respectively (Fig. 1).

Several common features characterize the classic hormones of the calcitonin gene family (Fig. 2). Calcitonin, CGRP (alpha and beta), amylin, and AM all have a ring

structure formed by a disulfide bridge at the amino terminus and an amidated amino acid at the carboxyl terminus. The midregion of each hormone forms an α-helical structure. Additionally, as will be discussed later, CT gene family peptides exert their biological effects by binding to one of two receptors: calcitonin receptor (CTR) or calcitonin receptor-like receptor (CRLR) with or without a co-receptor (receptor-activity-modifying protein, RAMP) (Table II). The homology seen among these peptide ligands suggests that the genes in this family are derived from a primordial gene, which underwent duplication and sequence-divergent events.

The peptide products of CALC-I gene (i.e., CT or CGRP-alpha), those most relevant to bone biology, arise through alternative RNA splicing of the primary mRNA transcript that includes or excludes specific exons; this process is tissue specific (Amara *et al*., 1982) (Fig. 1a). Although there is some overlap, CT mRNA is the major product in thyroid and other tissues, whereas CGRP-alpha mRNA is expressed mainly in neural cells in the brain, spinal cord, and various sympathetic ganglia. In the normal thyroidal C cell, 99% of the primary RNA transcript is processed via a CT-specific pathway; in neuronal tissue, 95% of the primary transcript is processed in a CGRP-specific manner (Lou and Gagel, 1998). The regulatory pathways that control alternative RNA processing are complex and involve multiple factors that promote inclusion (CT-specific pattern) or exclusion (CGRP-specific pattern) of exon IV containing the coding sequence for calcitonin. An enhancer element located downstream of exon IV was identified to facilitate polyadenylation and inclusion of the exon (Lou *et al*., 1996). A number of factors have been identified to affect the CT-specific pathway (Tran and Roesser, 2003; Zhu *et al*., 2003; Roesser 2004). Recently, Hu proteins, RNA-binding proteins involved in neuronal differentiation and maintenance, have been identified as the first neuron-specific regulators of the CT/GCRP system by blocking the activity of proteins (TIA-1/TIAR) required for the inclusion of exon IV (Zhu *et al*., 2006). Additionally, Fox-1 and -2 proteins were recently reported to mediate the neuron-specific splicing pattern by repressing exon IV inclusion (Zhou *et al*., 2007). The pattern that emerges is one in which inclusion or exclusion of exon IV from the final transcript appears to be a major regulatory event.

HUMAN CALCITONIN AND ITS SYNTHESIS

Biochemistry

Based on its primary structure, CT can be found in at least three categories of species: teleost/avian (i.e., salmon, eel, goldfish, and chicken), artiodactyl (i.e., porcine, bovine, and ovine), and primate/rodent (i.e., human and rat). In several different biological assays of capacity for lowering serum calcium and stimulating urinary cyclic adenosine monophosphate excretion (cAMP) after administration, CT can be ordered by species with regard to potency as follows: teleost/avian > artiodactyls > primate/rodent (Gennari *et al*., 1990). However, the absolute potency of CT is dependent on the specific species studied. Calcitonin from teleost and avian species is produced in the ultimobranchial glands, which remain in these species as discrete organs. In contrast, mammals demonstrate the greatest concentration of calcitonin-producing cells (i.e., C cells) within the thyroid gland, especially in the upper one-third of each thyroid lobe; embryologically, the C cells migrate from the neural crest to the developing thyroid gland.

Mature human CT is a 32-amino-acid peptide hormone with a molecular mass of 3418 Da. A disulfide bridge connects the cysteine residues at positions 1 and 7 to form a 7-amino-acid ring structure at the amino terminus. At the

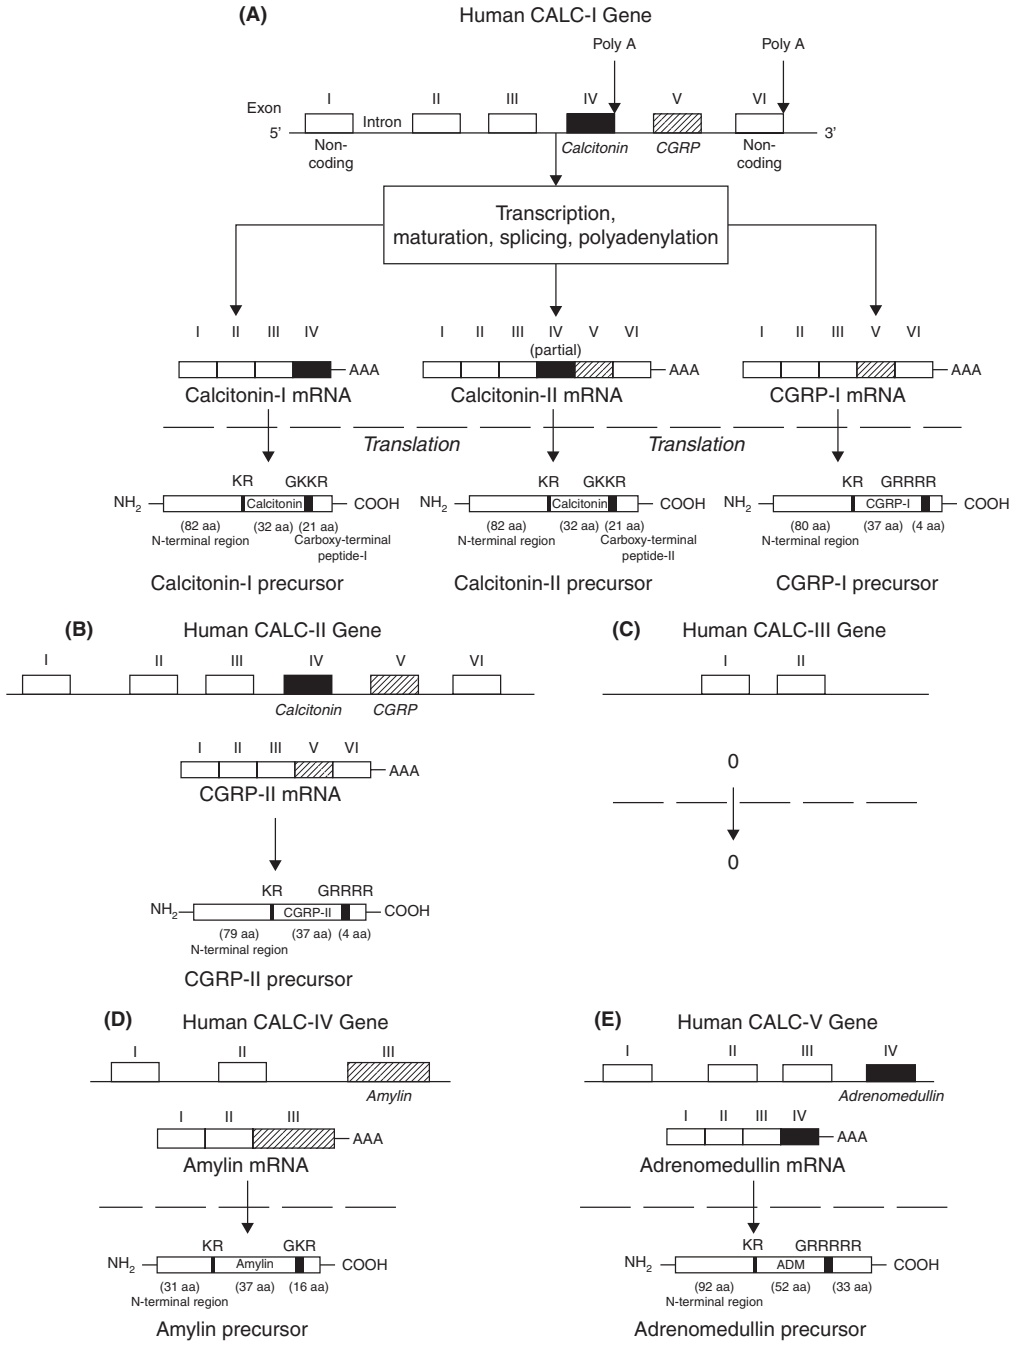

FIGURE 1 The human calcitonin (CT) gene family: organization of genes, mRNAs, and their hormone precursors. **(A)** The CALC-I primary transcript is processed by the inclusion or exclusion of exons through alternative RNA splicing into three different mRNAs: CT, CT-II, and CGRP-alpha (Jacobs *et al.,* 1981). Exons I to III are common to these three mRNAs. The combination of exons I, II, III, and IV codes for CT mRNA (with polyadenylation resulting in truncation of the mRNA immediately following exon IV). CT-II mRNA includes exons I, II, III, IV (partial), V, and VI. CGRP-alpha mRNA contains exons I, II, III, V, and VI. Each mRNA is translated into a specific precursor peptide. CT mRNA codes mainly for an N-terminal region, mature CT, and a specific C-terminal peptide (CCP-I, katacalcin, or PDN-21), constituting the CT-I precursor. The N-terminal region includes a signal peptide of 25 amino acids and an N-terminal peptide of 57 amino acids (i.e., NProCT or PAS-57). The C-terminal peptide region of CT-I precursor (CCP-I) differs from that of CT-II precursor (CCP-II) by its last 8 amino acids. CGRP-alpha mRNA codes for an N-terminal region, mature CGRP-alpha, and a cryptic peptide. **(B)** The CALC-II gene encodes only the precursor of the CGRP-beta peptide. The composition of six exons in this gene is similar to that of the CALC-I gene; however, examination of the exon 4-like region of CALC-II indicates that CT mRNA production is unlikely. The CGRP-beta peptide differs from CGRP-alpha by three amino acids (Steenbergh *et al.,* 1985). **(C)** The CALC-III gene contains only two exons, which have sequences homologous to exons 2 and 3 of CALC-I and -II genes. However, the CALC-III gene is not transcribed into RNA and, consequently, has no protein product. **(D)** The CALC-IV gene codes for a precursor to the amylin peptide. This gene, expressed predominantly in the islet cells of the pancreas, contains only three exons. The third exon codes for amylin. This 37-amino-acid peptide has marked homology with CGRP peptides. It has been suggested that CT and CGRP exons are derived from a primordial gene and that the different genes have arisen by duplication and sequence-divergent events. **(E)** The CALC-V gene is translated into adrenomedullin. This gene contains four exons. Adrenomedullin (AM) is coded by the fourth exon. The amino-terminal peptides, encoded by exons 2 and 3, also have some bioactivity. Modified from Becker (2001).

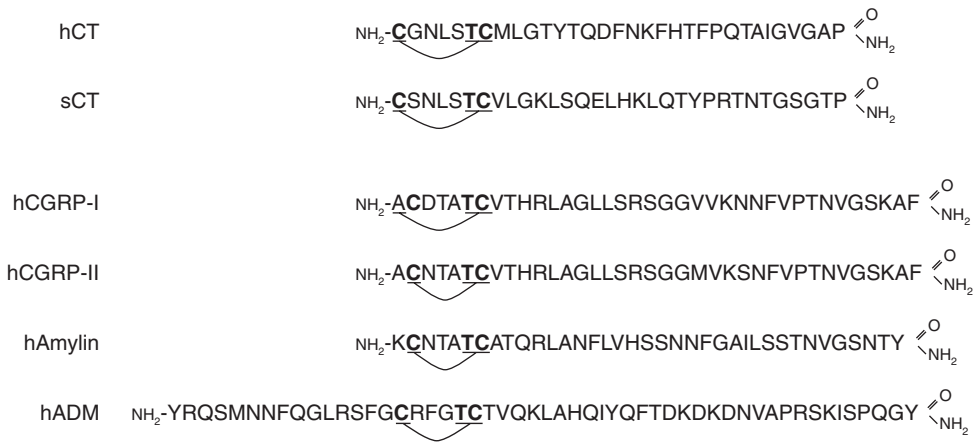

FIGURE 2 Amino acid sequences of human calcitonin (hCT), salmon CT (sCT), human CGRP-I (hCGRP-I), human CGRP-II (hCGRP-II), human amylin, and human adrenomedullin (hADM). Two structural features that are essential for full functional activity are conserved between the peptides: they contain two N-terminal cysteines that form a disulfide bridge resulting in an N-terminal loop and a C-terminal amide. Modified from Becker (2001).

TABLE II Affinity of Peptides of the Calcitonin Gene Family with Receptor Types Based on RAMP Expression

carboxyl terminus, there is an amidated proline. The polypeptide precursor of CT, preprocalcitonin (Pre-ProCT) (molecular mass, 15,466 Da), contains 141 amino acid residues (Le Moullec *et al.*, 1984). The leader sequence (signal peptide), composed of 25 amino acid residues, assists in the transport of the ribosomal precursor molecule into the cysternae of the rough endoplasmic reticulum. Early in post-translational processing, the leader sequence is cleaved from the Pre-ProCT precursor molecule by a signal peptidase. The resultant prohormone, procalcitonin (ProCT, also termed PAN-116), may be glycosylated. It consists of 116 amino acid residues (molecular mass, 12,795 Da), which are folded into their appropriate three-dimensional conformation. At the amino terminus portion of ProCT, there is a 57-amino-acid peptide called nProCT (also called PAS-57) (Fig. 3). The immature CT, which is placed centrally within ProCT, consists of 33 amino acid residues, including a carboxyl-terminal glycine. The final 21 amino acid residues comprise the CT carboxyl-terminal peptide-I (CCP) (also termed carboxyl-terminal flanking peptide-I, PDN-21, or katacalcin).

Regulation of Calcitonin Synthesis and Secretion

Synthesis

The mechanisms by which the large precursor, ProCT, is serially processed and its component peptides are sorted into nascent secretory vesicles involve a complex series of progressive modifications that eventuate in the final exocytosis of mature secretory products. Although the mechanisms for post-translational processing have not been fully clarified, much that has been learned from

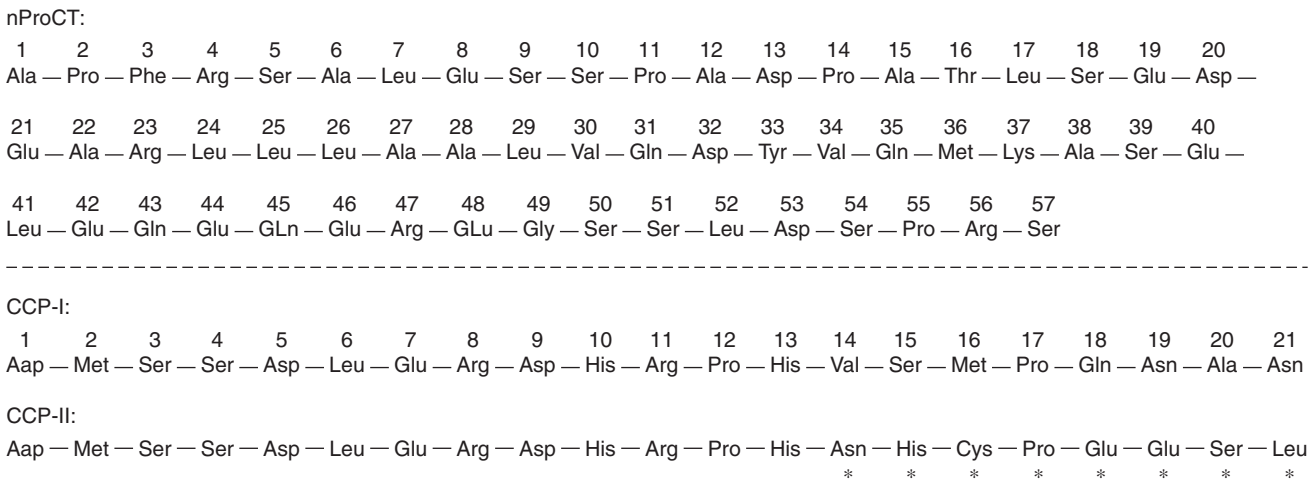

FIGURE 3 Sequence of human nProCT (*Top*) and the two CCP peptides (*Bottom*).

the study of other pro-peptides can be applied to ProCT. Topographically, highly organized traffic from the endoplasmic reticulum must pass through the Golgi apparatus, the dense-core secretory vesicles, and, eventually, the cell surface. During this process the ProCT is processed to monomeric calcitonin and flanking peptides. When the CT gene is expressed in cell types that do not possess this processing system (e.g., during sepsis), ProCT is the predominant secretory product (Snider *et al*., 1997).

After the biosynthesis and folding of ProCT, subsequent proteolytic processing occurs, both within the Golgi apparatus and, later, within the secretory granules (Chanat and Huttner, 1991) (Fig. 4). During early post-translational processing, the nProCT segment may act as a signal for sorting its parent ProCT molecule to nascent secretion vesicles of the regulated secretory pathway; such a role has been demonstrated for the N-terminal 26-amino-acid peptide of the prohormone of adrenocorticotropin (ACTH), pro-opiomelanocortin (POMC) (Cool and Loh, 1994). Furthermore, chromogranin B may function as a helper protein to favor *trans*-Golgi sorting to the regulated secretory pathway as it does for ACTH.

Within the newly formed secretion vesicles, proteolytic cleavage releases immature CT. Then, as amidation proceeds, mature CT is produced and is concentrated progressively within these vesicles (Treilhou-Lahille *et al*., 1986). The ensuing tight aggregation of hormones within the vesicle causes its subsequent electron-dense appearance. These secretory vesicles are destined to serve as storage repositories for later secretion. Without the appropriate external stimulus, they have a relatively long half-life. Ultimately, in response to the appropriate signal at the plasma membrane, there is a brief increased concentration of cytosol-free Ca^{2+}, which induces secretion. In this process, the secretory vesicles further migrate via an intracellular microtubular system toward the periphery of the cell, fuse with the apical portion of the plasma membrane, and discharge their hormonal contents in a quantal release by exocytosis. Studies in normal humans suggest that these secretory vesicles contain, in addition to mature CT, intact ProCT, nProCT, CT:CCP-I, CCP-I, and probably some free immature CT (Treilhou-Lahille *et al*., 1986; Snider *et al*., 1997).

Secretion

The primary regulatory loop controlling CT secretion is the inverse of that regulating parathyroid hormone secretion. An increase of the serum calcium concentration activates the calcium-sensing receptor (CaSR), a G protein-coupled receptor highly expressed on thyroid C cells, and stimulates the release of calcitonin (Garrett *et al*., 1995; Freichel *et al*., 1996; Fudge and Kovacs, 2004). This is an interesting physiological adaptation where the same receptor expressed by two different cell types (parathyroid hormone- or calcitonin-producing cells) is linked to opposite secretory effects (Fudge and Kovacs, 2004). Most importantly, these regulatory loops lead to maintenance of the serum calcium concentration within a narrow range. Deficiency of parathyroid hormone leads to hypocalcemia; absence of calcitonin causes an exaggerated extracellular calcium increase in response to parathyroid hormone, but the basal serum calcium concentration is normal (Lanske *et al*., 1998; Hoff *et al*., 2002).

There are other stimulants for CT secretion: magnesium, glucagon, gastrin, cholecystokinin, secretin, vasoactive intestinal peptide, and pentagastrin (Cooper *et al*., 1971; Selawry *et al*., 1975; Roos *et al*., 1976). The increase of serum CT in response to gastrin, and perhaps to cholecystokinin and glucagon, raises the question as to whether these gastrointestinal hormones regulate its secretion (Selawry *et al*., 1975). Although there is abundant evidence that gastrin is a potent stimulant of calcitonin secretion when given in pharmacological concentrations, the evidence that it plays a significant physiological role is

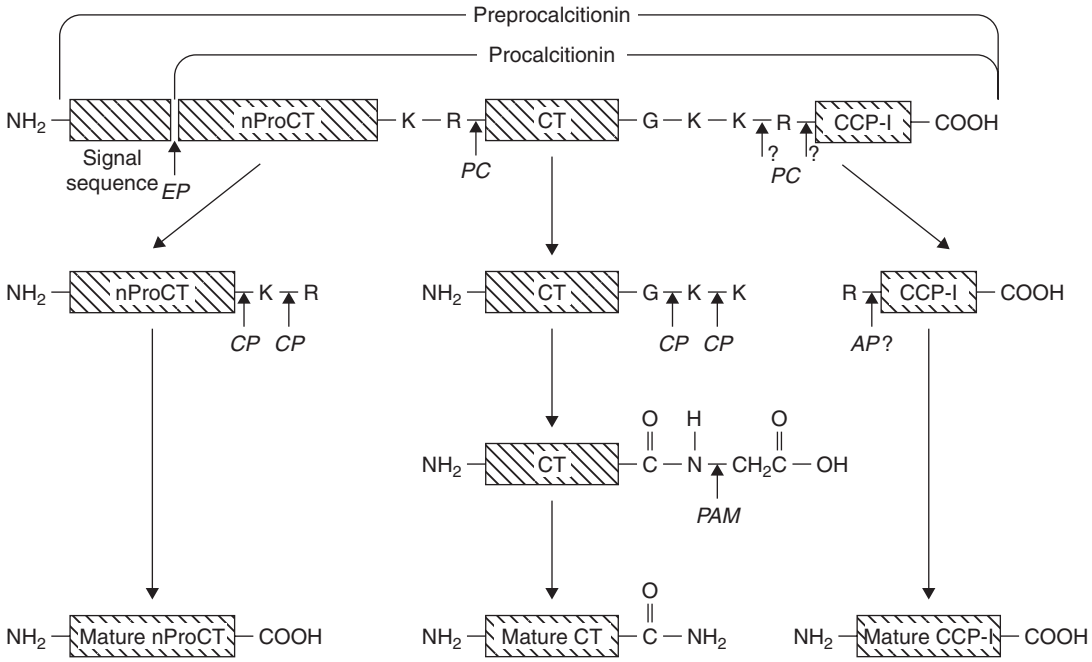

FIGURE 4 Enzymatic processing of pre-ProCT and its constituents. The cleavage of ProCT, and the consequent release of the immature CT, is accomplished by a prohormone convertase (PC) enzyme, which is calcium dependent. The appropriate order of proteolysis is modulated, in part, by autocatalytic self-activation, which in turn may be influenced by neuroendocrine "chaperone" peptides that aid in protein folding. For reasons detailed later, it is likely that the initial or preferential cleavage site of immature CT is at its amino terminus region, yielding a conjoined polypeptide of CT plus the CT carboxyl-terminal peptide (CT:CCP-I). The PC cleaves the pro-peptide at the carboxyl terminus of the dibasic paired Lys-Arg residues between nProCT and immature CT, and either between Lys and Arg or at the end of the Lys, Lys, Arg basic triplet, which is located at the junction between immature CT and CCP-I. If the cleavage is between Lys and Arg, an aminopeptidase enzyme would remove residual Arg. A carboxypeptidase removes residual Lys-Lys (or the Lys-Lys-Arg) from the immature CT prior to the action of PAM and removes Lys-Arg from the carboxyl terminus of nProCT. EP, an endopeptidase; PC, a prohormone convertase; CP, a carboxypeptidase; AP, an aminopeptidase; PAM, peptidylglycine α-amidating monoxygenase and its constituent enzyme peptidyl-α-hydroxyglycine α-amidating lyase (PAL); K, lysine; G, glycine; R, arginine.

limited. One hypothesis is that a large load of calcium in the upper gastrointestinal tract activates calcium-sensing receptors on the gastrin-producing cells, leading to gastrin release which in turn stimulates calcitonin secretion (Ray *et al*., 1997). Recent studies show that a loading dose of calcium gluconate (1 g) increases both gastrin and calcitonin, lending some credibility to this hypothesis in humans (Bevilacqua *et al*., 2005). The histamine-2 receptor blockers and proton pump inhibitors used to treat ulcer disease have been demonstrated to stimulate the release of gastrin and calcitonin (Erdogan *et al*., 2006). On the other hand, in rats who have undergone fundectomy, which leads to hypergastrinemia, CT levels did not rise above normal compared with sham-operated controls (Rumenapf *et al*., 1998).

Location of Calcitonin in the Body

Systematic studies have been done on immunoreactive CT (iCT) in tissues of humans and monkeys. In humans, the highest concentration of iCT is in the thyroid gland, where it is located within the C cells, mostly found in the central portion of each lobe. Scattered C cells may also be found in adjacent tissues (i.e., parathyroid glands and thymus). However, a survey of approximately 20 tissues of other regions of the human body has yielded iCT values for many tissues that are appreciably higher than in the blood; the highest levels have been found in small intestine, thymus, urinary bladder, lung, and liver (Becker *et al*., 1979). In mammalian species, calcitonin expression has been demonstrated in thymus, jejunum, lung, urinary bladder, prostate, brain, pituitary gland, mammary gland, endometrium, and testis (Maddineni *et al*., 2007). When one considers the weights of most of these extrathyroidal tissues, their total iCT content is considerable. In nearly all of the extrathyroidal tissues where appreciable amounts of iCT are found, neuroendocrine cells have been identified, and in some of these tissues, immunohistochemical staining reveals the presence of iCT. These extrathyroidal neuroendocrine cell contents contribute to the serum content of iCT, and these cells can be induced to secrete both locally and distally under the influence of various stimuli.

Mature Calcitonin

Modification of a precursor pro-peptide through a series of enzymatic processes produces mature CT (Fig. 4). Initially,

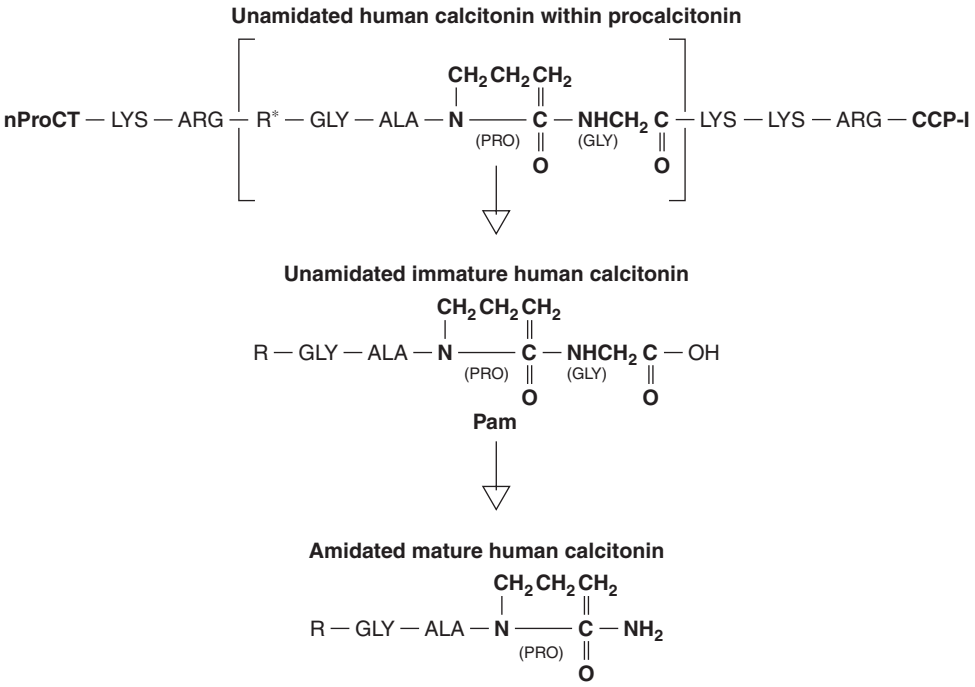

FIGURE 5 Sequential steps involved in the amidation of CT (see text). R*, 29 amino acids of human CT not shown.

there is cleavage at an endoproteolytic site (e.g., the Lys-Lys-Arg locus) within ProCT, and there is a prerequisite glycine residue at the carboxyl-terminal side of the amino acid residue that undergoes subsequent amidation. As is the case for a very large number of bioactive peptides, mature CT possesses an α-amide moiety at its carboxyl terminus. Although the exact biological function of the amide is not completely understood, there are indications that it contributes the mature peptide's stability, bioactivity, and interaction with its specific receptor (Walsh and Jefferis, 2006).

The sequential steps leading to amidation are shown in Figure 5. Peptidylglycine α-amidating monooxygenase (PAM) is the key enzyme involved in amidation (Eipper *et al.*, 1992). The preliminary step performed by PAM is oxidation of the α-hydrogen of glycine to form an α-OH. Within the PAM protein, a second enzyme resides, peptidyl-α-hydroxyglycine α-amidating lyase (PAL). This enzyme acts on the intermediate molecule; it catalyzes amidation of the adjacent proline of CT, thus removing glycine in the form of a glyoxylate. The product of this two-step enzymatic action is a mature 32-amino-acid CT with an amidated proline at its carboxyl terminus.

Measuring Mature Serum Calcitonin

Serum immunoreactive calcitonin (iCT) is measured most commonly by a two-site immunoassay. Specificity and sensitivity is provided by use of two monoclonal antibodies that target different epitopes on monomeric CT. One of these antibodies is immobilized on a matrix and binds to a single epitope on monomeric CT; a second antibody targets a second epitope and also contains a detection system (radioactivity, colorimetric, or chemiluminescent molecules). Calcitonin is sandwiched between the two monoclonal antibodies. Assays for ProCT target an epitope in monomeric CT and a second within the precursor portion of the peptide.

The principal clinical use of mature CT measurement is the detection and follow-up of patients with medullary thyroid cancer (MTC). Initial assays using polyclonal antisera identified not only monomeric CT but larger precursor molecules; as monoclonal technology evolved, assays specific for monomeric CT or ProCT were developed (Motte *et al.*, 1988; Seth *et al.*, 1989; Guilloteau *et al.*, 1990; Perdrisot *et al.*, 1990). Normal serum or plasma concentrations using these second- and third-generation assays is <2 pg/mL and may increase to 10–15 pg/mL after calcium or pentagastrin stimulation.

BIOACTIONS OF CALCITONIN

Calcitonin and the Skeletal System

CT plays an important role in skeletal homeostasis by modulating osteoclast action and bone resorption as protection from bone loss during stressful times of potential calcium deficiency (e.g., growth, pregnancy, and lactation) (Friedman and Raisz, 1965; Zaidi *et al.*, 1993; Woodrow

et al., 2006). Mammalian osteoclasts contain abundant, high-affinity receptors for CT (Nicholson *et al*., 1986; Lin *et al*., 1991; Gorn *et al*., 1992). The complex process of bone resorption involves osteoclast attachment to the bone surface using podosomes present in an actin-rich ring (the sealing zone) and the formation of the ruffled border, the main resorptive organelle in the osteoclast. CT has been shown to disassemble podosomes, disrupt the actin-rich ring and ruffled border, and eventually lead to osteoclast detachment (Kallio *et al*., 1972). Recently, it has been shown that this may be mediated by CT modulation of Pyk2 and Src activities (Bruzzaniti and Baron, 2006; Shyu *et al*., 2007). The hormone inhibits bone resorption by acutely inducing quiescence of osteoclast cell motility (Q effect) within 1 min, followed by a more gradual pseudopod retraction of osteoclasts (R effect), which together decrease cell contact with bone surface (Zaidi *et al*., 1990; Inzerillo *et al*., 2002). The Q and R effects are distinct cellular processes mediated by G proteins. The Q effect is associated with an elevation of intracellular cyclic adenosine monophosphate (cAMP) after direct activation of a cholera toxin-sensitive G_s protein by CT (Nicholson *et al*., 1986). The R effect is thought to be coupled to a pertussis toxin-sensitive G_i protein, which increases intracellular free calcium concentration (Moonga *et al*., 1992). Retraction of the pseudopods is associated with the formation of intracellular retraction fibers and a cessation of membrane ruffling; the final result is a small, rounded, nonmotile cell (Gravel *et al*., 1994). CT-induced retraction has also been attributed to protein kinase C activation in osteoclasts (Su *et al*., 1992). Additionally, *in vivo* studies of patients with Paget's disease of bone found that CT administration led to alteration of the ultrastructure of osteoclasts and a significant decrease in osteoclast number (total per area and within resorptive pits) (Singer *et al*., 1976; Williams *et al*., 1978).

CT inhibits other components of the osteoclast, which in turn contributes to its antiresorptive effects. Tartrate-resistant acid phosphatase (TRAP) is specifically expressed in osteoclasts to a high degree; serum concentrations of TRAP correlate with rates of bone resorption (Stepan *et al*., 1989; Halleen *et al*., 2002). TRAP release from osteoclasts is potently inhibited by calcitonin, even when incubated with osteoclastic activating factors like receptor activator of nuclear factor kappa B ligand (RANKL) and interleukin-1 (IL-1) (Kirstein *et al*., 2006). CT decreases carbonic anhydrase II, the enzyme expressed by osteoclasts that leads to the production of protons required for bone resorption, expression in a dose-dependent manner (Zheng *et al*., 1994). Thus, by various mechanisms, mature CT diminishes osteoclastic activity, a phenomenon that is so marked that its *in vitro* effect on bone resorption can be used as a bioassay to measure picomolar concentrations of the hormone (Zaidi *et al*., 1994).

However, within 48 hours of continuous or repetitive exposure to CT, there is a loss of inhibitory effects by CT on osteoclast-mediated bone resorption (Wener *et al*., 1972; Heersche, 1992). The "escape phenomenon" from CT inhibition of bone resorption appears to be associated with reduction of CT-receptor (CTR) expression by osteoclasts, development of rapid resistance by the osteoclast, and desensitization to CT (Samura *et al*., 2000). Additionally, administration of a monoclonal antibody to Kat1-antigen, a unique cell surface antigen expressed on rat osteoclasts distinct from RANK, led to stimulation of osteoclast formation only when in the presence of calcitonin (Kukita *et al*., 2001). This indicates a potential role of Kat1-antigen in the "escape phenomenon" from CT inhibition of bone resorption. However, owing to its inhibitory effects on the osteoclast, CT is used successfully in the therapy of disorders of bone loss or of rapid bone turnover. Additionally, its hypocalcemic activity allows it to be used clinically in hypercalcemic disorders. This is further described in the next section.

Calcitonin appears to interact with osteoprotegerin (OPG), RANKL, and RANK (Mancini *et al*., 2000). Some data suggest that CT may also exert a stimulatory effect on the osteoblast. The hormone increases the concentrations of IGF-I and IGF-II in cultures of human osteoblast cell lines in a dose- and time-dependent manner (Farley *et al*., 2000).

One of the vexing issues related to the physiology of CT has been the apparent lack of effect of removal of the thyroid gland, the major source of CT, on bone physiology. Numerous studies have failed to document significant effects of thyroidectomy on long-term bone mass (Tiegs *et al*., 1985; Hurley *et al*., 1987). A potential explanation lies in the aforementioned expression of the CT gene by neuroendocrine cells in many tissue types. Several rodent models have been developed in recent years to more directly address the question of long-term deficiency of calcitonin.

The first is a model that targeted the CT/CGRP-alpha gene (Hoff *et al*., 2002; Dacquin *et al*., 2004). The initial report described animals studied at the F_3 generation that exhibited greater calcemic responses to PTH and a significant increase in bone formation and bone volume. In a subsequent report using the same F_3 generation CT/CGRP-alpha animals, it was shown that the bone mass differences were maintained and the CT/CGRP-alpha-deficient animals developed a robust pattern of trabecular remodeling as they aged (Hoff *et al*., 2002). Taken together these findings suggested a role for CT in the regulation of bone formation and remodeling. However, subsequent studies utilizing mice backcrossed for 10 generations (F_{10}) to a pure C57B6 background, showed no significant differences in trabecular bone volume, bone formation, trabecular number, or any other measured parameter until 12 months of age. Examination of 12- and 18-month-old female animals demonstrated profound cortical and trabecular thinning, increased cortical tunneling, and biochemical evidence of increased bone resorption (Gagel *et al*., 2007).

In addition, there was a profound remodeling of cortical bone into trabecular bone near the cortical surface. These results document a profound effect of CT deficiency in older, gonadal-insufficient animals.

Examination of skeletal metabolism in these same animals, bred for 10 generations against a black Swiss mouse background, demonstrated profound skeletal changes during lactation. CT/CGRP-alpha-deficient mice lose approximately twice as much bone mass during lactation and the time for these mice to normalize their bone mass is significantly greater than for the wild-type mice.

There are two other models that address this question. The first is a targeted deletion of the CTR (Dacquin *et al*., 2004). Homozygous animals have an embryonic lethal phenotype-characterized profound edema of the developing embryo. This is analogous to the model of mouse embryos with targeted deletion of the CRLR, also an embryonic lethal situation caused by a failure of normal lymph system development (Dackor *et al*., 2006). Studies in this model system performed in younger CTR +/− animals show no evidence of bone loss (Dacquin *et al*., 2004).

Collectively, these results suggest an important role for calcitonin in the regulation of skeletal resorption and remodeling, particularly during periods of stress such as lactation, exposure to bone resorption stimulators, or gonadal steroid deficiency associated with aging. Experience in this model system identifies an important role of calcitonin in the prevention of cortical bone loss in older individuals. Extension of these observations to humans would suggest that the declining CT secretion seen in older patients may indeed have the physiological consequence of causing increased cortical bone loss. The apparent discrepancy between the CT/CGRP-alpha-deficient and the CTR heterozygous mice needs to be resolved by development of an osteoclast-specific deletion of the CTR.

Calcitonin may also have a protective role in osteoarthritis, a form of degenerative joint disease involving changes in subchondral bone, as well as cartilage. Calcitonin receptors have been identified on chondrocytes. Calcitonin has been demonstrated to increase cAMP levels in chondrocytes which, in turn, mediate the attenuation of the activity of matrix metalloproteinase (Sondergaard *et al*., 2006; Karsdal *et al*., 2007). With the findings that calcitonin administration decreases cartilage destruction in animal models, considerable attention has been directed to the potential therapeutic utility of calcitonin for osteoarthritis in humans (El Hajjaji *et al*., 2004; Manicourt *et al*., 2006; Sondergaard *et al*., 2007). The results of ongoing studies are highly anticipated.

Calcitonin and Calcium and Phosphate Metabolism

Since Copp's initial report of the hypocalcemic effect of CT in animals, CT has been considered to have a physiological protective role against hypercalcemia by inhibiting osteoclast-mediated bone resorption and promoting renal calcium excretion (Azria *et al*., 1995). Secretion of CT is directly related to elevation of extracellular calcium concentration as mentioned earlier (Deftos *et al*., 1973). Acutely, CT administration decreases the serum calcium of laboratory animals. Although salmon CT administration to sham rats can lead to a significant, acute decrease in calcium levels, the hypocalcemic effect is exaggerated in ovariectomized rats, where the higher bone resorption state associated with estrogen deficiency leads to greater decreases in calcium concentrations (Davey and Morris, 2005).

In human studies, the effects of CT on serum calcium vary with the species from which the hormone was obtained, dosage, method of administration, and concurrent bone turnover rate of the human subject. The hypophosphatemic effect of CT is dose dependent and parallels the hypocalcemic effect. In studies of healthy persons, CT transiently lowers serum calcium and phosphate concentrations and raises urinary excretion of calcium; however, these changes are usually clinically irrelevant (Buclin *et al*., 1987; Thamsborg *et al*., 1990; Buclin *et al*., 2002). In healthy humans and dogs, pharmacological doses of salmon CT result in hypocalcemia that is characterized by marked fluctuations, and paradoxical above-baseline increases of serum calcium; these patterns may be partly owing to parathyroid hormone overcompensation. Interestingly, serum calcium levels are normal in hypercalcitonemic patients with medullary thyroid cancer (MTC) (Deftos and Parthemore, 1974).

In patients with high bone turnover (e.g., Paget's disease of bone, immobilization, multiple myeloma, and hyperparathyroidism), CT exhibits greater hypocalcemic effects (Minkoff *et al*., 1985). In myeloma patients, greater reduction of calcium levels is predictive for new lytic bone lesions with or without hypercalcemia, indicating the association with greater degrees of hypocalcemia during states of increased osteoclastic resorption (Bataille and Sany, 1982; Bataille *et al*., 1985). In patients with hypercalcemia of malignancy, human calcitonin given intravenously will normalize calcium concentrations within the first 24 hours of administration, but a sustained effect was not noted after treatment was discontinued (Chevallier *et al*., 1988). Additionally, hypocalcemia usually does not occur after CT administration in these patients.

There has been documentation of an interrelationship between CT and vitamin D metabolism. Calcitonin significantly increases the production of 1,25-dihydroxyvitamin D_3 in rats, likely through stimulation of 1α-hydroxylase activity in the proximal tubule (Kawashima *et al*., 1981; Armbrecht *et al*., 1987; Wongsurawat and Armbrecht, 1991). There is also evidence demonstrating an increase in the expression of the renal 1α-hydroxylase gene in normocalcemic rats by calcitonin (Shinki *et al*., 1999). Furthermore, intestinal 24-hydroxylase enzymatic

expression, which is required for the process of inactivating vitamin D_3 metabolites, is diminished by CT administration and contributes to increased 1,25-dihydroxyvitman D_3 activity (Beckman *et al*., 1994).

Calcitonin and the Central Nervous System

Calcitonin has specific receptor-binding sites within the central nervous system and pituitary gland. Many studies have identified changes in the hypothalamic or pituitary system in response to CT administration. The physiological significance of these findings is still unclear; however, these studies, as well as others, do support other functions of CT besides regulation of bone metabolism and calcium balance. The intracerebral injection of CT suppresses food and water intake in rats (Chait *et al*., 1995). The hormone also increases body temperature, acting on specific regions of the thalamus and hypothalamus (Sellami and de Beaurepaire, 1993). In the rat, intracerebral administration of salmon CT and rat CGRP decreases the frequency and amplitude of spontaneous growth hormone secretory pulses, which may have a role in regulating appetite (Tannenbaum and Goltzman, 1985). In humans, large doses of salmon CT reduce the serum concentrations of testosterone, LH, and FSH, probably acting at the hypothalamic level (Mulder, 1993). It has been shown that salmon CT and calcitonin-like pituitary peptide (pit-CT) are inhibitors of prolactin synthesis, secretion, and pituitary lactotroph proliferation (Shah *et al*., 1999). A transgenic mouse model with overexpression of pit-CT demontrates hypoprolactinemia and, consequently, decreased fertility rates (Yuan *et al*., 2005)

Calcitonin has been characterized to have analgesic effect on chronic bone pain secondary to osteoporosis, Paget's disease of bone, or malignant processes (Ziegler, 1984; Singer, 1991; Ofluoglu *et al*., 2007). Other than through the effects on bone resorption, the antinociceptive activity of CT may be mediated, in part, via central cholinergic or serotonergic influences (Colado *et al*., 1994; Chen and Lee, 1995). Reduced nociception appears to rely on the presence of spinal serotonin receptors, which are reduced in ovariectomized rats but normal in ovariectomized rats treated with calcitonin (Yoshimura, 2000; Yoshimura *et al*., 2001; Furue *et al*., 2005). Additionally, salmon CT potentiates the analgesic effectiveness of opioid agonists, especially delta- and kappa-agonists, and of antidepressants (Goicoechea *et al*., 1999; Ormazabal *et al*., 2001).

In a recent study, subcutaneous administration of salmon CT for 2 weeks to women with postmenopausal osteoporosis significantly increased plasma beta-endorphin levels and improved pain and quality-of-life scores (Ofluoglu *et al*., 2007). This is contrasted to the findings of another study of osteoporotic women treated with intranasal calcitonin, where no reduction of chronic back pain intensity was demonstrated (Papadokostakis *et al*., 2006). A recent meta-analysis evaluating the effectiveness of CT (via intramuscular, intranasal, or rectal routes) compared with placebo for the treatment of acute pain in patients with recent osteoporotic vertebral compression fractures concluded that there was clear benefit imparted by CT with respect to pain relief and earlier mobilization (Knopp *et al*., 2005). Epidural CT was found to provide greater postoperative analgesia in patients undergoing total hip arthroplasty in comparison with epidural opioid (Gabopoulou *et al*., 2002). Salmon CT has been reported to relieve postherpetic neuralgia when given intravenously to an elderly man who did not respond to other pharmacotherapies (Visser and Kwei, 2006).

Calcitonin and the Respiratory System

The total amount of immunoreactive CT in normal lungs exceeds that of any tissue of the human body, including the thyroid gland (Becker *et al*., 1979). The hormone is found within pulmonary neuroendocrine (PNE) cells, which are situated near the basement membrane and often extend to the lumen of the airway extending from the nasal respiratory epithelium, laryngeal mucosa, and throughout the respiratory tract from the trachea to terminal airways (Becker *et al*., 1980; Weichselbaum *et al*., 2005). Hamsters exposed to noxious stimuli, such as cigarette smoke or diethylnitrosamine, have demonstrated increased levels of immunoreactive CT in the serum and lung tissue (Linnoila *et al*., 1984; Tabassian *et al*., 1989). These findings and the presence of the great number of PNE cells in the fetus and newborn suggest that CT may play a role in pulmonary maturation and pathophysiology. Immunoreactive calcitonin has been found in high concentrations in sputum and lung tissue from cystic fibrosis patients, which may represent either an underlying pathological effect of cystic fibrosis or an inflammatory response to the infectious process present in lung tissue from cystic fibrosis patients (Wolf *et al*., 1986) Patients with lung cancer of all histological subtypes have demonstrated elevated serum CT concentrations, with extensive small-cell lung carcinoma being associated with the highest levels (Krauss *et al*., 1981). However, other than in the case of medullary thyroid carcinoma, serum CT is not used routinely as a tumor marker. Recently, more evidence has come to support neuropeptides, such as CGRP, as being important markers and mediators of pulmonary disorders and systemic inflammation, as will be discussed later in this chapter.

Calcitonin and the Gastrointestinal System

Although CGRP-α has become recognized as an important modulator of intestinal function and pathology (discussed later in this chapter), CT was initially noted to have gastrointestinal effects, as well (Lenz *et al*., 1985). In humans, pharmacological doses of CT increase gastric acid and

pepsin secretion, decrease pancreatic amylase and pancreatic polypeptide production, and increase small intestinal motility (Demol *et al*., 1986). Additionally, serum motilin and gastric inhibitory peptide levels are decreased. Somatostatin levels in the serum are increased. The small intestinal secretion of potassium, sodium chloride, and water is augmented. Thus, at high concentrations, CT increases the net secretion of water and electrolytes from the human jejunum and ileum while shortening transit time; it has been postulated that these effects may contribute to the diarrhea seen in some patients with medullary thyroid cancer (Demol *et al*., 1986).

Calcitonin and the Reproductive System

Calcitonin expression occurs in both the mammalian uterus and placenta (Balabanova *et al*., 1987). Calcitonin is present in human, monkey, and rat endometria during the luteal stage of the menstrual cycle (Ding *et al*., 1994; Kumar *et al*., 1998; Diao *et al*., 2002). This period of increased CT expression overlaps with that which is considered the window of uterine receptivity for embryonic implantation, supporting the use of calcitonin as a biomarker of receptivity (Giudice, 1999). In the rat, CT messenger RNA is present in the glandular epithelial cells of the uterus at the time of implantation and may have a regulatory role in early pregnancy after implantation of the embryo (Ding *et al*., 1994). Uterine CT expression is stimulated by progesterone. Furthermore, administration of mifepristone, an antiprogestin drug, decreases CT expression in the uterus and inhibits implantation. Early uterine expression of CT may also be important in preimplantantion embryonic development because calcitonin has been shown to accelerate blastocyst differentiation through elevation of cytosolic ionized calcium concentration (Wang *et al*., 1998; Armant *et al*., 2000). Recently, it was reported that endometrial cell production of tissue transglutaminase type II (tTGase), an enzyme that catalyzes calcium-dependent protein cross-linking, is upregulated upon exposure to progesterone and CT; therefore, tTGase likely represents a downstream target of CT (Li *et al*., 2006).

Calcitonin receptors are present in the human placenta within the syncytiotrophoblast brush border that faces the mother and in the basal plasma membrane that faces the fetus (Lafond *et al*., 1994). The intraplacental presence of CT receptors and immunoreactive CT suggests a role of the CT-CTR system in implantation, regulation of placental function, and/or mineral metabolism during fetal life. A recent study of CT/CGRP-alpha null mice evaluated whether CT and/or CGRP-alpha are required for placental calcium transfer or fetal mineral regulation (McDonald *et al*., 2004). Interestingly, fetal CT/CGRP-alpha null mice demonstrated reduced levels of serum and skeletal magnesium levels. In contrast, there was no disruption of serum ionized calcium concentration, skeletal calcium content, or placental transfer of calcium in these mice. Another finding from this study that highlights the physiological importance of CT is that CT/CGRP-alpha null mice had significantly fewer viable fetuses *in utero* compared with heterozygous CT/CGRP-alpha (+/−) and wild-type mothers; however, viable, developmentally normal pups have been shown to be born to CT/CGRP-alpha null mice (Hoff *et al*., 2002; McDonald *et al*., 2004).

Human breast milk from women who have a history of total thyroidectomies contains large amounts of immunoreactive CT, indicating independent production of CT from the mammary gland (Bucht *et al*., 1986). Calcitonin expression and secretion is identified in mouse mammary glands during pregnancy and is progesterone-dependent; CTR expression is not affected by progesterone (Ismail *et al*., 2004). Calcitonin receptors localized in rat mammary glands are expressed in varying degrees depending on the reproductive status: slightly increased during pregnancy and markedly increased during lactation (Ishii *et al*., 2006). Ishii and colleagues noted that CT inhibited thymidine incorporation into DNA in lactating mammary gland cells. They hypothesized that CTR upregulation during lactation mediates CT's regulation of DNA synthesis to prevent mammary gland cell proliferation. Additionally, the possible role of CT as a modulator of mineral and electrolyte concentrations of milk merits study.

Immunoreactive CT production by breast cancer was first reported by Coombes and colleagues (1975). Although suggested as a potential tumor marker in breast cancer, calcitonin later was found to have very little correlation to stage of disease (Bezwoda *et al*., 1981). In fact, it has been reported recently that there is decreased expression of CTR mRNA in breast cancer cells, particularly with invasive tumors, as compared with matched cancers and unaffected ductal epithelia from the same patients (Wang *et al*., 2004). A follow-up study by the same investigators found that CT administration inhibited breast cancer cell invasiveness (Han *et al*., 2006).

Calcitonin and CTR have been localized to human prostate neuroendocrine cells (Davis *et al*., 1989; Shah *et al*., 1992; Wu *et al*., 1996). Significantly greater levels of CT are found in hyperplastic prostates than in normal specimens (Davis *et al*., 1989). The presence of the CT-CTR system in prostatic tissue indicates a possible role in regulation of prostatic growth. In fact, small-cell carcinoma of the prostate, a rare histological subtype of prostate cancer involving neuroendocrine cells, is associated with increased serum CT concentrations (Sim *et al*., 1996). Calcitonin appears to be involved in the regulation of prostate cancer cell growth as supported by the induction of DNA synthesis and cell proliferation by exogenously administered CT to prostate cell cultures and by the presence of high CT and CTR expression in prostate cancer cells (Chien *et al*., 2001). Further evaluation supports the proliferative effects of CT as the downregulation of CT expression in prostate cancer cell

lines leads to diminished oncogenicity, as expressed by cellular growth rates and invasiveness (Thomas *et al*., 2006).

Calcitonin and the Renal System

The primary action CT has in the human kidney is the enhancement of calcium excretion through inhibition of tubular calcium resorption (Ardaillou *et al*., 1969; Cochran *et al*., 1970). In humans, intravenous administration of CT stimulates diuresis and fractional excretion rates of calcium, phosphate, sodium, chloride, magnesium, and potassium (Gnaedinger *et al*., 1989). However, in some species (e.g., rat), CT stimulates the renal tubular reabsorption of calcium and magnesium, probably within the thick ascending limb of the loop of Henle, and decreases urinary excretion of calcium and magnesium (Di Stefano *et al*., 1985; Carney, 1992).

The kidney is a principal site of CT degradation (Hysing *et al*., 1991). Serum CT concentrations are elevated in chronic renal failure; however, postdialysis levels of CT are unchanged or increased when compared with predialysis levels, indicating that some mechanism other than decreased renal clearance contributes to hypercalcitonemia in renal failure patients (Niccoli *et al*., 1995). In fact, Messa and colleagues demonstrated in patients with varying degrees of renal failure compared with normal controls that CT concentrations varied in response to fluctuations of serum calcium levels, indicating that variable CT secretion by thyroid C cells occurs rather than variable renal excretion (Messa *et al*., 1995).

Renal effects after binding of CT to CTR are mediated through the activation of protein kinase or cAMP pathways, with selection of a specific pathway occurring in a cell cycle-dependent manner (Chakraborty *et al*., 1991). Besides regulating renal absorption of calcium, CT is a natriuretic; it decreases sodium reabsorption via effects on the Na/K ATPase and Na/H exchanger in the renal proximal tubule in a cell cycle-dependent manner (Chakraborty *et al*., 1994).

CLINICAL CONDITIONS WITH INCREASED PRODUCTION OF CALCITONIN PRECURSORS

Humans normally produce measurable, albeit low, levels of procalcitonin (ProCT), amino-terminal peptide (nProCT), conjoined calcitonin-calcitonin carboxyl-terminal peptide (CT:CCP-I), free CCP-I, and mature CT (Snider *et al*., 1997) (Fig. 6). Collectively, we refer to the component peptides as calcitonin precursors (CTpr). Moreover, in several pathological states (e.g., hyperplasia or malignancy, and states of inflammation or infection), CTpr biosynthesis and secretion are augmented whereas mature CT levels are normal or minimally elevated owing to incomplete post-translational processing.

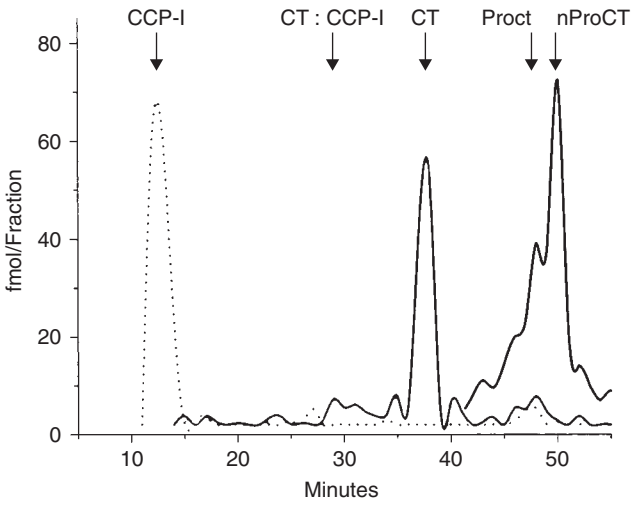

FIGURE 6 Procalcitonin and its component peptides in normal human serum. CT radioimmunoassay (thick line), CCP-I radioimmunoassay (dashed black line), and nProCT radioimmunoassay (thin line). Modified from Snider *et al.* (1997).

Extrathyroidal Neuroendocrine Cell Hyperplasia or Tumors

In addition to C-cell hyperplasia of the thyroid, extrathyroidal neuroendocrine cell hyperplasia is associated with increased serum iCT levels. The study of some chronic nonneoplastic pulmonary conditions with region-specific antisera has demonstrated slight to moderate increases of serum iCT associated with an apparent increase of CT precursors (most prominently, procalcitonin); whereas, levels of free mature CT usually remain within the normal range. These conditions include patients with chronic bronchitis, chronic obstructive pulmonary disease, and chronic pulmonary tuberculosis (Becker *et al*., 1981; Nylen *et al*., 1996). Immunoreactive CT-containing PNE cells demonstrate hyperplasia in some chronic lung diseases (Becker *et al*., 1980; Linnoila *et al*., 1984). Additionally, increased levels of pro-CT may be related to underlying infections associated with these pulmonary processes. This will be described further in the next section. Insufficient studies have been performed to fully characterize the nature and distribution of the precursor forms secreted in extrathyroidal neuroendocrine cell hyperplasia.

Serum mature CT has proven to be a very important clinical marker to detect and follow the course of medullary thyroid carcinoma (MTC), the neoplasm of the thyroid C cells. In addition, the use of region-specific antisera and separatory techniques has demonstrated that MTC secretes large amounts of high-molecular-weight forms of the hormone (i.e., pro-CT and CCP-II) (Becker *et al*., 1978; Minvielle *et al*., 1991) (Fig. 7).

Small-cell lung cancer and bronchial carcinoids, tumors involving pulmonary neuroendocrine cells, can produce large concentrations of iCT, consisting primarily

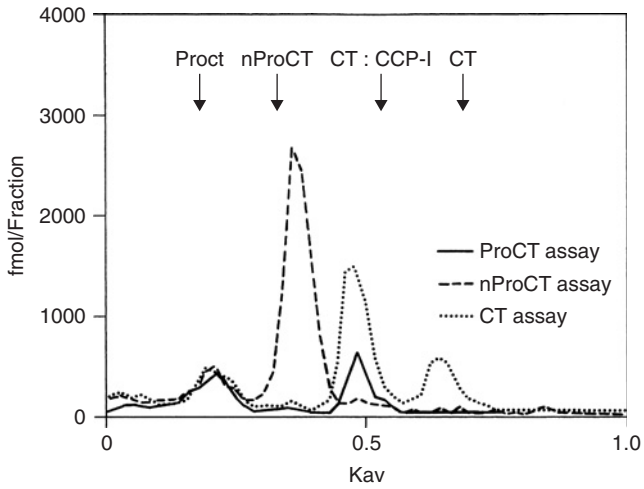

FIGURE 7 Gel filtration of serum of MTC patient. Note that the peak corresponding to the elution position of the CT:CCP-I peptide does not cross-react equally in both CT and ProCT assays. This may be due to the presence of some CT dimer (Tobler *et al.,* 1983), as it has a similar molecular mass.

of CT precursors (Cate *et al*., 1986). The ratio of levels of high-molecular-weight precursors to mature CT is usually much greater in bronchogenic tumors than MTC (Becker *et al*., 1978; Bertagna *et al*., 1978). Other neuroendocrine tumors have been reported to produce iCT *in vitro* and *in vivo* (e.g., pheochromocytoma, neuroendocrine carcinoma of prostate cancer, neuroendoocrine carcinoma of the larynx, carcinoid tumors [Mascolo *et al*., 2005], and pancreatic neuroendocrine tumor) (Deftos, 1998; Chung *et al*., 2004; Van den Eynden *et al*., 2007). Although excessive amounts of immunoreactive CT have been detected in the sera of patients with non-neuroendocrine tumors (e.g., breast cancer), there are few data specifically regarding levels of serum or tissue CTpr in the literature (Coombes *et al*., 1975).

Severe Inflammation, Infection, and Sepsis

In the United States, sepsis afflicts more than 750,000 persons annually and the in-hospital mortality rate ranges from 29% to 50% (Weycker *et al*., 2003). Marked insults, such as burns, trauma, surgical procedures, pancreatitis, or bacterial infections, commonly induce a hypersecretion of various proinflammatory cytokines, arachidonic acid metabolites, and other humoral substances that cause a syndrome of systemic inflammation: vasodilation, chemoattraction of hematopoietic cells, activation of macrophages, and capillary endothelial leakage. The appellation of "sepsis" is given to this clinical condition when it is attributable to a microbial source (Bone, 1995). In severe cases, this may lead to "multiple-organ dysfunction" characterized by myocardial insufficiency, circulatory hypoperfusion, hypoxemia, cerebral obtundation, renal failure, coagulopathy, and shock. Essentially, the patient becomes severely ill primarily because of a hyperresponsivity of the humoral reaction to the initial injury.

Over the past two decades, studies have indicated that serum concentrations of CTpr, specifically ProCT, are increased markedly in severe inflammation and are often associated with microbial infections (Assicot *et al*., 1993; Tang *et al*., 2007). In sepsis, circulating levels may be increased hundreds- to thousands-fold. Importantly, because of incomplete processing, there is very little or no elevation of serum mature CT, as seen in cases of tumors associated with increased CT production described earlier. In fact, it was recommended that ProCT be included into the international definition of sepsis because it may differentiate sepsis from noninfectious causes of systemic inflammatory response syndrome (SIRS) (Levy *et al*., 2003). Procalcitonin has been identified as a useful marker of sepsis in various populations or injuries: pediatrics (Assicot *et al*., 1993), emergency department (Hausfater *et al*., 2002), ventilator-associated pneumonia (Duflo, 2002), acute respiratory distress syndrome (Brunkhorst, *et al*., 1999), burn injury (Carsin *et al*., 1997), post-cardiac surgery (Aouifi *et al*., 2000), bacterial meningitis (Viallon *et al*., 1999), secondary peritonitis (Rau *et al*., 2007), and acute pancreatitis (Rau *et al*., 2007). However, a recently published meta-analysis evaluating the value of ProCT in critical care settings found that ProCT cannot differentiate sepsis from noninfectious causes of SIRS, limiting its generalized use (Tang *et al*., 2007). The conclusion of this review should not be applied to the utility of ProCT measurements in identifying sepsis in noncritical care settings or in specific disease processes.

The most proximal stimulus to increased CTpr in sepsis may be endotoxin, a product of gram-negative bacteria. Endotoxin administration to healthy human individuals has been shown to increase tumor necrosis factor-alpha (TNF-alpha) and other cytokines within hours of exposure, correlating with a rise of procalcitonin concentration plateauing at 24 hours and remaining high for more than 7 days after exposure (Dandona *et al*., 1994; Preas *et al*., 2001). Gram-negative bacteremia or translocation of *Escherichia coli* (or its endotoxin), normal intestinal flora, from the gut across the bowel wall into the bloodstream may be initial sources of endotoxin to initiate the inflammatory pathway. In the specific case of burn injury, which is highly associated with sepsis and mortality, high levels of endotoxin and cytokines [e.g., TNF-alpha and interleukin-6 (IL-6)] have been found (Guo *et al*., 1990; Yamada *et al*., 1996). This may be attributable to increased gut permeability demonstrated within 48 hours of injury causing translocation of intestinal bacteria (Ryan *et al*., 1992). However, a study of 40 patients with thermal burn injuries found that ProCT and IL-6 levels increased acutely, correlating significantly with severity of skin burn, without any evidence of infection nor

increase in endotoxin or TNF-alpha concentrations (Carsin *et al*., 1997). Thus, increased levels of ProCT may not be related directly to an infectious source or endotoxin exposure in burn injury. Sepsis induced by gram-positive bacteria also has been reported to increase circulating ProCT levels (Feezor *et al*., 2003). Thus in the presence of contradictory reports, the stimulus for increased ProCT production in sepsis or inflammatory disorders is still unknown.

The source of ProCT in sepsis or systemic inflammation has been studied in animal models and humans. Studies in septic hamsters, pigs, and humans have revealed detectable CT mRNA not only in the thyroid gland, but also in all extrathyroidal tissues studied (brain, gut, kidney, liver, lung, testes, muscle, etc.) (Muller *et al*., 2001). In contrast, in control animals, CT mRNA is detectable only in thyroid (i.e., C cells) and lung (i.e., PNE cells). In septic humans and animals, *in situ* hybridization studies have demonstrated that multiple cell types within these organs and tissues are involved. Thus, in sepsis, the entire organism is transformed into an endocrine gland (Muller *et al*., 2001). A similar phenomenon has been found for the expression of CGRP and AM, two other peptides of the CALC gene family (Domenech *et al*., 2001). It appears that increased gene transcription is induced by microbial infection-specific sepsis response elements in the gene promotor. Thus, these findings indicate that calcitonin gene products can follow either a classical hormonal expression or, alternatively, a cytokine-like expression pathway. In this regard, these gene products are a prototype of "hormokine" mediators (Domenech *et al*., 2001; Muller *et al*., 2001). Recent studies have indicated that liver and adipose tissue may be significant sources of ProCT and other calcitonin gene products (Meisner *et al*., 2003; Linscheid *et al*., 2005).

The correlation between serum CTpr levels and the severity of systemic inflammation/infection/sepsis suggests that one of these peptides, in particular, ProCT, might be contributing to the morbidity and mortality of the host. Indeed, injection of ProCT into septic hamsters was found to increase mortality greatly, and immunoneutralization of ProCT with antisera raised to different regions of the molecule improved the clinical course of experimentally induced sepsis markedly (i.e., severe peritonitis) in hamsters and pigs (Nylen *et al*., 1998; Wagner *et al*., 2002). In contrast, Hoffman and colleagues postulated that the increased production of ProCT seen in sepsis or shock, rather than being directly toxic, may reflect a counterregulatory mechanism to limit the release of nitric oxide, a mediator of vasodilation and cell death typical in septic shock (Hoffmann *et al*., 2001). The authors demonstrated in an *in vitro* cell culture line that ProCT inhibited (in a dose-dependent manner) TNF-alpha and interferon-gamma stimulation of inducible nitric oxide synthase gene expression, which is stimulated in sepsis and septic shock (Hoffmann *et al*., 2001). At this time, the function of ProCT in sepsis is unclear and further studies are required in this area.

Calcitonin Gene-Related Peptides Alpha And Beta

The CALC-I gene encodes either CT or CGRP-alpha by tissue-specific alternative processing of the primary RNA transcript (see Fig. 1) (Amara *et al*., 1982). CGRP-alpha (also termed CGRP-I; molecular mass, 3789 Da) is a 37-aminoacid peptide. In humans, CGRP-beta (or CGRP-II; molecular mass, 3794), the product of the CALC-II gene, differs from CGRP-alpha in three of the 37 amino acids (Steenbergh *et al*., 1985). There is no alternative processing of the RNA transcript to produce CGRP-beta. As is the case for the structure of CT, both types of CGRP have an amidated carboxy1 terminus and a disulfide bridge at the amino terminus. The first N-terminal residues (1–7) are necessary for receptor activation, and loss of the disulfide bridge linking amino acids 2 and 7 will eliminate the biological activity of CGRP (Tippins *et al*., 1986; Maggi *et al*., 1990). In fact, CGRP(8–37), where the first seven N-terminal amino acids are removed, is a CGRP-receptor antagonist with high affinity (Chiba *et al*., 1989). Additionally, the amidated carboxyl terminus is important for CGRP binding to its receptor (Banerjee *et al*., 2006).

CGRPs are neuropeptides; they are found mostly in the central and peripheral nervous systems (e.g., brain, ganglia, spinal cord, and peripheral nerves) and the cardiovascular system. They also are located in C cells of the thyroid and in neuroendocrine cells of the respiratory tract, where often they coexist with CT. Serum levels of CGRPs are detectable in normal persons and may arise in the setting of hypercalcemia, but this response does not seem to be physiologically relevant. Both CGRPs also have been identified in cerebrospinal and joint fluid (Wimalawansa, 1996). CGRPs have been located in a variety of tumors: medullary thyroid carcinoma, bronchogenic lung cancer, carcinoid tumor, pheochromocytoma, insulinoma, prostate cancer, parathyroid adenoma, and promyelocytic leukemia (Wimalawansa, 1996).

The two CGRPs exhibit nearly identical biological activities; thus, they will be collectively referred to as CGRP for the remainder of this discussion. CGRP is an extremely potent endogenous vasodilator and can reduce blood pressure. This last function is supported by the finding that the CT/CGRP gene knockout mouse model has elevated baseline blood pressure (Gangula *et al*., 2000). Involved in the regulation of gastric vascularity, gastric acid secretion, and intestinal motility, CGRP may maintain gastric mucosal integrity (Holzer, 1998; Gyires, 2004). In fact, mice lacking CGRP expression developed adult-onset colitis (Thompson *et al*., 2007). The hormone may play a role in various pulmonary pathophysiological settings: bronchial asthma or chronic obstructive pulmonary disorder (Groneberg *et al*., 2004; Springer *et al*., 2004), and fetal and neonatal lung disease (Johnson *et al*., 1988). Serum CGRP is increased slightly in sepsis, which may be a counter-regulatory

mechanism to inhibit the process of local acute inflammation (Gomes *et al*., 2005). Much attention has focused recently on the association of CGRP with migraine attacks, leading to the study of CGRP antagonists in the treatment of migraines (Edvinsson, 2001; Lassen *et al*., 2002; Olesen *et al*., 2004).

CGRP may cause a slight diminution of bone resorption, the physiological relevance of which is unknown (Owan and Ibaraki, 1994). The hormone inhibits osteoclast bone resorption by inducing quiescence (Zaidi *et al*., 1990). This inhibition is mediated in part via cAMP (Akopian *et al*., 2000). Additionally, CGRP has been shown to have direct proliferative effects on osteoblast cells (Villa *et al*., 2006). CGRP increases the number of bone colonies in cultured rat bone marrow (Bernard and Shih, 1990). Bone tissue contains CGRP-immunoreactive nerves, which increase in concentration at times of bone remodeling and fracture healing (Hukkanen *et al*., 1993; Li *et al*., 2007). Recently, Villa and colleagues demonstrated that CGRP reduces the release of osteoprotegerin (OPG) by osteoblasts, and, consequently, modulates the OPG/RANKL/RANK system to favor osteoclastogenesis and bone resorption (Villa *et al*., 2006). The overall weakly anabolic activity of CGRP may result from a balance of stimulatory actions on both bone formation and resorption. It is clear that CGRP is a neuromodulator with a broad spectrum of biological effects, mediated by receptors that are distributed widely throughout the body.

AMYLIN

Amylin, encoded by the CALC-IV gene located on chromosome 12, is a 37-amino-acid peptide (molecular mass, 3903 Da) that was identified in amyloid deposits in an endocrine pancreatic tumor and in patients with type 2 diabetes mellitus (Cooper *et al*., 1987). Amylin, which is co-secreted with insulin from pancreatic beta cells in response to similar stimuli (e.g., meals, glucose load), essentially delays glucose entry into circulation (i.e., inhibits postprandial glucagon secretion, delays gastric emptying, and confers early satiety). Serum levels of amylin are elevated in some patients with insulin resistance, obesity, and hypertension. High concentrations of this peptide lead to amylin aggregation and amyloidosis, which has been shown to be cytotoxic to pancreatic beta cells and may be the pathogenic basis in the development of type 2 diabetes (Zhang *et al*., 2003).

In the kidney, the hormone stimulates plasma renin secretion (Cooper *et al*., 1995). Amylin promotes renal sodium excretion by acting on sites within the brain (Mathai *et al*., 2005). Similar to CGRP, amylin has vasodilating and anti-inflammatory properties (Clementi *et al*., 1995). Amylin also has been localized to the gut (primarily in the pyloric antrum), nerves in the dorsal root ganglia (co-localized with CGRP), and osteoblasts (Gilbey *et al*., 1991; Miyazato *et al*., 1991; Mulder *et al*., 1995).

Amylin affects bone and mineral metabolism by inhibiting osteoclastic bone resorption, and hence, leading to hypocalcemia (Datta *et al*., 1989). Amylin causes hypocalcemia in patients with Paget's disease of bone (Wimalawansa *et al*., 1992). Amylin inhibits bone resorption by inhibiting osteoclasts motility (Alam *et al*., 1993). Amylin-knock-out mice models experience bone loss owing to uncontrolled bone resorption (Lerner, 2006). Interestingly, amylin also stimulates rat osteoblast proliferation *in vitro* and increases mineralized bone volume in mice *in vivo* (Cornish *et al*., 1995). Bone loss in the setting of estrogen deficiency was salvaged with amylin administration to ovariectomized rats (Horcajada-Molteni *et al*., 2000).

ADRENOMEDULLIN

Adrenomedullin is a bioactive peptide originally isolated from human pheochromocytoma tissue (Kitamura *et al*., 1993) (see Fig. 2). This 52-amino-acid peptide (molecular mass, 6029 Da) is also amidated at the carboxy1 terminus and possesses an intramolecular disulfide bridge between cysteine residues at positions 16 and 21, thus, forming a six-residue ring structure (Ishimitsu *et al*., 1994). These characteristics, plus its moderate amino acid homology to CGRP and a slight amino acid homology to amylin, suggest that it belongs to the calcitonin gene family of peptides (Wimalawansa, 1997). As is the case for CALC-I, -II, and -III genes, its encoding gene (CALC-V) is found on human chromosome 11. In contrast to CT, CGRP, and amylin, which possess a disulfide ring structure at or near the amino terminus, adrenomedullin contains an additional 15 amino acid residues situated on the amino terminus side of its disulfide ring. This preceding peptide segment is not required for hormonal bioactivity; biological activity depends on the terminal 40 amino acids (Brain and Grant, 2004). On the other hand, within the precursor proadrenomedullin molecule (185 amino acids), there is an N-terminal 20-residue peptide segment that may be biologically active through a mechanism distinct from that of adrenomedullin (Shimosawa *et al*., 1995).

Adrenomedullin is found normally in adrenal medulla, heart, lung, kidney, pancreas, intestine, vascular smooth muscle, and plasma (Hinson *et al*., 2000). The hormone activates adenylate cyclase through a G protein-coupled mechanism and mobilizes intracellular Ca^{2+}. Various pharmacological stimulants of its secretion include cortisol, aldosterone, interleukin-1 alpha and beta, TNF-alpha and -beta, and lipopolysaccharide (Sugo *et al*., 1995).

The primary physiological effect adrenomedullin is vasodilation. Adrenomedullin has been shown to increase pulmonary blood flow, reduce mean blood pressure owing to the decrease in peripheral vascular resistance, and increase blood flow in other areas of the body (e.g., heart, retina, and skin)

(Kitamura *et al*., 1993; Lippton *et al*., 1994; Ueda *et al*., 2005; Hasbak *et al*., 2006). It appears that part of the vasodilatory effect is mediated by indirect induction of nitric oxide synthesis (Hattori *et al*., 1999). Other actions include bronchodilation, modulation of hypothalamic-pituitary-adrenal axis, and inhibition of angiotensin-induced aldosterone release (Kanazawa *et al*., 1994; Yamaguchi *et al*., 1995; Shan *et al*., 2003). In the brain, adrenomedullin exerts vasorelaxant and antidipsogenic effects and may function as a neurotransmitter-neuromodulator (Murphy and Samson, 1995). In transgenic mice that overproduce adrenomedullin, adrenomedullin will promote vasodilation, vascular regeneration and neurogenesis after induced-ischemic brain injury, supporting investigation of this hormone in the management of ischemic brain (Miyashita *et al*., 2006).

Increased concentrations of adrenomedullin are seen in cardiovascular diseases (heart failure, hypertension), renal failure, and sepsis. Given the vasodilatory activity of this hormone, it can be surmised that increased adrenomedullin production may be a compensatory process in these conditions. In fact, as was seen with ischemic brain injury, adrenomedullin may have potential therapeutic or modulating properties in other disorders: pulmonary hypertension (Qi *et al*., 2007), diabetic retinopathy (Kaneko *et al*., 2006), heart failure (Nishikimi and Matsuoka, 2005), and ischemic heart disease.

In both *in vivo* and *in vitro* studies, adrenomedullin has been found to be a potent stimulator of osteoblasts (Cornish *et al*., 1997). Adult mice injected with adrenomedullin into the calvariae demonstrated two- to threefold increase in bone formation. Adrenomedullin may be a local regulatory of bone metabolism as osteoblasts express both adrenomedullin peptides and receptors (Naot *et al*., 2001). Indeed, administration of the bioactive portion of adrenomedullin(27–52) to adult male mice led to significant increases in cortical width (21%), trabecular bone volume (45%), and bone strength (Cornish *et al*., 2001). Growth plate thickness also was shown to increase after exposure to adrenomedullin, indicating that chondrocytes may be an additional target. Insulin-like growth factor-1 (IGF-1) receptors on osteoblasts appear necessary to mediate the effects of adrenomedullin, as well as amylin, in the bone (Cornish *et al*., 2004). The study of effect of adrenomedullin on bone development has been difficult to conduct because adrenomedullin knockout mice die *in utero* (Caron and Smithies, 2001). To date, the effect of the hormone on the osteoclast, if any, is unknown.

NOVEL CALCITONIN GENE FAMILY PEPTIDES

A few novel peptides recently have been identified to belong to the calcitonin gene family of peptides: calcitonin receptor-stimulating peptide types-1, -2, and -3 (CRSP-1, CRSP-2, and CRSP-3) and intermedin (IMD, also referred to as adrenomedullin-2) (Katafuchi *et al*., 2003a and 2003b; Roh *et al*., 2004; Takei *et al*., 2004). All subtypes of CRSP were first isolated from porcine brain tissue and found to have approximately 60% amino acid sequence homology to human CGRP-alpha and CGRP-beta. CRSPs are expressed primarily in the thyroid, pituitary, and central nervous system, with only a few sites showing variable subtype expression (Katafuchi *et al*., 2003a). Despite the structural similarity to CGRP, CRSP-1 did not lead to hypotension when administered to rats; however, a transient reduction of plasma calcium concentration occurred (Katafuchi *et al*., 2003b). Besides additional evidence indicating that exogenously administered CRSP-1 may affect renal ion (sodium and calcium) transport and renal cell growth (Hamano *et al*., 2005) and energy homeostasis (Sawada *et al*., 2006), CRSP-1 inhibited the formation of multinucleated osteoclast-like cells in a dose-dependent manner and destroyed the actin ring associated with osteoclast resorptive activity (Notoya *et al*., 2007). CRSP has not been identified in humans or rodents and its biological function remains unclear (Katafuchi and Minamino, 2004).

Intermedin, a 47-amino-acid peptide with a disulfide bridge at the amino terminus, has been localized to submaxillary gland, kidney, stomach, uterus and ovary, lymphoid tissues, and pancreas (Takei *et al*., 2004). Biological activities of intermedin include: vasodilation (of pulmonary, mesenteric, and renal vascular beds) (Burak Kandilci *et al*., 2006; Chauhan *et al*., 2007); suppression of gastric emptying and appetite (Roh *et al*., 2004); and stimulation of plasma renin, aldosterone, and atrial and brain natriuretic peptide levels (Charles *et al*., 2006). Intermedin has been found to inhibit pituitary release of growth hormone mediated by inhibition of growth hormone-releasing hormone (GHRH) effects, an activity not seen with the other members of the CT gene family of peptides (Taylor *et al*., 2006). Effects on bone or mineral metabolism have yet to be reported in the literature.

RECEPTORS OF THE PEPTIDES OF THE CALCITONIN GENE FAMILY

Bioactivity of the peptides of the CT gene family is exerted by binding to their receptors. These are seven-transmembrane-domain G protein-coupled receptors, in which guanidine nucleotide guanosine triphosphate facilitates the actions of the peptide by binding to specific mediator proteins. There are two subgroups of receptors for the CT gene family: CT receptor (CTR) and CT receptor-like receptor (CRLR) (Lin *et al*., 1991; McLatchie *et al*., 1998). Interestingly, CRLRs were not identified until it was recognized that a member of another novel family of single-transmembrane-domain proteins, called receptor-activity-modifying protein (RAMP), must also be expressed to

transport the CRLR to the cell membrane and to convey ligand specificity (McLatchie *et al*., 1998). Each of the CT gene family of peptides binds with variable affinities to these receptors. Consequently, some of their bioeffects overlap. Calcitonin is unique in that it alone can activate a specific G protein receptor in the absence of a RAMP. The RAMP together with either the calcitonin receptor (CTR) or calcitonin receptor-like receptor (CRLR) binds the other ligands of this family of peptides (see Table 2).

The complicated and unique overlapping of receptivity of CTRs and CRLRs owes to their multipotentiality when associated with various RAMPs. Three RAMPs (RAMP-1, -2, and -3) have been identified. The presence, concentration, and/or timing of one or more of the three accessory proteins determines the specific phenotype and ligand specificity of the receptor that is ultimately expressed on the cell surface (see Table 1) (McLatchie *et al*., 1998; Buhlmann *et al*., 1999; Muff *et al*., 1999; Leuthauser *et al*., 2000; Hay *et al*., 2004; Roh *et al*., 2004). This process has given rise to seven distinct, molecularly characterized receptors for CT, CGRP, amylin, and adrenomedullin (Lerner, 2006). Additionally, RAMPs modify gene expression of the CTR, transport CRLR to the plasma membrane, and assist with cellular recycling of receptor complexes (Bomberger *et al*., 2005). The profile of RAMP expression and activity is altered by the local milieu and is subject to humoral influences (Frayon *et al*., 2000). Modification of the CRLR also can modify its binding affinity to different peptides; the deletion of a sequence of the CRLR led to continued affinity for CGRP (in the presence of RAMP-1) but eliminated its binding to adrenomedullin (in the presence of RAMP-2) (Koller *et al*., 2004). This extraordinarily elegant and complex system allows for a diversification of receptor function, thus modulating the action of the CT gene products according to ambient needs.

CONCLUSION

In the early 1960s, CT was discovered as a hormone that had hypocalcemic effects but had an undetermined role in human physiology. Since then, it has been found to be only one peptide among a vast array of related circulating peptides comprising the CT gene family of peptides. A valid hypothesis for the function of CT, in part, made more than two decades ago, is that CT maintains bone mineral in emergency situations (i.e., to combat hypercalcemia) and may play a role in the conservation of body calcium stores in certain physiological but stressful states (i.e., growth, pregnancy, and lactation). However, it is clear from the growing body of literature that the CT gene family of peptides, as a whole, has many important physiological and pathological functions. Further investigations into this broad family of peptides should provide great insight into the physiology of the human in healthy and disease states.

Chapter 39

Amylin and Calcitonin Gene-Related Peptide

Dorit Naot*, Ian R. Reid and Jill Cornish
Department of Medicine, University of Auckland, Auckland, New Zealand

INTRODUCTION

Calcitonin gene-related peptide (CGRP) and amylin are homologous 37 amino acid peptides. Their biological activities have been reviewed recently (Wimalawansa, 1997; Young, 2005a). The genes for amylin and CGRP have a common ancestral origin, and both peptides have a 6 amino acid ring structure at the N terminus created by a disulfide bond between cysteine residues at positions 2 and 7 (see Fig. 1). In addition, C termini are amidated. αCGRP is generated by alternative processing of mRNA from the calcitonin gene, located on the short arm of chromosome 11. This gene has six exons, the first four of which produce the mRNA for the precursor of calcitonin, preprocalcitonin. This is subsequently converted to calcitonin itself and N- and C-terminal flanking peptides. An alternative mRNA for the αCGRP precursor, preproCGRP, is formed from exons 1, 2, 3, 5, and 6. This peptide is cleaved to produce an N-terminal flanking peptide similar to that from procalcitonin and αCGRP itself, which is coded by exon 5. The alternative splicing of calcitonin mRNA is tissue specific – calcitonin mRNA is produced mainly in parafollicular cells of the thyroid, whereas in the nervous system, αCGRP mRNA is the predominant form. A second form of CGRP, βCGRP, differs from αCGRP by only one amino acid in the rat and three amino acids in the human (see Fig. 1). It is produced by a separate gene also on the short arm of chromosome 11, thought to have arisen as a result of exon duplication (Zaidi *et al.*, 1987a). Both CGRPs have approximately 20% homology with calcitonin, which is also amidated and contains a disulfide bridge.

Amylin has 43% sequence identity with αCGRP, 49% with βCGRP, and 13% with calcitonin in the human. It was originally isolated from amyloid deposits in the pancreases from patients with insulinoma or diabetes mellitus (Cooper *et al.*, 1987; Westermark *et al.*, 1987). Human amylin appears to be produced from a single gene on the short arm of chromosome 12, consisting of three exons. Like calcitonin and CGRP, amylin is synthesized as a prepropeptide, an 89 amino acid precursor that is subsequently processed to proamylin (67 amino acids) and thence to amylin itself. Amylin is the only known hormonal product of this gene.

Amylin is produced principally in β cells of the islets where its tissue content is less than 1% that of insulin. It is co-secreted with insulin, and evidence shows that insulin and amylin genes share transcriptional regulators (German *et al.*, 1992). Thus, hyperglycemia stimulates amylin secretion (O'Brien *et al.*, 1991), whereas hypoglycemia reduces it (Alam *et al.*, 1992). Destruction of the β cell with streptozotocin reduces amylin secretion (Ogawa *et al.*, 1990). The excursion in circulating insulin levels following a glucose challenge appears to be greater than that seen with amylin (Mitsukawa *et al.*, 1990). Amylin secretion, however, may be more sustained following glucose administration (Mitsukawa *et al.*, 1990). In some experimental models, dissociation of the secretion of the two peptides has been achieved but this does not commonly occur *in vivo*.

Amylin has also been detected in tissues of the gastrointestinal tract, with tissue concentrations about 1% of those in the pancreas being found in the pyloric antrum (Nakazato *et al.*, 1989). Amylin or its mRNA has also been found in lung, dorsal root ganglion, hypothalamus, neuroendocrine tumors, and in an osteoblast cell line (Gilbey *et al.*, 1991).

EXTRASKELETAL ACTIONS OF AMYLIN AND CGRP

Fuel Metabolism

The effects of amylin and CGRP on fuel metabolism appear to be comparable. In skeletal muscle the primary effects appear to be inhibition of glycogen synthesis and stimulation of glycogenolysis. Thus, muscle glycogen stores are decreased by amylin or CGRP, and this is accompanied by diminished glucose uptake and increased glycolysis, leading to increased lactate production. In the liver, glucose output is increased, probably as a result of increased gluconeogenesis. This may be contributed to by the increased flow of lactate from skeletal muscle, but has also been observed in some studies of isolated hepatocytes, implying an additional direct effect of amylin on liver cell function. Thus, in both skeletal muscle and liver, amylin and CGRP act as noncompetitive antagonists of insulin and produce insulin resistance (Young *et al.*, 1992). Amylin does not influence adipocyte metabolism, however, so the insulin resistance it produces is selective and could lead to a redirection of fuel from carbohydrate storage in liver and muscle to triglyceride storage in adipose tissue.

As well as antagonizing the actions of insulin (Hettiarachchi *et al.*, 1997; Gebre-Medhin *et al.*, 1998), amylin also reduces its secretion (Furnsinn *et al.*, 1994), possibly by altering glucose sensing at the β cell (Wagoner *et al.*, 1993). Overexpression of the amylin gene results in the development of diabetes in transgenic mice (Verchere *et al.*, 1996), but paradoxically, an amylin analog (pramlintide) reduces postprandial blood glucose excursion, probably by retarding gastric emptying (Thompson *et al.*, 1997). In some species, amylin can, in certain conditions, polymerize to form the β-pleated sheets characteristic of amyloid. Amyloid is toxic to pancreatic β cells (Lorenzo *et al.*, 1994), and its presence in type 2 diabetes may contribute further to reduced insulin secretion in that condition. Amino acids 25–29 in human amylin appear to be critical for amyloid formation. There is no homology between amylin and CGRP in this region, which may account for the failure of CGRP to form amyloid deposits.

Cardiovascular System

The important roles of CGRP in the cardiovascular system and particularly in the regulation of blood pressure have been reviewed recently (Deng and Li, 2005). CGRP is one of the most potent vasodilators known and its receptors are distributed widely throughout the vascular system. In some vessels, it appears to act directly on smooth muscle, whereas in others, CGRP receptors are expressed in endothelial cells, which release a diffusible mediator, probably nitric oxide. CGRP-containing nerves are also present in the heart, and CGRP exerts both positive inotropic and positive chronotropic effects. The wide distribution of CGRP-containing nerves throughout the vascular system makes it likely that CGRP has an important role in the regulation of regional blood flow, including renal and cerebral blood flow. CGRP administration is associated with a fall in systemic blood pressure. In a number of αCGRP-deficient mice models the cardiovascular system was unaffected; the mice had normal mean arterial pressure and heart rate (Lu *et al.*, 1999; Deng and Li, 2005). Other strains of αCGRP-deficient mice showed elevation of heart rate, systolic blood pressure, mean arterial pressure and peripheral vascular resistance (Gangula *et al.*, 2000; Oh-hashi *et al.*, 2001). Amylin shares the vasodilatory properties of CGRP but it is significantly less potent (Young *et al.*, 1993). Both peptides cause hypertrophy of cardiomyocytes (Bell *et al.*, 1995).

Nervous System

CGRP is distributed throughout the nervous system, being found in sensory, motor, and autonomic nerves, as well as in the hypothalamus, thalamus, and hippocampus. It is one of the most abundant peptides in the nervous system and it is frequently co-localized with other neuropeptides, such as substance P. This suggests that it may have a neuromodulatory role, acting in concert with other neurotransmitters. CGRP modulates pain perception and also appears to act centrally as an anorexiant (Lutz *et al.*, 1994). αCGRP-deficient mice showed elevated activity of the sympathetic nervous system (Oh-hashi *et al.*, 2001) and were different from wild-type mice in some specific aspects of pain perception, including reduced response to morphine-induced

analgesia (Salmon *et al.*, 1999) and reduced pain associated with neurogenic inflammation (Salmon *et al.*, 2001).

Amylin also appears to have a role in the nervous system. It is found in some sensory neurons (Mulder *et al.*, 1995) and modulates appetite, memory, and motor function (Morley *et al.*, 1995; Clementi *et al.*, 1996). Through the formation of oligomers, it may produce neuronal apoptosis (Tucker *et al.*, 1998). Although amylin does not have a central anti-nociceptive effect, when administered subcutaneously or intraperitoneally it was potently analgesic in a mouse model of visceral pain (Young, 2005b).

Other Tissues

These peptides increase renin secretion (Wookey *et al.*, 1996) and may also interact with other hormonal axes, as circulating amylin concentrations are higher in patients with primary hyperparathyroidism (Valdermarsson *et al.*, 1996), and CGRP is a growth hormone secretagogue (Nakamura *et al.*, 1998). They reduce gastric acid secretion (Rossowski *et al.*, 1997) and inhibit gastric emptying (Kolterman *et al.*, 1995; Young *et al.*, 1995). There is also evidence that both peptides can modulate inflammatory responses (Clementi *et al.*, 1995).

PEPTIDE ACCESS TO THE BONE MICROENVIRONMENT

The principal route by which amylin reaches bone is the circulation, which, in turn, derives its amylin from pancreatic secretion. Circulating amylin levels are of the order of 5 pmol/liter, rising to 10–20 pmol/liter following a meal. Amylin secretion is pulsatile, with peaks occurring at about 5-minute intervals (Juhl *et al.*, 2000). Levels are probably higher in obese subjects and those with type 2 diabetes (Butler *et al.*, 1990; Mitsukawa *et al.*, 1990; Hartter *et al.*, 1991; Sanke *et al.*, 1991; Reid *et al.*, 1993), but appear to be decreased by leptin (Karlsson *et al.*, 1998). There is one report of amylin mRNA expression and peptide secretion from a human osteoblast-like cell line (Gilbey *et al.*, 1991), raising the possibility of amylin production locally within the bone microenvironment, but we have been unable to detect amylin mRNA in primary rat osteoblasts and in primary human osteoblast samples from 12 different donors (Naot *et al.,* unpublished data).

Early reports suggested that CGRP circulated in concentrations of 30–40 pmol/liter (Zaidi *et al.*, 1986; Schifter, 1991), but it has been suggested more recently that the concentration is closer to 1 pmol/liter (Born *et al.*, 1991). Circulating concentrations are increased by sex hormone replacement therapy in postmenopausal women (Spinetti *et al.*, 1997). Some circulating CGRP may be secreted by the parafollicular cells of the thyroid and the balance is released by nerve endings. It is likely that bone may be exposed to significantly higher concentrations of CGRP as a result of local release of CGRP from nerve terminals. Sensory nerve fibers containing CGRP are widely distributed in bone, including bone marrow (Bjurholm, 1991; Hukkanen *et al.*, 1992; Ahmed *et al.*, 1994; Irie *et al.*, 2002). Innervation is richest at the epiphysis and periosteum (Hill and Elde, 1991). Immunostaining of CGRP-containing nerve fibers in bone tissue demonstrated changes in distribution during bone development and regeneration (Irie, 2002). When bone defects are created surgically, the development of CGRP-containing nerves is noted several days later, often in association with new blood vessels (Aoki *et al.*, 1994), suggesting a role in callus formation and bone healing. Similar responses are seen following fractures (Hukkanen *et al.*, 1993). It is interesting to note that CGRP-containing nerves are also seen in the growing deer antler (Gray *et al.*, 1992) and surrounding developing teeth (Fristad *et al.*, 1994). It is possible that CGRP aids bone growth in all these circumstances through its direct effects on osteoblast function. The intimate association of these nerves with blood vessels suggests that they may also have a role in regulating blood flow to sites of bone healing or growth.

There has been a report of CGRP mRNA in osteosarcoma cell lines and in human osteoblasts, raising the possibility that this peptide is produced locally in bone (Drissi *et al.*, 1997).

EFFECTS ON OSTEOCLASTS

CGRP

Following the discovery of CGRP, its common origin and sequence homology with calcitonin led to an investigation of its effects on bone resorption. This was first approached by injection of the peptide into intact animals. Tippins *et al.* (1984) found that CGRP had a calcitonin-like effect in the rat and rabbit, lowering circulating calcium concentrations. In the rabbit, it was approximately equipotent with calcitonin, although in the rat, concentrations 100- to 1,000-fold higher than those of calcitonin were required to produce hypocalcemia. However, in the rabbit, higher concentrations of CGRP produce hypercalcemia. In the chicken, the peptide causes only hypercalcemia.

These results led to more detailed assessments of CGRP effects on bone resorption. Yamamoto *et al.* (1986) studied the effect of human CGRP on ^{45}Ca release from prelabeled neonatal mouse calvariae (Fig. 2). CGRP produced a comparable degree of inhibition of both basal and parathyroid hormone-stimulated resorption, but the half-maximal concentration of CGRP was 500-fold higher than that of human calcitonin. Others have produced similar results in fetal rat bone organ cultures (D'Souza *et al.*, 1986; Roos *et al.*, 1986; Tamura *et al.*, 1992; Zhang *et al.*,

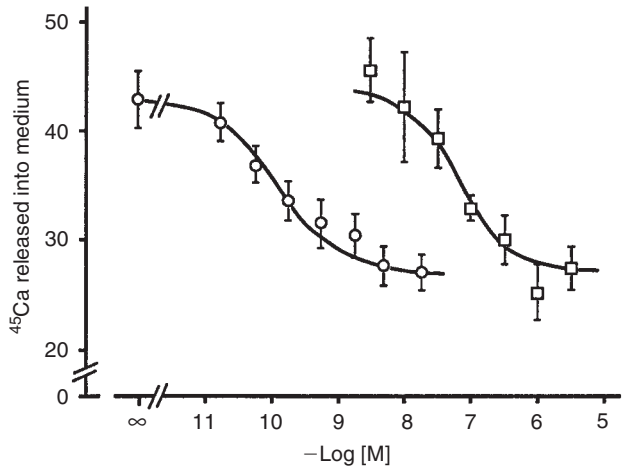

FIGURE 2 Effect of human calcitonin and human CGRP on PTH-stimulated bone resorption in neonatal mouse calvariae. Data are mean ± SE, $n = 6$. From Yamamoto *et al.* (1986), with permission.

1994). The antiresorptive effect of CGRP blocks the stimulation of bone resorption produced by a variety of osteolytic factors.

Studies of disaggregated neonatal rat osteoclasts have confirmed that both αCGRP and βCGRP directly inhibit bone resorption in these cells (Fig. 3). These two peptides are equipotent, but the effect requires nanomolar concentrations, in contrast to calcitonins, which require only picomolar concentrations to produce comparable inhibition (Zaidi *et al.*, 1987b; Zaidi *et al.*, 1987c). More recent studies in isolated osteoclasts have further characterized the effects of CGRP on these cells (Alam *et al.*, 1991; Alam *et al.*, 1993a; Alam *et al.*, 1993b). It inhibits osteoclastic bone resorption by inhibiting cell motility, probably via cAMP production, as this effect is reproduced by forskolin. Inhibition of cell motility is blocked by the CGRP fragment, CGRP-(8–37). Osteoclast retraction, which appears to be mediated by changes in intracellular calcium, is not seen with CGRP, although it is produced by calcitonin. These data imply that in this experimental system CGRP activates only the cAMP intracellular messenger system, whereas calcitonin also acts on osteoclasts via changes in intracellular calcium. This may contribute to the greater potency of calcitonin in inhibiting bone resorption.

CGRP has also been shown to be active in other osteoclast models. Tamura *et al.* (1992) demonstrated cAMP production in osteoclast-like multinucleated cells formed in cocultures of mouse osteoblasts and bone marrow cells in the presence of calcitriol. Concentrations 60-fold higher than those of human calcitonin were required, and CGRP in high concentrations displaced calcitonin from its specific binding site.

Evidence also suggests that CGRP may act on osteoclast precursors. Specific binding of CGRP to mouse bone marrow cells (Mullins *et al.*, 1993) and macrophages has been demonstrated, and CGRP inhibits the development of osteoclasts in macrophage-osteoblast cocultures (Owan and Ibaraki, 1994). We have addressed this question in cultures of mouse bone marrow, where CGRP inhibits the formation of mononuclear cells staining with tartrate-resistant acid phosphatase, as well as inhibiting the subsequent fusion of these cells to form multinucleated osteoclasts. Similar effects were seen with calcitonin at 1,000-fold lower concentrations (Cornish *et al.*, 2001). Akopian *et al.* (2000) have reported reduced formation of human osteoclasts following treatment with CGRP. These data suggest that CGRP binds specifically to osteoclast precursors and regulates osteoclast development.

Despite this consistent evidence of an effect of CGRP on osteoclastic resorption *in vitro*, a study of *in vivo* injection of CGRP over the calvariae of adult mice detected no significant inhibition of resorption (Cornish *et al.*, 1995; Cornish and Reid, 1999) (Fig. 4). However, Valentijn *et al.* (1997) have demonstrated incomplete suppression of post-ovariectomy increases in bone resorption in rats with CGRP treatment. This required the use of CGRP in a dose 500 times higher than that of calcitonin, which produced a greater therapeutic effect. Thus CGRP is antiresorptive *in vivo*, but its low potency suggests that this is unlikely to contribute to normal skeletal physiology except, possibly, in the region immediately adjacent to CGRP-producing cells.

Amylin

Within a short time of the description of amylin, its effect on indices of bone resorption had been assessed in studies paralleling those just described for CGRP. Thus its hypocalcemic actions in rats (Datta *et al.*, 1989; MacIntyre, 1989; Zaidi *et al.*, 1990), rabbits (Datta *et al.*, 1989), and humans (Gilbey *et al.*, 1991; Wimalawansa *et al.*, 1992)

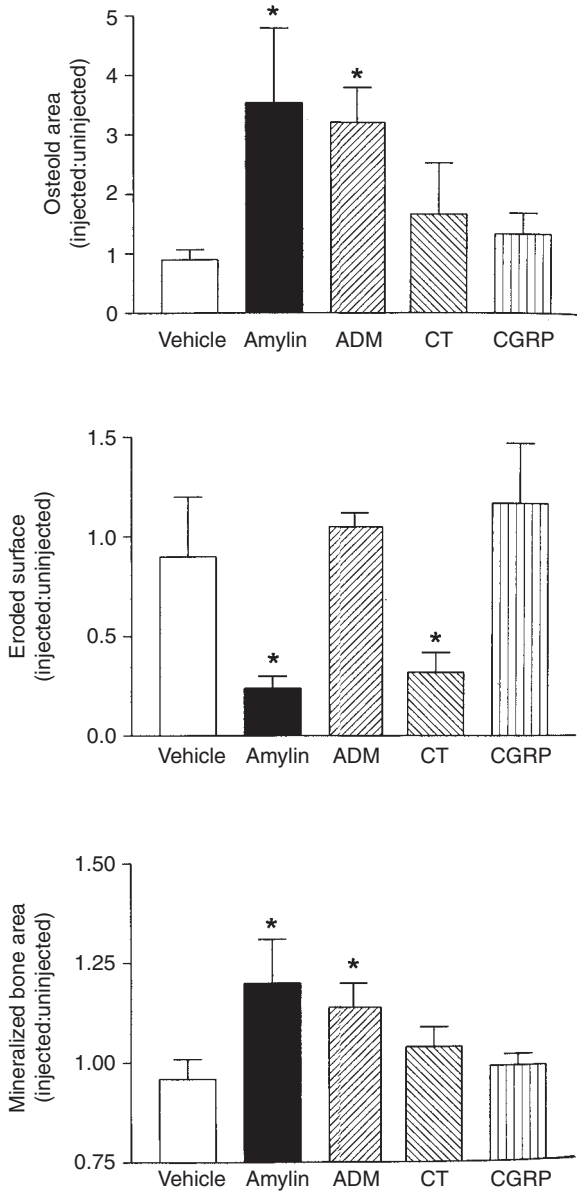

FIGURE 4 Comparison of the *in vivo* effects of rat amylin, human adrenomedullin, rat calcitonin (CT), and rat CGRP on bone histology in adult mice. Animals were injected daily with 4.1×10^{-9} mol of each peptide over the periosteum of one calvaria for 5 days and then sacrificed 1 week later. Data are expressed as the ratio of each index measured in the injected hemicalvaria to that measured in the contralateral, uninjected hemicalvaria. $n = 5$ in each group. Data are mean ± SE. Significant differences ($p < 0.05$) between injected and uninjected hemicalvariae are indicated by asterisks. From Cornish *et al.* (1999), with permission.

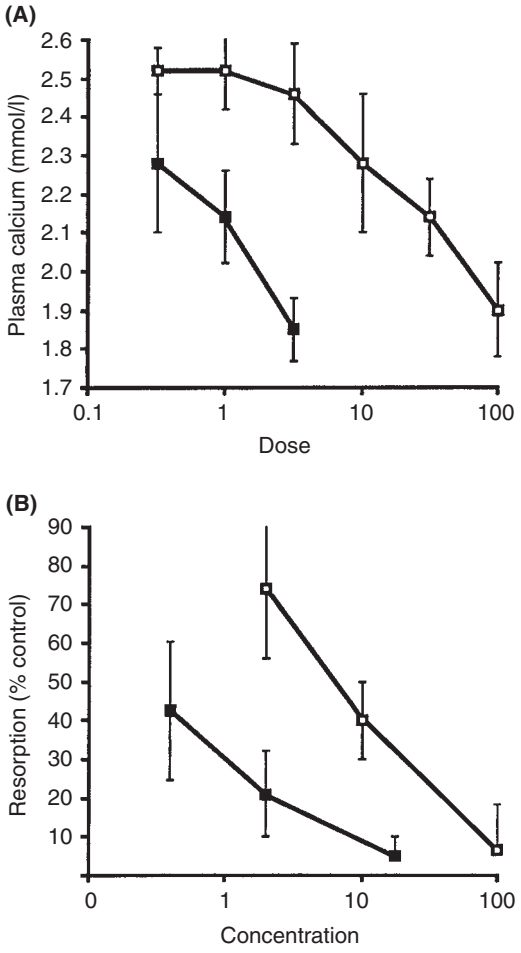

FIGURE 5 Effect of human amylin and human calcitonin on **(A)** plasma calcium in the rat and **(B)** bone resorption by isolated osteoclasts *in vitro*. Doses are given in pmol/rat **(A)** and in pmol/liter **(B)**. Data are mean ± SE. From MacIntyre (1989), with permission.

were reported (Fig. 5), and similar effects have been described in the goat (Min *et al.*, 1999). In the rat, 30-fold higher doses of amylin were required to produce comparable hypocalcemia to that of calcitonin, and human studies showed a similar trend. The effects of amylin on serum calcium in the rat, however, were significantly greater than those of CGRP (Zaidi *et al.*, 1990).

More detailed studies of the action of amylin on isolated osteoclasts have shown that its actions are qualitatively similar to those of CGRP. Thus amylin inhibits the motility of mature osteoclasts by way of increasing intracellular cAMP concentration. It is tenfold more potent than CGRP but an order of magnitude less potent than human calcitonin (Alam *et al.*, 1993). Amylin does not produce the osteoclast retraction seen with calcitonin. CGRP and amylin were equipotent in stimulating cAMP production in osteoclasts produced by coculture of osteoblasts and bone marrow cells (Tamura *et al.*, 1992), although 60-fold less potent than human calcitonin. In macrophages, amylin stimulated cAMP production but was 100-fold less potent than CGRP (Owan and Ibaraki, 1994). This effect was blocked by the CGRP antagonist, CGRP-(8–37). We have also studied the effect of amylin on osteoclast development in mouse bone marrow cultures (Cornish *et al.*, 2001).

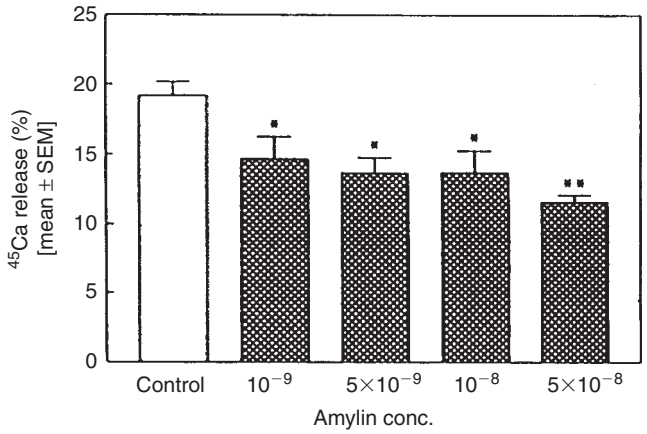

FIGURE 6 Effect of amylin on basal bone resorption in neonatal mouse calvariae. Based on data in Cornish *et al.* (1998b).

As with CGRP, there is an inhibition of both the formation of mononuclear osteoclast-like cells and the fusion of these cells. Dacquin *et al.* (2004) showed that amylin inhibition of osteoclastogenesis requires the activation of the extracellular signal-regulated protein kinase 1/2 (ERK1/2). In a bone marrow culture system, amylin inhibition of osteoclast differentiation was associated with a transient phosphorylation of ERK1/2 and moreover, when a negative dominant form of ERK1/2 was expressed in the cells, amylin was unable to inhibit osteoclast formation. The study also demonstrated that amylin had no effect on bone marrow cell proliferation, but in the presence of amylin osteoclasts were smaller and contained fewer nuclei.

Amylin has also been shown to reduce bone resorption in organ culture. It is approximately equipotent with CGRP in inhibiting calcitriol-stimulated resorption in fetal rat long bones (Tamura *et al.*, 1992). Amylin reduces both basal and parathyroid hormone-stimulated bone resorption in neonatal mouse calvariae, and cAMP production is also stimulated in this model (Pietschmann *et al.*, 1993; Cornish *et al.*, 1998b). In the studies of Cornish and colleagues (Fig. 6), inhibition of resorption was seen at concentrations as low as $10^{-9}M$.

These results should be interpreted in the light of the marked propensity for amylin to adhere to the surfaces of laboratory plasticware (Young *et al.*, 1992), suggesting that the actual concentrations of amylin in all *in vitro* experiments may be one to two orders of magnitude less than the amount added to the media. Thus, both osteoclast and calvarial studies imply that amylin may regulate bone resorption at physiological concentrations. This activity is dependent on the presence of the carboxyl-terminal amide group. In its absence, the potency of amylin in reducing osteoclastic resorption is comparable to that of CGRP (Datta *et al.*, 1989; Alam *et al.*, 1993). Amylin's inhibition of bone resorption in neonatal mouse calvariae only occurs with the intact molecule, in contrast to the situation with

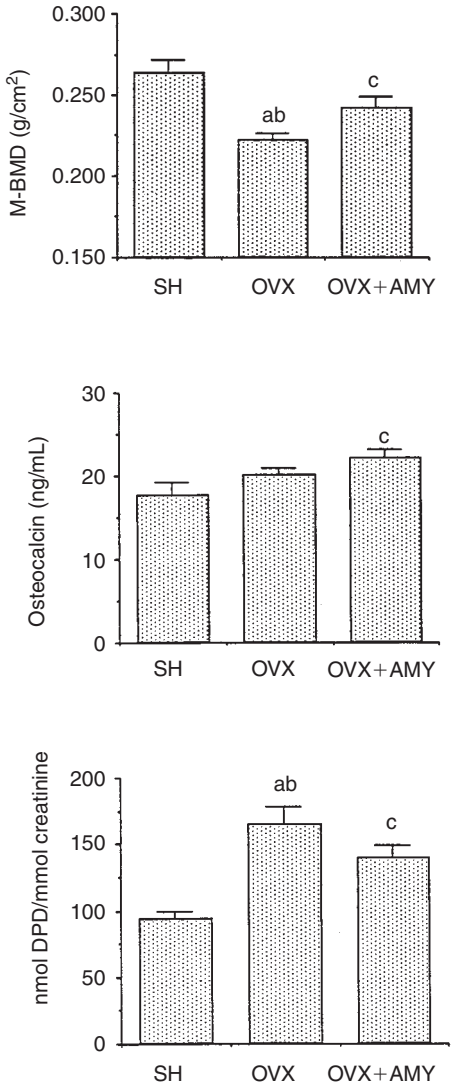

FIGURE 7 Effects of daily systemic administration of amylin (3 μg/100 g) to ovariectomized rats for 90 days. Indices assessed were distal metaphyseal bone mineral density of the femur (M-BMD), serum osteocalcin concentration, and urinary excretion of deoxypyridinoline (DPD). SH, sham operated; OVX, ovariectomized; AMY, amylin. a, significantly different from sham animals, $p < 0.01$; b, significantly different from amylin-treated group, $p < 0.05$; c, significantly different from sham, $p < 0.05$. Data from Horcajada-Molteni *et al.* (2000), with permission.

amylin action on osteoblasts. Amylin fragments, which act as antagonists in the osteoblast, do not modify the effect of amylin on osteoclasts (Cornish *et al.*, 1998b).

The effect of amylin on resorption *in vivo* has been studied histomorphometrically in several different models. Cornish *et al.* (1995) demonstrated 60–70% reductions in indices of bone resorption following daily local administration of amylin over the calvariae of adult mice. Very similar changes in resorption indices were seen following systemic administration of amylin to adult male mice for one month (Cornish *et al.*, 1998a) although the aminoterminal octapeptide of amylin is without effect on resorption in the same

model (Cornish *et al.*, 2000). In ovariectomized rats, intact amylin reduces urinary excretion of deoxypyridinoline and reduces bone loss (Horcajada-Molteni *et al.*, 2000) (Fig. 7). In contrast, the earlier experiment of Romero *et al.* (1995) in which amylin was administered systemically to rats, showed only a nonsignificant trend toward reduced resorption, and Borm *et al.* (1999) found no change in resorption markers in 23 diabetic patients receiving the amylin analog pramlintide for 1 year. The latter study needs to be interpreted with caution, as it used an amylin analog of unknown activity on bone and it was uncontrolled.

EFFECTS ON OSTEOBLASTS

CGRP

At the time that the effects of CGRP as a calcitonin analog in bone were being investigated, data began to emerge suggesting that it may also have an effect on osteoblasts. Michelangeli *et al.* (1986) demonstrated that CGRP increased cAMP formation in an osteogenic sarcoma cell line (UMR 106–01) that had an osteoblastic phenotype and was not calcitonin responsive. The same group subsequently studied mixed bone cell cultures obtained by sequential digestion of neonatal chicken, rat, or mouse calvariae and again demonstrated the presence of a cAMP response to CGRP when none to calcitonin was detectable (Michelangeli *et al.*, 1989). Other studies have demonstrated CGRP binding (Seitz *et al.*, 1986) and cAMP production (Thiebaud *et al.*, 1991; Bjurholm *et al.*, 1992; Tamura *et al.*, 1992) in normal or transformed osteoblast-like cells. Amino-terminal peptides and the disulfide bridge were both necessary to maintain activity of CGRP on osteoblasts (Thiebaud *et al.*, 1991).

There is some evidence that CGRP stimulates osteoblast proliferation. Cornish *et al.* (1995) showed small increases in proliferation in primary rat osteoblast-like cells in response to CGRP, but compared to amylin, a 1,000-fold higher concentration of CGRP was required to produce a similar effect (Fig. 8). In primary cultures of human osteoblast-like cells, CGRP stimulated proliferation with a maximal effect at 10nM. The proliferating activity of CGRP was not inhibited by the two antagonists, CGRP-(8–37) or amylin-(8–37) (Villa *et al.*, 2000). *In vivo*, Cornish *et al.* (1995) found no significant effect of local injection of CGRP on osteoblast indices in adult mice (Fig. 4) and Valentijn *et al.* (1997) found no change in bone formation rates in ovariectomized rats treated with CGRP. However, transgenic mice overexpressing CGRP in osteoblasts under the regulation of an osteocalcin promoter, showed increases in bone formation indices, bone volume, and bone density (Ballica *et al.*, 1999).

Several intracellular signaling pathways are activated by CGRP in osteoblast-like cells. Gupta *et al.* (1994) demonstrated a stimulation of Na^+/H^+ exchange in UMR 106 cells.

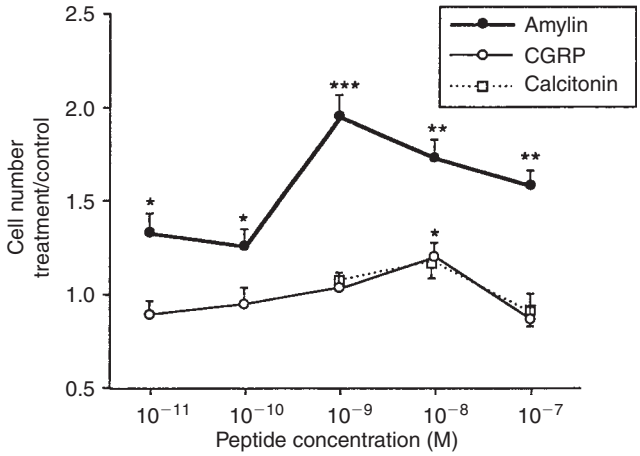

FIGURE 8 Dose dependence of the effects of rat amylin (●) rat CGRP-1 (○), and rat calcitonin (□) on numbers of primary rat osteoblast-like cells in culture over 24 hours. $n = 6$ in each group. Data are mean ± SEM. Statistical significance of differences from control: $*p \leq 0.05$; $**p < 0.005$; $***p < 0.001$. Reprinted with permission from Cornish *et al.* (1995).

Kawase *et al.* (1995), using the same cell line, showed that CGRP induces a transient twofold increase in intracellular calcium concentrations by mobilization of calcium from intracellular stores. Similar results were obtained in the human preosteoblastic cell line MG-63, where CGRP initially stimulated calcium discharge from intracellular stores in a cAMP-independent mechanism, and subsequently stimulated calcium influx in a cAMP-dependent manner (Burns *et al.*, 2004). In the osteosarcoma cell line OHS-4, CGRP increased intracellular calcium concentrations but had no detectable effect on cAMP (Drissi *et al.*, 1999). CGRP was also shown to stimulate potassium efflux, inducing membrane hyperpolarization that results in rapid changes in cell morphology (Kawase and Burns, 1998). Villa *et al.* (2003) demonstrated that calcitonin, CGRP, and amylin induced proliferation in a primary culture of human osteoblasts, and all three peptides significantly activated protein kinase C. Using the specific inhibitor, staurosporine, they showed that the activation of protein kinase C is necessary for the proliferative effect of CGRP in these cells. Of all three peptides, calcitonin, CGRP, and amylin, only CGRP stimulated cAMP production in the primary human osteoblasts.

There is also evidence that CGRP may act on preosteoblasts (Thiebaud *et al.*, 1991; Tamura *et al.*, 1992), influencing their development from precursor cells (Mullins *et al.*, 1993). Bernard and Shih (1990) have demonstrated that the number and size of bone colonies developing in bone marrow cultures are increased by CGRP and that systemic treatment with CGRP increases the number of bone colonies developing in marrow cultures.

The effects of CGRP on cytokine/growth factor production have been assessed. Sakagami *et al.* (1993) found

that CGRP increased cAMP and interleukin-6 production in a preadipocyte-like stromal cell line. CGRP also inhibited the proliferation of these cells. In primary osteoblasts, however, CGRP increased IGF-1, IGF-2, and osteocalcin mRNA, and this effect on IGF-1 has been confirmed by others (Vignery and McCarthy, 1996). In primary rat osteoblast cultures, CGRP has also been shown to substantially reduce tumor necrosis factor-α production and to weakly stimulate interleukin-6 production by these cells (Millet and Vignery, 1997). Thus CGRP may regulate the function of both precursor cells and mature osteoblasts by modulating the production of cytokines and growth factors. In a recent publication, Villa *et al.* (2006) reported that CGRP dose-dependently inhibited the expression and secretion of osteoprotegerin (OPG) from primary cultures of human osteoblast-like cells. This effect could be blocked by CGRP(8–37) and by an inhibitor of protein kinase A. The inhibition of OPG by CGRP is unexpected, as previous studies showed that CGRP inhibited bone resorption whereas decreased OPG suggests activation of osteoclasts.

We have raised the possibility that these relatively weak effects of CGRP on osteoblast function may be mediated by receptors that have a higher affinity for amylin than for CGRP (Cornish *et al.*, 1999b). In cultures of fetal rat osteoblasts, amylin increased cell number, thymidine, and phenylalanine incorporation at 100-fold lower concentrations than those of CGRP and its maximal effects were about twice as great as those of CGRP. There was no additivity between maximal doses of the peptides on these indices. The CGRP receptor blocker, CGRP-(8–37), completely blocked the effect of CGRP at blocker concentrations $\leq 10^{-9}$ *M*. In contrast, the amylin receptor blocker, amylin-(8–37), completely blocked the effects of CGRP when the blocker was present in concentrations as low as 10^{-11} *M*. In converse experiments studying the blockade of maximal doses of amylin, amylin-(8–37) 10^{-10} *M* was effective, whereas a 100-fold greater concentration of CGRP-(8–37) was necessary to achieve the same effect. It was concluded that amylin and CGRP probably act through a common receptor to stimulate osteoblast growth and that this receptor has a higher affinity for amylin than for CGRP.

Amylin

Shortly after its discovery, amylin was shown to stimulate cAMP production in a preosteoblastic cell line, possibly through binding of a putative CGRP receptor (Tamura *et al.*, 1992). Cornish *et al.* (1995) demonstrated stimulation of proliferation of fetal rat osteoblasts by amylin in concentrations as low as 10^{-11} *M*, as shown in Fig. 8. Similar effects have been shown in human osteoblasts by Villa *et al.* (1997) and by ourselves (unpublished data). Amylin-(1–8) also stimulates osteoblast proliferation, although its half-maximally effective concentration is tenfold higher than that of the intact peptide (Cornish *et al.*, 1998b). This octa-peptide also stimulates thymidine incorporation in neonatal mouse calvariae (Cornish *et al.*, 1999). In rat primary osteoblasts, amylin activated the ERK1/2 signaling pathway, most likely through activation of Gi proteins (Cornish *et al.*, 2004). Phosphorylation of ERK1/2 was required for the mitogenic effect of amylin in these cells, as PD-98059, a specific inhibitor that prevents the phosphorylation of ERK1/2, also inhibited amylin-induced proliferation. Interestingly, the mitogenic effect of amylin in osteoblasts requires the presence of an IGF-1 receptor, although there is no direct binding of amylin to this receptor, nor a paracrine effect of osteoblast-derived IGF-1 (Cornish *et al.*, 2004). *In vivo*, daily injections of amylin induced a transient elevation of serum osteocalcin in rats (Romero *et al.*, 1995). Cornish *et al.* (1995) (Fig. 4) have shown two- to fourfold increases in histomorphometric indices of osteoblast activity in adult mice to whom amylin was administered locally over the calvariae daily for five days. Systemic administration of amylin over one month produced an increase of 30–100% in these indices (Cornish *et al.*, 1998a). Horcajada-Molteni *et al.* (2000) demonstrated increases in serum osteocalcin concentrations in ovariectomized rats treated systemically with amylin (Fig. 7), although the small human study with pramlintide did not detect any changes in osteoblast function (Born *et al.*, 1999).

When amylin-(1–8) was administered by local injection over the calvariae of female mice, this peptide increased the double-labeled surface threefold. The effect was dose dependent from 0.4 to 40 n*M* and greater than that of an equimolar dose of hPTH-(1–34). The mineral apposition rate was increased by 40 n*M* amylin-(1–8) but not by hPTH-(1–34). Daily systemic administration of this peptide to sexually mature male mice for four weeks almost doubled histomorphometric indices of osteoblast activity (Cornish *et al.*, 2000). Thus, a number of studies have found evidence of an anabolic action of amylin and its amino terminus in osteoblasts.

EFFECTS ON BONE MASS

The effects of amylin and CGRP on the total amount of mineralized tissue in bone have been assessed in several experimental systems, including local injections, systemic administration, and more recently, in genetically modified animals.

CGRP

In ovariectomized rats that were given daily subcutaneous injections of CGRP for 28 days, Valentijn *et al.* (1997)

reported decreased bone resorption and a modest reduction in post-ovariectomy bone loss from 60% to 46%. In a study of transgenic mice overexpressing the CGRP gene in osteoblasts, Ballica *et al.* (1999) demonstrated a 5% increase in distal femoral bone density at the age of 12 weeks. A quite different approach to determining the effect of CGRP on bone mass was used by Hill *et al.* (1991). Reasoning that most of the CGRP that gains access to bone does so via sensory nerves, they studied the effect of sensory denervation using capsaicin treatment in rats. This intervention produced no change in tibial histomorphometry although the osteoclast surface in the mandible was decreased. In a more recent study, Offley *et al.* (2005) showed that capsaicin treatment destroyed the unmyelinated sensory axons containing CGRP and the reduced CGRP signaling was associated with a decrease in bone mass.

The first knockout mouse model that was used to study the physiological effect of CGRP deficiency was missing the *Calca* gene that encodes for both calcitonin and αCGRP (Hoff *et al.*, 2002). Previously, many *in vitro* and *in vivo* studies had shown that the hypocalcemic hormone calcitonin is an inhibitor of bone resorption (Zaidi *et al.*, 1987c; Cornish *et al.*, 2001). Binding of calcitonin to the calcitonin receptor on osteoclasts results in inhibition of osteoclast activity, and therefore it was expected that *Calca*-deficient mice would have an osteoporotic phenotype due to accelerated bone resorption. The bone phenotype of the animals was unexpected. There was no change in osteoclast number or bone resorption markers, and moreover, the animals had higher bone volume and trabecular number with a decrease in trabecular spacing. Double calcein-labeling studies in the knockout animals showed that the high bone volume was a result of a significant increase in bone formation, rather than a decrease in bone resorption. The unexpected finding of increased bone formation in the *Calca*-deficient mice suggests a yet unrecognized effect of calcitonin or αCGRP to inhibit bone formation.

To differentiate between the contributions of the calcitonin deficiency to that of αCGRP, the bone phenotype of the *Calca*-deficient mice was compared to that of specific αCGRP-deficient mice (Schinke *et al.*, 2004). αCGRP-deficient mice had osteopenia caused by reduced bone formation rate. Therefore, studies in these two mice strains imply that *in vivo*, calcitonin inhibits osteoblast activity and bone formation, whereas αCGRP is a physiological activator of bone formation. A subsequent long-term study of the bone phenotype of these animals showed that the osteopenia displayed by the αCGRP-deficient mice was also evident at 6, 12, and 18 months of age (Huebner *et al.*, 2006). In the *Calca*-deficient mice the bone phenotype developed with age, and at 12 and 18 months, along with the increased bone formation there was evidence for increased bone resorption. The high bone turnover resulted in hyperostotic lesions in 20% of the *Calca*-deficient mice.

Amylin

As discussed previously, local injection of intact amylin over the calvariae of adult mice produced a substantial decrease in bone resorption, an increase in bone formation, and a 20% increase in mineralized bone area after only five daily injections (Fig. 4) (Cornish *et al.*, 1995). Romero and colleagues (1995) administered amylin systemically to normal male rats for 18 days, producing no changes in histomorphometric indices of formation or resorption but increasing cancellous bone volume of the proximal tibia by 25%. In a similar study in normal male mice, Cornish *et al.* (1998a) showed an increase of 70% in total bone volume in the proximal tibia (Fig. 9), as well as increased cortical width, tibial growth plate width, tibial length, body weight, and fat mass. A similar experiment using amylin-(1–8) increased bone volume by 36%, tibial cortical thickness by 8%, and resulted in increased bone strength as assessed by three-point bending (Cornish *et al.*, 2000). In the study of

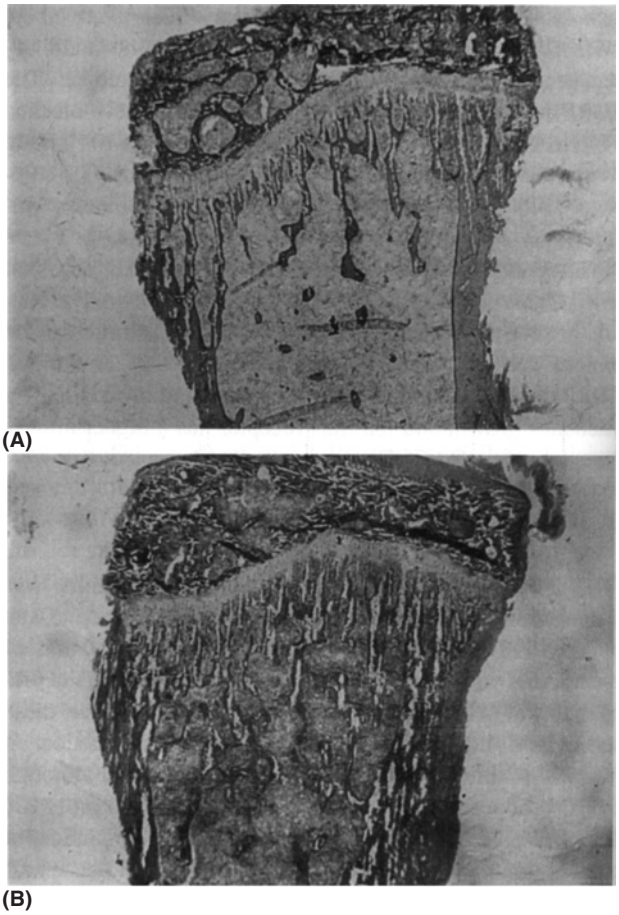

FIGURE 9 Photomicrographs of proximal tibiae of mice treated systemically with **(A)** vehicle or **(B)** amylin 10μg/day for 4 weeks. Trabecular bone volume is increased 70% in amylin-treated animals. Reprinted from Cornish *et al.* (1998a), with permission.

systemic administration of intact amylin to ovariectomized rats, reported by Horcajada-Molteni *et al.* (2000), both distal metaphyseal and total femoral bone densities were higher in animals receiving peptide (Fig. 7).

The phenotype of *amylin*-deficient mice was described by Dacquin *et al.* (2004). Analysis of the animals showed that in this model system amylin was dispensable for regulation of food intake, body weight, and glucose metabolism. At the age of 24 weeks, the *amylin*-deficient mice had a typical osteoporotic phenotype; showing decreased bone density of long bones, low bone mass, and a 50% decrease in trabecular bone volume. The number of osteoblasts, as well as the bone formation rate, assessed by double calcein injection, were similar between the *amylin*-deficient mice and the wild-type controls, suggesting that the osteoporotic phenotype was not a result of a defect in bone formation. In contrast, the *amylin*-deficient mice had an increased number of osteoclasts and an increase in degradation products of collagen in the urine, suggestive of accelerated bone resorption. Further studies of *amylin*-deficient mice demonstrated that the bone effects were sex-dependent. *Amylin*-deficient males showed increased trabecular thickness at 4 and 6 weeks of age and increased femoral length at 26 weeks, while female mice were no different from the wild type (Davey *et al.,* 2006).

In summary, the bone phenotypes of the calcitonin, αCGRP, and amylin knockout mice were quite unexpected, and changed our understanding of the possible physiological role of these peptides. Thus, the main effect of calcitonin on bone appears to be inhibition of bone formation. αCGRP has the opposite effect, acting as a stimulator of bone formation, whereas amylin turns out to be the most robust inhibitor of bone resorption within this group of peptides. Further studies will be required to fully understand the physiological role of the peptides and their mechanisms of action.

EFFECTS ON CALCIUM METABOLISM *IN VIVO*

Serum calcium levels were within the normal range in *amylin*-deficient mice (Dacquin *et al.*, 2004), αCGRP-deficient mice (Schinke *et al.*, 2004), and *Calca*-deficient mice (Hoff *et al.*, 2002). Therefore, amylin, αCGRP, and calcitonin do not appear to have an important role in the regulation of baseline serum calcium levels in mice. However, when injected with either PTH or 1,25$(OH)_2$-vitamin D_3, *Calca*-deficient mice showed significantly higher levels of serum calcium in comparison to wild-type animals, a response that could be reversed by calcitonin but not by CGRP. Therefore, the hypocalcemic effect of calcitonin seems to be important under calcium stress.

In earlier experiments that tested changes in systemic calcium metabolism in response to injection of amylin or CGRP, the most apparent effect of amylin or CGRP was the induction of hypocalcemia, which has been demonstrated in a number of species, as discussed earlier. For amylin, this is probably substantially attributable to inhibition of osteoclastic bone resorption. However, amylin, like calcitonin, may have a direct calciuretic effect on the kidney. Rat amylin binds to the renal porcine calcitonin receptor with an affinity comparable to that of porcine calcitonin itself. Both peptides comparably stimulate cAMP production via this receptor (Sexton *et al.*, 1994). CGRP does not compete for binding to this receptor. However, in rat renal tubular membranes, CGRP and amylin stimulated cAMP production with comparable half-maximal concentrations, and the effects of both peptides were blocked by CGRP(8–37) (Osajima *et al.*, 1995). Consistent with these results is the finding of Miles *et al.* (1994) that amylin infusion doubles urinary calcium excretion in dogs. However, the increased urinary loss of calcium accounted for less than 10% of the fall in serum calcium, suggesting that reduced osteoclastic resorption was the principal contributor to the hypocalcemic effect. These changes were accompanied by a doubling of PTH but no change in circulating calcitonin concentrations.

In the rat, CGRP, like amylin, is hypocalcemic with a potency slightly greater than that of amylin (Young *et al.*, 1993). However, in the chicken it has the opposite effect, elevating serum calcium within 20 minutes of administration (Ancill *et al.*, 1990; Bevis *et al.*, 1990). The mechanism of this effect has not been elucidated.

RECEPTORS

Specific amylin and CGRP receptors are formed by heterodimerization of the seven transmembrane domain calcitonin receptor or calcitonin receptor-like receptor (CRLR) with a receptor activity-modifying protein (RAMP). Calcitonin receptor belongs to the type II seven transmembrane G protein-coupled receptors, and has been cloned initially from porcine (Lin *et al.*, 1991) and subsequently from rat (Sexton *et al.*, 1993), human (Kuestner *et al.*, 1994; Gorn *et al.*, 1995), and other species. In most species, calcitonin receptor RNA is alternatively spliced, resulting in the expression of several isoforms (Sexton *et al.*, 1993; Kuestner *et al.*, 1994; Albrandt *et al.*, 1995; Gorn *et al.*, 1995). The various isoforms differ from each other not only structurally, but also in their tissue distribution, affinity for ligands and their signaling pathways (Egerton *et al.*, 1995; Moore *et al.*, 1995). CRLR shares about 55% amino acid sequence homology with calcitonin receptor, and was initially described as an orphan receptor (Fluhmann *et al.*, 1995). McLatchie *et al.* (1998) cloned a CGRP receptor from a human neuroblastoma cell line, and discovered that specific CGRP binding requires the coexpression of two proteins: CRLR and RAMP1. RAMP1

belongs to a family of proteins with a single transmembrane domain, which includes three members: RAMP1, RAMP2, and RAMP3. Further studies established that different combinations of calcitonin receptor and CRLR with RAMPs produce receptors with different affinities for peptides of the calcitonin family. Thus, heterodimerization of the calcitonin receptor with each of the three RAMPs produces receptors with high affinity for amylin, the combination of CRLR with RAMP1 creates a CGRP receptor, and CRLR with either RAMP2 or RAMP3 acts as an adrenomedullin receptor (Lerner, 2006).

The way in which RAMPs control the specificity of calcitonin receptors and CRLR for their ligands is still not fully understood. Cross-linking experiments with radioactive ligands demonstrated that RAMP and its seven transmembrane-domain partner are in very close association on the cell surface, forming complexes that are maintained following ligand binding (McLatchie *et al.*, 1998; Christopoulos *et al.*, 1999). RAMPs were also shown to regulate the glycosylation state of the receptors, which affects their transportation to the cell membrane. For example, when CRLR was coexpressed with RAMP2, it had only core glycosylation, while together with RAMP1, it was terminally glycosylated (McLatchie *et al.*, 1998). In contrast, other studies showed that the glycosylation state does not affect the specificity for the ligand (Aldecoa *et al.*, 2000; Hilairet *et al.*, 2001).

The pattern of expression of RAMPs, calcitonin receptor, and CRLR in bone cells has been investigated by several groups. RAMP1–3 and CRLR are expressed ubiquitously, and mRNA for all four have been identified in primary calvarial osteoblasts from rat and mouse as well as in the osteoblastic cell lines UMR106–06 and MC3T3–E1 (Naot *et al.*, 2001; Uzan *et al.*, 2004). Expression of CRLR and RAMP2 was also demonstrated in osteoclast-like cells by laser capture microdissection and RT-PCR (Nakamura *et al.*, 2005). Calcitonin receptor is highly expressed in osteoclasts. Its expression is induced by the activation of receptor activator of nuclear factor kappa B (RANK), and mRNA for the calcitonin receptor can be first identified on progenitor cells just prior to multinucleation (Lee *et al.*, 1995). Most osteoblasts and osteoblast-like cell lines do not express the calcitonin receptor (Sexton *et al.*, 1993; Izumi *et al.*, 2001; Naot *et al.*, 2001). Using the sensitive method of real-time PCR and RNA from cells of eight different donors we were unable to detect calcitonin receptor expression in these cells (unpublished results). In contrast, Villa *et al.* (2003) demonstrated the expression of calcitonin receptor in human osteoblast-like cells using RT-PCR.

Using specific amylin agonists and antagonists it was possible to dissociate the effect of amylin on bone formation from its effect on bone resorption (Cornish *et al.*, 1998b). Proliferation of primary osteoblasts was induced by intact amylin and by the peptide amylin-(1–8), whereas amylin-(8–37), terminally deamidated amylin and reduced amylin acted as antagonists. In contrast, inhibition of bone resorption in neonatal mouse calvariae only occurred with the intact amylin molecule and was not antagonized by any of these peptides, suggesting that amylin acts through two separate receptors on osteoclasts and osteoblasts (Cornish *et al.*, 1998b).

A number of studies showed that in various experimental systems the effects of peptides of the calcitonin family are transient, and prolonged exposure results in desensitization of the treated cells. In bone, this effect has been investigated mainly in osteoclasts treated with calcitonin. Early studies showed that stimulation of bone resorption in organ cultures by PTH could be inhibited by the addition of calcitonin, but over time the cells managed to 'escape' this inhibitory effect (Wener *et al.*, 1972). This 'escape phenomenon', was lated found to be due to ligand-induced internalization of the receptor, as well as inhibition of de novo synthesis of the calcitonin receptor (Takahashi *et al.*, 1995; Wada *et al.*, 1995). Similar escape from the inhibitory effect of amylin on PTH-stimulated bone resorption has also been described (Pietschmann *et al.*, 1993). Interestingly, cells treated with amylin for 48 hours were desensitized to further inhibition by amylin, but addition of calcitonin at this time point produced an inhibitory effect. Therefore, it appears that the mechanisms involved in desensitization to amylin are not identical to those involved in calcitonin desensitization (Pietschmann *et al.*, 1993). The escape phenomenon has not been studied directly in osteoclasts treated with CGRP, but there is some evidence from studies in microvascular endothelial cells and in vascular smooth muscle cells that exposure to CGRP also results in desensitization to further CGRP treatment (Drake *et al.*, 2000; Nikitenko *et al.*, 2006).

Recently, knockout animals have been used to study the physiological role of the calcitonin receptor and CRLR and their contribution to the activity of peptides of the calcitonin family in bone. *Calcr* (calcitonin receptor) homozygous deficiency and *Calcrl* (CRLR) homozygous deficiency are both embryonic lethal. *Calcrl*-deficient embryos have very similar phenotype to embryos that carry a targeted deletion of adrenomedullin, indicating that CRLR is the primary receptor through which adrenomedullin acts during the embryonic development (Dackor *et al.*, 2006). Heterozygous mice, with deletion of one copy of the calcitonin receptor gene, are viable and have a reduced expression of calcitonin receptor in their osteoclasts. These mice had high bone mass due to an increase in bone formation, similar to the calcitonin knockout mice. In contrast, *amylin*-deficient mice display a low bone mass phenotype and increased bone resorption. The difference between the *amylin*-deficient phenotype and that of the calcitonin-receptor heterozygous knockout animals indicates that the calcitonin receptor is not the main receptor through which amylin affects bone remodeling *in vivo* Dacquin *et al.,* 2004.

In summary, although the recently identified heterodimeric receptors for peptides of the calcitonin family have been investigated and characterized in detail, the bone effects of amylin and CGRP cannot be fully explained by their interactions with these receptors, and it seems that other receptors have yet to be identified.

SIGNIFICANCE OF AMYLIN AND CGRP TO BONE PHYSIOLOGY

What role amylin and CGRP play in normal bone metabolism and bone pathology in humans remains to be determined. It has been hypothesized that amylin secretion following a meal directs the absorbed calcium and protein from the meal into new bone synthesis by increasing bone growth at a time when the substrates are available (MacIntyre, 1989; Zaidi *et al.*, 1993). Amylin may also contribute to the relationship between body mass and bone density. Body mass, or more particularly fat mass is the principal determinant of bone density in women (Reid *et al.*, 1992a; Reid *et al.*, 1992b). While this might be mediated to some extent by the effect of weight on skeletal load bearing and by adipocyte production of estrogen, neither of these explanations is adequate to explain the published results (Reid *et al.*, 1992a; Reid *et al.*, 1992b; Reid *et al.*, 1993; Reid *et al.*, 1994; Reid *et al.*, 1995; Reid, 2002). Because both insulin and amylin are hypersecreted in obesity and because both may potentially act directly or indirectly to increase bone mass, they may contribute significantly to this relationship. Indeed, circulating insulin levels are directly related to bone density in normal postmenopausal women (Reid *et al.*, 1993), and because amylin is co-secreted with insulin, it would seem likely that a similar relationship for this peptide exists.

Because most of the CGRP gaining access to bone does so via sensory nerves, it is likely that this peptide is involved in the response of bone to injury and to other stimuli, such as exercise. The association of CGRP-containing nerves with healing and growing bone supports this contention.

INTRODUCTION

Sex steroids influence sexual dimorphism and reproductive functions of the skeleton. In the process they modify bone growth and remodeling. Estrogens regulate osteoblast-mediated bone formation and osteoclast-mediated bone resorption at multiple levels, including progenitor cell recruitment, proliferation, differentiation, and programmed cell death. In contrast to estrogen, the role of progesterone in bone physiology is less well understood. However, recent studies in progesterone receptor null mice suggest that progestins have novel actions on bone growth and turnover. This chapter reviews the actions of estrogen and progesterone on bone, emphasizing progress since the publication of the second edition of this book in 2002.

The effects of sex steroids on the skeleton are complex. Multiple receptor isoforms for the estrogen receptor (ER) and progesterone receptor (PR) have been identified in bone cells. Added to these variables is the existence of steroid receptor coregulators, including nuclear transcription factors that modulate steroid receptor interactions with the transcriptional machinery, tissue-specific distribution of enzymes that metabolize sex steroids, and membrane receptor- and nonreceptor-mediated actions of these hormones on target cells. Estrogen and progesterone also have indirect effects (e.g., through the hypothalamic-pituitary-gonadal axis) on bone and mineral homeostasis at multiple levels. With the complexity of molecular and cellular events that mediate the actions of estrogen and progesterone, it is easy to lose sight that these hormones' primary function is in reproduction.

The topics covered in this chapter include: the skeleton as a reproductive organ, ER and PR structure and function, roles of the receptor isoforms and receptor coregulators, receptor isoform expressions in skeletal tissues, alternative pathways of estrogen action, effects of treatment with estrogen and progesterone on bone cells *in vitro* and on the skeleton *in vivo,* sex steroid metabolism, and consequences of ER and PR gene deletions on skeletal structure and bone metabolism. Additionally, owing to the increasing clinical and scientific interest in these substances, the actions of estrogen-related compounds (selective estrogen receptor modulators or SERMs, estrogen metabolites, and phytoestrogens) on the skeleton are discussed.

THE SKELETON AS A REPRODUCTIVE ORGAN

The skeleton has primary as well as secondary roles in reproduction. The essential function of the skeleton in reproduction is most clearly evident in birds. Female birds produce medullary bone prior to the start of their egg-laying cycle. This bone has no biomechanical function. Instead, it provides an essential source of minerals for eggshell formation. In turn, the eggshell is partially resorbed during embryonic development, thereby providing the majority of the minerals for skeletal development. Following the reproductive period any remaining medullary bone is resorbed. Sex steroids play a pivital role in regulating medullary bone formation and utilization. The critical role of estrogen for reproductive success in birds is illustrated by the devastating effect of the pesticide DDT on

*Corresponding author: Russell T. Turner Department of Nutrition and Exercise Sciences, Oregon State University, Corvallis, OR

exposed populations. DDT acted as an endocrine disrupter because of its ability to bind to and compete with estrogen for ER, impairing mobilization of calcium from bone for eggshell formation (Kupfer and Bulger, 1976; Turner and Eliel, 1978). The reader is referred to a prior review for a more complete discussion of the important and unique effects of sex steroids on the skeleton during reproduction in oviparous vertebrates (Turner and Riggs, 1994).

The skeleton is also important in mammalian reproduction. Bone provides a significant source of mineral for the fetal skeleton and is a major source of mineral during lactation. Estrogen (and perhaps progesterone) plays a vital role in the accumulation of minerals in the skeleton beyond what is required to fulfill bones' biomechanical function. Changes in estrogen levels likewise play a significant role in the appropriate mobilization of stored minerals from maternal bone during pregnancy and lactation.

The skeleton exhibits species-specific secondary sex characteristics that are in part determined by estrogen (and perhaps progesterone). The sex difference in bone mass is evident in our own species. Although the evolutionary explanation for the more robust skeleton in men is subject to debate, the consequences are clear. The net suppressive effect of estrogen on the accumulation of cortical bone prior to skeletal maturity is one of the factors that predisposes women to a higher risk for fractures later in life. This predisposition is exaggerated by the effects of menopause on the skeleton, which may recapitulate the temporary physiological effects of reduced estrogen signaling during pregnancy and lactation.

STEROID HORMONE MECHANISMS OF ACTION

Estrogen and progesterone are produced primarily in the gonads and released into circulation. Additional estrogens are produced locally in tissues, including bone, owing to the aromatization of circulating androgens to estrogens (Miki *et al.,* 2007). Circulating estrogen is preferentially bound to sex steroid-binding globulin and progesterone is preferentially bound to corticosteroid-binding globulin. The concentrations of these steroid-binding globulins in serum influence the metabolism and bioavailability of the steroid hormones. Steroids diffuse passively into cells and are retained intracellularly by complexing specific receptor proteins, which are steroid and target tissue-specific.

Steroid hormone receptor (ER and PR) concentration in bone is low relative to reproductive tissues. However, the absence of enzymes that inactivate estrogen in skeletal tissues may accentuate the responsiveness of bone cells to low physiological levels of the hormone compared to some reproductive tissues.

The diffusion of steroids into cells and the formation of the ligand-receptor complex are rapid, occurring within minutes of steroid injection into an animal. Following steroid-receptor complex formation (1–4 minutes post-treatment) the complex binds to nuclear binding sites at target gene promotors (2–5 minutes). This nuclear binding regulates the transcription of early (~60 minutes) or late (~8 hours and beyond) genes. Changes in protein profiles owing to regulation of late gene expression begin to occur 12 to 24 hours post-treatment. The major physiological effects of steroids in reproductive and skeletal tissues begin to occur by 24 to 48 hours after steroid treatment. Cell and tissue responses that occur at 36 to 72 hours after treatment probably represent downstream effects of steroid-regulated paracrine/autocrine factors. The 2- to 3-hour period elapsing between steroid receptor binding to the nuclear acceptor sites and the delayed, but major, transcriptional response of the late structural genes has been termed the lag phase. This is a period during which early response genes, coding for transcription factors and other proteins, are activated to subsequently regulate late gene expression. The latter process has been termed the cascade model of steroid hormone action (Landers and Spelsberg, 1992).

Steroid hormone receptors are a subclass of a larger (~100 member) family of zinc finger-containing, nuclear hormone receptors that function as transcriptional regulators (Tsai and O'Malley, 1994). The ligands bind with high affinity (K_d 10^{-10} to 10^{-8} M), but reversibly, to their respective receptors. Ligand binding triggers receptor activation, which induces a conformational change, dissociation of accessory proteins, receptor dimerization, and oligomerization and, in some cases, post-translational modifications such as phosphorylation. Activated receptors either bind directly to regulatory DNA elements (hormone response elements) in the promoter region of target genes or bind indirectly with other DNA-binding transcription factors (e.g., AP-1 factors) via protein-protein interactions, which then bind to the promoter. Once bound, either directly or indirectly, to the DNA, the activated receptor complex recruits transcription factors, termed coregulator proteins. These, in turn, bind to the core proteins of the transcriptional activation complex to regulate gene transcription (Bevan and Parker, 1999; McKenna *et al.,* 1999; Robyr *et al.,* 2000).

ESTROGEN

Estrogen Receptor Isoforms

Two ERs, ERα and ERβ, have been identified. The discovery of ERβ, a product of a different gene than the first described estrogen receptor (ERα) has revealed an additional level of complexity to estrogen action in the skeleton and other tissues (Kuiper *et al.,* 1996; Mosselman *et al.,* 1996). As depicted in Fig. 1, ERα and ERβ possess a high degree of homology in their DNA-binding domains and a moderate degree of conservation in their C-terminal ligand-binding domains (Kuiper and Gustafsson, 1997). The former explains why the two receptor isoforms interact with the same DNA response elements and the latter explains

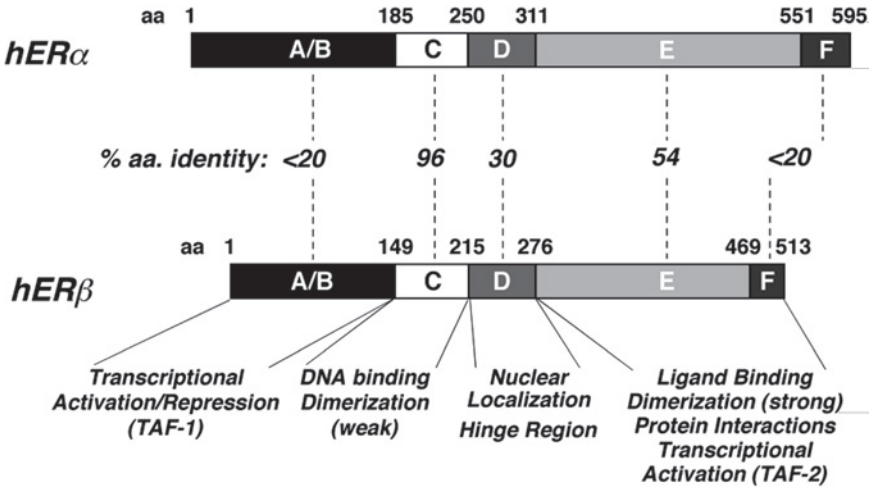

FIGURE 1 Model of human estrogen receptor isoforms, their domains, functions, and homologies.

why both isoforms bind many natural estrogens, SERMs, and antiestrogens, but sometimes with different affinities (Kuiper and Gustafsson, 1997). ERα and ERβ are most divergent in their N-terminal A/B domains, which harbor the ligand-independent AF-1 transactivation function and that interact with proteins of the core transcriptional machinery to regulate gene expression. The tissue distributions of ERα and ERβ proteins also differ. Concentrations of the ERβ isoform are high in prostate, ovary, vasculature, brain, and bladder, but low or absent in uterus, breast, kidney, pituitary, and epididymis (Kuiper *et al.,* 1996; Kuiper and Gustafsson, 1997), tissues that contain high levels of ERα. In certain cell types, transfection-reporter gene analysis using an estrogen-response element reporter gene construct indicates that ERβ is a weaker regulator of gene transcription than ERα (Kuiper *et al.,* 1996; Kuiper and Gustafsson, 1997; Paech, *et al*., 1997; Hall and McDonnell, 1999). Also, in response to estrogen treatment, ERα interacts with AP-1 factors and binds to AP-1 regulatory elements, a site where ERβ is inactive when complexed with estrogen (Paech *et al.,* 1997). Interestingly, ERβ activates AP-1 regulatory elements in response to treatment with SERMs, including tamoxifen and raloxifene (Paech *et al.,* 1997). Similarly, transactivation through Sp1 elements has been noted for both ER*a* and ERβ (Saville *et al.,* 2000). In some systems, however, the partial agonist activity of tamoxifen manifested through ERα is completely abolished upon coexpression of ERβ (Hall and McDonnell, 1999). Additionally, ERβ has 5 known carboxyl-terminal isoforms (ERβ1-5) derived from alternative splicing. ERβ1 is a full-length receptor, whereas the ERβ 2, 4, and 5 variants do not have full-length helix 11 and do not form homodimers. The truncated variants of ERβ heterodimerize with ERβ1 and alter its transactivation in a ligand-dependent manner (Leung *et al.,* 2006). ERβ2 lacks the activation function (AF)-2 core required for ligand-dependent transcriptional activation but behaves as a dominant-negative receptor affecting the function of ERα (Chakravarty *et al.,* 2007).

Distinct patterns of estradiol-dependent gene expression are induced by ERα and ERβ in U2OS osteosarcoma cells (Monroe, *et al.,* 2003; Monroe *et al*., 2005; Monroe *et al.,* 2006). These findings suggest that during osteoblast differentiation a unique pattern of gene responses will occur when either receptor type predominates. Similar results have been shown for breast cancer cells (Secreto *et al.,* 2007). A pattern of gene expression occurs when both ERα and ERβ are present as heterodimers in U2OS cells (Monroe *et al.,* 2005) which differs from cells containing exclusively ERα or ERβ homodimers.

Steroid Receptor Coregulators

The activity of steroid nuclear receptors is modulated by a family of steroid receptor coregulators composed of coactivators and corepressors (Bevan and Parker, 1999; McKenna *et al.,* 1999; Robyr *et al.,* 2000). Each receptor isoform (ERα and ERβ, or A and B isoforms of PR) adopts a unique conformation that is dependent on the particular isoform and the agonist/antagonist/mixed agonist nature of the ligand (Brzozowski *et al.,* 1997; Paige *et al.,* 1999). The unique conformation adopted by each receptor isoform following ligand binding determines the relative interaction of the receptor with either coactivators or corepressors, and thereby the differential transactivation of hormone-responsive promoters. Coactivators, when bound to active receptor conformations (usually formed with agonists)*:* mediate favorable interactions with the basal transcriptional machinery, stabilize the preinitiation complex and stimulate gene transcription. Conversely, corepressors bind preferentially to inactive receptor conformations (usually formed with antagonists or unliganded receptors) and prevent the interaction of the receptor with coactivators, resulting in nonproductive transcription factor complexes, which suppress gene transcription.

There is little information on the differential regulation of transcription by ERα andERβ homo- or heterodimers on osteoblasts. ERα andERβ coexpression was found to decrease transcriptional capacity compared to each ER isoform alone on an estrogen response element-dependent reporter gene. Overexpression of the steroid hormone coactivator 1 (SRC1) resulted in preferential transcriptional enhancement by ERβ as well as coexpressed ERα and ERβ· SRC2 overexpression preferentially enhanced ERα transactivation. SRC3, on the other hand, failed to increase estrogen-dependent transactivation of any ER combination in osteoblasts. These findings suggest the transactivation capacity of various ER isoforms is dependent on SRC (Monroe, Johnsen *et al.,* 2003).

Expression and Distribution of ERα and ERβ in Bone Cells and Skeletal Tissue

The important effects of estrogen on bone growth and turnover were recognized well before estrogen receptors were first detected in bone cells. After the initial discovery of ERα in cultured osteoblastic cells (Eriksen *et al.,* 1988; Komm *et al.,* 1988*):* the mRNAs for ERα and ERβ were identified in several osteosarcoma and immortalized osteoblast cell lines (Etienne *et al.,* 1990; Masuyama *et al.,* 1992; Lau *et al.,* 2006) and *in vivo* in osteoblast lineage cells (Zaman *et al.,* 2006).

Estrogen receptor abundance is low in bone cells compared to reproductive tissues and liver. Although many studies have monitored ERα and ERβ mRNA levels, little is known regarding the number and turnover of functional estrogen receptors in bone cells. ERα mRNA has been detected in a murine bone marrow stromal cell line, and the levels were upregulated by 1,25-dihydroxyvitamin D_3 (Bellido *et al.,* 1993). The expression of ERα mRNA was increased following glucocorticoid-induced differentiation of human bone marrow stromal cells (Oreffo *et al.,* 1999), consistent with findings from rat calvarial osteoblasts. Although estrogen modulated the expression of certain osteoblast marker genes in an osteogenic murine stromal cell line (Mathieu and Merregaert, 1994): proliferation and osteogenic differentiation of primary rat bone marrow stromal cells were unaffected by estrogen (Rickard *et al.,* 1995). However, developmental expression of ERα mRNA bone marrow stem cells was reported to correlate with osteogenic differentiation of these cells (Wang *et al.,* 2006). It is clear that ERs are present within differentiated osteoblasts, but it remains uncertain whether osteoblast progenitor cells express ERα and/or ERβ and thus represent additional targets for estrogen action.

The expressions of ERα and ERβ typically increase during osteoblast differentiation *in vitro.* In fetal rat calvarial-derived osteoblast cultures, the level of ERα mRNA was initially low in proliferating cells but increased at the onset of alkaline phosphatase expression and progressively increased thereafter to reach a maximum level in fully differentiated osteoblasts (Bodine *et al.,* 1998). In a human fetal osteoblast line, expression of ERβ mRNA also increased steadily as cells differentiated and then deposited a mineralized matrix (Arts *et al.,* 1997). In contrast, the level of ERβ transcripts in primary rat calvarial cultures was maintained at a high level throughout differentiation (Onoe *et al.,* 1997).

As discussed in the next few paragraphs, the skeletal distribution of ER is not limited to osteoblasts. The expression of ERα mRNA and protein has been reported in isolated avian and human osteoclasts and giant cell tumors of bone (Oursler *et al.,* 1991; Oursler *et al.,* 1994). The human leukemic cell line FLG 29.1, which can be induced by phorbol esters to form cells exhibiting many features typical of osteoclasts, possesses ERα (Oursler *et al.,* 1991; Oursler *et al.,* 1994; Fiorelli *et al.,* 1995; Fiorelli *et al.,* 1997). In addition, osteoclast precursors present in murine hematopoietic blast cell cultures have been shown to express ERα mRNA (Kanatani *et al.,* 1998). The presence of ERβ in osteoclasts and osteoclast precursors has also been reported (Sorensen *et al.,* 2006) but corroborating studies are needed. Estrogen attenuates human osteoclastogenesis through an ERα-mediated pathway, but has no effect on resorption by mature osteoclasts (Sorensen *et al.,* 2006). In contrast, Cre-lox-ERα studies strongly support a role for ERα in osteoclastogenesis and regulation of bone resorption *in vivo* in mice (Nakamura *et al.,* 2007).

Although the distribution of ERα or ERβ in the skeleton is incompletely known, the expression pattern of the two isoforms appears to overlap considerably. Both ERα and ERβ have been localized to chondrocytes in growth plate cartilage, but the exact distribution of ER isoforms within the growth plate may depend upon species and growth stage (Ben-Hur *et al.,* 1993; Kusec *et al.,* 1998; Nilsson *et al.,* 1999). ERα and ERβ are expressed in the human growth plate throughout puberty. In children, both ERα- and ERβ-positive cells were detected at a greater frequency in resting and proliferative zones than in the hypertrophic zone (Nilsson *et al.,* 2003).

In rats, the expression of ERα protein and mRNA was examined in the temporomandibular joint of adult males by immunocytochemistry and *in situ* hybridization. Intense ERα immunoreactivity was localized in the synovial lining cells, stromal cells in the articular disc, and chondrocytes in the temporomandibular joint (Yamada *et al.,* 2003). In contrast, ERβ but not ERα was expressed in high amounts in normal human synovia (Dietrich *et al.,* 2006).

The general consensus for ER distribution in bone is that both receptor isoforms are localized predominantly to osteoblasts and lining cells of cancellous bone, with lower levels in osteocytes and osteoclasts. However, other patterns of distribution of ERα have been obtained. For example, immunofluorescence detection of ERα in human

female and pig bone revealed strongest reactivity in about 50% of the osteocytes, with indistinct staining of osteoblasts and lining cells (Braidman *et al.,* 1995). Using a more sensitive *in situ* reverse transcriptase (RT) polymerase chain reaction (PCR) technique to identify ERα mRNA in actively remodeling human fracture callus, Hoyland *et al.* (1997) reported that osteoblasts expressed the highest levels of ERα, whereas osteocytes and osteoclasts expressed lower levels. Similar results were reported in another study in which the ERα mRNA and protein were predominantly localized to osteoblasts and lining cells of cancellous bone from human and rabbit, with no clear expression in osteocytes or osteoclasts (Kusec *et al.,* 1998).

The *in situ* RT-PCR technique has detected a loss of ERα mRNA expression from osteoblasts and osteocytes in males with idiopathic osteoporosis, suggesting estrogen resistance contributed to the bone loss (Braidman *et al.,* 2000). In an immunolocalization study of mouse and human trabecular bone and fracture callus, ERβ was identified in osteoblasts, osteocytes, and osteoclasts, with the latter cells exhibiting cytoplasmic rather than nuclear immunoreactivity (Vidal *et al.,* 1999). Similar results were obtained for ERβ mRNA in neonatal rat bone where the transcripts were expressed predominantly by osteoblasts covering cancellous bone surfaces with lower signals in osteocytes and bone marrow (Windahl *et al.,* 2000).

In rats, the relative levels of ERα and ERβ mRNA are lower in cortical than cancellous bone, with ERα being dominant at both locations (Onoe *et al.,* 1997; Lim *et al.,* 1999). The weak expression of ERβ in cortical bone is an intriguing observation given that the most striking skeletal phenotype in ERβ knockout mice is increased cortical bone mineral content in postpubertal females only (Windahl *et al.,* 1999). In these mice, more than 90% of tibial osteocytes express ERα, and the level per osteocyte is higher in cortical than cancellous bone. Ovariectomy is associated with decreased ERα protein expression/osteocyte, suggesting that estrogen regulates ER expression levels.

In summary, these *in vitro* and expression studies indicate mRNA levels for ERα are generally higher than ERβ in osteoblasts at all stages of differentiation. The levels for ER isoforms in osteoclasts, cartilage, and connective tissues associated with bone are more variable. It remains unknown what concentration of each receptor isoform is required for responsiveness in target cells or whether one isoform modulates the activity of the other when both are expressed.

Effects of Estrogens on Bone *In Vivo*

The important role of gonadal hormones in bone metabolism is well established. Sex steroids influence most if not all aspects of bone development, growth, and remodeling. The physiological actions of sex steroids contribute to: (a) sexual dimorphism of the skeleton, (b) timing of epiphysealclosure, (c) peak bone mass, (d) maintenance of mineral homeostasis during reproduction, and (e) maintenance of bone mass, architecture, and mineral homeostasis in adults. Despite recognition that gonadal insufficiency is the most important risk factor for osteoporosis, the mechanisms of action of sex steroids on bone *in vivo* are poorly understood and have received surprisingly moderate attention by investigators. Because human studies have provided only a limited understanding of the underlying cellular and molecular mechanisms that mediate hormonal action, studies in laboratory animals have proven extremely useful in identifying an impressive range of physiological actions of gonadal hormones on bone and mineral homeostasis. The strengths and weaknesses of the most well-established animal models for osteoporosis have been reviewed (Iwaniec and Turner, 2008).

Sexual Dimorphism of the Skeleton

Bone growth, modeling, and remodeling represent the major processes that determine bone mass and architecture. Bone growth and modeling are most important prior to achieving peak bone mass. In contrast, remodeling and modeling are important in adults. Elongation of the skeleton by longitudinal bone growth ceases shortly after puberty, whereas increases in bone cross-sectional volume owing to radial bone growth continues at a slow rate throughout the remainder of life.

The sexual dimorphism of the skeleton is species-specific (see Table I) and is acquired prior to and during puberty. In humans, males have a taller stature and more robust skeleton than females, a larger tooth size, and greater muscularity (Frayer and Wolpoff, 1985). The origin of human sexual dimorphism is hotly debated but, unfortunately, beyond the scope of this review. However, it is clear that sex differences in the accretion of bone prior to achieving peak bone mass play an underappreciated role in the etiology of osteoporosis.

Premenopausal women have a higher cortical bone mineral density compared to their male counterparts (Kontulainen *et al.,* 2006). However, the excess bone in pubertal girls is largely endocortical, a location inconsistent with it having an important mechanical function but consistant with it being a storage site for bone that can be mobilized as required during gestation and lactation. In contrast, during puberty there is a disproportionate increase in bone size and strength in males compared to females (Macdonald *et al.,* 2006). At age 67–69, men had 25–32% larger cross-sectional bone size than women, supporting the hypothesis that sex differences in bone size and strength continue into old age (Sigurdsson *et al.,* 2006).

Sex steroids play a role in mediating gender differences in peak bone mass and bone architecture that define skeletal sexual dimorphism. Based on the principle that increased estrogen levels during puberty accelerate epiphyseal closure, the hormone was used to reduce stature

TABLE I Species, Age, and Compartment-Specific Effects of Estrogen on Bone Metabolism

$$$Change owing to a tissue level increase in bone formation.

in tall girls (Venn *et al.,* 2004). In contrast, administration of androgens to boys with delayed puberty increased height (Ahmed *et al.,* 2004). A prospective, randomized, placebo-controlled study evaluated whether suppression of estrogen synthesis in pubertal boys delays bone maturation and ultimately results in increased adult height. During the 18-month follow-up, an increase of 5.1 cm in predicted adult height was observed in boys who received testosterone and the aromatase inhibitor letrozole, with no change seen either in boys who received testosterone alone or in untreated boys. These findings suggest pubertal increases in estrogen levels antagonize bone growth in males as well as females (Dunkel and Wickman, 2002). Finally, in 19-year-old males, free estradiol in serum was a negative predictor while free testosterone was a positive predictor of cortical bone size (Lorentzon *et al.,* 2005).

In summary, increased estrogen levels at puberty advance epiphyseal closure in males and females. Additionally, androgens increase bone length and cross-sectional area. Thus, the smaller bone size in females compared to males is because, at least in part, of the inhibitory actions of estrogen on bone growth. The generally earlier menarche in girls would enhance the hormonal-mediated sex differences in the skeleton. Physiologically, estrogen-mediated decreases in bone mass, size, and strength during puberty are also important because they may predispose women to osteoporosis later in life.

Effect of Ovariectomy on Bone Metabolism

Similar to humans, there are profound sex differences in bone size in rats (Fig. 2a). In rat tibiae, the volume of the

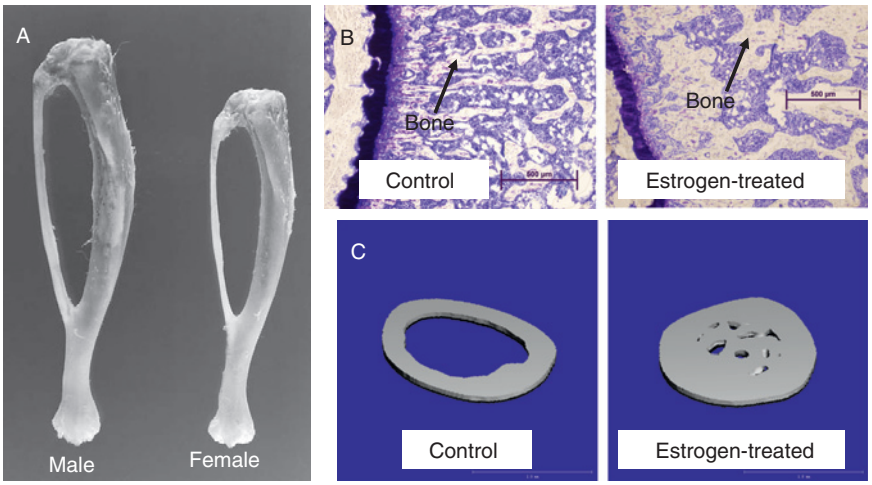

FIGURE 2 Effects of estrogen on bone architecture and histology. A) Sexual dimorphism of the rat tibia showing the size difference between an adult male and an adult female. The bone from the male is longer and more robust. The sex difference is greatly reduced by prepubertal gonadectomy. Bones from gonadectomized rats are intermediate between intact males and females in size. B) Estrogen increases cancellous bone volume in growing animals by preventing the resorption of primary spongiosa. C) Estrogen treatment results in osteosclerosis in mice. The observed endocortical bone formation is not observed in humans. (See plate section)

medullary canal is enlarged following ovariectomy owing to a net increase in bone resorption (Turner, Wakley *et al.*, 1987; Kalu, *et al.*, 1989). Osteoclast number is increased on the endocortical bone surface (Turner, Wakley *et al.*, 1987) and bone formation remains unchanged or increased (Turner, Wakley *et al.*, 1987; Turner, Colvard *et al.*, 1990). In contrast, there is increased bone formation at the periosteal surface (Turner, Wakley *et al.*, 1987). As a result of the opposing changes in radial growth and endocortical modeling, cortical bone volume generally does not decrease in ovariectomized rats (Turner, Wakley *et al.*, 1987; Turner, Colvard *et al.*, 1990). Cortical (and total) bone volume may, in fact, increase in rapidly growing rats following ovariectomy because the addition of extra bone to the periosteal surface of bone often exceeds the increase in endocortical resorption (Turner, Colvard *et al.*, 1990). The cellular mechanism for the differential response of the periosteal and endocortical bone surfaces of the midshaft of rat long bones appears related to the different populations of cells that comprise the two bone envelopes.

Diaphyseal osteoclasts are uncommon on the periosteum and are not notably increased following ovariectomy. This low level of resorption contrasts with the endocortical surface that undergoes bone modeling during growth, to increase the volume of the marrow cavity, and remodeling during adulthood, to repair microdamage and adapt to changing physiological needs (e.g., reproduction or changes in mechanical loading). In turn, endocortical bone turnover is generally much lower than cancellous turnover. Estrogen suppresses radial bone growth by inhibiting periosteal bone formation (Turner, Riggs *et al.*, 1994) while ovariectomy accelerates periosteal bone formation in growing and adult rats. Periosteal expansion occurs in aging humans and is the principal adaptive factor compensating for age-related endocortical and intracortical bone loss. However, this process does not appear to accelerate following menopause (Szulc *et al.*, 2006). The effects of menopause on intracortical (Haversian) bone remodeling have not been extensively investigated. The few studies reported to date suggest aging women have increased turnover of cortical bone, resulting in a negative cortical bone balance. However, the contribution of these changes to bone fragility is unknown.

Theoretically, it is possible to explore the significance of sex steroid action on cortical bone remodeling using animal models. Unfortunately, the skeletons of small rodents do not normally undergo extensive cortical bone remodeling. Cortical bone remodeling occurs in dogs and other large animals. Ovariectomy increases endocortical bone resorption surface and cortical porosity in dogs (Karambolova *et al.*, 1987): however, bone balance appears to be preserved because no net loss of cortical bone was reported (Martin *et al.*, 1987). Additional studies in large animals are necessary to adequately characterize the possible effects of sex steroids on Haversian bone remodeling. In this regard, a recent study suggests that ovariectomy increases periosteal bone turnover in aging monkeys (Bliziotes *et al.*, 2006).

As discussed earlier, estrogen deficiency owing to ovariectomy leads to a bone deficit in adult rodents and primates (Lindsay *et al.*, 1978; Jayo *et al.*, 1990; Kalu *et al.*, 1991). These changes are because of destructive endocortical bone modeling, and destructive cancellous bone modeling and remodeling (Turner *et al.*, 1987; Wronski, *et al.*, 1988). Destructive modeling and remodeling occur when bone resorption exceeds bone formation. Similar changes occur in rats (Goulding and Fisher, 1991) and monkeys

(Mann *et al.,* 1990) following administration of GnRH agonists, a chemical intervention that decreases serum estrogen levels comparable to ovariectomy. The important role of estrogen is further implicated by the observation that the skeletal changes following treatment of rats with ICI 182,780, a potent estrogen receptor antagonist, are similar to ovariectomy (Sibonga *et al.,* 1998). The conclusion that estrogen is critical is further supported by the consistent finding that the skeletal changes that follow ovariectomy are antagonized by pharmacological replacement with the hormone.

Ovariectomy results in (1) severe cancellous osteopenia in long bones and vertebrae of rats (Wronski *et al.,* 1989)*:* (2) strain-specific but generally mild to moderate osteopenia at these sites in mice (Iwaniec *et al.,* 2006)*:* and (3) variable bone loss in vertebrae of monkeys (Jerome *et al.,* 1986; Longcope *et al.,* 1989). The response to ovariectomy in dogs has been inconsistent, with no change (Snow and Anderson, 1985) and bone loss (Martin *et al.,* 1987) reported. The rate of bone loss from rat vertebrae occurs more slowly than from long bones (Wronski *et al.,* 1988; Wronski, *et al.,* 1989). Furthermore, there appears to be regional differences within bones. Cancellous osteopenia in rat tibia is much more prominent in the proximal metaphysis than the distal metaphysis or proximal epiphysis. However, it is important to note that the rate of bone loss may be related to differences in the cellular distribution within bone marrow and prevailing levels of mechanical loading (Westerlind *et al.,* 1997). Additional evidence suggests there is overlap between mechanical signaling and estrogen action on bone (Damien *et al.,* 1998; Tomkinson *et al.,* 1998). In addition, estrogen influences the differentiation and function of neurons, adipocytes, hematopoietic cells and immune cells, each of which, in turn, can affect bone cells. Thus, site-specific actions of estrogen on bone metabolism involve the integrated tissue-level actions of the hormone on a complex assortment of cells.

Ovariectomy increases osteoblast-lined perimeter, osteoclast-lined perimeter, and osteoclast size in long bones of rats (Wronski *et al.,* 1986; Turner *et al.,* 1988). There are simultaneous increases in the mineral apposition and bone formation rates, suggesting that ovariectomy results in high bone turnover. Cancellous bone turnover remains elevated in rats at some skeletal sites a year or more after ovariectomy (Wronski *et al.,* 1989; Sibonga *et al.,* 2000). Bone formation is increased in ovariectomized monkeys (Jerome *et al.,* 1986; Longcope *et al.,* 1989), suggesting bone loss in nonhuman primates is also associated with increased bone turnover. Dempster *et al.* (1995) reported temporal changes in cancellous bone architecture of the distal rat femur after ovariectomy. These investigators demonstrated that the primary mechanism of ovariectomy-induced bone loss is osteoclastic perforation and removal of the trabecular plates. Generalized, gradual trabecular thinning is not observed. Interestingly, a similar process is responsible for removal of the most distal trabeculae during normal bone elongation (Turner, 1994).

Effects of Estrogen Replacement on Bone Metabolism in Ovariectomized Laboratory Animals

Estrogen replacement prevents the ovariectomy-induced increase in the size of the medullary cavity of a rat long bone by reducing osteoclast number (Turner, Wakley *et al.,* 1987). Similarly, estrogen replacement prevents increases in periosteal bone formation (Turner, Vandersteenhaven *et al.,* 1987), and, as a result, decreases bone cross-sectional area and cortical bone area. Because there are very few osteoclasts on the periosteal surface at most skeletal sites, it is unlikely this inhibitory effect of estrogen on bone formation is coupled to decreased bone resorption. Estrogen reduces the number of preosteoblasts in the S phase of the cell cycle, suggesting that the hormone inhibits the proliferation of osteoblasts. At the same time, estrogen decreases steady-state mRNA levels for bone matrix proteins and IGF-I, reduces bone matrix synthesis and osteoblast number, and increases the population of bone-lining cells (Turner *et al.,* 1990; Turner, *et al.,* 1992). Thus, estrogen influences bone growth by decreasing bone formation, as well as bone resorption.

In growing ovariectomized rats, estrogen replacement increases cancellous bone mass by inhibiting the resorption of primary spongiosa (Fig. 2b). In contrast, in adult ovariectomized rats estrogen replacement stabilizes cancellous bone volume by reducing bone turnover, reestablishing a neutral or positive balance between bone resorption and bone formation, and preventing the destruction of trabecular plates (Turner *et al.,* 1988; Wronski *et al.,* 1988; Kalu *et al.,* 1991; Wronski *et al.,* 1993). Estrogen accomplishes these actions, in part, by antagonizing the initiation of new sites of bone remodeling. Osteoclast number is reduced in estrogen-treated rats by a combination of decreased fusion of the osteoclast precursors (Turner, Evans *et al.,* 1994) and reduced osteoclast life span (Kameda *et al.,* 1997). The former may be important in preventing initiation of remodeling, whereas the latter may improve remodeling balance.

The effects of estrogen on cancellous bone formation involve direct as well as indirect actions of the hormone. There is general agreement that the inhibitory effects of estrogen on initiation of bone remodeling leads to an overall coupled decrease in bone formation as well as improved bone remodeling balance. The latter change may be owing to an increased osteoblast life span as well as the previously mentioned decreased osteoclast life span (Gohel *et al.,* 1999). Time course studies have shown that estrogen results in rapid decreases in mRNA levels for bone matrix proteins and collagen synthesis, suggesting that the hormone also has a direct inhibitory effect on bone formation (Turner, 1999). As a consequence of direct and

indirect inhibition of bone formation, estrogen does not increase bone volume in adult rats with established bone loss (Wronski *et al.,* 1993).

The Mouse as a Model for Postmenopausal Osteoporosis

The ovariectomized rat is a well-characterized and validated preclinical model for postmenopausal osteoporosis (Iwaniec and Turner, 2008). Because of the proven value of the mouse as a genetic model, there has been great interest in the mouse as an alternative rodent model for postmenopausal bone loss. To date, the results have been discouraging. In general, ovariectomy results in accelerated cancellous bone turnover in mice (Beamer *et al.,* 1996; Gong *et al.,* 2001; Springer *et al.,* 2003; Forlino *et al.,* 2005). However, the magnitude of the change is strain-dependent and much less consistent than in rats (Kuivaniemi *et al.,* 1991; Clark and Rowe, 1996; Lazner *et al.,* 1999). The minute amount of cancellous bone found in mice, especially in long bones, is also a major disadvantage. This limitation is exasperated by age-related cancellous bone loss, which begins in some commonly studied mouse strains shortly after peak bone mass is achieved at around four months of age (Lazner *et al.,* 1999). The net result is too little starting cancellous bone at many important skeletal sites to accurately measure changes in indices of bone mass and turnover following ovariectomy. Unfortunately, one of the most challenging mice to evaluate is C57BL/6, a strain commonly used in genetic manipulations. This strain exhibits especially low cancellous bone volume. For example, the mean cancellous bone volume at the distal femur of seven-month-old ovary intact C57BL/6 mice is often as low as 3% (Iwaniec *et al.,* 2006). Measurement of dynamic histomorphometry and osteoblast perimeter and osteoclast perimeter is problematic because of the paucity of bone. To reliably detect bone loss following ovariectomy in skeletally mature C57BL/6 mice would require reducing the bone volume to near 0%, making it even more unlikely that measurement of fluorochrome labeling and bone cells will accurately reflect changes in bone turnover. Other than agents that induce *de novo* bone formation, it is unlikely that a model system in which there is so little cancellous bone can be reliably used to evaluate the efficacy of pharmacological interventions to restore bone mass in an osteopenic skeleton.

The limitations discussed here can be at least partially addressed by investigating skeletal sites, such as lumbar vertebrae, which have a higher cancellous bone volume. Even so, the vertebral bone loss 3 months following ovariectomy is modest, averaging about 27% (change in bone volume from ~12 to ~9%) (Iwaniec *et al.,* 2006).

There are major differences between human and mouse physiology regarding the actions of estrogens and estrogen analogs such as tamoxifen (Modder *et al.,* 2004). Administration of estrogen to mice induces endocortical bone formation often resulting in near total obliteration of the marrow cavity (Sims *et al.,* 2003) (Fig. 2c). This pathological condition does not occur in humans that overproduce estrogen or are treated with high levels of the hormone. Tamoxifen shows far less tissue discrimination in mice than in humans. These species differences often contraindicate the use of the mouse in studies in which it is important to accurately model the human skeletal response to estrogen (Table I).

Skeletal Phenotypes of Mice with Targeted Disruption of ER Genes

The development of mice exhibiting targeted gene deletions (knockout) in ERα, ERβ, or both genes simultaneously has proven to be a valuable tool for investigating ER signaling. As a note of caution, the mutant phenotype of knockout animals may result from multiple influences that occur as a consequence of the targeted mutation, and therefore the mechanisms responsible for the phenotype may not be restricted solely to the specific mutation. Additionally, disturbing ER signaling in all tissues from conception may destabilize the feedback loops regulating the synthesis of other sex steroids in addition to estrogen, thereby leading to changes in the circulating levels of these hormones, some of which also possess major activity on bone. For example, the ERα knockout female mouse has markedly elevated levels of estrogen, whereas the ERα knockout male has increased levels of testosterone (Couse and Korach, 1999). As a further complexity, phenotypes in single ER gene mutants may arise as a result of the β isoform being able or unable to compensate for the loss of the α isoform or, alternatively, suppress ERα activity. In the latter case, loss of ERβ could conceivably enhance rather than suppress estrogen responsiveness in a cell type that normally expresses both ER isoforms.

Severe loss of function mutations in ER isoforms resulting in tissue resistance to estrogens is very rare in humans and, therefore, is not a significant cause of osteoporosis. In contrast to ER knockout mice, women with postmenopausal osteoporosis have greatly reduced estrogen levels. Because of the substantial species-specific actions of sex steroids on skeletal development, growth and turnover (Table I), extrapolation of ER knockout data generated in mice to human physiology should generally be avoided.

Homozygous deletion of the ERα gene results in reduced cortical bone density and cortical bone formation in both male and female mice, suggesting that estrogen stimulates cortical bone formation via ERα (Korach *et al.,* 1997). There is delayed closure of the epiphyseal growth plate in ERα null mice. However, linear growth in long bones is generally reduced and the decrease is more pronounced in females (Korach *et al.,* 1997; Schmidt *et al.,* 2000). The effect of ERα ablation on cancellous bone is

less certain. Using independently generated animals, cancellous bone has been either modestly decreased in both sexes (Korach *et al.,* 1997) or unaffected in females but showing an age-related increase in males (Sims *et al.,* 2003). In contrast to ER knockout mice, both a man with aromatase P450 deficiency (causing complete estrogen deficiency) and a man with a mutation in the ERα gene (causing partial estrogen resistance) exhibited continued longitudinal bone growth. The increased stature of these individuals was accompanied by delayed epiphyseal growth plate closure. In addition, these men had marked cancellous osteopenia and elevated biochemical markers for bone remodeling (Smith *et al.,* 1994; Carani *et al.,* 1997). Consequently, the lack of marked cancellous bone loss suggests that in mice ERβ compensates for loss of ERα.

Female ERα knockout mice lose bone following ovariectomy to the same extent as the wild-type mice. However, estrogen responsiveness in the ERα knockout female appears to be reduced, because higher estrogen concentrations were required to prevent bone loss compared to ovariectomized wild-type mice (Ederveen and Kloosterboer, 1999).

Similar to ERα deletion, deletion of the ERβ gene results in delayed growth plate closure. However, in adult female ERβ knockout mice, the longitudinal bone growth for some long bones is increased (Windahl *et al.,* 1999). Studies suggest the cortical and cancellous bone parameters of male ERβ knockout mice do not differ from wild-type mice (Vidal *et al.,* 2000). In contrast, female ERβ knockout mice exhibit increased whole body bone mineral content owing to increased cortical bone, although this is only observed in the postpubertal stage (Windahl *et al.,* 1999). The increased cortical bone results from elevated periosteal (radial) bone formation, suggesting that ERβ is required for pubertal feminization of the mouse skeleton.

Older (~4 months to 1 year old) female ERβ knockout mice are partially protected against age-related cancellous bone loss, as these animals exhibit higher cancellous bone volume than either male ERβ knockout or wild-type mice (Ederveen and Kloosterboer, 1999; Windahl *et al.,* 2000). The increase in cancellous bone is thought to be owing to enhanced bone formation rather than to changes in growth plate kinetics or altered bone resorption because osteoblast markers and ERα transcript levels are elevated (Windahl *et al.,* 2000). Increased cancellous bone in female ERβ knockout mice may be caused by removal of the dominant-negative function of ERβ on ERα activity (Sims *et al.,* 2002). Female ERβ knockout animals lose cortical and cancellous bone after ovariectomy similarly to wild-type mice (Windahl *et al.,* 1999). Moreover, estrogen treatment prevents ovariectomy-induced bone loss in ERβ knockout female mice to the same extent as in wild-type mice (Ederveen and Kloosterboer, 1999; Ke *et al.,* 2002). Thus, ERβ seems to be nonfunctional in the skeleton of male mice, whereas in females, ERβ mediates the estrogen-induced suppression of periosteal bone growth. In female mice, ERβ is not required for the maintenance of cancellous bone in the presence of ERα, but is required in the absence of ERα. Supporting the hypothesis that ERβ does not mediate estrogen responses in cancellous bone in males, testosterone, but not estrogen, completely prevented the decrease in bone at cancellous sites in orchidectomized ERα knockout males (Vandenput *et al.,* 2001). However, if ERβ is truly nonfunctional in the male mouse skeleton, it is not clear why the ERα knockout male does not exhibit estrogen resistance, characterized by elevated bone turnover rates and osteopenia, rather than the unaltered or slightly increased cancellous bone characteristic of the knockout phenotype (Sims *et al.,* 2003).

Deletion of both ER isoforms in double (ERα/β) knockout mice generates a skeletal phenotype in the male very similar to that caused by ERα single deletion; namely reduced postpubertal longitudinal and periosteal (cortical) bone growth and normal cancellous bone (Vidal *et al.,* 2000). Interestingly, the reduced bone growth in the male knockout has been correlated with decreased serum IGF-1 levels (Vidal *et al.,* 2000). Similarity of the skeletal defects resulting from ERα or ERα plus ERβ gene inactivation in the male knockout is further evidence for the lack of involvement of the β isoform in growth and remodeling of the male skeleton.

In contrast to knockout males, the bone defects in the ERα/β knockout female mice are distinct from those produced by deletion of either ER isoform alone, thus supporting a role for both isoforms in the female skeleton. In postpubertal ERα/β knockout females, cortical thickness and cancellous bone are reduced because of decreased bone formation (Sims *et al.,* 2002). Both ER isoforms participate in normal cancellous bone remodeling. Because female ERα knockout animals fail to exhibit cancellous bone loss, ERβ in females can compensate for the loss of ERα.

Overall, the data suggest ERα and ERβ likely perform different functions in cortical and cancellous bone and that the relative importance of the two isoforms differs between the sexes. However, it is unclear whether the ER isoforms perform identical functions during skeletal growth and turnover in humans. Perhaps the most surprising result arising from the ER knockout analysis is that double ERα/β knockout mice are viable with grossly normal skeletons, demonstrating that both ER isoforms are dispensable for the normal development of cartilage and bone in mice.

Effects of Estrogen on Bone Cells *in Vitro*

Estrogen Regulation of Early and Late Response Genes

As outlined earlier, sex steroids regulate the expression of early response genes within 30 minutes to 2 hours following hormone exposure. The best examples of this are the nuclear

proto-oncogenes, including c-myc, c-jun, jun-B, c-fos, N-myc, and the TGFβ-inducible early gene, TIEG (Spelsberg *et al.,* 1992; Tau *et al.,* 1998). These early response genes are expressed and regulated by sex steroids in many different reproductive (Murphy *et al.,* 1987; Fink *et al.,* 1988) and skeletal tissues (Eriksen *et al.,* 1988; Oursler *et al.,* 1991; Oursler *et al.,* 1994; Harris *et al.,* 1995; Tau *et al.,* 1998; Monroe, Getz *et al.,* 2003; Monroe, Johnsen *et al.,* 2003; Monroe *et al.,* 2006; Hawse *et al*., 2007). Thus, these genes are excellent markers for steroid actions and interactions. Because early response genes are regulated by steroids in all tissues containing steroid hormone receptors, and most of these early gene products in turn regulate the gene expression of late genes, a role for nuclear protooncogenes as early response (regulatory) genes in a cascade model of steroid action in bone and reproductive tissues has been proposed (Landers and Spelsberg, 1992; Spelsberg *et al.,* 1992).

In contrast to these rapidly induced genes, which are universal markers of steroid actions, many late responsive (24–48 hour) structural genes are specific to different cell types and some, like the growth factor/cytokine genes, mediate the effects of estrogen on various target cells and tissues. Control of late gene expression by estrogen has been investigated in numerous osteoblast cell culture systems. Unfortunately, despite extensive efforts, only a few putative target genes have shown consistent regulation. The most reliable responses are increases in type I collagen, transforming growth factor (TGF)β, and insulin-like growth factor (IGF)-I production (for a review, see Spelsberg *et al.,* 1999). In fact, estrogen has been shown to induce TGFβ production by both osteoblasts and osteoclasts (Oursler, 1998). These findings suggest estrogen has a direct bone anabolic effect on cultured osteoblasts. TGFβ plays an important role in chondrogenesis and TGFβ and IGF-I promote the proliferation and differentiation of osteoblast precursors. Under some conditions, TGFβ inhibits the formation of osteoclasts. In addition to regulating IGF-I synthesis, estrogen may modulate IGF bioactivity by regulating the production of IGF-binding proteins, including IGFBP-2, -3, and -4, which in turn enhance or suppress the activities of IGF-I and IGF-II. TGFβ and IGF-I are both sequestered in bone matrix at relatively high concentrations. See Fig. 4 for a detailed list of estrogen responses in cultured osteoblasts and osteoclasts.

In vivo studies in humans and most animal models provide overwhelming evidence that estrogen inhibits intramembranous as well as endochondral bone growth, and as a consequence suppresses bone formation and reduces peak bone mass. Although less completely characterized, the effects of estrogen on the expression of early and late response genes in skeletal tissues *in vivo* follows a time course similar to that in cultured osteoblasts (Turner *et al.,* 1999). However, in contrast to its action *in vitro*, in rats estrogen reduces mRNA levels for bone matrix proteins and decreases bone collagen synthesis. The large discrepancy between osteoblast culture and *in vivo* suggests that the direct actions of the hormone on osteoblasts are modified by other cells and regulatory pathways that are not present in the cell culture environment. As a consequence, cell culture data, although essential for characterizing molecular pathways of action, should not be relied upon to accurately predict the *in vivo* actions of estrogen on bone metabolism.

Estrogen Regulation of Cytokine Synthesis

A hallmark of estrogen deficiency is an elevated rate of bone turnover in which both osteoclast-mediated bone resorption and, perhaps secondarily, osteoblast-mediated bone formation occurs at an increased rate. Physiologically, reduced estrogen levels during pregnancy and lactation may facilitate mobilization of calcium stores from bone for deposition into the fetal and neonatal skeleton, respectively. There is evidence to suggest that release of an estrogen-imposed suppression of bone-resorbing cytokine synthesis plays a role in the accelerated bone turnover. The osteoblast and/or monocyte/macrophage lineage produces cytokines capable of increasing osteoclast formation, differentiation, or activity that are inhibited by estrogen. However, the cytokines that are most important for mediating the skeletal actions of estrogen remain elusive. One hypothesis proposed that bone marrow monocyte/macrophage-derived interleukin (IL-1) and tumor necrosis factor (TNF) induce the production of other cytokines, including macrophage colony-stimulating factor (M-CSF): granulocyte-macrophage CSF (GM-CSF): and IL-6 by osteoblasts and hematopoietic cells, which together promote osteoclast resorptive activity. Evidence in support of this pathway is as follows: (1) release of IL-1, TNF, and GM-CSF by peripheral blood monocytes from untreated osteoporotic women is higher than from estrogen-treated osteoporotic and nonosteoporotic women (Pacifici *et al.,* 1989; Pacifici *et al.,* 1991): (2) production of M-CSF by osteoblastic/stromal cells is increased by ovariectomy in mice and is dependent on bone marrow synthesis of IL-1 and TNF (Kimble *et al.,* 1996): (3) neutralization of TNF activity either by the inhibitory TNF-binding protein (TNFbp) or by expression of an inhibitory soluble TNF type 1 receptor in mice prevents ovariectomy-induced bone loss (Ammann *et al.,* 1997*):* (4) type 1 IL-1 receptor-null mice fail to lose bone following ovariectomy (Lorenzo *et al.,* 1998): and (5) simultaneous blockade of both IL-1 and TNF activity by IL-1 receptor antagonist (IL-1ra) and TNFbp completely prevents ovariectomy-induced bone loss in rats (Kimble *et al.,* 1995; Kimble *et al.,* 1997).

An alternative proposed pathway favors IL-6 as the mediator of bone loss in an estrogen-deficient state. Evidence for this pathway is as follows: (1) production of IL-6 is inhibited by estrogen in cells of the stromal/osteoblastlineage *in vitro* (Girasole *et al.,* 1992; Passeri *et al.,* 1993): although this is not a universal finding (Rickard

et al., 1992; Rifas *et al.,* 1995): (2) the production of IL-6, as well as the number of osteoclast precursors and osteoclast formation is increased in bone marrow cultures from ovariectomized mice compared to sham control animals (Miyaura *et al.,* 1995): (3) all of these effects, as well as the increased population of osteoclasts present in cancellous bone of ovariectomized mice, can be prevented by treatment with estrogen or an anti-IL-6 antibody (Jilka *et al.,* 1992): (4) estrogen may reduce the responsiveness of osteoblast lineage cells and possibly also osteoclasts to IL-6 by decreasing expression of the ligand-binding gp80 and signal-transducing gp130 subunits of the IL-6 receptor (Lin *et al.,* 1997): and (5) IL-6-deficient mice are protected from ovariectomy-induced bone loss (Poli *et al.,* 1994).

Other factors such as osteoprotegerin (OPG), a soluble member of the TNF receptor family, may also mediate the inhibitory effect of estrogen on bone resorption. OPG binds to and inhibits the activity of the endogenous ligand of RANK (RANKL), a TNF-related cytokine produced by bone marrow stromal cells, osteoblasts, megakaryocytes, mast cells, and B cells (Bord *et al.,* 2004; Ali *et al.,* 2006; Kawai *et al.,* 2006; Rauner *et al.,* 2007), which is essential for osteoclast formation. Deletion of the OPG gene in mice generates severe osteopenia in both cancellous and cortical bone (Bucay *et al.,* 1998*):* whereas mice overexpressing OPG develop osteopetrosis and do not lose bone as a result of estrogen deficiency (Simonet *et al.,* 1997). Estrogen increases OPG expression in osteoblasts overexpressing the ERα gene (Hofbauer *et al.,* 1999). This effect may be mediated by TGFβ, which has been shown to increase OPG production by bone marrow stromal osteoblast precursor cells (Takai *et al.,* 1998). Although OPG may be a key mediator of the antiresorptive effects of estrogen, compelling *in vivo* evidence to support this hypothesis is lacking. In fact, OPG levels are increased in women following menopause and are decreased in postmenopausal women treated with estrogen (Khosla *et al.,* 2002; Han *et al.,* 2005).

The studies described here focused on respective roles of osteoblasts and monocytes as sources of proinflammatory cytokines such as IL-1, IL-6, and TNFα. More recent work suggests that other cells may play an important and perhaps predominant role in their generation. These include T cells, mast cells, and adipocytes. T cells and mast cells differentiate from bone marrow-derived hematopoietic stem cells, whereas adipocytes differentiate from bone-marrow derived mesenchymal stem cells (Blair *et al.,* 2007; Hallgren and Gurish, 2007). Estrogen deficiency increases the populations of each of these cell types within the marrow cavity. In addition to the bone-regulating cytokines discussed so far, T cells and mast cells produce RANKL (Ali *et al.,* 2006; Kawai *et al.,* 2006) and mast cells produce histamine and heparin. Histamine-deficient mice are resistant to bone loss following ovariectomy and heparin is an endogenous inhibitor of OPG (Fitzpatrick *et al.,* 2003; Irie *et al.,* 2007).

Adipocytes, in addition to being important sources of proinflammatory cytokines, produce numerous additional adipokines, several of which have been shown to influence bone metabolism by acting directly on bone cells or by acting through the sympathetic arm of the central nervous system. The bone active adipokines include adiponectin (Luo *et al.,*2006*):* resistin (Thommesen *et al.,*2006*):* visfatin (Xie *et al.,* 2007*):* and leptin. The most well studied of the adipokines is leptin. Leptin-deficient ob/ob mice are obese and have bone compartment-specific abnormalities in bone mass and architecture (Hamrick *et al.,* 2004). Although infertile, these mice have normal or elevated cancellous bone mass. Central leptin gene therapy reverses the skeletal abnormalities in growing ob/ob mice without increasing circulating levels of the hormone (Iwaniec *et al.,* 2007). Some studies suggest that leptin inhibits bone formation by increasing sympathetic tone (Karsenty, 2001). However, this proposed mechanism is not supported by the observations that leptin increases bone growth (Steppan *et al.,* 2000) and that neonatal sympathectomy does not alter bone growth (Hill *et al.,* 1991). Furthermore, leptin receptors are located on chondrocytes and osteoblasts (Steppan *et al.,* 2000; Iwamoto *et al.,* 2004) and systemic leptin was found to reduce bone loss in rats following ovariectomy (Burguera *et al.,* 2001). Thus, leptin can potentially have direct effects on bone and cartilage cells, as well as indirect effects that are mediated through the central nervous system. Although no consensus exists regarding the precise role of leptin in regulating bone metabolism, most studies are consistent with the hypothesis that leptin is primarily a permissive factor. According to this view, leptin levels reflect energy reserves and low circulating levels of the hormone initiate adaptive mechanisms to cope with starvation. These adaptations include reduced gonadal hormone secretion that prevent pregnancy and decreased bone growth and turnover (Hamrick, 2004).

Although generally not considered a cytokine, the skeletal growth factor IGF-I functions as an autocrine, paracrine, and hormonal factor. IGF-I is arguably the most important physiological regulator of bone growth and turnover in the postnatal skeleton. IGF-I is produced not only by osteoblasts but also by adipocytes (Zizola *et al.,* 2002). Adipocytes reside within the bone marrow compartment and the local concentration of IGF-I in the vicinity of osteoblasts and osteoclasts could exceed the circulating levels of the growth factor. The principle regulator of systemic and local IGF-I is growth hormone (LeRoith and Yakar, 2007). Growth hormone secretion, in turn, is regulated by estrogen (Meinhardt and Ho, 2006). Hypophysectomy, in addition to preventing the synthesis of growth hormone, results in gonadal insufficiency comparable to ovariectomy. In contrast to ovariectomy, hypophysectomy results in greatly decreased bone turnover and cessation of bone growth

(Yeh *et al.,* 1997). Administration of estrogen to hypophysectomized rats has minimal effects on bone metabolism (Kidder *et al.,* 1997; Yeh *et al.,* 1997). Thus, the actions of sex steroids on the skeleton require growth hormone/IGF-I signaling. Based on the dramatic skeletal effects of growth hormone and the knowledge that there are gender differences in its regulation, it is surprising that the role of growth hormone/IGF-I signaling in the etiology of postmenopausal osteoporosis has received so little attention.

In summary, there is no shortage of bone active cytokines, hormones, and skeletal growth factors whose synthesis is influenced by estrogen. The data do not favor the regulation of a single agent or a single cell lineage as responsible for mediating the physiological actions of estrogen on the skeleton. It seems more likely that multiple cytokines, hormones, and growth factors produced by a plethora of cells contribute to the complexity of estrogen action on bone.

Molecular Mechanism of Estrogen Regulation

The molecular mechanisms involved in the estrogen regulation of several cytokine/late gene promoters produced by bone cells have been elucidated. Many of these promoters lack consensus estrogen response elements (EREs) and thus have revealed alternative mechanisms of transcriptional control by the ER. In some instances, these do not require direct binding of the ligand-activated ER to DNA. Instead, ER interacts with other transcription factors and coregulators to modulate the binding affinity of these proteins to their cognate regulatory sites in the DNA. For example, repression of the IL-6 promoter by estrogen occurs because protein-protein interactions between the ligand-activated ERα and NF-*K*B and C/EBPβ prevent binding of the latter factors to their respective sites on DNA (Stein and Yang, 1995; Galien *et al.,* 1996). In contrast, estrogen stimulates transcription by the IGF-I promoter via enhanced binding of fos/jun heterodimers to AP-1 elements by interaction with activated ERα (Umayahara *et al.,* 1994). Numerous genes, including retinoic acid receptor-α1 (RAR-α1): c-fos protooncogene, cathepsin D, IGFBP-4, and the epidermal growth factor receptor gene, among others, are modulated by estrogen through the binding of ER/Sp1 transcription factor complexes with either Sp1 sites alone or Sp1/ERE half-sites (Krishnan *et al.,* 1994; Rishi *et al.,* 1995; Salvatori *et al.,* 2000).

Estrogen Regulation of Bone Cell Metabolism

Similar to the conflicting reports on the estrogen regulation of late response genes in cultured osteoblasts, there is a lack of a general consensus with regard to the effects of estrogen treatment on osteoblast proliferation. Estrogen stimulates cell proliferation in primary and immortalized fetal rat calvarial cells (Ernst *et al.,* 1989): normal adult human osteoblasts (Scheven *et al.,* 1992): mouse MC-3T3E1 cells (Majeska *et al.,* 1994): and synchronized human osteosarcoma cells (Ikegami, Inoue et al., 1994). Other investigators report no effect of the hormone on primary cultures of osteoblasts from normal adults (Keeting *et al.,* 1991; Rickard *et al.,* 1993) and no alteration of cell growth in osteoblasts stably transfected with the ERα gene (Watts *et al.,* 1989; Kassem *et al.,* 1996; Robinson *et al.,* 1997). *In vivo*, estrogen decreases osteoblast proliferation in cortical and cancellous bone compartments of growing female rats (Turner *et al.,* 1992; Westerlind *et al.,* 1993; Turner *et al.,* 1999).

The effect, if any, of estrogen on the proliferation of less differentiated osteoblast progenitor cells is unclear. The proliferation rate of bone marrow-derived osteoblast precursor cells, isolated from ovariectomized rats, increased compared to cells from sham-operated animals (Modrowski *et al.,* 1993). However, the *in vitro* treatment of rat bone marrow stromal cells with estrogen showed no effect on cell growth (Rickard *et al.,* 1995).

In vivo, osteoblast and osteoclast formation is tightly coupled owing, at least in part, to the dependence of osteoclast precursor development on support from cells of the stromal/osteoblast lineage through the provision of cytokines and other stimuli, and of osteoblast precursor development on factors released from bone matrix by osteoclast activity. As discussed earlier, estrogen deficiency causes not only increased osteoclast formation possibly as a result of increased production of bone-resorbing cytokines, but also stimulates osteoblast formation (Turner *et al.,* 1992; Turner *et al.,* 1993; Westerlind *et al.,* 1997). In support of this, ovariectomy in rodents increases the number of bone marrow-derived osteoblast progenitor cells (Scutt *et al.,* 1996; Jilka *et al.,* 1998). In mice, this increase was transient and partially independent of increased bone resorption, suggestive of a possible direct action of estrogen on osteoblast proliferation and/or differentiation (Jilka *et al.,* 1998). Such mechanisms may partially account for the elevated bone turnover immediately after ovariectomy/menopause. However, estrogen has been shown to have inhibitory effects on bone formation in rats that occur much too quickly to be caused by a prior decrease in bone resorption (Turner *et al.,* 1999). Based on biomarkers, the stimulated rates of bone remodeling owing to gonadal steroid deficiency are thought to be only temporary and with time after menopause bone remodeling declines to levels approximating premenopausal rates. However, this hypothesis has never been verified by tissue level (histomorphometric) analysis. In this regard, no age-related decrease in bone formation was detected in iliac crest biopsies of healthy postmenopausal women (Turner, unpublished data). In rats, long-term effects of ovariectomy on bone re-modeling are site-specific; a transient increase in bone turnover was noted at the proximal tibial metaphysis, whereas bone turnover remained greatly elevated in the epiphysis. Biomechanical signaling may explain the

divergent responses of the two bone compartments to estrogen deficiency. Metaphyseal bone, at least in rodents, functions primarily in mineral homeostasis. In contrast, the structural function of the epiphysis greatly outweighs its role in mineral homeostasis. Estrogen deficiency results in elevated turnover of the metaphysis and epiphysis but the higher strain energy levels of the latter bone appear to protect against bone loss. Harold Frost suggested that estrogen influenced the set point of the mechanical sensing system in bone (Frost, 1987). In this regard, recent studies suggest that the mechanical transduction system of bone is dependent upon ER signaling (Lee *et al.,* 2004; Zaman *et al.,* 2006; Armstrong *et al.,* 2007; Saxon *et al.,* 2007).

Estrogen has opposite effects on apoptosis in osteoclasts and osteoblasts. In osteoclasts, apoptosis is stimulated by estrogen via a TGFβ-mediated mechanism (Hughes *et al.,* 1996; Kameda *et al.,* 1997). However, apoptosis is prevented by estrogen in osteocytes (Tomkinson *et al.,* 1997; Tomkinson *et al.,* 1998) and other osteoblast lineage cells (Gohel *et al.,* 1999; Manolagas, 1999). Physiologically, osteoclast apoptosis plays an important role in the rapid removal of osteoclasts during the bone remodeling reversal at termination of lactation (Miller and Bowman, 2007). Thus, the enhancement of osteoclast apoptosis could contribute to the antiresorptive effects of estrogen.

The physiological significance of a decrease in apoptosis in osteoblast linage cells is less clear. The great majority of osteoblast lineage cells are osteocytes and bone lining cells, cells that are not producing bone matrix. As a consequence, prevention of apoptosis in osteocytes and bone lining cells should have no direct effect on bone formation. At present, there is no evidence to suggest that apoptosis occurs in osteoblasts actively synthesizing bone matrix. Therefore, an increase in apoptosis of osteoblast lineage cells during estrogen deficiency may be associated with a reduced interval of bone matrix synthesis by osteoblasts. However, the deficiency in bone formation resulting from a reduced osteoblast life span would have to compensate for the observed increased rate of matrix production by osteoblasts following ovariectomy (Turner *et al.,* 1992; Turner *et al.,* 1993).

Increased apoptosis of osteocytes may play an important indirect role in mediating estrogen-induced bone loss by promoting increased bone turnover (Tomkinson *et al.,* 1998). Also, apoptosis may play an especially important role during cell turnover by limiting the number of daughter cells that undergo further differentiation, for example in the proliferative zone of the growth plate (Sibonga *et al.,* 2002). However, the level of estrogen regulation of apoptosis on the differentiation of mesenchymal stem cells to osteoblasts has not been extensively evaluated.

Recent studies by Kato and coworkers (Nakamura *et al.,* 2007) using a Cre-lox osteoclast-specific knockout of ERα, show that ERα located in osteoclasts is required for maintenance of cancellous bone in female, but not male mice. In addition to indirect effects of estrogen on the formation, differentiation, and activity of osteoclasts via regulation of cytokine synthesis by osteoblasts, estrogen has direct effects on osteoclasts and their precursors (see Fig. 3). Early studies demonstrated not only the presence of ERα in osteoclasts, but also the regulation of gene expression by estrogen in these cells (Oursler *et al.,* 1993; Oursler *et al.,* 1994). Subsequent studies have shown that the bone-resorbing activity of avian, rabbit, and human osteoclasts

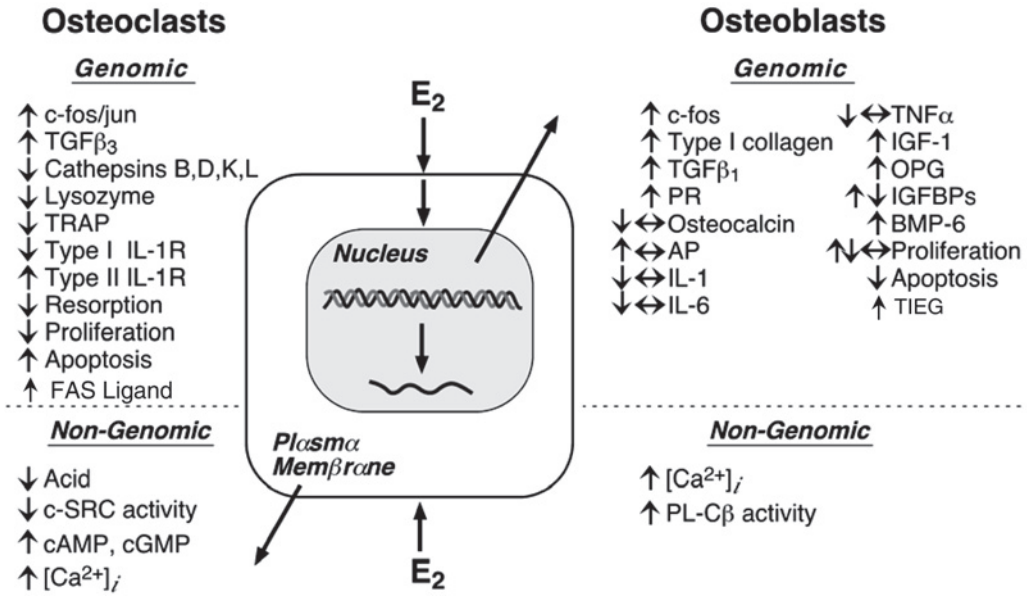

FIGURE 3 Model outlining the reported effects of estrogens on osteoblast and osteoclast functions. Arrows indicate the changes induced by estrogen. Double/triple arrows indicate published differences in reported responses.

is decreased by estrogen treatment, which is owing, in part, to a reduced population of osteoclasts via apoptosis (Hughes *et al.,* 1996; Kameda *et al.,* 1997). Estrogen may further inhibit bone resorption by acting directly on osteoclast progenitors to reduce osteoclast formation, as demonstrated by (1) the ability of estrogen to reduce proliferation and increase apoptosis of FLG 29.1 preosteoclastic cells (Zecchi-Orlandini *et al.,* 1999*):* (2) the antagonism by estrogen of the differentiation of murine hemopoietic blast cells into multinucleated osteoclasts induced by GM-CSF and PTH/PTH-related peptide (Kanatani *et al.,* 1998*):* and (3) the finding that estrogen suppresses the production of TRAP-positive, multinucleated osteoclasts from primary murine bone marrow myeloid progenitors and the mouse monocytic cell line RAW 264.7 cultured in the presence of soluble RANKL and M-CSF, but in the absence of stromal/osteoblast support cells (Shevde *et al.,* 2000). This latter effect of estrogen may be owing to downregulation of RANKL-induced JNK activity in osteoclast progenitors (Srivastava *et al.,* 2001).

Estrogen inhibits the expression/secretion of matrix-degrading agents by isolated osteoclasts, including acid and the lysosomal enzymes cathepsin B, D, K, and L, and lysozyme (Kremer *et al.,* 1995; Mano *et al.,* 1996). For a review, see Oursler (1998). Similar to the studies on osteoblasts, the effects of estrogen on isolated avian osteoclasts *in vitro* appear to be determined by the level of ERα (Pederson *et al.,* 1997). Furthermore, the antiresorptive effects of estrogen on osteoclasts may, in part, be mediated by reducing the responsiveness of osteoclasts to resorption-stimulatory cytokines through the modulation of cytokine receptor levels and/or postreceptor signaling. For example, the IL-1 pathway is a stimulator of bone resorption. In isolated human osteoclasts, estrogen directly reduces mRNA expression of the signaling type I IL-1 receptor while simultaneously increasing levels of the decoy type II IL-1 receptor and release of soluble IL-1RII (Sunyer *et al.,* 1999).

Nongenomic Effects of Estrogen on Osteoblasts and Osteoclasts

The cascade model explains many apparent nongenomic actions of steroids that are, in fact, genomic processes. However, there is a growing body of evidence that steroids also influence the cell surface by nongenomic effects, which involve responses to steroids that are too rapid to be explained by genomic processes (Moss *et al.,* 1997; Revelli *et al.,* 1998). For instance, a possible cardioprotective effect of estrogen has been shown to occur through the induction of endothelial nitric oxide synthase in human vascular endothelial cells via a ligand-dependent interaction between ERα and phosphatidylinositol-3-OH kinase (Simoncini *et al.,* 2000). In osteoblasts, treatment with estrogen has been shown to cause a rapid (within seconds) increase in intracellular calcium ion concentration owing to influx across the plasma membrane and release from intracellular stores (Lieberherr *et al.,* 1993). Additionally, estrogen stimulates the hydrolysis of phosphatidylinositol phospholipids with the generation of diacylglycerol and inositol 1,4,5-trisphosphate, which in turn activate other second messenger pathways. In female rat osteoblasts, this effect of estrogen is mediated by the activation of phospholipase C-β2 via a pertussin toxin-sensitive G protein β subunits, further supporting the existence of a nonclassical membrane ER (Le Mellay *et al.,* 1999). Activation of MAP kinases and increases in cAMP and cGMP has been reported in osteosarcoma cells (Endoh *et al.,* 1997).

Several nongenomic effects of estrogen in osteoclasts have been reported. Treatment of isolated chick osteoclasts with estrogen inhibited the basal and PTH-stimulated production of acid within 15 minutes (Gay *et al.,* 1993). This effect appears to be mediated at the plasma membrane because membrane-impermeable conjugates of estrogen produced the same response (Brubaker and Gay, 1994). Estrogen treatment of avian osteoclasts is also associated with rapid and transient changes in cell shape and level of phosphotyrosine proteins at the plasma membrane (Brubaker and Gay, 1999). One of the phosphorylated proteins has been identified as pp60src, a tyrosine kinase required for the bone resorptive function of osteoclasts. Treatment with estrogen affects the degree of phosphorylation, and hence activity, of *src* as well as its subcellular distribution (Pascoe and Oursler, 2001). However, translocation of the *src* protein both to (Brubaker and Gay, 1999) and away (Pascoe and Oursler, 2001) from the cell surface has been reported. Active *src* kinase phosphorylates many substrates, including ras and the MAP kinases, which are stimulated via a nongenomic pathway in estrogen-treated MCF-7 breast cancer cells and rat osteosarcoma cells (Migliaccio *et al.,* 1996; Endoh *et al.,* 1997). Interestingly, constitutive activation of *src* decreases lysosomal enzyme secretion similar to treatment with estrogen, further implicating *src* as an intermediate in the action of estrogen in osteoclasts (Pascoe and Oursler, 2001). Finally, specific cell surface binding sites for estrogen have been reported in chick osteoclasts and FLG 29.1 human preosteoclastic cells in which treatment with estrogen affected intracellular calcium ion concentrations and pH within seconds to minutes (Brubaker and Gay, 1994; Fiorelli *et al.,* 1996).

The nongenomic effects of estrogen have been attributed to classical ER residing in cell membranes as well as to nonclassical receptors (de Wilde *et al.,* 2006; Heberden *et al.,* 2006). In the latter case, estrogen can interact with a variety of proteins. For example, estrogen activates signal transducer and activator of transcription-1 (STAT-1) in human fetal osteoblasts not having classical ER by a mechanism dependent on *src* kinase activity (Kennedy *et al.,* 2005). Also, estrogen can be metabolized to metabolites that act through alternative pathways. In some cases these involve receptors for other classes of sex steroids.

For example, the prodrug tibolone is metabolized in a tissue-specific manner to metabolites that interact with ER, androgen receptor, and PR (Kloosterboer, 2004). Physiologically, testosterone is metabolized in a tissue-specific manner to estrogen and dihydrotestosterone, metabolites that interact with ER and androgen receptor, respectively. Additionally, estrogen is metabolized to 2-methoxyestradiol (2ME) by two sequential enzymatic reactions, hydroxylation of the 2 position on the A ring followed by methylation of the 2-position, which leads to loss of binding of the molecule to ER but confers novel activity. 2ME activates non-ER-mediated cell-specific signaling pathways. Although having no detected effects on primary osteoblasts, 2ME induced interferon gene expression and apoptosis in cultured osteosarcoma cells (Maran *et al.,* 2002). Additionally, double-stranded RNA-dependent protein kinase is involved in 2ME-mediated cell death of osteosarcoma cells (Shogren *et al.,* 2007). Importantly, these effects were not mimicked by estrogen or inhibited by the antiestrogen ICI 182,780. *In vivo*, 2ME slows bone loss in ovariectomized rats (Sibonga *et al.,* 2003). In cell culture, 2ME inhibits differentiation and is cytotoxic to osteoclasts. The 2ME-mediated decrease in osteoclast survival was partially inhibited by anti-lymphotoxinβ antibodies, suggesting that 2-ME-dependent effects involve lymphotoxinβ (Maran *et al.,* 2006). Although the biological significance of endogenously produced 2ME remains to be determined, the anti-tumor, anti-angiogenic, and anti-osteoclastic actions of this estrogen metabolite are under investigation for its therapeutic potential for treatment of primary cancer and tumor metastasis to bone (Cicek *et al.,* 2007).

A nongenomic mechanism involving the *src* tyrosine kinase and MAP kinase signaling pathway has been reported to mediate the anti-apoptotic effects of estrogen on primary and immortalized osteoblastic and osteocytic cells (Kousteni *et al.,* 2001). Intriguingly, the anti-apoptotic effect of both estrogen and the androgen dihydroxytestosterone were mediated equivalently via both ER receptors or by the androgen receptor (AR). Furthermore, only the ligand-binding domain of the receptor protein appeared to be required and the anti-apoptotic function was dissociated from the receptors' transcriptional activity (Kousteni *et al.,* 2001). One possible interpretation of these observations is that ER and/or AR proteins localized at the plasma membrane exhibit unique properties and perform distinct functions from that of the nuclear localized receptor. A compound, 4-estren-3alpha,17beta-diol (estren) was reported to selectively activate the nongenomic pathway and prevent bone loss in mice (Kousteni *et al.,* 2002). However, subsequent studies have shown that estren activates ER-mediated genomic pathways and also acts through androgen receptors (Krishnan *et al.,* 2005; Windahl *et al.,* 2006). Many of the reported tissue selective effects of estren, whereby the compound is more active on bone than in the uterus, are consistent with the well-established actions of weak estrogens (Hewitt *et al.,* 2006). Furthermore, osteoblasts produce the potent androgen 19-nortestosterone from estren by way of a 3α-hydroxysteroid dehydrogenase-like activity (Centrella *et al.,* 2004).

In summary, the response of the target cell to estrogen may include both genomic and nongenomic effects, although the physiological importance of the nongenomic effects is still unclear. The putative membrane receptors for steroid hormones remain unknown and only a few non-ER alternative targets for estrogen have been identified.

Effects of SERMs, Estrogen Metabolites, and Phytoestrogens

SERMs

Despite the success of hormone replacement therapy in the treatment of postmenopausal osteoporosis, prolonged treatment with estrogen, even when supplemented with a progestin, is associated with an increased risk of heart disease, and breast and uterine cancer. Consequently, there has been a tremendous effort to develop synthetic tissue-specific, partial estrogen agonists that possess the desirable estrogen agonist properties in bone without the undesirable growth-promoting effects in reproductive tissue. The benzothiophene derivative raloxifene (LY139481 HC1) largely satisfies these criteria in both laboratory animals and postmenopausal women.

Although raloxifene binds with similar affinity to ERα and ERβ (Kuiper *et al.,* 1998) the compound induces distinctly different conformational changes in ERα (Brzozowski *et al.,* 1997) and ERβ (Paige *et al.,* 1999) when it binds to the ligand-binding domain. The fact that the conformational differences affect the coregulatory factors recruited by each receptor provides a molecular explanation for the divergent effects of estrogen and raloxifene on gene transcription from various estrogen-inducible promoters (e.g., AP-1 sites) depending on which ER isoform is present (Paech *et al.,* 1997; Watanabe *et al.,* 1997). The tissue-selective responses to raloxifene and other partial estrogen agonists may be explained by a combination of the relative level of ERα to ERβ, the repertoire of coregulators present in the cells (described earlier) and the type of DNA response element present in the promoter.

In the ovariectomized rat model of postmenopausal osteoporosis, raloxifene prevented bone loss from sites of both cancellous and cortical bone and reduced serum cholesterol, but did not stimulate uterine hyperplasia (Black *et al.*, 1994; Turner, Sato *et al.*, 1994). Similar to estrogen, raloxifene prevented the increases in longitudinal and radial bone growth as well as cancellous bone resorption induced by ovariectomy (Evans *et al.,* 1994). In adult rats with established osteopenia, raloxifene prevented additional bone loss but, as with estrogen, was unable to replace lost bone (Evans *et al.,* 1996). The prevention of cancellous bone loss by raloxifene occurred by a mechanism mimicking the

anti-resorptive action of estrogen in which osteoclast numbers and eroded trabecular perimeters were reduced.

Analogs of raloxifene that are more potent antagonists in the uterus prevented ovariectomy-induced bone loss when administered to rats immediately following ovariectomy, as well as blocked continued bone loss when administered to osteopenic animals (Li *et al.,* 1998). Raloxifene only partially inhibited bone loss during high turnover phase after ovariectomy, but completely prevented bone loss during the subsequent slower phase of post-ovariectomy bone loss. In clinical trials of postmenopausal women, raloxifene, comparable to the effects of conjugated estrogens, reduced markers of bone resorption and formation and increased bone mineral density relative to patients receiving the placebo (Draper *et al.,* 1996; Delmas *et al.,* 1997). Additionally, raloxifene therapy reduced the serum concentrations of total and low-density lipoprotein (LDL) cholesterol but, unlike estrogen, did not stimulate the endometrium.

Although the *in vivo* effects of raloxifene have been studied extensively and in bone appear to closely parallel those of estrogen, comparatively little is known about the cellular and molecular effects of SERMs on bone cells *in vitro* (Bryant *et al.,* 1999). In osteoblast lineage cells, raloxifene stimulates creatine kinase activity (Fournier *et al.,* 1996) total protein, and type I collagen α-chain synthesis (Qu *et al.,* 1999): and the expression of TGFβ3 mRNA (Yang *et al.,* 1996). Similar changes have been reported with estrogen. Lin *et al.* report that raloxifene increased bone nodule formation in cultures of SaOS-2 osteosarcoma cells and blunted the inhibitory effect of parathyroid hormone on nodule formation and alkaline phosphatase activity (Lin *et al.,* 2004). Also, raloxifene produced a decrease in mRNA IL-6 expression in cultured human osteoblasts (Mendez-Davila *et al.,* 2004).

To date, the few known actions of raloxifene on osteoclast lineage cells are very much analogous to those of estrogen. Treatment of ovariectomized mice with raloxifene decreased the number of bone marrow-derived preosteoclasts (GM-CFU) (Liu *et al.,* 2000). This effect of raloxifene may be direct, given that specific high-affinity-binding sites for raloxifene have been demonstrated in a human leukemic preosteoclastic cell line (Fiorelli *et al.,* 1997). Furthermore, raloxifene suppressed osteoclastic differentiation induced by a combination of M-CSF and OPGL in the osteoclastogenic mouse monocytic cell line RAW264.7 (Shevde *et al.,* 2000). Finally, raloxifene inhibited osteoclast differentiation in human bone marrow mononuclear cultures (Ramalho *et al.,* 2002).

Estrogen Metabolites

The importance of steroid hormone metabolism in conferring tissue selectivity is well established but often underappreciated. Steroid hormone activity can be increased or decreased in tissues by enzymatic activity. Circulating testosterone acts largely as a prohormone that is a substrate for aromatase, which converts it to estrogen, and 5α-reductase, which converts it to the potent androgen dihydrotestosterone. Although aromatase is primarily located in the gonads, the enzyme is present in numerous cells and, in some cells there is sufficient aromatase activity to increase intracellular levels of estrogen to values that greatly exceed circulating hormone levels (Brueggemeier *et al.,* 2007; Yamaguchi, 2007). In the bone environment, osteoblasts and adipocytes have significant levels of aromatase activity and are thus capable of converting androgens to estrogens (Belanger *et al.,* 2002; Enjuanes *et al.,* 2005; Pino *et al.,* 2006).

Steroid sulfotransferase and sulfatase can act on sex steroids to produce inactive sulfated derivatives or to activate the sulfated derivatives, respectively. There is very little sulfotransferase activity in bone compared to uterus. This is a likely explanation for the observed tissue discrimination of the weak estrogen 16α-hydroxyestrone. Subcutaneous implantation of a continuous release pellet containing the steroid prevented bone loss in the ovariectomized rat but had minimal uterotrophic activity. In contrast, subcutaneous injection of 16α-hydroxyestrone resulted in a dose-dependent increase in uterine wet weight, presumably because the higher circulating levels owing to the rapid release of the estrogen exceeded the capacity of the uterine sulfotransferase to sulfate it. Whereas the reproductive tissues of mammals are highly sensitive to changes in the circulating levels of sex steroids that occur during the menstrual/estrus cycle, bone is much less responsive. From a physiological point of view, the absence of sulfotransferase in bone may confer increased sensitivity of the skeleton to low circulating levels of estrogen.

As mentioned earlier, tibolone is an example of a novel synthetic steroid that has tissue-selective estrogenic activity owing to differential metabolism (Fig. 4) into compounds with estrogenic, progestogenic, and androgenic activities. Tibolone has estrogenic activity on bone, vagina, and brain but not breast and the endometrium (Gallagher *et al.,* 1991; de Gooyer *et al.,* 2001; Kloosterboer, 2004; Reed *et al.,* 2004). Tibolone is rapidly metabolized to the 3α-hydroxy metabolite and the 3β-hydroxy metabolite, which bind to ER and have a half-life of ~7 hours. These putative estrogenic compounds are further metabolized to sulfated compounds; ~80% of circulating tibolone consists of 3α-and 3β-hydroxy mono- and disulfates. An additional metabolite (Δ^4 isomer) is produced, but is rapidly cleared from the circulation (Timmer and Huisman, 2002). The parent compound and Δ^4 isomer bind to PR and androgen receptors while the 3α-and 3β-hydroxy tibolone exclusively bind to ER with a preference for ERα over ERβ (de Gooyer *et al.,* 2003). The tissue selective actions of tibolone differ from SERMs (Ederveen and Kloosterboer, 1999). Although the mechanisms of action of SERMs are incompletely understood, it is clear that they bind to ER in all estrogen target tissues and behave as mixed estrogen agonists/antagonists (Evans *et al.*, 1994; Harris, Tan *et al.*, 1995; Gustafsson,

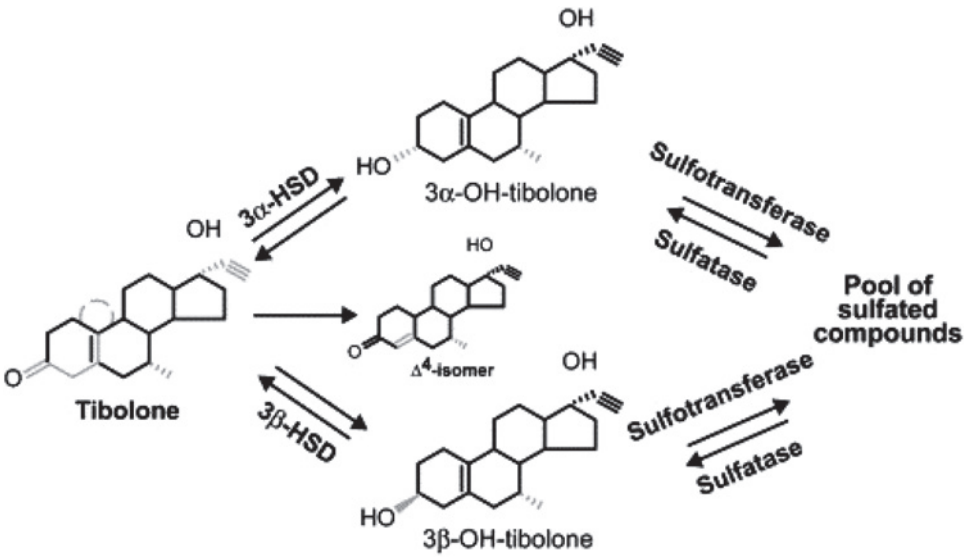

FIGURE 4 Tibolone is a prodrug that is metabolized to compounds that bind to ER, PR, and androgen receptors in a tissue selective manner. The tissue selective distribution of enzymes that metabolize estrogen plays an important role in the physiological actions of the hormone.

1998; Lonard and Smith, 2002). The relative level of agonism is tissue-specific and depends upon several factors, including the recruitment of tissue-specific coactivators and corepressors (Smith *et al.*, 1997). In contrast, the tissue selective action of tibolone depends upon its differential metabolism and enzyme regulation in individual estrogen target tissues (Yoshitake *et al.,* 1999; Kloosterboer, 2004; Reed *et al.,* 2004).

As previously mentioned, environmental or dietary compounds that bind to ER can act as endocrine disruptors. Similarly, chemicals that modify estrogen metabolism can influence the skeleton. Moderate alcohol consumption, for example, is thought to increase the levels of estrogen whereas abusive alcohol consumption patterns may reduce estrogen levels. Increased estrogen may be, in part, responsible for the protective effect of moderate alcohol consumption on bone mass in postmenopausal women, whereas the reduced estrogen levels may contribute to alcohol-induced bone loss in heavy drinkers.

Even though postmenopausal women lose bone at different rates, the level of serum estrogen does not differ greatly among them (Riis *et al.,* 1995). However, serum levels of adrenal androgens and the conversion of these androgens and estradiol to other estrogen metabolites do differ among individuals and ethnic groups and may play a role in maintaining bone mass in certain individuals.

The predominant postmenopausal estrogen, estrone (E_1): is primarily metabolized through two pathways (Fishman *et al.,* 1984; Martucci and Fishman, 1993). The catalytic conversions of E_1 by 2-hydroxylase or 16α-hydroxylase enzymes results in the formation of either 2-hydroxyestrone (2-OHE_1) or 16α-hydroxyestrone (16α-OHE_1) respectively. The 16α-OHE_1 has been shown to bind covalently and noncovalently to ER, but with reduced affinity compared to estradiol. However, its lack of binding to the serum-binding globulin makes it more available for estrogen target tissues (Fishman and Martucci, 1980; Swaneck and Fishman, 1988). In addition, 16α-OHE_1 serves as an estrogen agonist in reproductive tissues (Fishman and Martucci, 1980; Schneider *et al.,* 1984). In contrast, 2-OHE_1 binds very weakly (even less so than 16α-OHE_1) to the ER (Fishman and Martucci, 1980) and has been shown to have no estrogenic activity and, in some cases, to act as an estrogen antagonist (Schneider *et al.,* 1984; Vandewalle and Lefebvre, 1989).

Lim *et al.* (1997) reported that urinary levels of 16α-OHE_1 were lower and 2-OHE_1 levels were higher in postmenopausal osteopenic than in nonosteopenic individuals. Furthermore, the 16α-OHE_1/2-OHE_1 ratio was correlated positively with bone mineral density. African American women, who are at lower risk for developing osteoporosis, reportedly have increased 16α-hydroxylation and therefore have a higher 16α-OHE_1/2-OHE_1 ratio compared to Caucasian women (Coker *et al.,* 1997). When ovariectomized rats were treated with 16α-OHE_1, cancellous bone turnover associated with ovariectomy was prevented (Westerlind *et al.,* 1998). However, 2-OHE_1 displayed no estrogenic or antiestrogenic activities on cancellous bone turnover in ovariectomized rats. In agreement with these findings, 16α-OHE_1 but not 2-OHE_1, mimicked the effects of estradiol on the *in vitro* regulation of alkaline phosphatase activity and osteocalcin secretion in an estrogen-responsive osteoblast cell line stably expressing ERα (Robinson *et al.,* 2000).

Another naturally occurring estrogen metabolite is 2ME, produced primarily by the liver. This metabolite

has very low affinity for ER. As a consequence, its physiological effects are thought not to be mediated through the ER pathway (the nonclassical pathways of action of 2ME were discussed earlier). 2ME has antitumorigenic activity and may act as a physiological tumor suppressor (Zhu and Conney, 1998). Tumor cell proliferation is inhibited by molecular pathways that are specific to the lineage of tumor cell origin, and angiogenesis is reduced via increased senescence and apoptosis of endothelial cells by 2ME (Fotsis *et al.,* 1994). Administration of high concentrations of 2ME to rapidly growing rats inhibits longitudinal bone growth but has no effect on either radial bone growth or cancellous bone turnover (Turner and Evans, 2000). Thus, excessive 2ME reduces proliferation and/or stimulates apoptosis of rapidly dividing growth plate chondrocytes.

Phytoestrogens

Phytoestrogens are plant compounds that bind to and activate estrogen receptors. There are three main classes of phytoestrogens: isoflavones, lignans, and coumestans. A single dietary source often contains more than one class of phytoestrogens. Using a competition-binding assay, Kuiper *et al.* (1998) found that although the binding affinity of phytoestrogens for either ERα or ERβ was lower than that of estradiol, the relative binding affinity of phytoestrogens for ERβ was significantly greater than that for ERα. In contrast to phytoestrogens, the relative binding affinity of the SERMs, tamoxifen, and raloxifene, was greater for ERα than for ERβ. Using a reporter gene construct, the phytoestrogens tested activated both ER subtypes, although the overall potency of these compounds was approximately 1/100th to 1/1000th that of estradiol (Kuiper *et al.,* 1998).

Soy is especially rich in phytoestrogens and has been intensively studied. The phytoestrogens in soy consist primarily of isoflavones, predominantly genistein and diadzein. However, not all of the skeletal effects of soy are attributable to isoflavones. For example, soy protein is reported to be less calciuretic than casein. Soy protein would therefore be expected to improve calcium retention, which in turn has the potential to reduce parathyroid hormone levels and bone resorption rates (Breslau *et al.,* 1988; Arjmandi *et al.,* 1998).

Numerous studies have addressed the role of soy in preserving bone mass and ameliorating the effects of postmenopausal and age-related bone loss (Brynin, 2002; Balk *et al.,* 2005). Constituents of soy have been reported as having beneficial effects on the skeleton in postmenopausal women (Potter *et al.,* 1998). However, conclusions regarding the effects of soy as a food staple, or its specific components, on the musculoskeletal system are mixed with some studies showing positive effects, while others showing either no effects or detrimental effects. Importantly, there have been no placebo-controlled studies demonstrating the efficacy of soy in reducing bone fractures (Potter *et al.,* 1998). In lieu of well-controlled clinical studies, the most convincing evidence for soy effects on bone comes from laboratory animal studies. Several studies have examined the effects of phytoestrogens on bone loss models with generally positive findings. Both genistein in mice and coumestrol in rats reportedly prevented ovariectomy-induced osteopenia by reducing bone resorption and osteoclast number in a manner at least superficially similar to estradiol (Draper *et al.,* 1997; Ishimi *et al.,* 1999). Other studies have reported that the reduction in bone loss following ovariectomy in rats with genistein and soy protein was associated with unchanged indices of bone resorption but increased bone formation (Arjmandi *et al.,* 1998; Fanti *et al.,* 1998; Harrison *et al.,* 1998). These latter data suggest that there may be important differences in bone effects of phytoestrogens and estrogen. Animal studies to date, however, have serious limitations that contraindicate extrapolation of results based on animal models to postmenopausal and aging humans. The animal studies were largely performed in growing rodents, which are poor models for postmenopausal bone loss (Iwaniec and Turner, 2008). Other major limitations of prior research in evaluating dietary soy include one or more of the following: (1) administration of concentrated extracts and purified phytoestrogens; (2) delivery of active agents by injection rather than orally; (3) short treatment duration; (4) inadequacy of the skeletal endpoints measured; and (5) no examination of gender differences. A well-designed, 3-year-long, longitudinal study in ovariectomized monkeys failed to detect a beneficial effect of soy protein isolate containing phytoestrogens in protecting against bone loss resulting from estrogen deficiency (Register *et al.,* 2003). Thus, studies to date do not provide compelling evidence for beneficial effects of phytoestrogens on musculoskeletal health across the life span.

Many of the beneficial effects of a soy diet are believed to be mediated through phytoestrogens acting as partial estrogen agonists (Heaney *et al.,* 2005; Weaver and Cheong, 2005). Whereas estrogen receptor agonists could have beneficial effects on bone during aging, they could also have detrimental effects during growth and maturation. As discussed earlier, the sexual dimorphism of human and rat skeletons (whereby males have larger bone and muscle mass than females) is, in part, owing to the inhibitory effect of estrogen on growth (Iwaniec and Turner, 2008). Exposure of humans and rats during rapid skeletal growth to estrogens leads to premature epiphyseal closure (resulting in shorter bones) increased cancellous bone density, and a reduction in cortical bone owing to decreased periosteal growth. Muscle mass is also reduced. If the phytoestrogens act on the skeleton in the same manner as estradiol, consumption by adolescents could result in reduced peak bone and muscle mass, predisposing the skeleton to osteoporotic fractures later in life (Cutler, 1997). On the other hand, the biological effects of phytoestrogens are not well characterized. Circulating and tissue levels of phytoestrogens

are in competition with much more potent endogenous estrogens for ER and may have greater effects in the aged because of gender-specific declines in bioavailable estrogens and androgens.

The bioavailability of dietary phytoestrogens, which is influenced by their absorption, systemic metabolism, and tissue level metabolism, ultimately determines the physiological effects of plant-derived estrogens. These variables have not been explored in detail with soy phytoestrogens. However, studies performed using synthetic and endogenous estrogens reveal multiple levels of complexity. As described earlier, the synthetic steroid tibolone functions as a prodrug. It can behave as an estrogen, androgen, or progestin, or have no effect on potential target cells, depending upon tissue level metabolism (Eden, 2005). A similar role for local metabolism has been demonstrated for endogenous estrogens (Belanger *et al.,* 2002; Pino *et al.,* 2006; Brueggemeier *et al.,* 2007; Yamaguchi, 2007). These examples demonstrate why it is critically important to assess the whole-life musculoskeletal response *in vivo* to a phytoestrogens-rich diet using models that accurately mimic the delivery of these agents to humans.

Phytoestrogens have the potential to act as endocrine disrupters during reproductive tract development in males and females and could interfere with reproduction in adult females (Humfrey, 1998; North and Golding, 2000). High concentrations of dietary extracts of phytoestrogens have been associated with uterine hyperplasia in humans and rats and with breast cancer in men (Dimitrakakis *et al.,* 2004; Nakai *et al.,* 2005). For the reasons discussed previously, a food-based diet may avoid the detrimental effects associated with high concentrations of purified bioactive constituents. However, the issue of detrimental side effects on the musculoskeletal and reproductive systems needs to be thoroughly addressed. Because soy proteins have not been adequately shown to lessen vasomotor symptoms of menopause, slow postmenopausal bone loss, or prevent cancer, and because adverse effects have not been adequately evaluated, the American Heart Association Nutrition Committee has concluded that the use of isoflavin supplements in food or pills to reduce cardiovascular risk is not recommended (Sacks *et al.,* 2006).

PROGESTERONE

Progesterone is often given in conjunction with estrogen during hormone replacement therapy of postmenopausal women to minimize undesirable effects of estrogen on reproductive tissues. However, the effects of progesterone on bone physiology have not been examined as extensively as those for estrogen (for a review, see Prior *et al.,* 1990). As discussed earlier, progesterone exerts its effects on cells via mechanisms analogous to estrogen by binding and activating the PR, a member of the steroid nuclear receptor transcription factor family, which subsequently binds to the regulatory regions of target genes, classically at progesterone response elements (PREs) to modulate gene transcription. Nongenomic effects of progesterone in osteoblasts have also been documented (Le Mellay *et al.,* 1999; Grosse *et al.,* 2000).

Progesterone Receptors in Bone Cells

In humans, rats, and rabbits, PR exists as two isoforms, A and B (see Fig. 5), transcribed from the same gene using different promoters (Kastner *et al.,* 1990). Both PR promoters are estrogen inducible. The PR_B isoform is generally a stronger activator of gene transcription than PR_A, and in certain conditions, PR_A can reduce the transactivation

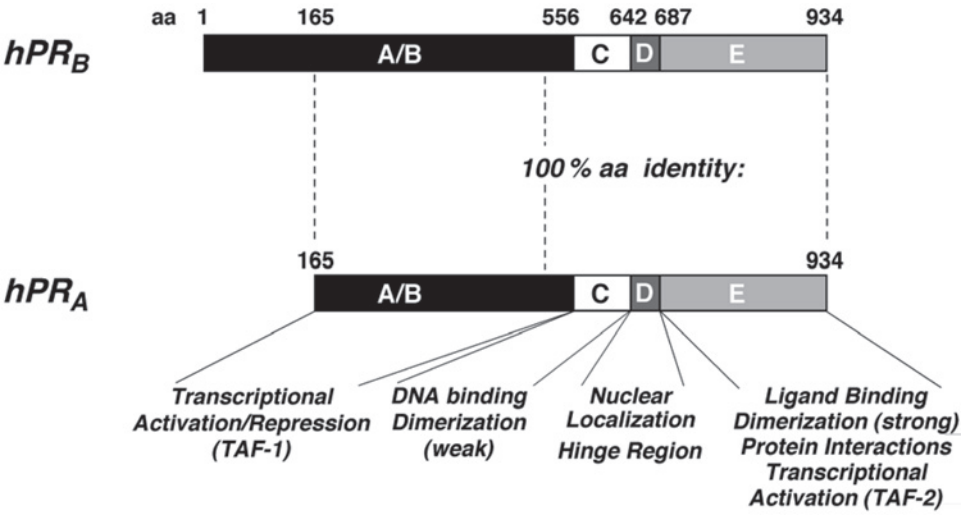

FIGURE 5 Model of human progesterone receptor isoforms with defined domain functions and homologies.

stimulated by PR_B and other steroid receptors, including the ER (Kraus *et al.,* 1995; Giangrande and McDonnell, 1999). Because of these important functional distinctions between the two PR isoforms, it is of interest to determine their relative expression level in target cells. The presence of PR mRNA and protein has been demonstrated in primary cultures of human osteoblasts (Eriksen *et al.,* 1988) and in several osteoblast and osteosarcoma cell lines (HOS TE85, MG-63, and SaOS-2) (Wei *et al.,* 1993; MacNamara *et al.,* 1995; MacNamara *et al.,* 1998). In some cases estrogen increases the level of PR expression (Eriksen *et al*., 1988; Harris, Enger *et al*., 1995; MacNamara *et al*., 1998). Consequently, some of the effects on bone metabolism that have been attributed to estrogen may in fact be mediated by progesterone.

Effects of Progesterone on the Skeleton

Progesterone reportedly affects osteoblast and osteoblast precursor cell proliferation and differentiated functions, but some data are conflicting. Canalis and Raisz (1978) reported that progesterone inhibited proliferation and collagen synthesis by fetal rat calvarial cells. In contrast, Slootweg *et al.* (1992) found that progesterone had no effect on proliferation of SaOS-2 cells but did stimulate cell growth synergistically with estrogen. In contrast, progesterone stimulated the proliferation of TE85 osteosarcoma cells and normal human osteoblasts (Tremollieres *et al.,* 1992). Other studies have also shown stimulatory effects of progesterone on proliferation of normal and transformed osteoblastic cells (Scheven *et al.,* 1992; Manzi *et al.,* 1994; Verhaar *et al.,* 1994). Progesterone increased the number of alkaline phosphatase positive colonies – and hence osteogenic development– of a subclass of osteoprogenitor cells isolated from rat vertebral bone explants (Ishida and Heersche, 1997; Ishida and Heersche, 1999). Additionally, progesterone treatment of primary human osteoblast and TE85 osteosarcoma cells increased IGF-II secretion (Tremollieres *et al.,* 1992) but inhibited IL-6 secretion in primary human osteoblasts and mouse bone marrow stromal cells (Girasole *et al.,* 1992). Progesterone may regulate components of the IGF system in human osteosarcoma cells by stimulating expression of IGFBP-5 by a transcription-dependent mechanism (Boonyaratanakornkit *et al.,* 1999). IGFBP-5 is unique among the various IGFBPs becasue it enhances the mitogenic activity of both IGF-I and IGF-II in osteoblasts *in vitro*. Taken together, these studies suggest that progesterone is capable of direct regulation of osteoblast metabolism.

A number of experimental animal studies have reported significant effects of progesterone on bone metabolism; progesterone stimulated mineralization of newly induced bone in rats (Burnett and Reddi, 1983) and increased cortical bone formation in spayed Beagle dams (Snow and Anderson, 1985). Moreover, progesterone prevented ovariectomy-induced bone loss in rats by reducing resorption and increasing bone formation (Barengolts *et al.,* 1990; Barengolts *et al.,* 1996). In addition, high circulating levels of progesterone in pseudopregnant rats were associated with preservation of bone mass despite estradiol levels comparable to ovariectomized rats (Bowman and Miller, 1996). Progesterone was also reported to have a significant stimulatory effect on bone formation and to act synergistically with estrogen to inhibit bone resorption in ovariectomized growing rats (Schmidt *et al.,* 2000) However, these generally positive results contrast with studies that failed to detect an action of progesterone on cancellous bone with or without co-administration of estradiol (Kalu *et al.,* 1991; Fujimaki *et al.,* 1995). Also, the PR antagonist RU486 was reported to reduce bone loss in ovariectomized rats (Barengolts *et al.,* 1995). This unexpected finding contrasts with the bone loss induced by estrogen antagonists. The effects of RU486 on bone may have been mediated by the drug's antiglucocorticoid effect. Long-term mifepristone (RU486) therapy was used to treat a patient with Cushing's syndrome and morbid osteoporosis. Although inducing benign endometrial hyperplasia, the treatment prevented further bone loss (Newfield *et al.,* 2001).

Skeletal Phenotype of Mice with Disruption of PR Genes

Mice have been generated with a homozygous mutation of the PR locus in which expression of both A and B isoforms of PR is prevented. The PR_B has been shown to be the dominant player in gene regulation in progesterone target cells (Giangrande and McDonnell, 1999). PR knockout mice (i.e., $PR_{A/B}$ knockouts) exhibit multiple reproductive abnormalities and homozygous females are infertile (Lydon *et al.,* 1995). Female PR knockout mice have been analyzed histomorphometrically for possible skeletal defects. Although preliminary studies suggested that PR knockout animals had peak cortical and cancellous bone mineral densities that were not significantly different from age-matched wild-type animals (Bain *et al.,* 1997) subtle alterations were evident at earlier ages. Specifically, young postpubertal PR knockout mice exhibited increased cortical bone thickness with no changes in cancellous bone (Rickard *et al.,* 1999). This initial finding has been verified using high-resolution μCT (Rickard *et al.*, 2008). Longitudinal bone growth was unaffected at all ages examined. These findings suggest that progesterone may be involved in the early growth and sexual dimorphism of the female skeleton. However, a more detailed analysis of the skeleton of PR knockout mice suggests that they are resistant to early onset age-related cancellous bone loss (Rickard *et al.,* 2008). If confirmed, this finding would suggest that PR signaling plays a role in mineral homeostasis during pregnancy and lactation, periods where the

circulating levels of progesterone are elevated. Studies on PR_A knockout female mice showed that progesterone had a larger effect in reproductive tissue compared to wild-type mice (Mulac-Jericevic *et al.,* 2000). This suggests that PR_A may play a dominant-negative role in the actions of PR_B. Future studies should include examining the skeleton of PR_A knockout female mice.

Humans

Despite some ongoing controversy (Waller *et al.,* 1996; De Souza *et al.,* 1997) the majority of evidence from human studies suggest a role for progesterone in bone metabolism. For example, women with ovulatory disturbances related to luteal phase defects have been shown to lose more bone mass over one year compared to women with normal menstrual cycles (Prior *et al.,* 1990) and to have increased bone mass in response to progesterone therapy during the luteal phase (Prior *et al.,* 1994). Several studies have found that progesterone treatment of postmenopausal women protects against bone loss, particularly at cortical sites (Gallagher *et al.,* 1991; McNeeley *et al.,* 1991; Grey *et al.,* 1996). Progesterone replacement therapy reduces postmenopausal bone loss in part by suppressing bone resorption (Mandel *et al.,* 1982; Lobo *et al.,* 1984). Although some studies have shown that treatment of postmenopausal women with either progesterone alone or combination therapy of estrogen with progesterone is as effective as estrogen alone in the prevention of bone loss (McNeeley *et al.,* 1991; Grey *et al.,* 1996) other trials have demonstrated a lesser effect of progesterone (PEPI, 1996; Prior *et al.,* 1997).

CONCLUSIONS

Numerous major advances have been made in recent years in the area of estrogen action on bone. It is now evident that estrogen affects bone at all levels of cellular regulation: progenitor cell proliferation, differentiation, activity, and life span. Consequently, estrogen regulation of bone growth and remodeling at the tissue level is recognized as extremely complex. How estrogen elicits its effects within the cell, as well as the range of possible responses, is also more diverse than previously believed. The latter is because, in part, of the identification of the second ER isoform, ERβ, exhibiting an activity and expression distinct from that of ERα. In addition, the presence of tissue specific metabolism, steroid receptor coregulators, and nongenomic pathways of estrogen regulation adds to the diverse responses. The differential expression and activities of the ER isoforms and the receptor coregulators provide explanations for the cell- and tissue-selective actions of SERMs.

Answers to several important questions remain incomplete. For example, what is the physiological significance of nongenomic signaling by estrogens? Do the two ER isoforms regulate the same target genes? Are the two isoforms coexpressed in osteoblasts and osteoclasts? Does the relative ratio of ERα to ERβ change during differentiation and, if so, is estrogen responsiveness affected? Is estrogen responsiveness in osteoblasts and osteoclasts also determined by alterations in the relative levels of the steroid receptor coactivators and corepressors? Further analysis of the various ER mutant mice should provide answers as to whether the effects of estrogen at particular skeletal sites (such as trabecular surfaces, periosteum, and growth plate) are mediated primarily by one or both ER isoforms. In addition, the generation of bone cell lines from each of the various ER-deficient genotypes should prove valuable in addressing many of the questions just posed.

Advances in our understanding of the actions and importance of progesterone in bone growth and remodeling have, unfortunately, been more modest. The availability of PR-deficient mice will make it possible to examine the interaction between estrogen and progesterone in bone, including the potential involvement of progesterone and PR as regulators of certain skeletal effects of estrogen. Lastly, and in analogy to studies with ERs, investigation into possible exclusive roles of the A and B isoforms of PR may reveal heretofore unrecognized effects of progesterone on bone.

Chapter 41

The Pharmacology of Selective Estrogen Receptor Modulators

Henry U. Bryant*
Musculoskeletal Research, Lilly Research Laboratories, Eli Lilly and Company, d/c 0424, Indianapolis, IN 46285

The widespread distribution of estrogen receptors (ERs), and their critical role in normal physiology and various pathophysiological states when estrogen levels decline indicate the importance of ER-targeted therapies for use in postmenopausal women. Controversy and concern over the use of estrogen replacement therapies creates the opportunity to design molecules to selectively modulate estrogen action in those tissues where estrogen agonism is the desired goal while simultaneously producing an estrogen-neutral or-antagonistic effect in tissues where estrogen-related side effects are a concern. Selective estrogen receptor modulators, or SERMs, are currently in clinical use for the treatment and prevention of osteoporosis (raloxifene), breast cancer prevention (tamoxifen and raloxifene) and treatment (tamoxifen and toremifene), and the induction of ovulation (clomiphene). To date, seven different SERMs have reached advanced clinical evaluation for postmenopausal osteoporosis with three molecules (droloxifene, idoxifene, and levormeloxifene) withdrawn for unfavorable risk/benefit profiles and three additional molecules (lasofoxifene, bazedoxifene, and arzoxifene) currently in phase 3 status or under regulatory review. Experience with these molecules reveals several key themes for chronic use of SERMs. (1) Each SERM generates a unique complex with the ER that influences cofactor recruitment in estrogen-target tissues responsible for the tissue-selective pharmacological profile, which translates to each SERM generating potentially an entirely unique overall safety and efficacy profile, indicating the need for thorough evaluation of each individual SERM across multiple tissue types for efficacy and safety determination. (2) Uterine safety historically has been the critical safety feature for chronic SERM use in osteoporosis therapy and careful assessment of the potential for uterine stimulation is a key element in the consideration of new molecules in this class. (3) The pharmacokinetic and distribution properties of SERMs offer an additional aspect influencing the magnitude of the overall biological response by either improving systemic bioavailability or altering uptake into important estrogen-responsive tissues.

INTRODUCTION

Research in the ER field has attracted considerable attention over the past 15 years with significant events ranging from very basic research discoveries, such as resolution of the liganded ER crystal structure and identification of a second ER form (ERβ), to important clinical observations regarding estrogen use in postmenopausal women from the Women's Health Initiative or WHI trial. Estrogen exhibits a "Jekyl and Hyde" therapeutic profile, as hormone replacement (estrogen + progestin) is associated with distinct benefits on the menopausal syndrome, including reductions in vasomotor symptoms and fracture incidence, as well as other benefits such as a reduction in colon cancer. However, these benefits are offset by significant increases in risk for coronary events (myocardial infarction and stroke) and breast and uterine cancer. In the early 1990s, research around the concept of SERMs—molecules that simultaneously agonized or antagonized estrogen action in different tissue types—offered a new way of looking at ER pharmacology and served to trigger the renewed interest in estrogen-related research in the mid-1990s.

Prior to the development of the "SERM-concept," ER ligands were generally thought of as falling into either the category of full agonists, partial agonists, or full antagonists across all tissue types (i.e., uterus, mammary, and bone). For example, steroidal hormones such as 17β-estradiol were known to behave as full agonists both *in vitro* and *in vivo* across multiple tissue types, whereas compounds such as fulvestrant (ICI-182,780) were known to be complete ER antagonists that bound tightly to the ER, but lacked intrinsic activity and, therefore, completely blocked the action of full

Principles of Bone Biology, 3rd Edition

ER agonists like 17β-estradiol. These "pharmacotypes" are depicted in Figure 1(A and B), respectively. Conversely, compounds such as tamoxifen were known to, in the presence of estrogen, block estrogen action in estrogen-responsive tissues (i.e., breast cancer cells) but, in the absence of estrogen, mimic estrogen in bone and uterus in estrogen-deficient animals and women, thus exhibiting a classical partial agonist profile (see Fig. 1C). Although this profile held some attractive features for use in ER-dependent breast cancer, the profile was prohibitive for chronic use in postmenopausal women for noncancer indications (like osteoporosis) where even the potentially less robust uterine stimulation induced by tamoxifen's partial agonist action produced untenable side effects that created a risk/benefit ratio that was unfavorable for use in diseases like osteoporosis (Kalu *et al.*, 1991). As a result, virtually no work was being done in the pharmaceutical industry developing novel ER ligands for osteoporosis, because the prevailing medical opinion at the time was that any molecule with sufficient estrogen agonism capable of producing a benefit in bone would also generate sufficient agonism (even if a partial agonist) in uterine tissue to create a risk that would unfavorably offset the bone benefit (Feldman *et al.*, 1989).

With the first preclinical and clinical descriptions of the unique profile of raloxifene in estrogen-deficient animals and postmenopausal women (Black *et al.*, 1994; Draper *et al.*, 1996), the concept of a SERM was born, radically shifting thought around use of ER-based ligands in postmenopausal women and opening the door for use in chronic diseases like osteoporosis. Accordingly, the initial goals of a SERM-based therapy for osteoporosis required the molecule to have estrogen-like efficacy on bone and concomitant fracture reduction without estrogen-like stimulatory effects on uterus or mammary tissue. As of the writing of this chapter, only four molecules with SERM-like profiles have achieved clinical use (Table I) and only one, raloxifene, has attained approval for use in the treatment and prevention of osteoporosis. However, other molecules have been evaluated clinically, or are currently under clinical evaluation, for postmenopausal osteoporosis and will be reviewed here as well as some other SERM applications that might benefit other diseases or disorders in postmenopausal women in the future.

SERM MECHANISM

The effects of SERMs on biological systems are predominately mediated by specific, high-affinity interactions with ERs that are primarily located in target cell nuclei (Nilsson *et al.*, 2001). Their nuclear hormonal action involves the complex interplay of a number of protein and genomic elements that allow SERMs to regulate gene transcription and subsequent protein production by the cell. Three key elements of the SERM mechanism are depicted in Figure 2, which include: (1) high-affinity interaction with the ER, (2) ER-ligand dimerization and the association with a tissue-specific set of coregulatory proteins, and (3) binding of the ER/adaptor protein complex to specific DNA response elements located in the promoter regions of nuclear target genes and ensuing regulation of gene transcription. Depending on the cellular

TABLE I SERMs Currently Approved for Human Use

SERM	Trade name	Approved indications	Daily dose
Clomiphene	Clomid®	Induction of ovulation	50–100 mg
Raloxifene	Evista®	• Osteoporosis prevention • Osteoporosis treatment • Breast cancer risk reduction in postmenopausal osteoporotic women and in high-risk postmenopausal women	60 mg
Tamoxifen	Nolvadex®	• Metastatic breast cancer treatment • Adjuvant breast cancer treatment • Ductal carcinoma *in situ* • Breast cancer risk reduction in high-risk women	20–40 mg
Toremifene*	Fareston®	Metastatic breast cancer treatment	60 mg

*Toremifene (Fareston®) is currently not approved in the United States, but is approved for metastatic breast cancer treatment in Europe.

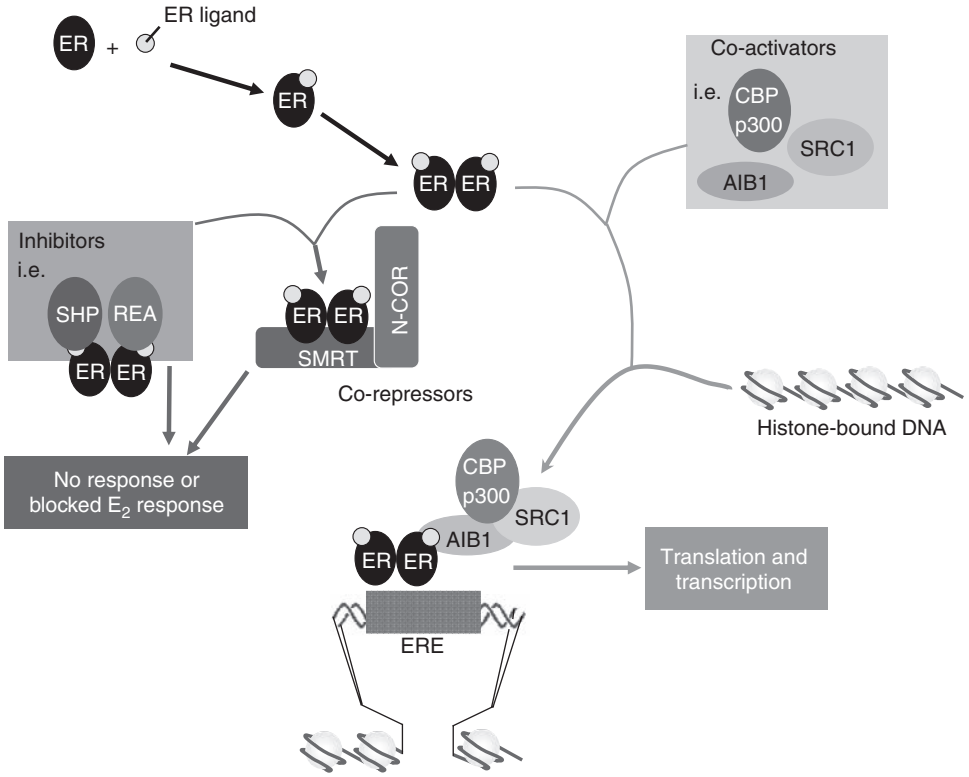

FIGURE 2 SERM mechanism of action.

and promoter context, the DNA-bound receptor can induce or inhibit the transcription of specific genes within the tissue.

The ability to specifically bind to the ER is perhaps the single most important feature of all molecules with a SERM profile. The affinities of several of the more extensively studied SERMs are provided in Table II. An important determinant of the ultimate pharmacological response is the shape of the ligand–ER complex, which is unique with each individual ligand (McDonnell *et al.*, 1995), with different SERMs leading to specific orientation of subunits of the ER (i.e., raloxifene; Brzozowski *et al.*, 1997). This conformation or shape of the ligand–ER complex

TABLE II Affinities of Various SERMs for Human Estrogen Receptor (ER)-α and ER-β

ER ligand	ERα(IC_{50})	ERβ(IC_{50})
17α-Estradiol	0.3–0.8*	0.9–2.5*
Tamoxifen	72–138	173–1204
4-Hydroxytamoxifen	0.22–0.98	1.5–2.46
Raloxifene	0.4–1.31	5.6–13.0
Fulvestrant (ICI-182,780)	0.8–1.0	1.12–3.6

*All values are in nM. As binding data often can vary from laboratory to laboratory, and various approaches can be taken to attaining binding affinities, ranges for ERα and ERβ obtained from representative references are presented (Sun et al., 1999; Brady et al., 2001; de Boer et al., 2004; He et al., 2005; Leblanc et al., 2007)).

then determines the subsequent protein–protein interactions that ensue. Herein lays the basis for the wide array of different pharmacological profiles produced by different SERMs, because the confirmation of the ER–SERM complex is distinct for each molecule (McDonnell *et al.*, 1995). It is important to recognize that a second form of the ER is known to exist, ERβ (Kuiper *et al.*, 1996). ERα and ERβ display unique patterns of tissue distribution typically with expression levels of one subtype dominating (Saunders *et al.*, 1997), although it should be noted that most tissues contain at least small amounts of both subtypes, and with the role of putative α:β-heterodimers unknown, it is possible that a low-expression subtype may be a key rate-limiting step in ultimate nuclear activity. To date, all of the SERMs that have reached advanced clinical evaluation show high affinity for both ERα and ERβ with sufficient circulating and tissue exposure to ensure binding of both subtypes, indicating that, for these molecules at least, differential ERα or ERβ activation does not explain the tissue-selective pharmacological effects.

In addition to the ERs themselves, a number of other coregulatory proteins, such as coactivators (which enhance transcription) and corepressors (which reduce transcription), play an essential role in determining the ultimate response of an individual cell to liganded ER. A number of various coactivators and corepressors that interact with the ligand-bound ER have been identified and are reviewed thoroughly elsewhere (Smith *et al.*, 1997).

The relative tissue expression of the different cofactors and the ability of the ER–ligand complex to interact with those cofactors determine the tissue-selective agonist/antagonist profile of the various SERM molecules. Cofactor tissue expression can also be altered with various pathophysiological states, such as breast cancer (Bautista *et al.*, 1998). The important nature of the tissue-relevant cofactor context was demonstrated by Shang and Brown (2002), who compared the effects of two SERMs, tamoxifen and raloxifene, to estrogen in two tissue contexts: a breast cancer cell line and a uterine endometrial carcinoma cell line. In the mammary cells that proliferate in response to estrogen, 17β-estradiol recruited coactivators leading to increased gene expression. In these same cells, where tamoxifen and raloxifene both display estrogen antagonist pharmacology, the ligand–SERM complex with both molecules recruited corepressors and not the coactivators observed with 17β-estradiol on ER-mediated transcription. However, in a uterine cell line where tamoxifen exhibits estrogen agonist pharmacology and raloxifene is a complete antagonist, tamoxifen was associated with the recruitment of a coactivator protein complex that is expressed at higher levels in uterine cells. The coactivator requirements for estrogen-stimulated gene expression in uterine cells were distinct from those for tamoxifen, indicating multiple signaling mechanisms even for the agonist response. Conversely, raloxifene failed to recruit a coactivator construct, rather it induced a corepressor construct in uterine cells (Shang and Brown, 2002). Thus, the relative abundance of ER-associated coactivators and corepressors are an important factor in the tissue-specific pharmacology of SERMs.

In addition to the layers of complexity provided by multiple ER–SERM conformations and tissue-selective cofactor recruitment, the mechanism of tissue selectivity of SERMs is further complicated by the existence of multiple DNA response elements. Many estrogen-responsive genes contain the classical estrogen response element (ERE), and a number of DNA response elements, such as activator protein-1 and steroidogenic factor-1 response element (Vanacker *et al.*, 1999). The mechanism for SERM activation (or inactivation) of ER-mediated function is further complicated by the presence of novel DNA response elements that are more apparent following formation of the ER–SERM cofactor complex.

Although there has been considerable strides in understanding the molecular biology of SERM action in a general sense, with the critical role of the ER, specific cofactors that are recruited to the transcriptional complex and the specific DNA response elements activated, it is important to recognize that each SERM has the potential to produce a unique fingerprint of pharmacological activity at the whole-organism level. Contributing to the eventual profile are the molecular mechanisms reviewed earlier, as well as other factors, such as absorption, distribution, excretion, and metabolism of the SERM, that add another layer of complexity for the ultimate pharmacological response, creating the need to fully characterize the tissue-specific effects of each individual SERM in an *in vivo* paradigm.

SERM CHEMISTRY

A key element in determining the pharmacological profile of each distinct SERM is influenced heavily by the chemical

makeup of the SERM, including the basic scaffold, the placement of the hydroxyl moieties, and the positioning and nature of the basic side chain. Crystal structures of various ligands bound to the ER indicate that small molecules can induce a spectrum of receptor conformations. As described previously, the specific SERM–ER conformation has tremendous impact on cofactor recruitment and ultimate genomic activation or inhibition by the SERM. Chemical scaffolds that have produced SERMs in current clinical use, or at least that have reached phase 3 clinical evaluation in humans, are depicted in Figure 3 and include triphenylethylenes (i.e., tamoxifen, droloxifene, idoxifene, clomiphene, and toremifene), benzothiophenes (raloxifene and arzoxifene), tetrahydronaphthylenes (lasofoxifene and nafoxidine), indoles (bazedoxifene), and benzopyrans (acolbifene and levormeloxifene). Key structural features of these molecules, which are indicated in Figure 4 for raloxifene versus 17β-estradiol, are typical for the entire class with the most important features being the hydroxyl moieties and the basic side chain, as described thoroughly elsewhere (Grese *et al.*, 1997).

SERM PHARMACOLOGY

Given the wide distribution of ER and the pleiotropic nature of estrogen and its multiple metabolites, SERMs should be expected to likewise affect multiple organ systems, and this is indeed the case. Because the focus of this volume is on skeletal pharmacology, emphasis here will be placed on the pharmacologic effects of SERMs on bone and on other tissues of relevance to safety in the clinical setting. Accordingly, emphasis will be placed on those SERMs where osteoporosis and bone has been the primary focus of research. SERMs primarily used for other indications (present or with future potential) will be briefly summarized as well.

Skeletal System

Preclinical Studies

Much as in postmenopausal women, estrogen deficiency in ovariectomized (OVX) animals leads to a rapid increase in

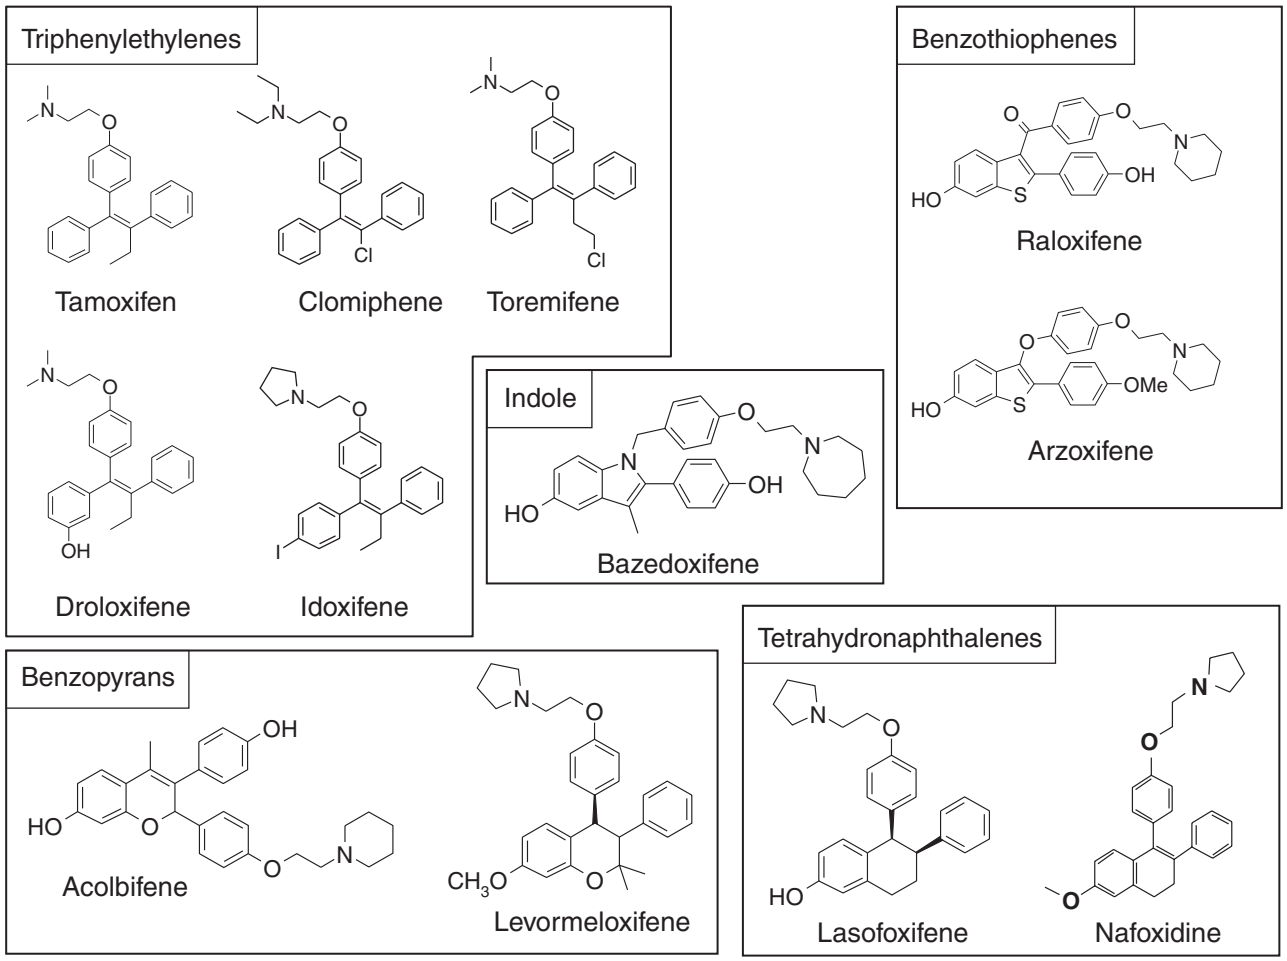

FIGURE 3 Structures and chemical class of SERMS currently in clinical use or that have reached phase 3 clinical trials in women.

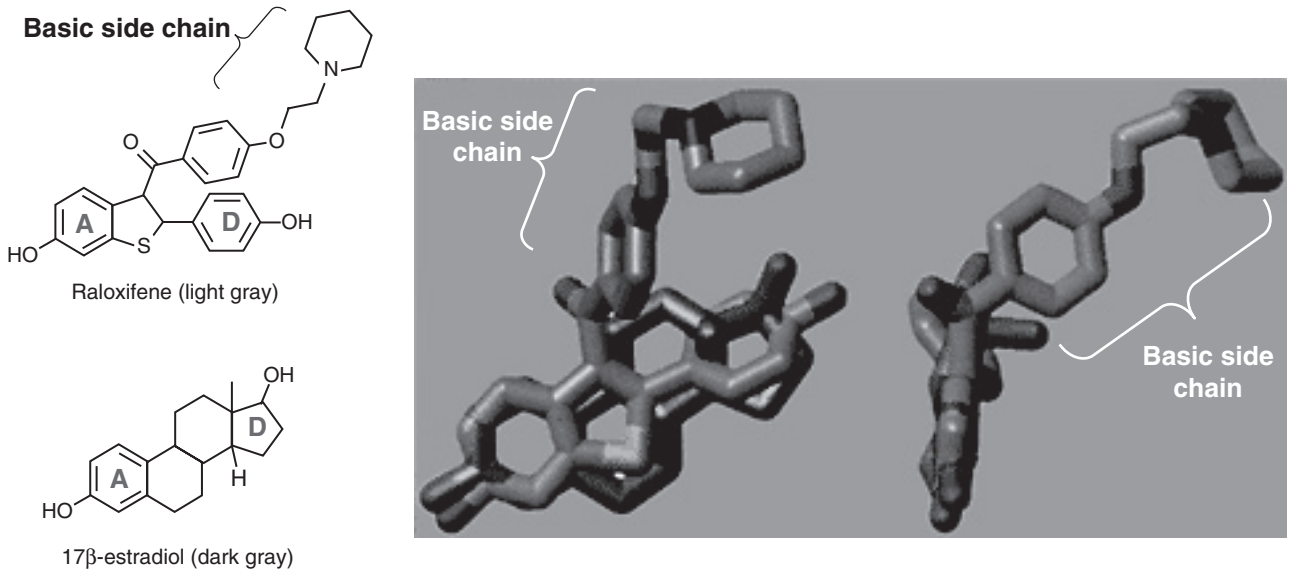

FIGURE 4 Key structural features of raloxifene versus 17β-estradiol.

bone turnover, where excessive osteoclast resorptive activity results in a marked decline in trabecular bone mass and strength, with concomitant increase in fractures. In rats, ovariectomy produces a rapid osteopenic response, which can be discerned within 5 weeks. All of the SERMs depicted in Figure 3 have been evaluated in the OVX rat, and demonstrate estrogen-like protection from bone loss induced by estrogen deficiency. In the OVX rat model, SERMs like raloxifene (Black *et al.*, 1994), arzoxifene (Sato *et al.*, 1998), tamoxifen (Sato *et al.*, 1996), droloxifene (Ke *et al.*, 1995), idoxifene (Nuttall *et al.*, 1998), clomiphene (Jiminez *et al.*, 1997), bazedoxifene (Komm *et al.*, 2005), lasofoxifene (Ke *et al.*, 1998), levormeloxifene (Galbiati *et al.*, 2002), toremifene (Qu *et al.*, 2000), and acolbifene (Martel *et al.*, 2000) prevent the loss of bone in vertebrae, distal femur, and proximal tibia, all trabecular-rich bone sites. In addition to maintaining bone mass, SERMs also preserve bone strength through improvements in bone microarchitecture (i.e., raloxifene; Turner *et al.*, 1994). For both bone mass and bone strength, the absolute magnitude of the effects of most SERMs in OVX rats are indistinguishable from those of estrogen and can approach values attained for sham-surgery controls, when the SERM is administered in a preventative mode. However, differences in potency for these bone-protective effects can occur, with third-generation SERMs like arzoxifene, bazedoxifene, and lasofoxifene producing equivalent efficacy to raloxifene in OVX rat trabecular BMD responses at approximately 10% of the dose (Ke *et al.*, 1998; Sato *et al.*, 1998). There have been preclinical hints for improved efficacy of some of these latter agents as well, for example, with arzoxifene, which improves cortical bone strength to a greater degree than observed with maximally effective doses of either estrogen or raloxifene (Sato *et al.*, 1998). Similarly with bazedoxifene, improved biomechanical properties in trabecular bone were observed relative to estrogen after 1 year of treatment in OVX rats (Komm *et al.*, 2007).

As with estrogen, the primary activity of SERMs responsible for the beneficial effect on bone is antiresorptive. Mechanistic studies *in vitro* demonstrated that raloxifene and estrogen exert their antiresorptive effects primarily as inhibitors of osteoclast differentiation, rather than as direct inhibitors of activated osteoclasts. Raloxifene acts to suppress mediators of osteoclast differentiation, such as the receptor activator of nuclear factor-κB (RANK), RANK-ligand (Bashir *et al.*, 2005) and increase endogenous antiresorptive factors such as osteoprotogerin (Viereck *et al.*, 2003). Biochemical markers of bone turnover (i.e., serum osteocalcin, urinary collagen cross-links) are suppressed in OVX rats in a manner similar to that observed with estrogen (Frolik *et al.*, 1996). Histomorphometric analysis of bone from raloxifene-treated, OVX, rats confirmed the antiresorptive mechanism of action for raloxifene (Evans *et al.*, 1994). Similar studies with the other SERMs discussed here indicate the same antiresorptive mechanism for bone protection. Of likely importance with respect to long-term safety in the skeleton is the finding that SERMs, like raloxifene, produce their inhibitory action on bone resorption with minimal suppressive effects on bone formation, leaving bone formation rates at levels comparable to sham-operated control animals (Evans *et al.*, 1994). The molecular fingerprint of SERMs in estrogen-deficient rat trabecular bone, as assessed by DNA microarray, is unique for each SERM, although it is clear that some SERMs are less suppressive of bone formation. For example, in OVX

rats raloxifene returned a cluster of genes associated with bone formation to ovary-intact control levels, as opposed to a bisphosphonate (alendronate), estrogen, or even another SERM (acolbifene), which exhibited a greater suppressive effect on bone formation-associated genes (Helvering *et al.*, 2005). The overall SERM profile on bone then represents a sharp distinction from the marked suppression of bone formation that occurs with other bone antiresorptives, such as the bisphosphonates. A final bone cell type that may be of relevance to the skeletal-protective effect of SERMs is the osteocyte. Whereas relatively less work has been done with this bone cell owing to technical challenges, work in MLO-Y4 cells (an osteocyte-like cell line) has indicated that raloxifene prevents oxidative stress-induced apoptosis and inhibits generation of reactive oxygen species with oxidative insults, such as hydrogen peroxide (Mann *et al.*, 2007).

Clinical Studies

The abundance of preclinical information on the effects of SERMs on bone has easily been matched by a plethora of long-term clinical trials that have been conducted on a number of different SERM molecules, either as the primary element of registration trials for postmenopausal osteoporosis or as part of the safety assessment for use in breast cancer. Certainly, the most extensively studied SERM on the human skeleton has been raloxifene, which has been investigated in nearly 40,000 clinical trial subjects enrolled in prospective, randomized trials (placebo or active comparator) that have ranged in duration from 1 to 8 years. In postmenopausal women raloxifene (60 mg/day) exhibits an antiresorptive action as evidenced by reductions in the accelerated bone turnover as measured by biochemical markers of bone resorption (Ettinger *et al.*, 1999), while only modestly suppressing bone formation. In calcium tracer kinetic studies in postmenopausal women, Heaney and Draper (1997) showed suppression of bone resorption with raloxifene whereas bone formation was not affected after 31 weeks of treatment. The observation of resorption inhibition with minimal formation suppression by raloxifene was confirmed by histomorphometric analysis of iliac crest bone biopsies (Ott *et al.*, 2002). This antiresorptive activity is associated with an approximately 2.5% increase in vertebral BMD, relative to placebo-treated controls. This increase in spine BMD that occurs following raloxifene treatment in postmenopausal women is less marked than observed with a bisphosphonate (alendronate; Johnell *et al.*, 2002). However, this magnitude of BMD improvement in the spine underestimates the mechanical improvement produced by raloxifene, as evidenced by the 55% reduction in new vertebral fractures in women with prevalent fractures (Ettinger *et al.*, 1999), a rate comparable to that produced by bisphosphonates. This observation has led to an increased attentiveness to potential effects of raloxifene (and putatively other SERMs as well in the future) on bone quality. The eventual resistance of bone to fracture is the result both of the content, or mass of the material (i.e., BMD), and the quality of that material, which is likely the result of bone microarchitecture and the nature of the mineralized matrix itself. In animal models, increased trabecular thickness and maintenance of plate-like trabecular structures (versus rod-like), both of which correlate with improved biomechanical strength of bone, were observed in OVX mice (Cano *et al.*, 2008). Although BMD is a noninvasive, easily quantifiable, parameter in clinical trials, bone quality remains a more difficult to quantify, because it is primarily revealed by the eventual incidence of fracture. A number of efforts have targeted better understanding, and quantifying, of bone quality where raloxifene has shown some benefits over other antiresorptive therapies such as histomorphometric analyses of trabecular bone architecture and microcrack frequency in bone (Allen *et al.*, 2000; Li *et al.*, 2005). One area where some aspect of bone quality is beginning to be elucidated is the proximal femur, where imaging technologies have been applied to postmenopausal clinical trial subjects to show an increase in resistance to axial and bending stresses in raloxifene-treated women (Uusi-Rasi *et al.*, 2006), indicating improved structural components of bone strength and stability with the SERM. Raloxifene produces positive effects on hip BMD, which increased 2.1% versus placebo after 3 years in postmenopausal women (Ettinger *et al.*, 1999), although without a significant effect on nonvertebral fracture rates (Ettinger *et al.*, 1999). However, an interesting trend was noted in a subset of women who entered the trials with severe vertebral fractures. In this subset of more severely osteoporotic women, raloxifene produced a 50% reduction in nonvertebral fractures (Delmas *et al.*, 2003). Finally, in addition to reduction of vertebral fracture in osteoporotic women, raloxifene also provides fracture risk protection to osteopenic women (Kanis *et al.*, 2003).

A number of other SERMs have attempted unsuccessfully to register for an osteoporosis prevention/treatment indication, are currently in phase 3 clinical trials, or are awaiting regulatory approval. Those molecules that have failed to achieve regulatory approval for osteoporosis failed primarily on the basis of safety and risk/benefit analysis, as each demonstrated some level of improvement on skeletal parameters in earlier clinical trials. Prior to discontinuation of the levormeloxifene phase 3 clinical trials because of gynecological-associated adverse events, phase 2 clinical trials demonstrated positive effects of this SERM on BMD and bone turnover (Alexandersen *et al.*, 2001). Idoxifene, a triphenylethylene also discontinued in phase 3 for uterine adverse events, produced clinically relevant increases in BMD in osteopenic postmenopausal women (Chestnut *et al.*, 1998). The most recent SERMs to report advanced clinical testing results for osteoporosis are the third-generation molecules, lasofoxifene and bazedoxifene,

both very potent SERMs with relatively high bioavailability (Gardner *et al.*, 2006; Patat *et al.*, 2003). In a 2-year trial in 410 postmenopausal women lasofoxifene at 0.25 or 1 mg/day suppressed bone turnover similarly to raloxifene, but lasofoxifene increased lumbar spine BMD by 3.6% and 3.9%, respectively, which outpaced the increase observed with raloxifene (McClung *et al.*, 2006). A 2-year BMD trial and 3-year fracture prevention trial demonstrated the skeletal protective effects of bazedoxifene relative to raloxifene. In the 3-year trial, nearly 7500 women were treated with 20 or 40 mg/day bazedoxifene, placebo, or raloxifene at 60 mg/day. In this trial, the bazedoxifene produced a significant reduction in the relative risk reduction for new vertebral fractures of 37% for the higher dose and 42% for the lower dose, with raloxifene producing a comparable 42% in relative risk of new vertebral fractures (Silverman *et al.*, 2007). Mean lumbar spine BMD was significantly improved, relative to placebo, by bazedoxifene with a magnitude of response comparable to raloxifene, and biochemical markers of bone turnover were also significantly lowered with bazedoxifene (Miller *et al.*, 2007).

A number of clinical trials have focused on the bone-sparing effects of two triphenylethylene SERMs used for breast cancer treatment: tamoxifen and toremifene. Although most studies demonstrate a skeletal benefit for these two agents, trials have typically been small and not placebo controlled in design. There is a consistent benefit observed with tamoxifen and toremifene primarily at trabecular bone sites, which is consistent with observations made with raloxifene in postmenopausal women. After 3 years of use, tamoxifen or toremifene in breast cancer patients led to a less-than-expected decline in vertebral BMD (Tiitinen *et al.*, 2004). In shorter trials (1 year), similar effects were observed with the effect of tamoxifen somewhat stronger than that of toremifene (2% higher BMD with tamoxifen versus toremifene, which basically prevented age-related decline over the 1-year trial; Marttenun *et al.*, 1998). Although many studies have reported similar benefits, particularly with tamoxifen, on BMD in postmenopausal breast cancer patients (e.g., Love *et al.*, 1992), there is at least one indication that use of tamoxifen in normal premenopausal women is associated with a reduction in bone mineral density (Powles *et al.*, 1996).

Reproductive System

Uterus

Atrophy of the uterus accompanies estrogen deficiency in humans and most animal species, and cessation of menses is a hallmark feature of the menopause in women. A major side effect of most current ER-based therapies is stimulation of the uterus resulting, in part, from estrogen-induced proliferation of uterine endometrial tissue. The cancer concern associated with this proliferative effect and the resumption of menses (when combined with progestin regimens as hormonal replacement therapy) are major limitations to estrogen replacement therapeutic approaches These uterine side effects of estrogen are often the primary deterrent in the risk/benefit decision for postmenopausal women to utilize or remain compliant with, hormonal estrogen therapies for chronic use with diseases such as osteoporosis. A major and significant advantage of SERMs like raloxifene, for postmenopausal women, over hormonal estrogen therapies, is the lack of uterine stimulation with the SERM. However, not all SERMs share the same degree of uterine safety that is observed with raloxifene and, thus, effects on the uterus also serve as an important distinguishing feature among various SERMs. To this regard, those SERMs that have failed to date in phase 3 clinical trials have done so primarily because of an untenable degree of uterine stimulation or uterus-related adverse events. The accumulated clinical experience with uterine safety for a number of SERMs can help one determine which preclinical models and parameters provide the optimal predictive value for uterine safety. The use of *in vitro* systems, estrogen-depleted animals, and estrogen-replete animals to assess antagonist potential form a triangulated approach for uterine safety assessment of SERMs.

Estrogen Agonism in the Uterus

Initial indication of the uterine estrogenic potential of SERMs can be demonstrated using Ishikawa cells, a human endometrial cancer cell line. Ishikawa cell proliferation is stimulated by 17β-estradiol, tamoxifen, or 4-hydroxytamoxifen (active metabolite of tamoxifen), but not by uterine-sparing SERMs such as raloxifene (Koda *et al.*, 2004). More subtle changes among various SERMs can be detected by evaluating their effects on ER-mediated alkaline phosphatase production, creatine kinase production, or expression of progesterone receptor. The more uterine stimulatory SERMs produce greater induction of alkaline phosphatase and progesterone receptor expression, and are less effective antagonists of 17β-estradiol-stimulated responses in Ishikawa cells (Bramlett *et al.*, 2002). Of note, whereas uterine-safe SERMs like raloxifene fail to stimulate creatine kinase production in Ishikawa cells, raloxifene induces this activity in cell lines with an osteoblast background, consistent with the "SERM" activity profile (Koda *et al.*, 2004).

Lack of biologically meaningful stimulation of the uterus in the estrogen-depleted state (e.g., postmenopausal women or OVX animals) is the crux of SERM uterine safety evaluation. The uterine effects of tamoxifen and raloxifene have been thoroughly evaluated in numerous clinical settings, as well as in a variety of preclinical models. Raloxifene does not produce estrogen-like stimulatory effects in the uterus of OVX rats (Black *et al.*, 1994). In the OVX rat model, a slight, non-dose-related elevation of

uterine weight is frequently observed. However, this phenomenon contrasts markedly with the robust, dose-related elevation of uterine weight produced by estrogen in these animals. Raloxifene fails to stimulate other estrogen-sensitive markers in the uterus of OVX rats, such as uterine eosinophilia, or uterine epithelial cell height (Black *et al.*, 1994). In large-scale clinical trials after 8 years of chronic use in postmenopausal women, extensive uterine safety evaluation revealed no significant uterine-stimulatory effects of raloxifene in humans (Delmas *et al.*, 1997). Indeed, a significant reduction in endometrial cancer of the uterus has been noted in postmenopausal women using raloxifene (Delmas *et al.*, 1997).

As indicated, not all SERMs exhibit the uterine safety profile demonstrated with raloxifene. This is perhaps most evident in the extensive work done with tamoxifen. Studies in the uterus of OVX rats demonstrate robust, dose-related stimulatory effects of tamoxifen on uterine weight, uterine epithelial cell height, and uterine eosinophilia (Adrian *et al.*, 1996). Clinical experience with tamoxifen is consistent with these observations, as uterine bleeding and significant elevation of endometrial cancer has been observed in women exposed to tamoxifen in long-term studies (Fisher *et al.*, 1994).

Thus, raloxifene and tamoxifen serve as bookend profiles for uterine safety for chronic SERM use in postmenopausal women where molecules can be assessed for either a "raloxifene-like" profile of little or no uterine stimulation, or a more estrogenic, "tamoxifen-like" profile. Several SERMs have advanced to clinical research and have corroborated the preclinical observations for those molecules. For example, droloxifene, idoxifene, and levormeloxifene all produced dose-related elevation of uterine weight, uterine epithelial height, and uterine eosinophilia in the OVX rat (Adrian *et al.*, 1996), and were eventually halted in clinical development on the basis of uterine liabilities such as increased bleeding, increased endometrial thickness, and polyps that developed in phase 3 studies for osteoporosis (Silfen *et al.*, 1999). The other triphenylethylenes used clinically today, clomiphene and toremifene, also exhibit an overall uterine stimulatory profile in OVX rats (Turner *et al.*, 1998; Carthew, 1999), although uterine safety is less of a concern with the acute therapeutic use of clomiphene, and the risk/benefit profile for toremifene use in breast cancer treatment has a different weighting of risk. Mixed effects have been observed with lasofoxifene, which in some preclinical reports produced significant, dose-related stimulation of uterine epithelial cell height and uterine eosinophilia (Cole *et al.*, 1997), but not in others (Ke *et al.*, 1998). The outcome of clinical trials with lasofoxifene at this time is incomplete, although initial observations indicate statistically significant uterine stimulation with approximately an 80% increase in endometrial thickness relative to placebo-treated controls and an increased incidence of leukorrhea with lasofoxifene (McClung *et al.*, 2006). On the other hand, bazedoxifene, arzoxifene, and acolbifene produced very little stimulation of the uterus in OVX rats (Komm *et al.*, 2005; Sato *et al.*, 1998; Martel *et al.*, 2000) and, at least with bazedoxifene, studies in postmenopausal women have corroborated the animal work (Adachi *et al.*, 2007).

A significant uterine-related adverse event, which emerged in a number of clinical trials, is relaxation of the pelvic floor and typically associated prolapse of the uterus. Estrogen therapy was traditionally thought to improve structural integrity of pelvic tissue with expected favorable effects on symptoms such as urinary incontinence. However, data from both the WHI Trial and the Heart and Estrogen/progestin Replacement Study (HERS) provided evidence for increased incidence of urinary incontinence in association with estrogen use (Hendrix *et al.*, 2005). Related to this, pelvic organ prolapse was associated with both levormeloxifene and idoxifene within one year of therapy (Fleischer *et al.*, 1999, Goldstein *et al.*, 2002). These observations, taken together, suggest that these uterine wall-associated adverse events with idoxifene and levormeloxifene might also be because of their more estrogen-like uterine activity. The mechanism by which estrogen and some SERMs compromise the uterine wall in postmenopausal women may be linked to an increase in collagen-degrading enzymes, such as metalloproteinase (MMP)-2 based on OVX rat studies. In OVX rats, uterine MMP-2 levels were reduced relative to ovary-intact animals. Estrogen, as well as levormeloxifene, produced marked increases in uterine MMP-2 expression (Helvering *et al.*, 2005). Not all SERMs, however, have been associated with pelvic floor problems, because no increase in this adverse event has been related to chronic use of tamoxifen, toremifene, bazedoxifene, or lasofoxifene (Fisher *et al.*, 1994, Maenpaa *et al.*, 1997, McClung *et al.*, 2006, Adachi *et al.*, 2007). Consistent with its uterine-safe overall profile, the extensive uterine safety evaluations with raloxifene show no increase in the incidence of problems associated with pelvic floor relaxation. Rather, in at least one report, raloxifene produced benefit with significant reduction in the frequency of surgery for pelvic floor relaxation in a population of postmenopausal women (Goldstein *et al.*, 2001).

Estrogen Antagonism in the Uterus

The final important component in assessment of the uterine safety profile of SERMS relies primarily on preclinical data: the ability of SERMs to antagonize the uterine stimulatory effects of estrogen. Further insight into the uterine activity profile of SERMs is gleaned from effects on the uterus in the presence of estrogen, because this allows assessment of the uterine estrogen antagonist potential for these compounds. As in the estrogen-deficient state, the various SERMs also produce one of two general activity profiles in estrogen-replete animals: that of either a complete

estrogen antagonist or that of a partial agonist at the ER. In the uterus of either estrogen-treated immature or adult-OVX rats, SERMs producing desirable uterine safety profiles in postmenopausal women like raloxifene, arzoxifene, and bazedoxifene produce a complete estrogen antagonistic effect (Adrian *et al.*, 1996, Sato *et al.*, 1998, Komm *et al.*, 2005). This effect is most clearly demonstrated in the estrogen-treated immature rat, a model classically used to determine uterine liability of ligands for the ER. In this model, raloxifene blocks the uterotrophic effects of estrogen with an ED_{50} of 0.3 mg/kg (Silfen *et al.*, 1999), whereas arzoxifene and bazedoxifene completely antagonizes the estrogen response with greater potency (Sato *et al.*, 1998; Komm *et al.*, 2005). A key feature of this antagonistic effect with SERMs like raloxifene in the immature rat uterus is the complete antagonism of the uterotrophic effect of estrogen. That is, uteri from estrogen-treated immature rats given doses of raloxifene exceeding 3 mg/kg are indistinguishable from those of non-estrogen-treated immature rats (Adrian *et al.*, 1996). This is in dramatic contrast to other SERMs, best exemplified by tamoxifen, which behaves as a classical partial agonist in the uterus. That is, tamoxifen does significantly antagonize the effects of estrogen in the immature rat uterus. However, in the case of tamoxifen, the maximal degree of this antagonism is only approximately 50% (Adrian *et al.*, 1996). The primary reason for this incomplete antagonistic effect of tamoxifen is that, at higher doses, the inherent uterine stimulatory capacity of tamoxifen limits further suppression of the estrogen-induced uterotrophic response. Other triphenylethylene SERMs, as well as levormeloxifene (Adrian *et al.*, 1996), produce partial estrogen agonist profiles in estrogen-stimulated immature rats.

In addition to usefulness of this parameter for SERM uterine safety assessment, the complete estrogen antagonistic effects of SERMs like raloxifene have been utilized successfully in a variety of preclinical models of estrogen-stimulated uterine pathologies with some limited success in clinical studies. For example, *in vitro* and *in vivo* models of uterine leiomyoma (fibroids) demonstrated favorable responses to raloxifene (Porter *et al.*, 1998) with some reports of successful use of high-dose raloxifene to prevent the progression of uterine leiomyomas in small groups of premenopausal and postmenopausal women, either alone or in combination with a GnRH agonist (Jirecek *et al.*, 2004; Palomaba *et al.*, 2002b, 2005) via a combined antiproliferative/proapoptotic effect. However, other small clinical trials have failed to detect a benefit of raloxifene on uterine leiomyoma (Palomba *et al.*, 2002a), indicating the need for randomized, well-controlled clinical trials for this indication, which would be necessary to balance benefit on leiomyoma status versus the additional risk of SERM use in premenopausal women of ovarian stimulation (discussed later; note: raloxifene is not currently indicated for any uses in premenopausal women). In a rat model of another estrogen-dependent, uterine-related pathology, endometriosis, raloxifene inhibited the estrogen-dependent growth of peritoneal uterine explants (Swisher *et al.*, 1995). In monkeys with spontaneous endometrial lesions, raloxifene eliminated the occurrence of peritoneal endometriosis lesions (Fanning *et al.*, 1997).

The uterine estrogen antagonist effect of SERMs is also of potential benefit in the treatment of endometrial cancer, the most common neoplasm of the female urogenital tract. In many cases, endometrial cancer is susceptible to hormonal-targeted therapies involving both progestin-based and estrogen-depletion strategies. Given the role of estrogens, both directly and indirectly via regulation of progesterone receptor, SERM approaches have been explored. Tamoxifen was evaluated in a small cohort of advanced or recurrent endometrial carcinoma patients with limited success, dissuading the use of tamoxifen as a single agent for this tumor type (Thigpen *et al.*, 2001). Promising efficacy in endometrial cancer treatment was reported with the third-generation SERM, arzoxifene. In early studies in a small number of treatment-refractory endometrial cancer patients, arzoxifene produced a favorable clinical response rate and stabilized the disease in a substantial number of women (Burke and Walker, 2003). In a phase 2 open-label study, ER-positive and progesterone receptor-positive patients with recurrent/advanced endometrial cancer also exhibited a high response rate and duration of response with a favorable side effect profile after administration of arzoxifene (McMeekin *et al.*, 2003).

Mammary

The effects of estrogens on mammary tissue in normal adult animals or women are not typically as clear and robust as those effects observed in the uterus. However, clearly, a majority of mammary tumors are ER positive, and respond favorably to estrogen antagonism (Wakeling *et al.*, 1987). The role of estrogen replacement in the risk of breast cancer is a topic of some controversy and, clearly, the concomitant use of progestins in most hormonal replacement therapy paradigms is confounding. In the WHI Trial, a significant increase in risk of breast cancer in postmenopausal women was a key finding (Writing Group for WHI Investigators, 2002), contributing to dramatic reductions in the use of estrogen replacement strategies for various postmenopausal indications. The role of the progestin in this observation was suggested by a follow-up study in hysterectomized women using unopposed conjugated equine estrogens for more than 7 years, where no increase in breast cancer risk was observed (Stefanick *et al.*, 2006). Although some controversy remains over the exact potential for risk of breast cancer with estrogen therapies, it is clear that concern over this risk has limited patient compliance with steroidal estrogen therapies. A major advantage of the SERM class of molecules is the lack of this

cancer concern with respect to mammary tissue. Indeed, SERMs as a class have demonstrated a benefit in either treating or preventing breast cancer in animal models and women. The effects of SERMs in normal mammary tissue, as breast cancer therapies and preventatives, will be summarized here.

In normal mammary tissue, the effects of SERMs are largely unnoticeable. Extensive use of tamoxifen in both premenopausal and postmenopausal women for the use of breast cancer risk reduction has not been associated with untoward effects on mammary tissue, although in developing mammary glands in mice, tamoxifen impaired growth of mammary ducts and increased mammary alveolar development (Hovey *et al.* (2004)). A cautionary note in interpreting animal data with respect to SERMs on mammary tissue is worth mentioning. The rat is unique in that male mammary tissue exhibits a layering of epithelial cells that has a somewhat hypertrophic appearance, which is an androgen-dependent phenotype in rats. SERMs with highly effective estrogen antagonism in mammary tissue can sufficiently block estrogen influence on mammary epithelia in rats permitting the low ambient level of androgen in the female rat to predominate and convert mammary histological phenotype to resemble that of the male rat (Rudmann *et al.*, 2005), a phenomenon known not to exist in humans. Caution should be taken not to confuse this female/male phenotype conversion in the rat with hypertrophy of mammary tissue.

The antitumor effects of SERMs can be demonstrated readily in mammary tumor cell lines (i.e., MCF-7, T-47D, ZR-75-1) *in vitro*. Each of the SERMs depicted in Figure 3 are estrogen antagonists in one or all of these cell lines (Short *et al.*, 1996, Simard *et al.*, 1997, Komm *et al.*, 2005). The MCF-7 human mammary tumor cell line is an excellent, estrogen-dependent, *in vitro* system for determining antagonism of estrogen-induced proliferative activity of compounds. Most SERMs inhibit estrogen-stimulated proliferation in the 0.2 to 1 n*M* range in this assay, although for those triphenylethylene SERMs requiring formation of active metabolites, such as tamoxifen and toremifene, one must evaluate the active metabolite to see this level of potency. For example, the IC_{50} for tamoxifen in MCF-7 cells is 200 n*M* vs. 1.2 n*M* for 4-hydroxytamoxifen (Suh *et al.*, 2001). Des-methylarzoxifene, a likely active metabolite of arzoxifene, is the most potent inhibitor of MCF-7 proliferation with an IC_{50} value of 0.05 n*M* (vs. 0.4 n*M* IC_{50} for arzoxifene in this cell line; Suh *et al.*, 2001). Also of relevance in the MCF-7 tumor cell line, raloxifene fails to induce proliferation of these cells in the absence of exogenous estrogen, contrasting raloxifene with other SERMs, such as tamoxifen, which produce a low level of MCF-7 proliferation in estrogen-deficient cell culture media (Sato *et al.*, 1995).

Consistent with the mammary tumor cell culture work is the estrogen antagonist effects of SERMs in animal models of estrogen-dependent breast cancer. Various animal models have shown the ability of SERMs such as tamoxifen, toremifene, and raloxifene to blunt the growth of established mammary tumors induced by carcinogens such as dimethylbenzanthrocene (Clemens *et al.*, 1983; Robinson *et al.*, 1988) or in breast cancer tumor cell line xenografts in athymic mice (Fuchs-Young *et al.*, 1997; Qu *et al.*, 2000). Tamoxifen, raloxifene, and lasofoxifene are also effective in preventing mammary tumors induced by other chemical carcinogens, such as nitrosomethylurea (Gottardis *et al.*, 1987; Anzano *et al.*, 1996; Cohen *et al.*, 2001). Of great interest is the apparent increase in mammary tumor efficacy that has been demonstrated preclinically for some of the more recently developed SERMs. For example, arzoxifene, a third-generation SERM molecule, produced a significantly improved efficacy in preventing mammary tumor growth *in vivo* (Suh *et al.*, 2001).

With respect to treatment of human breast cancer, numerous options are in current use that employ endocrine-based strategies with some patients considered suitable for estrogen reduction or antagonism strategies alone (i.e., estrogen-positive tumors) and others using endocrine manipulation approaches as an adjunct to traditional tumor chemotherapy. Two SERMs, tamoxifen and toremifene, are currently approved for chemo/endocrine treatment in the management of postmenopausal women with node-positive breast cancer. With respect to breast cancer, tamoxifen has been in use the longest of any SERM, with greater than 20 years of clinical use. When used as an adjunct, tamoxifen reduces the risk of recurrent cancer and also decreases the risk of new tumors arising in the other breast. Both tamoxifen and toremifene show similar efficacy in terms of 5-year overall survival and disease-free survival rates (the disease-free rate for tamoxifen is 69%, and for toremifene is 72%) for early-stage breast cancer and also demonstrate similar efficacy as first line therapy for metastatic breast cancer in postmenopausal women (International Breast Cancer Study Group, 2004). The only other SERM in late-stage clinical development with clinical assessment of breast cancer treatment potential is arzoxifene, which has been evaluated in several phase 2 trials in advanced breast cancer patients, where some benefit in terms of time to progressive disease and clinical benefit rate were observed (Baselga *et al.*, 2003).

The other significant current application of SERMs is in breast cancer prevention. A number of environmental and genetic factors are associated with increased risk of developing breast cancer in women, including advanced age, family history of breast cancer, and a greater lifetime estrogen exposure (assessed via surrogate indicators such as estradiol levels, use of estrogen therapy, age at menopause, and body mass index). The best current tool for overall assessment of breast cancer risk is the Gail model, where a risk factor of greater than or equal to 1.67 defines a woman at risk (Costantino *et al.*, 1989). Tamoxifen was

the first SERM to show reduced risk of breast cancer through a number of large, placebo-controlled trials. In the Breast Cancer Prevention Trial, tamoxifen was evaluated in a cohort of 13,388 women at increased risk of breast cancer and produced a 49% reduction in the relative risk of invasive breast cancer, with a 69% reduced risk of ER-positive mammary tumors (Fisher *et al.*, 1998). However, despite this substantial reduction in risk, and inclusion of breast cancer risk reduction as an approved use for tamoxifen, the clinical use of tamoxifen for this indication has been rather lackluster—primarily owing to a side effect profile that tilts the risk/benefit ratio in a negative direction in the mind of most physicians and women. The side effects profiles will be reviewed in subsequent sections, but for tamoxifen include endometrial cancer, uterine sarcoma, stroke, venous thrombus events, and cataracts. The increase in endometrial cancer in postmenopausal women likely stems from the uterine stimulatory properties of tamoxifen and represents one area for improvement in other SERMs. In this regard, raloxifene has recently received approval for reducing the risk of invasive breast cancer in postmenopausal women with osteoporosis and in postmenopausal women at high risk for invasive breast cancer. After 8 years of monitoring 4,011 postmenopausal women with osteoporosis, a 66% reduction in the incidence of invasive breast cancer was observed with raloxifene use (Martino *et al.*, 2004). In the Study of Tamoxifen and Raloxifene (STAR) Trial, a head-to-head comparison of the two SERMs was conducted in 19,000 postmenopausal women at high risk of breast cancer, where tamoxifen and raloxifene were found to produce similar reductions in the incidence of invasive breast cancer (Vogel *et al.*, 2006), with the primary benefit being a reduced risk of ER-positive invasive breast cancers (Barrett-Conner *et al.*, 2006). The most significant differences between raloxifene and tamoxifen in the STAR trial were significantly fewer uterine-associated adverse events with raloxifene (most notably the lack of endometrial cancer), whereas tamoxifen appeared to have a greater effect on noninvasive breast cancer incidence than raloxifene (Vogel *et al.*, 2006). These differences between tamoxifen and raloxifene, although subtle, indicate a difference from preclinical and even early clinical indicators and, as such, demonstrate the need for thorough clinical evaluation before accurate therapeutic risk/benefit assessment and approval of indications can be made for human use. In this regard, several SERMs in development, such as acolbifene and bazedoxifene (Labrie *et al.*, 2004; Adachi *et al.*, 2007), have preclinical and early clinical profiles that are promising for potential use in reduction of risk for breast cancer, but until sufficient clinical evaluation has been completed, it is too early to predict the ultimate utility of these molecules in this regard.

The mechanism by which SERMs such as tamoxifen, raloxifene, and toremifene inhibit breast cancer development or progression is likely the result of multiple beneficial effects. Direct antagonism of estrogen action at ER in target cells in breast tissue, as previously described, is a key component of the action of the SERMs, given the strong positive linkage of estrogen exposure to relative risk for developing breast cancer and the fact that SERMs are much more effective versus ER-positive breast cancers. However, it is also likely that antitumor effects to reduce estrogen bioavailability as well as effects independent of estrogen contribute to the ultimate anti-breast cancer effect. Raloxifene is known to elevate levels of sex hormone-binding globulin (Reindollar *et al.*, 2002), which would be expected to reduce bioavailable estrogen levels and thereby further reduce the risk of estrogen-associated breast cancer. Other beneficial indirect SERM effects include: (1) modification of signaling proteins with a role in tumor cell biology, as is observed with tamoxifen on protein kinase C, TGFβ, calmodulin, ceramide, MAP-kinases (Mandlekar and Kong, 2001); (2) induction of apoptosis in mammary tumor cell lines, as with tamoxifen, raloxifene, and toremifene (Mandlekar and Kong, 2001; Diel *et al.*, 2002; Houvinen *et al.*, 1993); and/or (3) dampening of growth factor systems known to play a role in tumor progression. The latter of these indirect mechanisms may be the most important, because the contribution of growth factors in the pathogenesis of breast cancer is attracting considerable attention. The insulin-like growth factor (IGF) system, inclusive of signaling factors, IGF-receptors, and IGF-binding proteins, has strong connections to the malignant transformation of normal breast epithelium and thus is implicated in the development and progression of breast cancer (Ward *et al.*, 1994). The IGF system protects cancer cells from apoptosis, thus promoting their survival. Beneficial effects of SERMs on the IGF system were demonstrated in postmenopausal women after 2 years of raloxifene treatment. Raloxifene reduced circulating IGF-1 levels and increased IGF-binding protein-3 levels, which would be expected to be associated with reductions in bioavailable IGF-1 (Lasco *et al.*, 2006).

Mammographic density of the breast depends on the contributions of the predominant cell types in the breast: stromal, epithelial (both of which are higher-density tissue types), and fat tissue (which is relatively radiolucent by standard mammography). Although the role of breast density in prediction of relative breast cancer risk remains a topic of debate, most investigators agree that breast cancer risk is higher in women with higher-density breast tissue (Boyd *et al.*, 1995). Whether this is related to a protective effect of increased abundance of fatty tissue, or simply impedance in detecting small amounts of cancerous tissue in higher-density breast is not clear. However, it is clear that estrogen use is associated with a significant increase in mammographic density (Breendale *et al.*, 1999). Conversely, SERMs, specifically raloxifene and arzoxifene, were associated with a reduction of breast density in postmenopausal women (Lasko *et al.*, 2006; Kimler *et al.*, 2006).

Other

In addition to the uterus and mammary tissue, other components of the female reproductive system are under the direct or indirect control of estrogen and, thus, are also susceptible to the effects of SERMs. Depending on the patient, those SERM effects may be desirable, undesirable, or neutral.

Ovarian Effects

The ovary is an important regulator of cyclicity in the female reproductive system and the predominant source of circulating estrogen, and it is indirectly regulated via estrogen action on the hypothalamic-pituitary-ovarian (HPO) axis. In mice, 15- to 24-month exposure to tamoxifen, toremifene, or raloxifene is associated with ovarian tumors. However, there is no evidence of increased ovarian cancer risk with these agents in women. Careful evaluation of multiple randomized, placebo-controlled studies indicates that raloxifene did not increase ovarian cancer in postmenopausal women compared with placebo (Neven *et al.*, 2002). Thus, the murine observations may be owing to species differences in ovarian responses in terms of tumor development between mice and humans. The endocrine system plays a key role in the production of ovarian tumors in mice, particularly when gonadotropins are sustained at elevated levels for extended periods of time (Murphy *et al.*, 1973). In this regard, raloxifene produces a sustained, dose-related increase in serum luteinizing hormone (LH) levels and inhibition of ovarian follicle maturation in mice, both effects being reversible upon discontinuation of the SERM (Cohen *et al.*, 2000). *In vitro*, raloxifene is an antagonist of 17β-estradiol in pituitary gonadotrophs (Ortmann *et al.*, 1988), suggesting the elevation of LH with SERMs is related to blockade of the feedback inhibitory properties of estrogen on the HPO axis.

Hormonal Effects

In women, the most striking effects of SERMs on ovarian function are primarily through hormonal effects on the HPO axis. Because ovarian function is obviously a major difference between the premenopausal and postmenopausal state, the effects of SERMs are likewise different with each state of ovarian function. The HPO axis is a complex endocrine system for which normal physiology requires the interplay of a number of steroid and peptidyl hormones, including GnRH from the hypothalamus, follicle-stimulating hormone (FSH), prolactin and LH from the anterior pituitary, and estradiol as a hormone primarily originating from the ovary (although multiple tissue types possess the necessary enzymes to interconvert estrogen and testosterone, as well as generate multiple estrogen metabolites).

In premenopausal women, SERMs predominately exert a stimulatory effect on the HPO axis and ovulation, with stimulatory effects on GnRH, FSH, and LH, and marked increases in serum estradiol levels (Adashi *et al.*, 1996). Depending on the situation, this may be a desired therapeutic goal or an undesirable side effect. This effect has been taken advantage of for more than 40 years with the widespread use of clomiphene for induction of ovulation in women with ovulatory dysfunction who desire pregnancy. For this indication, clomiphene is used acutely to induce ovulation and increase the number of follicles produced in a given cycle. Use of clomiphene for more than twelve cycles in women who failed to become pregnant has been associated with an increase in ovarian cancer, leading to the recommendation to limit use of this agent to no more than six cycles if a pregnancy does not occur (Rossing *et al.*, 1994). The other two SERMs currently approved for use in premenopausal women are tamoxifen and toremifene, used in the management of breast cancer. In these women, chronic treatment with the SERM results in ovarian-associated adverse effects. Of note is the induction of ovarian cysts and high circulating levels of estradiol that frequently occur with tamoxifen in reproductive age women (Cook *et al.*, 1995). Although these ovarian cysts can cause discomfort, they rarely require surgical intervention.

By far, the predominant use of SERMs is in postmenopausal women, either for osteoporosis treatment or prevention (raloxifene), breast cancer treatment (tamoxifen or toremifene), or breast cancer risk reduction (tamoxifen or raloxifene). After the menopause or in estrogen-deficient OVX animals, estrogen levels drop and the lack of negative feedback provided by estrogen on the hypothalamus-anterior pituitary leads to an increase in FSH and LH levels or pulses. In general, SERMs exhibit a partial agonist effect on the HPO axis in postmenopausal women. Raloxifene, tamoxifen, and toremifene are associated with reductions in LH and FSH levels in postmenopausal women (Cheng *et al.* 2004, Ellmen *et al.*, 2003). HPO axis-related adverse effects, such as ovarian cysts, are not typically seen in postmenopausal women and have been reported only occasionally with tamoxifen use (Shushan *et al.*, 1996).

Another important estrogen-regulated hormonal product of the anterior pituitary is prolactin. In premenopausal women, raloxifene failed to alter circulating prolactin levels (Faupel-Badger *et al.*, 2006). In postmenopausal women, raloxifene (Cheng *et al.*, 2004) and clomiphene (Garas *et al.*, 2006) reduced serum prolactin, operating either directly on lactotropes in the anterior pituitary, or via increasing opiatergic tone in the hypothalamus (Lasco *et al.*, 2002).

Vaginal Effects

The drop in circulating estradiol levels associated with menopause is responsible for various vaginal-related symptoms, including itching, dryness, and dyspareunia. Various forms of estrogen or hormone replacement, via both systemic and local delivery routes, have been widely used to provide relief for postmenopausal women who have these

symptoms. SERMs demonstrate a range of profiles on vaginal symptoms of menopause. Most reports in postmenopausal women indicate estrogen-like maturation of vaginal epithelial cells with tamoxifen and toremifene (Ellmen *et al.*, 2003; Friedrich *et al.*, 1998). Conversely, there is some indication for antagonism of estrogen influence on vaginal tissue, because both toremifene and tamoxifen produce a fourfold increase in vaginal dryness in postmenopausal women (Marttunen *et al.*, 2001), and toremifene partially antagonized the effect of estrogen on vaginal epithelium in postmenopausal women (Homesley *et al.*, 1993). The background estrogen status of the individual may be an important determinant, because, in women with a high estrogenic activity (with respect to hormonal cytology), tamoxifen produced no vaginal estrogen-like effects, whereas women with lower estrogen levels saw an increase in vaginal tissue maturation index (Shiota *et al.*, 2002). Even with these modest estrogen-like effects produced by toremifene or tamoxifen on the vagina, no beneficial or untoward urogenital effects of either agent have been observed in postmenopausal women (Marttunen *et al.*, 2001). Raloxifene use in postmenopausal women is associated with a more neutral profile on vaginal tissue in postmenopausal women, because it failed to affect vaginal epithelium in this population (Komi *et al.*, 2005) and is not associated with adverse vaginal symptoms (Davies *et al.*, 1999). Raloxifene also did not antagonize the beneficial effect of vaginal estrogen cream or an estradiol-releasing ring on vaginal atrophy or sexual function in postmenopausal women (Kessel *et al.*, 2003). One SERM that has been extensively studied for potential beneficial effects on postmenopausal vaginal-associated symptoms in phase 3 clinical trials is lasofoxifene. In clinical trials, lasofoxifene improved the vaginal epithelium maturation index (as was observed with tamoxifen and toremifene), but also reduced vaginal pH and reduced the incidence of dyspareunia (Portman *et al.*, 2004; Bachmann *et al.*, 2004). These unique effects of lasofoxifene might be related to increased vaginal mucus formation, which was observed in vaginal tissue from OVX rats treated with lasofoxifene (Wang *et al.*, 2006)—effects not observed with raloxifene or tamoxifen.

Cardiovascular System

Menopause is associated with a dramatic increase in cardiovascular disease and characteristic changes in a number of heart disease-associated risk factors, such as an increase in serum cholesterol and specifically LDL-cholesterol, with a decline in the cardioprotective HDL-cholesterol, elevated levels of lipoprotein(a) [Lp(a)], increased insulin resistance and fat mass resulting in a classic "metabolic syndrome" profile for heart disease risk (Spencer *et al.*, 1997). Unfavorable markers of vascular endothelial damage, such as elevations in homocysteine levels and C-reactive protein (CRP) also accompany the declining ovarian function during menopause (Hak *et al.*, 2000). The fact that women enjoy a relatively "cardioprotected" status prior to menopause relative to their male counterparts historically presented the impression that estrogen replacement should be beneficial for reducing cardiovascular disease in postmenopausal women. Certainly, in both estrogen-deficient animal models as well as in postmenopausal women, estrogen produces a number of effects that would be associated with an improvement in risk for cardiovascular disease, such as reduction of total circulating cholesterol levels, LDL-cholesterol, in particular, and a concomitant increase in HDL-cholesterol. Accordingly, observational clinical trials suggested a significant reduction of cardiovascular disease in women who used hormone replacement therapy after menopause (i.e., Stampfer and Colditz, 1991). Thus, it was an unanticipated result when randomized clinical trials, which were conducted to confirm the beneficial effects of hormone replacement therapy on the cardiovascular system, indicated the opposite effect: an increase in cardiovascular disease associated with estrogen/progestin use. The first trial to indicate this was the HERS trial, where no reduction in coronary heart disease was detected, but an increase in cardiovascular-related deaths in the initial year of therapy was observed (Hulley *et al.*, 1998). Similarly, the WHI Trial failed to demonstrate any beneficial effects of estrogen use, but again an increased risk of adverse cardiovascular outcomes, including increased incidence of myocardial infarction and stroke (Manson *et al.*, 2003). Finally, the Women's Estrogen for Stroke Trial (WEST) indicated an early increase in risk of fatal stroke during the first year of estrogen use in women with preexisting cerebrovascular disease (Viscoli *et al.*, 2001). Both observational and randomized, placebo-controlled studies in postmenopausal women have indicated a significant increase in risk of deep venous thrombosis and pulmonary embolism in association with hormone replacement (Manson *et al.*, 2003).

Thus, it is clear with SERMs that one needs to address two important considerations. First, and foremost, the cardiovascular safety profile of SERMs in postmenopausal women must be thoroughly evaluated based on the risk ascribed to hormone replacement therapy by trials such as HERS, WHI, and WEST. The second consideration revolves around potential beneficial effects on cardiovascular risk factors, which might be instructive in determining additional benefit of these molecules. However, if we are to learn a lesson from the hormone replacement field, one needs to be careful to rely on randomized, well-controlled trials to make this assessment. The cardiovascular safety of SERMs in clinical use and their potential cardiovascular benefits are discussed here.

Cardiovascular Safety of SERMs

The primary adverse event associated with every chronically used ER ligand is the occurrence of venous thrombolicevents (VTEs), typically as deep vein thromboses or

pulmonary emboli. The relative frequency of VTEs with SERMs is typically 2- to 3-fold greater than placebo when assessed in randomized clinical trials, a rate that is comparable to that observed with use of oral estrogen replacement therapy (Cosman and Lindsay, 1999). Such an increase in venous thromboses has been described with tamoxifen or toremifene use in breast cancer patients (Cuzick *et al.*, 2003, Harvey *et al.*, 2006) and raloxifene use in osteoporotic patients (Duvernoy *et al.*, 2005). Comparable rates of venous thromboses have also been described in the 2- and 3-year phase 3 clinical trials for lasofoxifene and bazedoxifene (Adachi *et al.*, 2007; McClung *et al.*, 2006). The incident rate of VTEs is elevated in postmenopausal women subjected to prolonged periods of inactivity (i.e., extended bed stay during invasive surgical procedures) and, as such, SERMs used chronically carry a recommendation to discontinue drug therapy during periods of anticipated immobility of several hours or more (Cuzick *et al.*, 2002; Seeman, 2001). The mechanism for increased incidence of VTEs with SERMs is not clear, although a number of clinical trials have noted procoagulant changes with estrogen replacement, tamoxifen, or raloxifene along with impairment of anticoagulant factors with these three regimens. Although there is some variability in the results of different studies with respect to specific factor changes, such as fibrinogen that is increased by raloxifene in some reports (Sgarabotto *et al.*, 2007) but decreased in others (Walsh *et al.*, 1998), some clear trends have emerged. In a randomized, placebo-controlled trial in healthy postmenopausal women (Cosman *et al.*, 2005), estrogen replacement increased the coagulation factor VII and reduced the anticoagulation factors antithrombin and plasminogen activator inhibitor-1 (PAI-1). Tamoxifen generated an overall procoagulant profile, although via an increase in clotting factor VIII, factor IX, and von Willebrand factor on the coagulant side, and decreases in antithrombin, protein C, and PAI-1 on the anticoagulant side. Raloxifene produced a different pattern of changes, with some similarity to that of tamoxifen, although without elevation in clotting factor IX or reduction of protein C (Cosman *et al.*, 2005). In a separate study, Dahm *et al.* (2006) demonstrated that estrogen replacement, tamoxifen, and raloxifene all acted to reduce human endothelial production of tissue factor pathway inhibitor-1 (TFPI), an anticoagulant factor. Thus, some clear trends have emerged as the most critical determinants for VTE occurrence with estrogen or SERMs, being reduction of important factors such as antithrombin, PAI-1 and TFPI, all anticoagulant functional proteins. However, this remains more of a correlative hypothesis as, to date no chronically used SERM has avoided the 2% to 3% rate of VTE occurrence. No preclinical models or predictors are available to predict the relative likelihood for VTEs in humans with SERMs or estrogens.

With respect to the more severe cardiovascular adverse events observed with hormone replacement in the HERS, WHI, and WEST clinical trials, there are mixed reports with respect to incidence of stroke or myocardial infarction with various SERMs. Although a coronary heart disease neutral profile was reported initially with tamoxifen in the breast cancer prevention trial, an increased risk for stroke with tamoxifen was eventually observed (Reis *et al.*, 2001). The long-term clinical trials that supported raloxifene approval for osteoporosis indications found no change in the incidence of myocardial infarction relative to the placebo (Martino *et al.*, 2005). Analysis on a per year basis showed no increase in cardiovascular events in the first year of raloxifene use, which contrasts with the pattern reported for estrogen replacement in the HERS and WHI trials (Keech *et al.*, 2005). Cardiovascular events were the primary outcome of the Raloxifene Use for The Heart or RUTH trial, where no increase in coronary events or stroke incidence was observed, but a statistically significant increase in stroke-associated mortality was reported (Barrett-Conner *et al.*, 2006).

Potential Cardiovascular Benefit of SERMs

Although the large, randomized, placebo-controlled trials conducted with SERMs have not shown a significant reduction in cardiovascular events, smaller trials or subsets of the larger placebo-controlled trials have demonstrated some favorable trends, leaving open the possibility that a cardioprotective SERM is a possibility. With tamoxifen, one clinical study concluded a slight reduction in cardiac death and reduced risk for myocardial infarction (Rutqvist *et al.*, 1993). In the raloxifene osteoporosis registration clinical trial, a positive effect on the incidence of cardiovascular events was observed in a subset of women at high risk for heart disease (Barrett-Conner *et al.*, 2002). Despite the lack of verifiable cardiovascular outcomes with SERMs, most SERMs evaluated in both the clinical and preclinical settings show largely favorable effects on most cardiovascular risk factors for heart disease, including lipid metabolism, clotting factors, and vessel wall factors. However, the "fingerprint" of each SERM on the wide array of cardiovascular surrogates is strikingly distinct, suggesting each SERM needs to be carefully evaluated clinically before a complete assessment of cardiovascular benefit or risk can be ascribed.

The most clear and robust effect that can be observed with SERMs on cardiovascular relevant parameters in preclinical models is the reduction of serum cholesterol levels (i.e., raloxifene, Black *et al.*, 1994; tamoxifen, Sato *et al.*, 1996; clomiphene, Turner *et al.*, 1998; toremiphene, Qu *et al.*, 2000; acolbifene, Martel *et al.*, 2000; lasofoxifene, Ke *et al.*, 1998; bazedoxifene, Komm *et al.*, 2005; arzoxifene, Palkowitz *et al.*, 1997). As with the skeletal responses in OVX rats, all of the SERMs depicted in Figure 3 are capable of reducing serum cholesterol to roughly the same magnitude, thus mimicking the response to estrogen in this

animal model, although differences in potency are evident. This hypocholesterolemic effect of SERMs is mediated by the ER, as demonstrated in the case of raloxifene by a very close correlation of ER-binding affinity and cholesterol lowering *in vivo* for a series of raloxifene analogues (Kauffman *et al.*, 1997).

In clinical trials, most of the SERMs depicted in Figure 3 reduced total serum cholesterol and LDL-cholesterol (Reid *et al.*, 2004; Joensuu *et al.*, 2000; McClung *et al.*, 2006) even in hypertriglyceridemic women (Dayspring *et al.*, 2006), with raloxifene and tamoxifen also reducing Lp(a) (Love *et al.*, 1994; Mijatovic *et al.*, 1999)—all effects that are cardioprotective with respect to cardiovascular disease risk factors. Neither tamoxifen nor raloxifene elevated HDL-cholesterol (Love *et al.*, 1994; Walsh *et al.*, 1998), a cardiovascular beneficial effect of estrogen replacement. Triglyceride elevation, an undesired effect often associated with estrogen replacement, is increased in most clinical trials with tamoxifen, although a triglyceride-neutral profile was observed with raloxifene or toremifene (Walsh *et al.*, 1998; Kusama *et al.*, 2004).

Preclinical models focused on the vessel wall have produced beneficial effects after SERM administration. In rats, neointimal thickening following aortic denudation injury was reduced by either raloxifene or tamoxifen, where both of these SERMs were shown to regulate vascular smooth muscle cell function, indicating a potential benefit against restinosis following percutaneous transluminal coronary angioplasty (Savolainen-Peltonen *et al.*, 2004). Even though SERMs are linked to increases in VTEs in clinical studies, preclinical work has indicated a beneficial effect of raloxifene in a model of carotid artery thrombosis. In OVX mice, estrogen deficiency amplifies thrombosis following carotid photochemical injury. In this model system, raloxifene, as well as estrogen, significantly reduces intraarterial thrombosis prolonging time to occlusion, likely via a mechanism that involves reduced platelet adhesion and increased expression of COX-2 (Abu-Fanne *et al.*, 2008). Vascular anti-inflammatory effects of raloxifene were also linked to vasorelaxant properties (Pinna *et al.*, 2006).

Cardiovascular disease surrogates associated with vessel wall function and inflammation are also generally improved in clinical studies following raloxifene and tamoxifen. CRP, a marker that is linked to vascular injury and reflects inflammatory activity in the vascular wall is elevated with estrogen replacement (Cushman *et al.*, 1999) but is reduced with raloxifene and tamoxifen (Cushman *et al.*, 2001; Walsh *et al.*, 2000), as is homocysteine (Anker *et al.*, 1995; De Leo *et al.*, 2001), a circulating factor linked to toxicity of vascular endothelial cells. Improved endothelial function with tamoxifen (Stamatelopoulos *et al.*, 2004) and reduction in endothelin-1 (Saitta *et al.*, 2001), an endogenous vasoconstrictor, has also been described.

Clearly other factors, in addition to circulating lipids, influence the ultimate potential cardiovascular benefit provided by compounds like the SERMs. In this regard, direct effects of SERMs on cardiovascular tissue has been the subject of extensive investigation in recent years and agents such as raloxifene produce a number of effects of potential cardiovascular benefit. For example, raloxifene produces an antioxidant effect on serum lipoproteins (Zuckerman and Bryan, 1996), inhibits vascular smooth muscle migration (Wiernicki *et al.*, 1996), and elevates vascular endothelial cell nitric oxide production (Saitta *et al.*, 2001). Preclinical studies in models of atherogenesis have provided mixed results. Raloxifene failed to prevent the reduction of the coronary artery intimal area in cholesterol-fed, OVX monkeys (Clarkson *et al.*, 1998). However, six-month exposure to raloxifene did reduce aortic atherogenesis in cholesterol-fed, OVX rabbits (Bjarnason *et al.*, 1997) and improved the coronary artery intimal area in OVX sheep (Gaynor *et al.*, 2000). Given that nearly all of the direct cardiovascular studies with SERMs in postmenopausal women over the past few years have been conducted with raloxifene, it is difficult to know at this point whether these particular effects can be generalized across the SERM class, or whether, as in the uterus, distinct cardiovascular SERM profiles will emerge.

Central Nervous System (CNS)

The mixed biological results observed with estrogen in the cardiovascular system are paralleled by the profile of estrogen activity in the CNS. Extensive *in vitro* and animal studies suggest neuroprotective and other beneficial effects of estrogen on central processes ranging from cognition to fine motor control and mood. However, translational work to human neurodegenerative disease has failed to corroborate the preclinical data and, as in the cardiovascular system, suggests potential untoward effects of estrogen on the human CNS.

Clearly the ER is broadly distributed throughout the brain. Original thoughts were that ER was predominately restricted to the hypothalamus and associated with well-known functions such as regulation of reproductive hormones in the periventricular nucleus and thermoregulation in the lateral hypothalamus. The discovery of the ERβ subtype and improved antibodies for detection of ERα, however, led to reconstruction of ER distribution neuroanatomical charts to include higher brain regions such as the cortex and hippocampus, specifically on neurons associated with learning and memory, such as pyramidal cells throughout the CA1 and CA3 regions of the hippocampus and cortex (Shugrue and Merchenthaler, 2001).

Estrogen produces a number of beneficial effects *in vitro* and in animal models. In neuronal cell culture, 17β-estradiol has neurotrophic effects and inhibits neuronal damage induced by neurotoxicants (O'Neill *et al.*, 2004). In OVX rats, estrogen increases hippocampal choline acetyltransferase activity, which leads to increased acetylcholine

levels, a neurotransmitter associated with cognition (Wu *et al.*, 1999). Estrogen also reduces neural damage after experimental forebrain ischemia (Simpkins *et al.*, 1997) and produces beneficial effects in animal models of Parkinson 's disease (Gomez-Mancilla and Bedard, 1992). Estrogen also affects central serotonergic neurotransmission in animal models, leading to increased serotonin production and firing and reduced degradation (Bethea *et al.*, 2002). Dopaminergic neurotransmission in the striatum is influenced by estrogen (Landry *et al.*, 2002) as are glutamate receptors (Cyr *et al.*, 2001).

The preclinical data are consistent indicating a beneficial effect of estrogen on CNS function. However, clinical data have not supported this conclusion. Certainly, early observational studies suggested up to a 30% reduction in risk of dementia with estrogen use (Yaffe *et al.*, 1998). However, because these trials were not well-controlled prospective studies, there is considerable room for group-related artifacts (e.g., education status), which may affect data interpretation. In this regard, in large, randomized, placebo-controlled trials, estrogen not only failed to reduce the incidence of dementia, but also was associated with an increased risk of dementia and stroke (Shumaker *et al.*, 2003). Additional data are clearly needed, because the role of progestin in studies where hormone replacement is employed is a complicating factor, although even with estrogen only use of a similar profile was observed (Shumaker *et al.*, 2004). Other potential effects of estrogen on the brain, e.g., on mood, are equally controversial at this time. Clearly, in consideration of SERMs, careful attention must be paid not only to potential beneficial effects, but also to CNS safety.

CNS Safety of SERMs

No outwardly neurotoxic effects of tamoxifen, raloxifene, or any of the SERMs depicted in Figure 3 have been reported in either neuronal cell culture or in animal studies. Some differences among various SERMs have been reported with respect to their ability to antagonize estrogen effects in the brain. For example, tamoxifen blocks the effect of estrogen on serotonin 2 A receptor expression in the forebrain or dorsal raphe of rats (Sumner *et al.*, 1999), whereas raloxifene fails to show an antagonist profile on this receptor subtype in these brain regions (Cyr *et al.*, 2000).

In clinical studies, use of tamoxifen for 5 years in women for breast cancer therapy did not alter performance on a series of cognitive tests compared with breast cancer patients who had never used tamoxifen, although an increase in physician visits for memory problems was noted (Paganini-Hill and Clark, 2000b). The confounding variable of the ongoing disease state in these women must be factored into consideration though, because studies conducted in elderly women found no differences in mental functional tests or speed of response with tamoxifen use (Ernst *et al.*, 2002). In pilot studies conducted to evaluate the safety of raloxifene on cognitive function in postmenopausal women with osteoporosis, no negative effects on memory function were detected as determined by a number of mental acuity tests (Nickelsen *et al.*, 1999). Follow-up work in more than 7700 postmenopausal women with osteoporosis confirmed the initial observation of no negative effects of raloxifene on cognitive performance (Yaffe *et al.*, 2001). Consistent with the latter observation, no untoward effects of raloxifene have been observed on mood, sexual behavior, or sleep in postmenopausal women.

CNS Efficacy of SERMs

Much as with estrogen, SERMs are largely associated with preclinical profiles that suggest neuroprotection and an overall positive CNS profile. Although certain subtle differences can be observed among different SERMs, further indicating the need to thoroughly evaluate each specific SERM molecule. Positive effects of SERMs can be demonstrated *in vitro*; as in a neural cell line, raloxifene increased neurite outgrowth in culture (Nilsen *et al.*, 1998). Raloxifene and tamoxifen were neuroprotective in a neuroepithelial cell line by conferring resistance to β-amyloid-induced toxicity via an elevation of seladin-1 (Benvenuti *et al.*, 2005), a factor known to be downregulated in brain regions affected by Alzheimer's disease (Greeve *et al.*, 2001).

Neurotransmitter-related changes within the CNS by the various SERMs can be similar for some transmitters in some brain regions, but can differ in other neurotransmitter systems. Much as with estrogen, raloxifene and tamoxifen increase hippocampal choline acetyltransferase activity (Wu *et al.*, 1999) indicating comparable effect of these two SERMs on acetylcholine neurotransmission, a neurotransmitter associated with cognition. Raloxifene and tamoxifen, however, produce different overall profiles on serotonin neurotransmission in the brain. In both rats and monkeys, raloxifene produces a spectrum of changes in the forebrain that are favorable for serotonin neurotransmission, such as increased tryptophan hydroxylase, increased serotonin 2A receptor expression, and reduced serotonin transporter (Cyr *et al.*, 2000; Smith *et al.*, 2004). In contrast, tamoxifen does not affect serotonin transporter and reduces tryptophan hydroxylase activity in the forebrain (Sumner *et al.*, 1999), a profile unfavorable for serotonin neurotransmission. Of note, the SERM arzoxifene produces a pattern of effects on forebrain serotonin neurotransmission that parallels that produced by raloxifene (Bethea *et al.*, 2002). Other differences on neurotransmitter profiles can be observed with dopaminergic systems, as in the lateral striatum dopamine receptor expression is increased in response to raloxifene, but not affected by tamoxifen (Landry *et al.*, 2002).

Distinct SERM efficacy profiles can also be detected in various CNS pathology animal models. Hippocampal neurodegeneration can be induced in rats by systemic injection of kainic acid, which leads to induction of inflammatory astroglia and neural loss that is protected by pretreatment with estrogen. In OVX rats injected with kainic acid, tamoxifen, raloxifene, and bazedoxifene all prevented hippocampal neural loss without affecting the reactive gliosis component (Ciriza *et al.*, 2004), a profile distinct from that of 17β-estradiol, which was both neuroprotecive and anti-inflammatory in this model. Again, not all SERMs behaved the same in this model system as lasofoxifene failed to exhibit a neuroprotective profile (Ciriza *et al.*, 2004). Neuroprotective effects of SERMs in other animal models have also been observed. In separate studies, tamoxifen and arzoxifene reduced neural damage following occlusion of the middle cerebral artery in OVX rats, an experimental model for stroke (Mehta *et al.*, 2003; Rossberg *et al.*, 2000). The mechanism for SERM protection from focal cerebral ischemia in these animal models remains unclear, because raloxifene induced a relaxation of rat cerebral arteries *in vitro* via an inhibition of L-type calcium channels (Tsang *et al.*, 2004), although direct effects on cerebral blood flow were ruled out in one study (Rossberg, 2000). Attenuation of excitatory amino acid release and putative antioxidant effects have also been demonstrated as potentially contributing to the neuroprotective effect of tamoxifen and raloxifene (Osuka *et al.*, 2001; Siefer *et al.*, 1994). Finally, neuroprotective effects of tamoxifen and raloxifene were observed in 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-induced dopamine depletion in a Parkinsonian model (Obata and Kubota, 2001; Grandbois *et al.*, 2000).

A number of metabolic-based imaging and cognitive performance clinical trials suggest potential CNS benefits with some SERMs. Proton magnetic resonance spectroscopy in elderly women who had taken tamoxifen for at least 2 years for breast cancer treatment demonstrated a reduction in myo-inositol, a glial marker that reflects glial proliferation in response to brain injury (Ernst *et al.*, 2002), suggesting a neuroprotective effect of tamoxifen. Although the disease status of these women complicates interpretation of these data, it is interesting to note that in a comparable population of women taking estrogen replacement therapy, but without breast cancer, a similar effect on myo-inositol was observed (Ernst *et al.*, 2002). Assessment of adverse CNS events in the randomized, placebo-controlled osteoporosis registration studies for raloxifene revealed no negative effects during the course of safety assessment, these studies did suggest some interesting trends for raloxifene related improvement in cognitive performance, specifically, higher verbal memory and attention scores, putative harbingers of mild cognitive impairment and Alzheimer's disease (Nickelsen *et al.*, 1999; Yaffe *et al.*, 2001). Women over the age of 70, in particular, experienced smaller declines in memory and attention on raloxifene (Yaffe *et al.*, 2005). In studies focused on the risk for Alzheimer's disease in postmenopausal women with osteoporosis, Yaffe and colleagues (2005) reported one-third risk reduction of mild cognitive impairment with a trend for reduced risk of Alzheimer's disease. In both studies where cognitive improvement was suggested with raloxifene, it is worth noting that the benefit was primarily observed in women receiving 120 mg/day of raloxifene. These benefits of raloxifene were not observed in similar women taking 60 mg/day of raloxifene, the standard and approved daily dose for osteoporosis prevention and treatment and breast cancer risk reduction. The potential requirement for a greater dose of raloxifene to generate meaningful CNS benefits is consistent with preclinical literature, such as the increase in hippocampal choline acetyltransferase activity, which also requires higher doses of raloxifene than are necessary for the bone effects in OVX rats (Wu *et al.*, 1999), and the recognition that raloxifene has a poor penetration of the blood-brain barrier (Bryant *et al.*, 1997). The relative estrogen background may be a complicating factor, because women with undetectable circulating estrogen levels prior to administration of raloxifene show a greater benefit for mild cognitive impairment risk than women with higher circulating estrogen levels at baseline (Yaffe *et al.*, 2005). The precise process of cognitive function that the SERMs affect remains an area of research. Although executive function/decision making is the ultimate output of cognitive networks, these activities depend on more basic processes, such as alertness and arousal, to be operational. To this regard, it is interesting to note that in a study conducted in a small cohort of elderly men using functional magnetic resonance imaging, raloxifene improved memory function via increasing arousal during initial encoding of information, likely via a neurogenic effect (Goekoop *et al.*, 2005).

The important principle of drug exposure for the SERMs will be reviewed in the next section, but is particularly germane to the brain, as a central pharmacological tenant, is that for agents to exert their effect on a receptor, they must be available to the receptor. The limited brain exposure with raloxifene predicted by the preclinical models is certainly an important factor. ER-binding studies also suggest reduced exposure of tamoxifen in the brain relative to peripheral tissues, such as the uterus (Bowman *et al.*, 1982). Clearly the functional studies with various SERMs in animal models with raloxifene and tamoxifen argue strongly that there is sufficient exposure to exert a biological response to these SERMs in the brain. However, critical factors such as dose, duration, and agonist/antagonist potential may be severely or subtly affected by the ability of the molecule to penetrate the brain. As a result, dose–response relationships that are expected based on peripheral tissues may not be monitored for effects within the CNS.

General Safety Profile and Other Pharmacological Considerations

Other Safety

In addition to the adverse events already reviewed (i.e., VTEs observed with all SERMs and uterine stimulation observed with some SERMs), SERMs are associated with other untoward effects that should be considered in the risk/benefit decision for each patient. Of these other adverse events observed in clinical trials, leg cramps and the induction of hot flushes are observed in women, to at least some extent, with all of the SERM molecules depicted in Figure 3. Hot flushes, or vasomotor symptoms, are a hallmark indicator of the menopausal transition, occurring in up to 70% of U.S. women. The incidence of hot flushes is likely reflective of declining, or changing, estrogen status and typically abates when circulating estrogen levels reach their postmenopausal, steady-state concentration. However, in a small percentage of women, vasomotor symptoms can be severe and extend well into the menopause. Estrogen replacement clearly is effective in relieving postmenopausal hot flushes. With SERM use, however, it is likely that an estrogen withdrawal-like response is initiated producing a state similar to that experienced by women who are estrogen depleted with subsequent hot flushes. Although it is unclear as to whether this phenomenon is caused by estrogen antagonist or agonist properties of the SERM at ER in hypothalamic thermoregulatory centers, SERM-induced hot flushes are transient in nature, because, with continued use in most cases, this side effect subsides, typically within 6 months, likely as the thermoregulatory setpoint reestablishes (Tataryn *et al.*, 1980). Consistent with this proposed mechanism, proximity to the climacteric state may influence the incident rate, and severity, of SERM-induced hot flushes. In postmenopausal women over the age of 55, significantly fewer hot flushes are observed in response to raloxifene compared with younger postmenopausal women. In a similar context, tamoxifen-induced hot flushes tend to be more severe in premenopausal breast cancer patients than in postmenopausal patients.

One problem in the assessment of the incident rate of hot flush induction following SERM administration is the relatively high placebo response rate in the postmenopausal population. In observational studies performed on randomized, placebo-controlled trials, the rate of reported hot flushes in postmenopausal women receiving placebo was 21% over a 30-month trial period (Cohen and Lu, 2000). In this study, the incidence of hot flushes in postmenopausal women using raloxifene was 28%. Others have confirmed an approximate 7% increase in hot flush incidence as a side effect of raloxifene use (Davies *et al.*, 1999). Of note, the hot flushes induced by raloxifene are in the mild to moderate category in terms of severity, as severe hot flushes in postmenopausal women using raloxifene occur at a rate indistinguishable from that of placebo controls. Finally, the increase in hot flush incidence with raloxifene is transient, because no differences relative to placebo controls are observed after 6 months (Davies *et al.*, 1999).

The observation of hot flush incidence is typical for other SERM molecules as well. Tamoxifen use in both premenopausal and postmenopausal women for breast cancer treatment has long been associated with hot flushes as a side effect in 10% to 20% of patients, and is more common in women with higher estrogen levels (Legha, 1988). Toremifene also induces hot flushes at rates equivalent to or slightly greater than tamoxifen (Hays *et al.*, 1995). Clomiphene use for induction of ovulation increases hot flushes, as well (Derman and Adashi, 1994). Levormeloxifene (Alexanderson *et al.*, 2001), lasofoxifene (McClung *et al.*, 2006), and bazedoxifene (Adachi *et al.*, 2007) also increase hot flush incidence in postmenopausal women.

An interesting note of relevance to hot flushes and SERMs is the potential application of SERMs in combination with estrogen use for the treatment of hot flushes. In a small study of postmenopausal women, who were using 17β-estradiol in combination with raloxifene, a significant decrease in hot flushes was observed (compared with raloxifene treatment alone), although signs of endometrial stimulation were detected as well with this combination (Stoval *et al.*, 2007). Large, randomized, placebo-controlled clinical trials have evaluated the combination of bazedoxifene and conjugated equine estrogens as a potential alternative for treatment of hot flushes (and potentially other menopausal symptoms) without the need to include a progestin for maintenance of uterine safety. Uterine assessment at 1- and 2-year intervals demonstrated the lack of endometrial hyperplasia for the bazedoxifene/conjugated equine estrogens combination (Pickar *et al.*, 2007), indicating that the SERM had effectively blocked the potent stimulatory action of the estrogenic component of the combination. The combination also produced an increase in lumbar spine BMD in postmenopausal women that was superior to both placebo and raloxifene (Lindsay *et al.*, 2007). Full assessment of the risk/benefit ratio of the bazedoxifene/conjugated equine estrogens combination for use in relief of menopausal symptoms will require full assessment of hot flush and other symptom efficacy, as well as effects on other adverse events, such as VTEs.

Other adverse events not already discussed that are associated with some of the triphenylethylene SERMs are those associated with the eye. These ocular-related untoward effects include retinopathy, macular crystal formation, corneal keratopathies, and cataracts. Eye pathologies have been primarily associated with the use of tamoxifen and toremiphene with comparable incidence of 7% to 10% (Hays *et al.*, 1995). Visual disturbances have also been noted with clomiphene use (Asch and Greenblat, 1976), but are not increased with non-triphenylethylene SERMs,

such as with raloxifene use in postmenopausal women (Cohen and Lu, 2000). Length of therapy increases the risk of cataract development with tamoxifen use (Paganini-Hill and Clark, 2000a). One mechanism that has been proposed for cataract formation with tamoxifen is the blockade of chloride channels in the lens of the eye, which are important for maintenance of lens hydration (Zhang *et al.*, 1994). Of importance, this effect of tamoxifen on chloride channels in the lens seems to be independent of interaction with ER, and as such, is likely off-target toxicity for certain triphenylethylene SERMs.

Pharmacokinetics

Pharmacokinetic properties of the SERMs are an important consideration in the overall effects of these molecules and have served as a focal point for development of novel and improved agents. For example, the third-generation SERMs arzoxifene, bazedoxifene, and lasofoxifene all have pharmacokinetic properties that represent improvements over raloxifene and tamoxifen. The ultimate advantage of these improvements to patients remains to be seen, as these molecules have yet to achieve registration approval. More information as to this impact will certainly be revealed in the upcoming years.

As previously indicated, tamoxifen generates active metabolite(s) with greater affinity and efficacy at the ER (Coezy *et al.*, 1982). After a single oral dose of tamoxifen, maximal plasma levels are reached within several hours with an elimination half-life of 5 to 7 days (Fromson *et al.*, 1973). Steady-state concentrations are attained within 3 to 4 weeks of chronic dosing (Adam *et al.*, 1980). The potential for preferential tissue distribution to some tissues was suggested in animal studies where greater levels of radioactive tamoxifen were detected in mammary gland, uterus, and liver than in blood (Furr and Jordan, 1984). In humans, elevated uterine levels of tamoxifen, with respect to circulating concentrations, were observed with endometrial levels twice that of myometrial or cervical concentrations (Fromson and Sharp, 1974). The primary route of elimination of tamoxifen follows hepatic metabolism, primarily glucuronidation, and subsequent biliary excretion with fairly little of the parent molecule being excreted in the urine and the potential for enterohepatic recirculation suggested in animal studies (Furr and Jordan, 1984).

Toremifene also is a triphenylethylene SERM that generates active metabolites (i.e., deaminohydroxytoremifene; DeGregorio *et al.*, 2000). Peak plasma concentrations of toremifene occur within 2 to 4 hours after a single oral dose, with nearly complete absorption, and plasma levels are linear with dose over a fairly wide dose range (Anttila *et al.*, 1990). The elimination half-life of toremifene is 5 days, and steady-state circulating concentrations are reached within 2 to 4 weeks of chronic dosing. There is evidence in animal models for relatively increased tissue distribution of toremifene in some tissues, with mammary gland uptake similar to tamoxifen (Kargas *et al.*, 1989). Toremifene is extensively metabolized in the liver via demethylation, hydroxylation, and side-chain oxidation modifications (Anttila *et al.*, 1990) and the primary route of elimination is fecal elimination following enterohepatic recirculation (Anttilla *et al.*, 1990). Hepatic impairment significantly increases the half-life of toremifene, nearly doubling it (Anttila *et al.*, 1995).

Clomiphene is the only triphenylethylene SERM in current clinical use for which there are no known active metabolites. Clomiphene is a racemic mixture of *cis*- (zuclomiphene) and *trans*- (enclomiphene) isomers that is rapidly absorbed following oral administration. Peak plasma concentrations are achieved in approximately 6 hours, with a half-life of approximately 5 days (Dickey and Holtkamp, 1996), although metabolites have been detected up to 6-weeks after a single dose, suggesting likely enterohepatic recirculation (Kausta *et al.*, 1997). Clomiphene is hepatically metabolized and fecally excreted (Adashi, 1996).

The pharmacokinetics of raloxifene, a benzothiophene SERM, have some features similar to the triphenylethylenes but also some considerable differences. Like tamoxifen and its relatives, raloxifene is rapidly absorbed from the gastrointestinal tract after oral administration, with peak blood levels attained in approximately 6 hours and 60% of the oral dose absorbed (Heringa, 2003). Raloxifene is also highly bound to plasma proteins (approximately 95%; Heringa, 2003). However, in contrast to the triphenylethylenes, the elimination half-life of raloxifene is considerably shorter at 28 hours and there are no known active metabolites of raloxifene in humans or rodents. Although there is virtually no P450 metabolism of raloxifene in the liver, it is extensively metabolized by first-pass hepatic glucuronidation, yielding an absolute oral bioavailability of only approximately 2% in humans (Snyder *et al.*, 2000). Raloxifene is widely distributed, and as with the triphenylethylenes, very little is excreted in the urine with the bulk of clearance through biliary excretion and loss in the feces (Knadler *et al.*, 1995).

Relatively less information is available on pharmacokinetic profiles of the third-generation SERMs, arzoxifene, bazedoxifene, and lasofoxifene. Lasofoxifene demonstrates improved bioavailability because the molecule was designed to resist intestinal wall glucuronidation (Gennari *et al.*, 2006). The elimination half-life of lasofoxifene is 165 hours, and there is a linear relationship between plasma concentrations and dose (Gardner *et al.*, 2006). The primary metabolic route for lasofoxifene is hepatic oxidation and subsequent conjugation (Branson *et al.*, 2006). Bazedoxifene produces an absolute bioavailability of 6.2% following an oral dose, which is about threefold greater than that produced by raloxifene. Bazedoxifene demonstrates kinetic linearity at dose levels of 5 to 40 mg

(Ermer *et al.*, 2003). Maximal circulating concentrations of bazedoxifene are achieved within 1 to 2 hours after oral exposure and the elimination half-life is approximately 28 hours with steady-state circulating levels attained in 7 days (Ermer *et al.*, 2003). As with raloxifene, there is very little P450-mediated metabolism of bazedoxifene, and glucuronidation is the major metabolic route. The primary route of elimination is the feces, with evidence for enterohepatic recirculation (Chandrasekaran *et al.*, 2003). Arzoxifene also exhibits pharmacokinetic advantages over raloxifene. Over a dosage range of 10 to 100 mg, blood levels of arzoxifene increase linearly with respect to dose, with maximal levels attained at 2 to 6 hours and an elimination half-life of 30 to 35 hours over this dose range (Munster *et al.*, 2001). Arzoxifene is metabolized (demethylated) to desmethylarzoxifene, which is an active metabolite with a high binding affinity for the ER (Rash and Knadler, 1997).

FUTURE DIRECTIONS WITH SERMS

In addition to the use of SERMs for osteoporosis, breast cancer, or the induction of ovulation, the ability of ER-activity-modulating agents to favorably impact other diseases and syndromes, both in women and men, is under active discovery and early clinical development efforts. The overall scope of these drug discovery efforts is broad and beyond the focus of this review, and thus, only a few examples of potential new SERM agents or novel applications for existing SERMs are briefly discussed here.

SERMs for Hot Flushes

As previously mentioned, estrogen replacement is a highly effective therapeutic tool for relief from hot flushes induced by estrogen deficiency. However, concerns around estrogen use often limits patient willingness to initiate estrogen replacement therapy, particularly in women with a history of breast cancer. The lack of sufficiently effective alternatives for hot flushes creates an undressed medical need for new hot flush treatment alternatives. Currently available SERMs do not offer benefit for hot flushes; indeed, they induce vasomotor symptoms as a side effect in some women as previously indicated. Preclinical drug discovery efforts have focused on identifying molecules with a favorable SERM-profile on bone, mammary, and uterus that also produce an estrogen-like attenuation of thermoregulatory vasomotor responses. A spiroindane SERM was identified by Watanabe *et al.* (2003) that produces estrogen-like effects on thermoregulation and bone in OVX rats, with only a stimulation of the uterus and modest stimulatory effects on mammary tumor cell proliferation. A more favorable preclinical profile was reported for a benzopyran SERM, with a clear estrogen-like effect on elevated tail skin temperature in an OVX rat hot flush model and prevention of bone loss on OVX rats. This benzopyran produced a more complete estrogen antagonist profile with minimal uterine stimulatory activity and minimal stimulation of MCF-7 cells *in vitro* (Wallace *et al.*, 2006). A third, chromane-derived SERM also shows efficacy in a rat model of hot flushes with minimal stimulation of Ishikawa or MCF-7 tumor cell lines (Jain *et al.*, 2006). A key point of emphasis is that, because animals do not experience clinical "hot flushes," contrived models typically use induced withdrawal in morphine-dependent rats as the gold standard for assessment of thermoregulatory modulation. None of these models have reported clinical results as yet, and as such, remain in the proof-of-concept phase of inquiry.

SERMs for Vaginal Atrophy/Dryness

Vaginal atrophy and dryness are also common features of estrogen deficiency that respond favorably to estrogen replacement, delivered systemically or locally. As with vasomotor symptoms, SERMs that may produce beneficial vaginal effects are currently under clinical investigation. As previously discussed, lasofoxifene was evaluated in phase 3 clinical trials for potential vaginal benefits. Currently, ospemifene, a triphenylethylene SERM, is in early clinical development for vaginal atrophy. Ospemifene, a metabolite of toremifene, prevents bone loss and lowers serum cholesterol in OVX rats and inhibits dimethylbenzanthrocene-induced mammary tumors in rats (Qu *et al.*, 2000). In postmenopausal women, administration of ospemifene for 3 months produced an estrogen-like effect to suppress FSH levels, and also produced a clear estrogenic effect on vaginal epithelium, with neither effect observed in a raloxifene comparator arm. Over this short treatment period, ospemifene produced no apparent uterine endometrial stimulation (Komi *et al.*, 2005). In postmenopausal women, ospemifene reduced bone turnover markers with a magnitude, and in a time frame, that was comparable to that observed with raloxifene (Komi *et al.*, 2006). Currently under preclinical evaluation for this indication is the chromane SERM described under the "hot flushes" subheading earlier. In addition to the hot flush-reducing activity this molecule also increased the amount of vaginal fluid in OVX rats (Jain *et al.*, 2006), providing preclinical indications for possible additional benefits of this SERM on postmenopausal vaginal symptoms.

SERMs for Gynecological Indications

A number of gynecological disorders, such as endometriosis and leiomyoma (uterine fibroids) are frequently estrogen-driven pathologies. Given their ability to antagonize estrogen action in the uterine environment, SERMs are a potential option for these diseases. Clearly, estrogen deprivation, such as with chronic GnRH administration,

is efficacious for endometriosis and leiomyoma, although bone loss induced by ovarian shutdown produced by these regimens limits the time of therapy, with symptoms typically returning upon discontinuation of the GnRH agonist. As previously mentioned, SERMs like raloxifene produce some benefit versus these gynecological disorders. However, because the primary treatment population for endometriosis and leiomyoma is premenopausal women, the concern over ovarian stimulation and ovarian cyst formation, as has been observed with tamoxifen in these women (Cook *et al.*, 1995), has limited application of currently available SERMs for therapy of estrogen-associated gynecological disorders in ovulating women. In preclinical studies a naphthalene-SERM, with minimal CNS penetration (Richardson *et al.*, 2007), was identified. This molecule exhibits a unique profile among SERMs in preclinical testing with potent and complete uterine antagonism in the uterus of estrogen-replete animals, lack of uterine stimulation in estrogen-deficient animals, and a prevention of bone loss in OVX animals without stimulation of the HPO axis with subsequent elevation of ovarian-derived estrogen and ovarian cyst production in ovary-intact rats (Geiser *et al.*, 2005).

SERMs for Osteoarthritis

A loose connection between estrogen status and osteoarthritis has long been known, first identified in 1925 by Cecil and Archer and later confirmed by multiple epidemiological studies (Wluka *et al.*, 2000). Although there has been some controversy over the relative benefit in osteoarthritis provided by estrogen replacement, there is a growing body of evidence suggesting significant benefit, ranging from reduced risk of radiographic osteoarthritis in postmenopausal women who use estrogen (Nevitt *et al.*, 1996) to a reduction in hip and knee joint replacement in women using unopposed estrogen (Cirillo *et al.*, 2006). The presence of ER in articular cartilage in both animals (Tsai and Liu, 1992) and humans where both ERα and ERβ are expressed (Ushiyama *et al.*, 1999) and beneficial effects of estrogen on cartilage in animal models of osteoarthritis (Turner *et al.*, 1997), suggests that a SERM approach could provide a safe and effective therapeutic alternative for osteoarthritis disease modification. Indeed, some beneficial effects of SERMs have been established in osteoporosis clinical trials that are suggestive of a benefit in the prevention or treatment of osteoarthritis. Levormeloxifene reduced cartilage degradation as determined by collagen type II degradation products (CTX-II) in postmenopausal women (Christgau *et al.*, 2004), and raloxifene was associated with a reduction in musculoskeletal pain in an observational study of postmenopausal women, as well as a reduction in consumption of analgesics (Scharla *et al.*, 2006). In preclinical development, a chromane-SERM both reduced CTX-II levels in OVX rats, as well as reduced articular cartilage degradation and erosion in the knee of OVX rats with minimal uterine stimulation (Hoegh-Andersen *et al.*, 2004), suggesting the potential for development of ER-selective disease-modifying agents for osteoarthritis.

SERMs for Use in Males

A few SERMs have been studied in men for various potential therapeutic applications. For example, clomiphene was evaluated for the management of male infertility, where some beneficial effects on seminal vesicle hypofunction owing to high sperm chromatin stability were identified (Gonzalez *et al.*, 1998). Consistent stimulation of FSH and LH can also be attained in men with clomiphene, which can be associated with reversal of infertility in a subset of hypogonadotrophic men (Whitten *et al.*, 2006). Similar data have been generated with toremifene. Administration of toremifene for 3 months to men with idiopathic oligozoospermia increased sperm count and motility and improved sperm morphology, most likely owing to increased FSH secretion (Farmakiotis *et al.*, 2007).

Applications of SERMs to various endocrine tumors have met with some success in men as well. High-dose estrogen has long been recognized as beneficial for certain forms of prostate cancer (Huggins and Hodges, 1941), via reduction of circulating androgens and likely direct antiproliferative effects on the prostate (Ferro *et al.*, 1989). These effects of estrogen are likely ER-mediated, which is present in the prostate epithelium (ERβ) and stroma (ERα; Lau *et al.*, 2000). SERMs are quite effective antimetastatic agents in animal models of prostate cancer. For example, in the PAIII rat prostatic adenocarcinoma model, raloxifene markedly reduces tumor metastases to lymphatic and pulmonary beds and increases survivability (Neubauer *et al.*, 1995). Accordingly, some stabilization of androgen-independent prostate cancer was observed with raloxifene in small pilot clinical trials (Shazer *et al.*, 2006). Although, in other phase 2 clinical trials with fairly high doses of toremiphene, no benefit was observed in androgen-independent prostate cancer patients (Stein *et al.*, 2001). Whether this reflects a difference among various SERMs for this particular indication or simply insufficient clinical trial experience for this indication remains an uncertainty. Another important consideration is the dose, because in more recent work, considerably lower dose levels of toremifene (doses comparable to those used in women for breast cancer therapy) led to a reduction in the incidence of prostate cancer in a high-risk population of men, suggesting that toremifene might be effective at prevention of prostate cancer (Price *et al.*, 2006). SERMs are also potentially valuable as an adjunct to other common forms of prostate cancer therapy, specifically the use of androgen deprivation therapies, which are frequently associated with bone loss, increased risk of cardiovascular disease, gynecomastia, as well as

a number of other undesirable side effects (Sharifi *et al.*, 2005). The beneficial effect of SERMs on a number of the side effects of androgen deprivation therapy has led to their evaluation in combination with agents such as the GnRH agonists—a commonly used form of androgen deprivation therapy. In men receiving GnRH agonists, raloxifene produced a significant increase in BMD of the hip (1.1% increased hip BMD vs. 2.6% decline in hip BMD in men not receiving raloxifene; Smith *et al.*, 2004), with a trend for increase in spine BMD. Recent results with toremifene suggest a similar ability to counter untoward effects of androgen deprivation therapy, because an improvement in bone turnover biomarkers and BMD was observed (Taneja *et al.*, 2006). It is important to note, though, that BMD alone is not sufficient and full assessment of the impact of these agents on bone fracture is required.

SERMs have also been evaluated for therapeutic benefit in male breast carcinoma, a low-incidence tumor with males representing only about 1% of all breast cancer diagnoses. However, a very high percentage of male breast carcinomas are ER and progesterone receptor positive (Kinne, 1991), suggesting a possible benefit to be derived from ER blockade. Owing to the low incidence of male breast carcinoma, clinical trial sizes are small, but in 301 cases of male breast cancer, adjuvant therapy with tamoxifen for 1 year was associated with 86% reduction of ER/progesterone receptor-positive patients showing a positive result (Ribeiro, 1985). A third tumor type that is responsive to SERM therapies is desmoid tumors, the benign mesenchymal tumors that can lead to destruction of vital structures and/or organs. In clinical trials involving only small numbers of patients to date, both raloxifene (Tonelli *et al.*, 2003) and toremifene (Heidemann *et al.*, 2004) decreased desmoid tumor and mesenteric fibromatosis size and symptoms, possibly via a combined antiangiogenic and antiproliferative mechanism.

A number of other potential uses for SERMs in males have been explored in clinical trials. In adolescent boys with persistent pubertal gynecomastia, a significant reduction in breast nodule diameter with tamoxifen (41% of patients) and raloxifene (86% of patients) was observed, with no significant side effects, following 6 to 9 months of dosing (Lawrence *et al.*, 2004). In men with acromegaly, both tamoxifen and raloxifene decreased circulating IGF-1 levels (Cozzi *et al.*, 1997; Dimaraki *et al.*, 2004). In elderly men, raloxifene enhanced brain activation, with improved retrieval of information in memory function tests (Goekoop *et al.*, 2006), and in another trial, increased circulating testosterone levels (Duschek *et al.*, 2004).

SUMMARY

SERMs are a diverse class of molecules that affect a broad spectrum of biological systems with potential therapeutic benefit for a variety of diseases. Current concern over long-term use of estrogen-containing regimens has created an opportunity for application of SERMs to chronic indications such as osteoporosis treatment or prevention. The unique SERM profile also allows their use in other chronic indications of interest to postmenopausal women, most notably, breast cancer risk reduction and treatment. However, safety considerations are a very important consideration for SERM use in these chronic indications. The pleiotropic nature the ER and its role in numerous physiological systems raise the importance of considering potential SERM benefits and/or adverse events in the cardiovascular system and other tissues.

As reviewed here, several central themes are key considerations for use and development of SERMs in postmenopausal women. These include:

1. A central feature of all SERMs and a central aspect of their mechanism of action, is high-affinity interaction with ERα and ERβ (for SERMs currently used in humans). Each SERM produces a unique conformation of the SERM:ER complex, which dictates which cofactor proteins bind to activate or repress gene transcription in a given cell.
2. A wide variety of chemical scaffolds can be used to generate molecules with SERM-like properties. Key structural features of the molecular backbone of SERMs are the location of hydroxyl moieties that interact with specific residues within the binding pocket of the ER and the presence of a basic side chain that, in some cases, reorients specific domains of the ligand-bound ER.
3. Bone efficacy in estrogen-deficient states, both in animal models and postmenopausal women, are features demonstrated by most SERMs. Although the skeletal response in terms of BMD may not be as robust with some SERMs as is observed with other skeletal agents (such as the bisphosphonates), SERMs produce comparable rates of fracture reduction. This latter observation suggests likely important beneficial effects of SERMs on bone quality.
4. SERMs in clinical use today share certain common adverse events in some women, with induction of hot flushes and VTEs being the most common. However, the most important safety parameter SERMs used for chronic indications, such as osteoporosis, revolves around uterine safety. SERMs that have failed in clinical trials for osteoporosis have done so primarily because of excessive risk for uterine side effects, as predicted by excessive stimulation of uterine endometrial thickness or induction of uterine prolapse.
5. The widespread distribution of the ER in cardiovascular, central nervous system, and reproductive tissue create the possibility of either additional potential benefits of SERMs in these tissues,

or the possibility of adverse events. Clearly these then represent important tissues in the toxicological and safety assessment of SERMs. Simply put, no two SERMs are necessarily equal in terms of overall tissue activity profiles. Careful preclinical and clinical evaluation is necessary to fully understand the risk/benefit ratio of novel SERM agents across multiple tissue types.

6. Pharmacokinetics play an important role in determining the magnitude and duration of SERM efficacy responses. Third-generation SERM molecules are emerging for osteoporosis with decidedly improved bioavailability and linear kinetics for dose and exposure.

A wide variety of new SERM agents are beginning to enter early-stage clinical development for use in multiple indications in women, and even men, that could significantly expand the armory of SERM-like molecules available to clinicians for the treatment of a myriad of human diseases.

Chapter 42

Mechanisms of Estrogen Action in Bone

Roberto Pacifici
Division of Endocrinology, Metabolism, and Lipids Department of Medicine Emory University Atlanta, Georgia

INTRODUCTION

Postmenopausal osteoporosis is a heterogeneous disorder characterized by a progressive loss of bone tissue that begins after natural or surgical menopause and leads to fracture within 15 to 20 years from the cessation of the ovarian function. Although suboptimal skeletal development ("low peak bone mass") and age-related bone loss may be contributing factors, a hormone-dependent increase in bone resorption and accelerated loss of bone mass in the first 5 or 10 years after menopause appears to be the main pathogenetic factor (Riggs and Melton, 1986a; Riggs and Melton, 1986b) of this condition. The ability of bones to withstand mechanical loading depends upon the establishment and the maintenance of proper bone mass and architecture. In women, the rapid loss of bone associated with menopause alters bone structure with consequent increase in bone fragility, although how estrogen influences the relationship between bone mass and bone loading remains largely unknown (Lanyon *et al.,* 2004).

That estrogen deficiency plays a major role in postmenopausal bone loss is strongly supported by the higher prevalence of osteoporosis in women than in men (Nilas and Christiansen, 1987), the increase in the rate of bone mineral loss detectable by bone densitometry after artificial or natural menopause (Genant *et al.,* 1982; Riggs *et al.,* 1981; Slemenda *et al.,* 1987), the existence of a relationship between circulating estrogen and rates of bone loss (Johnston *et al.,* 1985; Ohta *et al.,* 1992), and the protective effect of estrogen replacement with respect to both bone mass loss and fracture incidence (Ettinger *et al.,* 1985; Lindsay *et al.,* 1980). Both a decreased ovarian production of sex steroids and an increase in follicle-stimulating hormone (FSH) production secondary to estrogen deficiency contribute to postmenopausal bone loss (Iqbal *et al.,* 2006; Sun *et al.,* 2006).

Menopause also alters the expression of estrogen receptors (ER) in bone. A reduction in ERα expression after estrogen withdrawal has been demonstrated and results in a less osteogenic response to loading (Armstrong *et al.,* 2007; Zaman *et al.,* 2006). Thus, the bone loss associated with estrogen deficiency could be regarded, in part, as a consequence of reduction in ERα expression in bone cells that reduces the anabolic response of bone cells to strain.

The potential fracture risk for any postmenopausal female depends on the degree of bone turnover, the rate and extent of bone loss, associated disease processes that induce bone loss, age of menarche and menopause, and the bone mass content achieved at skeletal maturity. The latter depends on the extent of estrogen exposure, habitual physical activity, quantity of calcium intake, and genetic predisposition.

The bone-sparing effect of estrogen is mainly related to its ability to block bone resorption (Weitzmann and Pacifici, 2005), although stimulation of bone formation is likely to play a contributory role (Manolagas *et al.,* 2002). Estrogen-dependent inhibition of bone resorption is, in turn, owing to both decreased osteoclastogenesis and diminished resorptive activity of mature osteoclasts. However, inhibition of osteoclast formation is currently regarded as the main mechanisms by which estradiol (E_2) prevents bone loss (Weitzmann and Pacifici, 2005).

CELLS AND CYTOKINES THAT REGULATE OSTEOCLAST FORMATION

The dominant acute effect of estrogen is the blockade of new osteoclast formation. Osteoclasts arise by cytokine-driven proliferation and differentiation of monocyte precursors that circulate within the hematopoietic cell pool (Teitelbaum, 2000). This process is facilitated by bone marrow stromal cells, which provide physical support for nascent osteoclasts and produce soluble and membrane-associated factors essential for the proliferation and differentiation of osteoclast precursors (Fig. 1).

The minimal essential cytokines required for osteoclast formation under basal conditions are receptor activator of NFκB ligands (RANKL) and macrophage colony-stimulating factors (M-CSF). These factors are produced primarily by bone marrow stromal cells, osteoblasts, and activated T cells (Khosla, 2001). RANKL is a tumor

Principles of Bone Biology, 3rd Edition

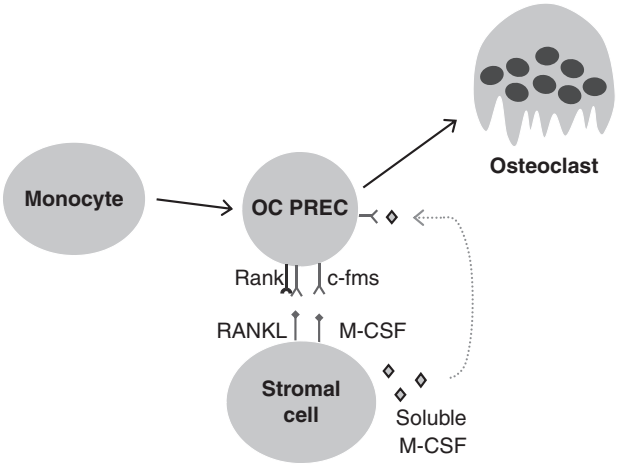

FIGURE 1 Cells and cytokines responsible for physiological osteoclast formation. Osteoclast precursors may be differentiated from the monocyte/macrophage population, among which they circulate, by virtue of their expression of the receptor RANK. When RANKL binds to its receptor (RANK) in the presence of the trophic factor M-CSF, which in turn binds to its receptor, colony-stimulating factor receptor 1 (c-Fms), osteoclast precursors differentiate and fuse together to form mature multinucleated bone resorbing osteoclasts. Under physiological conditions the dominant source of RANKL and M-CSF in the bone marrow microenvironment is from the bone forming cells, the osteoblasts, and their stromal cell precursors.

necrosis factor (TNF) superfamily member that exists in membrane-bound and soluble forms. RANKL binds to the transmembrane receptor RANK expressed on the surface of osteoclasts and osteoclast precursors. RANKL also binds to osteoprotegerin (OPG), a soluble decoy receptor produced by numerous hematopoietic cells. Thus, OPG, by sequestering RANKL and preventing its binding to RANK, functions as a potent anti-osteoclastogenic cytokine (Khosla, 2001). RANKL promotes the differentiation of osteoclast precursors from an early stage of maturation into fully mature multinucleated osteoclasts. RANKL is also capable of activating mature osteoclasts, thus stimulating the capacity of these cells to resorb bone. M-CSF induces the proliferation of early osteoclast precursors, the differentiation of more mature osteoclasts, the fusion of mononucleated preosteoclasts, and increases the survival of mature osteoclasts.

Although RANKL and M-CSF are essential for physiologic osteoclast renewal, additional cytokines are responsible for the upregulation of osteoclast formation observed in a variety of conditions such as inflammation, hyperparathyroidism, and estrogen deficiency (Grey *et al.,* 1999; Pacifici, 1998). One such factor is TNF, a cytokine that enhances osteoclast formation by upregulating the stromal cell production of RANKL and M-CSF (Hofbauer *et al.,* 1999; Sherman *et al.,* 1990), and by augmenting the responsiveness of osteoclast precursors to RANKL (Cenci *et al.,* 2000; Lam *et al.,* 2000). The ability of TNF to increase the osteoclastogenic activity of RANKL is because of synergistic interactions at the level of NFκB and AP-1 signaling (Lam *et al.,* 2000). In addition, TNF and RANKL synergistically upregulate RANK expression in osteoclast precursors (Zhang *et al.,* 2001). Furthermore, TNF stimulates osteoclast activity (Fuller *et al.,* 2002) thus further driving an imbalance between bone formation and bone resorption. Earlier studies have suggested that TNF inhibits osteoblastogenesis (Nanes, 2003), but recently it has been proposed that ascorbic acid masks the capacity of TNF to stimulate bone formation. Therefore in ascorbate-free culture systems TNF stimulates rather than inhibiting bone formation (Iqbal *et al.,* 2006). Additional studies will be required to define the net effect of TNF on bone formation *in vivo*.

Like TNF, interleukin-1 (IL-1) promotes RANKL expression by BM stromal cells and osteoblasts and stimulates osteoclast life span and activity. IL-1 directly targets osteoclast precursors and promotes osteoclast differentiation in the presence of permissive levels of RANKL. Furthermore, IL-1 mediates, in part, the osteoclastogenic effect of TNF by enhancing stromal cell expression of RANKL and by directly stimulating differentiation of osteoclast precursors (Wei *et al.,* 2005). TNF and IL-1 have potent anti-apoptotic effects in osteoclasts prolonging osteoclast life span and contributing toward accelerated bone resorption (Kwan Tat *et al.,* 2004).

Another cytokine relevant for osteoclast formation is IL-7 (Ross, 2003). IL-7 is a powerful lymphopoietic cytokine that has previously been recognized as a potent inducer of bone destruction *in vivo* (Miyaura *et al.,* 1997). How IL-7 leads to bone loss is controversial, and its mechanisms of action are only now beginning to be elucidated. IL-7 is a stimulator of both B- and T-cell lineages, and it has been suggested that IL-7 induces bone loss by a mechanism involving the expansion of cells of the B lineage, in particular $B220^{+}IgM^{-}$ B cell precursors (Masuzawa *et al.,* 1994; Miyaura *et al.,* 1997; Onoe *et al.,* 2000; Sato *et al.,* 2001), as estrogen deficiency has been reported to potently induce the expansion of these cells (Masuzawa *et al.,* 1994; Miyaura *et al.,* 1997). How B-lineage cells may lead to bone destruction is not presently understood but may involve overexpression of RANKL, a property of activated B cells (Manabe *et al.,* 2001). Alternatively, early $B220^{+}IgM^{-}$ precursor cells have been found to be capable of differentiating into osteoclasts in response to M-CSF and/or RANKL *in vitro* (Lee *et al.,* 2003; Sato *et al.,* 2001; Toraldo *et al.,* 2003) and hence IL-7 may increase the pool of early osteoclast precursors. However, other studies have reported that IL-7 inhibits the differentiation of $B220^{+}$ cells into osteoclasts *in vitro* in the presence of saturating concentrations of RANKL and M-CSF (Lee *et al.,* 2003). IL-7 is also established to regulate multiple stages of T-cell metabolism (Fry and Mackall, 2001). IL-7-/- mice are severely lymphopenic (von Freeden-Jeffry *et al.,* 1995) and IL-7 receptor -/- mice have been reported to

display increased bone volume and bone mineral density (Miyaura *et al.,* 1997). In contrast, IL-7 transgenic mice have expanded BM cavities with focal osteolysis of cortical bone and eroded bone surfaces (Valenzona *et al.,* 1996). These data suggest that IL-7 may induce bone loss by a T cell mediated mechanism. Indeed, IL-7 has been reported to induce production of RANKL by human T cells (Weitzmann *et al.,* 2000), and injection of IL-7 into mice *in vivo* induces bone destruction (Miyaura *et al.,* 1997; Toraldo *et al.,* 2003) by eliciting the secretion by T cells of the key osteoclastogenic cytokines RANKL and TNF (Toraldo *et al.,* 2003). In addition, levels of IL-7 are significantly elevated following ovariectomy. Attesting to the key role of IL-7 in the bone destruction associated with estrogen deficiency, *in vivo* IL-7 blockade, using neutralizing antibodies, is effective in preventing ovariectomy induced bone destruction (Weitzmann *et al.,* 2002). Furthermore, IL-7 induced osteoclastogenesis and bone loss is compounded by suppression of bone formation leading to uncoupling of bone formation from resorption.

An important, yet controversial, osteoclast-regulating factor is IFNγ. This factor was initially described as an anti-osteoclastogenic cytokine because it is a potent inhibitor of osteoclastogenesis *in vitro* (Takayanagi *et al.,* 2000). The notion that IFNγ is an inhibitor of bone resorption was reinforced by the finding that silencing of IFNγR-/- signaling leads to a more rapid onset of collagen-induced arthritis and bone resorption (Vermeire *et al.,* 1997) as compared to wild-type controls, and by the report that IFNγ decreases serum calcium and osteoclastic bone resorption in nude mice (Sato *et al.,* 1992; Tohkin *et al.,* 1994).

However, observations in humans and in experimental models of disease indicate that IFNγ promotes bone resorption and causes bone loss in a variety of conditions. Studies with IFN -/- and IFNR -/- mice have revealed that among these conditions are estrogen deficiency and endotoxin-induced bone disease (Cenci *et al.,* 2003; Gao *et al.,* 2007). Mice lacking IFNγ production are also protected against infection-induced alveolar bone loss (Baker *et al.,* 1999), whereas in erosive tubercoloid leprosy and psoriatic arthritis IFNγ production correlates positively with tissue destruction (Arnoldi *et al.,* 1990; Firestein *et al.,* 1990). In addition, randomized controlled trials have shown that IFNγ does not prevent bone loss in patients with rheumatoid arthritis (Cannon *et al.,* 1989; Veys *et al.,* 1997), nor the bone-wasting effect of cyclosporin A (Mann *et al.,* 1994). Furthermore, IFNγ has been reported to be efficacious in the treatment of osteopetrosis through restoration of bone resorption, both in humans (Key *et al.,* 1995) and rodents (Rodriguiz *et al.,* 1993). These latter findings conclusively demonstrate that in some conditions, including estrogen deficiency, the net effect of IFNγ *in vivo* is that of stimulating osteoclastic bone resorption.

The complex effects of IFNγ can be explained by the fact that IFNγ influences osteoclast formation both via direct and indirect effects (Gao *et al.,* 2007). IFNγ directly blocks osteoclast formation through targeting of maturing osteoclast (Takayanagi *et al.,* 2002). This effect is best observed *in vitro* (Fox and Chambers, 2000; Takayanagi *et al.,* 2000). However, IFNγ is also a potent inducer of antigen presentation and thus of T-cell activation. Therefore, when IFNγ levels are increased *in vivo*, activated T cells secrete pro-osteoclastogenic factors and this activity offsets the anti-osteoclastogenic effect of IFNγ.

A factor that plays a key, complex role in osteoclastogenesis is TGFβ, a pleiotropic growth factor with wide-ranging effects (Attisano *et al.,* 1994; Massague, 1990; Shi and Massague, 2003). Three isoforms (TGFβ1, 2, and 3) have been described in mammals and all use the same receptor complex for signaling (Massague, 1990). TGFβ1 is the predominant TGFβ isoform in lymphoid organs and is the major species in serum. Conversely, TGFβ2 and 3 are predominantly expressed in mesenchimal tissues and bone (Millan *et al.,* 1991; Pelton *et al.,* 1989; Schmid *et al.,* 1991). TGFβ is produced by a large number of cells including BM cells, osteoblasts, and stromal cells and is secreted in a latent form that must be activated to mediate its effects (Prud'homme and Piccirillo, 2000). Latent TGFβ is also abundantly present in the bone matrix. Latent TGFβ is noncovalently linked to a precursor molecule termed latency-associated peptide. Mature TGFβ can be released from the latent complex in an active form *in vitro* by a variety of treatments such as heating or acidification (Prud'homme and Piccirillo, 2000). Although several mechanisms of activation *in vivo* have been proposed, the precise mechanism is not known, though a role for extreme pH, free radicals, transglutaminase, or thrombospondin has been suggested (Derynck and Feng, 1997). The mechanism by which TGFβ is activated in the BM and lymphoid organs is presently unknown. Both *in vitro* and *in vivo* studies have shown that TGFβ1, 2, and 3 have complex effects on bone. For example, these growth factors stimulate or repress proliferation of osteoblasts and osteoclasts depending on cell lines used and culture conditions *in vitro* (Breen *et al.,* 1994; Fagenholz *et al.,* 2001; Spinella-Jaegle *et al.,* 2001; Yan *et al.,* 2001). Furthermore, mice with osteoblast-specific overexpression of TGFβ2 develop high turnover osteoporosis (Erlebacher and Derynck, 1996) while administration of TGFβ2 into the periosteum increases bone formation locally, but has no effects systemically.

TGFβ has also been implicated in the pathogenesis of ovariectomy-induced bone loss because local injection of TGFβ1 and TGFβ2 prevent bone loss at the site of the injection in ovariectomized rats (Beaudreuil *et al.,* 1995; Kalu *et al.,* 1993). Furthermore estrogen is known to upregulate the expression of TGFβ in murine osteoblasts, bone extracts, and BM cells (Finkelman *et al.,* 1992; Gray *et al.,* 1989) and long-term *in vivo* estrogen treatment has been shown to increase serum TGFβ1 and 2 levels in humans (Bord *et al.,* 2001).

T CELLS AND OVARIECTOMY-INDUCED BONE LOSS

Early work by McSheehy *et al.* and Thompson *et al.* showed that conditioned media derived from osteoblasts that were stimulated by a variety of factors increased osteoclastogenesis (McSheehy and Chambers, 1986a, 1986b; Thomson *et al.,* 1987; Thomson *et al.,* 1986). These results suggested that substances were expressed by osteoblasts that mediated differentiation of osteoclast precursors. After several inflammatory cytokines were found capable of producing this response, research focused on discerning their relative contributions in estrogen deficiency mediated bone loss. A lively debate ensued with proponents for IL-1, TNF, or IL-6 as the major players. The osteoclastogenic response to all three cytokines *in vitro* was based on sound data (Manolagas *et al.,* 1995; Pacifici, 1996). However; the use of different experimental models to evaluate cytokine production after estrogen deprivation may have yielded different results. Several studies reported increased production of TNF by cultures of mononuclear cells derived from postmenopausal women, an effect reversed by estrogen replacement (Pacifici *et al.,* 1991a; Ralston *et al.,* 1990; Rickard *et al.,* 1992). In this model, secretion of IL-1, but not always IL-6, mirrored that of TNF (Girasole *et al.,* 1992; Rickard *et al.,* 1992).

The production of TNF, interleukin-1, -4, -6, and IFNγ by blood cells can be negatively correlated with the estrogen level in premenopausal women. Interestingly, the levels of these cytokines also correlate inversely with bone density after menopause, bolstering the hypothesis that cytokines have an important role in menopausal bone loss (Zheng and Flavell, 1997).

The major cytokine responsible for augmented osteoclastogenesis during estrogen deficiency is TNF, and its relevance has been demonstrated in multiple animal models. For example, ovariectomy fails to induce bone loss in TNF knockout mice and in mice lacking the p55 TNF receptor (Roggia *et al.,* 2001). Likewise transgenic mice insensitive to TNF owing to the overexpression of a soluble TNF receptor (Ammann *et al.,* 1997), and mice treated with the TNF inhibitor TNF-binding protein (Kimble *et al.,* 1997) are protected from ovariectomy-induced bone loss. TNF neutralization has also been found to prevent the increase in bone resorption induced by E deficiency in humans (Charatcharoenwitthaya *et al.,* 2007).

The presence of increased levels of TNF in the BM of ovariectomized animals and in the conditioned media of peripheral blood cells of postmenopausal women is well documented (Pacifici *et al.,* 1991b; Ralston *et al.,* 1990; Shanker *et al.,* 1994). However, the cells responsible for this phenomenon had not been conclusively identified. Studies on highly purified BM cells have revealed that estrogen regulates the production of TNF by T cells, but not by monocytes (Cenci *et al.,* 2000), and that earlier identifications of TNF production by monocytes from estrogen-deficient donors were likely owing to T-cell contamination of monocytes purified by adherence. Thus, the ovariectomy-induced increase in TNF levels is likely to be because of, at least in part, T-cell TNF production. However, it is now clear that FSH directly stimulates TNF production from bone marrow granulocytes and macrophages (Iqbal *et al.,* 2006). Together the available evidence suggests that multiple cell lines contribute to the elevation of the BM levels of TNF observed after natural and surgical menopause. T cells are likely to be the main source of TNF under direct estrogen control, while BMMs and granulocytes may represent relevant FSH-regulated sources of TNF.

These findings in the mouse are concordant with those of others in humans, who demonstrated that adherent mononuclear blood cells contain $CD3^+$ $CD56^+$ lymphocytes, a TNF-producing subset of adherent T cells (Abrahamsen *et al.,* 1997). In that study the number of $CD3^+$ $CD56^+$ T cells was decreased by estrogen treatment and inversely correlated with bone density. These results are not surprising as T cells have the capacity to secrete a wide repertoire of cytokines, some pro-osteoclastogenic and some anti-osteoclastogenic. In the absence of strong activation signals, T cells appear to repress osteoclast formation (Grcevic *et al.,* 2000), but the relevance of this phenomenon *in vivo* has not been established. In contrast, activated T cells play a key role in the regulation of osteoclast formation through increased production of RANKL and TNF (Horwood *et al.,* 1999; Kong *et al.,* 1999; Weitzmann *et al.,* 2001). The net effect of T cells on osteoclast formation may consequently represent the prevailing balance of anti- and pro-osteoclastogenic T-cell cytokine secretion. However, it appears that during stimulated conditions such as inflammation (Kong *et al.,* 1999) and estrogen deficiency (Cenci *et al.,* 2000) pro-osteoclastogenic cytokines prevail.

Attesting to the relevance of T cells in estrogen deficiency induced bone loss *in vivo*, measurements of trabecular bone by peripheral quantitative CT and μCT revealed that athymic T-cell–deficient nude mice are completely protected against the trabecular bone loss induced by ovariectomy (Cenci *et al.,* 2000; Gao *et al.,* 2004; Roggia *et al.,* 2001) (Fig. 2). T-cell–deficient mice also fail to respond to ovariectomy with an expected increase in bone turnover (Cenci *et al.,* 2000; Gao *et al.,* 2004; Roggia *et al.,* 2001). T cells are key inducers of bone-wasting because ovariectomy increases T-cell TNF production to a level sufficient to augment RANKL-induced osteoclastogenesis (Cenci *et al.,* 2000). The specific relevance of T-cell TNF production *in vivo* was demonstrated by the finding that while reconstitution of nude recipient mice with T cells from wild-type mice restores the capacity of ovariectomy to induce bone loss, reconstitution with T cells from TNF-deficient mice does not (Roggia *et al.,* 2001). T-cell–produced TNF may

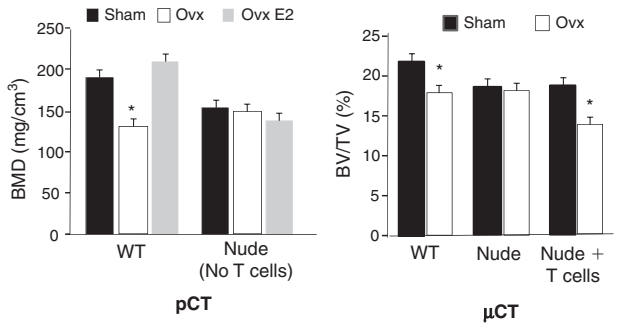

FIGURE 2 Nude mice are protected against the loss of trabecular bone induced by ovariectomy. Left panel. Trabecular BMD measurements by peripheral qCT at 4 weeks from surgery. further augment bone loss by stimulating T-cell RANKL production.

A confirmation of the key role of T cells in ovariectomy-induced bone loss has recently been provided by the demonstration that CTLA-4 Ig, an inhibitor of T-cell costimulation approved for the treatment of rheumatoid arthritis, completely prevents the bone loss induced by ovariectomy in wild-type mice (Grassi and Pacifici, 2007). CTLA-4 Ig is a human fusion protein combining the extracellular portion of cytotoxic T lymphocyte Ag 4 with the constant-region fragment of human IgG1 (Linsley *et al.,* 1992). CTLA4-Ig binds to human and murine CD80 (and CD86) blocking their interaction with CD28, promoting anergy and T-cell apoptosis (Moreland *et al.,* 2006; Ruderman and Pope, 2005). To our knowledge, this is the first immunosuppressant shown to prevent bone loss.

While another confirmation of the key role of T cells was provided by a report by Watanabe *et al.* (2001), a study by Lee *et al.* (2006) showed that nude mice lose trabecular bone after ovariectomy, although they are protected against the loss of cortical bone. In the same investigation ovariectomy was found not to induce cortical bone loss in either the spine or the femur in TCRα -/- and RAG2 -/- mice, although it induced trabecular bone loss in both strains. The partially negative outcome of that study is likely explained by age and experimental design differences, the presence of residual T cells in some strains, and by ovariectomy-independent alterations of bone resorption induced by either the concomitant lack of B cells (Li *et al.,* 2007) or genetic compensations.

In summary, upregulated T-cell production of TNF appears to be a key mechanism by which ovariectomy induces bone loss for the following reasons: (1) ovariectomy increases T-cell TNF production in the BM; (2) TNF increases the responsiveness of osteoclast precursors to RANKL (produced by either stromal cells/OBs or T cells), while simultaneously suppressing the magnitude of the compensatory increase in bone formation; (3) mice lacking or insensitive to TNF are completely protected against ovariectomy-induced bone loss; and (4) wild-type T-cell reconstitution in nude mice restores the capacity of ovariectomy to induce bone loss while reconstitution of nude mice with TNF -/- T cells fails to do so.

MECHANISMS OF ESTROGEN REGULATION OF T-CELL TNF PRODUCTION

The BM hosts fully functional mature T cells that exhibit several distinctive features. Both in humans and mice, T cells account for 3–8% of nucleated BM cells (Di Rosa and Pabst, 2005). The percentage of activated T cells is much higher in the BM than in other secondary lymphoid organs and this feature is both cytokine (IL-7 and IL-15) and antigen driven (Clark and Normansell, 1990; Di Rosa and Santoni, 2002). As a result, the BM is the lymphoid organ with the highest percentage and number of proliferating T cells, apart from the thymus.

The BM has long been recognized as a primary lymphoid organ, but it is now clear that the BM plays a key role in the immune response by hosting and regulating adaptive immunity. The BM serves as a site for the initiation of naïve T-cell responses (Feuerer *et al.,* 2003; Tripp *et al.,* 1997) and as a reservoir of CD4 and CD8 memory T cells (Di Rosa and Pabst, 2005). Donor T cells can be found in the BM a few hours after injection into recipient mice (Berlin-Rufenach *et al.,* 1999; Koni *et al.,* 2001) but memory T cells home to BM in higher numbers than naïve T cells (Di Rosa and Santoni, 2003). This selective T-cell homing is more pronounced in recipient mice that possess a normal T-cell repertoire (Di Rosa and Santoni, 2003). The mechanism by which CD8 memory T cells are preferentially recruited in the BM has recently been described (Mazo *et al.,* 2005). Because the entry into the BM of naïve T cells is limited by space availability and competition with other T cells (Di Rosa and Santoni, 2003), senescent memory T cells accumulate in the BM with aging (Effros, 2004). These T cells produce large amounts of TNF and exhibit increased reactivity to self-peptides and foreign Ag (Di Rosa and Santoni, 2003). Furthermore, a close anatomical co-localization of T cells and osteoclasts has been demonstrated. These reasons may explain why the accumulation of aging lymphocytes correlates with an increased incidence of fractures (Effros, 2004). In response to antigenic stimulation, memory CD4 and CD8 T cells of the BM produce effector cytokines (Di Rosa and Santoni, 2003; Mazo *et al.,* 2005). BM T cells encounter Ag presented by dendritic cells and BMMs, which reside or have returned to the BM. Resident dendritic cells and BMMs capture blood-born Ag, which circulates in the BM vessels, or Ag within the BM space (Feuerer *et al.,* 2004). BM T cells may move toward Ag bearing dendritic cells

in the BM or return to the BM after having encountered Ag loaded APCs outside the BM. In summary, BM T cells have specific functional characteristics that render them likely to play a pivotal role in ovariectomy-induced bone loss.

Ovariectomy upregulates T-cell TNF production primarily by increasing the number of TNF-producing T cells (Roggia *et al.,* 2001). This is the result of a complex pathway that involves the thymus and the BM (Fig. 3). In the BM, ovariectomy promotes T-cell activation, resulting in increased T-cell proliferation and life span through antigen presentation by macrophages and dendritic cells (Cenci *et al.,* 2003; Grassi and Pacifici, 2005). This process is owing to the ability of estrogen deficiency to upregulate the expression of MHCII and CD80 in macrophages and dendritic cells, respectively (Adamski *et al.,* 2004; Cenci *et al.,* 2003; Grassi and Pacifici, 2005).

Although the mechanism of T-cell activation elicited by estrogen deficiency is similar to that triggered by infections, the intensity of the events that follow estrogen withdrawal is significantly less severe and this process should be envisioned as a partial increase in T-cell autoreactivity to self-peptides resulting in a modest expansion in the pool of effector $CD4^+$ cells.

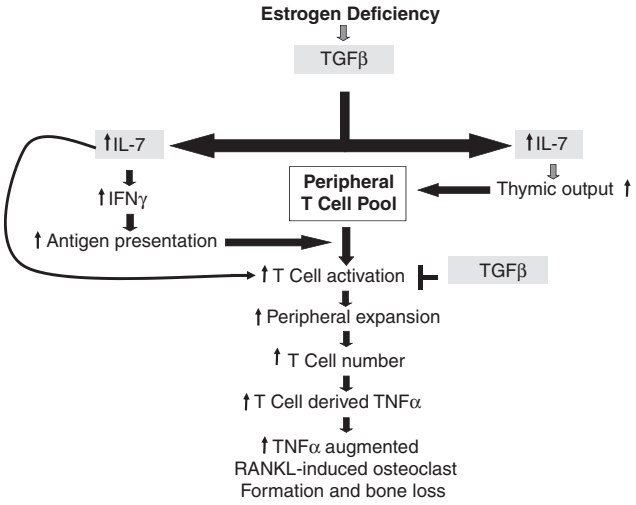

FIGURE 3 Schematic representation of the main mechanisms and feedback interactions by which estrogen deficiency leads to bone loss. The bone loss induced by estrogen deficiency is owing to a complex interplay of hormones and cytokines that converge to disrupt the process of bone remodeling. Estrogen deficiency leads to a global increase in IL-7 production in target organs such as bone, thymus, and spleen, in part through decreases in TGFβ. This leads to a first wave of T-cell activation. Activated T cells release IFNγ, which increase Ag presentation by dendritic cells and macrophages, amplifying T-cell activation and promoting release of the osteoclastogenic factors RANKL and TNF. Another mechanism by which estrogen suppresses T-cell TNF production is by regulating T-cell differentiation in the thymus. T-cell precursors originate in the bone marrow and migrate to the thymus where T-cell differentiation, selection, and expansion takes place, in large measure under the control of IL-7. Following release from the thymus (thymic export), these new T cells home to peripheral lymphoid organs including the bone marrow itself. Estrogen prevents decreases thymic output through an IL-7 dependent mechanism, blunting the size of the pool of bone marrow T cell available for activation and expansion.

The relevance of this mechanism *in vivo* was established by utilizing DO11.10 mice, a strain in which all T cells recognize a single peptide epitope of chicken albumin (ovalbumin) that is not expressed in mice. In the absence of ovalbumin antigen-presenting cells of DO11.10 mice are unable to induce T-cell activation. Therefore, if antigen-presenting cells are a relevant target of estrogen, these mice should be protected from the increased T-cell proliferation, the suppression of activation-induced T-cell death, and the bone loss that follows ovariectomy. As predicted ovariectomy fails to increase the pool of T cells and to induce bone loss in these mice (Cenci *et al.,* 2003). In addition, injection of ovalbumin, which permits the generation of the appropriate MHC-peptide antigen for these T cells, restores the capacity of ovariectomy to expand the T-cell pool by targeting proliferation and apoptosis and to induce bone loss. These data demonstrate that antigen presentation, specifically the generation of appropriate peptide-MHC complexes, is critical to the process by which ovariectomy increases T-cell proliferation and life span and leads to bone loss. Furthermore, the finding that T cells from ovariectomized mice exhibit an increased response to ovalbumin demonstrates that ovariectomy increases the reactivity of antigen-presenting cells to endogenous antigens rather than stimulating the production of a new antigen or modulating antigen levels.

The question thus arises as to the nature of the antigens. Estrogen deficiency is likely to increase T-cell reactivity to a pool of self- and foreign antigens physiologically present in healthy animals and humans. This is consistent with the fact that T-cell clones expressing T-cell receptors directed against self-antigens not expressed in the thymus, survive negative selection during T-cell maturation (Robey *et al.,* 1992). Such clones ("autoreactive" or "self-reactive" T cells) reside in peripheral lymphatic organs of adult individuals. In addition, foreign antigens of bacterial origin are physiologically absorbed in the gut. As these peptides come into contact with immune cells locally and systemically, they induce a low-grade T-cell activation (Rammensee *et al.,* 1993). Thus, a moderate immune response is constantly in place in healthy humans and rodents owing to presentation by MHCII and MHCI molecules of both self- and foreign peptides to $CD4^+$ and $CD8^+$ T cells (Grossman and Paul, 2000). This autoreactive response is thought to be essential for immune cell survival and renewal (Tanchot *et al.,* 1997).

The effects of ovariectomy on antigen presentation and the resulting changes in T-cell activation, proliferation, and life span are explained by a stimulatory effect of ovariectomy on the expression of the gene encoding class II transactivator (*CIITA*). The product of *CIITA* is a non-DNA–binding factor induced by IFNγ that functions as a transcriptional coactivator at the MHC II promoter (Boss

and Jensen, 2003). Increased *CIITA* expression in macrophages derived from ovariectomized mice results from ovariectomy-mediated increases in both T-cell IFNγ production and the responsiveness of *CIITA* to IFNγ (Cenci *et al.,* 2003), an inflammatory cytokine produced by helper T cell. The relevance of IFNγ is shown by the failure of IFNγR -/- and IFNγ -/- mice to sustain bone loss in response to ovariectomy (Cenci *et al.,* 2003; Gao *et al.,* 2007).

IFNγ production by T cells is induced by either a cyclosporin-A–sensitive T-cell receptor (TCR)-dependent mechanism, mediated by T-cell activation, or by the cytokines IL-12 and IL-18 through activation of the MAP kinase p38. The increased production of IFNγ by T cells from ovariectomized mice is suppressed by *in vitro* treatment with the selective p38 inhibitor SB203580, but not by the activation inhibitor cyclosporin-A, indicating that increased IFNγ production by $CD4^+$ cells in ovariectomized mice is cytokine-driven. The expression of the IL-12 and IL-18 genes in BM monocytes is induced by NFκB and AP-1, nuclear proteins whose transcriptional activity is directly repressed by estrogen (An *et al.,* 1999; Galien and Garcia, 1997; Shevde *et al.,* 2000). Unstimulated BM monocytes such as those from estrogen-replete mice are known to express low or undetectable levels of NFκB and AP-1 (Muegge and Durum, 1990). Accordingly, BM monocytes from estrogen-replete mice express minimal levels of IL-12 and IL-18 while those from ovariectomized animals produce increased amounts of IL-12 and IL-18. Thus, one mechanism by which estrogen represses *CIITA* is by decreasing IFNγ production via an inhibitory effect on the BM monocyte production of IL-12 and IL-18.

Another mechanism by which estrogen deficiency upregulates the production of IFNγ is through TGFβ. Estrogen has a direct stimulatory effect on the production of this factor, which is mediated through direct binding of estrogen/estrogen receptor complex to an estrogen response element region in the TGFβ promoter (Yang *et al.,* 1996).

TGFβ is recognized a powerful repressor of T-cell activation. Indeed, TGFβ exerts strong immunosuppressive effects by inhibiting the activation and the proliferation of T cells and their production of proinflammatory cytokines, including IFNγ. Studies in a transgenic mouse that expresses a dominant negative form of the TGFβ receptor exclusively in T cells have allowed the significance of the repressive effects of this cytokine on T-cell function in the bone loss associated with estrogen deficiency to be established (Gao *et al.,* 2004). This strain, known as CD4dnTGFβRII, is severely osteopenic owing to increased bone resorption. More importantly, mice with T-cell–specific blockade of TGFβ signaling are completely resistant to the bone-sparing effects of estrogen (Gao *et al.,* 2004). This phenotype results from a failure of estrogen to repress IFNγ production that, in turn, leads to increased T-cell activation and T-cell TNF production. Gain of function experiments confirmed that elevation of the systemic levels of TGFβ prevents ovariectomy-induced bone loss and bone turnover (Gao *et al.,* 2004).

A third mechanism by which estrogen regulates IFNγ and TNF production is by repressing the production of IL-7. Levels of IL-7 are significantly elevated following ovariectomy (Lindberg *et al.,* 2006; Ryan *et al.,* 2005; Weitzmann *et al.,* 2002) and *in vivo* IL-7 blockade, using neutralizing antibodies, is effective in preventing ovariectomy-induced bone destruction (Weitzmann *et al.,* 2002) by suppressing T-cell expansion and TNF and IFNγ production (Ryan *et al.,* 2005). Furthermore, a recent study shows that liver-derived IGF-I is permissive for ovariectomy-induced trabecular bone loss by modulation of the number of T cells and the expression of IL-7 (Lindberg *et al.,* 2006). Indeed, the elevated BM levels of IL-7 contribute to the expansion of the T-cell population in peripheral lymphoid organs through several mechanisms. Firstly, IL-7 directly stimulates T-cell proliferation by lowering tolerance to weak self-antigens. Secondly, IL-7 increases antigen presentation by upregulating the production of IFNγ. Thirdly, IL-7 and TGFβ inversely regulate each other's production (Dubinett *et al.,* 1995; Huang *et al.,* 2002).

The reduction in TGFβ signaling, characteristic of estrogen deficiency, may serve to further stimulate IL-7 production, thus driving the cycle of osteoclastogenic cytokine production and bone wasting. New studies further implicate IL-7 as a downstream effecter of IGF-I action in ovariectomy-induced trabecular bone loss (Lindberg *et al.,* 2006).

In estrogen deficiency, IL-7 compounds bone loss by suppressing bone formation thus uncoupling bone formation from resorption. Recent studies have also identified elevated levels of IL-7 in patients suffering from multiple myeloma and in multiple myeloma-derived cell lines (Giuliani *et al.,* 2002), and have suggested a role for IL-7 in the enhanced bone resorption and suppressed bone formation associated with multiple myeloma. Increased IL-7 expression has also been implicated in the bone loss sustained by patients with rheumatoid arthritis (De Benedetti *et al.,* 1995; van Roon *et al.,* 2003).

In summary, a complex pathway links estrogen, the immune system, and the development of postmenopausal bone loss in experimental animals.

T-CELL THYMIC OUTPUT AND BONE LOSS

The thymus undergoes progressive structural and functional declines with age, coinciding with increased circulating sex-steroid levels at puberty (Haynes *et al.,* 2000). However, under severe T-cell depletion secondary to HIV infection, chemotherapy, or BM transplant, an increase in thymic output (known as thymic rebound) becomes critical for long-term restoration of T-cell homeostasis. For example, middle-aged women treated with autologous BM transplants develop thymic hypertrophy and a resurgence

of thymic T-cell output that contributes to the restoration of a wide T-cell repertoire (Hakim *et al.,* 2005), although the intensity of thymic rebound declines with age.

The mechanism driving thymic rebound is not completely understood, but one factor involved is IL-7 (Mackall *et al.,* 2001). Importantly, IL-7 alone is not sufficient to enhance thymopoiesis in young mice (Chu *et al.,* 2004), but plays a more relevant role in aged mice (Alpdogan *et al.,* 2001).

Both androgens and estrogen have a profound suppressive effect on thymic function. Accordingly, castration reverses thymic atrophy and increases export of recent thymic emigrants to the periphery, (Utsuyama and Hirokawa, 1989), while the sex steroid inhibits thymus regeneration by promoting thymocyte apoptosis and an arrest of differentiation (Okasha *et al.,* 2001). Restoration of thymic function after castration occurs in young (Roden *et al.,* 2004) as well as in very old rodents (Sutherland *et al.,* 2005).

In accordance with the notion that estrogen deficiency induces a rebound in thymic function, ovariectomy expands thymic T cells and leads to the thymic export of naïve T cells (Ryan *et al.,* 2005). Indeed, stimulated thymic T-cell output accounts for ~50% of the increase in the number of T cells in the periphery, while the remaining 50% is owing to enhanced peripheral expansion. Similarly, thymectomy decreases by ~50% the bone loss induced by ovariectomy (Fig. 4), thus demonstrating that the thymus plays a previously unrecognized causal effect in ovariectomy -induced bone loss in mice. The remaining bone loss is a consequence of the peripheral expansion of naïve and memory T cells (Ryan *et al.,* 2005). This finding, which awaits confirmation in humans, suggests that estrogen deficiency-induced thymic rebound may be responsible for the exaggerated bone loss in young women undergoing surgical menopause (Hreshchyshyn *et al.,* 1988) or for the rapid bone loss characteristic of women in their first 5–7 years after natural menopause (Riggs *et al.,* 2002). Indeed, an age-related decrease in estrogen deficiency-induced thymic rebound could mitigate the stimulatory effects of sex steroid deprivation and explain why the rate of bone loss in postmenopausal women diminishes as aging progresses (Riggs *et al.,* 2002).

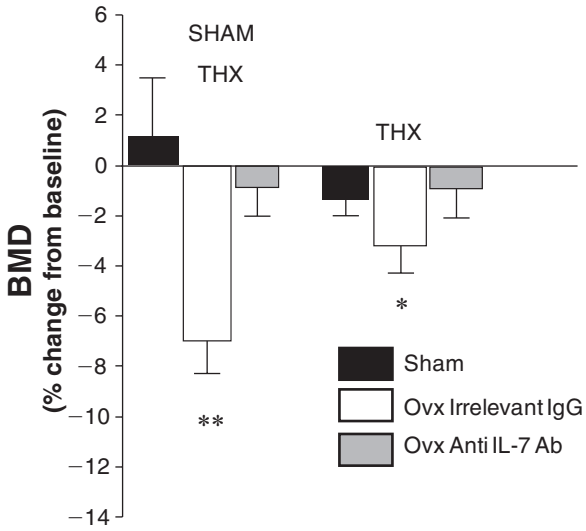

FIGURE 4 Ovariectomy causes a twofold lower bone loss in thymectomized mice than in euthymic controls. BMD (Mean + SEM) as c export), these new T cells home to peripheral lymphoid organs including the bone marrow itself. Estrogen prevents T-cell activation in the bone marrow in part by directly blunting antigen presentation, and in part via repression of IL-7 and IFNγ production. This effect is amplified by the upregulation of the IL-7 suppressor, TGFβ. The net result of these actions is a decrease in the number of TNF-producing T cells. The blunted levels of TNF diminish RANKL-induced osteoclast formation preventing bone loss.

FROM ANIMAL MODELS TO HUMAN DISEASE

Owing to the inherent difficulties associated with human experimentation, the majority of studies discussed herein represent investigations in animals. Consequently, their applicability to human disease, in particular postmenopausal osteoporosis, remains unproven. However, a number of lines of evidence suggest that pro-osteoclastogenic immunological perturbations are not uncommon in estroprevic humans and evidence is beginning to accumulate to suggest that T cells play a relevant role in regulating bone resorption in humans. It has recently been reported that RANKL expression on lymphocytes and marrow stromal cells is significantly elevated during estrogen deficiency in humans and correlates directly with increases in bone resorption markers and inversely with serum estrogen levels (Eghbali-Fatourechi *et al.,* 2003). Furthermore, in postmenopausal women, production of cytokines representative of TH1 lymphocytes are increased, an effect reversed by supplemental estrogen and one report describes a case in which a defect in T-cell immunoregulation resulted in severe osteoporosis associated with increased osteoclast activity (Rubin *et al.,* 1988).

The production of increased levels of TNF and IL-1 in the conditioned media of peripheral blood cells derived from postmenopausal women is well established (Pacifici *et al.,* 1991b), while the number of CD3+ CD56+ T cells (a TNF-producing adherent T-cell population) is reported to show a highly significant negative correlation with femoral and lumbar bone density in estroprevic postmenopausal women (Abrahamsen *et al.,* 1997).

Furthermore, animal studies of postmenopausal osteoporosis show striking similarities to autoimmune diseases. A significant body of evidence suggests that estrogen is indeed a relevant player in autoimmune disease in humans. Firstly the majority of autoimmune diseases have a gender bias toward the female population. In particular Sjögren

syndrome, systemic lupus erythematosus (SLE), autoimmune thyroid disease (Hashimoto's thyroiditis as well as Graves' disease) and scleroderma, in which the patient population is >80% women, and rheumatoid arthritis, multiple sclerosis (MS), and myasthenia gravis, in which the sex distribution is 60–75% women. Secondly, puberty, menopause, and pregnancy all alter the incidence and the course of many autoimmune diseases, further suggesting a role for sex hormones in autoimmunity. These modifications of disease activity by sex steroids have been suggested to involve the generation of a hormonal environment that favors a TH2 response. In MS and rheumatoid arthritis, this environment may suppress the ongoing TH1 responses to central nervous system and joint antigens whereas in SLE a TH2 environment would enhance antibody production and possibly exacerbate disease progression (Whitacre, 2001). Evidence from a variety of sources thus implicates a role for sex hormones in modulating the incidence, course, and severity of autoimmune diseases.

CONCLUSIONS

Remarkable progress has been made in the last two decades in our understanding of the mechanisms of bone destruction during estrogen deficiency (Fig. 4). Most new data are derived from studies in mice and remain to be validated in humans, which will be essential for defining the role of inflammatory cytokines in postmenopausal bone loss, as selective inhibitors might be developed as new therapeutic agents.

The ovariectomized mouse is an excellent model to investigate the acute effects of estrogen withdrawal, although it is not suitable for studies of the long-term effects of menopause on the skeleton, as bone loss subsides within a few weeks after ovariectomy. Thus, additional animal models and long-term human studies are needed. Because critical effects of estrogen on bone involve regulation of precursor cell differentiation and signaling pathways that are few and short-lived, many pivotal effects of estrogen *in vivo* are difficult to reproduce *in vitro*. Similarly, regulatory events observed *in vitro* are often not relevant *in vivo*. It is therefore essential for *in vitro* studies to be validated *in vivo*. For example, while estrogen stimulates IFNγ production in cells in cultures (Fox *et al.,* 1991), estrogen represses it *in vivo* (Cenci *et al.,* 2003). Similarly, while IFNγ blocks osteoclast formation through direct targeting of maturing osteoclasts, IFNγ stimulates osteoclastogenesis and bone resorption in estrogen-deficient mice (Cenci *et al.,* 2003; Gao *et al.,* 2007).

In conclusion, if the findings in experimental animals are confirmed in humans, it will, perhaps, be appropriate to classify osteoporosis as an inflammatory or even an autoimmune condition and certainly new therapeutic "immune" targets will emerge.

Chapter 43

Thyroid Hormone and Bone

Paula H. Stern, PhD

Department of Molecular Pharmacology and Biological Chemistry, Northwestern University Feinberg School of Medicine, Chicago, IL

INTRODUCTION

Thyroid hormone is essential for skeletal development and also affects mature bone. Depending on the hormone concentration and stage of life, the effects of thyroid hormone can be either beneficial or deleterious to the skeleton. This chapter focuses on the relationship of the *in vitro* effects of thyroid hormone on bone cells to the observed effects of the hormone on the skeleton *in vivo* in both experimental animals and humans. Studies published since the previous edition provide information on thyroid hormone effects on additional genes of interest in osteoblasts and further assessment of the skeletal risks of excess thyroid hormone. A new paradigm related to thyroid hormone effects on bone is the proposed role of thyroid stimulating hormone (TSH) as an independent regulator of skeletal responses and a mediator of skeletal effects of thyroid hormones *in vivo*. These new aspects of the skeletal physiology are accompanied by an expansion of the section on the basic mechanisms of thyroid hormone receptor action based on recent studies in many tissues.

MECHANISM OF THYROID HORMONE ACTION ON THE SKELETON

Nuclear Receptors: Structural and Genetic Studies

Thyroid hormone receptors are members of the steroid receptor superfamily (Evans, 1988). All of these receptors share a common modular structure with a centrally located DNA-binding domain composed of two zinc fingers and a carboxy-terminal ligand-binding domain that is also involved in receptor dimerization and interactions with coactivators and corepressors. The receptors are nuclear proteins capable of binding to cognate DNA elements in the absence of their ligands. Binding of the ligand to the receptor alters the receptor conformation and subsequently enables the activation or repression of specific genes. Similar to the pattern for retinoid and vitamin D receptors, DNA-binding sites for thyroid hormone receptors include monomeric, palindromic, inverted repeat, and direct repeat response elements derived from a common AGGT(C/A)A motif. Multiple functional forms exist for thyroid hormone receptors, including monomers, homodimers, heterodimers between thyroid hormone isoforms, and heterodimers with retinoid and vitamin D receptors. In bone (Williams *et al.,* 1994; Williams *et al.,* 1995), as in other tissues (Glass, 1994; Brent *et al.,* 1991), DNA binding and transcriptional activation are enhanced when the thyroid hormone receptor isoforms are present as heterodimers with retinoid or vitamin D receptors. In osteoblast cell lines, interactions among the retinoid, vitamin D, and thyroid hormone ligands appeared to mediate specific responses (Williams *et al.,* 1994, 1995). Studies on the effects of treatment combinations on the expression of osteoblast phenotypic genes in the cell lines revealed complex responses that indicated the importance of dose, treatment duration, and degree of confluence in dictating the magnitude of the response (Williams *et al.,* 1995). In primary rat osteoblastic cells, alteration of the ligand combinations did not influence the responses (Bland *et al.,* 1997).

Most commonly, the unliganded thyroid hormone receptor represses gene transcription. Interaction of the unliganded receptor with a corepressor complex, including nuclear receptor corepressor (NCoR), silencing mediator for retinoic acid receptor, the repressor Sin3, and histone deacetylases (Torchia *et al.,*1998; Yen *et al.,* 2006), results in the condensation of chromatin structure and repression of transcription through decreased access of transcription factors (Koenig, 1998; Wu and Koenig, 2000). Interaction of the receptor with the active thyroid hormone triiodothyronine (T3) results in a conformational change that leads to dissociation from the repressor complex and interaction with activation complexes. One activation complex involves the steroid receptor coactivator (SRC) family, which can also interact with CREB-binding protein (CBP) and the p300 protein, which in turn interacts with p300/CBP associated factor (PCAF) (McKenna and O'Malley,

2002; Torchia *et al.,* 1998). These factors have histone acetyltransferase activity. A second activation complex is the vitamin D receptor interacting protein/thyroid hormone receptor (TR) associated protein (DRIP/TRAP) complex (Sharma and Fondell, 2002; Burakov *et al.,* 2002). Recruitment of this complex can result in recruitment and stabilization of RNA polymerase II (Ito and Roeder, 2001; Rachez and Freedman, 2001). Other chromatin remodeling proteins having ATPase activity have also been proposed as components leading to activation (DiRenzo *et al.,* 2000). Differential recruitment of coactivators and histone acetylation have been demonstrated for different genes in GH3 pituitary cells (Liu *et al.,* 2006).

Thyroid hormone receptors are encoded by two genes: one found on chromosome 17 encoding TRα and one on chromosome 3 encoding TRβ. Alternative splicing of TRα transcripts results in the generation of several carboxy-terminal products (Izumo and Mahdavi, 1988; Chassande *et al.,* 1997). The TRα1 isoform is a commonly expressed active isoform of the receptor. TRα2, which is homologous to the v-erb A oncogene, is a nonbinding isoform resulting from alternative splicing of the TRα primary transcript. TRα2 fails to heterodimerize with retinoic acid receptors (RXR) (Reginato *et al.,* 1996) and may act as a dominant-negative repressor (Koenig *et al.,* 1989; Sap *et al.,* 1986). The TRβ1 and the amino-terminal splice variant, TRβ2, are both active. Tissue expression of TRβ2 is limited, and this isoform is expressed most significantly in the hypothalamus and pituitary (Lazar, 1993). TR isoforms have been found in skeletal tissues. mRNAs for TRα1, TRα2, and TRβ are found in MG63, ROS 17/2.8, and UMR-106 cell lines (Williams *et al.,* 1994; Allain *et al.,* 1996). TRβ2 mRNA has been found in osteoblasts (Abu, 2000). mRNA for TRα1 was 12 times higher than TRβ1 mRNA in tibia and femur of 7-week-old male mice (O'Shea *et al.* 2003). TRα1, TRα2, TRβ1, and TRβ2 mRNAs were expressed in chondrocytes at all stages of differentiation. TRα1, TRα2, and TRβ1 mRNAs were highly expressed in osteoblasts at bone-remodeling sites; and mRNA for all of the isoforms was present and highly expressed in multinucleated osteoclastic cells from an osteoclastoma (Abu *et al.,* 1997). TRα1, TRα2, and TRβ1 mRNA have also been detected in rat femurs and vertebrae (Milne *et al.,* 1999). Immunohistochemical staining with antibodies recognizing a TRα epitope or specific TRα2 and TRβ revealed the presence of receptor protein in osteoblast cell lines and in osteoclasts in tissue smears from a human osteoclastoma (Allain *et al.,* 1996). In contrast to mRNA expression, TRα1 protein expression was not seen in the osteoclastoma cells and was limited to osteoblasts at sites of remodeling and undifferentiated chondrocytes (Abu *et al.,* 2000).

To determine the role(s) of specific TR isoforms, TR-deficient mouse strains have been generated by homologous recombination. TR$\alpha1^{-/-}$ mice did not show bone defects (Wikstrom *et al.,* 1998), whereas mice in which both TRα isoforms were deleted showed growth retardation and impaired development of epiphyseal bone, with disorganization of chondrocyte columns, decreased hypertrophic chondrocytes, and low ossification (Fraichard *et al.,* 1997). The animals died shortly after weaning. TRβ knockout mice failed to show bone defects (Gauthier *et al.,* 1999; Gothe *et al.,* 1999), suggesting that the TRβ isoform is not essential for bone development in the mice. The TR$\alpha1^{-/-}$ TR$\beta^{-/-}$ double knockout produced viable mice, the majority of which survived at least through 12 months, although there was increased mortality compared to wild-type mice (Gothe *et al.,* 1999). TR$\alpha1^{-/-}$ TR$\beta^{-/-}$ double knockout mice exhibited retarded growth and significantly reduced levels of growth hormone (GH) and insulin-like growth factor I (IGF-I). Bone length was decreased significantly in limbs and vertebrae, with the effect being most marked in the femur. Growth plates were disorganized and epiphyseal ossification was delayed. Dual x-ray absorptiometry showed decreased bone area and bone mineral content but no significant effect on bone mineral density. Middiaphyseal peripheral quantitative computed tomography (pQCT) scans of the femurs revealed decreased cortical density, cortical area, bone mineral content, and periosteal circumference. Cross-sectional moment of inertia and moment of resistance were decreased significantly. It was noted that the phenotype was less severe than that resulting from thyroidectomy and this was postulated to be a reflection of the fact that in the case of thyroidectomy, T3 would not be available to alleviate the transcriptional repression effected by the TRs (Gothe *et al.,* 1999).

Skeletal alterations associated with mutations in the TRβ1 gene have been described in patients with resistance to thyroid hormones (RTH). In most reported cases, the defect shows an autosomal dominant pattern of inheritance. The mutations are clustered and largely located within domains in the carboxy-terminal region. They are mainly nucleotide substitutions that result in single amino acid changes (Refetoff, 1993). The mutant alleles may act by a dominant-negative mechanism to inhibit the ability of the normal allele to elicit normal receptor function (Chatterjee *et al.,* 1991; Sakurai *et al.,* 1990). The dominant-negative action appears to be at the level of DNA binding (Kopp *et al.,* 1996). The mutant phenotypes are heterogeneous, but some patients have shown evidence of retarded bone age and stippled epiphyses, similar to characteristics of hypothyroidism, with resulting short stature. In other patients there is accelerated bone age, accelerated chondrocyte maturation, and early epiphyseal closure, again resulting in short stature (Behr *et al.,* 1997). The target sites at which resistance occurs (pituitary or peripheral) may determine the phenotype. A novel syndrome resulting in advanced bone age was associated with a mutation in the MCT8 thyroid hormone transporter gene (Herzovich *et al.*, 2007). A single nucleotide change (Q261X) in exon 3 on the X chromosome resulted in low serum T4 and free T4, and elevated

serum T3 and free T3, and slightly elevated TSH. The child had severe neurological abnormalities and normal growth, which had been previously noted in other patients with mutations in this gene (Dumitrescu *et al*., 2004).

Replicating a human mutation resulting in severe resistance to thyroid hormone has resulted in mouse models that have provided considerable new information on the roles of TRα and TRβ in bone and other tissues (Kaneshige *et al.,* 2000; Kaneshige *et al.,* 2001; O'Shea *et al*., 2003; O'Shea *et al.,* 2005; O'Shea *et al.,* 2006). The mutation (mutant PV) is a frameshift mutation that has complete loss of T3 binding and transactivation activity. Knockout of TRβ in the mouse model eliminated expression of DNA and ligand binding domains of TRβ1 and TRβ2. The knockout showed that TRβ was the predominant regulator of hypothalamic and pituitary responses to thyroid hormone, as these animals had marked increases in T3, T4, and TSH. There was advanced endochondral and intramembranous ossification in utero, premature closure of the growth plates and shortened body length, along with increased mineralization and craniosynostosis. The narrower growth plate appeared to be a consequence of faster transition through the proliferative zone. The TRβ knockout animals had decreased trabecular bone mass, more resorption and a greater number of TRAP-positive cells. Knockout of TRα in the mouse model abolished the generation of TRα1, TRα2, and the splice variants TR$\Delta\alpha$1 and TR$\Delta\alpha$2. The TRα knockout failed to markedly affect the hypothalamic pituitary axis. Thyroid hormones were normal and TSH was only slightly decreased in these animals. This knockout resulted in animals with a wider growth plate, transiently decreased bone calcification and transiently decreased bone growth, decreased resorption and and decreased TRAP-positive cells. The results suggested that TRα is functionally predominant in bone and that the hyperthyroid osteoporotic phenotype in the TRβ PV mutation was mediated predominantly by TRα.

The paradigm for the effects of thyroid hormone on bone was challenged by studies that proposed a role for TSH as an independent regulator of bone formation and resorption (Abe *et al.,* 2003; Hase *et al.,* 2006). A mouse model was generated in which the TSH receptor was knocked out through homologous recombination in embryonic stem cells. The mice exhibited a phenotype of decreased body weight, decreased femur length and decreased weight. Bone histology showed osteoporosis together with focal sclerosis, and histomorphometry revealed increased TRAP-labeled surface and decreased trabecular bone area. The results were consistent with the possibility that the bone loss in hyperthyroid state was due to the suppressed TSH. TNFα, JNK, and NFκB were implicated in the osteoclast response, and LRP-5 and Flk-1, but not Runx-2 or osterix, in the osteoblast response. Treatment of hematopoetic stem cells or RAW-C3 bone cells with rhTSH (at the rather high concentration of 10 U/ml) decreased osteoclast markers and stimulated apoptosis of osteoclast precursor cells and osteoclasts. In other studies, TSH increased alkaline phosphatase and osteocalcin and stimulated mineralization in osteoblastic cells (Sampath *et al*., 2007). Several methods were used to demonstrate TSH receptors in bone cells. In the knockout model, exon 1 was replaced with a GFP cassette, allowing GFP fluorescence to be used as an indicator of the presence of TSH receptors in bone cells. Receptors were also demonstrated by specific ^{125}I-TSH binding (Abe *et al.,* 2003). In other studies, TSH stimulated cAMP production in SaOS-2 human osteosarcoma cells and expression of TSHR was demonstrated in SaOS-2 cells and NHOst normal human osteoblast cells by RT-PCR (Morimura *et al*., 2005). In these cells, TSH (0.1–10 U/ml) stimulated type 2 iodothyronine deiodinase, which converts T4 to T3 (Morimura *et al*., 2005). T4, rT3, and T3 all inhibited the deiodinase activity.

Other studies have challenged the conclusions about the role of TSH on the skeleton. In primary cultures of human osteoblast-like cells, the evidence for expression and function of TSH was weak, with no effects on calcium signaling and only small effects on cAMP (Tsai *et al*., 2004). TSHR mRNA could not be demonstrated by RNase protection assay, although it could be detected by RT-PCR and nucleotide sequencing (Tsai *et al*., 2004). Selective knockout of TRα or TRβ, described earlier, produced results that were inconsistent with the hypothesis of the role of TSH. The TRβ knockout animals, which had marked increases in T3, T4, and TSH owing to the essential role of the TRβ in mediating feedback inhibition at the hypothalamus and pituitary, had decreased trabecular bone and evidence of increased osteoclast activity (Bassett *et al*., 2007). Thus, these results were inconsistent with the hypothesis that TSH was a suppressor of bone loss. Bassett *et al.* (2007) noted that in the study by Abe *et al*. (2003) the TSHR knockout mice received hormone replacement with thyroid extract after weaning, and therefore hypothyroidism during early development could have resulted in a period of catch-up growth and accelerated bone development when thyroid hormone was replaced. These apparently incompatible findings will undoubtedly be the subject of future investigations. An important question will be the local thyroid hormone concentrations within bone cells and their actions.

Differential expression of TRα and β isoforms could also allow for the development of thyroid hormone analogs that have tissue specificity owing to their preferential interaction with one receptor isoform. The TRβ-selective agonist GC-1 had greater effects on lipid metabolism and less on cardiac activity (Trost *et al.,* 2000). In a direct comparison of the effects of GC-1 and T3 on bone in female adult rats, T3 significantly reduced bone mineral density in lumbar vertebrae, femur, and tibia, and reduced trabecular volume, thickness, and number. GC-1 did not have these skeletal effects, although it did reduce serum TSH and cholesterol (Freitas *et al*., 2003). Another agonist, tiratricol (3,5,3′-triiodothyroacetic acid), showed enhanced effects

on hepatic lipids and skeletal metabolism (Sherman *et al.,* 1997). Interestingly, when used topically it was found to reverse glucocorticoid-induced skin atrophy (Yazdanparast *et al*., 2006).

Competitive Binding Studies

Two studies of T3 binding to nuclei from ROS 17/2.8 cells gave the following parameters: K_d 5 n*M*, B_{max} 0.13 ng/mg DNA, with incubation for 60 min at 37° C (Rizzoli *et al.,* 1986) and K_d 150 p*M*, B_{max} 24 fmol/100 μg DNA, with incubation for 2.5 hours at 37° C (Sato *et al.,* 1987). In UMR-106 cells, two nuclear binding sites were identified: one with K_d 260 p*M*, B_{max} 7.7 pg/mg DNA, and one of lower affinity, K_d 1.8 n*M* (LeBron *et al.,* 1989). In MC3T3-E1 cells, K_d for T3 binding was 120 p*M* (Kasono *et al.,* 1988). T3 receptors were also found in cell lines (ROS 25/1, ROS 17/2.8–3) that did not show an alkaline phosphatase response to T3, suggesting that there is a postreceptor defect in these cell lines (Sato *et al.,* 1987). There was good agreement between the relative affinity of different ligands [T3 = 1, thyroxin (T4) = 0.1, 3,3′-diiodothyronine = 0.013, reverse T3 (rT3) = 0.002, monoiodotyrosine = 0, diiodotyrosine = 0] and their ability to increase alkaline phosphatase in ROS 17/2.8 cells (Sato *et al.,* 1987). In another study, T4 had a 20-fold lower and rT3 a 400-fold lower affinity compared with T3 in ROS 17/2.8 cells (Rizzoli *et al.,* 1986). In binding studies with a nuclear fraction from neonatal mouse calvaria, carried out for 60 minutes at 22° C, K_d for T3 was 3 n*M* and the B_{max} 1.9 pmol/mg DNA (Krieger *et al.,* 1988). The cardiotonic agent milrinone, which has structural homology to T4 (Mylotte *et al.,* 1985), did not compete for binding to the calvarial receptors. Both time and temperature dependence were observed in the binding studies, with binding being more rapid at 37° C than at 22° C (Krieger *et al.,* 1988; Sato *et al.,* 1987). Kinetic analysis of normal nuclear receptors gave K_a of $9 \times 10^8 M^{-1}$ min^{-1} and K_d of 0.016 min^{-1} with a $t_{1/2}$ of approximately 36 minutes (Krieger *et al.,* 1988). For binding studies in the cell lines, the method of Samuels *et al.* (1979) was used to remove thyroid hormones from serum used in the growth medium. The procedure involves treatment of the serum with AG1-X8 resin and removes more than 90% of the T4 and 95% of the T3.

Relevance of *in Vitro* Concentrations and *in Vivo* Dosages of Thyroid Hormone to Physiological and Pathophysiological Concentrations

It has been reported that the normal range for free T3 in serum is similar in rats and humans, and is 3.3–8.2 p*M* (Jurney *et al.,* 1983). Wide concentration ranges of thyroid hormones have been used in experimental studies, especially *in vitro,* and often markedly different dosages are required to obtain the same response in a different cell line, model system, or laboratory. The differentiation state and the production of modulating factors are potential variables that can affect the response in a given system. In addition, the presence of thyroid hormone in the added sera or the presence of binding sites in stripped sera can dramatically influence the free hormone available to the cells or tissue. Several studies have estimated the amount of free hormone available under the experimental conditions used (Sato *et al.,* 1987; Allain *et al.,* 1992). In one study, an equilibrium dialysis method was used to determine free T4 and T3 after treating fetal calf serum with AG1-X8 resin (Sato *et al.,* 1987). T4 and T3 concentrations in the fetal calf serum prior to extraction were 11.1 μg/dl and 157 ng/dl, respectively. It was determined that addition of 10 n*M* T4 to the stripped serum provided 80 p*M* free T4 and that addition of 1 n*M* T3 provided 40 p*M* free T3. In the other study, in which 10% neonatal calf serum was used, the free T3 was measured by radioimmunoassay (Allain *et al.,* 1992). It was determined that the addition of 10 p*M* T3 yielded a free T3 concentration of 2.1 p*M,* that 0.1 n*M* yielded 4 p*M,* that 1 n*M* yielded 2.1 p*M* and that 10 n*M* yielded >39 p*M* (Allain *et al.,* 1992). Although the type and percentage of serum would influence the final values, these measurements and calculations are of value in comparing studies and in relating *in vitro* concentrations to the concentrations of thyroid hormones in normal serum.

Membrane Actions and Signal Transduction Pathways

Thyroid hormones interact with several signal transduction pathways in bone cells. These results suggest that extranuclear actions could initiate some of the thyroid hormone effects on bone. Rapid (within 30 seconds) increases in inositol mono-, bis-, and trisphosphates are elicited by treatment of fetal rat limb bones with 100 n*M* and 1 μ*M* T3 (Lakatos and Stern, 1991). The inactive analogs diiodothyronine and rT3 did not increase inositol phosphates. This effect of T3 was inhibited by indomethacin and could represent an initiation pathway for the prostaglandin-dependent effects of thyroid hormones on bone resorption, discussed later. Thyroid hormones at high doses inhibit cyclic AMP phosphodiesterase (Marcus, 1975). T3 at 0.1 and 1 n*M* increased ornithine decarboxylase and potentiated the responses of this enzyme to parathyroid hormone (PTH) (Schmid *et al.,* 1986). Specific cellular functions associated with membrane receptors have not been identified, although it has been proposed that nongenomic actions of thyroid hormones serve homeostatic functions for membrane transport and may modulate genomic actions of the hormones (Davis and Davis, 1996).

GENE PRODUCTS

Osteoblast Phenotypic Markers

Thyroid hormone promotes the proliferation and differentiation of osteoblastic cells (Ohishi *et al.,* 1994; Ishida *et al.,* 1995). This is reflected in the increased expression of a number of markers.

Alkaline Phosphatase

T4 (10 n*M*) and 1 n*M* T3 increased alkaline phosphatase in ROS 17/2.8 cells (Sato *et al.,* 1987). The effect was seen within four days of culture. Responses were more robust in subconfluent cells and were inhibited by 1 μg/ml cycloheximide or 0.1 μg/ml actinomycin D. T3 modulated the stimulatory effect of hydrocortisone on alkaline phosphatase. At low hydrocortisone concentrations (1 n*M,* 10 n*M*), 1 μ*M* T4 resulted in an additive effect, whereas at higher hydrocortisone concentrations (0.1 μ*M,* 1 μ*M*), coincubation with T4 decreased the stimulatory effect (Sato *et al.,* 1987). T3 also increased alkaline phosphatase in MC3T3-E1 cells (Kasono *et al.,* 1988; Klaushofer *et al.,* 1995). In one study, significant responses were elicited with 0.1 n*M* T3 and 10 n*M* T4; the effect of T4 was further increased by concentrations up to 1 μ*M* and was less at 10 μ*M*; the effect of T3, however, was maximal at 1 n*M,* and no increase was observed at 100 n*M* (Kasono *et al.,* 1988). T3 failed to affect alkaline phosphatase in UMR-106 cells (LeBron *et al.,* 1989; Huang *et al.,* 2000), possibly owing to the high basal expression of the enzyme in this cell line. T3 had biphasic effects on alkaline phosphatase in normal rat osteoblastic cells (Ernst and Froesch, 1987), stimulating at concentrations of 0.01 and 0.1 n*M* and inhibiting at a concentration of 10 n*M*. In neonatal rat calvarial cells, mRNA for alkaline phosphatase was decreased by 1 or 4 days exposure to 1 n*M* T3 (Schmid *et al.,* 1992). In cells derived from human trabecular bone explants and cultured in medium containing charcoal-stripped serum, alkaline phosphatase in the cell layer was increased by T3 at concentrations up to 200 n*M* (Kassem *et al.,* 1993). Alkaline phosphatase was also increased by thyroid hormone in isolated tibiae (Stracke *et al.,* 1986) and in primary human (Kassem *et al.,* 1993) and rodent (Egrise *et al.,* 1990) osteoblasts. Thus, most but not all osteoblastic cells respond to thyroid hormones with an increase in alkaline phosphatase. Effects are seen at concentrations in the physiologic range; however, the dose dependence of the effect is quite variable and may be dependent on cell type and culture conditions.

Osteocalcin

T3 increased osteocalcin in a dose-dependent manner in ROS 17/2.8 cells (Rizzoli *et al.,* 1986; Sato *et al.,* 1987). In medium containing 2% T3-depleted serum, a significant effect was seen at 1 n*M,* with a half-maximal effect at 2.5 n*M*; the osteocalcin concentration in the control medium was 9 ng/10^6 cells and was increased to 12.3 ng/10^6 cells by 1 n*M* T3 (Rizzoli *et al.,* 1986). A striking difference in the response of osteocalcin mRNA to T3 was observed between cells derived from femoral and vertebral bone marrow, cultured under conditions leading to osteogenic differentiation (Milne *et al.,* 1998). In cultures from femoral marrow, T3 supplementation (10 or 100 n*M*) prevented the time-dependent decrease in osteocalcin mRNA observed in untreated cells. In cultures from the vertebral marrow, osteocalcin mRNA expression was maintained over time in untreated cells, and T3 failed to augment the response. T3 failed to increase osteocalcin mRNA in the bone marrow-derived stromal cell line ST2 (Varga *et al.,* 2004). T3 stimulation of osteocalcin expression and its inhibition by 1,25$(OH)_2D_3$ in murine (MC3T3-E1) osteoblasts were shown to potentially be mediated through a sequence in the mouse OG2 promoter that was able to bind TRα1 and contained a rat VDRE-like sequence (Varga *et al.,* 2003).

Collagen

In cultured rat osteoblastic cells, decreases in collagen and noncollagenous protein synthesis were noted with 0.01 and 0.1 n*M* T3, but not with higher concentrations (Ernst and Froesch, 1987). Thyroid hormones did not inhibit collagen synthesis in rat calvaria (Canalis, 1980). In neonatal mouse calvaria precultured with indomethacin to inhibit prostaglandin synthesis, both collagen and noncollagenous protein synthesis were stimulated by T3 and by triiodothyroacetic acid at concentrations in the 0.01–10 n*M* range (Kawaguchi *et al.,* 1994a). Cells from human trabecular bone explants showed decreased type I procollagen carboxyterminal propeptide production when treated with T3 (Kassem *et al.,* 1993). The synthesis of collagen thus appears to be regulated by T3 in a complex manner and may be influenced by T3 stimulation of other cellular products, such as prostaglandins. Collagen type I gene expression was regulated differentially by T3 in marrow cultures from femoral and vertebral bones, with a more marked stimulatory effect in the femoral bones (Milne *et al.,* 1998).

Other Phenotypic Responses

A series of studies has characterized other changes elicited by T3 in MC3T3-E1 osteoblastic cells (Luegmayr *et al.,* 1996; Fratzel-Zelman *et al.,* 1997; Varga *et al.,* 1997, 1999; Luegmayer *et al.,* 1998, 2000; Fratzel-Zelman *et al.,* 2003). In addition to alkaline phosphatase, expression of c-fos, c-jun, and an osteocalcin-related protein were increased in T3-treated cells. Morphological changes were also observed. T3-treated cells ceased proliferation and became flattened, enlarged, and polygonal. The amount of F-actin

increased and the patterns of actin expression were altered. Pancadherin/β catenin immunoprecipitation was increased by T3, which could reflect the organization of adherens junctions. Apoptosis was accelerated. Matrix metalloproteinase-13 was also markedly increased (Fratzl-Zelman *et al.*, 2003). T3 also increased the expression of osteoprotegerin in MC3T3-E1 cells, an effect that was antagonized by 1,25 $(OH)_2D_3$ (Varga *et al.*, 2004). In ROS 17/2.8 cells, treatment with T3 increased expression of receptors for PTH: conversely, PTH increased binding of T3 (Gu *et al.*, 2001).

Insulin-like Growth Factors, IGF-Binding Proteins, FGF Receptor

IGF-I has significant anabolic effects on bone, increasing cell replication and both collagen and noncollagen protein synthesis (Canalis, 1980; Hock *et al.*, 1988; McCarthy *et al.*, 1989; Centrella *et al.*, 1990; Pirskanen *et al.*, 1993). IGF-I is increased in fetal rat bones treated with thyroid hormone (Schmid *et al.*, 1992; Lakatos *et al.*, 1993; Varga *et al.*, 1994; Klaushofer *et al.*, 1995). At 1 n*M*, T3 stimulates IGF-I production in neonatal rat calvarial osteoblasts (Schmid *et al.*, 1992). There is a dose-dependent, biphasic effect of T3 and T4 on IGF-I production in UMR-106 cells and fetal rat bone organ cultures (Lakatos *et al.*, 1993). IGF-I mRNA is increased by T3 treatment in MC3T3-E1 cells (Varga *et al.*, 1994; Klaushofer *et al.*, 1995). T3 increased IGF-I expression more markedly in cells from vertebral marrow than in cells from femoral marrow (Milne *et al.*, 1998). Interference with IGF-I action by decreasing expression or function of the IGF-I receptor by the use of antisense oligonucleotides, antibodies, and antagonist peptide decreased the anabolic effects of T3 on MC3T3-E1 cells and primary mouse calvarial osteoblasts, including effects on alkaline phosphatase, osteocalcin, and collagen synthesis (Huang *et al.*, 2000). The effects of thyroid hormones on IGFs may be modulated by changes in IGF-binding proteins (IGFBPs). The physiological role of the binding proteins is not fully understood; however, they can influence the cellular uptake and turnover of IGF-I. The binding proteins may represent a mechanism for retention of IGFs in the bone matrix (Bautista *et al.*, 1991). IGFBPs can also modulate IGF action in osteoblastic cells. IGFBP-2 and IGFBP-4 can inhibit IGF-I actions (Mohan *et al.*, 1989; Feyen *et al.*, 1991). Both enhancing and inhibitory (Schmid *et al.*, 1995) effects are produced by IGFBP-3 (Ernst and Rodan, 1990; Schmid *et al.*, 1991). In rat osteoblasts, T3 stimulates the production of IGFBP-2 and IGFBP-3 (Schmid *et al.*, 1992). T3 increases IGFBP-4 expression in MC3T3-E1 cells (Glantschnig *et al.*, 1996), which could regulate the response to T3 and contribute to the decreased anabolic effects observed at higher concentrations. Alterations in thyroid status *in vivo* influence the expression of IGFBPs in a complex manner. In hyperthyroid rats, IGFBP-3 gene expression in liver is decreased; however, in hypothyroid (propylthiouracil-treated) animals, IGFBP-1 and IGFBP-2 gene expression are increased and IGFBP-3 mRNA is decreased (Rodriguez-Arnao *et al.*, 1993). In hyperthyroid patients, serum IGFBP-3 and IGFBP-4, but not IGFBP-5, are increased (Lakatos *et al.*, 2000).

Fibroblast growth factor may also play an important role in thyroid hormone effects on bone. Treatment of osteoblasts with T3-stimulated expression of fibroblast growth factor receptor-1 (FGFR1) mRNA and protein (Stevens *et al.*, 2003). The effect was inhibited by actinomycin or cycloheximide, implicating an intermediate protein. TRα knockout mice had decreased expression of FGFR1 (Stevens *et al.*, 2003).

CELL AND TISSUE PHENOTYPIC RESPONSES

Osteoblast Proliferation

T3 can increase proliferation of rodent and human osteoblastic cells (Ernst and Froesch, 1987; Kassem *et al.*, 1993). In the rodent cell cultures, 0.01 and 1 nM were stimulatory, and 10 nM was inhibitory in longer term cultures (Ernst and Froesch, 1987). Cell number was decreased after eight days of incubation with T4 in MC3T3-E1 cells; inhibition was observed with 10 n*M* T3 and was maximal at 1 μM (Kasono *et al.*, 1988). In other investigations, T3 did not significantly affect growth of ROS 25/1, UMR-106, or ROS 17/2.8 cells (Sato *et al.*, 1987; LeBron *et al.*, 1989; Williams *et al.*, 1994). The diversity of the responses obtained suggests that in addition to thyroid hormone dose, the cell type, passage number, degree of confluence, and the presence or production of other factors can determine the particular outcome that is observed. In explanted neonatal mouse calvaria, T3 stimulated thymidine incorporation in a dose-dependent manner and was significant at 10 pM (Kawaguchi *et al.*, 1994a). A preculture period was required to demonstrate the effect, as high levels of prostaglandin production from untreated tissues appeared to mask treatment effects.

Nodule Formation

Bone nodule formation has been used as a parameter of bone cell differentiation, presumably representing the capability of the cell to generate a mineralized matrix. T3 or T4, at concentrations of 1 nM–0.1 μM, decreased nodule formation by 21-day fetal rat calvarial cells cultured in medium containing 15% heat-inactivated fetal bovine serum, and lower concentrations, starting at 1 pM, had no effect (Ishida *et al.*, 1995). When serum was depleted of T3 with AG-1X-10 resin (Samuels *et al.*, 1979), basal bone nodule formation was increased (Ishida *et al.*, 1995). Dexamethasone (10 nM), enhanced bone nodule formation markedly. This

was promoted by low concentrations of T3 (1 and 10 pM) and inhibited by higher concentrations (10 and 100 nM). Although the results suggest that high concentrations of thyroid hormones can inhibit mineralization, the authors point out that the procedure to strip serum of thyroid hormone could remove other inhibitory factors as well.

Osteoclast Activation

Two studies indicate that the resorptive effects of thyroid hormones on bone are mediated indirectly through the stimulation of osteoblasts or other cell types present in bone. T3 failed to activate isolated osteoclasts; however, when mixed bone cells were added to the cultures, a significant response was observed with 1 μM T3, although not with lower concentrations (Allain *et al.,* 1992). UMR-106 cells failed to activate the osteoclasts in the presence of T3, suggesting that a different cell type or a different osteoclast stage might be responsible for the activation observed with the mixed bone cells. In another study, either UMR-106-01 cells or rat calvarial cells were able to activate the osteoclasts (Britto *et al.,* 1994). Responses were detected at lower T3 concentrations in the latter study, perhaps owing to the use of stripped serum.

Resorption

T3 stimulates resorption in bone organ cultures. Fetal rat limb bones (Mundy *et al.,* 1979; Hoffmann *et al.,* 1986; Lakatos and Stern, 1992) and neonatal mouse calvaria (Krieger *et al.,* 1988; Klaushofer *et al.,* 1989; Kawaguchi *et al.,* 1994b) are the models that have been studied most extensively. In both the limb bones and calvaria, responses to T3 are slower to develop than the effects of PTH (Mundy *et al.,* 1979; Klaushofer *et al.,* 1989; Kawaguchi *et al.,* 1994b) and the dose-response curves are generally shallow (Mundy *et al.,* 1979; Hoffmann *et al.,* 1986; Krieger *et al.,* 1988). Higher doses of thyroid hormones *in vitro* can have inhibitory effects on resorption (Orbai and Gazariu, 1982). One of the most striking differences from the effects of PTH is that the maximal responses to thyroid hormones are lower (Mundy *et al.,* 1979; Lakatos and Stern, 1992; Kawaguchi *et al.,* 1994b), sometimes only about 50% of those elicited with maximal concentrations of PTH. The slower responses and lower efficacy of thyroid hormones compared with PTH may be the basis for the observation that thyroxin does not exhibit "escape" from the inhibitory effects of calcitonin (Krieger *et al.,* 1987; Klaushofer *et al.,* 1989). Alternatively, this may reflect a different mechanism for the direct effect of thyroid hormones compared with PTH. Further evidence for such a difference between the mechanism of T3 and PTH responses is the contrast in their interaction with TGFβ (Lakatos and Stern, 1992). TGFβ enhanced the early responses to PTH and inhibited the later effects, whereas the interaction with T3 displayed a somewhat reverse time course. A range of threshold concentrations was observed for both T3 and T4 in the different studies, with no clear basis in terms of the composition of the medium. 3,5,3′-Triiodothyroacetic acid, an analog that binds to nuclear receptors, especially β forms, with higher affinity than T3, was a more potent stimulator of resorption than T3 (Kawaguchi *et al.,* 1994b). In cultured fetal bones, T3 increases collagen degradation (Halme *et al.,* 1972). T3 increased mRNA for the metalloproteinases collagenase-3 and gelatinase B in cultures of osteoblastic cells, effects that were not inhibited by indomethacin (Pereira *et al.,* 1999).

Several mechanisms may mediate thyroid hormone-stimulated resorption. In neonatal mouse calvaria, resorption was inhibited by indomethacin, implicating a prostaglandin-dependent pathway (Krieger *et al.,* 1988; Klaushofer *et al.,* 1989; Kawaguchi *et al.,* 1994b). Other studies have shown prostaglandin-independent effects on the calvaria (Conaway *et al.,* 1998). In fetal rat limb bones, the T3 effect is not affected by indomethacin. However, in limb bone cultures, T3 potentiates the bone-resorbing effect of IL-1 (Tarjan and Stern, 1995), and the effect of IL-1 and the IL-1/T3 combination is sensitive to indomethacin. T3 also potentiates the IL-1-mediated production of IL-6 in this model (Tarjan and Stern, 1995), as well as in MC3T3-E1 osteoblastic cells (Tokuda *et al.,* 1998) and in bone marrow stromal cells (Kim *et al.,* 1999). In contrast, in MC3T3-E1 cells, T3 reduced the IL-6 production elicited by prostaglandin, cholera toxin, and forskolin, possibly reflecting crosstalk through effects on a cAMP pathway (Tokuda *et al.,* 1998). In mouse bone marrow cultures, T3 promoted calcitriol-induced osteoclast formation through an IL-6-dependent pathway (Schiller *et al.,* 1998). T3 also increased IL-6 production in MG-63 cells and human bone marrow stromal cells (Siddiqi *et al.,* 1999). These findings suggest that the indirect stimulation of osteoclast differentiation by IL-6 may be a component of the resorptive effect of thyroid hormone. The IL-1 receptor antagonist protein did not prevent the resorptive effect of thyroid hormones in limb bone cultures (Kawaguchi *et al.,* 1994b). Thyroid hormone effects on resorption were blocked by aphidicolin or cortisol (Kawaguchi *et al.,* 1994b) and by hydroxyurea (Conaway *et al.,* 1998), indicating the involvement of cell replication. Immunosuppressive cyclosporins blocked the thyroid hormone effects in limb bone cultures (Lakatos and Stern, 1992), and interferon-β (Klaushofer *et al.,* 1989) and the antibody to TGFβ (Klaushofer *et al.,* 1995) blocked the thyroid hormone effects in calvaria, consistent with the participation of other local factors in the resorptive response to thyroid hormone.

Remodeling

Most *in vitro* studies have focused on either anabolic or catabolic effects of thyroid hormone, under conditions

designed to optimize the study of the particular response. However, because there are dose-dependent biphasic effects on formation parameters and delayed (Klaushofer *et al.,* 1989) and submaximal (Mundy *et al.,* 1979; Krieger *et al.,* 1988; Lakatos and Stern, 1992) effects on resorption, it may be that neither effect can be studied to the exclusion of the other, and the net effects on bone remodeling may be accessible to *in vitro* investigation. A model system designed to study growth, mineralization, and resorption in radii and ulnae of 16-day fetal mice (Soskolne *et al.,* 1990) revealed interesting differences between effects of T3 and PTH. Effects of T3 were studied over a 0.1 nM–10 μM dose range. T3 concentrations in the 10 nM–0.3 μM range resulted in increases in diaphyseal length, in calcium, phosphate, and hydroxyproline content, and in decreases in ^{45}Ca release. At higher concentrations (1 and 10 μM), T3 stimulated ^{45}Ca release. In contrast, when PTH was studied over a 1 pM–0.1 μM range, only resorptive effects were observed, these being at concentrations of 1 nM and higher.

Chondrocyte Responses

Thyroid hormones block clonal expansion of the proliferative cell layer of the epiphyseal growth plate and promote chondrocyte maturation (Nilsson *et al.,* 1994). In earlier studies on isolated cells, T3 was found to inhibit chondrocyte proliferation (Burch *et al.,* 1987). T3 suppressed the synthesis of DNA, protein, and type II collagen when added to rapidly proliferating chicken growth plate chondrocytes cultured in serum-free media (Ishikawa *et al.,* 1998). When T4 was added to a chemically defined medium containing insulin and growth hormone, there were dose-dependent increases in type X collagen and in alkaline phosphatase in chondrocytes (Ballock and Reddi, 1994). T3 was approximately 50 times more potent than T4 in promoting expression of the hypertrophic markers in prehypertrophic chondrocytes in cells cultured with insulin/transferrin/selenium (Alini *et al.,* 1996). There was a biphasic dose dependency of the effects of T3 and T4 to stimulate the synthesis of type II collagen and chondroitin sulfate-rich proteoglycans in cultured rabbit articular chondrocytes (Glade *et al.,* 1994). In an *in vitro* model of cartilage formation from a chondrocyte pellet, the developing cartilage assumed the structural architecture of the normal epiphysis if thyroid hormones were present, whereas the structure was random in their absence (Ballock and Reddi, 1994). In serum-free long-term micromass cultures of chick embryonic limb mesenchyme in which the sequence of chondrogenesis, chondrocyte maturation, hypertrophy mineralization, and apoptosis can be reproduced T3 inhibited proliferation and stimulated alkaline phosphatase and hypertrophy and promoted apoptosis (Mello and Tuan, 2006). TGFβ1 or serum disrupted the appearance of columnar organization of chondrocytes in control or T3-treated cultures. Findings from cocultures of vascular endothelial cells and chondrocytes suggest that vascular endothelial cells may produce factors that act synergistically with thyroid hormone to derepress the late differentiation of resting chrondrocytes and permit them to become hypertrophic and express type X collagen and alkaline phosphatase (Bittner *et al.,* 1998), leading to mineralization. The antiproliferative and differentiation effects of T3 on primary chondrocytes from mouse rib were shown to be mediated by the TRβ receptor isoform, but not the TRα isoform (Rabier *et al*., 2006).

IN VIVO RESPONSES OF THE SKELETON TO THYROID HORMONES AND TSH: ANIMAL STUDIES

When thyroid hormones are administered to young rats, bone growth is enhanced (Glasscock and Nicoll, 1981). This response is not seen in older rats, suggesting that the stage of cellular differentiation or the environment in terms of other hormones and local factors can influence the manifestation of thyroid hormone responses. T3 treatment of neonatal rats elicited a narrowing of the sagittal suture and increased mineral apposition rates at the osseous edges of the sutures (Akita *et al.,* 1994). Histomorphometric analysis was consistent with the conclusion that T3 is critical for bone remodeling (Allain *et al.,* 1995). *In vivo* effects of TSH were investigated in ovariectomized Sprague-Dawley rats (Sampath *et al*., 2007). Rat TSH prevented the bone loss and resulted in improvements in bone mineral density and histomorphological measurements. For many of the parameters, maximal effects were seen at the lowest dose administered (0.1 ug). Responses to TSH were seen in the absence of increases in T3 or T4, and with long-term (up to 6-week) treatment, thyroid hormone concentrations were decreased in some groups receiving the higher TSH doses.

Hypothyroidism

Animal models of hypothyroidism include the use of the antithyroid agents propylthiouracil or methimazole to block the synthesis of thyroid hormones. Treatment of young rats with methimazole for seven weeks resulted in a marked increase in trabecular bone volume of the subchondral spongiosa of the mandibular condyles and a decrease in cartilage cellularity (Lewinson *et al.,* 1994). IGF-I was present in the condyles of control rats, but lacking in hypothyroid rats. Replacement of T4 during the last two weeks of treatment restored the parameters to normal (Lewinson *et al.,* 1994). Histomorphometric studies in iliac crest biopsies of young rats made hypothyroid by a 12-week treatment with propylthiouracil showed that both osteoid surfaces and eroded surfaces were reduced and cancellous bone volume was increased (Allain *et al.,* 1995). In a study

in which 21-day rats were made hypothyroid by administration of methimazole, T4 given daily at doses of 2 to 64 μg/kg/day for 21 days elicited biphasic effects on epiphyseal growth plate width and logitudinal growth rate (Ren *et al.,* 1990). The dose-response curve paralleled that of serum IGF-I concentrations, which were postulated to contribute to the growth responses (Ren *et al.,* 1990).

An interesting animal model for hypothyroidism utilizes transgenic mice (line TG66-19) in which the bovine thyroglobulin promoter drives the expression of the herpes simplex type I virus thymidine kinase gene in thyrocytes. This enzyme converts ganciclovir to ganciclovir-5′-phosphate, which inhibits DNA replication, resulting in loss of thyrocytes, loss of follicles, and undetectable T3 and T4; levels of PTH and CT are unaffected (Wallace *et al.,* 1991, 1995). In this transgenic mouse model, administration of 15 or 50 μg of ganciclovir to mouse dams during days 14–18 of gestation resulted in growth delay in pups carrying the transgene (Wallace *et al.,* 1995). The authors point out that the reason their effects were more dramatic than those obtained with the *hyt/hyt* mouse, a strain that has an inactivating mutation in the TSH receptor, is that in the latter model, circulating T4 is still 10–20% of normal (Adams *et al.,* 1989). Effects of mutations in thyroid hormone receptors in mouse models were discussed earlier.

Hyperthyroidism

A range of T4 regimens has been used to elicit hyperthyroidism in animal models. The duration of treatment is generally at least three weeks and dosages range from 200 μg to 1 g/day. Lower concentrations have been used in animals previously made hypothyroid with antithyroid drugs (Lewinson *et al.,* 1994). When the animals were rendered hyperthyroid by treatment with T4 (200 μg/day for 12 weeks), the mineral apposition rate and the mineral formation rate were increased markedly, with a smaller increase in eroded surfaces (Allain *et al.,* 1995). A greater sensitivity of cortical bone (femur) than trabecular bone (spine) to thyroid hormone-induced bone loss has been noted in animal models of hyperthyroidism (Ongphiphadhanakul *et al.,* 1993; Suwanwalaikorn *et al.,* 1996, 1997; Gouveia *et al.,* 1997; Zeni *et al.,* 2000). Tooth movement was greater in T3-treated rats undergoing orthodontic procedures than in control untreated animals, probably reflecting greater root resorption (Shirazi *et al.,* 1999). Ten-day-old rats treated with 100 μg/kg/day for up to 60 days displayed altered parameters of cranial width, narrowing of the suture gap of the sagittal suture, and intense immunohistochemical staining for IGF-I along the suture margins, consistent with the possibility that local IGF-I is involved in the effect of thyroid hormone to cause premature suture closure (Akita *et al.,* 1996).

Ovariectomized rats treated with a low dose of T4 (30 μg/kg/day for 12 weeks) showed increased bone turnover and decreased bone density compared with controls; however, in the presence of 17β-estradiol, their bone mass and mineral apposition rate were greater than those of controls (Yamaura *et al.,* 1994). T4, (250 μg/kg/day for five weeks) increased serum osteocalcin and urinary pyridinolines and produced a greater loss of bone mineral compared with either ovariectomy alone or T4 alone (Zeni *et al.,* 2000). In contrast to the effects of these high doses of T4, administration of a more physiological concentration (10 μg/kg/day) to ovariectomized rats resulted in a generalized increase in bone mineral density at both lumbar and vertebral sites (Gouveia *et al.,* 1997). Estradiol prevented T3-stimulated decreases in bone mineral density in ovariectomized thyroidectomized rats, but had no effect in animals that were not treated with T3 (DiPippo *et al.,* 1995). These results raise the possibility of crosstalk at the level of binding of estradiol and T3 receptors to DNA target sites.

PATHOPHYSIOLOGICAL EFFECTS OF ALTERED THYROID HORMONE STATUS IN HUMANS

Hypothyroidism

Bone turnover is decreased in hypothyroidism (Mosekilde and Melson, 1978). In juvenile hypothyroidism, there is delayed skeletal maturation and epiphysial dysgenesis. In a study of children with congenital hypothyroidism treated with T4, the bone age at 1.5 years was correlated positively with the dose of T4 administered during the first year and with the concentrations of serum T4 (Heyerdahl *et al.,* 1994). As discussed previously, multiple skeletal abnormalities have been described in syndromes of RTH, including short stature, delayed skeletal maturation, and stippled epiphyses (Refetoff *et al.,* 1993). Serum IGF-I is lower in hypothyroid patients (Lakatos *et al.,* 2000). Bone resorption is decreased in patients with hypothyroidism, as indicated by reduced urinary pyridinium cross-links (Nakamura *et al.,* 1996).

Hyperthyroidism

Since the initial description of bone loss in thyrotoxicosis by Von Recklinghausen (1891) more than a century ago, substantial additional evidence has shown that excessive thyroid hormone production can lead to bone loss. In patients with hyperthyroidism, markers of bone turnover are increased. Pyridinoline and hydroxypyridinoline cross-link excretion are elevated (Harvey *et al.,* 1991; Garnero *et al.,* 1994; Nagasaka *et al.,* 1997; Engler *et al.,* 1999), as are urinary N-terminal telopeptide of type I collagen (NTX) (Mora *et al.,* 1999; Pantazi *et al.,* 2000) and serum carboxyterminal-1-telopeptide (ICTP) (Loviselli *et al.,* 1997; Miyakawa *et al.,* 1996; Nagasaka *et al.,* 1997). Evidence of

activation of osteoblasts in hyperthyroidism is the elevation of alkaline phosphatase (Mosekilde and Christensen, 1977; Cooper *et al.,* 1979; Martinez *et al.,* 1986; Nagasaka *et al.,* 1997; Pantazi *et al.,* 2000), osteocalcin (Martinez *et al.,* 1986; Lee *et al.,* 1990; Mosekilde *et al.,* 1990; Nagasaka *et al.,* 1997; Loviselli *et al.,* 1997; Pantazi *et al.,* 2000), and carboxyterminal propeptide of type I procollagen (PICP) (Nagasaka *et al.,* 1997). Osteocalcin showed a better correlation than alkaline phosphatase with thyroid hormone concentrations (Martinez *et al.,* 1986; Garnero *et al.,* 1994). Greater increases in the resorption markers than the formation markers suggest an imbalance between resorption and formation, leading to bone loss (Garnero *et al.,* 1994; Miyakawa *et al.,* 1996). Histomorphometric analyses show increased osteoclast numbers and resorbing surfaces, with loss of trabecular bone volume (Meunier *et al.,* 1972; Mosekilde and Melsen, 1978). Histomorphometric data yield a kinetic model demonstrating accelerated bone remodeling, with a disproportionately greater increase in resorption and a net loss of bone with each cycle of remodeling (Eriksen, 1986). Decreased bone mineral content in hyperthyroidism is well documented (Fraser *et al.,* 1971; Krolner *et al.,* 1983; Toh *et al.,* 1985), and fracture risk is increased in hyperthyroidism (Fraser *et al.,* 1971; Cummings *et al.,* 1995; Wejda *et al.,* 1995; Vestergaard *et al.,* 2000a). Mild hyperthyroidism may increase bone loss in postmenopausal women (Lakatos *et al.,* 1986). In children, however, thyrotoxicosis can lead to acceleration of growth and skeletal development (Schlesinger and Fisher, 1951; Saggese *et al.,* 1990). A study of Japanese male patients with Graves' disease showed significant prevalence of cortical bone loss, which was more marked in older patients (Majima *et al*., 2006a). There was a negative correlation between bone mineral density and TSH receptor autoantibodies In view of the proposed role of TSH on bone, studies of the bone effects of the TSH receptor autoantibodies could be interesting.

Stimulation of the production of local factors by thyroid hormone, which was observed *in vitro* and animal studies, is also seen in humans. Thyroid hormone increased circulating IL-6 (Lakatos *et al.,* 1997; Siddiqi *et al.,* 1999). A lack of correlation between IL-6 and remodeling markers was noted in a study of hyperthyroid patients (Akalin *et al*., 2002). In patients with Graves' disease, but not in patients with nontoxic nodular goiter, there was a correlation between TSH receptor autoantibodies and serum IL-6 (Bossowski and Urban, 2001). However, another study did not find a correlation (Salvi, 2000). Thyroid hormone increases IGF-I (Brixen *et al.,* 1995; Kassem *et al.,* 1998; Foldes *et al.,* 1997; Lakatos *et al.,* 2000). One can speculate that the greater rate of production of IGF-I in children could explain the findings of studies in which large doses of thyroid hormone were not deleterious to bone in children (Kooh *et al.,* 1996; Verrotti *et al.,* 1998; Dickerman *et al.,* 1997; Leger *et al.,* 1997; van Vleit *et al.,* 1999; Turner *et al.,* 1999). The anabolic effect of the increased IGF-I could compensate for or override the bone breakdown. Studies have shown effects of thyroid hormones and TSH on OPG. The mechanism and role of this response are not yet clear. Consistent with the molecular studies (Varga *et al*., 2004) showing that T3 increases OPG in osteoblastic cells, elevated OPG has been reported in patients with Graves' disease (Amato *et al*., 2004; Mochizuki *et al*., 2006). In the Amato study, the elevated OPG correlated with free T3 but not free T4. In the Mochizuki study, antithyroid treatment decreased the elevated OPG and this change correlated with free T4; the correlation of OPG with free T3 was close to statistical significance, and there was no correlation with TR antibodies. The possibility that the increase in OPG has a counterregulatory function to protect against excessive turnover stimulated by thyroid hormone was proposed (Amato *et al*., 2004). TSH was found to inhibit RANKL and upregulate OPG production in the thyroid gland (Hofbauer *et al*., 2002).

Several reviews (Greenspan and Greenspan, 1999; Lakatos, 2003) provide useful overviews of the bone effects of overt and subclinical hyperthyroidism and exogenous thyroid hormone treatment at suppressive and lower doses. The studies cited indicate that the hyperthyroid condition can result in bone loss and fracture risk and that subclinical hyperthyroidism could be an additional risk factor for postmenopausal women.

T4 Therapy and Bone Loss

A particularly critical issue regarding the effects of thyroid hormone on the skeleton is the question of what amounts of exogenously administered thyroid hormones increase the risk of bone loss, especially among individuals already at risk for osteoporotic fractures from other causes. Thyroid hormones are given as replacement therapy for hypothyroidism after thyroidectomy, as well as in other states where patients may have inadequate thyroid hormone secretion and goiter, such as autoimmune thyroiditis. Thyroid hormones are also used as suppressive therapy for toxic nodular goiter or for thyroid cancer. There may be patients who used excess thyroid hormones in the past for weight loss or as a tonic.

There have been, and continue to be diverse clinical findings on the skeletal effects of treatment with suppressant doses of thyroid hormones. Decreased bone density, accelerated bone turnover, and increased risk of fracture in patients treated with T4 have been documented extensively (Fallon *et al.,* 1983; Coindre *et al.,* 1986; Ross *et al.,* 1987; Paul *et al.,* 1988; Stall *et al.,* 1990; Taelman *et al.,* 1990; Adlin *et al.,* 1991; Diamond *et al.,* 1991; Greenspan *et al.,* 1991; Lehmke *et al.,* 1992; Frevert *et al.,* 1994; Garton *et al.,* 1994; Grant *et al.,* 1995; McDermott *et al.,* 1995; Campbell *et al.,* 1996; Affinito *et al.,* 1996; Jodar *et al.,* 1998; Hadji *et al.,* 2000). Several studies and

a meta-analysis (Marcocci *et al.,* 1994; Uzzan *et al.,* 1996; Greenspan and Greenspan, 1999; Campbell *et al.,* 1996; Affinito *et al.,* 1996) concluded that the dose of T4 and duration of treatment are major determinants of the occurrence of bone loss. Other factors that appear to amplify the risk include a previous history of hyperthyroidism (Grant *et al.,* 1995), age (Duncan *et al.,* 1994), and postmenopausal status (Greenspan *et al.,* 1991; Stepan and Limanova, 1992; Franklyn *et al.,* 1994; Garton *et al.,* 1994; Affinito *et al.,* 1996; Jodar *et al.,* 1998). It has been suggested that a low dietary calcium intake can contribute to the risk of T4-induced bone loss (Kung *et al.,* 1983). Estrogen and HRT protected against the bone loss associated with T4 treatment (Schneider *et al.,* 1994; Franklyn *et al.,* 1995). Consistent with the importance of dose and duration, TSH has been a useful predictive marker for bone loss (Wartofsky, 1991). A meta-analysis of 13 publications in which TSH was suppressed by thyroid hormone treatment projected that a premenopausal woman at an average age of 39.6 years, treated with L-T4, (164 μg/day for 8.5 years), would have an excess annual bone loss of 0.31% and 2.67% less bone mass than a control (Faber and Galloe, 1994).

In contrast with these findings, a number of studies report that T4 treatment failed to produce bone loss (Toh and Brown, 1990; Ribot *et al.,* 1990; Franklyn and Sheppard, 1992; Grant *et al.,* 1993; Fujiyama *et al.,* 1995; Hawkins *et al.,* 1994; Schneider *et al.,* 1995; DeRosa *et al.,* 1995; Saggase *et al.,* 1990, 1997; Marcocci *et al.,* 1997; Gurlek and Gedik, 1999; Rachedi *et al.,* 1999; Nuzzo *et al.,* 1998; Knudsen *et al.,* 1998; Hanna *et al.* 1998; Langdahl *et al.,* 1996a). One explanation for this apparent disparity, in the case of patients receiving T4 replacement therapy, is that their cortical bone density was initially higher owing to their hypothyroidism and that T4 replacement resulted in normalization (Ross, 2000). A longitudinal study would indicate bone loss, whereas a cross-sectional study would not reveal a significant difference from the control group. Another possible basis for some of the diversity of findings is that the accelerated bone turnover and increased fracture risk with T4 treatment can be a transient phenomenon. In one report, correlations between serum-free T4 and serum procollagen III peptide, which had been noted after six months of T4 treatment, were not found in patients treated chronically (Nystrom *et al.,* 1989). There may be an initial increase in cortical width and bone porosity that results in increased fracture risk until a new steady-state condition is established (Coindre *et al.,* 1986). Another study found a temporary increase in fracture risk in previously hypothyroid patients, which was most prevalent in patients over 50 years of age and limited to forearm fractures (Vestergaard *et al.,* 2000b). Studies published since the previous version of this chapter indicate that the issue of bone risk of suppressive therapy is still unclear. Some studies show no significant deleterious effect of treatment (e.g., Mikosch *et al.*, 2001, Reverter *et al.*, 2005). Close monitoring of TSH may allow suppressive treatment without risk to bone. A three-year study in women with benign nodular goiter showed that doses of LT4 that reduced TSH to below the lower limit of normal but maintained it above above 0.005 μU/ml and maintained normal free T3 and free T4 had no effect on BMD or serum markers of bone turnover in pre-postmenopausal women (Appetecchia, 2005). A recent review of 21 studies of TSH-suppressive thyroid hormone therapy on bone metabolism in patients with well-differentiated thyroid carcinoma concluded that postmenopausal women with DTC receiving TSH-suppressive therapy were at high risk for bone loss whereas premenopausal women and men did not share this risk (Heemstra *et al.*, 2006). OPG was elevated in patients receiving suppressive therapy for differentiated thyroid cancer (Mikosch *et al.*, 2006). A study in patients being monitored for thyroid carcinoma, all of whom had subclinical thyrotoxicosis as a consequence of T4 treted, tested the effects of short-term stimulation with recombinant human TSH on skeletal remodeling (Mazziotti *et al.*, 2005). Two intramuscular doses of 0.9 mg TSH were administered. Measurements made two days and one week after the treatment showed decreases in serum c-telopeptides of type-1 collagen (CrossLaps). in patients who were postmenopausal. Bone alkaline phosphatase was increased, and there was no significant change in OPG. The conclusion was that TSH inhibited bone resorption, but that it did not regulate OPG in bone.

Reversibility/Treatment/Prevention of Thyroid Hormone-Stimulated Bone Loss

Recovery of bone loss in hyperthyroid patients following antithyroid treatment has been inconsistent (Fraser *et al.,* 1971; Toh *et al.,* 1985; Saggese *et al.,* 1990; Diamond *et al.,* 1994; Mudde *et al.,* 1994, Oikawa *et al.*, 1999, Kumeda *et al.*, 2000, Barsal *et al.*, 2004), but may be achieved more readily in younger individuals (Fraser *et al.,* 1971; Saggese *et al.,* 1990). Studies have documented protective effects of methimazole (Langdahl *et al.,* 1996b; Nagasaka *et al.,* 1997; Mora *et al.,* 1999). Surgery and radioactive iodine also prevented bone loss in hyperthyroid patients (Langdahl *et al.,* 1996c; Arata *et al.,* 1997), but were less protective than methimazole (Vestergaard *et al.,* 2000a). The protective effects of estrogen during treatment with T4 were noted earlier, and androgen may also be beneficial (Lakatos *et al.,* 1989). Calcium and calcitonin were also found to offer some protective benefit (Kung and Yeung, 1996).

Bisphosphonates may protect against thyroid hormone-induced bone loss. Both animal (Ongphiphadhanakul *et al.,* 1993; Rosen *et al.,* 1993a; Yamamoto *et al.,* 1993; Kung and Ng, 1994) and human (Rosen *et al.,* 1993b; Lupoli *et al.,* 1996) studies have demonstrated that bisphosphonates are effective in preventing thyroid hormone-stimulated bone loss. Etidronate (0.5 mg/100 g administered

twice weekly) prevented decreased bone mineral density and increased mRNA for alkaline phosphatase, tartrate-resistant acid phosphatase, and histone H4 in femurs of rats treated with L-T4 for 20 days (Ongphiphadhanakul *et al.,* 1993). The combination of L-T4 and etidronate resulted in lower expression of mRNA for type I collagen, osteocalcin, and osteopontin, which was lower than that of controls, although neither L-T4 nor etidronate alone affected these parameters. Alendronate (1.75 mg/kg orally twice weekly) prevented increased bone turnover resulting from the administration of excess T4 for three weeks (Lupoli *et al.,* 1996). The preventive effect was assessed by histomorphometry and measurement of osteocalcin. Bone volume was above control in all alendronate-treated groups in the study. Pretreatment of rats with pamidronate (5 μmol/kg/day subcutaneously for one week prior to T3) prevented increases in alkaline phosphatase and osteocalcin at one week and losses of bone mineral density at three weeks in the femur and spine (Rosen *et al.,* 1993b). Pamidronate pretreatment (30 mg IV, daily for two days) prevented increases in urinary calcium/creatinine ratio, urinary hydroxyproline, and urinary pyridinoline cross-links in normal male subjects treated with T3 (Rosen *et al.,* 1993a). The addition of risedronate, 2.5 mg/day to a methimazole regimen for 6 or 12 months improved bone mineral density at the lumbar spine and distal radius and reduced turnover markers in a study in male patients with newly diagnosed Graves' disease (Majima *et al*., 2006b).

OVERVIEW, SPECULATIONS, AND FUTURE DIRECTIONS

Thyroid hormones act at receptor, cellular, and organismal levels to modulate or interact with many of the other factors and pathways that determine the status of the skeleton. There are interactions with both nuclear receptors and membrane-binding sites in bone cells and effects on many of the phenotypic responses of bone cells. The relative importance of the different nuclear receptor isoforms for bone responses and the mechanisms of this are now clearer. The responses mediated by the membrane-binding sites are still not defined. It is clear that thyroid hormones have importance in normal skeletal physiology, because deficiency or excess of thyroid hormone can alter skeletal development and maintenance. There is a dose dependence to the effects, with anabolic effects declining and catabolic effects becoming more prominent with the higher concentrations of thyroid hormone present in hyperthyroidism and with the higher doses that are used for suppressive therapy. Determination of TSH to guide thyroid hormone dosage can decrease the occurrence of bone loss resulting from the therapeutic use of thyroid hormone. However, factors other than dosage can influence the response to thyroid hormone. The anabolic effects of thyroid hormone on bone are more apparent in younger animals and children, consistent with the possibility that growth factors can have significant mediating or modulating effects. Thyroid hormones increase IGF-I in osteoblasts and experimental animals; elevated circulating thyroid hormones are associated with increases in IGF-I and IGFBPs in patients and other growth factors, including FGF, are also likely to be involved. Other physiological factors modulate the skeletal effects of thyroid hormones, e.g., estrogens can decrease the deleterious effects of excess thyroid hormone. The pharmacological inhibition of bone resorption with bisphosphonates can also diminish thyroid hormone-stimulated bone loss. Thyroid hormones stimulate osteoblast proliferation, promote the differentiation of this cell type, and stimulate differentiated functions, as shown by increases in alkaline phosphatase activity, osteocalcin expression, and stimulation of collagen synthesis. The variation in the responses when different model systems are used indicates that there are additional modulating factors that are not yet understood. The osteoblast is the target cell for thyroid hormone activation of mature osteoclasts. The promotion of resorption by thyroid hormones may be mediated through the activation of cytokine pathways that lead to osteoclast differentiation. The role of the thyroid hormone-stimulated increase in osteoprotegerin is an interesting and open question. TSH as an effector of responses in bone will undoubtedly be the topic of further basic and clinical investigations. Even as more information is gained regarding the actions of thyroid hormone, there are continuing and new unanswered questions.

Chapter 44

Clinical and Basic Aspects of Glucocorticoid Action in Bone

Barbara E. Kream*, Leland Graves III† and Barbara P. Lukert†

INTRODUCTION

Glucocorticoid-induced osteoporosis (GIOP) was first reported by Cushing when he described osteoporosis in patients with high levels of cortisol owing to an adrenocorticotrophin-producing tumor of the pituitary gland (Cushing, 1932). The problem became clinically significant in 1949 when pharmacological doses of glucocorticoids were introduced for therapeutic use because of their potent anti-inflammatory and immunosuppressive effects. It became clear that treatment with glucocorticoids causes a loss of bone mass and pathological fractures. Since then, efforts have been made to elucidate the cause of steroid-induced bone loss.

Cortisol, the glucocorticoid secreted by the adrenal gland, is essential in physiological doses for the differentiation and function of osteoblasts and osteoclasts, and it modulates the effects of other hormones and mediators of cell function, even though supraphysiological doses inhibit bone formation. These direct effects on bone, combined with effects on other systems that indirectly regulate bone metabolism, cause rapid bone loss in patients treated with glucocorticoids. The mechanisms involved and the resulting clinical picture are the subjects of this chapter.

Pharmacology of Glucocorticoids

Synthetic derivatives of cortisol with less mineralocorticoid effect have been developed. The compounds most frequently prescribed are prednisone, prednisolone, methylprednisolone, betamethasone, dexamethasone, and triamcinolone. Prednisone is metabolized to prednisolone. The 4,5-double bond and the 3-ketone structures are both necessary for typical adrenocorticoid activity. Introduction of 1,2-double bond, as in prednisone or prednisolone, enhances the ratio of carbohydrate-regulating potency to sodium-retaining potency. 6α-Methylation of the B ring (6α-methylprednisolone) increases anti-inflammatory potency while reducing electrolyte-retaining properties. 9α-Fluorination enhances all biological activities, whereas 16-methylation eliminates the sodium-retaining effect, but only slightly alters other effects on metabolism or inflammation. Substitution in the 17α-ester position produces a group of extremely potent steroids, beclomethasone dipropionate and budesonide, which are effective when applied topically to skin or administered by inhalation (Gilman *et al.*, 1990). The absorption of inhaled steroids is virtually equivalent to that of oral administration and absorption from skin is significant if applied over a large surface or under plastic film. Despite this, inhaled or topical steroids reduce side effects because the drugs are targeted to the site of the disease and lower doses can be used. Deflazacort, an oxazoline derivative of prednisone, has been developed with the hope of reducing the catabolic effects of glucocorticoids while maintaining anti-inflammatory effects (Gennari *et al.*, 1984), but the results have been disappointing. The recent development of synthetic glucocorticoids that dissociate transactivation and AP-1 transrepression and yet exhibit anti-inflammatory activity holds promise for the development of glucocorticoid-based drugs that separate beneficial from deleterious effects.

Glucocorticoids are widely used in the treatment of asthma, collagen-vascular disease, inflammatory bowel disease, and granulomatous and skin diseases. The skeletal response to glucocorticoids is not disease specific, and accelerated bone loss has been described in patients with each of these diseases when they are treated with steroids (de Deuxchaisnes *et al.*, 1984; Reid *et al.*, 1986a; Rizzato *et al.*, 1988).

Principles of Bone Biology, 3rd Edition

Characteristics of Bone Loss and Fracture Risk

Bone loss, measured by dual-energy x-ray absorptiometry in patients receiving glucocorticoids for more than a year, has been reported to average 0.6% to 6% per year (Laan *et al.*, 1993; Lukert *et al.*, 1992; Sambrook *et al.*, 1990). Trabecular bone and the cortical rim of the vertebral body are more susceptible to the effects of glucocorticoids than the cortical bone of the extremities (Laan *et al.*, 1993; Seeman *et al.*, 1982). Consequently, compression fractures of the spine are frequently the first sign of glucocorticoid-induced bone loss, and the proximal femur becomes more fragile. Although bone loss appears to be most rapid during the first 6 to 12 months of treatment, loss remains above average for the duration of treatment (Gennari, 1985; Lukert *et al.*, 1992). The risk for hip fracture is doubled and the risk for vertebral fracture is increased by 5-fold by oral doses of prednisone exceeding 7.5 mg/day (Van Staa *et al.*, 2000). The risk for fracture increases within the first 3 months after the initiation of glucocorticoid therapy and decreases within 3 months after discontinuation. Approximately 30% to 50% of patients taking glucocorticoids long term and 50% of patients with Cushing's disease (excessive endogenous production of steroids) have at least one atraumatic fracture (Adinoff *et al.*, 1983; Ross *et al.*, 1982). In patients who have been exposed to the equivalent of prednisone 10 mg/day for longer than 90 days, the risk of hip and spine fractures is increased by 7- and 17-fold, respectively, even in patients taking glucocorticoids intermittently (Steinbuch *et al.*, 2004). Vertebral compression fractures are commonly asymptomatic. In a cross-sectional study, 37% of postmenopausal women taking glucocorticoids for more than 6 months showed morphometric changes in vertebral bodies without symptoms (Angeli *et al.*, 2006). The fracture threshold for vertebral fractures appears to be higher for patients taking steroids than for those with involutional osteoporosis (Luengo *et al.*, 1990; Van Staa *et al.*, 2000); that is, fractures occur at a higher bone density in steroid-treated patients. Quantitative computed tomography (QCT) studies of the hip have shown lower integral, cortical, and trabecular bone mineral density (BMD) and cortical volume in glucocorticoid-treated postmenopausal women than in postmenopausal controls. These findings may partially explain why individuals treated with glucocorticoids have increased risk for hip fracture than age-matched controls (Lian *et al.*, 2005).

Glucocorticoid-induced bone loss is partially reversible after cessation of prednisone administration or removal of the cause of excessive endogenous production of cortisol (Laan *et al.*, 1993; Manning *et al.*, 1992; Rizzato *et al.*, 1993; Van Staa *et al.*, 2000). Bone loss is also partially reversible during treatment with estrogen/progesterone therapy, bisphosphonates, calcitonin, parathyroid hormone, or sodium fluoride, whereas prednisone is continued (Lane *et al.*, 2000; Luengo *et al.*, 1990; Lukert *et al.*, 1992; Meunier *et al.*, 1987; Reid *et al.*, 2000; Saag *et al.*, 1998; Struys *et al.*, 1995).

Histomorphometric studies on bone from glucocorticoid-treated patients show that glucocorticoids cause apoptosis of osteoblasts and osteocytes, and depress osteoblastic function, whereas, at the same time, the frequency of activation of bone remodeling units is increased. Thus, there is an increase in the number of sites at which bone is being resorbed, and the ability of osteoblasts to replace bone at each site is decreased. This results in reduced wall thickness of cancellous bone packets, and eventually, to perforation and removal of trabecular plates (Bressot *et al.*, 1979; Dempster, 1989; Meunier *et al.*, 1982; Plotkin *et al.*, 1999; Weinstein *et al.*, 1998).

Bio-markers of Bone Remodeling

Serum levels of osteocalcin, the most abundant noncollagen bone matrix protein and a biochemical marker of bone formation, are suppressed in patients receiving either oral or inhaled glucocorticoids (Lukert *et al.*, 1986; Puolijoki *et al.*, 1992). Surprisingly, urinary hydroxyproline and pyridinium cross-links, markers of bone resorption, are not increased by glucocorticoids (Cosman *et al.*, 1994; Lukert *et al.*, 1995). Conversely, serum tartrate-resistant acid phosphatase was elevated during short-term steroid therapy. It was felt that the high doses used in this study could have been toxic to osteoclasts causing cell death and liberation of cytoplasmic tartrate-resistant acid phosphatase (TRAP)into serum in the absence of increased bone resorption (Cosman *et al.*, 1994). The finding of a 96% increase in osteoclast perimeter observed in vertebrae taken from mice receiving prednisolone for 7 days makes it more likely that osteoclastic bone resorption is indeed increased early in the course of glucocorticoid administration (Weinstein *et al.*, 1998).

Risk Factors for Glucocorticoid-Induced Bone Loss

The usual risk factors for involutional osteoporosis (age, race, sex, weight, and parity) do not apply to the same extent to glucocorticoid-induced bone loss (Dykman *et al.*, 1985). Everyone taking high doses (greater than 10 mg/day of prednisone) loses significant amounts of bone (Garton *et al.*, 1993). Postmenopausal women receiving equivalent doses of steroids are more at risk for fractures than premenopausal women or men, presumably because they also have age- and menopause-related bone loss. It is unlikely that there is a threshold dose of glucocorticoid below which bone loss does not occur. A recent retrospective cohort study showed that the risk for fracture is increased even for doses below 7.5 mg/day and increases further with increasing

daily and cumulative doses (Van Staa *et al.*, 2000). Even high doses of some inhaled steroids (Ip *et al.*, 1994), but not others (Medici *et al.*, 2000), cause bone loss.

The reasons for individual variation in response to glucocorticoids are numerous. Polymorphisms in the glucocorticoid receptor are associated with differences in BMD and body composition (Russcher *et al.*, 2005; van Rossum *et al.*, 2003, 2004). Responses to glucocorticoids may be related to peripheral enzymes that interconvert active and inactive glucocorticoids. Two 11β-hydroxysteroid dehydrogenases regulate the interconversion between cortisone and the active cortisol, and prednisone to prednisolone, thus playing a role in the modulation of glucocorticoid activity (Tomlinson *et al.*, 2004). 11β-Hydroxysteroid dehydrogenase type 1 (11β-HSD1) is a glucocorticoid activator, converting cortisone to cortisol. 11β-Hydroxysteroid dehydrogenase type 2 (11β-HSD2) is a glucocorticoid inhibitor, converting cortisol to cortisone, and is present in mineralocorticoid target tissues. 11β-HSD1 is expressed in bone, as well as other glucocorticoid target tissues, and its ability to convert glucocorticoids to their most active form is enhanced by glucocorticoids (Cooper *et al.*, 2001; Tomlinson *et al.*, 2004). An inverse relationship has been observed between 11β-HSD1 activity and the differentiation of osteoblasts (Cooper *et al.*, 2002). 11β-HSD1 activity increases with age and this may partially explain the greater sensitivity of the elderly to glucocorticoid-induced bone loss (Cooper *et al.*, 2002). The underlying disease obviously affects the susceptibility to the adverse effects of glucocorticoids. Rheumatoid arthritis, chronic obstructive pulmonary disease, and inflammatory bowel disease have all been shown to be associated with bone loss without glucocorticoid treatment (Lekamwasam *et al.*, 2005; Romas, 2005; Sin *et al.*, 2003). Nutritional factors, such as inadequate protein, calcium, and/or vitamin D consumption, and nonspecific frailty and muscle weakness influence the response to glucocorticoids, in particular, the risk for fractures.

INDIRECT MECHANISMS FOR THE PATHOGENESIS OF GLUCOCORTICOID-INDUCED BONE LOSS

Glucocorticoids affect nearly every system in the body. We will first discuss the effects of glucocorticoids on systems that indirectly modulate bone metabolism to set the stage for a discussion of the direct effects of glucocorticoids on bone.

Effects on Pituitary Function

Growth Hormone

The secretion of growth hormone (GH) is partially controlled by glucocorticoids. Prednisone inhibits pituitary secretion of growth hormone in response to GH-releasing hormone in healthy men, most likely by increasing hypothalamic somatostatin tone (Giustina *et al.*, 1995; Kaufmann *et al.*, 1988). The growth hormone response to growth hormone-releasing hormone is reduced in patients receiving long-term inhaled steroids, illustrating that the control of growth hormone secretion is disrupted even by very small doses of glucocorticoids (Malerba *et al.*, 2005). Nevertheless, serum concentrations of growth hormone and insulin-like growth factor-1 (IGF-1) are normal in patients receiving glucocorticoids (Gourmelen *et al.*, 1982; Kaufmann *et al.*, 1988; Morris *et al.*, 1968). Despite normal levels, IGF-1 activity measured by bioassay is decreased in patients with glucocorticoid excess, perhaps because of an IGF-1 inhibitor that has been found in the serum of children receiving glucocorticoids (Unteman *et al.*, 1985). This inhibitory factor may be one of the IGF-binding proteins. Curiously, despite these findings, administration of growth hormone appears to reverse some of the adverse effects of chronic glucocorticoid treatment on bone (Giustina *et al.*, 1995).

A clearer understanding of the role of IGF-binding proteins on IGF activity has emerged and shed light on the mechanisms through which glucocorticoids may exert their effect. As discussed later, glucocorticoids may affect IGF-binding proteins (IGFBPs), which inhibit or enhance IGF activity. Glucocorticoids increase circulating levels of IGFBP-1, which may limit the activity of IGF-1; this effect has been associated with glucocorticoid-induced fetal growth retardation (Prince *et al.*, 1992). The importance of serum levels of growth factors or their binding proteins is unknown because growth factors are produced locally by bone cells. Growth hormone and parathyroid hormone (PTH) are trophic hormones (Ernst *et al.*, 1988; McCarthy *et al.*, 1989) for growth factors produced in bone, and the increase in bone density observed with the administration of PTH may be caused by stimulation of the production of growth factors in bone (Lane *et al.*, 2000).

Hypothalamic-Pituitary-Gonadal Axis

Glucocorticoids blunt pituitary secretion of luteinizing hormone (Sakakura *et al.*, 1975). A subset of gonadotropin-releasing-hormone (GnRH)-containing neurons in the rat hypothalamus possesses glucocorticoid receptors that bind dexamethasone *in vitro* with high affinity. Glucocorticoids repress transcription in a hypothalamic cell line, and glucocorticoid receptors present within GnRH neurons could be at least partly responsible for negative regulation of the hypothalamic-pituitary-gonadal axis. Suppression of gonadotropin levels by chronic elevations in glucocorticoids may be accounted for in part by suppression of GnRH mRNA levels, whereas the block of the gonadotropin surge by short-term glucocorticoids appears to involve other mechanisms including decreased follicle-stimulating hormone β (FSHβ) mRNA levels (Gore *et al.*, 2006).

Glucocorticoids also have direct effects on the gonads inhibiting FSH-induced estrogen production by ovarian granulosa cells and testosterone production by the testes (Hsueh *et al.*, 1978). The adrenal secretion of androgens is also decreased owing to suppression of ACTH secretion. Inhaled beclomethasone in doses of 1 mg/day or greater lower mean serum levels of DHEA by 35% in postmenopausal women (Smith *et al.*, 1994). As a result of these combined effects, serum concentrations of estradiol, estrone, dehydroepiandrosterone sulfate (DHEA), androstenedione, and progesterone are decreased in women; and DHEA and testosterone are decreased in men receiving glucocorticoids (MacAdams *et al.*, 1986). In mice even small doses dexamethasone impair ovarian production of androgens, estrogens, and progestins (Van Merris *et al.*, 2007). A single dose of dexamethasone was shown to disrupt gonadal function and fertility in rats for at least 30 days (Illera *et al.*, 2005).

It is very likely that deficiencies in these anabolic hormones accelerate bone loss. There is a direct correlation between bone mineral density and plasma estradiol levels in glucocorticoid-treated women (Montecucco *et al.*, 1992); furthermore, women receiving estrogen/progesterone replacement therapy and men given medroxyprogesterone acetate while taking glucocorticoids were protected against bone loss (Grecu *et al.*, 1990; Lukert *et al.*, 1992).

Calcium and Phosphorus Transport, Parathyroid Function, and Vitamin D Metabolism

Gastrointestinal Absorption of Calcium

Patients taking pharmacological doses of glucocorticoids have impaired gastrointestinal absorption of calcium, hypercalciuria and phosphaturia, and higher levels of serum PTH and $1,25(OH)_2D$ when compared with patients not taking steroids (Adams *et al.*, 1981; Bikle *et al.*, 1993; Favus *et al.*, 1973; Shrivastava *et al.*, 2000). Even very small oral doses of beclomethasone, similar to doses that may be swallowed by patients using the drug in inhaled form, decrease calcium absorption for the intestine (Smith *et al.*, 1993).

Calcium is absorbed from the intestine by passive (paracellular) and active (transcellular) transport. Active calcium absorption is primarily localized in the duodenum and tightly regulated. Transcellular calcium transport can be described in three sequential cellular steps, including transfer of luminal calcium into the enterocyte by the epithelial Ca^{2+} channel TRPV6, translocation of cytosolic Ca^{2+} toward the basolateral membrane by calbindin-D_{9K}, and active extrusion into the circulation by the plasma membrane ATPase 1b (PMCA1b) (Huybers *et al.*, 2007; van Abel *et al.*, 2003).

The diminished active Ca^{2+} absorption induced by glucocorticoids is associated with diminished TRPV6 and calbindin-D_{9K} expression in the first part of the duodenum in the presence of normal levels of calcitriol suggesting a calcitriol-independent effect of glucocorticoids on calcium absorption. *In vitro* studies of calcium absorption have also shown evidence of a non-vitamin D-dependent inhibition of calcium transport (Adams *et al.*, 1980; Charney *et al.*, 1975). These effects on transport may not be caused solely by changes in calcium receptors or other proteins or enzymes involved in transport (a genomic effect), but also by direct effects on membrane permeability, post-transcriptional events, basolateral membrane transport, changes in paracellular transport, or other adverse effects. Possible mechanisms include depletion of mitochondrial adenosine triphosphate (Krawitt, 1972) or paracellular back flux caused by to stimulation of the sodium-potassium-ATPase pump by glucocorticoids (Adams *et al.*, 1980; Charney *et al.*, 1975).

Parathyroid Hormone and Vitamin D Metabolites

High PTH levels have traditionally been attributed to prolonged negative calcium balance, and the rise in $1,25(OH)_2D$ has been attributed to the stimulatory effect of PTH. However, recent acute longitudinal studies have shown that serum $1,25(OH)_2D$ levels increase and serum phosphorus levels decrease within 2 hours after intravenous administration of methylprednisolone, before PTH had risen significantly. These findings suggest that glucocorticoids alter transport across a number of biological membranes and may produce nongenomic effects. PTH levels then increased progressively during the first 2 weeks of high-dose treatment. All of these parameters returned to baseline at 3 weeks when methylprednisolone was given orally but still at a high dose (Cosman *et al.*, 1994).

Although the acute studies showed that the changes in PTH and $1,25(OH)_2D$ were transient, it is important to note that others have found PTH and $1,25(OH)_2D$ levels higher than disease-matched controls, although within the normal range, and higher levels of urinary cAMP and reduced tubular reabsorption of phosphate in patients taking glucocorticoids for more than a year and in those with Cushing's disease (Bikle *et al.*, 1993; Findling *et al.*, 1982; Lukert *et al.*, 1976). This suggests that glucocorticoids have an acute effect on transport, which inhibits gastrointestinal absorption of calcium, decreases renal tubular reabsorption of calcium and phosphorus, and may decrease intracellular calcium and phosphorus. This in turn promotes synthesis of $1,25(OH)_2D$. Long-term glucocorticoid administration causes negative calcium balance, which perpetuates secondary hyperparathyroidism with its accompanying hypophosphatemia and elevated serum $1,25(OH)_2D$ levels. The high levels of cAMP and decreased tubular reabsorption of phosphate indicate that the increase in PTH (even though in

the normal range) is of physiological significance because both of these changes are known effects of PTH on the kidney. Glucocorticoids decrease the tonic release of PTH and increase pulsatile bursts of the hormone. In healthy subjects, PTH is secreted by low-amplitude, high-frequency pulses superimposed on tonic secretion (Bonadonna *et al.*, 2005). The increase in pulsatile bursts may have important end-organ effects. The sensitivity of osteoblasts to PTH is increased by glucocorticoids. Glucocorticoids probably act on or near the stimulatory guanine nucleotide-binding regulatory protein complex. The potentiation of PTH-induced increases in cAMP response appears to be caused by increases in cAMP activity and inhibition of phosphodiesterase (Chen *et al.*, 1978). Whether or not renal tubules are more sensitive to PTH effects on cAMP response in the presence of glucocorticoids remains unclear.

Phosphate Transport

In addition to the effects of glucocorticoid-induced elevation of PTH levels on phosphate transport, glucocorticoids have direct effects, on renal tubular reabsorption of phosphate acting through the Na^+-H^+ exchange activity in the proximal tubule thus decreasing Na^+ gradient-dependent phosphate uptake (Frieberg *et al.*, 1982).

Osteonecrosis

Osteonecrosis [avascular necrosis (AVN) or aseptic necrosis] is a well-recognized complication of glucocorticoid excess. Glucocorticoid-induced osteonecrosis was first recognized in 1957. Previous administration of glucocorticoids can be implicated in 16% to 34% of patients presenting with "idiopathic" osteonecrosis (Fisher *et al.*, 1971). The femoral head is most frequently affected, followed by the head of the humerus and distal femur, but osteonecrosis may occur in other long bones and the bones of the feet. A similar lesion characterized by a transverse radiolucent cleft running under an endplate is seen in the vertebra and resembles subchondral fracture seen in long bones. The risk for osteonecrosis increases with both the dose of glucocorticoids and the duration of treatment (Zizic *et al.*, 1985). However, osteonecrosis may develop in patients who receive steroids in very high doses for a short period of time (Taylor, 1984), moderate doses over a long period of time (Metselaar *et al.*, 1985), or by intra-articular or epidural injection.

The mechanisms responsible for glucocorticoid-induced osteonecrosis remain obscure. Etiological considerations invoke several theories. One is a mechanical theory that attributes ischemic collapse of the epiphysis to osteoporosis and the accumulation of unhealed trabecular microcracks resulting in fatigue fractures. Others include a vascular theory proposing that ischemia is caused by microscopic fat emboli and a theory that increased intraosseous pressure owing to fat accumulation as part of Cushing's syndrome leads to mechanical impingement on the sinusoidal vascular bed and decreased blood flow (Mankin, 1992). The number of apoptotic osteoblasts and osteocytes is increased in femoral necks removed from patients developing avascular necrosis while taking steroids, although this phenomenon was not observed in patients with AVN due to other causes (Weinstein *et al.*, 1998). The induction of early cell death may play a pivotal role in the etiology of steroid-induced AVN.

Clinically, pain is the usual presenting symptom and may be mild or vague in chronic forms of the disease, but it is usually acute and severe. Osteonecrosis may remain silent as long as it is not associated with epiphyseal collapse that appears to initiate symptoms (Maldague *et al.*, 1984). Early osteonecrosis of the hip may be managed by prolonged avoidance of weight bearing, but prosthetic replacement of the joint is frequently necessary. Surgical decompression may be attempted but the results are not encouraging (Mankin, 1992).

Summary of Cumulative Effects of Glucocorticoid-Induced Metabolic Changes on Bone

Overall effects of glucocorticoids are catabolic (Fig. 1). Inhibition of pituitary secretion of growth hormone and alterations in IGF-binding proteins leads to a fall in the biological activity of growth factors with loss of their anabolic effect on bone and other tissues. Gonadotrophin secretion is inhibited and, along with direct inhibitory effects of glucocorticoids on gonadal secretion of estrogen/testosterone, leads to a fall in circulating gonadal hormone concentrations. Deficiency in gonadal hormones causes an increase in bone resorption.

Membrane transport systems are altered by glucocorticoids resulting in inhibition of gastrointestinal absorption of calcium and decreased renal tubular absorption of calcium and phosphorus. Lowered intracellular phosphorus causes an acute rise in $1,25(OH)_2D$ synthesis. PTH secretion is increased despite elevated serum levels of calcium and $1,25(OH)_2D$. Chronically, increased PTH secretion and the resultant elevation in $1,25(OH)_2D$ production are perpetuated by negative calcium balance. The elevated levels of PTH and $1,25(OH)_2D$, along with deficiency of gonadal hormones, increase the number of sites undergoing bone resorption. The direct inhibition of osteoblastic bone formation at each bone remodeling site further augments the rate of bone loss.

Glucocorticoid-induced bone loss can be prevented by bisphosphonates, hormone replacement, PTH, and perhaps calcitonin (Cohen *et al.*, 1999; Lane *et al.*, 1998a; Luengo *et al.*, 1990; Lukert *et al.*, 1992; Reid *et al.*, 1996; Saag *et al.*, 1998). Fracture risk is reduced by bisphosphonates but fracture data are not available for the other modalities.

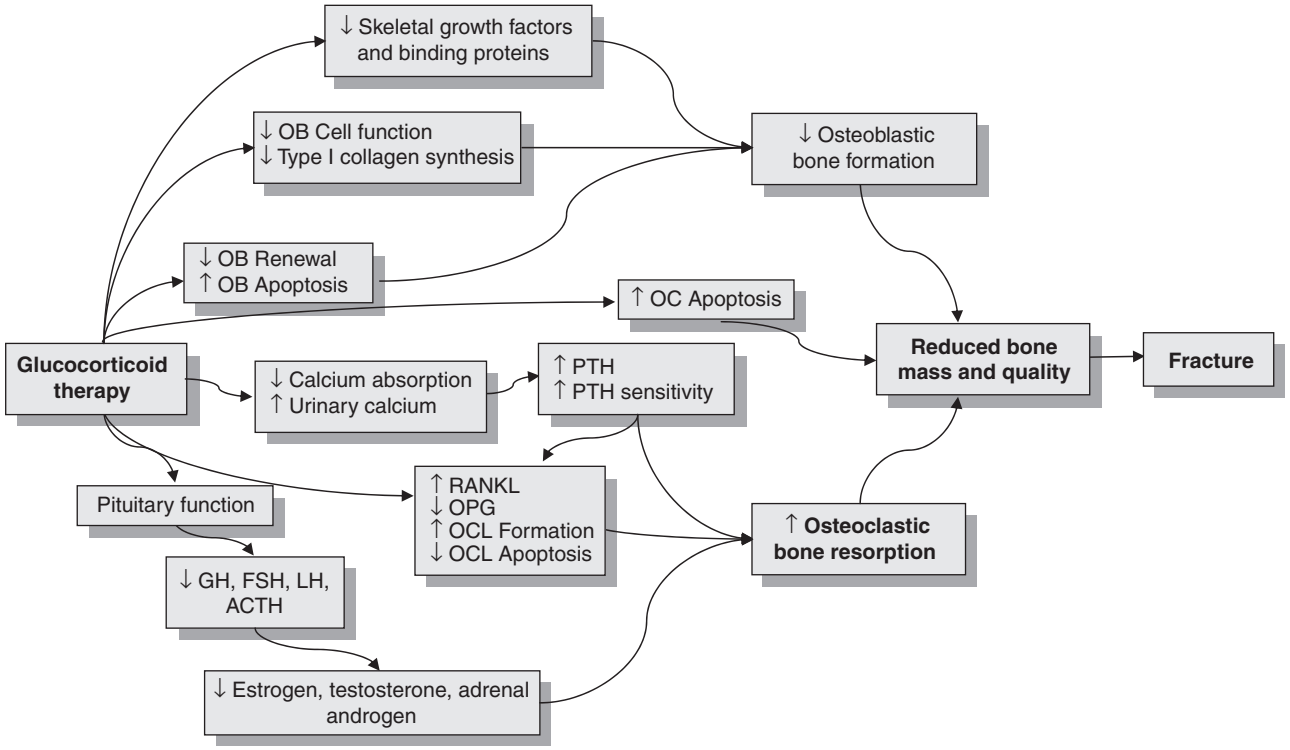

FIGURE 1 Mechanisms of glucocorticoid-induced bone loss. PTH, parathyroid hormone; OB, osteoblast; OC, osteocyte; OCL, osteoclast; GH, growth hormone; FSH, follicle-stimulating hormone; LH, luteinizing hormone; ACTH, adrenocotropic hormone; OPG, osteoprotegrin; RANKL, receptor activator of NF-κB ligand.

In addition to inhibiting bone resorption, bisphosphonates and calcitonin appear to decrease the number of apoptotic osteocytes and osteoblasts observed in bone biopsies from patients treated with prednisolone (Plotkin *et al.*, 1999). Estrogen has a similar effect in estrogen-deficient states but it is not known whether estrogen prevents apoptosis in the presence of glucocorticoids. Protection from glucocorticoid-induced apoptosis may play a major role in prevention of early bone loss in patients taking glucocorticoids. The major effects of glucocorticoids on bone are the direct effects on osteoblasts, which are discussed below.

DIRECT ACTIONS OF GLUCOCORTICOIDS ON BONE

Bone Formation and Osteoblast Differentiation

Glucocorticoids have many effects on osteoblasts that result in alterations in bone remodeling (Alesci *et al.*, 2005; Canalis *et al.*, 2007; Cooper *et al.*, 1999; Ishida *et al.*, 1998; Manolagas *et al.*, 1999; Mazziotti *et al.*, 2006). A hallmark of glucocorticoid-induced osteoporosis in humans is decreased mean wall thickness of trabecular bone, reflecting a reduction in the amount of new bone replaced in each remodeling cycle (Dempster *et al.*, 1983). Cells of the osteoblast lineage contain glucocorticoid receptors (Abu *et al.*, 2000; Chen *et al.*, 1977; Haussler *et al.*, 1980; Manolagas *et al.*, 1978), and high concentrations of glucocorticoids decrease protein, RNA, and DNA synthesis in primary bone cell cultures (Chen *et al.*, 1977; Choe *et al.*, 1978; Peck *et al.*, 1967; Wong, 1979). These studies are consistent with the well-described catabolic effects of high levels of glucocorticoids on human bone. Likewise, glucocorticoid treatment also decreases bone formation in dogs, rats, and mice (Altman *et al.*, 1992; Ortoft *et al.*, 1995; Quarles 1992; Turner *et al.*, 1995; Weinstein *et al.*, 1998). In some rat studies, glucocorticoid treatment decreases bone formation but does not induce osteopenia. This is because of an inhibition of turnover, because both bone resorption and formation are reduced, and bone mass does not decrease (Li *et al.*, 1996; Shen *et al.*, 1997). In mice, however, there is an increase in osteoclast surface shortly after glucocorticoid treatment, which is followed by a decrease in the rate of bone formation and a reduction in bone mass (Weinstein *et al.*, 1998). Thus, it has been suggested that mice, compared with rats, may be more like humans in the response of bone to pharmacological doses of glucocorticoids (Manolagas *et al.*, 1999).

By contrast to the striking inhibitory effect of pharmacological doses of glucocorticoids on bone formation *in vivo*, glucocorticoids cause both catabolic and anabolic effects on bone formation and osteoblast differentiation

in vitro. Although the relevance of the *in vitro* anabolic effect is not completely clear, it may reflect the role of glucocorticoids in the maintenance of the osteoblast phenotype during bone remodeling. Analysis of data from *in vitro* studies is complicated by a plethora of experimental variables, including the concentration of hormone, the molecular form of the glucocorticoid used, the timing of hormone addition, the presence of serum, and the species, cellular heterogeneity, and developmental stage of the model system. There are examples of species differences in the response of osteoblasts to glucocorticoids. Mouse calvaria osteoblast cultures show a biphasic glucocorticoid dose response with respect to mineralized nodule formation in culture, whereas rat cells show a stimulatory effect over the same dose range (Bellows *et al.*, 1998). Moreover, the enhancement of nodule formation by glucocorticoids is less robust in mouse cultures (Bellows *et al.*, 1998). Other differences between the response of rat and mouse cells to glucocorticoids include the proliferative effects (Chen *et al.*, 1983a). In mouse bone marrow cultures, dexamethasone increases alkaline phosphatase activity despite its marked inhibition of cell proliferation (Chen, 2004). Thus, in mouse osteoblast cultures, the inhibition of proliferation may mask positive effects of glucocorticoids on differentiation. However, despite the differences in the models used to study the effects of glucocorticoids on bone cells, some generalizations can be made. *In vitro*, physiological concentrations of glucocorticoids enhance the differentiation of early osteoprogenitors and stimulate the formation of bone in developmental models of bone formation. By contrast, pharmacological concentrations of glucocorticoids inhibit cell proliferation, impair the function of more mature osteoblasts, and increase osteoblast and osteocyte apoptosis. These effects ultimately lead to a decrease in bone mass.

Organ cultures reflect both the anabolic and catabolic effects of glucocorticoids on bone formation. Organ explants of folded periostea from embryonic chick calvaria form new bone during culture (Tenenbaum *et al.*, 1985). When dexamethasone is added at the onset of culture, there is enhanced osteoid formation, alkaline phosphatase activity, and a transient increase in the replication of cells adjacent to the newly formed bone surface. However, when dexamethasone is added late in the culture period after bone has formed, there is a decrease in alkaline phosphatase activity (Tenenbaum *et al.*, 1985). Thus, it appears that glucocorticoids initially cause the proliferation and differentiation of a distinct population of osteoprogenitor cells that participate in bone formation, but then limit further cell proliferation in the cultures (McCulloch *et al.*, 1986).

Glucocorticoids both stimulate and inhibit type I collagen synthesis in serum-free organ cultures of fetal rat calvaria depending on the dose of hormone and duration of hormone treatment (Canalis, 1983; Dietrich *et al.*, 1978; Kream *et al.*, 1990b). In fetal rat calvaria, physiological concentrations of cortisol (30–100 nM) stimulate collagen synthesis after 24 hours, whereas pharmacological concentrations (1000 nM) are inhibitory at 48 to 96 hours (Dietrich *et al.*, 1978). Likewise, there is a rapid stimulatory effect of cortisol on collagen synthesis in newborn rat calvaria (Hahn, 1984). In fetal rat calvaria, the early stimulation of collagen synthesis is blocked by the addition of IGFBP-2, which binds and inactivates secreted IGFs (Kream *et al.*, 1997). These data suggest that the initial stimulation of collagen synthesis by glucocorticoids depends on the activity of endogenous IGF-1 and may be owing to increased osteoblastic differentiation.

Many studies show that glucocorticoids can enhance osteogenic differentiation in long-term primary calvaria cell cultures that form mineralized bone nodules in the presence of serum, ascorbic acid, and β-glycerol phosphate. These cultures are defined by the stages of cell proliferation, extracellular matrix maturation, and matrix mineralization, each characterized by the expression of cell growth and tissue-specific genes (Gerstenfeld *et al.*, 1987; Owen *et al.*, 1990; Stein *et al.*, 1990). Glucocorticoids increase the formation of bone nodules and the expression of genes associated with the osteoblast phenotype in primary rat osteoblastic cell cultures (Bellows *et al.*, 1987, 1989, 1990; Shalhoub *et al.*, 1992). The effect of glucocorticoids is biphasic: low concentrations of dexamethasone and hydrocortisone increase nodule formation, whereas pharmacological concentrations are less effective or not stimulatory (Bellows *et al.*, 1987). In this model, the anabolic effect of glucocorticoids has been attributed to the enhanced proliferation and differentiation of glucocorticoid-dependent osteoprogenitor (Bellows *et al.*, 1989, 1990). High concentrations of glucocorticoids inhibit osteogenic differentiation in MC3T3-E1 (Lian *et al.*, 1997) and primary murine osteoblast cultures (Bellows *et al.*, 1998).

Bone marrow stromal cell cultures grown in the presence of serum, ascorbic acid, and β-glycerolphosphate also have been used extensively as a model system to study the stages of osteoblast differentiation. Osteoprogenitor cells within the bone marrow stromal network, when activated to differentiate, provide a renewable source of osteoblasts for the endosteal and trabecular bone surfaces. Glucocorticoids enhance the expression osteoblastic phenotypic traits such as alkaline phosphatase activity, osteocalcin, type I collagen, osteopontin, and bone sialoprotein and the formation of mineralized bone nodules in cultures of chick, rat, and human bone marrow stromal cells (Aubin, 1999; Cheng *et al.*, 1994, 1996; Herbertson *et al.*, 1995; Kamalia *et al.*, 1992; Kasugai *et al.*, 1991; Malaval *et al.*, 1994; McCulloch *et al.*, 1991; Rickard *et al.*, 1994). Bone stromal cell cultures contain a glucocorticoid-dependent osteoprogenitor cell that gives rise to mineralized bone nodules (Aubin, 1999).

High concentrations of glucocorticoids inhibit osteoblast function and preosteoblast replication. Glucocorticoids inhibit collagen synthesis in organ cultures of fetal rat (Canalis,

1983; Dietrich *et al.*, 1978) and mouse calvaria (Woitge *et al.*, 2000). In subclones of osteoblastic ROS 17/2 osteosarcoma cells, glucocorticoids either stimulate or inhibit collagen synthesis depending on the state of maturation of the cells; in less mature osteoblasts, glucocorticoids stimulate collagen synthesis, whereas in more mature osteoblasts they inhibit collagen synthesis (Hodge *et al.*, 1988). In confluent cultures of primary osteoblastic cells, glucocorticoids generally inhibit collagen synthesis (Chen *et al.*, 1978; Kim *et al.*, 1989; Ng *et al.*, 1989). The inhibitory effect of glucocorticoids on collagen synthesis in fetal rat calvaria is accompanied by a decrease in periosteal cell content (Canalis, 1984; Chyun *et al.*, 1984; Dietrich *et al.*, 1978). Glucocorticoids also decrease the number of cells in the osteoblastic and periosteal layers of fetal rat parietal bone organ cultures (Gronowicz *et al.*, 1994). These effects in organ culture reflect, at least in part, the antiproliferative effect of glucocorticoids seen in osteoblastic cell cultures (Chen *et al.*, 1977; Hodge *et al.*, 1988; Hughes-Fulford *et al.*, 1992). Glucocorticoids decrease osteocyte formation in these cultures, which may reflect an inhibition of osteoblast renewal (Gohel *et al.*, 1995) and/or osteoblast apoptosis (Gohel *et al.*, 1999). High concentrations of glucocorticoids inhibit proliferation in primary human bone marrow stromal cell cultures (Silvestrini *et al.*, 2000; Walsh *et al.*, 2001). Glucocorticoids inhibit cell cycle progression in committed osteoblasts by activating glycogen synthase kinase-3β (GSK-3β), which in turn downregulates c-Myc (Smith *et al.*, 2000, 2002). Not all of the effects of glucocorticoids on osteoblast function can be attributed to an inhibition of cell replication. For example, the inhibitory effect of glucocorticoids on collagen synthesis, although blunted, still persists in the presence of DNA synthesis inhibitors, suggesting that glucocorticoids also inhibit the function of differentiated osteoblasts (Lukert *et al.*, 1991). In cultured bone marrow stromal cells, a low concentration of dexamethasone (10 nM) promotes the osteogenic differentiation, whereas a higher concentration (100 nM) was also osteogenic but decreased cell number. These data suggest that glucocorticoids enhance osteoblastic differentiation but that a decrease in proliferation of osteogenic precursors ultimately limits the extent of bone formation (Walsh *et al.*, 2001).

Glucocorticoids increase the apoptosis of osteoblasts (Gohel *et al.*, 1999; Silvestrini *et al.*, 2000; Weinstein *et al.*, 1998) and osteocytes (Plotkin *et al.*, 1999; Weinstein *et al.*, 1998). Chronic treatment of adult mice with prednisolone increases apoptosis of osteoblasts in vertebrae and osteocytes in metaphyseal cortical bone and decreases bone mass (Weinstein *et al.*, 1998), which is reduced by bisphosphonate treatment (Plotkin *et al.*, 1999). Acute treatment of neonatal mice with dexamethasone increases apoptosis of osteoblasts in calvaria (Gohel *et al.*, 1999) and this effect was reversed by cotreatment with 17β-estradiol. Apoptotic osteocytes and cancellous lining cells are seen in femoral heads from patients with glucocorticoid-induced osteonecrosis (Weinstein *et al.*, 2000). Glucocorticoids increase apoptosis in part by increasing caspase 3 activity (Liu *et al.*, 2004; Plotkin *et al.*, 1999). In primary fetal rat calvarial cell cultures, the increase in osteoblast apoptosis is associated with a decrease in the Bcl-2/Bax protein ratio (Gohel *et al.*, 1999). Bcl-2, an antiapoptotic integral membrane protein, has been targeted to mature osteoblasts of transgenic mice with a 2.3-kb fragment of the rat Col1a1 promoter (Col2.3-Bcl2). Transgenic mice are smaller than wild type and display an abrogation of the differences between male and female bone parameters and a blunting of age-related bone loss. *Ex vivo* primary calvarial osteoblast cultures show increased differentiation markers but decreased mineralization (Pantschenko *et al.*, 2005; Zhang *et al.*, 2007). In addition to increasing osteocyte apoptosis, glucocorticoids modify the osteocyte lacuna and affect bone quality. Mice treated with prednisolone show increased lacunae size, a halo of hypomineralized bone surrounding the lacunae, and a reduced mineral-to-matrix ratio. These changes are accompanied by decreased elastic modulus of bone adjacent to osteocytes and reduced whole bone strength (Lane *et al.*, 2006).

Chronic glucocorticoid administration decreases osteoblastogenesis (Manolagas, 1999, 2000). When mice are treated with pharmacological levels of glucocorticoids *in vivo*, the generation of fibroblast colony-forming units in *ex vivo* bone marrow cultures is decreased, suggesting that glucocorticoids deplete the bone marrow of osteogenic precursors (Simmons *et al.*, 1990). Likewise, glucocorticoid treatment of adult mice for one month suppresses osteogenic differentiation in *ex vivo* bone marrow cultures (Weinstein *et al.*, 1998).

Collectively, these data suggest that pharmacological doses of glucocorticoid induce osteoporosis owing to a decrease in bone formation that results from an impairment of osteoblast function, reduced osteoblastogenesis, and preosteoblast proliferation and increased osteoblast apoptosis (see Fig. 1). However, physiological concentrations of glucocorticoids may be important for maintaining osteoblast differentiation.

Bone Resorption and Osteoclast Differentiation

Glucocorticoids have both direct and indirect effects on osteoclasts that result in changes in bone resorption. Data from various studies may be conflicting owing to differences in experimental models and the dosage and timing of glucocorticoid addition. Glucocorticoids inhibit basal and agonist-stimulated resorption of fetal rat long bones (Raisz *et al.*, 1972) but increase resorption of fetal rat parietal bones (Gronowicz *et al.*, 1990) and mouse calvaria (Conaway *et al.*, 1996; Reid *et al.*, 1986b). Glucocorticoids decrease the

activity and increase the apoptosis of rat osteoclasts (Dempster *et al.*, 1997; Tobias *et al.*, 1989). Dexamethasone increases osteoclastogenesis in mouse bone and spleen cell cocultures (Kaji *et al.*, 1997). Glucocorticoids increase macrophage colony-stimulating factor (M-CSF) in osteoblasts (Rubin *et al.*, 1998). They also increase the production of receptor activator of NF-κB (RANKL) and decrease the production of osteoprotegerin (OPG) in osteoblasts (Hofbauer *et al.*, 1999; Sivagurunathan *et al.*, 2005). An increase in the RANKL/OPG ratio is consistent with a stimulation of osteoclast formation and may explain the early stimulation of resorption in humans and mice. Glucocorticoids decrease osteoclast progenitor number but increase osteoclast lifespan (Weinstein *et al.*, 2002). The antiapoptotic effect is caused by glucocorticoid receptor-dependent glucocorticoid signaling in osteoclasts (Jia *et al.*, 2006; Kim *et al.*, 2006). At the same time, glucocorticoids disrupt actin ring formation resulting in dysfunctional osteoclasts *in vitro* and *in vivo* (Kim *et al.*, 2006). This study shows that glucocorticoids can decrease bone formation by signaling in osteoclasts (Kim *et al.*, 2006).

Permissive Effects of Glucocorticoids on Osteoblasts

Some of the physiological effects of glucocorticoids on bone may be in part owe to their ability to act as permissive hormones, thereby allowing other hormones to function optimally. Low doses of glucocorticoids enhance PTH-stimulated adenylate cyclase in rat, mouse, and human bone cells (Chen *et al.*, 1978; Rodan *et al.*, 1984; Wong 1980; Wong *et al.*, 1990) and PTH-mediated bioactivities (Wong, 1979). The enhancement of the PTH-dependent cAMP response may be caused by an increase in cAMP activity and a decrease in phosphodiesterase activity (Chen *et al.*, 1978). Glucocorticoids also increase the number of PTH receptors and levels of PTH/PTHrP receptor mRNA (Urena *et al.*, 1994; Yamamoto *et al.*, 1988).

The effect of glucocorticoids on 1,25-$(OH)_2$D receptors and biological activity, however, is not as clear. In rat bone cytosol and primary rat osteoblastic cells, glucocorticoids maintain or increase 1,25-$(OH)_2$D receptor number (Chen *et al.*, 1983b; Manolagas *et al.*, 1979) and enhance the biological actions of 1,25-$(OH)_2$D (Chen *et al.*, 1986). However, in one study using primary mouse osteoblastic cells, the effect of glucocorticoids on 1,25-$(OH)_2$D receptor number was dependent on the stage of growth of the cells; receptor number was decreased at early log phase growth and at confluence and increased at late log phase growth (Chen *et al.*, 1982). In another study, glucocorticoids were shown to increase 1,25-$(OH)_2$D biological activities in primary mouse osteoblastic cells (Wong, 1980). In human MG-63 cells, glucocorticoids decrease the expression of 1,25-$(OH)_2$D receptor mRNA (Godschalk *et al.*, 1992). Taken together, these findings indicate that glucocorticoids can increase or decrease 1,25-$(OH)_2$D receptor levels depending on the experimental model.

Glucocorticoids alter the IGF-1 pathway. They inhibit IGF-1 mRNA and protein expression by osteoblasts (as discussed later) but increase IGF-1 receptor number (Bennett *et al.*, 1984). Physiological concentrations of cortisol enhance the stimulatory effects of IGF-1 on collagen synthesis, producing a larger anabolic effect than with IGF-1 alone (Kream *et al.*, 1990a). The ability of glucocorticoids to augment IGF-1 activity may represent a compensatory response that helps maintain bone mass and growth during periods of diminished IGF-1 supply, such as starvation. A similar enhancing effect of glucocorticoids on IGF-1 action occurs in fibroblast cultures (Bird *et al.*, 1994; Conover *et al.*, 1986). Cortisol enhances the anabolic effects of exogenous prostaglandins on collagen and DNA synthesis in organ cultures of rat calvaria, which may be dependent partly on the IGF-1 pathway (Raisz *et al.*, 1993). Physiological concentrations of glucocorticoids may amplify the stimulatory effect of PGE_2 on the IGF-1 promoter through induction of C/EBP family transcription factors (McCarthy *et al.*, 2000b).

Target Cell Metabolism of Glucocorticoids in Bone Cells

Target cell metabolism has emerged as an important mechanism for regulating the sensitivity of cells to glucocorticoids (Eyre *et al.*, 2001). As discussed earlier, glucocorticoids undergo target cell metabolism by two 11β-hydroxysteroid dehydrogenases that catalyze the interconversion of cortisol and cortisone in humans and corticosterone and 11-dehydrocorticosterone in rodents (Chapman *et al.*, 2006a; Draper *et al.*, 2005; Krozowski 1999; Krozowski *et al.*, 1999; Stewart *et al.*, 1999; Tomlinson *et al.*, 2004). The 11β-HSD enzymes control the local concentration of glucocorticoids available to engage in receptor binding and subsequent signaling (Rabbitt *et al.*, 2002). The 11β-HSD system is distinct from both the glucocorticoid biosynthetic pathway in the adrenal and the degradative pathway in the liver, both of which involve different enzymatic cascades. The NAD-dependent enzyme 11β-HSD2 has dehydrogenase activity and catalyzes the unidirectional conversion of biologically active glucocorticoids to inactive metabolites, and the bidirectional interconversion of dexamethasone to 11-dehydrodexamethasone. 11β-HSD2 is highly expressed in kidney where it protects the mineralocorticoid receptor from activation by glucocorticoids and is abundant in placenta where it protects the fetus from maternal glucocorticoids. Mice with a targeted deletion of 11β-HSD2 develop hypertension because glucocorticoids, which fail to be metabolized in kidney cells, evoke mineralocorticoid effects via the mineralocorticoid receptor (Kotelevtsev *et al.*, 1999). The NADP-dependent 11β-HSD1 has oxoreductase activity

and catalyzes the bidirectional conversion of inactive glucocorticoids to active metabolites. In cell-free systems, 11β-HSD1 is also capable of catalyzing the conversion of cortisol to cortisone (dehydrogenase activity). However, in intact cells, oxoreductase activity predominates most likely because of the topography of 11β-HSD1 in the endoplasmic reticulum, where the active site of the enzyme faces the lumen in close proximity to hexose-6-phosphate dehydrogenase, which generates NADPH for oxoreductase activity (Atanasov *et al.*, 2004; Lavery *et al.*, 2006; Seckl *et al.*, 2001). Deletion of *Hsd11b1* abolishes the conversion of 11-dehydrocorticosterone to corticosterone in liver, providing strong evidence that 11β-HSD1 is the only 11-reductase in mice (Holmes *et al.*, 2001).

Nearly all glucocorticoid target tissues express 11β-HSD1 as a means of generating a locally acting pool of active hormone. 11β-HSD1 expression in the liver provides a ready source of cortisol for the stimulation of gluconeogenesis (Kotelevtsev *et al.*, 1997). The reactivation of cortisone by 11β-HSD1 in macrophages aids in the resolution of inflammation (Chapman *et al.*, 2006a, 2006b; Gilmour *et al.*, 2006). A noteworthy function of 11β-HSD1 is its role in promoting adipocyte differentiation and the development of visceral obesity (De Sousa Peixoto *et al.*, 2008a; Morton *et al.*, 2008; Tomlinson *et al.*, 2002). Glucocorticoids stimulate adipocyte differentiation and 11β-HSD1 expression, which ensures an adequate local source of hormone for fat differentiation (Kim *et al.*, 2007). Transgenic mice with adipocyte-targeted 11β-HSD1 have visceral obesity and elevated levels of adipose corticosterone despite normal serum levels of corticosterone (Masuzaki *et al.*, 2001). By contrast, Hsd11b1 knockout mice are protected against obesity and the metabolic consequences of a high fat diet (De Sousa Peixoto *et al.*, 2008a).

Rat and mouse calvarial osteoblast cultures can convert inactive glucocorticoids to active metabolites, and the 11β-HSD inhibitor carbenoxelone partially blocks the effects of corticosterone on bone nodule formation in rat and mouse osteoblast cultures, indicating that osteoblasts contain 11β-HSD1 activity (Bellows *et al.*, 1998). Both 11β-HSD1 and 11β-HSD2 are expressed in osteoblasts of rat and human osteoblasts (Cooper *et al.*, 2000). Rat and human osteoblastic osteosarcoma cell lines express 11β-HSD2 (Bland *et al.*, 1999; Eyre *et al.*, 2001). Primary human osteoblasts and adult human bone explants express both 11β-HSD1 and 11β-HSD2 (Bland *et al.*, 1999). The glucocorticoid sensitivity of osteosarcoma cell lines with equivalent numbers of glucocorticoid receptors is directly correlated with the level of 11β-HSD2 expression (Eyre *et al.*, 2001). Moreover, ROS 17/2.8 and MC3T3-E1 cells transfected with 11β-HSD2 show reduced responsiveness to natural glucocorticoids but remain responsive to the synthetic glucocorticoid dexamethasone (Woitge *et al.*, 2001). In human osteosarcoma cell lines, 11β-HSD1 expression is induced by the inflammatory cytokines IL-1β and TNFa (Cooper *et al.*, 2001). In primary human osteoblasts, 11β-HSD1 expression increases with donor age and may play a role in age-related bone loss (Cooper *et al.*, 2002). 11β-HSD1 is highly expressed during the early stages of osteoblast cultures and expression declines as differentiation ensues (Eijken *et al.*, 2005, 2006). Thus, 11β-HSD1 may regulate the sensitivity of osteoblasts to glucocorticoids and play a role in the early stages of osteoblast differentiation. The *Hsd11b1* knockout model, however, shows normal bone physiology in young and old mice (Justesen *et al.*, 2004). A confounding feature of the model is a 2-fold increase in circulating corticosterone and adrenal hyperplasia owing to activation of the hypothalamic-pituitary-adrenal axis (Holmes *et al.*, 2001). Thus, it is possible that the high serum levels of glucocorticoid in *Hsd11b1* knockout mice may have reduced the requirement for locally produced glucocorticoids. Moreover, bone marrow adipocytes were absent in this model, raising the possibility that the number of pluripotent progenitor cells available for osteoblast recruitment was increased.

11β-HSD2 cDNA has been cloned upstream of osteoblast-targeted promoters to develop glucocorticoid loss-of-function models based on the role of 11β-HSD2 in kidney and placenta to inactivate glucocorticoids. These models would prevent glucocorticoid signaling by the glucocorticoid receptor, and possibly the mineralocorticoid receptor, in osteoblasts. A 2.3-kb promoter fragment of the rat Col1a1 gene has been used to target 11β-HSD2 expression to differentiating osteoblasts (Sher *et al.*, 2004, 2006). Col2.3-HSD2 mice have decreased vertebral trabecular bone mass, decreased femoral cortical width and area, and reduced osteoblast markers and mineralization in *ex vivo* calvarial cultures. The Col2.3-HSD2 transgene led to a shift in mesenchymal cell fate owing to a decrease in Wnt signaling, suggesting a feedback signal from mature osteoblasts to early progenitors (Zhou *et al.*, 2008). 11β-HSD2 has been used to target mature osteoblasts with the osteocalcin (OG2) promoter (O'Brien *et al.*, 2004). OG2-HSD2 transgenic mice do not have alterations in bone development and turnover, but are protected from dexamethasone-induced osteoblast apoptosis and diminution of vertebral strength (O'Brien *et al.*, 2004). Differences between the models are likely owing to distinct temporal and spatial patterns of transgenic 11β-HSD2 expression as well as the level of transgene expression.

GLUCOCORTICOID-REGULATED GENE EXPRESSION IN BONE

Molecular Mechanisms of Glucocorticoid Action

At the molecular level, glucocorticoids alter the expression of a wide variety of genes in osteoblastic cells, including those for structural proteins, growth factors, receptors, and enzymes. Glucocorticoids elicit biological responses in

their target cells by binding to and activating the intracellular glucocorticoid receptor. The structure and function of the glucocorticoid receptor, its intracellular trafficking, and glucocorticoid receptor-dependent transcription are discussed in detail in many excellent reviews (Beato *et al.*, 1996; Defranco 2000; Duma *et al.*, 2006; McKay *et al.*, 1999; Webster *et al.*, 1999; Zhou *et al.*, 2005). The glucocorticoid receptor contains an amino-terminal domain that encodes a transactivation function, and a carboxyl-terminal domain that specifies ligand binding, dimerization, heat shock protein (hsp) binding, and transactivation functions. The most highly conserved region is the 66-amino-acid DNA-binding domain consisting of two zinc finger motifs with cysteine residues that are coordinated with zinc atoms (Freedman *et al.*, 1988). Unligated glucocorticoid receptors are found in the cytoplasm in association with a variety of molecular chaparone proteins including hsp90, an FK506-binding immunophilin protein, and p23 (Cheung *et al.*, 2000; Defranco, 2000). Upon hormone binding, a conformational change enables the receptor to translocate to the nucleus, dimerize, and bind to DNA. Transcriptional activation by a glucocorticoid receptor homodimer occurs when the DNA-binding domains interact with a glucocorticoid response element (GRE). The GRE consensus sequence is GGTACAnnnTGTTCT (Beato, 1989). Transcriptional activation involves protein–protein interactions between the receptor dimer and basal transcription factors and RNA polymerase II (Mitchell *et al.*, 1989). Cofactors are recruited to the GRE by activated glucocorticoid receptor including those with histone acetyltransferase and methyltransferase activity (Lonard *et al.*, 2005), which facilitate alterations in chromatin structure and the recruitment of additional components of the transcriptional complex (Lu *et al.*, 2006). Glucocorticoid-dependent inhibition of gene expression has become a molecular paradigm for understanding mechanisms of transcriptional repression by steroid hormone receptors (Webster *et al.*, 1999). Transcriptional repression by glucocorticoid receptors occurs by direct interaction with DNA through negative GREs (Sakai *et al.*, 1988), by blocking the access of positive transcription factors to DNA sequences (Akerblom *et al.*, 1988), and by protein–protein interaction with transcription factors (Chatterjee *et al.*, 1991). An example of the latter mechanism is glucocorticoid inhibition of collagenase expression, which is thought to occur by interaction of the glucocorticoid receptor with the AP-1 transcription factor complex (Jonat *et al.*, 1990; Schule *et al.*, 1990; Yang-Yen *et al.*, 1990).

Effects on Gene Expression

Primary Response Genes and Transcription Factors

Glucocorticoids cause a rapid and transient increase in the mRNA levels of c-fos (Birek *et al.*, 1991; Shalhoub *et al.*, 1992; Shur *et al.*, 2005; Subramaniam *et al.*, 1992) and c-myc (Subramaniam *et al.*, 1992) in human and rodent osteoblasts and chick periosteal cultures. The rat c-fos promoter contains a putative GRE that may mediate glucocorticoid-dependent induction (Wang *et al.*, 1994). Cell lines prepared from tumors of c-fos transgenic mice show changes in osteoblast phenotypic markers but have unaltered glucocorticoid responsiveness (Grigoriadis *et al.*, 1993). The induction of primary response genes may be a key event in the regulation of downstream genes such as those that encode growth factors and matrix proteins. Id (inhibitor of differentiation) is a member of the helix-loop-helix (HLH) family of transcription factors that binds to other HLH factors and suppresses differentiation (Benezra *et al.*, 1990). Id mRNA is detectable in early cultures of MC3T3-E1 cells and then decreases as the cells differentiate (Ogata *et al.*, 1993). Dexamethasone maintains the high levels of Id mRNA in confluent MC3T3-E1 cells (Ogata *et al.*, 1993).

Type I Collagen

Type I collagen is the most abundant protein in the bone matrix and its expression is regulated by a wide variety of hormones, growth factors, and cytokines (Raisz, 1988). Glucocorticoids decrease a1(I) collagen (Col1a1) mRNA levels in osteoblastic cells and calvarial organ cultures (Delany *et al.*, 1995a; Kim *et al.*, 1989; Kream *et al.*, 1990a; Lukert *et al.*, 1991) and in calvaria of neonatal mice given *in vivo* dexamethasone (Advani *et al.*, 1997). Glucocorticoid downregulation of Col1a1 mRNA occurs by an inhibition of Col1a1 transcription and a decrease in the stability of Col1a1 mRNA (Delany *et al.*, 1995a). Dexamethasone decreases the activity of transfected Col1a1 mRNA promoter–reporter constructs in stably transfected osteoblastic cells, indicating a transcriptional effect (Petersen *et al.*, 1991). The precise molecular mechanisms by which glucocorticoids inhibit Col1a1 transcription in osteoblastic cells have not been elucidated. However, studies performed in fibroblasts provide mechanistic clues. Glucocorticoids decrease type I collagen mRNA levels in fibroblasts by decreasing transcription of collagen genes and the stability of collagen mRNA (Cockayne *et al.*, 1986; Hamalainen *et al.*, 1985; Raghow *et al.*, 1986). Glucocorticoids also decrease Col1a1 mRNA stability by affecting protein binding to 3' UTRs (Maatta *et al.*, 1993). Glucocorticoids decrease the activity of transfected murine Col1a2 promoter–reporter constructs in fibroblasts through sites contained in regions from −2048 to −981 bp and −506 to −351 bp (Perez *et al.*, 1992). In stably transfected fetal skin fibroblasts, the inhibitory effect of dexamethasone on rat Col1a1 promoter activity is maintained when the promoter is deleted to −900 bp. This region contains a putative GRE half-site; however, a mutation of this site does not block glucocorticoid-dependent inhibition of Col1a1 promoter activity (Meisler *et al.*, 1995). In this study, it was suggested that glucocorticoids decrease

Col1a1 transcription in fibroblasts by acting at a TGFβ-responsive site (Meisler *et al.*, 1995).

Noncollagen Proteins of Bone

Glucocorticoids alter the expression of a variety of noncollagen proteins in bone. Glucocorticoid treatment of rats and mice decreases osteocalcin mRNA levels in bone (Advani *et al.*, 1997; Ikeda *et al.*, 1992). Glucocorticoids inhibit basal and agonist-induced osteocalcin production and mRNA levels in osteoblasts (Schepmoes *et al.*, 1991; Wong *et al.*, 1990) and repress 1,25-$(OH)_2$D-mediated osteocalcin transcription (Morrison *et al.*, 1989). It has been proposed that this occurs by binding of the glucocorticoid receptor the TATA box in the proximal promoter region of the osteocalcin gene (Meyer *et al.*, 1997; Stromstedt *et al.*, 1991). Glucocorticoids suppress osteocalcin expression through an Egr2/Krox20 DNA-binding motif just upstream of a Runx2 site in the osteocalcin promoter (Leclerc *et al.*, 2005). Glucocorticoids also decrease Krox20 mRNA levels in osteoblasts (Leclerc *et al.*, 2008).

Glucocorticoids increase alkaline phosphatase activity and mRNA levels in human osteoblastic cells (Subramaniam *et al.*, 1992), SaOS-2 osteosarcoma cells (Murray *et al.*, 1987), and ROS 17/2.8 cells (Majeska *et al.*, 1985). In ROS17/2.8 cells, the increase in mRNA occurred after a lag period of 12 hours and is blocked by cycloheximide, indicating the requirement for new protein synthesis (Green *et al.*, 1990). Actinomycin D blocked the stimulatory effect of glucocorticoids on alkaline phosphatase mRNA levels, indicating transcriptional regulation (Green *et al.*, 1990). Osteoblasts synthesize the bone/liver/kidney/placenta form of alkaline phosphatase; this gene contains two alternative promoters spaced 25 kb apart; baseline and glucocorticoid-stimulated alkaline phosphatase mRNA in calvaria and ROS 17/2.8 cells is transcribed from the upstream promoter (Zernick *et al.*, 1991).

Bone sialoprotein is a glycoprotein containing an arginine-glycine-aspartic acid (RGD) sequence that mediates attachment of cells to extracellular matrix proteins. Glucocorticoids increase bone sialoprotein mRNA levels in fetal rat calvarial, bone marrow, ROS 17/2.8, and UMR106-06 cells in part by a transcriptional mechanism (Ogata *et al.*, 1995). The bone sialoprotein promoter contains a GRE between −906 and −931 bp that may mediate this transcriptional effect of glucocorticoids (Ogata *et al.*, 1995). There have been few studies examining the direct effect of glucocorticoids on the expression of osteonectin, an abundant noncollagenous glycoprotein. In one study, dexamethasone increased osteonectin mRNA levels and the activity of an osteonectin promoter–reporter construct in preosteoblastic UMR 201 cells (Ng *et al.*, 1989).

Glucocorticoids decrease fibronectin (Gronowicz *et al.*, 1991) and β1 integrin (Doherty *et al.*, 1995) mRNA levels in fetal rat parietal bone organ cultures. The inhibitory effect on β1 integrin expression is accompanied by a disruption of osteoblast organization on the bone surface and a decrease in calcification of the bone (DiPersio *et al.*, 1991). In primary rat osteoblast cultures and ROS 17/2.8 cells, glucocorticoids decrease plasma membrane β1 integrin staining, adhesion of the cells to bone matrix proteins, and β1 integrin mRNA levels (Gronowicz *et al.*, 1995). Glucocorticoids decrease the expression of cells containing the α2 and α4 integrin subunits in bone marrow stromal cultures (Walsh *et al.*, 2001).

Glucocorticoids decrease interstitial collagenase mRNA levels in human skin fibroblasts by reducing the half-life of collagenase mRNA (Delany *et al.*, 1992). By contrast, glucocorticoids increase the expression of collagenase mRNA in rat osteoblastic cells (Delany *et al.*, 1995b; Shalhoub *et al.*, 1992) by a mechanism that involves increased collagenase mRNA stability (Delany *et al.*, 1995b). Cortisol antagonized the phorbol ester-mediated increase in activity of a transiently transfected rat collagenase promoter–reporter construct (Delany *et al.*, 1995b). Glucocorticoid induction of interstitial collagenase expression in osteoblasts may be related to biological activities such as growth factor activation or the activation of osteoclastic bone resorption (Delany *et al.*, 1995b).

Growth Factor Pathways

IGF-1 is an important anabolic growth factor for bone (Rosen, 2004). The inhibitory effects of glucocorticoids on bone formation may be caused in part by a decrease in the production of IGF-1 (McCarthy *et al.*, 1990). Glucocorticoids decrease IGF-1 mRNA expression in rat tibia, organ cultures of fetal rat calvaria, and primary osteoblastic cell cultures (Chen *et al.*, 1991; Luo *et al.*, 1989; McCarthy *et al.*, 1990). However, glucocorticoids do not regulate IGF-II mRNA levels in primary rat osteoblastic cells (McCarthy *et al.*, 1992) but they decrease IGF-II peptide production in fetal rat calvarial cultures (Canalis *et al.*, 1991). Inhibitory effects of glucocorticoids on bone formation persist when IGFBP-2 is added to cultures of fetal rat calvaria to inactivate IGFs (Kream *et al.*, 1997). Moreover, calvaria from mice with a complete ablation of the Igf1 gene maintain responsiveness to glucocorticoids (Woitge *et al.*, 2000). These studies suggest that inhibitory effects of glucocorticoids are partly independent of the IGF-1 pathway.

IGFBPs regulate the storage, transport, and bioactivities of IGFs (Clemmons *et al.*, 1993). Six IGFBPs, termed IGFBP-1 through -6, have been identified in a variety of tissues (Shimasaki *et al.*, 1991). The expression of IGFBPs in osteoblastic cells of different origins is cell line specific (Hassager *et al.*, 1992). IGFBPs generally inhibit IGF-1 action *in vitro* (Feyen *et al.*, 1991; Mohan *et al.*, 1989), except for IGFBP-5, which may act as an anabolic growth factor (Andress *et al.*, 1992; Miyakoshi *et al.*, 2001). Glucocorticoids decrease IGFBP-3, -4, and -5 production in

the normal human osteoblastic cells (Okazaki *et al.*, 1994), and decrease IGFBP-3 production in transformed osteoblastic cell lines (Nakao *et al.*, 1994). Glucocorticoids decrease IGFBP-5 transcription in rat osteoblasts (Gabbitas *et al.*, 1996b), and decrease IGFBP-2 production in rat calvarial osteoblastic cells (Chen *et al.*, 1991) and immortalized rat osteoblastic PyMS cells (Schmid *et al.*, 1988). However, glucocorticoids increase the expression of IGFBP-6 in fetal rat calvarial cell cultures (Gabbitas *et al.*, 1996a). Because IGFBP-6 has higher affinity for IGF-2 than IGF-1, glucocorticoid stimulation of IGFBP-6 may limit the availability of IGF-2 as an anabolic agent (Gabbitas *et al.*, 1996a). Because glucocorticoids decrease IGF-1 production in bone, the inhibitory effect of glucocorticoids on IGFBP expression may provide a mechanism by which osteoblastic cells are more responsive to the residual pool of IGF-1. Alternatively, downregulation of IGFBP-5 production could represent the removal of an anabolic factor and result, in part, in the inhibitory effects of glucocorticoids. Glucocorticoids alter the expression of other growth factor systems in cultured fetal rat calvarial osteoblasts such as mac25 (IGFBP-related peptide), connective tissue growth factor, and hepatocyte growth factor and its receptor c-met (Blanquaert *et al.*, 2000; Pereira *et al.*, 1999, 2000). As of yet, the role of these factors in mediating glucocorticoid responses in bone is not known.

Some of the inhibitory effects of glucocorticoids may be because of the antagonism of the Wnt pathway, a positive regulator of osteoblast differentiation and proliferation and bone mass accrual (Manolagas *et al.*, 2007; Westendorf *et al.*, 2004). Glucocorticoids inhibit canonical Wnt/β-catenin signaling in osteoblasts (Ohnaka *et al.*, 2005), and enhance the expression of Dickkopf, an inhibitor of Wnt signaling that prevents Wnt ligand from binding to its receptor complex on the cell membrane (Ohnaka *et al.*, 2004, 2005). Glucocorticoids maintain the activity of GSK-3β, which phosphorylates β-catenin and targets it for degradation and inhibits LEF/TCF-dependent transcription (Smith *et al.*, 2005).

TGFβ is anabolic for bone formation and either stimulatory or inhibitory for bone resorption depending on the experimental model and the culture conditions (Centrella *et al.*, 1994). TGFβ binds to three cell surface receptors, termed TGFβRI, II, and III, which have been demonstrated in osteoblastic cells (Centrella *et al.*, 1991). The type I and II receptors are thought to mediate TGFβ signaling (Massague, 1992); the type III receptor, betaglycan, is a cell surface proteoglycan that is more abundant than the types I and II receptors but has lower affinity for TGFβ1 (Lopez-Casillas *et al.*, 1993). Glucocorticoids modify the expression of molecules in the TGFβ pathway (McCarthy *et al.*, 2000a). Glucocorticoids decrease the stimulatory effects of TGFβ1 on DNA synthesis and collagen synthesis in fetal rat osteoblastic cells and increase the binding of TGFβ1 to betaglycan in primary cultures of fetal rat osteoblastic cells (Centrella *et al.*, 1991). Dexamethasone increases betaglycan mRNA levels in immortalized MC3T3-E1 and RCT1 osteoblastic cells (Nakayama *et al.*, 1994). If the function of betaglycan is to decrease the amount of TGFβ available for signaling, these effects of glucocorticoids would reduce the anabolic effects of TGFβ1 on osteoblastic cells. In fetal rat osteoblasts, glucocorticoids suppress Cbfa1 (Runx2) expression, which is associated with a decrease in the expression and activity of the TGFβRI (Chang *et al.*, 1998).

Glucocorticoids can affect signaling by members of the bone morphogenetic protein (BMP) family of proteins. The molecular pathway by which glucocorticoids enhance osteogenic differentiation *in vitro* may involve BMP pathway signaling. BMP-2 and glucocorticoids exert a synergistic enhancement of the osteogenesis in rat bone marrow stromal cells (Rickard *et al.*, 1994) and fetal rat calvarial cells (Boden *et al.*, 1996). In the calvarial model, BMP-4 and BMP-6 are synergistic with glucocorticoids in promoting osteogenesis (Boden *et al.*, 1996). Moreover, glucocorticoid-dependent differentiation of fetal rat calvarial cells is blocked by antisense oligonucleotides to BMP-6 (Boden *et al.*, 1997). However, in a gene-profiling experiment of MC3T3-E1 cells, dexamethasone added at the time of commitment (near confluency) was shown to antagonize the BMP pathway. Dexamethasone increased the expression of the BMP antagonists *Dan* and *Follistatin* and decreased the expression of *Tieg* (TGF-β-inducible early growth response) (Leclerc *et al.*, 2004), which is stimulated by BMPs (Hefferan *et al.*, 2000).

Plasminogen activator is a serine protease that activates plasminogen to the serine protease plasmin. The plasminogen activator–plasmin system may have a role in bone resorption by activating latent collagenase or TGFβ (Hamilton *et al.*, 1985). Glucocorticoids decrease plasminogen activator activity in normal rodent osteoblasts and UMR 106-01 cells (Hamilton *et al.*, 1985); this is primarily because of an increase in plasminogen activator inhibitor-1 mRNA and protein level (Fukumoto *et al.*, 1992). Glucocorticoid inhibition of plasminogen activator activity, therefore, might limit the activation of locally produced TGFβ, leading to a decrease in bone formation (Fukumoto *et al.*, 1992). However, glucocorticoids enhance the activation of latent TGFβ1 in normal human osteoblastic cells without an alteration of TGFβ1 mRNA levels (Oursler *et al.*, 1993). Such an effect of glucocorticoids might be expected to increase the availability of TGFβ as an anabolic bone growth factor; alternatively, enhanced TGFβ activation might lead to increased bone resorption. Taken together, the effect of glucocorticoids on the TGFβ activity in bone may result from a combination of the actions described earlier.

Prostaglandins

Prostaglandins are produced by bone cells and can affect both bone formation and resorption. Prostaglandins directly

inhibit the activity of isolated osteoclasts (Fuller *et al.*, 1989) but increase bone resorption by increasing the formation of new osteoclasts (Dietrich *et al.*, 1975). Prostaglandins have both stimulatory and inhibitory effects on bone formation in organ cultures of rodent calvaria depending on the dose and hormonal milieu that is used (Raisz *et al.*, 1990). Glucocorticoids decrease baseline and agonist-induced prostaglandin production in bone (Hughes-Fulford *et al.*, 1992; Klein-Nulend *et al.*, 1991; Marusic *et al.*, 1991). The mechanisms for this inhibition likely include both a decrease in arachidonic release from membranes and a decrease in the expression of the cyclooxygenases that convert arachidonic acid to prostaglandins. Osteoblasts express two cyclooxygenases, the constitutive prostaglandin synthase-1 (PGHS-1) and the inducible prostaglandin synthase-2 (PGHS-2) (Kawaguchi *et al.*, 1995; Pilbeam *et al.*, 1993). Endogenous glucocorticoids suppress PGHS-2 in mice, and this suppression is relieved when the animals are adrenalectomized (Masferrer *et al.*, 1992). The induction of PGHS-2 by interleukin-1 and PTH in mouse calvaria and by serum in MC3T3-E1 cells is antagonized by glucocorticoids (Kawaguchi *et al.*, 1994). In summary, glucocorticoid inhibition of prostaglandin production in bone occurs primarily by a decrease in agonist-induced PGHS-2 expression.

PREVENTION AND TREATMENT OF GLUCOCORTICOID-INDUCED BONE LOSS

Prevention Recommendations

The severity and rapid onset of the increased risk of fracture with glucocorticoid use, along with the effectiveness of prevention and treatment strategies, have lead several specialty organizations to develop aggressive prevention and treatment recommendations (Recommendations for the Prevention and Treatment of Glucocorticoid-Induced Osteoporosis: 2001 Update. American College of Rheumatology Ad Hoc Committee on Glucocorticoid-Induced Osteoporosis, 2001; Compston, 2004). The American College of Rheumatology recommends a combination of calcium (1500 mg daily), vitamin D (800 IU daily), lifestyle modification (smoking cessation and reduction in alcohol, if excessive), and weight-bearing physical exercise for all patients beginning therapy with glucocorticoids or receiving chronic glucocorticoid therapy. For patients just beginning therapy with glucocorticoids (prednisone or equivalent $\geq$5 mg daily) with plans for a treatment duration of at least 3 months, bisphosphonate (alendronate or risedronate) therapy is recommended. Calcitonin is recommended as a second-line agent if the patient has intolerance or a contraindication to a bisphosphonate. For patients who are receiving chronic glucocorticoid therapy, replacement of gonadal sex hormones if deficient or otherwise clinically indicated is recommended. For patients receiving chronic glucocorticoid therapy, bisphosphonate therapy is recommended if the BMD is below normal (*T* score below -1). Again, calcitonin is recommended if there is a contraindication or intolerance to a bisphosphonate. The Royal College of physicians recommends bisphosphonates for primary prevention if the patient is older than 65 years of age or has a history of fragility fracture. They recommend bisphosphonate therapy based on a BMD *T* score less than -1.5 or with a reduction in BMD of more than 4% after one year.

Calcium and Vitamin D

Evidence supports the effectiveness of calcium and vitamin D in preventing the bone loss associated with glucocorticoid therapy. Calcium alone does not appear to prevent the bone loss observed in glucocorticoid-treated patients compared with no therapy (Amin *et al.*, 1999). In the randomized placebo-controlled trials investigating the effectiveness of bisphosphonate therapy, both treatment and placebo groups received calcium and vitamin D therapy. Bone density in the lumbar spine was maintained in the group receiving calcium and vitamin D without bisphosphonate (Cohen *et al.*, 1999; Saag *et al.*, 1998). Meta-analysis of retrospective clinical trails with calcium and vitamin D demonstrate improved bone density in the spine and radius for glucocorticoid-treated patients receiving calcium and vitamin D (Amin *et al.*, 1999; Homik *et al.*, 2000b). The active vitamin D metabolites, alphacalcidiol and calcitriol, have also been shown effective in the prevention of bone loss in patients starting glucocorticoid therapy. These agents may have an additional direct effect to increase bone mass or reduce bone resorption (Reginster *et al.*, 1999; Sambrook *et al.*, 1993). However, there was significant toxicity in the patients treated with calcitriol and calcium with nearly 25% of patients developing hypercalcemia. A meta-analysis estimating the effects of vitamin D and calcitriol on bone loss did not demonstrate an improved effect of calcitriol over vitamin D_3 (Amin *et al.*, 2002). Therefore, until further studies provide more information, it seems most appropriate to provide vitamin D_3 as opposed to the active metabolites. At present, there is a lack of prospective data to confirm a reduction in fracture risk with calcium and vitamin D in glucocorticoid-treated patients (Homik *et al.*, 2000b). Patients receiving calcium and vitamin D should have urinary calcium excretion determined over a 24-hour period. Patients who excrete more than 300 mg may benefit from a low-dose thiazide diuretic and dietary sodium restriction. Serum potassium should be monitored and replaced as needed. Hypokalemia may be avoided with the use of a combination potassium-sparing diuretic such as amiloride. Long-term effects of thiazide diuretics on bone loss in glucocorticoid-treated patients have not been done but, in the absence of glucocorticoid therapy, thiazide use is associated with higher bone density and reduction in fracture risk (Cauley *et al.*, 1993).

Bisphosphonates

Bisphosphonate therapy has become an important part of the prevention and treatment of GIOP because evidence has shown it results in improvement in bone density and a reduction in the risk of fracture (Adachi *et al.*, 2001; Cohen *et al.*, 1999; Reid *et al.*, 2000; Saag *et al.*, 1998; Wallach *et al.*, 2000). In a study of 477 men and women, alendronate, calcium, and vitamin D increased the bone density of the spine and hip compared with the group receiving only calcium and vitamin D; additionally, there was a reduction at 2 years in vertebral fractures (Saag *et al.*, 1998). The effect of alendronate was greater in postmenopausal women than in premenopausal women. In a prospective placebo-controlled trial with risedronate, there was a 70% overall reduction in the relative risk for vertebral fracture, 66% reduction in men, and 73% reduction in postmenopausal women. There were no fractures observed in premenopausal women (Wallach *et al.*, 2000). A recent meta-analysis of bisphosphonates for GIOP examined 13 controlled clinical trials reporting on 842 participants. All 13 studies reported data on lumbar spine BMD. On average, the lumbar spine BMD of the bisphosphonate-treated groups was 4% higher than the group not receiving bisphosphonates. Four of the trials reported data for the femoral neck BMD, which was 2.1% higher in the bisphosphonate-treated groups (Homik *et al.*, 2000a). In this meta-analysis, there was a 24% reduction in the odds of vertebral fracture, which did not reach statistical significance. Pamidronate has also been demonstrated to increase vertebral bone density in patients treated with glucocorticoids when given orally or intravenously. An intravenous route of 90 mg once yearly or 90 mg initially followed by 30 mg intravenously every 3 months both prevented bone loss (Boutsen *et al.*, 2001; Reid *et al.*, 1988). Etidronate has also been shown to improve bone density in glucocorticoid-treated patients when given cyclically with calcium and vitamin D (Amin *et al.*, 2002). There are no fracture reduction data available with the use of pamidronate or etidronate in glucocorticoid-treated patients. At present, alendronate and risedronate have Food and Drug Administration (FDA) approval for use in prevention and treatment of GIOP.

Hormone Replacement

Evidence suggests that postmenopausal women are at greatest risk for GIOP. In a trial of women receiving glucocorticoids for rheumatoid arthritis (RA), individuals were randomized to receive hormone replacement therapy (HRT) or placebo. A 2% increase in lumbar spine density was observed in the HRT group compared with controls (Hall *et al.*, 1994). In another study of 15 women receiving glucocorticoid therapy for asthma, HRT was associated with an increase in bone density of the lumbar spine at 1 year (Lukert *et al.*, 1992). There are no data showing the effect of HRT on hip BMD in glucocorticoid-treated patients and no trials at present demonstrating fracture reduction with HRT in glucocorticoid-treated patients. The recent report from the Women's Health Initiative demonstrated an increased risk of breast cancer and cardiovascular disease in postmenopausal women treated with long-term HRT (Rossouw *et al.*, 2002). The routine use of HRT in postmenopausal women for prevention of GIOP may not be indicated in light of these results. Raloxifene, a selective estrogen receptor modulator, has been shown to increase vertebral BMD in postmenopausal women and reduce vertebral fracture risk; however, there are few data on its use in GIOP (Ettinger *et al.*, 1999).

Glucocorticoid therapy is associated with a reduction in testosterone in men. A recent randomized placebo-controlled trial examined the effects of testosterone or nandrolone replacement in 51 glucocorticoid-treated men. The mean dose of glucocorticoids was 12.6 mg of prednisone daily. At 12 months, both testosterone and nandrolone increased muscle mass significantly over placebo by 3.5% and 5.8%, respectively. Muscle strength was increased as well. Testosterone increased the BMD of the lumbar spine significantly by 4.7%. There was no significant change seen with nandrolone and no significant change demonstrated with testosterone or nandrolone for BMD of the hip or total body. Testosterone but not nandrolone was associated with an improvement in quality-of-life assessment. As testosterone but not nandrolone may undergo peripheral aromatization, the lack of effect of nandrolone on BMD suggests that aromatization of testosterone may be important for the effect on bone density (Crawford *et al.*, 2003). These data would support the current recommendation to replace testosterone in testosterone-deficient men receiving glucocorticoid therapy (Recommendations for the Prevention and Treatment of Glucocorticoid-Induced Osteoporosis: 2001 Update. American College of Rheumatology Ad Hoc Committee on Glucocorticoid-Induced Osteoporosis, 2001; Compston, 2004). There are no data at present demonstrating a reduction in fracture with testosterone replacement in GIOP.

There are few studies examining HRT in premenopausal women receiving glucocorticoid therapy. Menstrual irregularities may occur in these patients owing to the effects of glucocorticoid therapy. In premenopausal women athletes with oligomenorrhea or amenorrhea, oral contraceptive therapy has been associated with a higher BMD than a comparison group who did not take oral contraceptive therapy (Drinkwater *et al.*, 1986). It seems reasonable, until further information is available in this area, to offer oral contraceptives or cyclic estrogen and progesterone if no other contraindications exist.

CALCITONIN

Calcitonin has been shown to reduce bone loss in the spine in patients receiving glucocorticoid therapy. A recent meta-analysis studied the effects of nine retrospective clinical

trials investigating calcitonin for GIOP in 221 patients. The BMD of the spine was increased over placebo at all time points from 6 to 24 months. The weighted mean difference at 24 months was 4.5%. There was an increase in the radius BMD of 3.1% at 12 months but not at 24 months. There was no difference in BMD at the femoral neck and there have been no trials to date demonstrating a reduction in fracture risk with calcitonin treatment for GIOP (Cranney *et al.*, 2000). This evidence supports the use of calcitonin as a second-line drug if bisphosphonate therapy is contraindicated or not tolerated.

Parathyroid Hormone and Other Anabolic Agents

PTH is the most encouraging of the agents at present that simulates bone formation. A recent 18-month randomized controlled trial studied 428 men and women receiving prednisone equivalent to 5 mg daily for at least 3 or more months (Saag *et al.*, 2007). Subjects were randomized to teriparatide at 20 μg daily or alendronate at 10 mg daily. The bone density of the lumbar spine increased more in the teriparatide group than the alendronate group (7.2±0.7% versus 3.4±0.7%, $P < 0.001$). At 18 months, there was a greater improvement in the density of the total hip in the teriparatide group compared with the alendronate group (3.8±0.6% versus 2.4±0.6%, $P = 0.0005$). Though fracture was not the primary outcome there were fewer vertebral fractures in the teriparatide group compared with the alendronate group (0.6 versus 6.1%, $P = 0.004$). The nonvertebral fractures were greater in the teriparatide group, but this did not reach significance (5.6% versus 3.7%, $P = 0.36$). In this prospective trial of glucocorticoid-treated patients at high risk for fracture, there was greater bone density gain with teriparatide in both the hip and spine and significantly less fracture of the spine over the 18-month trial. An earlier randomized placebo-controlled trial over a 12-month time period studied 49 women receiving glucocorticoids (5–20 mg prednisone per day). All women received HRT. Subjects had a baseline *T* score at the femoral neck or spine of less than −2.5. Women receiving PTH and HRT demonstrated an increase in BMD of the spine of 11.9% over baseline at 12 months. Women receiving only HRT had a stable spine BMD of +1% over baseline. The BMD changes at the radius and hip were not significant (Lane *et al.*, 1998b). A follow-up study examined this group 12 months after discontinuing PTH. The gain in BMD in the spine by DXA was maintained at 13% over the baseline pretreatment BMD. At 24 months (12 months off PTH) there was a 4.7% increase in BMD at the femoral neck. BMD of the lumbar spine and femoral neck remained unchanged in the group receiving HRT only (Lane *et al.*, 2000). These results are encouraging and for patients at highest risk for fracture PTH therapy may be the best initial choice.

Sodium fluoride has been studied in GIOP along with calcium and vitamin D and in combination with cyclical etidronate. In these studies, fluoride was associated with an increase in BMD in the spine but not in the hip. In the group receiving etidronate plus fluoride the fractures were higher than the group receiving only etidronate (Lems *et al.*, 1997a, 1997b). In light of the lack of data on the reduction of fracture risk and data suggesting a possible increased risk of fracture with sodium fluoride, it is not currently recommended for the treatment of GIOP.

SUMMARY AND CONCLUSIONS

A variety of *in vitro* models have been developed to examine the direct effects of glucocorticoids on bone formation and resorption. These experiments show that glucocorticoids have diverse and complex direct effects on bone and can modify the expression of a wide variety of genes in osteoblastic cells. It is likely that the experimental outcomes in different models are affected by the concentration of glucocorticoid used, the timing of glucocorticoid addition, the presence of serum and growth factors, and the developmental stage of the model and species differences. However, several general principles can be drawn from these studies. Glucocorticoids can either stimulate or inhibit bone formation *in vitro* and these effects depend on the developmental stage of the model. Low concentrations of glucocorticoids are permissive for hormone action in bone (allowing other hormones to have optimal activity) and are associated with increased osteoblastic differentiation and bone formation. The daily secretion of physiological concentrations of cortisol may render osteoblasts and/or osteoprogenitor cells highly responsive to the effects of systemic and locally produced hormones. The ability of glucocorticoids to enhance the activity of some anabolic hormones may represent a compensatory response that helps maintain bone mass during periods of diminished growth factor supply. Pharmacological doses of glucocorticoids inhibit osteoprogenitor proliferation, osteoblast renewal, osteoblast function, and osteoblast and osteocyte apoptosis; glucocorticoids also increase osteoclast formation and life span. These multiple actions lead to a decrease in bone mass and quality (see Fig. 1). Understanding the molecular pathways that mediate these diverse effects of glucocorticoids will enable the development of effective therapeutic modalities for GIOP.

Chapter 45

Effects of Diabetes and Insulin on Bone Physiology

Johan Verhaeghe and Roger Bouillon*

Katholieke Universiteit Leuven, Laboratory for Experimental Medicine and Endocrinology, and Department of Obstetrics and Gynecology, Leuven, Belgium

INTRODUCTION

The term "diabetic bone disease" is used to describe the changes in bone growth, remodeling, and density as well as fracture risk imparted by the presence of type 1 diabetes (T1DM) or type 2 diabetes (T2DM). T1DM is caused by pancreatic β-cell destruction, usually leading to an absolute insulin deficiency; Northern Europeans are among the populations with the highest prevalence of T1DM. However, T2DM is currently by far the most prevalent form of diabetes in all continents. Its pathophysiology is heterogeneous, ranging from predominantly insulin resistance – i.e., at any of the classical insulin-sensitive tissues: liver, skeletal muscles, and adipose tissue – with relative insulin deficiency, to a predominantly insulin secretory defect with variable insulin resistance. Hence, insulin levels in T2DM vary widely, anywhere between hyper- and hypoinsulinemia. The majority of patients with T2DM are obese, and obesity itself aggravates insulin resistance. Body weight is, therefore, an important confounding factor when examining the pathophysiology of bone in T2DM individuals.

EFFECT OF DIABETES AND INSULIN ON ENDOCHONDRAL BONE GROWTH

T1DM and Skeletal Growth and Maturation in Children

At onset of T1DM, there is no difference in height compared with nondiabetic children. In fact, some but not all studies have documented that children are slightly taller at onset of diabetes compared with reference values (Holl *et al.,* 1998).

However, growth is affected from the clinical onset onward. In the preinsulin era, prepubertal growth virtually stopped, and stunted growth (Mauriac syndrome) was frequently observed in later decades of irregular insulin treatment. In addition, there was a delay in pubertal development and growth. Retarded growth and pubertal development remain common to this day among African children with T1DM (Elamin *et al.,* 2006). In Western countries, the majority of recent studies documented a mild reduction in growth from height *** (z) charts. This deficit was more pronounced in children with a prepubertal compared to a pubertal onset of T1DM (Holl *et al.,* 1998). Poor glycemic control predicts growth retardation: indeed, glycohemoglobin levels (a reflection of glycemic control in the previous two to three months) correlated inversely with height velocity (Danne *et al.,* 1997; Holl *et al.,* 1998). In one study, final height was reduced by a median of 0.5 SD, or 2–3 cm (Danne *et al.,* 1997).

At diagnosis, bone maturation – determined by radiographs of hand and wrist – was not different compared with nondiabetic children (Holl *et al.,* 1994; Danne *et al.,* 1997). However, there was a small but significant retardation of bone maturation with increasing T1DM duration (i.e., a one-year difference between chronological and bone age after eleven years of diabetes) (Holl *et al.,* 1994).

Skeletal Growth in T1DM Animal Models

The most frequently used animal models are rats or mice with T1DM induced by β-cell-destroying drugs: alloxan or – in the large majority of studies – streptozotocin (SZ); and BB (Bio-Breeding) rats with spontaneous immune-mediated diabetes. Although T1DM can be drug-induced at any age, BB rats develop diabetes past the peak growth rate ($\sim$7 weeks). In both rodent models, insulin levels are very low or undetectable. The growth plate width as well as the endochondral bone growth – assessed by double fluorochrome labeling of the calcifying cartilage – at the proximal tibia were consistently lower in untreated, severely hyperglycemic SZ-induced or spontaneously diabetic BB

TABLE I Histomorphometric Data from Proximal Tibial Metaphysis in Untreated and Insulin-Treated Male Spontaneously Diabetic BB Rats[a]

	Nondiabetic ($n = 14$)	Diabetic ($n = 11$)	Diabetic + insulin ($n = 15$)
Growth plate width (μm)	178 (8)	135 (8)***	230 (9)***,‡
Osteoblast surface (%)	1.5 (0.3)	0.04 (0.04)***	4.3 (0.8)**,‡
Osteoid surface (%)	1.5 (0.4)	0.04 (0.04)**	4.8(1.0)**,‡
Osteoclast surface (%)	0.4 (0.1)	0*	0.5 (0.2)†

[a]*From Verhaeghe et al. (1992), with permission of the Journal of Endocrinology Ltd. Measurements were performed about 4 weeks after onset of diabetes in diabetic rats and in nondiabetic littermates. Insulin-treated rats were treated with 3 U/day of insulin, infused SC with a miniosmotic pump for 14 days. Data are expressed as means (SEM). Statistical analysis:*, versus nondiabetic rats (*P < 0.05, **P < 0.01, ***P < 0.001);†, versus diabetic rats (†P < 0.05,‡P < 0.001).*

rats, and was remedied by systemic insulin treatment (Bain *et al.,* 1997; Epstein *et al.,* 1994; Scheiwiller *et al.,* 1986; Verhaeghe *et al.,* 1992) (Table I). The femur was shorter after twenty-eight days of SZ-diabetes (Lucas, 1987).

The effect of insulin on bone growth might be direct and/or indirect, for example by restoring the depressed hepatic release of insulin-like growth factor-I (IGF-I). Although it was reported that systemic administration of IGF-I in T1DM rats partly normalized growth plate width (Scheiwiller *et al.,* 1986), we did not corroborate this finding (Verhaeghe *et al.,* 1992). The low $^{35}SO_4$ uptake by rib cartilage explants from T1DM rats was also unresponsive to exogenous IGF-I (Kelley *et al.,* 1993). These data suggest that diabetic cartilage is, at least in part, resistant to the actions of IGF-I.

Effects of Insulin on Cartilage in Nondiabetic Animal Models and *in Vitro*

The classic experiments of Salter and Best (1953) demonstrated that insulin administration increased growth plate width in hypophysectomized rats. This could be a local effect, because insulin injection into the proximal tibial growth plate (Heinze *et al.,* 1989) or insulin infusion into one hind limb (Alarid *et al.,* 1992) produced widening of the treated growth plates only. Such local effect might be mediated by *in situ* production of IGF-I, because the trophic effect of insulin was nullified by coinfusion of an IGF-I antiserum (Alarid *et al.,* 1992). Mice with absent expression of insulin receptors in bone showed normal bone length (Irwin *et al.,* 2006). However, they overexpressed the IGF-I receptor, which could represent a compensatory response.

In vitro studies have documented the presence of insulin receptors in a chondrosarcoma cell line (Foley *et al.,* 1982). Chondrocyte proliferation and $^{35}SO_4$ incorporation were stimulated by insulin in several tissue and cell culture systems (Foley *et al.,* 1982; Heinze *et al.,* 1989; Maor *et al.,* 1993). These effects were obtained at physiological levels of insulin, as low as 1n*M*, but equimolar IGF-I was more potent than insulin.

Collectively, the available data suggest that IGF-I is more important than insulin for chondrocyte proliferation and maturation, but further research is mandatory.

EFFECTS OF DIABETES AND INSULIN ON BONE IN HUMANS

Introductory Remarks

Two critical issues hamper the interpretation of published data on bone in diabetic individuals. First, there is the sample size and heterogeneity issue: series are often small – especially for T1DM, and most contained female and male subjects with varying age, pubertal stage, diabetes duration, long-term glycemic control, and current insulinization; a variable proportion exhibited diabetes complications (retinopathy, neuropathy, atherosclerotic disease) that may have affected physical activity and capabilities; and some of the individuals smoked and/or used other medications than insulin – e.g., statins and thiazolidinediones (TZDs), which may have influenced bone mineral density (BMD) and fracture risk, as we will discuss later. Second, there is the methodology issue, because bone and mineral measurements present specific problems in diabetic subjects. A few examples suffice to illustrate this. Diabetes affects body weight and bone

size, which must be taken into account when interpreting areal bone mineral density (aBMD) results obtained by dual-energy x-ray absorptiometry (DXA), currently the reference densitometry technique. Serum total alkaline phosphatase is elevated in T1DM subjects (Bouillon *et al.,* 1995) owing to hypersecretion of the intestinal and hepatic but not the bone isoenzyme (Tibi *et al.,* 1988). Similarly, raised serum osteoprotegerin levels in T1DM subjects may well be derived from the vascular wall rather than bone (Rasmussen *et al.,* 2006). Finally, diabetes-induced changes in collagen metabolism in tissues other than bone may interfere with the measurement of the excretion of collagen breakdown products, particularly hydroxyproline or pyridinoline cross-links. Yet, in spite of these limitations, robust data have emerged over the last two decades that have much clarified the nature of diabetic bone disease.

T1DM and Bone Remodeling

Bone histomorphometry data are lacking, and the measurement of biochemical markers of bone formation/mineralization produced variable results. Yet in the largest study to date (229 T1DM individuals), Bouillon *et al.* (1995) documented that serum osteocalcin concentrations were 24–28% lower among diabetic children, adolescents, and adults compared to age- and gender-matched nondiabetic subjects (Fig. 1). Serum bone-specific alkaline phosphatase was decreased by 24% in diabetic adolescents, but there was no change among diabetic adults; serum PICP (procollagen carboxyterminal extension peptide) was unchanged in adolescents and adults. Of note, serum osteocalcin concentrations were well below the control range in children with new-onset T1DM but returned to the control range following two weeks of insulin treatment, and osteocalcin and glycohemoglobin levels were inversely correlated (Guarneri *et al.,* 1993).

No definitive data have been produced regarding biochemical markers of bone resorption in T1DM. In some studies, resorption markers were unchanged, or even slightly increased. Yet, total and free deoxypyridinoline excretion measured by high-performance liquid chromatography (HPLC) – the gold standard biochemical method to assess bone resorption – was reduced by ~20% in 84 adult T1DM individuals compared with 99 controls, and the decrease was proportional to their glycosuria (Cloos *et al.,* 1998).

T1DM and Bone Density

Thrailkill *et al.* (2005b) summarized the data obtained from numerous but generally small studies in T1DM children and adolescents, using a variety of methods [radiogrammetry, single and dual photon absorptiometry, DXA and quantitative computed tomography (QCT)]. Most though

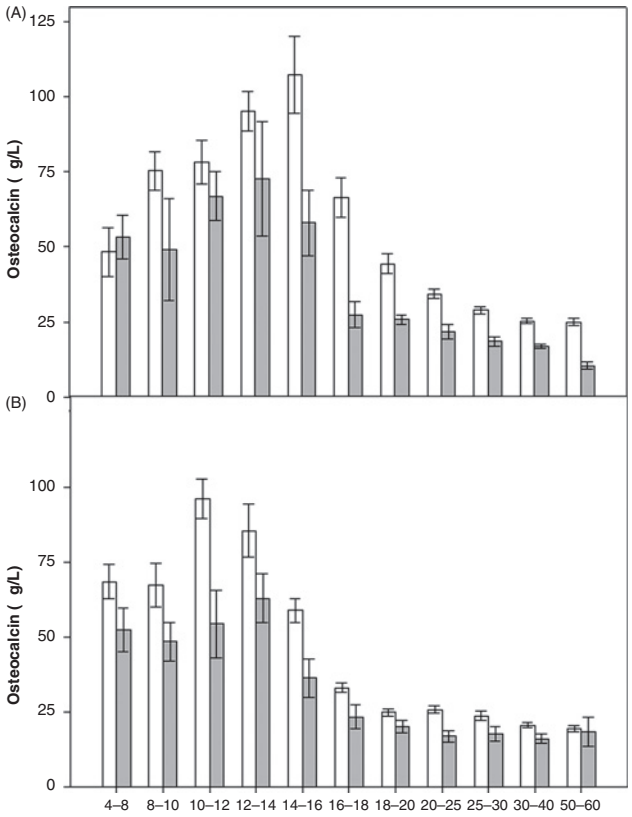

FIGURE 1 Serum osteocalcin concentrations in normal individuals (open bars) and individuals with type 1 diabetes (hatched bars): **(A)** male and **(B)** female. Data are presented as means±SEM. Multiple regression analysis showed a positive correlation between age and serum osteocalcin levels below 16 and 12 years for boys and girls, respectively, and a negative correlation above those ages ($p < 0.001$). A significant ($p < 0.005$) decreasing effect of diabetes on serum osteocalcin was observed for both genders. From Bouillon *et al.* (1995), with permission. © The Endocrine Society.

not all studies documented a mild reduction in bone area and BMD (~10% difference with controls, on average), but the average BMD z score in the diabetic group was generally at or above -1.0 SD. The differences were somewhat more pronounced when expressed relative to height or muscle mass; however, the reduction in volumetric BMD (vBMD, expressed in g/cm^3) appeared to be smaller than that in bone mineral content (BMC, in g) or aBMD (expressed in g/cm^2) (Moyer-Mileur *et al.,* 2004).

Comparable data were obtained for aBMD measurements at the lumbar spine and hip in T1DM adult women before menopause (Strotmeyer *et al.,* 2006). Thus, the available data indicate that there is an early but mild BMD deficit in T1DM individuals that does not appear to deteriorate over time (Krakauer *et al.,* 1995; Moyer-Mileur *et al.,* 2004). Whether or not long-term glycemic control is a determinant of this BMD deficit remains a matter of controversy (Thrailkill *et al.,* 2005b). The aBMD deficit

is more pronounced among T1DM adults with peripheral neuropathy (Rix *et al.,* 1999) or other microvascular complications (Strotmeyer *et al.,* 2006). The dynamics of bone loss during the peri- and postmenopausal years among T1DM women has not been investigated to date.

T1DM and Fractures (Table II)

The available epidemiologic studies concur that the risk of fractures is substantially increased in individuals with T1DM, more than could be explained by the mild BMD deficit – in effect, a 1-SD reduction in aBMD would translate into a twofold increased risk of hip fracture (Johnell *et al.,* 2005). A caveat is that many studies contained few incident fractures in the diabetic group (n = 1–18). The most robust evidence comes from a Swedish study, which identified >24,000 individuals hospitalized before age 31 for diabetes (presumably T1DM in the large majority of them). The incidence of hip fracture through 13 years was compared with that in the general population, and showed an eight- to tenfold elevated risk (Miao *et al.,* 2005). In another Swedish study, diabetes (presumably T1DM in the majority) was an independent risk factor for hip fracture among middle-aged men and women, and an independent risk factor for vertebral fracture among middle-aged women (Holmberg *et al.,* 2006).

T2DM and Bone Remodeling

Like T1DM, T2DM is accompanied by low bone formation and remodeling. In a small but interesting series of eight diabetic subjects (ages 37–67, diabetic for 2–36 years, 6 with T2DM), a transiliac bone biopsy was performed because of a low BMD; histomorphometry showed a significant decrease in osteoid thickness, mineralizing surface and mineral apposition rate (Krakauer *et al.,* 1995). Biochemical bone remodeling markers are also lower than in nondiabetics. This was demonstrated, for example, in middle-aged women (ages 42–52, from various ethnic backgrounds) examined in the Study of Women's Health Across the Nation (SWAN): diabetes (167/2,374 women, presumably T2DM in the majority of them) was associated with reduced serum osteocalcin concentrations and urinary N-telopeptide of type I collagen (uNTx) excretion (Sowers *et al.,* 2003). In Pima Indians, osteocalcin levels correlated negatively with postload glucose levels (Bouillon *et al.,* 1995). Similar findings were obtained in European women living in a nursing home (age 83 on average): serum osteocalcin and C-terminal telopeptide cross-links (β-CTxs) concentrations were 10–15% lower in 360 women with diabetes than in 588 women without diabetes (Dobnig *et al.,* 2006). Thus, reduced bone remodeling persists in elderly diabetic individuals. Improved glycemic control augmented serum osteocalcin concentrations and urinary pyridinoline excretion (Rosato *et al.,* 1998).

TABLE II Fracture Risk in Individuals with T1DM

First author (year)	Country (Study)	Sample size (Age at baseline)	Follow-up	Outcome#	N with diabetes (+ fractures)	Age-adjusted RR (95%CI)

Hyperinsulinemia and Bone Density

Hyperinsulinemia is the compensatory answer to hepatic and muscle insulin resistance; when inadequate, impaired fasting glucose and/or postload hyperglycemia (impaired glucose tolerance) ensue. Several population studies have demonstrated a correlation between – on the one hand – fasting insulin, the HOMA insulin resistance index, and/or postchallenge glucose and insulin concentrations and – on the other hand – the aBMD at the hip and/or the spine (Barrett-Connor and Kritz-Silverstein, 1996; Dennison *et al.,* 2004; Stolk *et al,* 1996; Thomas *et al.,* 2001). Yet adjusting for body mass index (BMI) or fat mass attenuated or abolished the correlation. Thus, insulin is thought to mediate the link between fat mass and aBMD, in addition to other hormonal mediators such as leptin and estrogens.

Established T2DM and Bone Density

The seminal report by Meema and Meema (1967) that the cortical thickness at the radius was higher in aged (65–101 years) white women with T2DM than in nondiabetics was followed by numerous studies using DXA. The majority of these studies showed that aBMD is mildly increased in T2DM subjects, even after controlling for BMI (Thrailkill *et al.,* 2005b). For example, in the Study of Osteoporotic Fractures, T2DM ($n \approx 500$) was associated with a 4.8% increase in aBMD at the radius and a 3.4% increase in aBMD at the femoral neck in multivariate analyses (Bauer *et al.,* 1993; Orwoll *et al.,* 1996). In the Rotterdam Study, lumbar spine and the femoral neck aBMD were also 3–4% higher in T2DM individuals ($n = 578$) (van Daele *et al.,* 1995). Similarly, in the Health ABC Study, total hip aBMD was 4–5% higher in black and white men and women with T2DM ($n = 566$) after adjusting for their altered body composition (i.e., higher fat and lean mass) (Strotmeyer *et al.,* 2004). However, total hip aBMD was inversely related to T2DM duration (Strotmeyer *et al.,* 2004), and white women with T2DM showed increased aBMD loss compared with their nondiabetic counterparts (Schwartz *et al.,* 2005); in addition, the aBMD of insulin-treated T2DM individuals was not different from that of controls in some studies (van Daele *et al.,* 1995; Tuominen *et al.,* 1999). The data suggest that aBMD decreases with waning β-cell function and insulin secretion. Indeed, aBMD in T2DM subjects correlated with fasting insulin and urinary C-peptide levels (Wakasugi *et al.,* 1993).

The contrasting effects of T1DM and T2DM on aBMD were confirmed in a Finnish study (Tuominen *et al.,* 1999). They examined subjects (ages 52–72) who developed diabetes after 30 years of age (i.e., after achievement of peak bone mass) and were insulin-treated, but differed in their baseline insulin secretory response (C-peptide levels after glucagon). Subjects with deficient insulin secretion (classified as T1DM) showed a lower aBMD at the hip than subjects with normal insulin secretion (classified as T2DM) or controls. After adjusting for age, BMI, and other factors, the difference was attenuated but still demonstrable.

However, the effects of T2DM on vBMD were much less pronounced than those on aBMD, and generally not significant (Register *et al.,* 2006; Strotmeyer *et al.,* 2004), indicating that T2DM induces larger rather than denser bones.

T2DM and Fractures

Table III shows that the risk of fractures is elevated in individuals with T2DM, but much less so than in T1DM. The largest cohorts – the Study of Osteoporotic Fractures (Schwartz *et al.,* 2001) and in particular the Women's Health Initiative Observational Study (Bonds *et al.,* 2006) – both confirmed a mildly increased risk (between one- and twofold). The latter study documented an elevated age-adjusted risk of fracture at all skeletal sites except the forearm/wrist/hand.

Limited evidence indicates that diabetes (T1DM or T2DM) delays the healing of clinical fractures, taking about twice as long (Loder, 1988).

Clinical Risk Factors for Fractures in T1DM and T2DM (Table IV)

Regarding T1DM, the Swedish study (Miao *et al.,* 2005) reported that the age-adjusted risk of hip fracture increased with longer diabetes duration. Longer diabetes duration means a greater likelihood of micro- and macrovascular complications; indeed, the risk of fracture was particularly high among T1DM patients with eye, nephropathic, neurologic, or cardiovascular complications. When controlling for diabetes complications, the risk of hip fracture among Norwegian T1DM patients was no longer significantly elevated (Forsén *et al.,* 1999).

For T2DM, the elevated risk of fractures was observed in both white and black U.S. women (Bonds *et al.,* 2006). BMI is not a critical factor, because the risk was comparably elevated in nonobese and obese T2DM women, and controlling for BMI did not meaningfully alter the risk ratio (Janghorbani *et al.,* 2006; Nicodemus and Folsom, 2001; Schwartz *et al.,* 2001). In some studies, the risk appeared to be higher among insulin-treated versus non-insulin-treated T2DM individuals (Janghorbani *et al.,* 2006; Ottenbacher *et al.,* 2002). This may reflect the association between longer duration of T2DM and fracture: in individuals with >12 years of T2DM, the risk was increased more than twofold (Janghorbani *et al.,* 2006; Nicodemus and Folsom, 2001). Again, longer diabetes duration means more complications. In the Australian Blue Mountains Eye Study, which examined 216 subjects (ages 49–97) with T1DM or T2DM, cortical cataract and especially retinopathy increased the risk of fractures (Ivers *et al.,* 2001). Neuropathy with or without

foot ulcers was another important predisposing factor for fractures in general (Strotmeyer *et al.,* 2005), and foot fractures in particular (Cavanagh *et al.,* 1994). Diabetic individuals with eye, neuropathic, and vascular complications – and poor physical health in general – are more likely to fall. Indeed, insulin-treated T2DM individuals showed a fourfold increased risk of falls (Schwartz *et al.,* 2002), and repeated falls in diabetic individuals with a foot ulcer predisposed to fractures (Wallace *et al.,* 2002). It is likely, therefore, that falls mediate a significant part of the diabetes-associated risk of fractures. As a corrolary, effective fall-prevention strategies should be developed to prevent fractures in individuals with long-standing diabetes or diabetes complications.

POSSIBLE MECHANISMS OF FRACTURES IN T1DM AND T2DM (Table IV)

T1DM bones are smaller and show a mild deficit in BMD (∼10% or ∼1 SD). Smaller bones are predisposed to brittleness and damageability under loading conditions (Tommasini *et al.,* 2005). As mentioned earlier, an average BMD *z* score of -1.0 in T1DM individuals would translate in about a doubling of the fracture risk (1.73 relative risk of any osteoporotic fracture, and 2.11 relative risk of hip fracture) (Johnell *et al.,* 2005).

In addition, both T1DM and T2DM are associated with reduced bone formation and remodeling. Interestingly, there appears to be a J- or U-shaped relationship between bone remodeling activity and fracture risk (Heaney, 2003). It has been postulated that diabetes impairs the healing of fatigue microfractures (also called microdamage, or microcracks) in load-bearing bones because of suppressed bone formation ("frozen bones"); and that accumulated microdamage may predispose diabetic individuals to overt fractures (Krakauer *et al.,* 1995). This interesting hypothesis has yet to be formally tested, but until such time we may gain some insight from examining the evidence in a similar debate: i.e., whether prolonged treatment with potent bisphosphonates in osteoporosis ultimately produces a detrimental effect on bone strength by accumulated microdamage. In a

TABLE IV Possible Clinical Risk Factors and Possible Mechanisms of Increased Fracture Incidence in Diabetic Individuals

Possible Clinical Risk Factors		Possible Mechanisms
Diabetes duration	Related to Bone:	Smaller bones (T1DM)
Eye disease: Diabetic retinopathy, cataract		Reduced BMD (T1DM)
Peripheral neuropathy		Low bone formation
Transient ischemic attack/stroke		Accumulation of microdamage
Atherosclerotic disease		Altered collagenous matrix
Hypoglycemic seizures		(eg, accumulation of AGEs)
Nycturia	Neuromuscular:	Higer incidence of falls
Use of thiazolidinediones		
Organ transplantation		

detailed study in dogs treated with clinically relevant doses of bisphosphonates, microdamage did indeed occur dose-dependently, but was not associated with bone fragility (Allen *et al.,* 2006). The authors proposed that the deleterious effects of microdamage were offset by the increase in mineralized bone volume. However, such "compensation" would be absent in individuals with T1DM.

Effect of Concurrent Medication use on Bone

A Danish case-control study found that diabetic individuals who used sulphonylureas had a lower risk of hip fracture than diabetic individuals in general (Vestergaard *et al.,* 2005). In counterpart, TZDs or peroxisome proliferator-activated receptor (PPAR)-γ agonists (e.g., pioglitazone, rosiglitazone) worsen diabetic bone disease. Indeed, aBMD loss at the spine and the whole body was higher among women – but not men – with T2DM who used a TZD (Schwartz *et al.,* 2006). In line with these data, in the ADOPT trial – which compared metformin, glyburide, and rosiglitazone during four years in 4,360 T2DM patients – the number of fractures (any site) was higher among women – but not men – treated with the TZD compared with the other two drugs (Kahn *et al.,* 2006). In mice, TZD treatment enhanced bone marrow adiposity and caused trabecular bone loss by uncoupling resorption (activated) and formation (suppressed) (Li *et al.,* 2006), the latter perhaps as a result of osteoblast/osteocyte apoptosis (Sorocéanu *et al.,* 2004). Clearly, further research is needed on the bone effects of TZDs. Statins are another frequently used class of drugs in diabetic patients. A small study suggested that statins increase bone density at the hip in T2DM patients (Chung *et al.,* 2000). However, the beneficial effects of statins on BMD and fracture risk are not undisputed at this time (Nguyen *et al.,* 2007).

Anti-osteoporosis drugs appear to be as effective in diabetic as in nondiabetic individuals. In a post hoc analysis of the Fracture Intervention Trial, alendronate 5–10 mg for three years increased aBMD at the spine and hip and reduced bone remodeling indices comparably in diabetic and nondiabetic postmenopausal women (Keegan *et al.,* 2004). Regarding estrogens, clinical trial data (e.g., from the Women's Health Initiative trial) have not been reported yet, but in the observational Iowa Women's Health Study, diabetic women who were using estrogen did not have an elevated hip fracture risk (Nicodemus and Folsom, 2001).

Advanced Diabetic Renal Disease and Bone

Several histomorphometric studies showed that the indices of bone formation and resorption are set lower in diabetic than in nondiabetic patients with chronic renal failure. Thus, high-turnover osteodystrophy is distinctly uncommon (Pei *et al.,* 1993, and references therein). Diabetic patients with chronic renal failure also have less Tc-99m methylenediphosphonate uptake on bone scintigraphy, confirming reduced osteoblastic activity (So *et al.,* 1998). These findings are echoed by comparable data obtained in experimental models: histomorphometric bone formation indices were repressed in 5/6-nephrectomized rats with SZ-induced diabetes compared with nondiabetic rats, which was reversed by insulin treatment (Jara *et al.,* 1995).

Fractures are well known to be more common among kidney transplant recipients. In one U.S. series, they were four times more likely to be hospitalized for a fracture in the three years following renal transplantation; diabetes (T1DM or T2DM) was an additive risk factor, conferring a twofold increased relative risk (Abbott *et al.,* 2001). Similarly, in 86 renal transplant recipients followed for a median of ten years, the relative risk of fracture at any site was 4.8 (95%CI, 3.6–6.4). Again, diabetes was an additional independent risk factor for fractures, raising the relative risk to 13 (95%CI, 8.2–20), with a preponderance of fractures at the lower limbs (Vautour *et al.,* 2004). The possible interaction between diabetes and cumulative corticosteroid, cyclosporine, or tacrolimus dosages needs further study. However, cyclosporine treatment did not affect bone volume and bone remodeling parameters in SZ diabetic rats (Epstein *et al.,* 1994).

THE EFFECT OF DIABETES AND INSULIN ON BONE IN EXPERIMENTAL ANIMALS

Bone Remodeling in Animal Models of T1DM and T2DM

Several animal models have been used for T1DM [alloxan- or SZ-induced diabetic rats and mice, spontaneously diabetic BB rats and nonobese diabetic (NOD) mice] and T2DM (db/db mice, Goto-Kakizaki rats). Untreated severe T1DM (hyperglycemia >300 mg/dl) was associated with low bone formation as shown by biochemical markers, in particular osteocalcin concentrations. Plasma osteocalcin dropped exponentially after onset of T1DM in BB rats to ~25% of nondiabetic levels after five weeks (Verhaeghe *et al.,* 1997b). Interestingly, diabetic BB rats already had lower circulating osteocalcin than their nondiabetic littermates at onset of glycosuria (Verhaeghe *et al.,* 1997b), similarly to what was reported in children (Guarneri *et al.,* 1993). Osteocalcin levels responded poorly, if at all, to exogenous $1,25(OH)_2D_3$ (Verhaeghe *et al.,* 1989, 1993). The half-life of plasma osteocalcin was similar in diabetic and nondiabetic BB rats, indicating that faster clearance does not explain reduced circulating osteocalcin (Verhaeghe *et al.,* 1989). Plasma osteocalcin gradually returned to the control range with increasing insulin dosage in BB rats (Verhaeghe *et al.,* 1997b), and was normalized by pancreas transplantation in SZ diabetic rats (Ishida *et al.,* 1992).

Histomorphometry consistently showed low bone formation on all bone surfaces (trabecular-endosteal, endocortical, and periosteal) in SZ-diabetic and BB rats. Static morphometry demonstrated a marked decline in osteoblast and osteoid surface or volume (Table I), and dynamic morphometry a decrease in both mineralizing surface and mineral apposition rate. These changes were (partly) reversed by insulin (Bain *et al.,* 1997; Epstein *et al.,* 1994; Glajchen *et al.,* 1988; Shires *et al.,* 1981; Verhaeghe *et al.,* 1992). Electron microscopy of the endocortical surface confirmed that active, cuboidal osteoblasts are virtually absent in SZ-diabetic rats and are replaced by inactive bone-lining cells with flattened nuclei and little or no endoplasmic reticulum (Sasaki *et al.,* 1991). Thus, most of the bone surface is in a quiescent state in severely hyperglycemic animals.

Osteoblast differentiation and maturation are disturbed in T1DM animals. After marrow ablation of the tibia (a validated model of intramembraneous bone formation), SZ-diabetic mice showed a quantitatively reduced but normal temporal expression pattern of genes involved in osteoblast differentiation (c-fos, Cbfa1/Runx-2, collagen type 1, osteocalcin) (Lu *et al.,* 2003). However, osteocalcin but not Runx-2 or alkaline phosphatase mRNA levels were reduced in tibias from SZ-diabetic mice (Botolin *et al.,* 2005), reinforcing the conclusion that loss of mature osteoblasts is a key finding in T1DM. Apoptosis of osteoblastic cells may be stimulated as well, as shown in calvaria from T2DM db/db mice following bacterial inocculation (a model of periodontal bone loss) (He *et al.,* 2004).

Regarding bone resorption, T1DM rats displayed diminished total and creatinine-corrected deoxypyridinoline excretion (Horcajada-Molteni *et al.,* 2001; Verhaeghe *et al.,* 2000). Most but not all histomorphometric data confirmed that the osteoclast surface/number is decreased moderately to severely in T1DM rats, and is reversed by insulin treatment (Glajchen *et al.,* 1988; Shires *et al.,* 1981; Verhaeghe *et al.,* 1992). Electron microscopy showed that most osteoclasts in T1DM rats lack a ruffled border-clear zone complex and that acid phosphatase activity is rarely detected (Kaneko *et al.,* 1990). Bacterial inocculation of the scalp in db/db mice also generated less osteoclasts (He *et al.,* 2004).

Interestingly, bone marrow adiposity was increased in SZ-diabetic mice and NOD mice, with upregulation of adipogenic genes such as PPAR-γ_2, adipocyte fatty acid binding protein (aP2), and resistin (Botolin *et al.,* 2005). More research is needed on the significance of this finding for bone physiology.

Bone Size and Density in Animal Models of T1DM and T2DM

Experimental T1DM had a negative effect on bone size (wet and dry weight, diaphyseal width) that was related to at least three factors: earlier age at which diabetes was induced or occurred spontaneously; longer diabetes duration; and more severe hyperglycemia (Dixit and Ekstrom, 1980; Einhorn *et al.,* 1988; Locatto *et al.,* 1993; Lucas, 1987). Thus, the impact on bone size was modest in T1DM models with onset of diabetes past the peak growth rate (Verhaeghe *et al.,* 1994, 2000). However, the calcium/phosphate concentrations of long bones (expressed per dry weight) was within the normal range in all T1DM models indicating that the mineralization of bone matrix remains adequate (Bain *et al.,* 1997; Dixit and Ekstrom, 1980; Shires *et al.,* 1981; Verhaeghe *et al.,* 1989, 1990). On histomorphometry, total bone area and cortical bone area at the tibial diaphysis were reduced by ~10% in T1DM rats, while the percentage of cortical/total bone area remained unchanged (Epstein *et al.,* 1994); μCT analysis confirmed that cortical thickness at the tibial midshaft is reduced in NOD mice (Thrailkill *et al.,* 2005a). In addition, femoral middiaphyseal BMC, as measured by DXA, was decreased in BB rats but the aBMD and bone mineral apparent density (BMAD, i.e., $BMC/area^2$) were comparable with values obtained in nondiabetic rats (Verhaeghe *et al.,* 1997a, 2000).

T1DM affects not only cortical bone, but also trabecular bone. The reduction in trabecular bone volume, measured by histomorphometry at the proximal tibia (Bain *et al.,*

1997; Glajchen *et al.,* 1988; Verhaeghe *et al.,* 1990), was related to the severity of hyperglycemia (Locatto *et al.,* 1993). This reduction was the result of thinner trabeculae, while the number and separation of trabeculae remained normal (Botolin *et al.,* 2005; Epstein *et al.,* 1994; Suzuki *et al.,* 2003; Thrailkill *et al.,* 2005a); thinner trabeculae are indeed compatible with osteoblast dysfunction. Although diabetic BB rats did not show a significant decrease in trabecular bone volume in many of our studies (Verhaeghe *et al.,* 1989, 1992, 1993, 1994, 2000), they showed the expected trabecular bone loss after ovariectomy (Verhaeghe *et al.,* 1994, 1997a), but not after immobilization (unilateral paralysis by sciatic neurectomy) (Verhaeghe *et al.,* 2000).

In contrast to T1DM, bone size was increased in T2DM models such as the Goto-Kakizaki rat, particularly at the diaphysis. Whereas cortical BMD, measured by QCT, was only mildly affected, trabecular BMD was markedly (33–53%) decreased in these rats (Ahmad *et al.,* 2003). T2DM may well have complex effects on bone with divergent responses generated by obesity and hyperglycemia. Disruption of leptin or leptin signaling in mice creates massive obesity with T2DM and increases bone mass via central nervous system pathways, some of which still need to be uncovered (Karsenty, 2006).

Bone Strength in Animal Models of T1DM

The breaking strength of the femoral or tibial midshaft was assessed in several T1DM models (SZ-diabetic and BB rats, NOD mice) by various methods (perpendicular pressure, torsion, three-point bending) (Dixit and Ekstrom, 1980; Einhorn *et al.,* 1988; Horcajada-Molteni *et al.,* 2001; Thrailkill *et al.,* 2005a; Verhaeghe *et al.,* 1990, 1994, 2000). Most though not all of these studies concluded that strength parameters were reduced after a critical period of diabetes (e.g., eight weeks in rats), even when correcting for their smaller bone size. Decreased strength was also documented at the femoral neck, which was partly restored by insulin treatment (Hou *et al.,* 1993); and at the femoral metaphysis (Suzuki *et al.,* 2003; Verhaeghe *et al*, 2000). However, there was no effect on vertebral body breaking strength (Verhaeghe *et al*, 2000).

One of the biomechanical parameters most affected was the energy absorption (reflecting bone brittleness versus toughness) (Verhaeghe *et al.,* 1994). Diabetic bone brittleness may be related to the reduced amount and altered composition of the collagenous matrix. In spontaneously WBN/Kob rats, a model of T1DM occurring at an advanced age (i.e., from 12 months), enzymatic collagen cross-links in femoral bone were reduced from the prediabetic stage (eight months), while non-enzymatic (glycosylated) cross-links increased from 12 months. Interestingly, the collagen cross-link parameters in prediabetic/diabetic WBN bones strongly correlated with biomechanical properties (Saito *et al.,* 2006).

Bone Repair in Animal Models of T1DM

Several models have been examined: a closed femur, tibia, or fibula fracture in SZ-diabetic or BB rats (Funk *et al.,* 2000; Gandhi *et al.,* 2006; Kawaguchi *et al.,* 1994; Kayal *et al.,* 2007); tibial distraction following a fibula fracture in NOD mice (Thrailkill *et al.,* 2005a); and surgical bone defects [a 1.0–2.1 mm hole in the parietal bone of SZ-diabetic mice (Santana *et al.,* 2003), or a 0.4–1.6 mm hole in the distal femur of BB rats (Follak *et al.,* 2004)]. In all models, defect repair was impaired at least temporarily in the diabetic animals, with less new bone formed – as assessed by radiographic, μCT, and histomorphometric analyses. Both endochondral and periosteal postfracture repair mechanisms were defective. Increased cartilage resorption may explain in part the impaired endochondral bone repair, because there was more osteoclast activity at the callus site in SZ-diabetic rats (Kayal *et al.,* 2007). Finally, callus strength was delayed by at least one week (Funk *et al.,* 2000). Again, the bone-healing impairment depended on the degree of glycemic control, and was reversed by systemic insulin treatment (Follak *et al.,* 2004). However, some local treatments also (partially) reversed the defective fracture repair, e.g., intramedullary delivery of insulin (Gandhi *et al.,* 2005), and topically applied autologous platelet-rich (and growth factor-rich) plasma (Gandhi *et al.,* 2006) or fibroblast growth factor (FGF) (Kawaguchi *et al.,* 1994).

CONCLUSION: INSIGHTS GAINED FROM T1DM ANIMAL MODELS

Experiments in T1DM models have confirmed that reduced bone formation is a key feature of severe hyperglycemia. They have taught us that osteoblast differentiation and maturation are downregulated, resulting in suppressed production of osteoid tissue and mineralized bone, and thus mostly "quiescent" bone surfaces. Osteoblast apoptosis may be increased, but this finding must be buttressed in future research. Although bone resorption is suppressed as well, there is likely some degree of uncoupling with formation being more repressed than resorption, as suggested by the reduced trabecular bone volume with thinner trabeculae. Hence, diabetic bone disease should be regarded as an osteoblast-induced low-turnover osteopenia. Decreased periosteal bone formation (modeling) results in thinner cortical shells and thinner bones. Biomechanical studies have demonstrated that bone strength is impaired, which could be related to the amount and composition of the collagenous bone matrix. Finally, T1DM substantially delays bone defect or fracture repair.

LOCAL EFFECTS OF GLUCOSE AND INSULIN ON BONE

The effects of supraphysiological glucose concentrations were examined *in vitro* in human MG-63 and mouse MC3T3-E1 osteoblast-like cells. Glucose effects on cell proliferation were contradictory, but mineralization parameters (osteocalcin expression, calcium uptake) were generally downregulated. Whether this is the result of osmotic stress or a specific effect of glucose is controversial (Balint *et al.,* 2001; Terada *et al.,* 1998; Zayzafoon *et al.,* 2000).

Abundant, high-affinity insulin receptors were documented in mature osteoblastic cell lines (UMR-106 and ROS-17/2.8) but not in preosteoblastic cells (UMR-201). In UMR-106, half-maximal displacement of ^{125}I-labeled insulin was attained at physiological insulin concentrations (between 0.5 and 1.0 n*M*), while proinsulin had 0.1% of insulin's binding potency; insulin binding was downregulated at supraphysiological insulin concentrations (10^{-7} *M*). Physiological concentrations of insulin (0.25–10 n*M*) stimulated the proliferation of osteoblastic cells, as well as their glucose uptake, expression of the glucose transporter GLUT1, active K^+ uptake, PO^{2-}_4 uptake, and collagen synthesis (Hickman and McElduff, 1989; Ituarte *et al.,* 1989; Thomas *et al.,* 1996).

In fetal rat calvaria organ cultures, insulin at 3 n*M* stimulated collagen synthesis and bone matrix apposition, whereas osteoblast replication was boosted at supraphysiological insulin concentrations only (10^{-7}–10^{-6}*M*). This discrepancy suggests that the stimulating effect of insulin on collagenous matrix production is not explained by its effect on osteoblast replication (Hock *et al.,* 1988).

Insulin binding *in vivo* was demonstrated by autoradiography in rat osteoblasts but not osteocytes (Martineau-Doizé *et al.,* 1986). Insulin receptor-α was also detected by immunohistochemistry in osteoblast precursors present in healing distraction gaps in mice (Thrailkill *et al.,* 2005a). Insulin, administered locally to the periosteum of one hemicalvaria of normal mice, markedly stimulated morphometric parameters of bone formation (osteoblast number/perimeter, osteoid area) (Cornish *et al.,* 1996). As mentioned previously, local insulin delivery also normalized fracture healing in T1DM rats (Gandhi *et al.,* 2005).

Cultured osteoclasts also contained abundant insulin receptors, and insulin dose dependently inhibited pit formation in a dentine slice assay (Thomas *et al.,* 1998). However, local injections of insulin did not increase osteoclast number/perimeter in mouse calvariae (Cornish *et al.,* 1996).

However, the significance of these findings was called into question by a study that examined mice with absent insulin receptor expression in bone. These mice showed normal bone remodeling and trabecular bone morphology, while cortical thickness was slightly increased. These surprising findings might be explained in part by the upregulation of IGF-I receptor expression in bone (Irwin *et al.,* 2006). Nonetheless, the remarkable effects on bone of circulating insulin deficiency appear to be largely if not completely indirect.

WHAT CAUSES DIABETIC BONE DISEASE?

The Diabetic Hormonal M*ilieu*

The effects of diabetes on bone growth and remodeling *in vivo* can be replicated in vitro using diabetic serum. Indeed, sera from T1DM individuals with poor glycemic control inhibited osteoblastic collagen synthesis (Brenner *et al.,* 1992). Similarly, diabetic rat serum inhibited collagen production by articular cartilage, which was reversed by *in vivo* insulin treatment of the animals but not by the direct addition of insulin to diabetic serum (Spanheimer, 1992).

Lower Circulating IGF-I

Lower circulating IGF-I is likely a crucial factor. Downregulation of hepatic IGF-I release resulted in a 73% drop in serum IGF-I levels in children with new-onset T1DM (Bereket *et al.,* 1995); circulating IGF-I remained below control levels in T1DM adolescents and adults receiving insulin treatment (Bouillon *et al.,* 1995; Léger *et al.,* 2006). IGF-I had powerful effects on osteoblast proliferation and bone matrix formation *in vitro* (Hock *et al.,* 1988). Also, disruption of the IGF-I gene resulted in 25–40% smaller bones in prepubertal mice and prevented periosteal expansion and BMD gain during puberty; serum osteocalcin levels in IGF-I knockout mice were reduced by 24–54% (Mohan *et al.,* 2003). Depletion of circulating IGF-I (while skeletal expression of IGF-I remained normal) equally resulted in decreased growth and periosteal expansion, which was restored by exogenous IGF-I (Yakar *et al.,* 2002). Insulin and IGF-I initiate cellular responses by binding to and activating the insulin and IGF-I (tyrosine kinase) receptors, and phosphorylation of insulin receptor substrate (IRS)-1. As would be predicted, IRS-1 knockout mice showed smaller bones with thinner growth plates, lower trabecular and cortical bone volume, thin trabeculae, and low bone formation and resorption (Ogata *et al.,* 2000). Our studies in T1DM animals showed a strong correlation between plasma IGF-I and osteocalcin levels (Verhaeghe *et al.,* 1997b). Similarly, IGF-I concentrations were correlated with biochemical bone formation markers in T1DM individuals (Bouillon *et al.,* 1995). In addition, serum IGF-I was an independent predictor of total body BMC in children and adolescents with T1DM (Léger *et al.,* 2006).

Upregulation of the hepatic expression of IGF-binding protein-1 (IGFBP1) by insulin deficiency caused a sevenfold increment in circulating IGFBP1 in children with new-onset T1DM (Bereket *et al.,* 1995). Through the accrued formation of binary IGF-I:IGFBP1 complexes (Frystyk *et al.,* 2002), the decrement in circulating free (bioavailable) IGF-I in

T1DM is more pronounced than that of total IGF-I. It is not surprising, therefore, that IGFBP1 inhibited the osteoblastic effects of IGF-I (Campbell and Novak, 1991). Elevated IGFBP1 levels might also explain, in part, why bone growth and remodeling in T1DM rats were resistant to the anabolic effects of exogenous IGF-I (Verhaeghe *et al.,* 1992).

Hypercortisolism

Hypercortisolism may also play an important role. New-onset T1DM and poorly controlled T1DM and T2DM are accompanied by an activation of the hypothalamo-pituitary-adrenal axis with increased cortisol levels (e.g., Bereket *et al.,* 1995); similarly, elevated serum corticosterone (the major glucocorticoid in rodents) was found in some though not all studies in animal models of severe T1DM (Unterman *et al.,* 1993; Verhaeghe *et al.,* 1997b). We documented that low osteocalcin levels in diabetic BB rats were normalized four days after adrenalectomy, whereas they remained suppressed when diabetic adrenalectomized animals were substituted with corticosterone (Verhaeghe *et al.,* 1997b). The effect of glucocorticoid excess on bone is probably mediated in part by decreased IGF-I and increased IGFBP1 gene expression in both liver and osteoblasts (Unterman *et al.,* 1993, Verhaeghe *et al.,* 1997b). In addition, glucocorticoids have direct effects on bone. Glucocorticoid excess, like diabetes, results in a suppression of osteoblastogenesis and osteoclastogenesis, and a stimulation of osteoblast/osteocyte apoptosis and adipogenic activity (Weinstein *et al.,* 1998).

Calciotropic Hormones

There is a great deal of controversy regarding the effects of T1DM on circulating PTH and $1,25(OH)_2D_3$ (reviewed by Verhaeghe *et al.,* 1999). Nonetheless, there may be some degree of "functional hypoparathyroidism" among T1DM individuals, perhaps related to urinary Mg loss. Decreased PTH levels were also reported in elderly T2DM women (Dobnig *et al.,* 2006). Intermittent administration of $hPTH_{1-34}$ to T1DM rats improved trabecular bone formation, volume, and strength (Suzuki *et al.,* 2003); however, intermittent PTH is a powerful anabolic agent for trabecular bone in various osteopenic conditions not necessarily associated with hypoparathyroidism (e.g., postmenopausal or glucocorticoid-induced osteopenia). Although T1DM rats displayed a higher metabolic clearance rate of $1,25(OH)_2D_3$ and lower (i.e., total but not free) circulating $1,25(OH)_2D_3$, $1,25(OH)_2D_3$ infusion did not affect the osteoblast and osteoid surface on histomorphometry and barely raised serum osteocalcin (Verhaeghe *et al.,* 1993).

Low Amylin

Amylin is a peptide co-secreted with insulin by pancreatic β-cells in response to nutrient stimuli. Amylin treatment of SZ-diabetic rats resulted in some improvement of the diabetic syndrome, and prevented the low-formation osteopenia observed in untreated rats (Horcajada-Molteni *et al.,* 2001). The role of amylin must be clarified in future research.

Impaired Vascularization of Diabetic Bones

It has been postulated by some that diabetic bone disease is another manifestation of microangiopathy, but evidence supporting this hypothesis is lacking. To be sure, the reduced bone remodeling is present well before microangiopathy develops. Nevertheless, bone vascularization is of great importance for bone growth, modeling, and remodeling. One study in SZ-diabetic rats showed that the blood flow to the tibia – examined by the injection of microspheres – was reduced by 65% after 14 days of T1DM and remained at the same level until day 56 (Lucas 1987). More research on the vascularization of diabetic bones (including the growth plate), and the factors that regulate vascularization (e.g., VEGFs), is sorely needed.

Altered Collagenous Bone Matrix

Increased Collagen Breakdown

Stimulation of collagenolysis has been documented in non-bone tissues (e.g., skin and periodontium) of T1DM rats (Bain *et al.,* 1997, and references therein). Tetracyclines inhibit collagenase (matrix metalloproteinase) activity in nonbone tissues as well as in bone via a mechanism independent of their antimicrobial effect. SZ-diabetic rats treated with minocycline exhibited a normalization of growth plate width and trabecular bone volume and an improvement of periosteal bone formation (Bain *et al.,* 1997). In addition, osteoblasts and osteoclast regained their normal morphology after tetracycline treatment (Kaneko *et al.,* 1990; Sasaki *et al.,* 1991). Low IGF-I levels and glucocorticoid excess in diabetic serum might be involved, because collagenase expression in osteoblastic cells was repressed by IGF-I but stimulated by glucocorticoids.

Increased Collagen Glycosylation

Nonenzymatic protein glycosylation and oxidation results in the gradual accumulation of "advanced glycation end products" (AGEs) in serum and various tissues. Proteins with a long half-life such as collagen are particularly susceptible to glycosylation. AGE accumulation in bone occurs with normal aging but is much accelerated in diabetes (Katayama *et al.,* 1996). Accumulation of AGEs in aging bone was associated with increased brittleness (Wang *et al.,* 2002), and may also be a determinant of diabetic

bone brittleness. Moreover, AGE accumulation in diabetic bones affected bone cell function: inhibition of osteoblastic cell differentiation and function (Katayama *et al.,* 1996), and stimulation of osteoblast apoptosis (Alikhani *et al.,* 2007). RAGE, one of the receptors for AGEs, was overexpressed in healing bone tissue of SZ-diabetic mice, and local delivery of a RAGE-ligand delayed bone healing in nondiabetic mice (Santana *et al.,* 2003). These data would indicate that accumulation of AGEs explains in part the impaired fracture repair in diabetes.

Reduced Enzymatic Collagen Cross-Linking

Spontaneously diabetic WBN/Kob rats showed reduced serum vitamin B6 (pyridoxal and pyridoxamine) and immature enzymatic collagen cross-links in femoral bone from the prediabetic stage onward; however, mature cross-links (pyridinoline and deoxypyridinoline) remained normal while non-enzymatic cross-links increased from the diabetic stage. As mentioned earlier, the altered collagenous matrix composition was correlated with reduced bone strength parameters (Saito *et al.,* 2006).

GENERAL CONCLUSIONS (see also Table V)

- Insulin has been called "an anabolic agent for bone" (Thrailkill *et al.,* 2005b) because bone cells (chondrocytes, preosteoblasts and osteoblasts, and osteoclasts) contain insulin receptors, and because insulin stimulates growth and bone formation *in vitro* and *in vivo*. However, absence of insulin receptor expression in bone does not cause diabetic bone disease, indicating that the effect of insulin-deficiency on bone is largely if not completely indirect.
- Severe T1DM causes stunted prepubertal and pubertal growth (Mauriac syndrome). In T1DM animal models, endochondral bone growth is retarded, resulting in smaller bones after medium- and long-term diabetes.
- Diabetes is accompanied by low bone remodeling (both formation and resorption). This is very apparent in animal models of T1DM with severe hyperglycemia, but has been demonstrated in humans with T1DM and T2DM as well. Circulating osteocalcin is the parameter most affected, and is reduced from the diagnosis of diabetes. Impaired osteoblast differentiation and perhaps also accrued osteoblast apoptosis contribute to the defect in mature osteoblasts.
- Bone formation appears to be more affected than bone resorption, because there is a reduction in the amount of trabecular and cortical bone in animal models of T1DM; trabecular thickness but not the number of trabeculae is reduced, consistent with reduced osteoblast activity. Less cortical bone results in thinner bones. Bone size and bone density are also mildly reduced in T1DM children/adolescents and adults (~10% or ~1 SD reduction), but this reduction does not appear to be progressive at least until menopause. Future studies should assess under which circumstances (gender, age, diabetes duration, menopause status, etc.) T1DM may constitute an indication for bone densitometry screening in clinical practice.
- T1DM is accompanied by low free IGF-I in serum while cortisol levels are raised. The bone morphology in T1DM animals is reminiscent of that observed in other "catabolic" conditions, e.g., in IGF-I and IRS-1 knockout animals or animals treated with glucocorticoids. It is likely that low circulating IGF-I and hypercortisolism orchestrate in part the events that ultimately result in the diabetic bone phenotype.
- In contrast to T1DM, pre-T2DM (impaired glucose tolerance) and early T2DM are associated with a mild

TABLE V Key Findings in Diabetic Bone Disease (T1DM)

• Metabolic and Hormonal milieu	↓Insulin → ↑Glucose → ↓IGF-I (free > total) → ↑Cortisol

(3–5%) increase in bone size and areal bone density, but changes in volumetric density appear to be smaller or nonexistent. Accelerated bone loss may occur in long-lasting T2DM, although this needs further research. There is also a need for amplified bone research in obesity and T2DM animal models.

- Both T1DM and T2DM are accompanied by a higher incidence of fractures, although the risk is far greater for T1DM individuals. The increased fracture incidence in T1DM is more pronounced than could be explained by the relatively small bone density deficit. Fracture risk increases with diabetes duration, and is higher among individuals with diabetes complications and limited physical capabilities; the higher incidence of falls in diabetic individuals is likely an important mediator.
- Bone strength is clearly impaired in T1DM animals. Diabetes-induced changes in the collagenous matrix are related to the biomechanical properties. These include: reduced enzymatic collagen cross-links but increased glycosylated collagen (AGEs). Accumulation of AGEs, in turn, appears to affect osteoblastic function.
- New bone formation following a fracture is impaired in T1DM animals and diabetic individuals. Whether diabetes results in microdamage accumulation, and whether this contributes to decreased bone strength, remains unknown.

Chapter 46

Androgens Receptor Expression and Steroid Action in Bone

Kristine M. Wiren, PhD
Oregon Health and Science University, Portland VA Medical Center, Portland, Oregon

INTRODUCTION

Much of the research describing the general action of gonadal steroids in bone has focused on the specific effects of estrogen (see Chapter 14) because of the obvious impact of the menopause on skeletal health. Nevertheless, it is clear that androgens, in both men and women, also have important beneficial effects on skeletal development and on the maintenance of bone mass. It has been demonstrated that androgens (a) influence growth plate maturation and closure, helping to determine longitudinal bone growth during development, (b) mediate regulation of cortical bone mass in a fashion distinct from estrogen, leading to a sexually dimorphic skeleton, (c) modulate peak bone mass acquisition, and (d) influence trabecular (cancellous) bone and inhibit bone loss (Wiren, 2005). In castrated animals, replacement with nonaromatizable androgens (e.g., 5α-dihydrotestosterone, DHT) yields beneficial effects that are clearly distinct from those observed with estrogen replacement (Turner *et al.,* 1989; Turner *et al.,* 1990b). In intact females, blockade of the androgen receptor (AR) with the specific AR antagonist hydroxyflutamide results in osteopenia (Goulding and Gold, 1993). Furthermore, treatment with nonaromatizable androgen alone in females results in improvements in bone mineral density (Coxam *et al.,* 1996). Finally, combination therapy with estrogen and androgen in postmenopausal women is more beneficial than either steroid alone (Castelo-Branco *et al.,* 2000; Miller *et al.,* 2000; Raisz *et al.,* 1996), indicating nonparallel pathways of action. Taken together, these reports illustrate the divergent actions of androgens and estrogens on the skeleton. Thus, in both men and women it is probable that androgens and estrogens each have important yet distinct functions during bone development, and in the subsequent maintenance of skeletal homeostasis in the adult. With an increased awareness of the importance of the effects of androgen on skeletal homeostasis (Vanderschueren *et al.,* 2004), and the potential to make use of this information for the treatment of bone disorders, much nevertheless remains to be learned.

THE ROLE OF ANDROGEN METABOLISM

Metabolism of Androgens in Bone: Aromatase, 17β-hydroxysteroid Dehydrogenase (17β-HSD), and 5α-Reductase Activities

Sex steroids, ultimately derived from cholesterol, are synthesized predominantly in gonadal tissue, the adrenal gland and placenta as a consequence of enzymatic conversions. The major pathways are shown in Figure 1. After peripheral metabolism, androgenic activity is represented in a variety of steroid molecules that include testosterone. There is accumulating evidence that in a range of tissues the eventual cellular effects of testosterone may not be the result (or not only the result) of direct action of testosterone, but may also reflect the effects of sex steroid metabolites formed as a consequence of local enzyme activities. The most important testosterone metabolites likely to influence bone are 5α-DHT (the result of 5α reduction of testosterone) and estradiol (formed by the aromatization of testosterone). Testosterone and DHT are the major and most potent androgens, with androstenedione (the major circulating androgen in women) and dehydroepiandrosterone (DHEA) as immediate androgen precursors that exhibit weak androgen activity (Mo *et al.,* 2006). DHEA, although a weaker androgen, is still considered anabolic (Labrie *et al.,* 2006). In men, the most abundant circulating androgen metabolite is testosterone, while concentrations of other weaker androgens like androstenedione and DHEA-sulfate are similar between males and females. Downstream metabolites of DHT and androstenedione are inactive at the AR, and include 5α-androstane-3α or 3β,17β-diol (3α/β-androstanediol) and 5α-androstanedione. Data suggest

Principles of Bone Biology, 3rd Edition

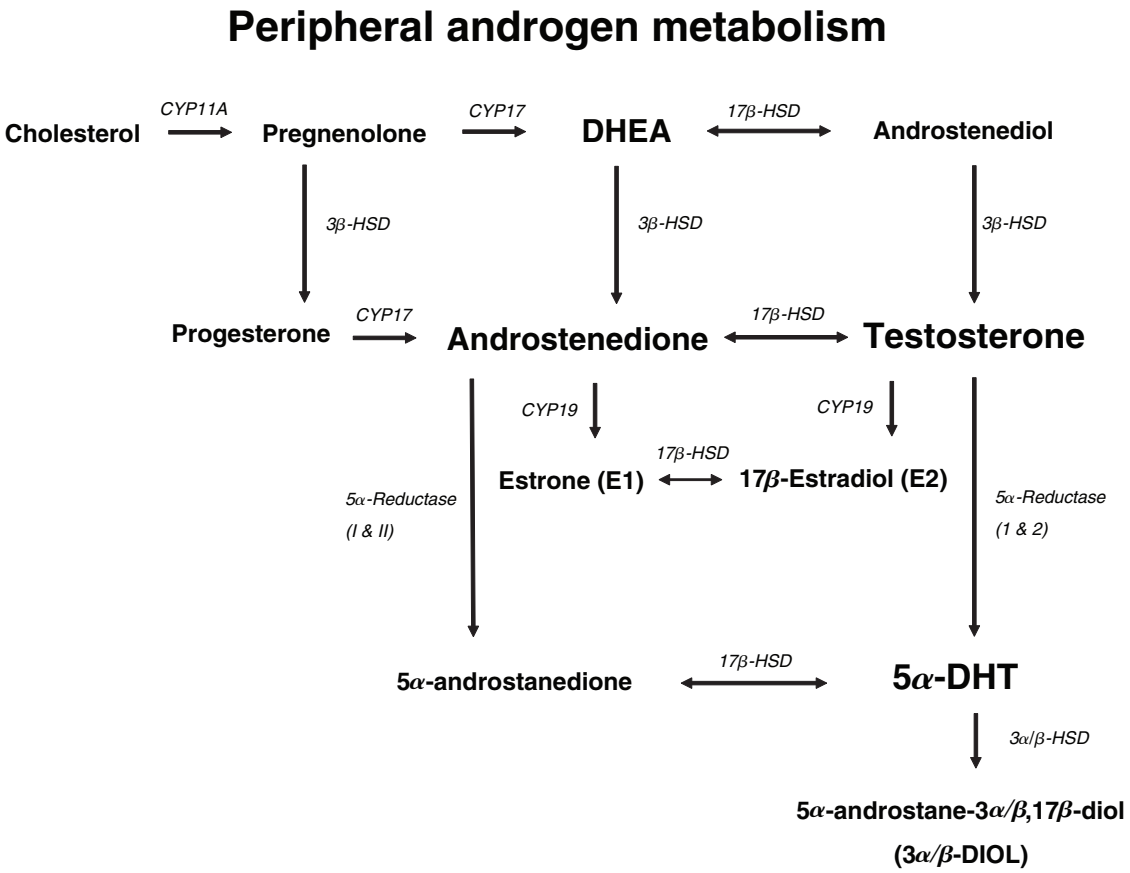

FIGURE 1 Principle conversions and major enzyme activities involved in androgen synthesis and metabolism. Steroid hormone synthesis involves metabolism of cholesterol, with dehydrogenation of pregnenolone producing progesterone that can serve as a precursor for the other gonadal steroid hormones. DHEA, dehydroepiandrosterone; CYP11A, cytochrome P450 cholesterol side chain cleavage enzyme; CYP17, cytochrome P450 17α hydroxylase/17,20 lyase; 17β-HSD, 17β-hydroxysteroid dehydrogenase; CYP19, aromatase cytochrome P450.

that aromatase cytochrome P450 (the product of the CYP19 gene), 17β-hydroxysteroid dehydrogenase (17β-HSD), and 5α-reductase activities are all present in bone tissue as described later, at least to some measurable extent in some compartments, but the biologic relevance of each remains somewhat controversial.

An important enzymatic arm of testosterone metabolism involves the biosynthesis of estrogens from androgen precursors, catalyzed by aromatase. Aromatase is well known to be expressed and regulated in a pronounced tissue-specific manner (Simpson *et al.,* 1994), and also exhibits species differences, given the low levels in mice. Modest levels of aromatase activity have been reported in bone from mixed cell populations derived from both sexes (Nawata *et al.,* 1995; Sasano *et al.,* 1997; Schweikert *et al.,* 1995) and from osteoblastic cell lines (Nakano *et al.,* 1994; Purohit *et al.,* 1992; Tanaka *et al.,* 1993). Aromatase expression in intact bone has also been documented by *in situ* hybridization and immunohistochemical analysis (Sasano *et al.,* 1997). At least in vertebral bone, the mesenchymal distal promoter I.4 is predominantly utilized (Shozu and Simpson, 1998). The enzyme kinetics in bone cells seem to be similar to those in other tissues, although the V_{max} may be increased by glucocorticoids (Tanaka *et al.,* 1993). Aromatase mRNA is expressed predominantly in lining cells, chondrocytes, and some adipocytes; however, there is little to no detectable expression in osteoclasts, or in cortical bone in mice (Wiren *et al.,* 2004b). Thus, whether the level of aromatase activity in bone is high enough to produce physiologically relevant concentrations of steroids locally remains an open question. Nevertheless, in the male only 15% of circulating estrogen is produced in the testes, with the remaining 85% produced by peripheral metabolism that could theoretically include bone as one site of conversion (Gennari *et al.,* 2004).

Aromatase catalyzes the metabolism of adrenal and testicular C19 androgens (androstenedione and testosterone) to C18 estrogens (estrone and estradiol), thus producing the potent estrogen estradiol (E2) from testosterone, and the weaker estrogen estrone (E1) from its adrenal precursors androstenedione and DHEA (Nawata *et al.,* 1995). Thus, because of aromatase activity, systemically administered testosterone may have effects either at the AR (with either testosterone or DHT as ligands) or at the estrogen

receptor (ERα or ERβ). Typically in the circulation, E2 will make up to 40% of total estrogen, E1 will make up an additional 40%, with estriol (E3) comprising the remaining 20% of total estrogen (Lin *et al.,* 2006). In addition to aromatase itself, osteoblasts contain enzymes that are able to interconvert estradiol and estrone (17β-HSD, see following section), and to hydrolyze estrone sulfate, the most abundant estrogen in the circulation, to estrone (steroid sulfatase) (Muir *et al.,* 2004; Purohit *et al.,* 1992). Dexamethasone and 1α,25(OH)$_2$D$_3$ synergistically enhance aromatase activity and aromatase mRNA expression in human osteoblast-like cells (Nawata *et al.,* 1995). In addition, both leptin and 1α,25(OH)$_2$D$_3$ treatment increased aromatase activity in human mesenchymal stem cells during osteogenesis, but not during adipogenesis (Pino *et al.,* 2006). Additional studies are needed to better define expression, given the potential importance of the enzyme, and its regulation by a variety of mechanisms (including androgens and estrogens) in other tissues (Abdelgadir *et al.,* 1994; Simpson *et al.,* 1994).

The clinical impact of aromatase activity, with an indication of the importance of conversion of circulating androgen into estrogen, is shown in reports of women and men with aromatase deficiencies who present with a skeletal phenotype (Jones *et al.,* 2007). The presentation of men with aromatase deficiency is very similar to that of a man with ERα deficiency (Smith *et al.,* 1994), namely an obvious delay in bone age, lack of epiphyseal closure, and tall stature with high bone turnover and osteopenia (Gennari *et al.,* 2004). These findings suggest that aromatase (and likely estrogen action) has an important role to play during skeletal development in the male. Interestingly, natural mutation is remarkably rare with only seven males and seven females reported to date (Jones *et al.,* 2007). In addition, estrogen therapy of males with aromatase deficiency has been associated with an increase in bone mass (Gennari *et al.,* 2004) particularly noted in the growing skeleton (Bouillon *et al.,* 2004). Inhibition of aromatization pharmacologically with nonsteroidal inhibitors (such as vorozole or letrozole) results in modest decreases in bone mineral density and changes in skeletal modeling in young growing orchidectomized males (Vanderschueren *et al.,* 1997), and less dramatically so in boys with constitutional delay of puberty treated for one year (Wickman *et al.,* 2003), suggesting short-term treatment during growth has limited negative consequences in males. Inhibition of aromatization in older orchidectomized males resembles castration with similar increases in bone resorption and bone loss, suggesting that aromatase activity likely does play a role in skeletal maintenance in males (Vanderschueren *et al.,* 1996). Combined, these studies herald the importance of aromatase activity (and estrogen) in the mediation of some androgen action in bone in both males and females. The characterization of these enzyme activities in bone clearly raises the difficult issue of the origin of androgenic effects in the skeleton; do they arise solely from direct androgen effects (as is suggested by the actions of nonaromatizable androgens such as DHT) or also from the local or other-site production of estrogenic intermediates? The results described here would indicate that both steroids appear to be important to both male and female skeletal health.

The 17β-HSDs (most of which are dehydrogenase-reductases, except type 5, which is an aldo-keto reductase) have been shown to catalyze either the last step of sex steroid synthesis or the first step of their degradation. This activity produces weak or potent sex steroids via oxidation or reduction, respectively, and can thus also play a critical role in peripheral steroid metabolism. The oxidative pathway forms 17-ketosteroids while the reductive pathway forms 17β-hydroxysteroids. The enzyme reversibly catalyzes the formation of androstenediol (an estrogen) from DHEA, in addition to the biosynthesis of estradiol from estrone, the synthesis of testosterone from androstenedione, and the production of DHT from 5α-androstanedione all via the reductive activity of 17β-HSD. Of the 13 enzyme isotypes of 17β-HSD activity (Lin *et al.,* 2006), either types 1–4 (Feix *et al.,* 2001) or types 1, 3, and 5 (Miki *et al.,* 2007) have been demonstrated in human osteoblastic cells.

5α-reductase is also an important activity with regard to androgen metabolism, because testosterone is converted to the more potent androgen metabolite DHT via 5α-reductase action (Bruch *et al.,* 1992). 5α-reductase activity was first described in crushed rat mandibular bone (Vittek *et al.,* 1974) with similar findings reported in crushed human spongiosa (Schweikert *et al.,* 1980). Two different 5α-reductase genes encode type 1 and type 2 isozymes in many mammalian species (Russell and Wilson, 1994); mRNAs encoding the type 2 isozyme are more abundant than type 1 mRNAs in most male reproductive tissues, whereas the type 1 predominate in peripheral tissues. Human osteoblastic cells express the type 1 isozyme (Issa *et al.,* 2002). Essentially the same metabolic activities were reported in experiments with human epiphyseal cartilage and chondrocytes (Audi *et al.,* 1984). In general, the K_m values for bone 5α-reductase activity are similar to those in other androgen responsive tissues (Nakano *et al.,* 1994; Schweikert *et al.,* 1980). However, the cellular populations in many of these studies were mixed and hence the specific cell type responsible for the activity is unknown. Interestingly, periosteal cells do not have detectable 5α-reductase activity (Turner *et al.,* 1990a), raising the possibilities that the enzyme may be functional in only selected skeletal compartments, and that testosterone may be the active androgen metabolite at this clinically important site.

From a clinical perspective, the general importance of this enzymatic pathway is uncertain, as patients with 5α-reductase type 2 deficiency have normal bone mineral density (Sobel *et al.,* 2006) and no significant correlation

was observed between enzyme activities and bone volume (Bruch *et al.,* 1992). Mutant null mice lacking both 5α-reductase type 1 (and type 2) have been created (Mahendroo *et al.,* 2001), but the effect on the skeleton has not been analyzed. Analysis of the importance of 5α-reductase activity has also been approached with the use of finasteride, an inhibitor of 5α-reductase activity that is selective for type 2 in humans, but comparably inhibits both type 1 and type 2 in rodents (Finn *et al.,* 2006). Finasteride treatment of male animals does not recapitulate the effects of castration (Rosen *et al.,* 1995). Furthermore, inhibition of type 1 5α-reductase using MK-434 does not block the effect of testosterone to reduce bone turnover in orchidectomized rats (Borst *et al.,* 2005). Combined, these studies suggest that reduction of testosterone to DHT is not the major determinant in the effects of gonadal hormones on bone. Consistent with this finding, testosterone therapy in hypogonadal older men, either when administered alone or when combined with finasteride, increases bone mineral density, again suggesting that DHT is not essential for the beneficial effects of testosterone on bone (Amory *et al.,* 2004). Thus, the available clinical data regarding the importance of 5α-reductase activity remain uncertain, and the impact of this enzyme, which isozyme may be involved, whether it is uniformly present in all cell types involved in bone modeling/remodeling, or whether local activity is important in any bone compartment, remain unresolved issues.

The administration of testosterone can stimulate bone formation and inhibit bone resorption, likely through multiple mechanisms that involve both androgen and estrogen receptor-mediated processes. However, there is substantial evidence that some, if in fact not most, of the biologic actions of androgens in the skeleton are mediated by AR signaling in bone. Both *in vivo* and *in vitro* systems reveal the effects of the nonaromatizable androgen DHT to be essentially the same as those of testosterone. In addition, blockade of the AR with the receptor antagonist flutamide results in osteopenia as a result of reduced bone formation (Goulding and Gold, 1993). Consistent with this result, complete androgen insensitivity results in a significant decrease in bone mineral density in spine and hip sites (Sobel *et al.,* 2006) even in the setting of strong compliance with estrogen treatment (Marcus *et al.,* 2000). These reports clearly indicate that androgens, independent of estrogenic metabolites, have primary effects on osteoblast function. However, the clinical reports of subjects with aromatase deficiency also highlight the relevance of metabolism of androgen to biopotent estrogens at least in the circulation, to influence development and/or bone mass maintenance. It thus seems likely that further elucidation of the regulation steroid metabolism, and the potential mechanisms by which androgenic and estrogenic effects are coordinated, will have physiological, pathophysiological, and therapeutic implications.

Synthetic Androgens

In addition to the endogenous steroid metabolites highlighted in Figure. 1, there are also a variety of drugs with androgenic activity. These include anabolic steroids, such as nonaromatizable oxandrolone that can bind and activate AR, albeit with lower affinity than testosterone (Kemppainen *et al.,* 1999). In addition, a class of drugs under extensive development, referred to as selective AR modulators (SARMs), demonstrate tissue-specific agonist or antagonist activities with respect to AR transactivation (Omwancha and Brown, 2006). These orally active nonsteroidal nonaromatizable SARMs are being developed to target androgen action in bone, muscle, fat, and to influence libido but to not exacerbate prostate growth, hirsutism, and acne. Several have recently been identified with beneficial effects on bone mass (Allan *et al.,* 2007; Kearbey *et al.,* 2007; Miner *et al.,* 2007). Thus, this class of drug may provide a new alternative to androgen replacement therapy.

ANDROGEN RECEPTOR AND SKELETAL CELLULAR BIOLOGY

Because there remains confusion clearly interpreting the skeletal actions of circulating sex steroids as noted, the specific mechanisms by which androgens affect skeletal homeostasis are becoming the focus of intensified research (Vanderschueren *et al.,* 2004; Wiren, 2005). As a classic steroid hormone, the biological cellular signaling responses to androgen are mediated through the AR, a ligand-inducible transcription factor. ARs have been identified in a variety of cells found in bone (Abu *et al.,* 1997). Characterization of AR expression in these cells thus clearly identifies bone as a target tissue for androgen action. The direct effects of androgen that influence the complex processes of proliferation, differentiation, mineralization, and gene expression in the osteoblast are being characterized, but much remains to be established. Androgen effects on bone may also be indirectly modulated and/or mediated by other autocrine and paracrine factors in the bone microenvironment. The rest of this chapter will review recent progress on the characterization of androgen action through the AR in bone.

Molecular Mechanisms of Androgen Action in Bone Cells: The AR

Direct characterization of AR expression in a variety of tissues, including bone, was made possible by the cloning of the AR cDNA (Chang *et al.,* 1988; Lubahn *et al.,* 1988). The AR is a member of the class I (so-called classical or steroid) nuclear receptor superfamily, as are the ERα and ERβ isoforms, the progesterone receptor, the mineralocorticoid, and glucocorticoid receptor (Mangelsdorf *et al.,*

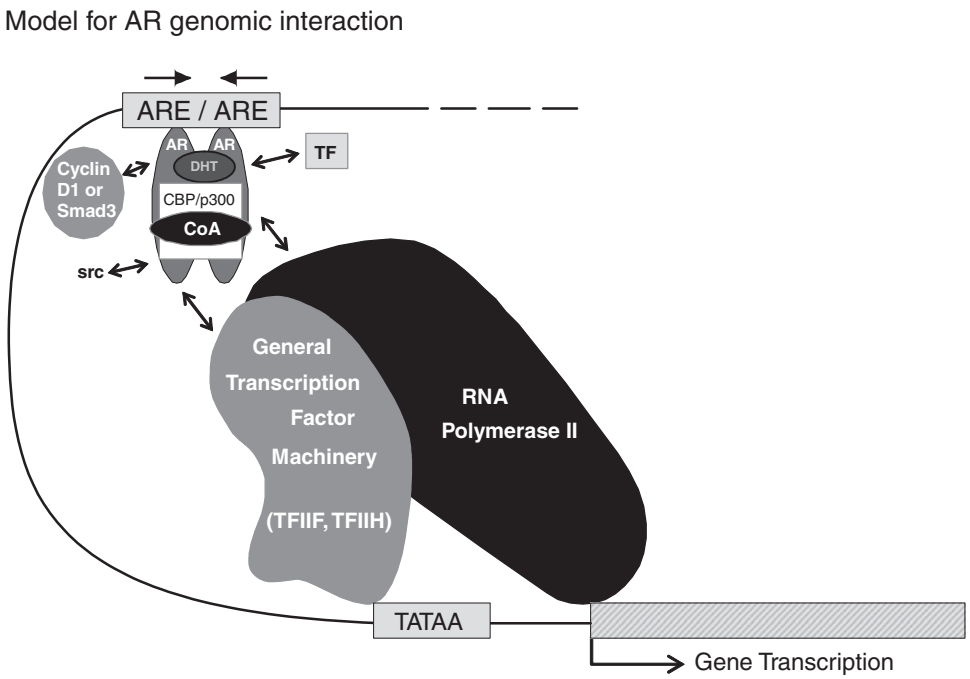

FIGURE 2 Model of AR regulation of gene expression. Binding of androgen promotes high-affinity dimerization, followed by DNA binding at the androgen response element (ARE) in an androgen-responsive gene promoter. Coactivators may remodel/modify chromatin through histone acetylase activity to open chromatin structure (Spencer *et al*., 1997), or act as a bridge to attract transcription factors (TFs) that target binding of TATA-binding protein to the TATAA sequence (Beato and Sanchez-Pacheco, 1996). Conversely, corepressors act through histone deacetylase activity to reduce accessibility of promoter sequences. Phosphorylation of receptor may result from activation of SRC by growth factors (Kraus *et al*., 2006). Smad3 can act as either a coactivator or corepressor (Hayes *et al*., 2001; Kang *et al*., 2002), while cyclin D1 is a corepressor of AR transactivation (Leader *et al*., 2006). AR can also directly contact TFIIH and TFIIF (Lee and Chang, 2003) in the general transcription machinery. Such interactions between the AR and the general transcription machinery, leading to stable assembly, results in recruitment of RNA polymerase II and subsequent increased gene transcription. Downregulation of gene expression can also be AR mediated.

1995). Steroid receptors are transcription factors with a highly conserved modular design characterized by three functional domains: the transactivation, DNA binding, and ligand binding domains. In terms of function, the DNA binding domain targets the receptor complex to a specific DNA sequence known as the hormone response element and has high homology among the steroid receptors; the transactivation function mediates transcriptional regulation of gene expression and is localized in both the amino and carboxyterminal of the molecule; the carboxyterminal ligand binding domain mediates not only ligand binding but also receptor dimerization and nuclear translocation, in addition to transcriptional regulation (Mangelsdorf *et al.,* 1995). In the absence of ligand, the AR protein is generally localized in the cytoplasmic compartment of target cells in a large complex of molecular chaperones, consisting of loosely bound heat-shock, cyclophilin, and other accessory proteins (Picard, 2006). Interestingly, in the unliganded form, AR conformation is unique with a relatively unstructured amino-terminal transactivation domain (Shen and Coetzee, 2005). As lipids, androgens can freely diffuse through the plasma membrane to bind the AR to induce a conformational change. Once bound by ligand, the AR dissociates from the multiprotein complex, translocates to the nucleus allowing the formation of homodimers (or potentially heterodimers), and recruits coregulators (coactivators or corepressors), to initiate a cascade of events in the nucleus that influence transcription (Chang *et al.,* 1995). It may be functionally significant that coactivators or corepressors are expressed in a cell type specific manner (Kumar *et al.,* 2006). Bound to DNA, the AR influences transcription and/or translation of a specific network of genes, leading to the specific cellular response to the steroid (see Fig. 2).

A steroid hormone target tissue is generally defined as one that expresses the steroid receptor, at a functional level, and with a measurable response in the presence of the hormone ligand. Bone tissue clearly meets this standard with respect to androgen. AR mRNA and specific androgen binding sites in normal human osteoblastic cells were first reported by these workers (Colvard *et al.,* 1989). The abundance of both AR and ER proteins was similar, suggesting that androgens and estrogens each play important roles in skeletal physiology. Subsequent reports have confirmed AR mRNA expression and/or the presence of androgen binding sites in both normal and clonal, transformed osteoblastic cells derived from a variety of species (Benz *et al.,*

1991; Liesegang *et al.,* 1994; Nakano *et al.,* 1994; Orwoll *et al.,* 1991; Takeuchi *et al.,* 1994; Zhuang *et al.,* 1992). The size of the AR mRNA transcript in osteoblasts (about 10 kb) is similar to that described in prostate and other tissues (Chang *et al.,* 1988), as is the size of the AR protein analyzed by Western blotting (~110 kDa) (Nakano *et al.,* 1994). There are reports of two isoforms of AR protein in human osteoblast-like cells (~110 and ~97 kDa) (Kasperk *et al.,* 1997a) as first described in human prostatic tissue (Wilson and McPhaul, 1994). It appears these isoforms do not possess similar functional activities in bone, particularly with respect to effects on proliferation (Liegibel *et al.,* 2003). The number of specific androgen binding sites in osteoblasts varies, depending on methodology and the cell source, from 1,000–14,000 sites/cell (Kasperk *et al.,* 1997a; Liesegang *et al.,* 1994; Masuyama *et al.,* 1992; Nakano *et al.,* 1994), but is in a range seen in other androgen target tissues. Furthermore, the binding affinity of the AR found in osteoblastic cells ($K_d = 0.5-2 \times 10^{-9}$) is typical of that found in other tissues. Androgen binding is specific, without significant competition by estrogen, progesterone, or dexamethasone (Colvard *et al.,* 1989; Kasperk *et al.,* 1997a; Nakano *et al.,* 1994). Finally, testosterone and DHT appear to have similar though not identical binding affinities for AR (Benz *et al.,* 1991; Nakano *et al.,* 1994). All these data are consistent with the notion that the direct biologic effects of androgenic steroids in osteoblasts are mediated at least in part via classic mechanisms associated with the AR as a member of the steroid hormone receptor superfamily described earlier.

In addition to the classical AR present in bone cells, several other androgen-dependent signaling pathways have been described. Specific binding sites for weaker adrenal androgens (such as DHEA) have been reported (Meikle *et al.,* 1992), thus raising the possibility that DHEA or similar androgenic compounds have direct effects in bone. DHEA can transactivate AR (Mo *et al.,* 2006), but DHEA and its metabolites may also bind and activate additional receptors, including ER, peroxisome proliferator activated receptor-α and pregnane X receptor (Webb *et al.,* 2006). It has been shown that DHEA rapidly inhibited c-*fos* expression in human osteoblastic cells (Bodine *et al.,* 1995), inhibition that was more robust than seen with the classical androgens (DHT, testosterone, androstenedione). In addition, DHEA may inhibit bone resorption by osteoclasts when in the presence of osteoblasts, likely through changes in osteoprotegerin (OPG) and receptor activator of NFγB ligand (RANKL) concentrations (Wang *et al.,* 2006), that are important mediators of osteoclastogenesis. Androgens may also be specifically bound in osteoblastic cells by a novel 63-kDa cytosolic protein (Wrogemann *et al.,* 1991). Finally, androgens may regulate osteoblast activity via rapid nongenomic mechanisms (Kang *et al.,* 2004; Kousteni *et al.,* 2003; Zagar *et al.,* 2004), through membrane receptors displayed at the bone cell surface (Lieberherr and Grosse, 1994). Nongenomic signaling generally involves either changes in intracellular calcium levels or rapid activation of kinase signaling cascades. However, the role and biologic significance of these nonclassical signaling pathways *in vivo* remains controversial (Neill, 2006), and most data suggest that genomic signaling through specific receptors may be the more significant regulator in bone and other tissues (Centrella *et al.,* 2004; Hewitt *et al.,* 2006; Sims *et al.,* 2003; van der Eerden *et al.,* 2002a; Windahl *et al.,* 2006).

Lastly, there are reports of AR polyglutamine tract (CAG/CAA) polymorphisms, leading to shorter or longer glutamine tract lengths in the receptor protein, which likely have a biological impact on androgen responses (Pettaway, 1999). Enhanced androgen action is associated with shorter AR CAG repeats and, conversely, hypoandrogenic traits are seen in patients with an elongation of more than 37 CAG repeats (Zitzmann *et al.,* 2005). Most studies have failed to find an effect of such polymorphisms in AR on bone mass (Kenny *et al.,* 2005; Valimaki *et al.,* 2005; Van Pottelbergh *et al.,* 2001). An exception to these findings is a reported association in postmenopausal women with long CAG AR isoforms, where spinal bone mineral density (BMD) was significantly lower compared to those with AR short alleles (Retornaz *et al.,* 2006). Different AR isoforms have the potential to interact in distinct fashions with other signaling molecules such as c-Jun (Grierson *et al.,* 1999), and may also influence variation in serum testosterone levels (Crabbe *et al.,* 2007). Thus, such AR CAG polymorphisms may have a significant influence on bone mass, although data remain underdeveloped.

Localization of AR Expression in Osteoblastic Populations

Ultimately, bone mass is determined by two biological processes: formation and resorption. Distinct cell types mediate these processes. The bone-forming cell – the osteoblast – synthesizes bone matrix, regulates mineralization, and is responsive to most calciotropic hormones. The osteoclast is responsible for bone resorption. Clues about the potential sequela of AR signaling might be derived from a better understanding of the cell types in which expression is documented. *In vivo* analysis has demonstrated expression of AR in all cells of the osteoblast lineage including osteoblasts and osteocytes, and in osteoclasts (van der Eerden *et al.,* 2002b). In the bone microenvironment, the localization of AR expression has been described in intact human bone by Abu *et al.* using immunocytochemical methods (Abu *et al.,* 1997). In developing bone from young adults, ARs were predominantly expressed in active osteoblasts at sites of bone formation and in bone marrow cells. ARs were also observed in osteocytes embedded in the bone matrix. Interestingly, both the pattern of AR distribution

and the level of expression were similar in males and in females. Expression of the AR has also been characterized in cultured osteoblastic cell populations isolated from bone biopsy specimens, determined at both the mRNA level and by binding analysis (Kasperk *et al.,* 1997a). AR levels varied according to the skeletal site of origin and age of the donor of the cultured osteoblastic cells: expression was higher at cortical and intramembranous bone sites, and lower in trabecular bone. This distribution pattern may correlate with androgen responsiveness in various bone compartments. AR expression was highest in osteoblastic cultures generated from young adults, and somewhat lower in samples from either prepubertal or senescent bone. Data indicate preferential nuclear staining of AR in males at sexual maturity, suggesting activation and translocation of the receptor in bone when androgenic steroid levels are elevated, consistent with androgen regulation of AR levels at such times (e.g., Wiren *et al.,* 1999; Wiren *et al.,* 1997). Again, no differences were found between male and female samples, suggesting that differences in receptor number per se do not underlie development of a sexually dimorphic skeleton. Because androgens are so important in bone development at the time of puberty, it is not surprising that ARs are also present in epiphyseal chondrocytes (Abu *et al.,* 1997; Carrascosa *et al.,* 1990). The expression of ARs in such a wide variety of cell types known to be important for bone modeling during development, and remodeling in the adult, provides evidence for direct actions of androgens in bone and cartilage tissue. These results also highlight the complexity of androgen effects on bone. Although bone is a target tissue with respect to androgen action, the mechanisms and cell types by which androgens exert their effects on bone biology remain incompletely characterized. An additional complexity in terms of mechanism is that androgens may influence bone directly by activation of the AR, or indirectly after aromatization of androgens into estrogens with subsequent activation of ER as described earlier.

Regulation of AR Expression

The regulation of AR expression in osteoblasts is incompletely characterized. Homologous regulation of AR mRNA by androgen has been described that is tissue-specific; upregulation by androgen exposure is seen in a variety of mesenchymal cells including osteoblasts (Takeuchi *et al.,* 1994; Wiren *et al.,* 1999; Wiren *et al.,* 1997; Zhuang *et al.,* 1992) whereas downregulation is observed after androgen exposure in prostate and smooth muscle tissue (Lin *et al.,* 1993; Wiren *et al.,* 1997). The androgen mediated upregulation observed in osteoblasts, at least in part, occurs through changes in AR gene transcription (Wiren *et al.,* 1999; Wiren *et al.,* 1997). No effect, or even inhibition, of AR mRNA by androgen exposure in other osteoblastic models has also been described (Hofbauer *et al.,* 1997; Kasperk *et al.,* 1997a). Interestingly, a novel property of the AR is that binding of androgen increases AR protein levels. This property distinguishes AR from most other steroid receptor molecules that are downregulated by ligand binding. At least in part, the elevated AR protein levels may be a consequence of increased stability mediated by androgen binding results from N-terminal and C-terminal interactions (Langley *et al.,* 1998), but the stability of AR in osteoblastic cells has not been determined to date. The mechanism(s) that underlie tissue specificity in autologous AR regulation, and the possible biological significance of distinct autologous regulation of AR, is not established. It is possible that AR upregulation by androgen in bone may result in an enhancement of androgen responsiveness at times when androgen levels are rising or elevated.

Quantitative determination of the level of receptor expression during osteoblast differentiation is difficult to achieve in bone slices. However, analysis of AR, ERα and ERβ mRNA and protein expression during osteoblast differentiation *in vitro* has been described, revealing that each receptor displays differentiation-stage distinct patterns in osteoblasts (Wiren *et al.,* 2002). In contrast to the ERs, AR expression level increases throughout osteoblast differentiation with the highest AR levels seen in mature osteoblast/osteocytic cultures. These results suggest that an important compartment for androgen action may be mature, mineralizing osteoblasts, and also indicate that osteoblast differentiation and steroid receptor regulation are intimately associated. Given that the osteocyte is the most abundant cell type in bone, and a likely mediator of focal bone deposition and response to mechanical strain (Seeman, 2006), it is not surprising that androgens may also augment the osteoanabolic effects of mechanical strain in osteoblasts (Liegibel *et al.,* 2002).

AR expression in osteoblasts can be upregulated by exposure to other steroid hormones, including glucocorticoids, estrogen or 1,25-dihydroxyvitamin D_3 (Kasperk *et al.,* 1997a). Whether additional hormones, growth factors, or agents influence AR expression in bone is not known. Further, whether the AR in osteoblasts undergoes post-translational processing that might influence receptor signaling (stabilization, phosphorylation, etc.) as described in other tissues (Ikonen *et al.,* 1994; Kemppainen *et al.,* 1992), and the potential functional implications (Blok *et al.,* 1996; Wang *et al.,* 1999a), are also unknown. Phosphorylation may be of particular interest in osteoblasts, as it is known to positively or negatively influence receptor interaction with coactivators and corepressors (Weigel and Moore, 2007). Ligand-independent activation of AR has also been described in other tissues (Dehm and Tindall, 2006), but has not been explored in bone.

Steroid receptor transcriptional activity, including that of the AR, is strongly influenced by coactivator or corepressor function (He *et al.,* 2006; Yoon and Wong, 2006).

These coregulators can influence the downstream signaling of nuclear receptors; their levels are influenced by the cellular context, and they can differentially affect specific promoters. AR specific coactivators have been identified (MacLean *et al.,* 1997), many of which interact with the ligand binding domain of the receptor (Yeh and Chang, 1996). Expression and regulation of these modulators may thus influence the ability of steroid receptors to regulate gene expression in bone (Haussler *et al.,* 1997), but this remains underexplored with respect to androgen action. The specific coactivator/corepressor profile present in cells representing different bone compartments (i.e., periosteal cells, proliferating or mineralizing cells) may influence the activity of the selective receptor modulators such as SARMs described earlier.

THE CONSEQUENCES OF ANDROGEN ACTION IN BONE CELLS

Effects of Androgens on Proliferation and Apoptosis

Evidence suggests that androgens act directly on the osteoblast and there are reports, some in clonal osteoblastic cell lines, of modulatory effects of gonadal androgen treatment on proliferation, differentiation, matrix production, and on mineral accumulation (Notelovitz, 2002). Not surprisingly, androgen has been shown to influence bone cells in a complex fashion. As an example, the effect of androgen on osteoblast proliferation has been shown to be biphasic in nature, with enhancement following short or transient treatment but significant inhibition following longer treatment. As a case in point, it was demonstrated (Kasperk *et al.,* 1990; Kasperk *et al.,* 1989) in osteoblast-like cells in primary culture (murine, passaged human) that a variety of androgens in serum-free medium increase DNA synthesis ([^{3}H]thymidine incorporation) and cell counts. Testosterone and nonaromatizable androgens (DHT and fluoxymesterone) were nearly equally effective regulators. Yet the same group (Kasperk *et al.,* 1997a) reported that prolonged DHT treatment inhibited normal human osteoblastic cell proliferation (cell counts) in cultures pretreated with DHT. In addition, prolonged androgen exposure in the presence of serum inhibited proliferation (cell counts) by 15–25% in TE-85, a transformed human osteoblastic line (Benz *et al.,* 1991). Testosterone and DHT again were nearly equally effective regulators. Other workers (Hofbauer *et al.,* 1998) examined the effect of DHT exposure on proliferation in hFOB/AR-6, an immortalized human osteoblastic cell line stably transfected with an AR expression construct (with ~4,000 receptors/cell). In this line, DHT treatment inhibited cell proliferation by 20–35%. Consistent with stimulation of proliferation, Somjen *et al.* have demonstrated after exposure to DHT for 24 hours an increase in creatine kinase specific activity in male osteoblastic cells (Somjen *et al.,* 2006). Although these various studies employed different model systems (transformed osteoblastic cells vs. second to fourth passage normal human cells) and culture conditions (including differences in the state of osteoblast differentiation, receptor number, phenol red-containing vs. phenol red-free, or serum containing vs. serum-free), it appears exposure time is an important variable. Time dependence for the response to androgen has been shown (Wiren *et al.,* 2004a), where osteoblast proliferation was stimulated at early treatment times, but with more prolonged DHT treatment osteoblast viability decreased. This result was AR dependent (i.e., inhibitable by coincubation with flutamide), and was observed in both normal rat calvarial osteoblasts and in stably transfected AR MC-3T3 cells. In mechanistic terms, reduced viability was associated with overall reduction in mitogen-activated (MAP) kinase signaling, and with downstream inhibition of *elk-1* gene expression, protein abundance, and extent of phosphorylation. The inhibition of MAP kinase activity after chronic androgen treatment again contrasts with stimulation of MAP kinase signaling and AP-1 transactivation observed with brief androgen exposure (Wiren *et al.,* 2004a), which may be mediated through nongenomic mechanisms at least *in vitro*.

As an additional component of control of osteoblast abundance, it is important to consider the process of programmed cell death, or apoptosis (Wyllie *et al.,* 1980). Apoptosis is important generally during development and for homeostasis, but it has also been shown that as the osteoblast population differentiates *in vitro*, the mature bone cell phenotype undergoes apoptosis (Lynch *et al.,* 1998). With respect to the effects of androgen exposure, chronic DHT treatment has been shown to result in enhanced osteoblast apoptosis *in vitro* in both proliferating osteoblastic at day 5, and in mature osteocytic mineralizing cultures at day 29 (Wiren *et al.,* 2006). In the same study, the enhancement observed with DHT treatment was opposite to the inhibitory effects on apoptosis seen with E_2 treatment. An androgen-mediated increase in the Bax/Bcl-2 ratio was also observed, predominantly through inhibition of Bcl-2 that was dependent on functional AR. The increase in the Bax/Bcl-2 ratio was at least in part a consequence of reductions in Bcl-2 phosphorylation and protein stability, consistent with inhibition of MAP kinase pathway activation after DHT treatment as noted earlier. Importantly, a similar response was observed *in vivo* with characterization of apoptosis in calvaria harvested from transgenic mice with overexpression of AR targeted throughout the osteoblast lineage. In male transgenic mice with the normal hormonal milieu (i.e., without systemic administration of androgen), enhanced TUNEL staining is observed in bone in both osteoblasts and osteocytes, even in areas of new bone growth (Wiren *et al.,* 2006). This may not be surprising, given an association between new

bone growth and apoptosis (Palumbo *et al.,* 2003), as has been observed in other remodeling tissues and/or associated with development and tissue homeostasis (Lanz *et al.,* 2003). Apoptotic cell death could thus be important in making room for new bone formation and matrix deposition, which may have clinical significance by influencing bone homeostasis and bone mineral density (Miura *et al.,* 2004). Thus, mounting evidence suggests that chronic androgen treatment increases neither osteoblast number nor viability in the mature bone compartment. It is interesting to speculate that, given strong androgen-mediated stimulation at the periosteal surface, such inhibitory action by androgens in osteoblasts at the endosteum (also see next section) is important for the maintenance of cortical width that is similar between males and females. Such a response would help pattern a skeleton in males that does not become excessively large and heavy during development or in the adult.

Effects of Androgens on Differentiation of Osteoblastic Cells

Osteoblast differentiation can be characterized by changes in alkaline phosphatase activity and/or alterations in the expression of important extracellular matrix proteins, such as type I collagen, osteocalcin, and osteonectin. Again, the effects of androgens on expression of these marker activities/proteins are poorly described and results are inconsistent between a variety of model systems. For example, enhanced osteoblast differentiation, as measured by increased matrix production, has been shown to result from androgen exposure in both normal osteoblasts and transformed clonal human osteoblastic cells (TE-89). Androgen treatment appeared to increase the proportion of cells expressing alkaline phosphatase activity, thus representing a shift toward a more differentiated phenotype (Kasperk *et al.,* 1989). Furthermore, the same group subsequently reported dose-dependent increases in alkaline phosphatase activity in both high and low-alkaline phosphatase subclones of SaOS2 cells (Kasperk *et al.,* 1996), and human osteoblastic cells (Kasperk *et al.,* 1997b). However, there are also reports employing a variety of model systems of androgens either inhibiting (Hofbauer *et al.,* 1998) or having no effect on alkaline phosphatase activity (Gray *et al.,* 1992; Takeuchi *et al.,* 1994). These various responses may reflect both the underlying complexity and dynamics of osteoblastic differentiation. Androgen-mediated increases in type Iα-1 collagen protein and mRNA levels (Benz *et al.,* 1991; Gray *et al.,* 1992; Kasperk *et al.,* 1996), and increased osteocalcin secretion (Kasperk *et al.,* 1997b), have also been described. Consistent with increased collagen production, androgen treatment has also been shown to stimulate mineral accumulation in a time- and dose-dependent manner (Kapur and Reddi, 1989; Kasperk *et al.,* 1997b; Takeuchi *et al.,* 1994). However, transgenic mice with targeted overexpression of AR in the osteoblast lineage showed decreased levels of most bone markers *in vivo* in RNA extracts derived from long bone samples, including decreased collagen, osterix, and osteocalcin gene expression (Wiren *et al.,* 2004b). These results suggest that, under certain conditions, androgens may enhance osteoblast differentiation and could thus play an important role in the regulation of bone matrix production and/or organization. On the other hand, many positive anabolic effects of androgen may be limited to distinct osteoblastic populations, for example in the periosteal compartment (Wiren, 2005; Wiren *et al.,* 2004b).

Androgen Effects on Other Cell Types in the Skeleton

Within the bone compartment, AR is detected in macrophages, megakaryocytes, and endothelial cells (Mantalaris *et al.,* 2001). Interestingly, ARs are also expressed in bone marrow stromal and mesenchymal precursor cells (Gruber *et al.,* 1999; Sinha-Hikim *et al.,* 2004), pluripotent cells that can differentiate into a variety of tissues including muscle, bone, and fat. Androgen action may modulate precursor differentiation toward the osteoblast and/or myoblast lineage, while inhibiting differentiation toward the adipocyte lineage (Singh *et al.,* 2003). These effects on stromal differentiation could underlie some of the well-described consequences of androgen administration on body composition including increased muscle mass (Herbst and Bhasin, 2004). Although it is an intriguing hypothesis to propose that androgen-mediated increases in muscle would indirectly increase bone mass through enhanced mechanical loading, to date it has not been established how significant such a contribution is. However, the time course required for oxandrolone (a synthetic testosterone analog) to positively effect bone mass in severely burned children is delayed relative to effects on lean mass, suggesting that alterations in muscle are indeed important (Bi *et al.,* 2007; Murphy *et al.,* 2004). In addition, androgen influences immune cells and hematopoiesis, and could play an indirect role in mediating effects on bone via immune cells. Although plausible, additional studies are needed to establish the importance of such indirect regulation of other tissues by androgen, to positively influence the skeleton.

Importantly, AR expression has also been detected in the osteoclast (Michael *et al.,* 2005; Mizuno *et al.,* 1994; van der Eerden *et al.,* 2002b), including human osteoclasts (Michael *et al.,* 2005), but see (Abu *et al.,* 1997; Noble *et al.,*1998), indicating modulation of osteoclast action by androgen. Thus, it has been shown that androgen treatment reduces bone resorption of isolated osteoclasts (Pederson *et al.,*1999), and inhibits osteoclast formation (Huber *et al.,* 2001) including that stimulated by parathyroid hormone (PTH) (Chen *et al.,* 2001). That AR may play a direct

role in regulating (inhibiting) osteoclast activity is also suggested by the high turnover osteopenia observed in AR null mice (Kawano *et al.,* 2003). Also of importance, androgens indirectly modulate osteoclastogenesis and osteoclast activity through effects mediated by osteoblasts (Michael *et al.,* 2005), consistent with increased levels of OPG observed following testosterone treatment in cultured osteoblasts (Chen *et al.,* 2004), and in both the serum and in bone derived from skeletally targeted AR3.6-transgenic male mice (Wiren *et al.,* 2004b). Thus, although estrogen also inhibits bone resorption, androgen regulation is distinct compared to estrogen utilizing both direct and indirect pathways (Michael *et al.,* 2005). In addition, DHEA treatment has been shown to increase the OPG/RANKL ratio in osteoblastic cells and inhibit osteoclast activity in coculture (Wang *et al.,* 2006). Androgen may be a less significant determinant of bone resorption *in vivo* than estrogen (Falahati-Nini *et al.,* 2000; Oh *et al.,* 2005), although this remains controversial (Leder *et al.,* 2003).

As with effects noted in osteoblastic populations, androgens also regulate chondrocyte proliferation and expression. Although some of the consequences of androgen action are mediated after metabolic conversion to estrogen, which limits long bone growth, nonaromatizable androgen stimulates longitudinal bone growth (Nilsson *et al.,* 2005). AR expression has been demonstrated in biopsies of proximal tibial growth plate cartilage (Nilsson *et al.,* 2003), and androgen exposure promotes chondrogenesis as shown with increased creatine kinase and DNA synthesis after androgen exposure in cultured epiphyseal chondrocytes (Carrascosa *et al.,* 1990; Somjen *et al.,* 1991). Increased [^{35}S]sulfate incorporation into newly synthesized proteoglycan (Corvol *et al.,* 1987) and increased alkaline phosphatase activity (Schwartz *et al.,* 1994) are androgen mediated. Regulation of these effects is obviously complex, as they were influenced by the age of the animals and the site from which the chondrocytes were derived. Thus, in addition to effects on osteoblasts, multiple cell types in the skeletal milieu are regulated by androgen exposure, and all are likely involved in mediating the effects of androgens on the skeleton.

Interaction with Other Factors to Modulate Bone Activity

The effects of androgens on osteoblast activity must certainly also be considered in the context of the very complex endocrine, paracrine, and autocrine milieu in the bone microenvironment. Systemic and/or local factors can act in concert, or can antagonize, to influence bone cell function. This has been well described with regard to modulation of the effects of estrogen on bone (see for example Horowitz, 1993; Kassem *et al.,* 1996; Kawaguchi *et al.,* 1995). Androgens have also been shown to regulate well-known modulators of osteoblast proliferation or function. The most extensively characterized growth factor influenced by androgen exposure is transforming growth factor-β (TGF-β). TGF-β is stored in bone (the largest reservoir for TGF-β) in a latent form, and has been shown to be a mitogen for osteoblasts (Centrella *et al.,* 1994; Harris *et al.,* 1994). Androgen treatment has been shown to increase TGF-β activity in human osteoblast primary cultures. The expression of some TGF-β mRNA transcripts (apparently TGF-β2) was increased, but no effect on TGF-β1 mRNA abundance was observed (Bodine *et al.,* 1995; Kasperk *et al.,* 1990) but also see (Wang *et al.,* 1999b). At the protein level, specific immunoprecipitation analysis reveals DHT-mediated increases in TGF-β activity to be predominantly TGF-β2 (Bodine *et al.,* 1995; Kasperk *et al.,* 1997b). DHT has also been shown to inhibit both TGF-β gene expression and TGF-β-induced early gene expression that correlates with growth inhibition in this cell line (Hofbauer *et al.,* 1998). The TGF-β-induced early gene has been shown to be a transcription factor that may mediate some TGF-β effects (Subramaniam *et al.,* 1995). These results are consistent with the notion that TGF-β may mediate androgen effects on osteoblast proliferation. On the other hand, TGF-β1 mRNA levels are increased by androgen treatment in human clonal osteoblastic cells (TE-89), under conditions where osteoblast proliferation is slowed (Benz *et al.,* 1991). Thus, the specific TGF-β isoform may determine osteoblast responses. It is interesting to note that *in vivo*, orchiectomy drastically reduces bone content of TGF-β levels, and testosterone replacement prevents this reduction (Gill *et al.,* 1998). Finally, androgen may modulate the levels of certain SMADs (Miki *et al.,* 2007), transcription factors that mediate TGF-β signaling. These data support the findings that androgens influence TGF-β cellular expression or activity, and suggest that the bone loss associated with castration is related to a reduction in growth factor activity induced by androgen deficiency.

Other growth factor systems may also be influenced by androgens. Conditioned media from DHT-treated normal osteoblast cultures are mitogenic, and DHT pretreatment increases the mitogenic response to fibroblast growth factor and to insulin-like growth factor II (IGF-II) (Kasperk *et al.,* 1990). In part, this may be due to slight increases in IGF-II binding in DHT-treated cells (Kasperk *et al.,* 1990), as IGF-I and IGF-II levels in osteoblast conditioned media are not affected by androgen (Canalis *et al.,* 1991; Kasperk *et al.,* 1990). In contrast to effects of estrogen, most studies have not found regulation of IGF-I or IGF-II abundance by androgen exposure (Canalis *et al.,* 1991; Kasperk *et al.,* 1990; Nakano *et al.,* 1994), but see (Gori *et al.,* 1999). Androgens may also modulate expression of components of the AP-1 transcription factor (Bodine *et al.,* 1995) or AP-1 transcriptional activation (Wiren *et al.,* 2004a). Thus, androgens may modulate osteoblast differentiation via a

mechanism whereby growth factors or other mediators of differentiation are regulated by androgen exposure.

Androgens may also modulate responses to other important osteotropic hormones/regulators. Testosterone and DHT specifically inhibit the cAMP response elicited by PTH or parathyroid hormone-related protein (PTHrP) in the human clonal osteoblast-like cell line SaOS-2 whereas the inactive or weakly active androgen 17α-epitestosterone had no effect. This inhibition may be mediated via an effect on the PTH receptor-G_s-adenylyl cyclase (Fukayama and Tashjian, 1989; Vermeulen, 1991). The production of prostaglandin E_2 (PGE_2), another important regulator of bone metabolism, is also affected by androgens. Androgens (both DHT and testosterone) were shown as potent inhibitors of both parathyroid hormone and interleukin1 stimulated PGE_2 production in cultured neonatal mouse calvaria (Pilbeam and Raisz, 1990). The effects of androgens on parathyroid hormone action and PGE_2 production suggest that androgens could act to modulate (reduce) bone turnover in response to these agents.

Finally, both androgen (Hofbauer and Khosla, 1999) and estrogen (Kassem *et al.,* 1996; Passeri *et al.,* 1993) (but see Rifas *et al.,* 1995) inhibit production of interleukin-6 by osteoblastic cells. In stromal cells of the bone marrow, androgens have been shown to have potent inhibitory effects on the production of interleukin-6 and the subsequent stimulation of osteoclastogenesis by marrow osteoclast precursors (Bellido *et al.,* 1995). Adrenal androgens (androstenediol, androstenedione, DHEA) have similar inhibitory activities on interleukin-6 gene expression and protein production by stromal cells (Bellido *et al.,* 1995). The loss of inhibition of interleukin-6 production by androgen may also contribute to the marked increase in bone remodeling and resorption that follows orchiectomy, in addition to modulation of osteoclast activity through changes in the OPG/RANKL ratio as noted earlier. Moreover, androgens inhibit the expression of the genes encoding the two subunits of the IL-6 receptor (gp80 and gp130) in the murine bone marrow, another mechanism that may blunt the effects of this osteoclastogenic cytokine in intact animals (Lin *et al.,* 1997). In these aspects, the effects of androgens seem to be similar to those of estrogen, which may also indirectly inhibit osteoclastogenesis via mechanisms that involve interleukin-6 inhibition and/or OPG/RANKL ratio changes.

The Skeletal Effects of Androgen: Animal Studies

The effects of androgens on bone remodeling have been examined fairly extensively in animal models. Much of this work has been in species such as rodents, not perfectly suited to reflect human bone metabolism (but see Kalu, 1991), and certainly the field remains incompletely explored. Nevertheless, animal models do provide valuable insights into the effects of androgens at organ and cellular levels. Many of the studies of androgen action have been performed in male rats, in which rapid skeletal growth occurs until about four months of age, at which time epiphyseal growth slows markedly (although never completely ceases at some sites). Because the effects of androgen deficiency may be different in growing versus more mature adult animals (see Vanderschueren *et al.,* 2004), it is appropriate to consider the two situations independently.

Effects on Epiphyseal Function and Bone Growth during Skeletal Development and Puberty

In most mammals there is a marked gender difference in bone morphology. The mechanisms responsible for these differences are complex, and presumably involve both androgenic and estrogenic actions. Estrogens are particularly important for the regulation of epiphyseal function, and act to reduce the rate of longitudinal growth via influences on chondrocyte proliferation and action, as well as on the timing of epiphyseal closure (Turner *et al.,* 1994). Androgens appear to have opposite effects, and tend to promote long bone growth, chondrocyte maturation, and metaphyseal ossification. Androgen deficiency retards those processes (Lebovitz and Eisenbarth, 1975). Excess concentrations of androgen will accelerate aging of the growth plate and reduce growth potential (Iannotti, 1990), possibly via conversion to estrogens.

Although the specific roles of sex steroids in the regulation of epiphyseal growth and maturation remain somewhat unresolved, there is evidence that androgens do have direct effects independent of those of estrogen. For instance, testosterone injected directly into the growth plates of rats increases plate width (Ren *et al.,* 1989). In a model of endochondral bone development based on the subcutaneous implantation of demineralized bone matrix in castrate rats, both testosterone and DHT increase the incorporation of calcium during osteoid formation (Kapur and Reddi, 1989). Interestingly, in this model androgens reduced the incorporation of [^{35}S]sulfate into glycosaminoglycans early in the developing cartilage. In sum, these data support the contention that androgens play a direct role in chondrocyte physiology, but how these actions are integrated with those of other regulators is unclear.

During childhood and adolescence, skeletal development is characterized by marked expansion of cortical proportions and increasing trabecular density. During this process, the skeleton develops distinctly in males and females, most significantly at the periosteal surface. Thus, sex differences in skeletal morphology and physiology occur at or around puberty. For that reason, it is hypothesized that gender differences, particularly with respect to "bone quality" and

architecture, i.e., predominantly bone width, are modulated by the sex steroids estrogen and androgen. Consistent with this, a distinct response to estrogen and androgen has been described *in vivo* especially in cortical bone. At the periosteum, estrogen suppresses while androgen stimulates new bone formation (Matsumoto *et al.,* 2006; Wiren *et al.,* 2004b), yet conversely at the endosteal surface estrogen stimulates but androgen strongly suppresses formation (Wiren *et al.,* 2004b). Thus, estrogen decreases but androgen increases radial growth in cortical bone through periosteal apposition, indicating that these two sex steroids may act in opposition in some situations at distinct bone compartments. These divergent responses to estrogen and androgen during growth likely play an important role in determining sexual dimorphism of the skeleton, i.e., that male bones are wider but not thicker than females (Seeman, 2003). Young men do have larger bone areas than women with increased whole bone cross-sectional area, particularly at peripheral sites (Riggs *et al.,* 2004). Low levels of estrogen in the obligate presence of androgen and AR may also be important for stimulation of periosteal bone formation during development (Bouillon *et al.,* 2004; Rochira *et al.,* 2007), but estrogen is not apparently important after puberty (Matsumoto *et al.,* 2006). Sex steroid effects can be influenced by interaction with the growth hormone IGF-I axis in the coordination of skeletal growth. Growth hormone deficiency in males has no net effect on endosteal growth but reduced by half expansion at the periosteal surface (Kim *et al.,* 2003), and produces greater deficits in females. The effect of growth hormone on periosteal formation may be mediated by increased IGF-I concentrations (Venken *et al.,* 2007). Although androgens did not affect IGF-I expression, both androgen and IGF-I were required for optimal stimulation at the periosteal surface. In contrast, analysis indicates that androgens stimulate trabecular bone modeling independent of growth hormone. Androgens are also essential for the production of peak total-body bone mass in males (Vanderschueren *et al.,* 2005), and a recent study has found that serum testosterone and IGF-1/IGFBP-3 ratio are major determinants of BMD at different stages of puberty in males (Pomerants *et al.,* 2007).

Mature Male Animals

Results from animal studies also support an effect of androgen on bone formation in the mature animal. Experimental strategies such as pharmacological or surgical (gonadectomy) intervention and examination of genetic models have all been employed to characterize androgen signaling in the adult. As expected, the consequences of either androgen administration or conversely withdrawal are complex, with effects in all bone compartments (see Fig. 3). In mature rats, castration eventually results in osteopenia and both cortical and trabecular compartments are affected. At a time when longitudinal growth has slowed markedly,

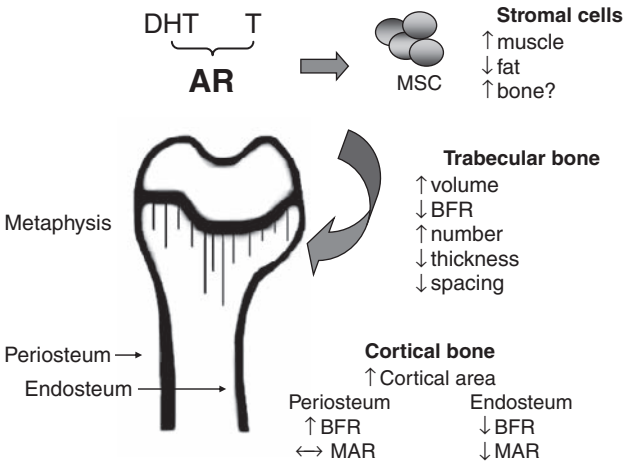

FIGURE 3 Model for androgen-mediated action in the skeleton, derived from androgen deficient or androgen replacement studies. References are cited in the text. AR activation by androgen influences a variety of skeletal compartments or target sites, including stromal cells, trabecular bone, intramembranous bone (not shown), and cortical bone. Arrows indicate the changes induced by androgen action. In general, AR activation in bone cells results in a low turnover phenotype and may also influence body composition.

pronounced differences as a consequence of castration appear in cortical bone ash weight per unit length, cross-sectional area, cortical thickness, and bone mineral density (Danielsen, 1992; Vanderschueren *et al.,* 1992; Verhas *et al.,* 1986; Wink and Felts, 1980). Distinct effects of androgen are seen with gonadectomy when comparing the effects of orchiectomy in male vs. ovariectomy in female rats. Generally castration results in changes in both trabecular and cortical bone compartments, and dramatic bone loss in trabecular bone is noted in both males and females, but sex-specific responses are most dimorphic in cortical bone. Ovariectomy and the associated loss of sex steroids in the female generally results in decreased trabecular area with increased osteoclast number. In cortical bone in ovariectomized females, an increase at the periosteal surface is seen with circumferential enlargement but a decrease in endosteal labeling. These results demonstrate that estrogen protects trabecular bone predominantly through inhibition of osteoclast activity/recruitment, but has an inhibitory action at the periosteal surface as noted earlier (for example, see Vandenput *et al.,* 2004). In the male, orchiectomy with the attendant loss of sex steroids also results in decreased trabecular area with increased osteoclast number as in females. However, careful histomorphometric analysis of androgen action in orchiectomized male mice has shown that the bone-sparing effect of AR activation in trabecular bone is distinct from a similar bone-sparing effect of ERα at that site (Moverare *et al.,* 2003). The analysis showed that AR activation does preserve the number of trabeculae, but does not preserve thickness, volumetric density, nor mechanical strength in cortical bone. In cortical bone,

periosteal formation is reduced with the loss of androgen after gonadectomy in males, in contrast to ovariectomized females. Androgen treatment is effective in suppressing the acceleration of bone remodeling normally seen after orchiectomy (Venken *et al.,* 2005a). This divergent response at the periosteal surface after castration in male and female animals abolishes the sexual dimorphism usually present in radial bone growth. In the intact animal, the stimulation of endosteal formation by estrogen compensates for the lack of periosteal formation, thus leading to no difference in cortical width between the sexes. Nevertheless, factors that influence periosteal apposition may constitute an important therapeutic class because periosteal bone formation is often a neglected determinant of bone strength (Seeman, 2003). Orchiectomy shows little net effect on the endosteal surface in males (Kim *et al.,* 2003) or slight reductions likely due to increased resorption. Consistent with this, increased intracortical resorption cavities are reported to result from orchiectomy (Prakasam *et al.,* 1999; Wink and Felts, 1980). As might be expected in light of these changes, breaking strength (N) is decreased in cortical bone (Kim *et al.,* 2003). Interestingly, DHT as a specific AR agonist is less effective than testosterone in the cortical bone compartment in elderly orchidectomized rats (Vandenput *et al.,* 2002; Wakley *et al.,* 1991). In addition, it appears that orchiectomy affects cranial development more than ovariectomy (Fujita *et al.,* 2004), suggesting that androgen action is particularly important in intramembranous bone.

Changes in the skeleton can occur rapidly after castration, and osteopenia becomes pronounced with time. This bone loss appears to result in part from increased bone resorption, as it is associated with increases in resorption cavities, osteoclasts, and blood flow (Verhas *et al.,* 1986; Wink and Felts, 1980). Initially, dynamic histomorphometric and biochemical measures of bone remodeling increase quickly, with evidence of increased osteoclast numbers only one week after castration (Gunness and Orwoll, 1995; Vanderschueren *et al.,* 1994a; Wink and Felts, 1980). Changes include an increase in osteoblastic activity as well as increased bone resorption, reflecting an initial high turnover state that is followed by a reduction in remodeling rates and low turnover osteopenia. In the SAMP6 mouse, a model of accelerated senescence in which osteoblastic function is impaired, the rise in remodeling following orchiectomy is blunted, which has been interpreted as evidence that the early changes after gonadectomy are dependent on osteoblast-derived signals (Weinstein *et al.,* 1997). As noted earlier, androgens reduce osteoclast formation and activity (Huber *et al.,* 2001), which may be partially indirectly mediated by increased OPG levels (Chen *et al.,* 2004; Wiren *et al.,* 2004b). The initial phase of increased bone remodeling activity subsides with time (Vanderschueren *et al.,* 1994a; Verhas *et al.,* 1986) and by four months there is evidence of a depression in bone turnover rates in some skeletal areas. As in younger animals, indices of mineral metabolism are not altered by these changes in skeletal metabolism (Vanderschueren *et al.,* 1992).

As a potential model for the effects of hypogonadism in humans (see Vanderschueren *et al.,* 2004), animal models therefore indicate an early phase of high bone turnover and bone loss after orchiectomy, followed by a reduction in remodeling rates and osteopenia. The remodeling imbalance responsible for loss of bone mass appears complex, as there are changes in rates of both bone formation and resorption, and patterns that vary from one skeletal compartment to another. Broad changes are similar (but not identical in detail) to those noted in female animals after castration, in which a loss of estrogen signaling has been associated with a stimulation of osteoblast progenitor differentiation, an increase in osteoclast numbers, bone resorption, and bone loss (Jilka *et al.,* 1998).

Androgens in the Female Animal

Of course androgens are present in both sexes and likely also affect bone metabolism in females. Although testosterone serum concentrations are much lower in females than in males, the concentration of other androgens like androstenedione and DHEA-sulfate are in fact similar between the sexes. In castrated female rats, DHT administration suppresses elevated concentrations of osteocalcin and of bone resorption markers (Mason and Morris, 1997). However, alkaline phosphatase activity increases further. Additional evidence to support the contention that androgens play a role in females includes the fact that antiandrogens are capable of evoking osteopenia in intact (i.e., fully estrogenized) female rats (Goulding and Gold, 1993; Lea *et al.,* 1996). This finding suggests that androgens provide crucial support to bone mass in females, in addition to a role for estrogens. Of interest, the character of the bone loss induced by flutamide suggested that estrogen prevents bone resorption whereas androgens may stimulate bone formation. In periosteal bone, DHT and testosterone stimulate periosteal formation after orchiectomy in young male rats, whereas in castrated females they suppress bone formation (Turner *et al.,* 1990b), perhaps reflecting an interaction or synergism between sex steroids and their effects on bone. However, in ovariectomized females with established osteopenia, treatment with DHT-stimulated periosteal bone formation whereas estradiol inhibited formation at the same surface (Coxam *et al.,* 1996). As noted earlier, combination therapy with estrogen and androgen in postmenopausal women is more beneficial than either steroid alone (Castelo-Branco *et al.,* 2000; Miller *et al.,* 2000; Raisz *et al.,* 1996), which has been confirmed in an animal model (Tivesten *et al.,* 2004). There is also some information concerning androgens in additional animal models, including primates. For instance,

in young female cynomolgus monkeys, testosterone treatment increased cortical and trabecular bone density as well as biomechanical strength (Kasra and Grynpas, 1995).

Gender Effects

In most mammals, there is a marked gender difference in morphology that results in a sexually dimorphic skeleton. The mechanisms responsible for these differences are obviously complex, and presumably involve both androgenic and estrogenic actions on the skeleton linked to different levels of each steroid between males and females. It is becoming increasingly clear that estrogens are particularly important for the regulation of epiphyseal function and act to reduce the rate of longitudinal growth via influences on chondrocyte proliferation and function, as well as on the timing of epiphyseal closure (Turner *et al.,* 1994). Androgens, on the other hand, appear to have opposite effects to estrogen on the skeleton. Androgens tend to promote long bone growth, chondrocyte maturation, and metaphyseal ossification as noted earlier (Cassorla *et al.,* 1984). Furthermore, the most dramatic effect of androgens is likely on bone size, consistent with gender-specific effects of androgens on periosteal bone formation (Turner *et al.,* 1990b). This difference of course has important biomechanical implications, with thicker bones being stronger bones (Seeman, 2003). Consistent with gender specificity, the response of the adult skeleton to the same intervention results is distinct responses in males and females. For example, in a model of disuse osteopenia, antiorthostatic suspension results in significant reduction in bone formation rate at the endosteal perimeter in males. In females, however, a decrease in bone formation rate occurred along the periosteal perimeter (Bateman *et al.,* 1997). However, DHT has also been shown to enhance periosteal bone formation after ovariectomy in females with established osteopenia (Coxam *et al.,* 1996), similar to the response in males noted earlier. Nevertheless, gender-specific responses *in vivo* and *in vitro* (for example, see Somjen *et al.,* 2006), and the mechanism(s) that underlie such responses in bone cells, may have implications in treatment options for metabolic bone disease.

ANIMAL MODELS OF ALTERED ANDROGEN RESPONSIVENESS

The specific contribution of AR signaling *in vivo* has also been approached in genetic animal models with global AR modulation, including the testicular feminization (Tfm) model of androgen insensitivity (Tozum *et al.,* 2004; Vandenput *et al.,* 2004) and with nontargeted (global) AR knockout mice (Kawano *et al.,* 2003; Yeh *et al.,* 2002). The Tfm male rat is AR signaling deficient, and provides an interesting model for the study of the unique effects of androgens in bone. In these rats androgens are generally incapable of action at the AR, but the model is complicated by the fact that estrogen and androstenedione concentrations are considerably higher than in normal males (Vanderschueren *et al.,* 1994b; Vanderschueren *et al.,* 1993b). Clear increases also exist in Tfm male rats in serum concentrations of osteocalcin, calcium, and phosphorus, whereas IGF-1 concentrations are decreased. Estimates of bone mass suggest that Tfm rats have reduced longitudinal and radial growth rates, but trabecular volume and density are similar to those of normal rats, likely a consequence of high serum estrogen levels. In selected sites, measures of bone mass and remodeling were intermediate between normal male and female values. With castration, bone volume is markedly reduced in Tfm male rats, suggesting a major role for estrogens as well in skeletal homeostasis. This model indicates that androgens do have an independent role to play in normal bone growth and metabolism, but the model as described is complex and not easily dissected. Tfm mice are different from Tfm rats in that Tfm mice develop a high-turnover trabecular bone phenotype (Vandenput *et al.,* 2004), associated with low levels of circulating testosterone and estradiol. Meticulous analysis in Tfm mice has shown that the positive effects of testosterone on cortical bone are generally mediated by stimulation of periosteal bone formation through the AR (Vandenput *et al.,* 2004), whereas testosterone effects on trabecular bone likely involves both AR and ER signaling. Thus, these studies demonstrate that AR-mediated testosterone action is essential for periosteal bone formation (in male mice), while AR contributes to trabecular bone maintenance along with ER. This is very similar to the study of humans with the androgen insensitivity syndrome. Even when compliance with estrogen replacement is excellent, there is a deficit in bone mineral density in women with androgen insensitivity (Marcus *et al.,* 2000) that has been observed at the spine (Danilovic *et al.,* 2007) or at both spine and hip sites (Sobel *et al.,* 2006). In addition, final height was intermediate between what would be predicted for males or males (Danilovic *et al.,* 2007). These results provide evidence for an important role for androgens in normal male growth and bone density that is not replaced by estrogens. However, inadequate estrogen replacement appeared to worsen the deficit (Marcus *et al.,* 2000), and other environmental factors are difficult to quantitate. Thus, in Tfm models that lack functional AR, orchiectomy demonstrates the importance of AR in mediating the positive effects of androgen to contribute to trabecular bone maintenance, and in cortical bone particularly at the periosteal surface (Tozum *et al.,* 2004; Vandenput *et al.,* 2004).

Global AR null mice, developed using a cre/loxP approach, have complete AR disruption from birth (De Gendt *et al.,* 2005; Sato *et al.,* 2002; Yeh *et al.,* 2002). The ARKO null model should not be confused with the aromatase null, or ArKO, mouse. The bone phenotype that

develops in male ARKO mice is a high-turnover osteopenia, with reduced trabecular bone volume and a significant stimulatory effect on osteoclast function (Kato *et al.,* 2004; Kawano *et al.,* 2003; Venken *et al.,* 2006; Yeh *et al.,* 2002). As expected, bone loss with orchiectomy in male ARKO mice was only partially prevented by treatment with aromatizable testosterone due to the lack of AR function. Interestingly, orchiectomy in control mice produced a similar trabecular bone phenotype to that observed in the ARKO male, indicating that AR activation is a major determinant of trabecular bone development (Venken *et al.,* 2006). Analysis of the impact of androgens with and without aromatase inhibitors suggests that aromatase inhibition of periosteal bone formation is dependent on AR expression, as aromatase treatment was without effect in ARKO mice but reduced the effect of androgen to stimulate periosteal apposition in controls (Venken *et al.,* 2006). In contrast, aromatase inhibition had no effect on protection of trabecular bone by either testosterone or DHT after orchiectomy, similar to results obtained in Tfm mice described earlier.

Final models for AR modulation are represented by generation of mice with skeletally targeted modification of AR expression, with either overexpression (Wiren *et al.,* 2004b) or deletion using a tissue-specific cre/loxP approach (Notini *et al.,* 2007). In the first model, full-length AR is under the control of the 3.6 kb type I collagen promoter, with AR overexpression in osteoblast stromal precursors and throughout the osteoblast lineage. AR3.6-transgenic mice are the only model with bone-targeted overexpression of AR, and demonstrate enhanced sensitivity to androgen in tissues where AR is overexpressed yet without changes in circulating steroids or the complication of systemic androgen administration (Wiren *et al.,* 2004b). AR overexpression in this model results in a complex phenotype predominantly in males, with increased trabecular bone mass (with increased trabecular number but not thickness) in the setting of inhibition of resorption due to reduced osteoclast activity. In addition, cortical formation is altered in an envelope-specific fashion, with periosteal expansion but inhibition of inner endosteal deposition, in line with the known effects of androgen to stimulate periosteal apposition and opposite to the effects of estrogen on these compartments. Inhibition of osteoclastic resorption may be responsible for altered trabecular morphology, consistent with reduced osteoclast activity and increased trabecular bone volume observed with androgen therapy in rodents and humans. In trabecular bone, AR signaling results in increased volume, increased trabecular number, and decreased spacing with a modest reduction of thickness. The dramatic inhibition of bone formation at the endosteal envelope may underlie the modest decrease in cortical bone area and subsequent reductions in biomechanical properties observed. A second model for specific bone targeting results in disruption of normal AR expression using col 2.3-cre mice crossed with floxed AR mice (Notini *et al.,* 2007). Knockdown of AR expression is confined to mature osteoblasts/osteocytes. During development, there is a progressive loss of trabecular bone with decreased trabecular number but increased spacing and increased width, opposite to the phenotype observed with AR overexpression. There was little effect on cortical bone in this model. Notably, the bone phenotype observed in these models is consistent with many of the known effects of androgen treatment on the skeleton. Combined, these results indicate that AR expressed in bone can be a direct mediator of androgen action to influence skeletal development and homeostasis.

EFFECTS ON THE PERIOSTEUM: THE ROLE OF AR VS. AROMATIZATION OF TESTOSTERONE

As noted earlier, androgen-mediated AR transactivation is likely a key determinant of the sexually dimorphic pattern of periosteal apposition, an effect that is clearly demonstrated in male AR3.6-transgenic mice even in the absence of hormone administration (Wiren *et al.,* 2004b). Furthermore, essentially all of the alterations induced by orchiectomy (in both growing and mature animals) can be prevented at least in part by replacement with either testosterone or nonaromatizable androgens (Kapitola *et al.,* 1995; Prakasam *et al.,* 1999; Schoutens *et al.,* 1984; Somjen *et al.,* 1994; Turner *et al.,* 1990b; Vanderschueren *et al.,* 1993a; Wakley *et al.,* 1991). In sum, these results strongly suggest that aromatization of androgens to estrogens cannot fully explain the actions of androgens on bone metabolism.

However estrogens also seem to play a role in the effects of androgen on apposition, likely through indirect mechanisms. Although AR activity is essential, low levels of estrogens are likely required for optimal stimulation of periosteal growth (Venken *et al.,* 2006), as observed in aromatase deficiency even in males (Bouillon *et al.,* 2004). Estrogens may also help prevent bone loss following castration in male animals. For example, it has been reported (Vanderschueren *et al.,* 1992) that estradiol (and also nandrolone) was capable of not only preventing the increase in biochemical indices stimulated by orchiectomy, but also preventing cortical and trabecular bone loss. In fact, estradiol resulted in an absolute increase in trabecular bone volume not achieved with androgen replacement. Many of these estrogen-mediated responses appear to be indirectly mediated through increased IGF-I levels (Venken *et al.,* 2005b); in contrast androgens stimulate periosteal apposition independent of the growth hormone -IGF axis as noted earlier (Venken *et al.,* 2007). Similarly, estrogen was reported to antagonize the increase in blood flow resulting from castration and to increase bone ash weight more consistently than testosterone.

The gender reversal of androgen administration to female animals is also instructive. Consistent with the stimulatory effect of androgen on the periosteal compartment, treatment with nonaromatizable DHT has been shown to increase periosteal bone formation in ovariectomized females with established osteopenia (Coxam *et al.,* 1996). Nonaromatizable androgens are also capable of preventing or reversing osteopenia and abnormalities in bone remodeling in ovariectomized females (Tobias *et al.,* 1994; Turner *et al.,* 1990b). These actions result from the suppression of trabecular bone resorption as well as stimulation of periosteal bone formation (Tobias *et al.,* 1994). Very similar results have been reported following the treatment of ovariectomized animals with DHEA (Turner *et al.,* 1990b). Moreover, blockage of androgen action with an AR antagonist in female rats already treated with an estrogen antagonist increases bone loss and indices of osteoclast activity more than treatment with an estrogen antagonist alone (Lea and Flanagan, 1999), again indicating that ovarian androgens (apart from estrogens) exert a protective effect on bone in females. Analogously, androstenedione reduces (although does not abrogate) trabecular bone loss and remodeling alterations in ovariectomized animals treated with an aromatase inhibitor. This protective effect was blocked by the addition of an AR antagonist (Lea and Flanagan, 1998; Lea *et al.,* 1998). Finally, although aromatase inhibition in male rats reduces bone mass, the large increase in remodeling induced by orchiectomy does not occur in these animals (Vanderschueren *et al.,* 1997). Also, orchiectomy in ERα null (α-ERKO) mice further reduces bone mass (Sims *et al.,* 2003). The latter observation implicates a role for androgens in the maintenance of bone mass in α-ERKO mice.

SUMMARY

The effects of androgens on bone health are obviously pervasive and complex (see Fig. 3). Androgens are important in the maintenance of a healthy skeleton, and have been shown to stimulate bone formation in the periosteum but reduce formation on the endosteal surface in cortical bone and in trabecular bone and reduce osteoclast activity. Androgens influence skeletal modeling and remolding by multiple mechanisms through effects on osteoblasts, osteoclasts, and even perhaps an influence on the differentiation of pluripotent stem cells toward distinct lineages. The specific effects of androgen on bone cells are mediated directly through an AR-signaling pathway, but there are also indirect contributions to overall skeletal health through aromatization and ER signaling. The effects of androgens are particularly dramatic during growth in boys, but almost certainly play an important role during this period in girls as well. Throughout the rest of life, androgens affect skeletal function in both sexes. Still poorly characterized, more needs to be done to unravel the mechanisms by which androgens influence the physiology and pathophysiology of bone, and there remains much to be learned about the roles of androgens at all levels. The interaction of androgens and estrogens, and how their respective actions in the skeleton and in other tissues can be utilized for specific diagnostic and therapeutic benefit, are important but unanswered issues. With an increase in the understanding of the nature of androgen effects will come greater opportunities to use their positive actions in the prevention and treatment of a wide variety of skeletal disorders.

Chapter 47

Kinins and Neuro-osteogenic Factors

Ulf H. Lerner, Emma Persson and Pernilla Lundberg
Department of Oral Cell Biology, Umeå University, Umeå, Sweden

INTRODUCTION

Inflammatory processes within soft tissues are characterized by intense vasodilatation, increased blood vessel permeability, and exudation of plasma to the perivascular adjacent tissue, followed by the migration of different leukocytes from the blood into the surrounding tissues. These vascular and cellular reactions are associated with clinical symptoms of inflammation and with altered metabolism in the surrounding milieu. Bone cells can react to a nearby inflammatory process with both anabolic and catabolic reactions. In most cases, this results in osteolytic loss of bone tissue, although in some cases, sclerotic reactions can be seen (Lerner, 2006a). These reactions are induced by inflammatory mediators capable of interacting not only with the inflammatory process, but also with bone cells. In recent years, the understanding of the interactions between cytokines from the immune cells and bone cells has expanded tremendously and the term "osteoimmunology" has been coined (reviewed in Takayanagi, 2007). This research area has been directed not only because of the possible role of cytokines in inflammatory bone disease, but also due to their possible roles in physiological bone remodeling and osteoclast development (reviewed in Takayanagi, 2005; Walsh *et al.,* 2006; Sato and Takayanagi, 2006), as well as their possible pathophysiological role in osteoporosis (reviewed in Pfeilschifter *et al.,* 2002; Lerner, 2006b). The discovery of the pleiotropic cellular effects of cytokines, and their important roles in the communication between different cells in inflammatory processes, has led to the interest in inflammation-induced bone loss, which has been focused on the role of these peptides (Lerner, 2006a). However, it has been known for many years that other peptides and nonpeptides are also involved in nonimmune, or classical, inflammatory reactions, e.g., the kallikrein-kinin system, the coagulation cascade, the fibrinolytic pathway, and prostaglandins are activated in inflammatory processes and play important roles in the tissue inflammatory response. Although these systems are most well known for their effects on vessel permeability and dilatation, pain, extravascular coagulation, and fibrinolysis, it has been demonstrated that they are also involved in cell activation, proliferation, migration, and control of proteolysis. As regarding bone, we and others have shown that kinins and thrombin stimulate bone resorption *in vitro* (reviewed in Lerner, 1994, 1997). Osteoblasts synthesize plasminogen activators and inhibitors of these activators in a manner controlled by stimulators of bone resorption (Leloup *et al.*, 1991); *in vitro* data indicate that this system may be involved in the degradation of noncollagenous bone matrix proteins without having any effect on osteoclast formation (Daci *et al.*, 1999). Interestingly, *in vivo* data show that the lack of plasminogen activator inhibitor 1 protects ovariectomized mice from trabecular bone loss without affecting cortical bone loss (Daci *et al.*, 2000), urokinase receptor knockout mice exhibit enhanced bone mass (Furlan *et al.,* 2007), and polymorphisms in the genes encoding urokinase plasminogen activator and plasminogen activator type I have been associated with increased alveolar bone loss in patients with periodontitis (Decarlo *et al.,* 2007).

The activities of bone cells can be regulated at a local level not only by cytokines and kinins. The immunohistochemical demonstration of nerve fibers containing different neuropeptides in the vicinity of bone tissue (reviewed in Bjurholm, 1989; Konttinen *et al.*, 1996; Lundberg, 2000; Persson, 2005) raises the possibility that neuropeptides, via neuro-osteogenic interactions, may directly or indirectly modulate the activity of bone cells in physiological and pathological conditions (reviewed in Lerner, 2000; Togari, 2002; Togari *et al.,* 2005; Elefteriou, 2005), in line with the view of neuroendocrine and neuroimmune interactions (van Hagen *et al.*, 1999). The presence of receptors for several neuropeptides on osteoblasts (Bjurholm *et al.*, 1992) and the finding that vasoactive intestinal peptide (VIP) can stimulate bone resorption in organ culture (Hohmann *et al.*, 1983), provide evidence for a possible direct effect of neuropeptides on bone. The reports that neuropeptides enhance the production of cytokines from a variety of cell types, including monocytes and bone marrow cells, indicate that signaling molecules from skeletal nerve fibers may indirectly affect the skeleton via a neuroimmune control of bone cells, in line with the view that neuroimmunoendocrine interactions are important

for the regulation of a variety of cells and tissues. The recent observations demonstrating the importance of signaling from hypothalamus for bone remodeling have elegantly shown the role of central nervous system for bone metabolism (reviewed in Karsenty, 2006; Patel and Elefteriou, 2007; Allison *et al.,* 2007; for further details see Chapter 5).

This chapter summarizes the knowledge of the effects of kinins on bone and the local neuronal influence on bone tissue, as well as the interactions among kinins, neuro-osteogenic factors, and cytokines on bone metabolism.

ACTIVATION OF THE KALLIKREIN-KININ SYSTEM

Kinins are blood-derived short peptides released from kininogens as a result of the enzymatic action of kallikreins, proteolytic enzymes present in most tissues and body fluids (Fig. 1). The biological effects of the kallikrein-kinin system are mainly exerted by bradykinin (BK) and kallidin (Lys-BK) acting on a variety of cells via cell surface receptors of the B2 subtype. In addition, BK and kallidin, without the carboxyterminal arginine residue (des-Arg^9-BK and des-Arg^{10}-Lys-BK; respectively), can exert effects via BK B1 receptors. The kallikrein-kinin system is briefly summarized here, without giving any references to original reports. Readers are referred to extensive reviews in which relevant references can be found (reviewed in Marceau and Regoli, 2004; Moreau *et al.,* 2005; Pesquero and Bader, 2006; Sharma, 2006).

Hageman Factor

Activation of the plasma kallikrein system is initiated by the Hageman factor (coagulation factor XII), a single chain globulin (molecular weight 80,000), which can be activated by exposure to an activating macromolecular anionic surface and by endotoxin, as well as by an autocatalytic mechanism. The kallikrein system is activated by the Hageman factor by the action of this enzyme on plasma prekallikrein (Fig. 1).

Kallikreins

Plasma prekallikrein is a single chain globulin encoded by a single gene and is synthesized and secreted by hepatocytes as an inactive proenzyme. Activated plasma kallikrein acts on high molecular weight (HMW) kininogen at two sites, Lys-Arg and Arg-Ser, to release BK, a peptide consisting of nine amino acids with arginine at both the amino- and the carboxyterminal ends (Fig. 1).

Plasma kallikrein is inactivated rapidly by the C1 inhibitor and may also be inhibited by α_2-macroglobulin and antithrombin III.

Tissue kallikrein is a member of a multigene family with tissue-specific expression. Several of the serine proteases belonging to this family have important roles in the activation of peptide prohormones and growth factors. Tissue kallikrein liberates kallidin (Lys-BK) from both HMW and low molecular weight (LMW) kininogens, but because LMW kininogen is the most abundant kininogen, the enzyme preferentially uses LMW kininogen as substrate (Fig. 1).

As compared to plasma kallikrein, tissue kallikrein is less susceptible to inhibition. In humans, mainly α_1-antiprotease has some inhibitory capacity. In inflammatory processes, tissue kallikrein may be more important for kinin generation, because it seems less susceptible to degradation and because it can use both HMW and LMW kininogen as substrate.

Kininogens

HMW (88–120 kDa) and LMW (50–68 kDa) kininogens are synthesized by hepatocytes as single chain glycoproteins with one amino-terminal heavy chain and one carboxyterminal light chain. The HMW and LMW kininogens are coded for by a single gene, and the different forms are a consequence of alternate splicing of the gene transcript. The heavy chain of both kininogens contains a domain with cysteine proteinase inhibitory capacity, suggesting the possibility that kininogens may possess both pro- and anti-inflammatory activities.

Rats have a unique kininogen, T-kininogen (68 kDa), from which T-kinin (Ile-Ser-BK) is released by T-kininogenase(s). The levels of T-kininogen in plasma seem to be influenced by estrogen, with concentrations being increased in females at puberty and decreased in mature females by ovariectomy.

Kinins

The term kinin is derived from the Greek word *kineo* (to move) and was originally used for substances acting on smooth muscles. Today the term kinin is mainly restricted to peptides related to the nonapeptide BK. In this chapter, the word kinin is used for endogenous mammalian peptides with sequence homology to BK, and the kinin analogs refer to synthetic peptides whose amino acid sequence is modified from that of BK.

The kinins are not synthesized and released by cells, but are bioactive, short, and potent peptides that constitute a small part of large proteins (kininogens) from which they are released extracellularly by kininogenases. Four different, but closely related, primary kinins have been described: BK, kallidin, Hyp^3-BK, and T-kinin. The amino acid sequences of these peptides are shown in Table I.

Kinins released have a very short half-life *in vivo*, being estimated to approximately 30 seconds due to the action of different kininases. An interesting aspect is that one of these kininases, cleaving off the carboxyterminal arginine, gives rise to peptides (des-Arg^9-BK and des-Arg^{10}-Lys-BK) that

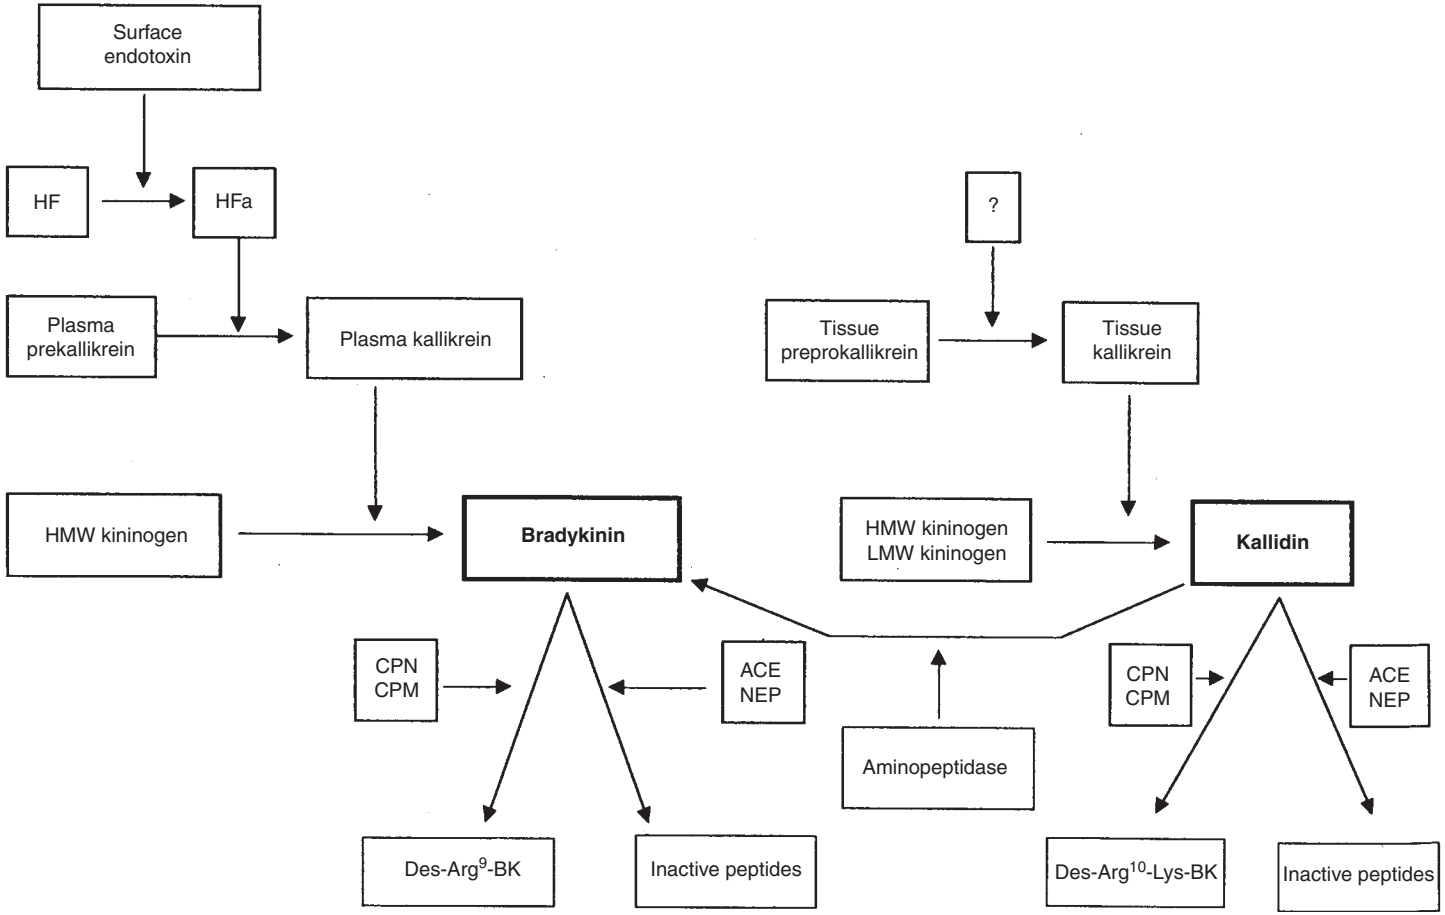

FIGURE 1 Schematic representation of activation of the kallikrein-kinin system and the formation of kinins.

TABLE I Amino Acid Sequences of Natural Kinins and Bradykinin Analogs with Receptor Antagonistic Properties

			1	2	3	4	5	6	7	8	9
B2 receptor agonists

are biologically active in several cell types and therefore des-Arg^9-BK and des-Arg^{10}-Lys-BK are also included in the group of naturally produced kinins with biological activities.

Kininases

Kinins formed have a short half-life because they are destroyed rapidly by the enzymatic action of different proteases, collectively called kininases (Fig. 2). These enzymes are present both as circulating and as cell-bound enzymes. Several kininases have been described, including carboxypeptidase N (CPN) and carboxypeptidase M (CPM), together called kininase-I. Other kininases are two different kininase-II enzymes called angiotensin-converting enzyme (ACE) and neutral endopeptidase (NEP). A third type of kininases is prolidase and aminopeptidase.

Kininases have been described in biological fluids and in a variety of cells, but no information on the presence of these enzymes in bone is available. However, the fact that some (but not all) kininase II inhibitors potentiate the bone-resorbing effect of BK (Lerner *et al.*, 1987) provides indirect evidence for the presence of BK-inactivating enzymes in bone.

Bradykinin Receptors

Two different kinin receptors, termed B1 and B2, have been demonstrated using pharmacological methods such as rank order potencies for different agonists, sensitivity to receptor antagonists, and radioligand-binding studies (reviewed in Leeb-Lundberg *et al.,* 2005).

Des-Arg^9-BK and des-Arg^{10}-Lys-BK are the natural agonists for B1 receptors with the latter being the more potent ligand. Substitution of phenylalanine at position 8 in des-Arg^9-BK by an amino acid with an aliphatic side chain gives rise to B1 receptor antagonists, the classical one being des-Arg^9-[Leu^8]-BK. Hoe-140-des-Arg^{10} has also been found to be a potent and selective antagonist for B1 receptors.

The natural kinins with affinity for the B2 receptors are BK and Lys-BK. Since the discovery that substitution of proline at position 7 of BK with phenylalanine converts BK agonists to antagonists, several B2 receptor antagonists have been developed, with D-Arg-[Hyp^3, Thi^{5,8}, D-Phe^7]-BK being a very potent one. Hoe 140 D-Arg-[Hyp^3, Thi^5, D-Tic^7, Oic^8]-BK has been shown to be the first totally selective B2 receptor antagonist.

The distribution of kinin receptors in different cells and tissues and the relative expression of B1 and B2 receptors have been studied extensively, mostly by the use of pharmacological methods. B2 receptors seem to be constitutively expressed in a variety of tissues. B1 receptor expression has so far been demonstrated in certain cell types. In most cells, however, B1 receptor expression can be induced by tissue injury and cytokines/growth factors, including interleukin-1 (IL-1), IL-2, oncostatin M, interferon-γ, and epidermal growth factor.

B1 and B2 receptors have been cloned molecularly from human, rabbit, rat, and mice species and found to be highly conserved (70–80% homology). In humans, the predicted sequences of the B1 and B2 receptors show proteins of 357 and 364 amino acids, respectively. However, the homology between the two receptor types is only 36%. Both receptors contain seven transmembrane-spanning domains, typical of G protein-coupled receptors, and are located on chromosome 14q32, in very close proximity to each other. Targeted disruption of the B1 and B2 receptor genes by homologous recombination results in mice who exhibit phenotypes related to the inflammatory response, including decreased extravasation of leukocytes, hypertension, and angiogenic response (e.g., Cayla *et al.,* 2007; Emanueli *et al.,* 2002), that develop normally with normotension, although failing to respond to B1 receptor agonists. No data are available concerning the skeletal phenotype of B1 and B2 receptor knockout mice. Both B1 and B2 receptor genes have been found to express several allelic polymorphisms, although any association to physiological or pathophysiological bone metabolism has not been studied.

EFFECTS OF KININS ON BONE METABOLISM

Studies on the effects of kinins on bone metabolism have been performed *in vitro*, mainly in bone organ cultures. Treatment of mouse calvarial bones with BK for 72–96-hour results in increased bone resorption, as assessed either by the release of ^{45}Ca (Gustafson and Lerner, 1984; Lerner *et al.*, 1987) or by bone matrix degradation (Lerner *et al.*, 1987). BK can stimulate the release of ^{45}Ca also from fetal rat long bones, although the response is less than that seen in mouse calvarial bones (Ljunggren and Lerner, unpublished results). The threshold for action of BK in the mouse calvariae is 3 n*M* and half-maximal stimulation (EC_{50}) is obtained at 100 n*M* (Lerner *et al.*, 1987).

Calcitonin, added simultaneously with BK, inhibits the bone-resorptive effect of BK (Lerner *et al.*, 1987). Because calcitonin can inhibit the activity of multinucleated osteoclasts, as well as the recruitment of new osteoclasts, data do not reveal if BK stimulates bone resorption by enhancement of the activity of preformed osteoclasts or by the formation of new osteoclasts. However, morphological studies using both light and electron microscopy have shown that osteoclasts present in the calvariae, when bones are dissected from the mice, disappear after the preculture period. This implies that the stimulation of bone resorption in this system is dependent on proliferation/differentiation/fusion of osteoclast progenitor cells to multinucleated active osteoclasts and thus suggests that BK stimulates bone resorption by enhancing osteoclast recruitment, a hypothesis supported by the fact that the action of BK on bone resorption is delayed, with no effect observed until after 24 hours (Lerner *et al.*, 1987). Because no hematopoetic cells are present in the mouse calvarial explants, the osteoclast precursor cells in these bones are probably late precursor cells in the osteoclastic cell lineage.

Inflammatory bone loss may not only be due to enhanced bone resorption, but also to decreased bone formation. As regarding osteoblast cell proliferation, biosynthesis of bone matrix proteins, and the activity of alkaline phosphatase, very little is known about the possible effects of BK. In the human osteoblastic osteosarcoma cell line MG-63, BK does not stimulate cell proliferation or the biosynthesis of type I collagen and osteocalcin (Rosenquist *et al.*, 1996), although these cells express B2 receptors coupled to a burst of prostanoid formation (Brechter and Lerner, 2002). B1 receptors have been suggested to play a role in fibrinogenesis in fibrotic disorders, and B1 receptor agonists have been shown to stimulate type I collagen biosynthesis in human fibroblasts due to the stabilization of connective tissue growth factor mRNA (Ricupero *et al.*, 2000). In MG-63 cells, however, we have not been able to find any effect on type I collagen biosynthesis by B1 agonists, although these cells express B1 receptors (Rosenquist *et al.*, 1996; Brechter and Lerner, 2002). In agreement with the findings

in MG-63 cells, BK has no effect on the proliferation of osteoblast-like cells isolated from human bone (Frost *et al.*, 1999).

Interestingly, whey protein obtained from milk and known to contain a variety of growth factors has been found to increase bone strength in ovariectomized rats (Takada *et al.*, 1997) and to stimulate proliferation and collagen synthesis in MC3T3-E1 cells (Takada *et al.*, 1996). The growth-promoting activity of milk has been purified and found to be a 17-kDa protein with an amino-terminal amino acid sequence very similar to an internal sequence of HMW kininogen (Yamamura *et al.*, 2000). This observation suggests the possibility that kininogens may not only be important for BK formation and cysteine protease inhibition, but also for bone growth.

PROSTAGLANDINS AS MEDIATORS OF BONE RESORPTION INDUCED BY BK

It was noted earlier that bone resorption induced by BK was inhibited by indomethacin, a potent inhibitor of prostaglandin biosynthesis (Gustafson and Lerner, 1984). It was later shown that several inhibitors of the cyclooxygenase pathway of arachidonic acid metabolism, including indomethacin, naproxen, meclofenamic acid, and flurbiprofen, abolish BK-induced mineral mobilization and bone matrix degradation (Lerner *et al.*, 1987). Similarly, all these nonsteroidal anti-inflammatory drugs also completely inhibit the bone resorptive effect of kallidin and Met-Lys-BK (Gustafson *et al.*, 1986; Ljunggren and Lerner, 1988). The glucocorticoids hydrocortisone and dexamethasone, which are potent inhibitors of prostaglandin biosynthesis, also inhibit BK-induced bone resorption (Lerner *et al.*, 1987). These observations indicate that the bone-resorptive effect of BK is totally dependent on the capacity of this peptide to activate prostaglandin formation. Interestingly, most stimulators of bone resorption *in vitro* also stimulate prostanoid formation in bone tissue and bone cells, although the magnitude of the prostaglandin response varies considerably between different stimulators. However, the bone resorptive effect and the biosynthesis of prostaglandins are not necessarily linked to each others. There are stimulators of bone resorption, including PTH, 1,25$(OH)_2$ vitamin D_3, TNF-α/TNF-β, and TGF-β, that are totally independent of prostaglandin formation (Palmqvist *et al.*, 2006). Other stimulators, e.g., IL-1, have a larger capacity to stimulate bone resorption in the presence of endogenous prostaglandin production, although a bone-resorptive effect of IL-1 still can be seen in the absence of prostaglandins (Lerner *et al.*, 1991). To a third group of stimulators, being unable to stimulate bone resorption in the absence of prostaglandin production, belong BK, kallidin, and Met-Lys-BK.

In primary cultures of mouse calvarial osteoblasts, BK causes a rapid burst of PGE_2 and 6-keto-$PGF_{1\alpha}$ (the stable breakdown product of PGI_2) that is maximal after 5–10 minutes (Lerner *et al.*, 1989). The half-maximal effect for the prostaglandin response (10 n*M*) is less than that for the bone-resorptive effect (100 n*M*), probably due to differences in the degradation of BK in short-term cell incubations compared to long-term organ cultures. The nontransformed mouse calvarial osteoblastic cell line MC3T3-E1, which both enzyme-histochemically and biochemically express a significantly lower activity of alkaline phosphatase compared to primary mouse calvarial osteoblasts (indicating that the MC3T3-E1 cells may represent a preosteoblastic phenotype; Lundberg and Lerner, unpublished results), also responds to BK with a burst of prostanoid formation (Lerner *et al.*, 1989). The time course, threshold for action, and EC_{50} value are similar to those found in primary mouse calvarial osteoblasts. A very similar prostanoid response to BK is also obtained in non-enzymatically isolated human bone cells (Ljunggren *et al.*, 1990; Rahman *et al.*, 1992) and in the human osteoblastic osteosarcoma cell line MG-63 (Brechter and Lerner, 2002).

KININ RECEPTORS IN BONE CELLS

BK, Lys-BK, and Met-Lys-BK have been demonstrated to stimulate bone resorption in mouse calvariae, indicating the presence of B2 receptors (Gustafson *et al.*, 1986; Lerner *et al.*, 1987; Ljunggren and Lerner, 1988). This view is further supported by the fact that the B1 receptor antagonist des-Arg^9-[Leu^8]-BK does not affect the bone-resorptive effect of BK (Lerner *et al.*, 1987), an observation that also suggests that the effect of BK is not due to the conversion of BK by kininase-I to the B1 receptor agonist des-Arg^9-BK.

Pretreatment of BK with kininase-I does not affect BK-induced bone resorption, whereas the effect of PTH is reduced significantly (Lerner *et al.*, 1987). This observation suggests that des-Arg^9-BK, a B1 receptor agonist, may be able stimulate bone resorption. In agreement with this view, it has been shown that the addition of des-Arg^9-BK to mouse calvarial bones results in enhanced release of ^{45}Ca (Lerner *et al.*, 1987; Ljunggren and Lerner, 1990), an effect that is inhibited by the B1 receptor antagonist des-Arg^9-[Leu^8]-BK (Ljunggren and Lerner, 1990), indicating that bone cells are also equipped with B1 receptors. The effect of des-Arg^9-BK is abolished by indomethacin, flurbiprofen, and hydrocortisone. In addition, prostanoid biosynthesis in mouse calvarial bones is stimulated by des-Arg^9-BK in 72-hour cultures, but, in contrast to BK, no prostaglandin response is seen in bones incubated for 30 minutes with des-Arg^9-BK.

Using the burst of PGE_2 and 6-keto-$PGF_{1\alpha}$ biosynthesis in primary mouse calvarial osteoblasts and in the osteoblastic cell line MC3T3-E1 as parameters, the following rank order potency for different agonist has been shown: BK = Lys-BK > Met-Lys-BK >>>> des-Arg^9-BK,

demonstrating the presence of B2 receptors on these osteoblasts (Ljunggren *et al.*, 1991a). The fact that D-Arg^0-[Hyp^3, Thi^{5,8}, D-Phe^7]-BK, but not des-Arg^9-[Leu^8]-BK, inhibits the initial rise of prostaglandins induced by BK further supports the presence of B2, and not B1, receptors on mouse osteoblasts. It has been shown that the human osteosarcoma cell line MG-63 shows a prostanoid burst in response to a wide variety of natural kinins and kinin analog with affinity to BK B2 receptors. The effect of BK in these cells is inhibited by B2 receptor antagonists, but not by B1 receptor antagonists (Brechter and Lerner, 2002). These observations and the finding that [Hyp^3]-BK is a weak agonist and T-kinin is a potent agonist further indicate that osteoblasts are equipped with B2 receptors linked to a burst of prostaglandin biosynthesis. This view is also compatible with the observations that BK and D-Arg^0-[Hyp^3, Thi^{5,8}, D-Phe^7]-BK, but not des-Arg^9-BK, compete with the binding of [^{3}H]BK to osteoblasts (Ljunggren *et al.*, 1991a). Leis *et al.* (1997) have demonstrated that responsiveness to BK, specific binding of [^{3}H]BK, and mRNA expression of BK B2 receptors in subclones of the murine osteoblastic cell line MC3T3-E1 are highest in clones with low alkaline phosphatase activity, indicating that it is mainly osteoblasts at early stages of differentiation that are responsive to BK. This observation is in agreement with findings by Lerner *et al.* (1989) demonstrating that the more confluent mouse calvarial osteoblasts are in cell cultures, the less is the BK responsiveness. Using BK-sensitive MC3T3-E1 cells, it has been shown that these cells express a single category of binding sites for [^{3}H]BK (Windischhofer and Leis, 1997). Radioligand-binding assays in MG-63 cells, using [^{3}H]BK as ligand, have demonstrated specific binding sites that can be competed for by B2 receptor agonists and antagonists. The rank order potency for kinin-induced stimulation of prostaglandin formation and radioligand-binding studies strongly indicate the constitutive expression of B2 receptors in MG-63 cells, a conclusion further supported by RT-PCR analysis showing mRNA expression of B2 receptors (Brechter and Lerner, 2002).

The acute rise of prostaglandin production in osteoblasts in response to BK is preceded by an accumulation of inositol phosphates, a transient increase of intracellular calcium, and an activation of protein kinase C (Ljunggren *et al.*, 1991b, 1993; Leis *et al.*, 1997). The initial, transient rise of intracellular calcium and the sustained influx of extracellular calcium seem to be regulated by different protein kinase C isoenzymes (Sakai *et al.*, 1992). By studying BK-induced release of arachidonic acid from MC3T3-E1 cells, evidence shows that BK receptors are linked to G proteins (Yanaga *et al.*, 1991), well in agreement with cloning data. These findings suggest that activation of BK receptors leads to a phospholipase C-mediated breakdown of phosphatidylinositol 4,5-bisphosphate with subsequent formation of the two putative second messengers: inostiol 1,4,5-trisphosphate (IP3) and diacylglycerol (DAG).

In agreement with the observation in mouse calvarial bones, treatment of primary mouse calvarial osteoblasts with des-Arg^9-BK results in a delayed enhancement of PGE_2 formation that can be observed at and after 24 hours (Ljunggren and Lerner, 1990). The effect of des-Arg^9-BK is inhibited by des-Arg^9-[Leu^8]-BK, indicating that des-Arg^9-BK exerts its effect via B1 receptors. Similar observations have been made in MG-63 cells using des-Arg^9-BK, des-Arg^{10}-Lys-BK, [Tyr-Gly-Lys-Aca-Lys]-des-Arg^9-BK, and Sar[D-Phe8]-des-Arg^9-BK as agonists. Stimulation caused by these B1 receptor agonists is inhibited by a variety of B1 receptor antagonists, but not by B2 receptor antagonists. In addition, MG-63 cells display specific binding sites using [^{3}H]-des-Arg^{10}-Lys-BK as ligand and mRNA expression of human B1 receptors (Brechter and Lerner, 2002). The delay in the action of B1 receptor agonists (as compared to B2 receptor agonists) could be due to different postreceptor signal-transducing mechanisms (indicated by findings that des-Arg^9-BK does not stimulate IP3 formation, intracellular calcium, and translocation of protein kinase C) or differences in the mechanism by which prostaglandin biosynthesis is stimulated.

Kinin receptor expression is regulated during inflammation and recently we have found that B1 and B2 receptors are increased when the human osteoblastic cell line MG-63 or intact mouse calvarial bone are stimulated by either IL-1β or TNF-α, with a larger enhancement observed for B1 receptors (Brechter *et al.*, 2008). This response is most likely due to increased gene transcription because mRNA steady-state levels for both B1 and B2 mRNA were increased with no effects by IL-1β on the stability of the transcripts. Electrophoretic mobility shift assay (EMSA) analysis using oligonucleotides specific for different responsive elements in the B1 promoter showed that IL-1β and TNF-α activated both NF-κB and AP-1 in the MG-63 cells and by the use of pharmacological inhibitors we found that NF-κB activity and MAP-kinases are important for the stimulatory effect of IL-1β and TNF-α on both B1 and B2 kinin receptors. Interestingly, TNF-α activated NF-κB via the canonical pathway (p50/p65) whereas IL-1β activated NF-κB via a non-canonical pathway (p52/p65). Differences were also seen for the activation of AP-1 with c-Jun involved for both cytokines but c-Fos only for TNF-α. The stimulatory effect on kinin receptors by IL-1β and TNF-α was not shared with other osteotropic cytokines including IL-6, IL-11, IL-17, leukemia inhibitory factor (LIF), or oncostatin M (OSM).

INTERACTIONS AMONG KININS, CYTOKINES, AND NEUROPEPTIDES

Although much interest has been focused on the role of cytokines, growth factors, hormones, kinins, and neuropeptides in bone metabolism and cell activities in general, the approach has often been to study the effect of these

substances in systems in which they have been tested one by one. It is apparent that cells are exposed *in vivo* to several agonists simultaneously and therefore the ultimate cell and tissue response will be dependent on interactions among a variety of hormones, cytokines, growth factors, kinins, and neuropeptides.

The possibility that kinins may interact with cytokines is supported by the findings that BK can stimulate IL-1 and TNF production in murine macrophages (Tiffany and Burch, 1989), cytokine release in rat spleen mononuclear cells (Reissmann *et al.*, 2000), and IL-6 formation in human bone cells (Rahman *et al.*, 1992). The capacity of BK to affect cytokine production has also been demonstrated in human gingival fibroblasts; in these cells, BK does not affect IL-1 production, but potentiates the stimulatory effect of TNF on the biosynthesis of IL-1α and IL-1β (Yucel-Lindberg *et al.*, 1995). Interestingly, hyperalgesia induced by BK is blocked by the IL-1 receptor antagonist and is enhanced by antiserum neutralizing the IL-1 receptor antagonist (Cunha *et al.*, 2000). Such observations should prompt future studies on the possible role of cytokines in BK-induced bone resorption.

It has been shown that BK synergistically potentiates the stimulatory effects of IL-1α and IL-1β on bone resorption and prostanoid biosynthesis in mouse calvarial bones (Lerner, 1991). A similar interaction in mouse calvariae has also been observed between BK and TNF (Lerner *et al.*, unpublished). We have observed that several B2 receptor agonists, as well as B1 receptor agonists, synergistically potentiate IL-1- and TNF-induced biosynthesis of PGE_2 and 6-keto-$PGF_{1\alpha}$ in the human osteoblastic cell line MG-63 (Brechter and Lerner, 2007). The effect is specific for IL-1β and TNF-α because other osteotropic cytokines do not synergistically interact with BK. One important molecular mechanism involved is synergistic potentiation by kinins of IL-1β and TNF-α induced mRNA and protein expression of cyclo-oxygenase-2 due to increased gene transcription. This effect was associated with enhanced phosphorylations of the MAP-kinases p38 and JNK and was inhibited by pharmacological inhibitors of these enzymes with no effect being observed by an inhibitor of ERK. IL-1β enhanced also membrane associated prostaglandin E synthase-1 mRNA and protein, but this response was unaffected by kinins, nor were any effects by IL-1 and kinins on the mRNA expression of other prostaglandin E synthases observed. As mentioned previously, the synergistic interaction is associated also with a cytokine-induced upregulation of binding sites for B1 and B2 receptor-specific ligands. Thus, both enhanced number of kinin receptors as well as potentiation of cytokine-induced cyclo-oxygenase contribute to the synergistic enhancement of prostaglandin formation.

Osteoclast formation and activation are critically dependent on expression of receptor activator of NF-κB (RANK) in osteoclast precursor cells and its activation by RANK ligand (RANKL) in osteoclast supporting cells such as osteoblasts, bone marrow stromal cells, and T-lymphocytes (reviewed in Lerner, 2004; Takayanagi, 2007). Most interestingly, IL-1β induced enhancement of RANKL mRNA and protein was synergistically enhanced by stimulation of either B1 or B2 receptors and this response was inhibited by indomethacin (Brechter and Lerner, 2007). The enhancement of RANKL by co-stimulation with IL-1β and kinins was considerably larger than that caused by maximally effective concentration of 1,25$(OH)_2$-vitamin D3. The interaction between RANKL and RANK is inhibited by the decoy receptor osteoprotegerin (OPG). However, in contrast to 1,25$(OH)_2$-vitamin D3, which decreased OPG, no effect by IL-1β and kinins on OPG mRNA or protein was observed. These observations explain the prostaglandin-dependent potentiation of IL-1β induced bone resorption caused by kinins with affinity for the B1 and B2 receptors.

Pretreatment of human osteoblast-like cells with estrogen upregulates the subsequent stimulation of prostaglandin production induced by BK (Cissel *et al.*, 1996), suggesting the existence of steroid hormone/kinin interactions in bone.

There are indications that the skeleton may be systemically affected in patients with chronic inflammatory diseases and in rats with experimentally induced chronic inflammation (Minne *et al.*, 1984; Motley *et al.*, 1993). The systemic factor involved is not known, but could be related to the demonstration that haptoglobin, one of the acute-phase proteins induced in the liver during chronic inflammation, stimulates bone resorption in neonatal mouse calvariae (Lerner and Fröhlander, 1992). Interestingly, BK synergistically potentiates the stimulatory effect of haptoglobin on PGE_2 formation in mouse calvarial osteoblasts (Fröhlander *et al.*, 1991).

Data indicate that skeletal neuropeptides may play important roles as local mediators regulating bone metabolism (see later). The observations that (i) BK stimulates the expression of β-adrenergic receptors (Yasunaga *et al.*, 2000), (ii) BK enhances the release of calcitonin gene-related peptide (Averbeck *et al.*, 2000), and (iii) kinins participate in neurokinin-1 receptor-dependent neutrophil accumulation in inflamed skin (Cao *et al.*, 2000) raise the possibility of a link between neurohormonal- and kinin-regulated bone metabolism. Our finding that the skeletal neuropeptide VIP regulates the mRNA expression of RANKL, RANK, and OPG in mouse bone marrow cultures and isolated calvarial osteoblasts (Mukohyama *et al.*, 2000; Persson *et al.,* in preparation) and observations showing that the same neuropeptide can affect the expression of IL-6 (Persson *et al.*, 2005; Persson and Lerner, 2005) in mouse calvarial osteoblasts suggest the possibility of a neuroimmune interplay in bone cell activities.

NEURONAL INFLUENCE ON BONE TISSUE

The activities of and interactions between different bone cells are regulated by a variety of systemic hormones,

cytokines, growth factors, and inflammatory mediators. Another proposed regulatory element is the nervous system, which, through the release of neuronal messengers, has been suggested to participate in bone metabolism. Although Hohmann *et al.* (1983) reported that the neuropeptide VIP can stimulate bone resorption in mouse calvariae, it has only been since the early 1990s that the possible role of neuroactive substances in the control of bone cell activities has been appreciated. This field of interest has gained tremendously larger interest since the hypothalamic control of bone metabolism was revealed (see Chapter 5).

INNERVATION OF BONE

During the first decades of the twentieth century, the presence of nerve fibers in bone and periosteum was demonstrated using routine histological techniques (reviewed by Hurrel, 1937; Sherman, 1963). The techniques applied were useful in establishing the distribution of nerves and in discriminating between myelinated and unmyelinated nerves in bone, but the information provided was limited by morphology. Three decades ago, a breakthrough in neuroscience occurred when the immunohistochemical technique was developed and made visualization of nerves according to their transmitter content possible. Numerous neuroactive substances have been demonstrated in many different tissues, but the difficulty in bone tissue was to demineralize the bone without destroying the antigenicity of the neuro-related substances. Bjurholm *et al.* (1989) and Hill and Elde (1990) developed techniques making it possible to preserve neuroactive substances in decalcified bone specimens. Following these reports, a number of neuronal messengers and their distribution in bone have been mapped extensively.

In addition to transmitter phenotyping with immunohistochemical techniques, surgical or chemical selective denervation has established the origin of the nerves in bone (reviewed by Lundberg, 2000). Both sensory and autonomic nerve fibers are present in bone tissue. Overall, a substantial part of skeletal nerve fibers are seen along blood vessels, but blood vessel-unrelated and free nerve endings have also been demonstrated. Fibers are spread in all the cell layers of the periosteum of bone and are expressed at a higher density in the epiphysis than in the diaphysis. Small branches of periosteal nerve fibers enter the cortical bone, usually associated with blood vessels located in Volkmann canals or in haversian canals (Bjurholm, 1989; Hill and Elde, 1991a; Hukkanen *et al.*, 1992). Entering the inner compartments of bone, nerve fibers are spread in the bone marrow and richly innervate the osteochondral junction of the growth plate. Interestingly, the epiphyseal part of the growth plate is intensively supplied by peptidergic nerves, whereas the metaphyseal part is innervated more poorly (Hukkanen *et al.*, 1992; Hukkanen, 1994). By injecting green fluorescent protein and β-galactosidase expressing pseudorabies virus into the femoral bone marrow of rats and analyzing the retrograde labeling, the hierarchically organized pathways have been described with virus found in several distinct anatomical areas in the brain and the spinal cord (Dénes *et al.*, 2005).

The immunohistochemical staining of bone tissue sections has demonstrated the presence of a wide variety of neuronal messengers, including both slowly acting transmitters, so-called neuropeptides, and rapidly acting small molecules, so-called classical neurotransmitters, in bone. Presently, the neuropeptides demonstrated in bone are substance P (SP), calcitonin gene-related peptide (CGRP), neurokinin A, and pituitary adenylate cyclase activating peptide 27 (PACAP 27) and 38 (PACAP 38), mainly representing the sensory system; vasoactive intestinal peptide (VIP) and neuropeptide Y (NPY), mainly representing the autonomic system; and met-enkephalin, representing the opioid system. The classical neurotransmitters present in bone are the amines serotonin and the catecholamine noradrenaline (NA) and the excitatory amino acid glutamate (reviewed by Konttinen *et al.*, 1996; Lerner, 2000; Kreicbergs and Ahmed, 1997; Lundberg, 2000). In addition to morphological demonstrations, neuroactive substances in bone have also been quantified biochemically. A technique has been developed to extract and quantify neuropeptides in bone and joints using radioimmunoassay (RIA) (Ahmed *et al.*, 1994). Using this technique, extracts from diaphyseal rat bone tissue, periosteum, and bone marrow have been analyzed for their contents of neuropeptides. SP, CGRP, NPY, and VIP could all be quantitated at all three localizations, with NPY exhibiting the highest concentration at all sites (Ahmed *et al.*, 1994). Moreover, neurotrophic factors such as neurotrophins, known to be important factors required for the development and maintenance of the central and peripheral nerve systems, have been demonstrated in bone tissue. Neurotrophins demonstrated in bone tissue so far are nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), and neurotrophin-3 (NT-3) (Asaumi *et al.*, 2000).

A neuronal regulation of bone metabolism would not only require the presence and release of neuronal messengers in the vicinity of bone cells, but also the presence of functional receptors for such factors on bone-forming or bone-resorbing cells. Therefore, several attempts have been made to study whether different neuropeptides, neurotransmitters, and neurotrophins can affect receptor-associated functions in osteoblasts and osteoclasts.

RECEPTORS AND EFFECTS BY NEUROPEPTIDES IN BONE

Vasoactive Intestinal Peptide

VIP is a member of the growing family denoted VIP/secretin/glucagon family of neuropeptides, which also includes

the structurally related peptides secretin, gastric inhibitory peptide, growth hormone-releasing hormone, peptide histidine isoleucine amide (PHI), PACAP 27 and 38, and the reptilian venom peptides helodermin, helospectin, and exendine.

VIP was first discovered as a vasodilator peptide (Said and Mutt, 1969). Isolation of VIP from porcine gut (Said and Mutt, 1970) revealed an amidated 28 amino acid peptide (Mutt and Said, 1974). VIP is a cleavage product of the 170 amino acid precursor pre-pro VIP, which also is the parent molecule of PHI (Itoh *et al.*, 1983). Using RIA and the immunofluorescence technique, VIP immunoreactivity was discovered in many tissues outside the gastrointestinal tract. In 1976, the finding of VIP in the brain and in peripheral nerves (Said and Rosenberg, 1976) introduced VIP as a neuropeptide.

VIP has been investigated extensively, and a broad range of biological actions has been ascribed to this peptide, both in animal and in human studies. Important actions of VIP in the cardiovascular (Henning and Sawmiller, 2001), reproductive (Fahrenkrug, 2001), pulmonary (Groneberg *et al.,* 2006), immune (Voice *et al.,* 2002; Delgado *et al.,* 2004), and gastrointestinal systems (Schuttleworth and Keef, 1995) have been reviewed. General physiologic effects encompass vasodilatation, bronchodilatation, immunosuppression, hormonal secretion, and increases in gastric motility. In the nervous system, VIP seems to participate in neuronal survival, maturation, and maintenance (reviewed by Gozes and Brenneman, 1993).

VIP is widely distributed in both the central (CNS) and the peripheral nervous systems (PNS). In the brain, VIP immunoreactive neurons are found in the hypothalamus and the cerebral cortex (Hökfelt *et al.*, 1982). In the PNS, VIP immunoreactive nerves, nerve plexus and terminals supplying blood vessels, nonvascular smooth muscles, glandular acinis, and ducts, in a variety of organs, have been described (Hökfelt *et al.*, 1982). VIP immunoreactivity is detected in nerve fibers with both sympathetic and parasympathetic origin and, to a minor extent, in sensory nerve fibers.

In 1986, Tashijan and colleagues initially demonstrated VIP immunoreactive (IR) nerve fibers in bone tissue (Hohmann *et al.*, 1986). VIP-IR nerve fibers with a postganglionic sympathetic origin were localized in the periosteum, associated with vascular elements of bones from different species. In a large study of neuropeptide expression in rat bone nerve fibers, Bjurholm *et al.* (1988a, 1988b) detected VIP-IR nerve fibers preferentially in the periosteum and the epiphysis. These VIP-IR nerve fibers, whose origins are uncertain, were only occasionally associated with blood vessels. In line with these data, Hill and Elde (1991a) also demonstrated VIP-IR in rat periosteum. These nerves were only partially associated with vascular elements. VIP, NPY, and dopamine-β-hydroxylase (DβH) immunoreactive nerves were reduced dramatically in guanethidine-treated animals, strongly indicating a sympathetic origin of theses nerves (Hill and Elde, 1991b).

Tashjian and coworkers provided the first *in vitro* evidence for functional neuropeptide receptors on bone cells, demonstrating that VIP stimulates calcium release in neonatal mouse calvariae (Hohmann *et al.*, 1983). In osteoblasts, the presence of functional receptors for VIP, linked to enhanced formation of cyclic AMP, has been demonstrated in a human osteosarcoma cell line (Saos-2) (Hohmann and Tashjian, 1984; Bjurholm *et al.*, 1992; Lerner *et al.*, 1994), in the rat osteosarcoma cell line UMR 106–01 cells, but not in rat osteosarcoma cell line ROS 17/2.8 cells (Bjurholm *et al.*, 1992; Lerner *et al.*, 1994). In addition, VIP has been found to stimulate cyclic AMP formation in isolated mouse calvarial osteoblasts and in the cloned, nontransformed, osteoblastic cell line MC3T3-E1 (Bjurholm *et al.*, 1992; Lerner *et al.*, 1994).

Since the early 1990s, three different subtypes of VIP receptors have been cloned. These receptors are designated VPAC1, VPAC2, and PAC1 (reviewed in Laburthe *et al.*, 2002). They are all seven transmembrane, G protein-coupled receptors and members of the VIP/secretin/PTH receptor superfamily. All three receptors are distributed in both the CNS and the PNS and can be distinguished by comparing their relative adenylate cyclase activating capacities and by radioligand-binding assays. PAC1 binds PACAP with a much higher affinity (100- to 1,000-fold) than VIP. VPAC1 and VPAC2 bind PACAP and VIP with similar affinities. The fact that VPAC1 binds secretin, and VPAC2 does not, can be used to distinguish between these two VIP receptors.

We have characterized the VIP-binding receptors in mouse calvarial osteoblasts. By comparing the rank order of response of peptides in the VIP/secretin/glucagon family on cyclic AMP formation, we found that PACAP 38 was tenfold more potent than VIP (Lundberg *et al.*, 2001). A similar tenfold difference in potency between PACAP and VIP has also been detected in the rat osteoblast-like tumor cell line UMR 106 (Kovacs *et al.*, 1996) and in the nontransformed murine calvarial cell line MC3T3-E1 (Susuki *et al.*, 1994). By comparing the relative potency of VIP and related peptides to displace ^{125}I-PACAP binding, we found a rank order of response similar to that obtained when cyclic AMP enhancement was quantified. The fact that PACAP-preferring VIP receptors do not bind secretin was confirmed by demonstrating that secretin did not elevate cyclic AMP levels and failed to displace ^{125}I-VIP or ^{125}I-PACAP 38 binding. Using atomic force microscopy (AFM), a novel technique modified to detect specific binding sites on cell surfaces, we have demonstrated specific binding of VIP, but not secretin, on mouse calvarial osteoblasts. Reverse transcriptase PCR further demonstrated that these undifferentiated osteoblasts express mRNA for VPAC2, but not for VPAC1 or PAC1. When these osteoblasts were cultured for 20 days to induce bone noduli formation, VPAC1, in addition to VPAC2, were expressed when the nodules started to mineralize at 12 days

(Lundberg *et al.*, 2001). Taken together, these data demonstrate that mouse calvarial osteoblasts express functional VPAC2, with higher affinity binding for PACAP than for VIP, and that VPAC1 expression is induced during osteoblastic differentiation. Information on mRNA expression of VIP/PACAP receptors in osteoblasts is limited to the observations in mouse calvarial osteoblasts and to a report by Togari *et al.* (1997), demonstrating that primary human osteoblasts and human osteosarcoma cell lines express VPAC1, but not VPAC2 or PAC1. The observed differences in VIP receptor expression in mouse and human osteoblasts may be a matter of differentiation discrepancies, although it cannot be excluded that it is due to species differences.

Interestingly, a differentiation-dependent manner of receptor expression in mouse osteoblasts is not only observed for VIP receptors, but also for vascular endothelial growth factors (VEGF) and their receptors in mouse osteoblasts (Deckers *et al.*, 2000). A role for VEGF in endochondral bone formation has been proposed because inactivation of VEGF inhibits endochondral bone formation via inhibition of angiogenesis (Gerber *et al.*, 1999). Therefore, the increased expression of VEGF receptors and their ligands during osteoblastic differentiation and mineralization supports the theory that VEGF plays an important role in the regulation of bone metabolism. The role of VPAC1 induction during osteoblastic differentiation remains to be elucidated. In contrast to differentiation-induced upregulation of VPAC1 and VEGF receptors, the expression of glutamate transporter in rat osteoblasts declines when mineralization starts in rat osteoblast cultures (Bhangu *et al.*, 2000).

Whether VIP receptors on osteoblasts are coupled to anabolic actions of VIP has been evaluated *in vitro* using mouse calvarial osteoblasts (Lundberg *et al.*, 1999). After six days of culture, VIP stimulates activity of the bone mineralization-associated enzyme alkaline phosphatase (ALP), and the mRNA expression of this enzyme, without affecting cell proliferation. The ALP-staining pattern in histochemical analysis demonstrated that VIP, to a minor extent, increased the number of ALP-stained cells, but mainly increased the staining of individual cells. These morphological analyses suggest that VIP treatment causes an increased differentiation of committed osteoblasts. In line with this, we found that VIP initially causes an increased accumulation of calcium in osteoblast cultures during the formation of mineralized bone nodules, but does not change the total amount of calcium found at the end of the culture. The fact that VIP stimulates ALP activity at six days of culture, a time point when only VPAC2 are expressed (Lundberg *et al.*, 2001), together with the absence of effect by secretin on ALP activity, clearly suggest that VPAC2 receptors mediate the anabolic events in bone caused by VIP. Whether VPAC1 may mediate similar bone-forming effects has to be ascertained.

The first documented *in vitro* effect of a neuropeptide on bone was that of Tashjian and coworkers, demonstrating a catabolic effect by VIP on bone metabolism (Hohmann *et al.*, 1983). Thus, VIP stimulated calcium release in organ-cultured mouse calvarial bones. This stimulation of calvarial bone resorption by VIP may be due either to enhanced activity of osteoclasts or to stimulation of osteoclast formation.

Morphological studies of isolated rat osteoclasts revealed that VIP treatment caused a rapid cytoplasmic contraction along with an associated decrease in motility (Lundberg *et al.*, 2000). Functional studies using an *in vitro* resorption assay showed that VIP caused a transient inhibition of osteoclastic bone resorption. When the osteoclast incubations were extended over time and performed in the presence of marrow-derived stromal cells/osteoblasts, the osteoclasts escaped from the initial inhibition and VIP caused a delayed stimulation of osteoclastic pit formation in bone slices. Similar to VIP, the initial inhibitory effect of calcitonin (CT) was lost over time. However, in contrast to VIP, CT-treated osteoclasts never start to resorb bone more than unstimulated controls. The finding of inhibitory effects, both on osteoclast morphology and on resorptive capacity, suggests that osteoclasts are equipped with VIP receptors and that VIP might be acting directly on osteoclasts.

In order to localize binding sites for VIP on osteoclasts, we took advantage of the newly developed AFM technique. Using AFM and measurements of intracellular calcium, specific VIP-binding sites on osteoclasts were found (Lundberg *et al.*, 2000). Further evidence for the presence of VIP receptors in osteoclasts is our finding of mRNA for VPAC1 and PAC1 in mouse bone marrow osteoclasts isolated by micromanipulation (Ransjö *et al.*, 2000). The late stimulatory effect of VIP is probably the basis of the finding that VIP stimulates resorption in calvarial organ culture (Hohmann *et al.*, 1983). When AFM was used to analyze the presence of VIP receptors in stromal cells/osteoblasts, we found that approximately 20% of the stromal cells/osteoblasts expressed specific binding sites for VIP. This was supported further by the observation that these cells also responded to VIP with a rapid enhancement of intracellular calcium (Lundberg *et al.*, 2000). These receptors might mediate the indirect bone-resorbing effect caused by VIP, both in the resorption pit assay and in the calvariae.

VIP has been reported to stimulate IL-6 production in stromal cells (Cai *et al.*, 1997) and in an osteosarcoma cell line (Greenfield *et al.*, 1996). We have confirmed these observations using mouse calvarial osteoblast. VIP was shown to stimulate IL-6 production in both time- and concentration-dependent manner (Persson *et al.*, 2005). Furthermore, VIP caused enhanced IL-6 promoter activity in cells from the osteoblastic cell line MC3T3-E1 transfected with an IL-6 promoter construct coupled to a luciferase reporter gene. By using several techniques,

including electrophoretic mobility shift assay (EMSA), we also showed that the effects by VIP on IL-6 production involved several intracellular pathways. Treatment of osteoblasts with VIP resulted in activation of the cyclic AMP/PKA pathway and increased DNA binding of the transcription factor C/EBP, whereas the DNA binding of the AP-1 complex was decreased by VIP. In contrast, our results indicated that regulation by VIP of IL-6 synthesis did not require activation of the NF-κB pathway (Persson *et al.*, 2005). In addition to the studies on involvement of different intracellular pathways in VIP signaling, we also evaluated which receptor type is responsible for the effects on IL-6 production. Besides VIP, PACAP-38 was also shown to increase IL-6 synthesis, whereas secretin did not have any effect, indicating that the effects by VIP and PACAP-38 are mediated by VPAC2 (Persson *et al.*, 2005).

VIP is a well-known regulator of inflammatory cytokine production in several cell types (reviewed in Delgado *et al.*, 2004). Having shown the stimulatory effects by VIP on IL-6 production in murine osteoblasts, we addressed the question whether VIP may interact with known osteotropic cytokines to regulate the IL-6 production in these cells. Indeed, VIP was found to increase the stimulatory effect by IL-1β, IL-11, IL-17, LIF, OSM, and TGF-β on IL-6 production in a synergistic manner (Persson and Lerner, 2005). In addition, VIP also potentiated the IL-1β-induced stimulation of IL-6 promoter activity in osteoblastic MC3T3-E1 cells transfected with the IL-6 promoter/luciferase construct (Persson and Lerner, 2005).

The stimulation of bone resorption by VIP in organ-cultured mouse calvariae can be explained either by an effect on osteoclast activity or by an effect on osteoclast formation. When osteoclastogenesis was studied in mouse bone marrow cultures, VIP did not enhance the number of osteoclasts (Mukohyama *et al.*, 2000). In contrast, VIP caused an inhibition of osteoclast formation induced either by 1,25$(OH)_2$ vitamin D_3 or by PTH. The anti-osteoclastogenic effect of VIP is associated with inhibitory effects on the 1,25$(OH)_2$ vitamin D_3-induced upregulation of RANK (receptor activator of NF-κB) and RANK ligand (RANKL). In addition, VIP counteracts the decrease of osteoprotegerin (OPG) caused by 1,25$(OH)_2$ vitamin D_3 (Mukohyama *et al.*, 2000). In summary, VIP inhibits osteoclast formation, probably by regulating the expression of RANK, RANKL, and OPG, three molecules known to be important for osteoclast formation. The fact that VIP stimulates osteoclast activity and inhibits osteoclast recruitment suggests that VIP may have a unique role in bone metabolic processes by acting as a fine-tuner of osteoclastic resorption.

In addition to the effects by VIP on bone cell function, recent studies have demonstrated that VIP also has a protective effect on bone destruction in experimentally induced arthritis. Treatment of mice exhibiting collagen-induced arthritis (CIA) with VIP resulted in delayed onset, reduced incidence, and decreased severity of the arthritis, as well as a dramatic decrease of cartilage damage and bone erosion in arthritic joints (Delgado *et al.*, 2001). In addition, VIP decreased levels of IL-1β, IL-6, IL-11, IL-17, and TNF-α, whereas the levels of IL-4 and IL-10 were elevated. VIP also decreased the RANKL/OPG ratio, mainly as a result of increased levels of circulating OPG (Juarranz *et al.*, 2005). In contrast to the effects of VIP on bone cell function and production of osteotropic cytokines by these cells, the effects seen in the arthritis models are believed to be a result of a neuroimmunomodulatory interaction, where VIP regulates the proliferation and differentiation of T lymphocytes, as well as pro-inflammatory cytokine production by T lymphocytes, macrophages, and fibroblasts in the synovial tissue. These findings suggest that VIP, in addition to the effects on bone cell function, may also have a possible role as a therapeutic target for treatment of arthritis.

Pituitary Adenylate Cyclase-Activating Peptide

PACAP was first isolated from ovine hypothalamus and described on the basis of its ability to increase adenylate cyclase activity in rat pituitary cells (Miayata *et al.*, 1989). PACAP occurs in two molecular forms: the 38 amino acid peptide PACAP 38 and the C-terminally truncated form PACAP 27. Both forms of PACAP share 68% amino acid homology with VIP at their N-terminal domains (reviewed by Arimura, 1991, 1992).

In addition to exhibiting extensive molecular similarities to VIP, PACAP partially shares receptors as well as functions with VIP. PACAP has been shown to be a pleiotropic neuropeptide, functioning as a hypothalamic hormone, neurotransmitter, neuromodulator, vasodilator, and a neurotropic factor. Examples of endocrine functions by PACAP are numerous. PACAP (i) stimulates the secretion of adrenaline from the adrenal medulla, (ii) stimulates insulin release from pancreatic β cells, and (iii) causes an increase of $[Ca^{2+}]_i$ in pancreatic β cells. One important developmental biological action of PACAP seems to be as a neurotrophic factor during the development of the brain (reviewed by Arimura, 1998).

PACAP immunoreactivity is detected in nearly all organs and tissues. In the brain, the highest concentration is found in the hypothalamus. In the PNS, the adrenal medulla and testis contain the highest concentrations of PACAP immunoreactivity when compared to those found in the gut and the adrenal gland. PACAP 38 is the predominant form in tissues, making up 90% of the total PACAP (reviewed by Arimura, 1998).

PACAP 27 and PACAP 38 have been demonstrated in cartilage channels in tissue sections from pigs (Strange-Vognsen *et al.*, 1997). Varicose PACAP immunoreactivity

fibers were demonstrated in association with blood vessels. Nearly all PACAP immunoreactive fibers contain CGRP and SP, suggesting that these are sensory nerve fibers (Strange-Vognsen *et al.*, 1997).

In mouse calvariae and in mouse calvarial osteoblasts, the presence of functional receptors for PACAP 27 and PACAP 38, linked to the enhanced formation of cyclic AMP, has been demonstrated (Lerner *et al.*, 1994). As described earlier (see VIP), VIP and PACAP share receptors. In addition to VPAC1 and VPAC2, which bind VIP and PACAP with equal affinity, several reports describe the cloning of a high-affinity PACAP receptor (PAC1). PAC1 was, within a year, cloned from rat, human (Ogi *et al.*, 1993), and bovine tissues (Miyamoto *et al.*, 1994). Moreover, PAC1 was demonstrated to exist in six splice variant forms (Svoboda *et al.*, 1993; Journot *et al.*, 1995). PACAP is 100- to 1,000-fold more potent than VIP in binding and stimulating adenylate cyclase activity in cells transfected with PAC1 (Rawlings and Hezareh, 1996). PAC1 has a widespread distribution in the CNS, with the highest levels being found in the olfactory bulb, the dental gyrus of hippocampus, pituitary, cerebellum, thalamus, and hypothalamus. Messenger RNA for PAC1 has been detected in a variety of tissues, including liver, lung, spleen, and intestine (reviewed by Christophe, 1993; Arimura, 1992; Arimura and Shioda, 1995).

Concerning skeletal cells, the presence of PAC1 and VPAC1 mRNA has been demonstrated in microisolated mouse marrow osteoclasts (Ransjö *et al.*, 2000). Using an AFM technique, both VIP and PACAP 38 showed high-affinity binding to rat marrow osteoclasts (Lundberg *et al.*, 2000). If rat osteoclasts express the same VIP/PACAP receptor subtypes as mouse osteoclasts is unknown. However, our preliminary observations that PACAP 38, as well as VIP and secretin, causes a decrease in isolated rat osteoclastic bone resorption, indicate that VPAC1 may have a functional role in the regulation of osteoclast function. Whether PAC1 also has a functional role in the rat osteoclasts is not known.

Similar to VIP, PACAP 38 inhibits $1,25(OH)_2D_3$-stimulated osteoclastogenesis in mouse bone marrow cultures (Mukohyama *et al.*, 2000). PACAP 38 also decreases RANKL and RANK expression and increases OPG in these bone marrow cultures.

Calcitonin Gene-Related Peptide

Calcitonin gene-related peptide (CGRP) is a 37 amino acid peptide belonging to a superfamily of peptides including CT, α-CGRP, β-CGRP, amylin (AMY), adrenomedullin (ADM), and the recently discovered intermedin (IMD) and calcitonin receptor-stimulating peptide (CRSP; reviewed in Lerner, 2006c). One domain of the insulin β chain also shares homology with these peptides, indicating that they may have diverged from a common ancestral gene during evolution. α-CGRP is produced by tissue-specific alternative splicing of the initial gene transcript encoding the precursor for CT. Consequently, α-CGRP is produced, not only in nerve fibers, but also in thyroid parafollicular C cells, together with CT. However, α-CGRP and CT seem not to be released in parallel, probably due to the fact that plasma levels of α-CGRP have a neurogenic origin. AMY is expressed predominantly in pancreatic β cells, whereas ADM is synthesized in several different tissues and is released from endothelial cells. IMD, initially identified from human and zebrafish expressed sequence tags and using a phylogenetic profiling approach also found in other mammals and teleosts (Roh *et al.*, 2004) has been found to be expressed in the pituitary and gastrointestinal tract. IMD was also in parallel cloned in the pufferfish, *Takifugo ribripes* (Takei *et al.*, 2004), and genome-wide analyses in mammalians and teleosts have indicated that five paralogous family genes in humans – *CT, CGRP, AMY, ADM,* and *IMD* – evolved before the emergence of vertebrates and that multiple copies of these coevolved genes are present in teleost genomes (Chang *et al.*, 2004). CRSP has been identified from porcine, pig, bovine, and canine cDNA libraries but not yet in rat and human (Katafuchi and Minamino, 2004). CGRP, AMY, IMD, and CRSP all have an amino-terminal ring created by a disulfide bond; this is lacking in adrenomedullin, which has a linear amino-terminal extension.

CT, CGRP, AMY, and ADM act via related heptahelical receptors. Whereas a CT receptor was cloned already in 1991 (Lin *et al.*, 1991), the receptors for CGRP, AMY, and ADM have been more elusive. CGRP and ADM both bind to a CT receptor-like receptor (CRLR), originally described as an orphan seven transmembrane receptor. Interestingly, CRLR requires interaction with single transmembrane proteins called receptor activity-modifying proteins (RAMP; Foord and Marshall, 1999). Three different RAMPs (RAMP1, RAMP2, and RAMP3) have been cloned and sequenced and found to be expressed in a wide variety of tissues. Cotransfection of CRLR and RAMP1 results in CGRP responsive receptors, whereas cotransfection of CRLR and RAMP2, or RAMP3, leads to expression of ADM responsive receptors (Bühlmann *et al.*, 1999). RAMPs are expressed more abundantly than CRLR, suggesting that RAMPs could be involved in the regulation of other receptors than CRLR. Interestingly, RAMP1, or RAMP3, cotransfection with a CT receptor results in a high-affinity AMY receptor (Muff *et al.*, 1999). The expression of CRLR mRNA and protein have been found in rat and mouse calvarial osteoblasts, and in the rat and mouse osteoblastic cell lines UMR 106-06 and MC3T3-E1 (Pondel, 2000; Uzan *et al.*, 2004, Schinke *et al.*, 2004; Granholm and Lerner, unpublished observations) as well as in multinucleated mouse osteoclasts (Nakamura *et al.*, 2005) and in mononucleated osteoclast precursor cells Granholm *et al.*, 2008). Nakamura *et al.* (2005) reported that mouse multinucleated osteoclasts express RAMP2 mRNA,

but not RAMP1 and RAMP3. We have found that mouse mononucleated osteoclast precursor cells from bone marrow express all three RAMPs both at the mRNA and protein level (Granholm *et al.*, 2007).

Receptors for CGRP, as assessed by a cyclic AMP response, have been demonstrated on the rat osteosarcoma cell line UMR 106–01 (but not on ROS 17/2.8), the human osteosarcoma cell line Saos-2, the mouse calvarial osteoblastic cell line MC3T3-E1, and enzymatically isolated osteoblastic cells from chick, rat, and mouse (Michelangeli *et al.*, 1986, 1989; Thiebaud *et al.*, 1991; Bjurholm *et al.*, 1992). Expression of receptors for CGRP seems to be a feature of the osteoblastic phenotype, as the degree of cyclic AMP formation in primary osteoblasts correlates with the activity of alkaline phosphatase and to the responsiveness to PTH (in terms of cyclic AMP formation; Michelangeli *et al.*, 1989). Using RT-PCR, CGRP receptors have been demonstrated in human periosteum-derived osteoblastic cells and in human osteosarcoma cell lines (Togari *et al.*, 1997). The presence of receptors recognizing AMY and ADM in osteoblasts is suggested by the observations that amylin stimulates cyclic AMP formation and that both peptides stimulate [^{3}H]thymidine incorporation into osteoblasts (Tamura *et al.*, 1992; Cornish *et al.*, 1995, 1997).

CGRP receptors are coupled to the stimulation of osteoblast proliferation and enhanced bone colony formation *in vitro* (Shih and Bernard, 1997a; Cornish *et al.*, 1999). An anabolic effect of CGRP *in vivo* is demonstrated by the findings that the targeted expression of calcitonin gene-related peptide to osteoblasts, under the control of the osteocalcin promoter, results in enhanced trabecular bone density, trabecular bone volume, and increased bone formation rates in mice (Ballica *et al.*, 1999). The same group has also reported that injection of CGRP into ovariectomized rats can partly prevent the bone loss caused by estrogen deficiency (Valentijn *et al.*, 1997).

Occupancy of AMY receptors in osteoblasts stimulates anabolic activities both *in vitro* and *in vivo*. Thus, AMY stimulates cell proliferation in osteoblast cell cultures (Cornish *et al.*, 1995, 1998; Villa *et al.*, 1997); AMY is more potent than CGRP but seems to act via a common CGRP/AMY receptor (Cornish *et al.*, 1999). Treatment of mice or rats with AMY leads to enhanced trabecular bone volume as a consequence of both increased trabecular thickness and number (Romero *et al.*, 1995; Cornish *et al.*, 1998). The increase of bone volume can also be achieved by injection of the amino-terminal fragment amylin 1–8, although the effect is less than that obtained by full-length amylin (Cornish *et al.*, 2000). Treatment with amylin leads to enhanced mechanical bone strength (Cornish *et al.*, 2000).

The stimulatory effects of CGRP and AMY on osteoblast cell proliferation are shared by ADM, which in fact is more potent than the other two peptides (Cornish *et al.*, 1997).

The interest of CGRP in bone resorption was initially prompted by the findings that CGRP shows amino acid sequence homology to CT in the amino-terminal region and that CGRP is costored with CT in thyroid C cells. Injection of CGRP into rats and rabbits causes a hypocalcemic reaction (Tippins *et al.*, 1984; Roos *et al.*, 1986). The fact that CGRP inhibits bone resorption in fetal rat long bones (Roos *et al.*, 1986; Tamura *et al.*, 1992) and in neonatal mouse calvariae (Yamamoto *et al.*, 1986) indicates that the decrease of serum calcium in intact animals is due to CGRP-induced inhibition of bone resorption. In the mouse calvarial system, rat β-CGRP is slightly more potent than rat α-CGRP, which is slightly more potent than human CGRP (Lerner, unpublished results). Similar to CT, the effect of CGRP is transient in both fetal rat long bones and in neonatal mouse calvariae (Roos *et al.*, 1986; Lerner, unpublished results). Inhibition of bone resorption can be due to inhibition of osteoclast activity and/or recruitment. An inhibitory effect of osteoclast activity has been observed in isolated rat osteoclasts as assessed by decreased pit formation (Zaidi *et al.*, 1987a, 1987b). In this system, α-CGRP and β-CGRP are equipotent. The hypocalcemic effect of CGRP, as well as the inhibitory effects on bone resorption in organ culture and on osteoclastic pit formation, is mimicked by AMY (Datta *et al.*, 1989; MacIntyre, 1989; Zaidi *et al.*, 1990; Tamura *et al.*, 1992; Pietschmann *et al.*, 1993). Interestingly, ADM, for reasons unknown, does not inhibit PTH-stimulated bone resorption in neonatal mouse calvariae (Cornish *et al.*, 1997; Lerner *et al.*, unpublished results).

Calcitonin-induced inhibition of bone resorption by isolated rat osteoclasts is associated with increased levels of intracellular Ca^{2+} and cyclic AMP, as well as with retraction and ceased motility of osteoclasts (Alam *et al.*, 1992a). At variance, inhibition caused by CGRP and AMY is associated with enhanced cyclic AMP and ceased motility, but not with increased intracellular Ca^{2+} and retraction (Alam *et al.*, 1991, 1992a, 1992b). These observations have prompted the speculation that the effects of CT are mediated via two separate receptors and that CGRP and AMY act only via one of these receptors (the one linked to cyclic AMP and motility). Further support for this hypothesis are the observations that CGRP 8–37 (i) inhibits the effects of AMY and CGRP on motility and (ii) inhibits the effect of CT on motility, but not on retraction. This would imply that retracted osteoclasts are still capable of motility. In contrast, Cornish *et al.* (1998) could not observe any antagonistic effect by CGRP 8–37 (or AMY 8–37) on the AMY-induced inhibition of bone resorption in neonatal mouse calvariae (an observation confirmed in the authors' laboratory), although the antagonists blocked the stimulatory effect by AMY on cell proliferation in the calvarial bones. The issue of which receptors in osteoclasts (CT receptor, CRLR/RAMP1, CRLR/RAMP2, CRLR/RAMP3) are used by CGRP (and AMY) and how these receptors

are linked to the mechanism causing inhibition of bone resorption still remains an open question. The observation made by Cornish *et al.* (1998) indicates that separate AMY receptors are present on osteoblasts and osteoclasts.

The degree of bone loss is not only dependent on osteoclast activity but also on osteoclast formation. Very few studies deal with effects of peptides in the CT family on osteoclastogenesis. CT has been reported to inhibit osteoclast formation in PTH stimulated feline marrow-derived mononuclear cell cultures (Ibbotson *et al.*, 1984) as well as D3 stimulated osteoclastogenesis in primate marrow cell cultures (Roodman *et al.*, 1985) and mouse bone marrow cultures (Cornish *et al.*, 2001). Also AMY and CGRP inhibited D3 stimulated osteoclast formation in the mouse bone marrow system. Recently, it has been found that CGRP can inhibit isoproterenol-induced osteoclast formation in mouse bone marrow cultures without affecting isoproterenol-stimulated RANKL mRNA expression, indicating that the effect was due to an effect directly on osteoclast precursor cells (Ishizuka *et al.*, 2005). CRSP-1 has been reported to decrease osteoclast formation in mouse bone marrow and spleen cell cultures stimulated by M-CSF and RANKL (Notoya *et al.*, 2007), further supporting the view that the effect is directly on osteoclast precursor cells. We have been able to demonstrate that CT acts directly on highly purified osteoclast precursor cells stimulated by M-CSF/RANKL and, interestingly, the inhibitory effect on osteoclast formation is independent on c-Fms and RANK-induced transcription of very many osteoclast genes involved in differentiation, fusion, and function (Granholm *et al.*, 2007).

Deletions of the genes for ligands in the CT family of peptides and for one of the receptors have revealed unexpected findings that have changed our view on the role of these peptides in bone remodeling. Because CT is such a well-known inhibitor of bone resorption *in vitro* and *in vivo*, it was assumed that deletions of the *CT/α-CGRP* and *CTR* genes would lead to bone loss. Surprisingly, it was found that *CT/α-CGRP*$^{-/-}$ and *CTR*$^{+/-}$ mice have increased bone mass due to increased bone formation (Hoff *et al.*, 2002; Dacquin *et al.*, 2004). *CT/α-CGRP*$^{-/-}$ mice have normal serum calcium and exhibit enhanced bone mass due to increased trabecular bone volume in both vertebral bodies and tibias. The histomorphometric analysis showed that *CT/α-CGRP*$^{-/-}$ mice had increased trabecular number. The number of osteoblasts was not affected by deletion of the *CT/α-CGRP* gene, but dynamic histomorphometry, using calcein double labeling, showed a 1.5- to 2-fold enhancement of bone formation rate. Interestingly, *CT/α-CGRP*$^{-/-}$ mice were resistant to ovariectomized-induced osteopenia because of increased bone formation rate. Confirming that lack of CT signaling via CTR leads to enhanced bone mass, it has recently been reported that heterozygous *CTR* knockout mice also exhibit increased bone mass due to enhanced bone formation rate (Dacquin *et al.*, 2004). It is not likely that the enhanced bone formation is caused by a lack of an inhibitory effect by CT or *α-CGRP* on osteoblasts, because the CTR is not expressed on osteoblasts and mice with a selective deletion of *α-CGRP* have low bone mass (Schinke *et al.*, 2004).

Because CTR are also present in the brain (Sexton, 1992), and because the CNS has been found to be able to regulate bone remodeling (see earlier discussion), it cannot be ruled out that the skeletal phenotype in *CT/α-CGRP*$^{-/-}$ mice is mediated by the CNS. Mapping of CTR in the brain has demonstrated the expression of CTR in very many areas, but, interestingly, ventromedial, lateral, and posterior hypothalamus are three sites in which expression of immonoreactive CTR has been observed (Becskei *et al.*, 2004).

Although it remains to be proven that it is the role of α-CGRP as a signaling molecule in skeletal nerve fibers that causes the skeletal phenotype in α-CGRP deficient mice, it is most likely the explanation. It should, however, be kept in mind that *α-CGRP*$^{-/-}$ mice still express β-CGRP and it will be interesting to know which will be the phenotype of *β-CGRP*$^{-/-}$ mice and of *α-CGRP*$^{-/-}$/*β-CGRP*$^{-/-}$ mice. It was recently shown that capsaicin treatment destroys the unmyelinated sensory axons expressing CGRP and that the reduced CGRP signaling was associated with decreased bone mass (Offley *et al.*, 2005), similar to patients with familial dysautomia, which lacks unmyelinated sensory neurons and exhibits decreased bone mass and increased fracture rate.

Under certain experimental conditions, the deletion of the *CT/α-CGRP* gene resulted in, as expected, increased bone resorption. Thus, *CT/α-CGRP*$^{-/-}$ mice showed significantly higher serum calcium after injection of either PTH or 1,25$(OH)_2$-vitamin D3, a response that could be reversed by CT, but not by α-CGRP (Hoff *et al.*, 2002).

Mice with deletion of the AMY gene, in contrast to *CT/α-CGRP*$^{-/-}$ and *CTR*$^{+/-}$ mice, exhibit bone loss due to enhanced bone resorption (Dacquin *et al.*, 2004). The low bone mass in amylin-deficient mice was observed after 12 weeks of age, but not earlier and was caused by decreased trabecular and cortical thickness. The loss of bone was not associated with any change in osteoblast number, or bone formation rate *in vivo*, nor in any differences in alkaline phosphatase activity, biosynthesis of type I collagen, and mineralization of bone noduli *in vitro*. In line with the observations that amylin can inhibit bone resorption *in vitro*, the urinary excretion of deoxypyridinoline was significantly enhanced already at 8 weeks of age and persisted at least for 24 weeks, which indicates that AMY deficiency leads to enhanced bone resorption, which was supported by the observation that osteoclast number was enhanced 1.6-fold.

These data suggest that CT may be a regulator of bone formation, wheras AMY might be a more physiological regulator of bone resorption. It is apparent that our understanding of the role of the CGRP and other members of the CT family of peptides has been changed dramatically and

much more data have to be gained before we fully understand the roles these peptides have in bone biology.

Substance P

The knowledge about the role of Substance P (SP) in bone is very limited. Neurokinin-1 (NK-1) and NK-2, but not NK-3, receptors recognizing SP have been immunolocalized in rat bone osteoblasts and osteocytes (Goto *et al.*, 1998; Fristad *et al.,* 2003). Osteogenesis, as assessed by bone colony formation in bone marrow cell cultures and in rat calvarial osteoblasts, can be stimulated by SP (Shih and Bernard, 1997b; Goto *et al.,* 2007). Interestingly, the NK-1 receptors were not expressed initially in the osteoblast cultures but induced during culture (day 14). The enhanced bone formation in rat osteoblasts was associated with increased expression of osteocalcin, runx2/cbfa1, and type I collagen. For reasons not understood, Azuma *et al.* (2004) report contrasting data showing that SP decreases the mRNA expression of alkaline phosphatase, bone sialoprotein, osteocalcin, and runx2 in fetal rat calvarial osteoblast cultures.

The abundance of NK-1 receptors in rat bone osteoclasts (Goto *et al.*, 1998) can be reconciled with observations that SP causes an acute rise of intracellular Ca^{2+} in rabbit osteoclasts and an increased pit area (but not an increase of pit number) excavated by osteoclasts when incubated on dentine slices (Mori *et al.*, 1999). The effects were blocked by two different NK-1 receptor antagonists. These observations indicate that SP may stimulate osteoclast activity by a direct effect on terminally differentiated osteoclasts. It has recently been shown that SP can stimulate osteoclast formation in mouse bone marrow cultures stimulated by M-CSF/RANKL and that this effect is associated with enhanced translocation of NF-κB to the nuclei (Sohn, 2005). SP not only can directly affect osteoclast progenitor cells but also indirectly stimulate osteoclastogenesis by enhancing the expression of RANKL and decreasing that of OPG in rat synovial fibroblasts (Matayoshi *et al.,* 2005). Coculture of SP stimulated synovial fibroblasts with rat blood monocytes resulted in enhanced osteoclast formation. Most interestingly, SP-deficient mice exhibit decreased bone loss and significantly fewer osteoclasts in the calvariae of mice locally treated with polyethylene particles (Wedemeyer *et al.,* 2007), in accordance with the *in vitro* findings, indicating that SP is a stimulator of osteoclastic bone resorption.

Neuropeptide Y

NPY mediates its action through the activation of five Y receptor subtypes (Y1, Y2, Y4, Y5, and in mouse, y6), which differ not only in their binding profiles but also in their distribution in the central nervous system and the periphery (Blomqvist and Herzog 2004; Lin *et al.,* 2005). There has been some controversy over whether or not bone tissue cells express Y receptors. Togari and collaborators showed expression of a Y receptor mRNA corresponding to the Y1 receptor in human osteoblastic and human osteosarcoma-derived cell lines (Togari *et al.,* 1997). In line with these findings, another group reported the expression of Y1 receptors in mouse bone marrow cells (Nakamura *et al.,* 1995). Recently, the expression of Y1 receptor mRNA in mouse bone marrow stromal cells and in mouse calvarial osteoblast has been reported (Lundberg *et al.,* 2007; Baldock *et al.,* 2007). Moreover, evidence for Y1 receptors *in situ* in mouse bone was provided (Lundberg *et al.,* 2007). In contrast, an earlier study by Baldock *et al.* (2002) did not detect transcripts for any of the Y receptors in primary murine osteoblastic cultures or whole long bone preparations using RT-PCR. Amano and collaborators recently demonstrated that crude bone marrow cell cultures express Y1 receptors but it was not elucidated which cells expressed the receptors (Amano *et al.,* 2007). To conclude, the presence of Y1 receptors in mouse bone marrow cells, osteoblasts, and stromal cells seems to be established but so far it is uncertain if any of the other Y receptors are present in bone.

The importance of the neuropeptide Y receptor system in the regulation of bone was first discovered in 2002 with the demonstration that germ line deletion of Y2 receptors resulted in increased bone formation in the distal femur of mice. The increased bone formation was shown to be due to increased osteoblast activity, resulting in a twofold greater trabecular bone volume and a significantly elevated cortical bone mass compared to wild-type mice (Baldock *et al.,* 2002; Baldock *et al.,* 2006). Intriguingly, conditional knockout of Y2 receptors solely in the hypothalamus of adult mice caused a comparable increase in bone volume and the study by Baldock *et al.* (2002) was the first indicating a centrally mediated pathway for NPY in the control of bone formation. This hypothesis was supported by a lack of change in levels of insulin-like growth factor-1, free T4, calcium, leptin, or testosterone.

Ducy *et al.* (2000) were the first to demonstrate an *in vivo* model in which bone formation was under the control of the central nervous system, with the discovery that in the absence of leptin (*ob/ob* mice), or its signaling receptor (*ObRb*), trabecular bone mass was increased. The similarity between *ob/ob* and $Y2^{-/-}$ mice pointed toward a mechanistic link between NPY and leptin for the regulation of bone. However, distinctions between the ObRb and Y2 pathways were initially revealed following central administration of NPY to both $Y2^{-/-}$ and wild-type mice. This resulted in markedly elevated body weight and subsequently elevated leptin levels, leading to reduced osteoblast activity in wild-type mice. Importantly, however, $Y2^{-/-}$ mice were able to maintain their elevated rate of osteoblast activity, revealing distinct pathways regulated by Y2 receptors and leptin with increasing leptin levels (Baldock *et al.,* 2005). Furthermore, subsequent studies demonstrated that the effects of the Y2 and leptin-deficient pathways were opposite in cortical

bone, with Y2 deletion consistently stimulating bone formation, again indicating that the actions of these two pathways may be separate (Baldock *et al.,* 2006).

In contrast to the Y2 knockout model, ablation of Y4 receptors does not alter bone mass from wild-type levels (Sainsbury *et al.,* 2003). Because deletion of Y4 receptors did not result in an altered bone phenotype, it was unexpected that $Y2^{-/-}/Y4^{-/-}$ double knockout male mice exhibited a synergistic threefold increase in trabecular bone volume, an effect that was not detectable in female mice (Sainsbury *et al.,* 2003). Interestingly, the female mice did not show any changes in plasma leptin, whereas the male mice levels were decreased by 60%, suggesting that the anabolic synergistic increase in bone volume observed in males could be the result of additive effects of the Y2- and leptin-associated anti-osteogenic pathways in the absence of functional Y4 receptors (Sainsbury *et al.,* 2003).

Interestingly, conditional deletion of hypothalamic neuropeptide Y2 receptors can prevent ongoing bone loss in sex hormone-deficient adult mice (Allison *et al.,* 2006). This effect was attributed solely to an osteoblastic bone formation response that counterbalanced the increased bone resorption due to sex hormone deficiency. Thus, the bone anabolic actions of the Y2 receptor pathway are independent of the presence of sex hormones.

Until now the mechanism by which Y2 receptor deletion causes a doubling in bone volume has not been revealed. Culturing bone marrow stromal cells from Y2-deficient mice demonstrated an increased mineralization *in vitro,* in line with the *in vivo* findings (Lundberg *et al.,* 2007). Following collagenase digestion of compact mice bones and depletion of hematopoietic cells, the collected cells were divided into immature mesenchymal stem cells (MSCs) and mature progenitor cells based on the presence or absence of stem cell antigen-1 (Sca-1). Sca-1 is a cell surface glycoprotein commonly used as a marker for the isolation of hematopoietic stem cells (HSCs) from mouse bone marrow. Sca-1 is also expressed on non-hematopoietic bone marrow stromal cells, and mice lacking Sca-1 develop late onset osteoporosis due to a deficiency in osteoprogenitor cells (Bonyadi *et al.,* 2003). Therefore, Sca-1 expression also appears to be required for the appropriate self-renewal of mesenchymal progenitors and identifies a population of immature mesenchymal cells with the ability to undergo osteoblast differentiation. The Sca-1+ cell population isolated from bone following depletion of hematopoietic cells, which represent an immature multipotential cell type (P. Simmons, personal communication, unpublished data) did not differ between $Y2^{-/-}$ mice and wild-type mice. Furthermore, additional sorting of the Sca-1^{-} population of cells using an antibody recognizing CD51, or the αV subunit of the vitronectin receptor, eliminated $CD51^{-}$ erythroid precursor cell types and yielded a more mature "osteoprogenitor" cell population. The number of Sca-$1^{-}CD51^{+}$ mature progenitor cells was twofold greater in bones from $Y2^{-/-}$ mice relative to wild-type (Lundberg *et al.,* 2007). The greater number of these more mature progenitor cells provides a likely mechanism by which mineralization and adipogenesis were increased in stromal cell cultures from $Y2^{-/-}$ mice compared with wild-type. These findings support the likelihood that an increase in the progenitor population may contribute to the increased bone formation and volume of $Y2^{-/-}$ mice *in vivo*.

Analysis of Y receptor transcripts in cultured stromal cells from wild-type mice revealed high levels of Y1 but not Y2, Y4, Y5, or y6 receptor mRNA (Lundberg *et al.,* 2007). One probable explanation to this event is that germ line Y2 receptor deletion causes Y1 receptor downregulation in stromal cells and bone tissue due to the lack of feedback inhibition of NPY release and subsequent overstimulation of Y1 receptors. It is a well-known phenomenon that Y2 receptors, which usually are expressed on the pre-synaptic side of sympathetic nerve terminals, act in an autoinhibitory fashion to regulate the release of NPY and other neurotransmitters (King *et al.,* 2000). Interestingly, in contrast to the germ line and hypothalamic Y2 receptor or germ line Y1 receptor deletion, conditional deletion of hypothalamic Y1 receptors in adult mice did not alter bone homeostasis, an indication of a peripheral action of Y1 receptors in bone (Baldock *et al.,* 2007). Furthermore, deletion of both Y1 and Y2 receptors did not produce additive effects in bone or adiposity pointing at a common signaling pathway for these Y receptors (Baldock *et al.,* 2007). Together, these findings indicate that the greater number of mesenchymal progenitors and the altered Y1 receptor expression within bone cells in the absence of Y2 receptors are a likely mechanism for the greater bone mineralization *in vivo* and *in vitro*. It is not known if the hypothalamic Y2 knockout mouse model also shows an increase in osteoprogenitor numbers and a downregulation of Y1 receptors in stromal cells. This possible regulatory route is supported by a recent study that used pseudorabies virus-based transneuronal tracing to map transsynaptically connected neurons from rat bone, providing direct evidence that nerve fibers within bone tissue are under the control of synaptic transmission from the hypothalamus (Dénes *et al.,* 2005). However, it cannot be excluded that part of the effect on Y1-receptor downregulation is due to NPY produced by cells locally in the bone marrow such as megakaryocytes (Ericsson *et al.,* 1987).

The effects by NPY on osteoclast formation and activity is limited to the study by Amano *et al*. (2006) demonstrating that NPY inhibits the isoprenaline-induced osteoclastogenesis in mouse bone marrow cultures, an effect associated with decreased cyclic AMP formation and reduced RANKL expression. The fact that NPY did not inhibit D3 or RANKL stimulated osteoclast formation in the bone marrow cultures demonstrates that NPY did not inhibit isoprenaline induced osteoclast formation by an effect directly on osteoclast progenitor cells. The observation that NPY inhibited isoprenaline induced cyclic

AMP formation, together with the finding that NPY inhibited osteoclast formation caused by forskolin, an activator of adenylate cyclase, but not that caused by a cyclic AMP analog activating PKA, shows that NPY affects osteoclast indirectly by inhibiting the synthesis of cyclic AMP in supporting stromal cells. This view is supported by the observation that NPY can inhibit noradrenaline induced cyclic AMP formation in the osteoblastic UMR106-01 cell line (Bjurholm *et al.*, 1988c).

Opioid Peptides

The opioid family of peptides is synthesized from three different precursor molecules: proopiomelanocortin (POMC), proenkephalin (PENK), and prodynorphin (PDYN). Due to tissue-specific processing, different opioid peptides are produced, not only in the nervous and endocrine systems, but also in several other tissues, including the skeleton (Rosen *et al.*, 1998). Opioid peptides exert their opiate-like activity via three different receptors – μ-opioid, δ-opioid, and κ-opioid receptors – all of which are seven transmembrane G proteincoupled receptors linked to inhibition of adenylate cyclase.

Prompted by their initial observation that PENK mRNA is expressed highly and transiently during embryonic development in mesenchymal tissues, including bone and cartilage (Keshet *et al.*, 1989), Rosen *et al.* (1991) reported that PENK mRNA, but not POMC or PDYN mRNAs, is highly expressed in rat calvarial osteoblasts, in rat osteosarcoma cell lines ROS 17/2.8 and ROS 25/1, and weakly in mouse MC3T3-E1 osteoblastic cells and in human Saos-2 osteosarcoma cells. The expression of PENK mRNA in osteoblasts is decreased by $1,25(OH)_2D_3$, PTH, and TGF-β (Rosen *et al.* 1991, 1995, 1998). In addition, it has been shown that osteoblasts synthesize enkephalin-containing peptides, including Met-enkephalin. Using immunohistochemistry, Met-enkephalin has been demonstrated not only in bone cells and bone marrow cells, but also in skeletal nerve fibers (Elhassan *et al.*, 1998).

The fact that Met- and Leu-enkephalin, as well as Met-enkephalin-Arg-Phe, decrease alkaline phosphatase activity in ROS 17/2.8 cells indicates that osteoblasts are equipped with opioid receptors and that opioid peptides may act as local regulators of bone cell differentiation in an auto- or paracrine manner (Rosen *et al.*, 1991). The reciprocal interrelationships between osteoblast maturation (as assessed by alkaline phophatase) and PENK expression further indicate that opioid peptide expression is linked to osteoblast differentiation. Based on these observations, Rosen and Bar-Shavit (1994) have proposed the hypothesis that the retained capacity in the adult skeleton to synthesize PENK-derived peptides, in a defined population of undifferentiated cells, may be important in local remodeling of the skeleton, including fracture repair.

In contrast to the observations in rat osteoblasts, opioid receptor agonists such as morphine and DAMGO do not affect alkaline phosphatase activity in the human osteosarcoma cell line MG-63 (Pérez-Castrillón *et al.*, 2000). This was not due to an absence of opioid receptors, as $1,25(OH)_2D_3$-stimulated secretion of osteocalcin was decreased by morphine and DAMGO, an effect that was abolished by naloxone. It was also shown that MG-63 cells express all three opioid receptors and that stimulation of μ-opioid receptors, but not of δ-opioid receptors, decreased osteocalcin expression. Also, human osteoblast-like cells isolated from cancellous bone seem to be equipped with opioid receptors; Met-enkephalin inhibits cell proliferation by a mechanism sensitive to inhibition by the opioid receptor antagonist naltrexone (Elhassan *et al.*, 1998). No analysis of alkaline phosphatase was performed in these cell cultures and therefore it is not known if Met-enkephalin affects osteoblast differentiation in human bone cells.

The effect of opioid peptides on osteoclast activity is indicated by the observation that the synthetic analgesic opioid buprenorphine inhibits rat osteoclast activity, as assessed by the pit formation assay (Hall *et al.*, 1996). However, the effect seems unrelated to opioid receptors, as it was not shared by other opioid receptor agonists nor blocked by the opioid antagonist naloxone.

Interestingly, Elhassan *et al.* (1998) found that Met-enkephalin levels are decreased significantly in ankle joints from Lewis rats with adjuvant arthritis. Using immunohistochemistry, a significant decrease was observed in synovial type A cells. If Met-enkephalin levels were affected also in bone cells, it was not reported.

Somatostatin

Somatostatin receptors have been immunolocalized to metaphysis immediately adjacent to hypertrophic cartilage (Mackie *et al.*, 1990). Somatostatin-binding cells stain positive for alkaline phosphatase and are probably osteoblast precursor cells, suggesting that somatostatin may be involved in the regulation of osteoblastic differentiation during enchondral ossification. Mature osteoblasts, as well as osteoclasts and chondrocytes, are negative for somatostatin receptors, which are also lacking in membranous bones. Somatostatin receptor agonists do not affect basal or PTH-stimulated bone resorption in neonatal mouse calvariae (Lerner and Feyen, unpublished observations).

RECEPTORS AND EFFECTS BY NEUROTRANSMITTERS IN BONE

Catecholamines

The presence of adrenergic receptors on osteoblasts has been reviewed (Lerner, 2000) and the important role of

β-adrenergic receptors on osteoblasts for the sympathetic control of bone formation is reviewed in a separate chapter (Chapter 5).

Glutamate, Glutamate Receptors, and Glutamate Transporter

The activity of excitatory amines released into synapses is controlled by a family of homologous excitatory amino acid transporters (EAATs), which are responsible for the reuptake of such amines into presynaptic terminals, a mechanism for the termination of synaptic transmission. To this group belong the glutamate/aspartate transporter (GLAST; EAAT1), Glu transporter-1 (GLT-1; EAAT2), excitatory amino acid carrier (EAAC1; EAAT3), EAAT4, and EAAT5. Moreover, vesicular glutamate transporters (VGLUT1, VGLUT2) are also involved in glutamate signaling. The expression of these transporters in the nervous system is well known, but their presence in non-neural tissues has also been recognized. The expression of GLAST, dopamine, and serotonin transporters has been demonstrated in bone cells. Mason *et al.* (1997) reported the expression of GLAST in osteocytes and osteoblasts, both at the mRNA and protein level, and the downregulation of its expression by mechanical loading using differential RNA display in samples from rat ulnae. Immunohistochemistry demonstrated that the GLAST expression in osteocytes disappeared after loading, whereas it was upregulated in periosteal osteoblasts at sites showing enhanced cellular proliferation and bone formation. The expression of GLAST is regulated *in vitro*, being downregulated during rat osteoblastic differentiation (Bhangu *et al.*, 2000). Osteoblasts are capable of taking up glutamate and releasing glutamate by calcium-sensitive mechanisms, similar to those used by neuronal cells. Skerry (1999) has put forward the hypothesis that glutaminergic signaling may be involved in the coupling between mechanical loading and anabolic events in the skeleton. The origin of glutamate in bone is, however, not fully known. Human and mouse osteoblasts are able to actively release glutamate (Genever and Skerry, 2000), but the possibility of glutamatergic innervation in bone is indicated by the immunolocalization of glutamate in skeletal nerve fibers (Serre *et al.*, 1999).

The action of glutamate is mediated by two different types of receptors: ionotropic receptors, which use the regulation of transmembrane ion fluxes as a signal-transducing mechanism, and metabotropic receptors, which are seven transmembrane-spanning domain, G protein-coupled receptors, using either stimulation of phospholipase C or inhibition of adenylate cyclase as intracellular signaling mechanisms (Chenu, 2002; Mason, 2004; Spencer *et al.*, 2007). Ionotropic receptors can be subdivided into three groups based on their sensitivities to *N*-methyl-D-aspartate (NMDA), AMPA, and kainate. Metabotropic receptors are classified into three groups: group I (mGluR1 and mGluR5), group II (mGluR2 and mGluR3), and group III (mGluR4, mGluR6, mGluR7, and mGluR8).

Using immunohistochemistry, *in situ* hybridization, and radio-labeled ligand binding, NMDA receptors have been demonstrated in mouse, rat, rabbit, and human osteoclasts (Chenu *et al.*, 1998; Patton *et al.*, 1998; Itzstein *et al.*, 2000; Merle *et al.*, 2003). The presence of functional NMDA receptors in osteoclasts has been confirmed using electrophysiological patch-clamp techniques (Espinosa *et al.*, 1999; Peet *et al.*, 1999). However, controversy exists as to whether these receptors can regulate the activity of terminally differentiated osteoclasts. Chenu and collaborators have reported that an antibody directed to the NMDA receptor 1 subunit, as well as four different specific NMDA receptor antagonists (D-AP5, MK 801, DEP, and L-689,560), inhibits rabbit osteoclastic bone resorption and decreases the percentage of osteoclasts with actin rings, while having no effect on osteoclast adhesion or apoptosis (Chenu *et al.*, 1998; Itzstein *et al.*, 2000). In contrast, Peet *et al.* (1999) reported that the NMDA receptor antagonist MK 801 inhibits glutamate-induced current in rabbit mature osteoclasts, but has no effect on actin ring formation in these cells nor inhibits pit formation by mature rabbit and rat osteoclasts or basal ^{45}Ca release from neonatal mouse calvarial bones.

The possibility that glutamate NMDA receptors may be involved in the regulation of osteoclastogenesis has been suggested by Peet *et al.* (1999). MK 801 inhibits osteoclast size, nuclearity, TRAP expression, and resorptive activity in cocultures of mouse bone marrow cells and calvarial osteoblasts stimulated by $1,25(OH)_2D_3$, suggesting that osteoclastogenesis is dependent on constitutive glutamate signaling. In agreement with these observations, Merle *et al.* (2003) reported that two different NMDA antagonists decreased RANKL stimulated osteoclast formation in mouse bone marrow cultures, as well as in the monocytic cell line RAW264.7. Furthermore, activation of NMDA stimulated the translocation of NF-κB to osteoclast nuclei.

Osteoclast has been shown to express VGLUT1 and, most interestingly, *VGLUT1*$^{-/-}$ mice exhibit low bone mass (Morimoto *et al.*, 2006).

NMDA receptor subunit 1 knockout mice do not seem to have any skeletal phenotype (Peet *et al.*, 1999), which could be due to redundancy given the expression of the many different glutamate receptor subtypes.

In contrast to previous observations in osteoclasts, Hinoi *et al.* (2007) have recently reported that osteoclasts do not express any of the ionotropic or metabotropic glutamate receptor subtypes, nor GLAST, EAAC1, EAAT5, or VGLUTs. However, GLT-1, EAAT4, and the cystine/glutamate antiporter were expressed in the purified mouse bone marrow osteoclasts. Glutamate inhibited RANKL induced osteoclastogenesis in a manner sensitive to an antiporter antagonist but not to EAAT inhibitors. In contrast, a large variety of agonists for ionotropic or metabotropic glutamate receptors did not affect osteoclastogenesis.

Moreover, intraperitoneal injection of glutamate prevented ovariectomy-induced cancellous bone loss in mice due to decreased number of osteoclasts on bone surfaces. The divergent results obtained by different groups may be explained by the techniques used to purify the osteoclast precursors although this remains to be proven. Clearly, much more work has to be done to clarify the role of glutamate in osteoclast formation and activity.

Immunohistochemistry and *in situ* hybridization have revealed the expression of ionotropic NMDA receptors in rat and human osteoblasts (Chenu *et al.*, 1998; Patton *et al.*, 1998; Gu and Publicover, 2000). NMDA glutamate receptors have also been demonstrated in the human osteoblastic cell lines MG-63 and Saos-2 using radioligand binding and electrophysiological assessments (Laketic-Ljubojevic *et al.*, 1999). Activation by glutamate resulted in increased levels of intracellular Ca^{2+} via a receptor sensitive to inhibition by MK 801, suggesting the presence of active NMDA receptors in these osteoblastic cell lines. Similarly, NMDA was found to increase intracellular Ca^{2+} in rat osteoblasts (Gu and Publicover, 2000). Bone lining osteoblasts in young rats express several ionotropic glutamate receptors and mechanical loading *in vivo* resulted in decreased expression of several of the receptor subtypes (Szczesniak *et al.*, 2005). The function of osteoblastic glutamate receptors is still elusive but glutamate has been found both to inhibit (Uno *et al.*, 2007) and to stimulate (Fatokun *et al.*, 2006) proliferation of osteoblastic MC3T3-E1 cells. NMDA antagonist suppresses rat calvarial osteoblast differentiation via decreased expression of runx2 (Hinoi *et al.*, 2003).

Gu and Publicover (2000) reported the presence of metabotropic GluR1 (but not mGluR2-6) in primary rat osteoblasts using RT-PCR analysis. Activation of these receptors resulted in an elevation of intracellular Ca^{2+}. Interestingly, electrophysiologic analysis and fluorometric studies on intracellular Ca^{2+} showed interactions between ionotropic and metabotropic glutamate receptors in these cells, suggesting a complex glutamatergic signaling in bone cells.

Serotonin Receptors and Serotonin Transporter

Using RT-PCR and radiolabeled ligand binding, Bliziotes and colleagues demonstrated the expression of the serotonin (5-HT) transporter (5-HTT) in several different rat osteoblastic cell lines and primary rat osteoblasts (Bliziotes *et al.*, 2001). The functional expression of 5-HTT was confirmed by studies on [^{3}H]5-HT uptake in ROS 17/2.8 cells. In addition, it was shown that rat osteoblasts express four different 5-HT receptors: 5-HT1A, 5-HT1D, 5-HT2A, and 5-HT2B. Interestingly, the expression of 5-HTT increased during the differentiation of rat osteoblasts (Bliziotes *et al.*, 2000a), in contrast to that of GLAST (Bhangu *et al.*, 2000). Also the osteocytic cell line MLO-Y4 expresses serotonin transporter and serotonin receptors (Bliziotes *et al.*, 2006). Similarly, Westbroek *et al.* (2001) demonstrated serotonin receptors in chicken osteoblasts and osteocytes. In addition, serotonin receptors and 5-HTT have been demonstrated in osteoclasts (Gustafsson *et al.*, 2006). 5-HTT expression is enhanced in RANKL stimulated RAW264.7 cells and the SSRI fluoxetine reduces osteoclast formation (Battaglino *et al.*, 2004). These findings show that all three bone cells can both respond to and regulate 5-HT activity.

Most interestingly, mice deficient of serotonin transporter ($5\text{-}HTT^{-/-}$) exhibit reduced cancellous bone volume, decreased cortical area, and reduced ultimate force of three-point bending (Warden *et al.*, 2005a). The phenotype was due to reduced bone formation rate with no effect on osteoclast surface/bone surface. Similarly, a selective serotonin reuptake inhibitor (SSRI) caused decreased bone mineral accrual in mice. These data indicate that treatment with SSRIs may enhance the risk of developing secondary osteoporosis (Warden *et al.*, 2005b). In agreement with this view, the use of SSRIs has been associated with lower bone mineral density in older men (Haney *et al.*, 2007). In contrast to this finding, fluoxetine treatment of mice has been found to enhance bone mass due to increased cancellous bone volume without affecting ovariectomy-induced bone loss (Battaglino *et al.*, 2007).

Although the data on effects by serotonin on the skeleton are not conclusive, the available information clearly demonstrates that serotonin can influence bone cell activities *in vitro* and bone metabolism *in vivo*.

Dopamine Transporter

The dopamine transporter (DAT) is believed to control the activity of released dopamine (DA) into presynaptic terminals (or possibly other DAT-expressing cells). Mice deficient in DAT exhibit decreased bone mass due to diminished cancellous bone volume, increased trabecular spacing, and reduced trabecular volume (Bliziotes *et al.*, 2000b). The skeletal phenotype includes a reduction in cortical thickness, cortical strength, and decreased femur length. It is not yet known whether the osteopenic phenotype is due to DAT deficiency in bone cells or is mediated by indirect mechanisms. RT-PCR in UMR 106–01 and ROS 17/2.8 cells has failed to demonstrate mRNA for DAT in these osteoblastic cell lines. No data are available regarding the possible expression of DA in skeletal nerve fibers or bone cells. The fact that serum and urinary calcium and phosphorus, as well as circulating PTH, are normal indicates that the mechanism does not involve abnormalities in calcium and phosphorus homeostasis. The possibility may exist that the pathogenesis may, at least partly, be related to the decreased body weight or the anterior pituitary hypoplasia observed in $dat^{-/-}$ mice.

RECEPTORS AND EFFECTS BY NEUROTROPHINS IN BONE

Neurotrophic factors, including the neurotrophins NGF, BDNF, and NT-3, are known to play important roles in development of the central and peripheral nervous systems. These factors are also known to promote the differentiation and survival of various types of neurons. The *trk* proto-oncogenes *trk*A, *trk*B, and *trk*C have been identified as receptors, linked to the activation of tyrosine kinase for these neurotrophins. Thus, the neurotrophins selectively recognize these receptors and NGF, BDNF, and NT-3 bind to the products of *trk*A, *trk*B and *trk*C, respectively. Several neurotrophins have been found to be expressed in bone, and it has been suggested that these factors may have a role not only in bone-associated neuronal biology, but also in bone metabolism.

In the case of bone tissues, there are several reports of osteoblastic expression of neurotrophins and neurotrophin receptors. Nakanishi *et al.* (1994a) reported that the mouse osteoblastic cell line MC3T3-E1 expresses mRNA for NGF, BDNF, and NT-3 and that the expresssion levels were upregulated during differentiation. The rat ROS 17/2.8 cell line expresses mRNA for NGF, but not for BDNF, and NGF levels are increased by $1,25(OH)_2D_3$ (Jehan *et al.*, 1996). MC3T3-E1 cells have also been demonstrated to express mRNA encoding *trk*C, the receptor for NT-3 (Nakanishi *et al.*, 1994b). A functional role of this receptor was suggested by the observations that NT-3, but not NGF, stimulated the proliferation of MC3T3-E1 cells and calcium incorporation in the cell layers. Also, ROS 17/2.8 cells have binding sites for NGF (Jehan *et al.*, 1996), although the regulatory role of NGF receptors in these cells has not been assessed. Furthermore, it has been shown that exogenous NT-3 induces DNA-binding activities in MC3T3-E1 cells at several sites, including the cyclic AMP responsive element, partly due to activation of c-fos and c-jun (Iwata *et al.*, 1996). In addition, NGF enhances cell proliferation and the biosynthesis of proteoglycans during chondrogenesis in organ culture (Kawamura and Urist, 1988). These *in vitro* findings suggest that neurotrophins may participate in the regulation of bone formation as auto- or paracrine factors.

Studies of neurotrophins and neurotrophic receptor expression during fracture healing further support the idea of neurotrophic effects in bone. Increased sensory and sympathetic innervation during fracture healing has been reported in animal experiments (Hukkanen *et al.*, 1993). NGF has been immunolocalized in normal rat bone preferentially in osteoprogenitor cells. During fracture healing, however, osteoprogenitor cells, as well as bone marrow stromal cells, osteoblasts, young osteocytes, and most of the chondrocytes in the callus, are expressing NGF protein (Grills and Schuijers, 1998). No NGF was seen in osteoclasts. In a large study including 70 rib-fractured mice, NGF, BDNF, and NT-3 were demonstrated in bone-forming cells at the fracture callus (Asaumi *et al.*, 2000). Interestingly, expressions of the three neurotrophins were increased during the process of healing, especially those of NGF and NT-3. Messenger RNA encoding their respective receptors, *trk*A and *trk*C, were also detected in the bone-forming cells at the fracture callus. An interesting speculation made by the authors is that the expression of NT-3 and *trk*C in osteoblast-like cells at the fracture callus and the increasing expression of NT-3 mRNA during the week after fracture indicate autocrine loop functions for the neurotrophic factor during fracture healing (Asaumi *et al.*, 2000). Such a view is supported by the findings that local application of NGF, at the site of fractured rat ribs, results in dramatically increased levels not only of norepinephrine and epinephrine, but also in increased healing rate and bone strength (Grills *et al.*, 1997). A possible local regulation of NGF expression in fracture sites by bone-derived molecules is suggested by the observation that BMP-2 (in the presence of TNF-α) strongly upregulates NGF in fibroblasts (Hattorl *et al.*, 1996).

RECEPTORS AND EFFECTS BY CANNABINOIDS IN BONE

The members of the cannabinoid system have, besides the classical psychotropic effects, diverse physiological functions including regulation of analgesic, immunomodulatory, and neurophysiological processes. The effects by both synthetic and endogenous cannabinoids are mainly exerted through the cannabinoid receptor type 1 and 2 (CB_1 and CB_2, respectively; for review, see Howlett *et al.*, 2002). Interestingly, recent publications have demonstrated that the cannabinoid system also plays a role in the regulation of bone metabolism. Ralston and colleagues demonstrated the presence of both CB_1 and CB_2 on osteoclasts. They also reported that mice lacking CB_1 developed a higher bone mass than wild-type littermates, and the knockout mice were also protected from ovariectomy-induced bone loss (Idris *et al.*, 2005). Furthermore, CB_1-selective antagonists were shown to inhibit osteoclast formation, whereas treatment with the endogenous cannabinoid receptor agonist anandamide stimulated osteoclast formation (Idris *et al.*, 2005). In contrast to this report, Bab and colleagues recently reported that their CB_1 knockout mice developed a low bone mass phenotype with decreased bone formation rate and increased osteoclast number (Tam *et al.*, 2006). The two studies were conducted using different mouse strain backgrounds, and the opposing results reported may be explained by the fact that the CB_1 deletion results in several different intra-species phenotypes.

In addition to the studies on the CB_1 receptor in regulation of bone metabolism, the importance of signaling through the CB_2 receptor has also been evaluated. Bab and

colleagues reported that deletion of the *CNR2* gene induced an increase in bone turnover resulting in a low bone mass phenotype (Ofek *et al.*, 2006). Expression of CB_2 mRNA was detected in both osteoblasts and osteoclasts, as well as in osteocytes. By the use of the synthetic CB_2 agonist HU-308, it was shown that CB_2 signaling in wild-type mice resulted in an increased number of osteoblast precursors and differentiation of osteoblasts. In contrast, the number of osteoclasts was decreased, which was suggested to be a consequence of both direct inhibitory action on the osteoclast precursors, as well as a decrease in RANKL expression after treatment with HU-308 of stromal cells/osteoblasts. Because CB_2 is expressed on many different cell types, including immune cells, indirect effects on bone metabolism by other cell types present in the bone microenvironment cannot be excluded.

Besides the animal studies on the importance of the cannabinoid system in bone metabolism, several reports have implicated that cannabinoids also play a role in human osteoporosis. Linkage analysis showed an association of single nucleotide polymorphisms on chromosome 1p36, which contains the *CNR2* gene, with low spine and hip BMD (Devoto *et al.*, 1998). Furthermore, a study by Karsak and colleagues demonstrated a significant association of single nucleotide polymorphisms encompassing the *CNR2* gene with low BMD in patients with postmenopausal osteoporosis (Karsak *et al.*, 2005).

In summary, animal studies have shown that members of the cannabinoid system function as regulators of bone mass and bone cell function, and that together with the human studies suggesting an important role of CB_2 in human osteoporosis further strengthen the role of cannabinoids as members of the growing network of known factors regulating bone metabolism.

EXPERIMENTAL DENERVATION

The idea that there is a close interaction among the bone neural network, the regulation of bone cell activity, and skeletal turnover is supported by experimental denervation in animals. It has been shown that developmental skeletal growth in the rat hind foot is reduced after surgical denervation. In denervated animals, CGRP and SP immunoreactive nerve fibers were not observed in the perichondrium or periosteum of the metatarsal bones. Metatarsal bones on the contralateral unoperated side exhibited a normal pattern of innervation. The skeletal phenotype could not be due to decreased physical activity, as tendectomized control rats exhibited normal metatarsal bone lengths (Edoff *et al.*, 1997). These results indicate that sensory nerve fibers have growth-promoting effects on immature limb bones.

The possibility that neuropeptides may also influence the metabolism of adult skeleton is suggested by studies demonstrating a significant change in osteoclast numbers in jawbones as a consequence of sensory and sympathetic denervation (Hill and Elde, 1991b). Treatment with guanethidine results in a dramatic decrease of the immunohistochemical staining for VIP, NPY, and DβH in the periosteum of mandible and calvariae in rats, indicating a sympathetic origin of these nerve fibers. This resulted in no change of bone formation, as assessed by periosteal apposition rate in tibiae, but a 50% increase of bone surface in mandible covered by osteoclasts. This could indicate that VIP, NPY, and/or catecholamines may have an inhibitory effect on osteoclast formation and/or activity. These results are in line with our findings that both VIP and PACAP decrease osteoclastogenesis in mouse marrow cultures (Mukohyama *et al.*, 2000). However, capsaicin treatment results in a 20% decrease of bone surface occupied by osteoclasts and, again, no effect on the periosteal apposition rate (Hill and Elde, 1991b). In contrast, Offley *et al.* (2005) reported that capsaicin treatment of rats reduced SP and CGRP content in nerves and caused reduced bone mass associated with increased number of osteoclasts and decreased osteoblast activity and bone formation rate.

In line with the effects of sympathetic depletions demonstrated by Hill and Elde (1991b), deprived sympathetic innervation of rat mandibular alveolar bones showed an increase of osteoclast number per sockets (Sandhu *et al.*, 1987). Moreover, the periosteal and endosteal apposition and mineralization rate was reduced in the sympathectomized jawbones (Sandhu *et al.*, 1987). Because the jawbones are unloaded, these effects cannot be due to decreased loading. Together, the data indicate that sympathetic neurons modulate bone resorption and bone remodeling *in vivo*.

CLINICAL OBSERVATIONS

Skeletal pain in patients with inflammatory and neoplastic disorders clearly suggests the existence of an extensive sensory nervous system in bone tissues. An increased fracture rate in paraplegic children due to myelomeningocele, subdural hematoma, spinal fractures associated with cord lesions, lumbrosacral root avulsion, transverse myelitis, and cord tumors indicates a role of the nervous system also in skeletal metabolism. Excessive callus formation during fracture healing in paraplegic patients further suggests a role of skeletal nerve fibers in bone metabolism (for references, see Lundberg, 2000). The fact that the neurotoxin thalidomide induces skeletal malformation further implicates the nervous system, not only in bone turnover and fracture healing, but also in embryonic skeletal development (McCredie and McBride, 1973).

Patients with tumors producing an excess of circulating VIP may develop hypercalcemia (Dohmen *et al.*, 1991; Lundstedt *et al.*, 1994). Although the pathogenesis is not known, the possibility may exist, given the capacity of VIP

TABLE II Receptor Expression and Effects on Bone Cell Functions by Neuro-osteogenic Factors

	Receptors[a]		Bone cell functions

to stimulate osteoclast activity (Lundberg *et al.*, 2000), that VIP-induced enhanced bone resorption may be involved.

It is well known that a high proportion of patients with hip fractures previously have had a stroke (Ramnemark, 1999). Skeletal fractures are also a frequent complication in paraplegic patients during rehabilitation. Most of these poststroke fractures are on the paretic side. Although a high incidence of falls may contribute to the high incidence of hip fractures, it has been suggested that decreased bone mass in the paretic side may be an important factor. Cross-sectional studies have all demonstrated reduced bone mass in the paretic side as compared to the nonparetic side (reviewed in Ramnemark, 1999). A prospective study found a time-dependent enhanced loss of bone mineral density in the paretic side during the first year after stroke (Ramnemark *et al.*, 1999a). Another prospective study for four months showed similar results (Hamdy *et al.*, 1995). The development of hemiosteoporosis is independent on weight changes after stroke (Ramnemark *et al.*, 1999b).

The loss of bone in paraplegic patients is highest during the first 12 months but continues at least for 36 months (Ramnemark, 1999). The fact that the bone resorption marker carboxyterminal telopeptide of type I collagen (ICTP) is increased in patients with hemiosteoporosis

(Fiore *et al.*, 1999; Ramnemark *et al.*, in manuscript) and that osteocalcin, carboxyterminal propeptide of type I collagen (PICP), and alkaline phosphatase are normal (Ramnemark *et al.*, in manuscript) indicate that the loss of bone in the paretic side is mainly due to enhanced bone resorption. Interestingly, both osteocalcin and PICP are increased significantly over a 12-month poststroke period (Ramnemark *et al.*, in manuscript), indicating the presence of high turnover osteoporosis in the paretic skeleton.

Patients with spinal cord injuries, similar to stroke patients, lose bone mineral contents in paralyzed areas of the skeleton (Biering-Sörensen *et al.*, 1988, 1990; Garland *et al.*, 1992; Wilmet *et al.*, 1995; Dauty *et al.*, 2000). The osteopenia is fastest in trabecular bone, showing a total loss of 50% in 18 months and then reaching a plateau phase. The decrease is slower in cortical bones, but continues for longer periods of time. The loss of bone in traumatic paraplegia is associated with an increase in urinary calcium, phosphate, hydroxyproline, and deoxypiridoline (Bergmann *et al.*, 1977–1978; Dauty *et al.*, 2000), indicating that enhanced bone resorption is an important pathogenetic mechanism, similar to the observations in stroke patients. No differences in serum levels of calcium, alkaline phosphate, or osteocalcin were observed. However, serum phosphate was increased.

It may be argued that hemiosteoporosis in paretic patients is due to disuse. However, the population of stroke patients studied by Ramnemark (1999) suffered from severe stroke and was therefore substantially immobilized and still developed local bone loss. Biering-Sörensen *et al.* (1988) reported that the decrease of bone mineral content seen in the lower extremities in patients with spinal cord injuries could not be prevented by spasticity or daily use of long leg braces. In the study by Dauty *et al.* (2000), patients with spinal cord lesions showed a 41% loss of bone mineral density in sublesional areas of the skeleton. However, there was no correlation among daily duration of sitting, daily verticalization, use of long leg braces, or bone mineral density. These observations suggest that osteoporosis in paretic patients cannot simply be classified as disuse osteoporosis. Thus, hemiosteoporosis may be caused by factors unrelated to lack of loading. This raises the possibility that loss of innervation and local control of bone metabolism by skeletal neuro-osteogenic factors may play a role. Most interestingly, Demulder *et al.* (1998) showed that osteoclast formation in $1,25(OH)_2D_3$-stimulated cultured bone marrow from iliac crest (below the lesional level) is increased significantly as compared to osteoclast formation in sternal bone marrow cultures (above the lesional level) established from paraplegic patients with spinal cord injuries. No such differences were seen in quadriparetic, quadriplegic, or healthy patients. Differences in the *ex vivo* osteoclast formation rate were observed in cultures established both 6 weeks and 12 months after the spinal cord lesion. The authors speculated that the deficiency of skeletal neuropeptides may be responsible for the enhanced osteoclastogenesis seen in bone marrow from paralyzed skeletal areas of paraplegic patients and have demonstrated that CGRP inhibits human osteoclast formation induced by $1,25(OH)_2D_3$ (Akopian *et al.*, 2000).

Clinical observations, together with findings using experimental denervation to knockout signaling molecules in the nervous system and *in vitro* and *in vivo* data showing effects of and receptor expression for neuropeptides, neurotransmitters, and neurotrophins (see Table II), strongly suggest that skeletal metabolism is controlled by neuro-osteogenic factors. In addition, the nervous system has been suggested to play an important role in the pathogenesis of osteoarthritis as well as rheumatoid arthritis (Vilensky and Cook, 1998; Cerinic *et al.*, 1998). Interestingly, mild mental stress, such as cage change or cold exposure, similar to injection of corticosterone, decreases plasma osteocalcin in rats (Patterson-Buckendahl *et al.*, 1988), suggesting that not only dramatic changes of the neuronal influence on the skeleton, but also more subtle fluctuations, may influence skeletal metabolism.

Chapter 48

Regulation of Bone Remodeling by Central and Peripheral Nervous Signals

Shu Takeda
Department of Orthopaedic Surgery, Graduate School, 21st Century Center of Excellence Program, Tokyo Medical and Dental University, Tokyo, Japan

Patricia Ducy*
Department of Pathology, Columbia University, College of Physicians and Surgeons, New York

INTRODUCTION

The 1990s have seen the explosion of mouse genetics driving skeletal biology toward a detailed understanding of the patterning and cell differentiation processes occurring during development. More recently, taking advantage of the availability of a growing number of genetically modified mouse models but also of the possibility to delete one or several genes at will in a defined time frame or in specific tissue(s), this research effort has been extended to skeletal physiology. This *in vivo* approach has been especially successful in uncovering the genetic bases of the regulation of bone remodeling. Among the most surprising findings several regulatory pathways linking the nervous system with bone formation and/or resorption have been uncovered. Although in most cases these pathways are still far from being fully defined, their identification has already attracted much attention from the basic and sometimes clinical science communities. One can therefore predict that their in-depth analysis will be one of the main challenges of the next decade.

Hints of a connection between the nervous system and the regulation of bone mass have long been present in the literature. For instance, osteoporosis is a known complication of spinal cord injury and experimental models of sensory or sympathetic denervation have shown that these two neuronal systems could be involved in bone development and remodeling (Chenu, 2004; Jiang *et al.,* 2006). Likewise, major depression is associated with low bone mass and increased incidence of osteoporotic fractures and the use of several types of central nervous system-active drugs, such as anticonvulsants and opioids, have been associated with increased risk of fracture (Kinjo *et al.,* 2005). Remarkably, these examples all point at a regulation of bone mass by the nervous system, i.e., at signals efferent from the brain (or nerves) to bone cells. This might explain why most of the earlier studies have focused on peripherally produced neuromediators (Chenu, 2002; Spencer *et al.,* 2007). Yet, if one accepts that either or both arms of bone remodeling are centrally controlled, it is legitimate to consider that one or several afferent signals may exist that influence(s) the brain's control of bone mass. The identification of such signal(s), which can be viewed as an archetype of the current effort of integrative biology, might bring into light connections between the skeleton and organs previously unsuspected to play a role in its biology. This emerging field of investigation may therefore become critical to develop novel concepts in drug development.

AFFERENT SIGNALS REGULATING BONE REMODELING VIA THE CENTRAL NERVOUS SYSTEM: LEPTIN AS A MEDIATOR BETWEEN FAT AND BONE METABOLISMS

At the present time the only signal known, *in vivo*, to affect bone mass via a central nervous system (CNS) relay is leptin. Leptin is a 16 kDa peptide hormone synthesized specifically by adipocytes that was originally identified by positional cloning of the mutation present in *ob/ob* mice, a natural mutant presenting morbid obesity and sterility (Zhang *et al.,* 1994). Leptin inhibits appetite and favors reproduction by binding to a receptor present on hypothalamic neurons; consequently, mice lacking the leptin receptor (*db/db* mice) are also obese and sterile (Tartaglia *et al.,* 1995). In spite of their hypogonadism, bone mass is

*Corresponding author: Patricia Ducy, Department of Pathology, Columbia University, College of Physicians and Surgeons, New York.

increased in leptin signaling-deficient (*ob/ob* and *db/db*) mice compared to wild-type mice (Ducy *et al.,* 2000). Importantly, *ob/ob* mice fed a low-fat diet have a normal weight at 1 month of age but they already display a high bone mass phenotype. The leptin-signaling deficient bone phenotype is owing to the absence of leptin not to the obesity of the *ob/ob* and *db/db* mice because mice lacking fat as the result of transgenic expression of a dominant-negative protein inhibiting the activity of b-ZIP adipocyte differentiation factors also display a high bone mass phenotype (Ducy *et al.,* 2000). Moreover, a leptin transgene can correct the high bone mass of these lipodystrophic mice indicating that leptin is the adipocyte-derived gene product responsible for their bone phenotype (Elefteriou *et al.,* 2004). It is worthwhile to note that glucocorticoid serum levels are elevated in *ob/ob* mice but not in lipodystrophic mice (or patients). Yet, they display an increase in bone formation activity, thus demonstrating that the bone phenotype caused by an absence of leptin signaling is not linked to their level of circulating glucocorticoids. Lastly, it is remarkable that the high bone mass phenotype observed in leptin-signaling deficient mice exists despite an increase in bone resorption caused by both leptin-independent (hypogonadism) and leptin-dependent mechanisms (see below).

Regulation of Both Arms of Bone Remodeling by Leptin

Histomorphometric analyses, which allow the most objective evaluation of bone parameters because their results do not need to be adjusted for differences of lean/fat mass between samples, have shown a nearly twofold increase in trabecular bone volume in *ob/ob* (or *db/db*) mice compared to wild-type littermates (Ducy *et al.,* 2000). This phenotype is observed in both sexes, in growing and remodeling animals, and in long bones as well as in vertebrae. Remarkably, it affects only trabecular bone, where it is marked by the presence of many more thick trabeculae; cortical bone is not affected (Ducy *et al.,* 2000). The high bone mass phenotype of leptin-signaling deficient mice is owing to a massive increase in bone formation rate. As for the increase in bone volume, an increased bone formation rate is already present in fat-restricted 1-month-old *ob/ob* mice and heterozygote *ob/+* mice, which are not obese, indicating that it is the absence of leptin, not an increase in fat mass, that is responsible for this phenotype in leptin-signaling deficient animals (Ducy *et al.,* 2000).

In addition to its negative action on bone formation, leptin also regulates bone resorption. Both *ob/ob* and *db/db* mice show an increase in the number of osteoclasts and increased elimination of deoxypyridinoline cross-links (Dpd) in the urine. Although some of this phenotype can be attributed to their hypogonadism (Ducy *et al.,* 2000) subsequent studies, presented later, demonstrated that leptin exerts a dual influence on bone resorption: On the one hand, it favors it through the sympathetic nervous system, and on the other hand, it inhibits it through another molecular relay, cocaine- and amphetamine-regulated transcript (CART) (Elefteriou *et al.,* 2005). Based on the existence of a high bone mass phenotype in *ob/ob* and *db/db* mice one can nevertheless conclude that leptin's antiosteogenic action on bone formation is dominant over its effect on bone resorption (Fig. 1).

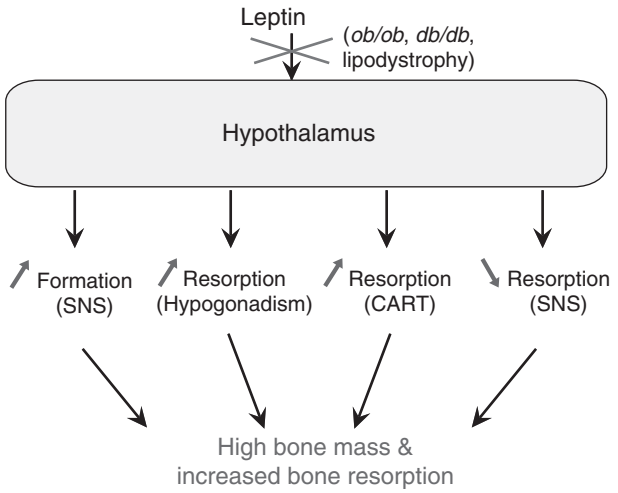

FIGURE 1 Dual effect of leptin on bone remodeling. The absence of leptin signaling in the hypothalamus causes a high bone mass phenotype despite an overall increase in bone resorption: disruption of the leptin-SNS dependent cascade both increases bone formation and decreases bone resorption while hypogonadism and a CART-dependent mechanism increase bone resorption.

Evidence of Leptin's Antiosteogenic Function in Human

Several observations provide pivotal evidence that the absence of leptin affects the function of osteoblasts in the same manner in human and mice. First, a patient harboring an inactivating mutation of the leptin gene was shown to display high bone mass (Elefteriou *et al.,* 2004). Second, lipodystrophic patients, whose serum leptin levels are extremely low because of the absence of adipocytes, display advanced bone age, an objective evidence of increased osteoblasts function, and osteosclerotic lesions (Westvik, 1996; Elefteriou *et al.*, 2004). Third, although they are based on less straightforward arguments, epidemiologic evidence also indicates that leptin antiosteogenic activity is conserved between mice and human. An early study noted an inverse association between serum leptin levels adjusted for fat mass and BMD in a group of 221 Japanese men (Sato *et al.,* 2001). Likewise, in a large cohort of young men (the Gothenburg Osteoporosis and Obesity Determinants [GOOD] cohort), leptin was found to be a negative independent predictor of areal BMD (aBMD), at several measured sites, and of cortical bone size of both the non–weight-loaded bone (radius) and the weight-loaded bone (tibia) (Lorentzon *et al.,* 2006). Importantly, this study was performed on a primarily healthy

population with normal body mass indexes sparing the need to adjust BMD readings for differences in lean and fat mass. In agreement with the absence of cortical phenotype in leptin-signaling deficient mice, this same study found that serum leptin levels were not independent predictors of cortical vBMD (Lorentzon *et al.,* 2006). Other cross-sectional studies have failed to show such negative association between serum leptin levels and areal aBMD (Goulding and Taylor, 1998; Martini *et al.*, 2001; Thomas *et al.*, 2001; Papadopoulou *et al.*, 2004). Most likely, some of the differences between these and other studies can be attributed to the way data are evaluated and presented either adjusted for body weight or unadjusted. For instance, in a large North American population-based study including a high representation of the elderly, non-Hispanic blacks, and Mexican Americans, BMD increases with increasing leptin concentration in men. However, after adjustment for body mass index (BMI) and other bone-related factors, an inverse association emerged, being most evident in men younger than age 60 (Ruhl and Everhart, 2002). Similarly, in a few recent studies in men, leptin was inversely correlated to aBMD, an association that became apparent only after adjustment of aBMD for body weight (Sato *et al.*, 2001; Morberg *et al.*, 2003). Additionally, one must be cautious when reporting the results of clinical studies including obese participants. Indeed, they are likely to show results shifted toward a positive association between serum leptin levels and BMD in response not to peripheral leptin levels but to central leptin resistance; the mere fact that obese individuals are overweight despite high levels of serum leptin demonstrates such leptin loss-of-function effect.

Anatomical Targets of Leptin's Action on Bone Remodeling

It is generally admitted that leptin's action on appetite and reproduction depends of its binding to a specific receptor located on hypothalamic neurons (Ahima and Flier 2000; Ahima, 2004). In agreement with this central mode of action intracerebroventricular (ICV) infusion of low doses of leptin in *ob/ob* mice, at a rate that does not result in any detectable leak of leptin in the general circulation, corrects their high bone mass (Ducy *et al.,* 2000). This rescue is complete, and occurs even at minimal doses that do not influence body weight (Elefteriou *et al.,* 2004), arguing that the central, presumably hypothalamic, action of leptin is its only physiological mode of action in terms of bone biology. Likewise, low doses of leptin administered by ICV infusion in wild-type animals induce a potent anti-osteogenic effect resulting in catastrophic bone loss within 1 month of infusion (Ducy *et al.,* 2000). This is an important point as peripheral injection of supra-physiological amounts of leptin to wild-type animals is correlated with a gain in bone mass (Cornish *et al.,* 2002; Martin *et al.,* 2005). However, as in obese individuals the presence of high levels of leptin in the serum of these treated animals is likely to induce central resistance and therefore induce in these animals a phenotype functionally similar to leptin deficiency i.e., bone gain.

Other experimental arguments also indicate that leptin, physiologically, does not act directly on osteoblasts. First, Stat3 phosphorylation cannot be detected following treatment of primary osteoblast cultures with physiological doses of leptin (Ducy *et al.,* 2000); an effect of leptin was observed only when high doses of leptin were used on osteoblastic cells differentiated *in vitro* (Thomas *et al.,* 1999). Second, a local action of leptin implies that the high bone mass observed in *db/db* mice, which lack the leptin receptor, is because of an osteoblast defect. Yet, cultured osteoblasts from *db/db* mice do not produce any more extracellular matrix than wild-type osteoblasts (Ducy *et al.,* 2000). Third, transgenic mice overexpressing leptin in osteoblasts have no overt bone abnormalities (Takeda *et al.,* 2002). Thus, at the present time there is no convincing evidence of a direct action of leptin on osteoblasts in physiological conditions *in vivo*.

Hypothalamic leptin receptors are known to be mainly present in two locations: neurons of the arcuate (ARC) nuclei, identified as most important in controlling leptin's function on appetite, and neurons of the ventromedial hypothalamic (VMH) nuclei. Lesioning neurons of the ARC nuclei in wild-type mice using monosodium glutamate (MSG) can increase appetite and induces obesity but does not affect bone formation parameters (Takeda *et al.,* 2002). In contrast, lesioning neurons of the VMH nuclei using gold thioglucose (GTG) induces an increase in bone mass because of an increase in bone formation parameters similar to the one observed in *ob/ob* mice (Takeda *et al.,* 2002). Moreover, in *ob/ob* mice whose VMH neurons have been lesioned leptin ICV infusion decreases body weight but does not affect bone formation parameters or bone mass. Conversely, leptin ICV fails to decrease body weight but decreases bone mass and bone formation in *ob/ob* mice whose ARC neurons have been lesioned (Takeda *et al.,* 2002). Thus, VMH neurons (or more precisely GTG-sensitive neurons) regulate bone formation under the control of leptin (Fig. 2). Importantly, if one considers the physiological implications of modulating leptin signaling to target bone formation disorders, this VMH rather than ARC mediation of leptin antiosteogenic effect dissociates this hormone's activity on appetite and bone mass.

EFFERENT SIGNALS AFFECTING BONE REMODELING

Cocaine- and Amphetamine-Regulated Transcript (CART)

CART is a neuropeptide precursor protein encoded by a gene expressed in hypothalamic neurons, in other parts

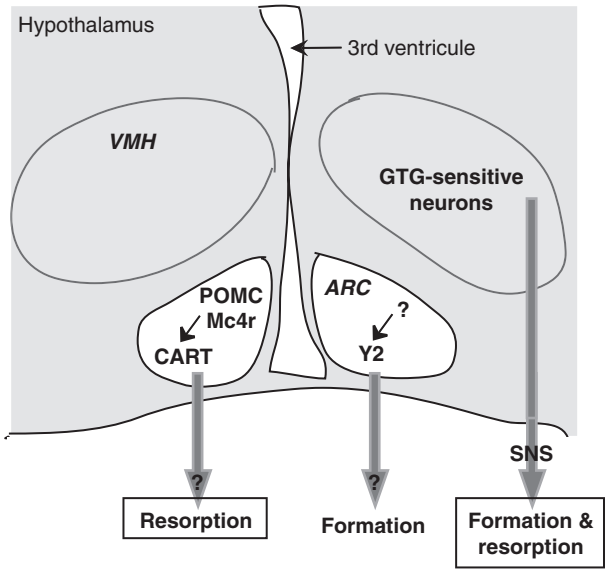

FIGURE 2 Role of hypothalamic regulations in the control of bone remodeling. The GTG-sensitive neurons present in the VMH nuclei mediate the leptin-dependent regulation of both arms of bone remodeling by the SNS. In addition, leptin, this time presumably in the ARC nuclei, controls a melanocortin (POMC/Mc4r)-dependent regulation of CART expression to act, via an unknown receptor, on the regulation of bone resorption by osteoblasts. Also presumably in the ARC nuclei signaling via the Y2 receptor has been proposed to regulate bone formation through an unknown cascade. At the present time only the CART and SNS pathways have been shown of relevance to human bone biology (boxed labels).

of the nervous system, in peripheral organs such as the pancreas and the adrenal glands but not in bone cells (Couceyro *et al.*, 1997; Elias *et al.*, 1998; Wierup *et al.*, 2004; Elefteriou *et al.*, 2005). That *Cart* expression is virtually undetectable in hypothalamic neurons of *ob/ob* mice suggested that it is positively regulated by leptin and could therefore act as a mediator of its function(s) (Douglass *et al.*, 1995; Kristensen *et al.*, 1998). Yet, Cart-deficient mice do not present a body weight or reproduction phenotype (Asnicar *et al.*, 2001). Instead, they display, in both sexes, a low bone mass phenotype at 6 months of age (Elefteriou *et al.*, 2005). Osteoblast numbers and bone formation rates are normal in these mice but osteoclast surface and number are nearly doubled in Cart-/- bones leading to a significant increase in urinary Dpd elimination. Considering the absence of *Cart* expression in *ob/ob* mice, this negative regulation of bone resorption by CART explains, at least in part, the increase in bone resorption observed in these mice. It was subsequently shown that *CART* polymorphism affects bone mass in postmenopausal women indicating that CART also regulates bone remodeling in humans (Guerardel *et al.*, 2006).

In agreement with the absence of *Cart* expression in bone cells, the Cart-/- phenotype is not bone cells autonomous as Cart-deficient bone marrow macrophages differentiate normally into osteoclasts and Cart-deficient bone marrow stromal cells can normally support osteoclastogenesis in coculture experiments (Elefteriou *et al.*, 2005). Analysis of gene expression in Cart-/- bones detected an increase in *Rankl* expression suggesting that Cart regulates bone resorption by ultimately modulating *Rankl* signaling (Elefteriou *et al.*, 2005; Ahn *et al.*, 2006). In absence of any identified CART receptor one can only speculate whether this factor acts directly on osteoblasts or uses one or several relays to signal to bone cells.

Melanocortin 4 Receptor

Melanocortins, a family of peptides produced by post-translational processing of pro-opiomelanocortin (POMC), regulate food intake and energy expenditure via binding to two melanocortin receptors expressed in the central nervous system (Mc3R, Mc4R). Although these receptors show a fairly widespread presence in the rodent brain (Mountjoy *et al.*, 1994; Kishi *et al.*, 2003), POMC has a limited distribution, with only two neuronal populations described: one in the arcuate nucleus of the hypothalamus (ARC) and the other in the nucleus of the tractus solitarius (NTS) of the brainstem (Palkovits *et al.*, 1987; Bronstein *et al.*, 1992). The POMC neurons of the ARC are known to be responsive to leptin via leptin receptors expressed on their surface and MC4R has thus been implicated in leptin's control of appetite (Cheung *et al.*, 1997; Cone, 1999). It was first reported that patients lacking Mc4R have high bone mineral density and advanced bone age (Farooqi *et al.*, 2000). Subsequently, Mc4r-/- mice were shown to have an increase in bone mass (Elefteriou *et al.*, 2005). This high bone mass phenotype is caused by an isolated decrease in osteoclast number and function while, throughout their life, these mice show normal bone formation parameters. Consistent with this phenotype, *Rankl* expression is lower in Mc4r-/- bones than in wild-type bones (Elefteriou *et al.*, 2005). The same decrease in bone resorption activity was also noted in MC4R-deficient patients (Ahn *et al.*, 2006).

Among the many abnormalities caused by Mc4R inactivation there is a nearly twofold increase in hypothalamic *Cart* expression (Elefteriou *et al.*, 2005). Likewise, serum CART levels are significantly increased in patients heterozygous for inactivating mutations of Mc4R (Ahn *et al.*, 2006). Analysis of Mc4R-deficient mice lacking either one or two copies of the *Cart* gene demonstrated that removing one allele of *Cart* is sufficient to normalize their bone resorption parameters and thereby their bone mass (Ahn *et al.*, 2006). Accordingly, *Rankl* expression is normalized in such compound homozygote mutant mice. In contrast, removing either one or two alleles of *Cart* from Mc4r-/- mice does not correct their obesity and their endocrine abnormalities (Ahn *et al.*, 2006). These results indicate that a high level of *Cart* expression, and thereby of CART

signaling, is the main molecular event accounting for the low-bone-resorption/high-bone-mass phenotype observed in absence of Mc4R but that it does not account for the accompanying metabolic abnormalities (Fig. 2).

Interleukin-1 (IL-1)

IL-1 is a polypeptide product that mediates several components of the acute-phase response to infection and injury. Its main sites of expression are the peripheral immune system and bone cells, as well as glia and neuron cells in the CNS (Lorenzo *et al.*, 1990; Dinarello, 1997). IL-1 is a potent stimulator of bone resorption; when injected subcutaneously it increases osteoclasts number and bone resorption surfaces in mice (Sabatini *et al.*, 1988). A natural IL-1 receptor antagonists has been identified, IL-1ra, that binds but does not activate the two known IL-1 receptors, IL-1RI and IL-1RII (Arend *et al.*, 1990; Dinarello, 1997). A role for peripheral IL-1 in regulating estrogen depletion-induced bone loss has been suggested as peripheral IL-1ra administration decreases osteoclast formation and bone resorption in ovariectomized mice (Kitazawa *et al.*, 1994), and IL-1RI-deficient mice do not lose bone after ovariectomy (Lorenzo *et al.*, 1998).

A recent study has implicated a central response to IL-1 in regulating bone remodeling (Bajayo *et al.*, 2005). Targeted overexpression of human IL-1ra to the central nervous system of mice using the murine glial fibrillary acidic protein promoter results in a low bone mass phenotype caused by a doubling of osteoclast numbers. Bone formation parameters are also increased, although moderately, in these transgenic mice. The relevance of this regulation to human physiology as well as the pathway connecting this central IL-1 signaling to bone remodeling is still unknown.

Y Receptors Signaling

The Y signaling system is complex, consisting of at least five receptors (Y1, Y2, Y4, Y5, and Y6) with different binding profiles and sites of expression in the central nervous system and the periphery, and of multiple endogenous ligands, Neuropeptide Y (NPY), peptide YY (PYY), and pancreatic polypeptide (PP) (Lin *et al.*, 2004). NPY is widely expressed in the central and peripheral nervous system and has been shown to play an important role in numerous physiological processes (Hokfelt *et al.*, 1998). Notably, increased NPY expression in the hypothalamus leads to increased food intake and obesity in mice if they are put on a high sucrose diet (Kaga *et al.*, 2001). In agreement with this observation, NPY fibers project from the ARC nuclei, which are known to participate in the control of appetite. The related family members peptide YY (PYY) and pancreatic polypeptide (PP) are produced in the small intestine and colon or in the pancreas, respectively (Hazelwood, 1993) where they affect gut motility, pancreatic and gall bladder secretion. PYY and PP can also access specific Y receptors in the hypothalamus and the brainstem to further influence pancreatic and gastric secretion. NPY and PYY have identical affinity for all known Y receptors (Y1, Y2, Y4, Y5, and in mouse also Y6), with PP preferring the Y4 receptor (Larhammar, 1996).

Although it is not clear which ligand(s) is/are involved because NPY-deficient mice show a normal bone mass (Elefteriou *et al.*, 2003), studies of genetically engineered mouse models have begun to shed some light on the role played by several Y receptors on bone biology in this species. Indeed, deletion of the Y2 receptor either germ line or hypothalamus-specific (via brain stereotaxic injection of Cre-expressing adenovirus) causes an increase in cancellous bone volume and cortical thickness secondary to accelerated bone formation (Baldock *et al.*, 2002; Baldock *et al.*, 2006). The Y2-deficient mice do not show an effect on bone resorption, as measured by osteoclast surface, but they have significantly reduced osteoclast numbers (Baldock *et al.*, 2002). More recently, it was shown that Y1-deficient mice also display a high bone mass phenotype characterized by increased cancellous bone volume and cortical density despite increased osteoclast surfaces (Baldock *et al.*, 2007). However, this phenotype cannot be observed when the Y1 deletion was restricted to the hypothalamus, indicating that this receptor does not act centrally to regulate bone mass (Baldock *et al.*, 2007). Instead, treatment of wild-type mouse calvarial osteoblasts with NPY markedly reduces cell numbers and this effect is abolished in Y1-deficient culture suggesting that Y1 regulates bone mass by acting directly on bone cells (Baldock *et al.*, 2007). Interestingly, the germ line deletion of Y2 causes a downregulation of Y1 expression in bone (Lundberg *et al.*, 2007) suggesting that part of the bone phenotype displayed by these mice could be caused, at least partly, by peripheral effects.

In contrast, bone mass is not altered in Y4-deficient mice (Sainsbury *et al.*, 2003). However, bone volume is increased threefold in Y2-/-;Y4-/- double mutant mice because of an increase in the bone formation rate (Sainsbury *et al.*, 2003). These changes are more pronounced than those observed in Y2-deficient mice, suggesting that the Y2 and Y4 signaling pathways act synergistically. Although these mice show an increase in circulating levels of PP, the preferred Y4 ligand, this abnormality is not responsible for their bone phenotype because neither Y4-deficient mice, which also show an increase in PP levels, nor transgenic mice overexpressing PP have a bone phenotype (Sainsbury *et al.*, 2003). In contrast, because the Y2 deletion results in elevated NPY levels in the hypothalamus (Sainsbury *et al.*, 2003) it is conceivable that the more severe phenotype observed in Y2/Y4-deficient mice compared to Y2 or Y4 single mutants results from an enhanced signaling by this neuropeptide on Y4 receptors that is disrupted in the double mutant mice. Another possibility could be that the decrease in serum leptin levels

observed in double Y2/Y4-deficient mice but not in single mutant mice (Sainsbury *et al.,* 2003) contributes to their phenotype.

NeuromedinU

NeuromedinU (NMU) is a neuropeptide produced by nerve cells in the small intestine and by structures in the brain, including the dorsomedial nucleus of the hypothalamus and the pituitary (Brighton *et al.,* 2004). It is generally assumed that NMU regulates various aspects of physiology including appetite, stress response, and SNS activation (Brighton *et al.,* 2004). Although NMU expression appears regulated by leptin (Howard *et al.,* 2000), NMU-deficient mice develop a leptin-independent obesity phenotype (Hanada *et al.,* 2004). However, NMU-deficient mice present a high bone mass phenotype associated with an increase in bone formation similar to the one displayed by *ob/ob* mice (Sato *et al.,* 2007). This phenotype is not cell autonomous as NMU-deficient osteoblasts in culture are indistinguishable from wild-type osteoblasts and treatment of wild-type osteoblasts with NMU do not affect their proliferation or differentiation. In contrast, ICV infusion of NMU in both NMU-/- mice and wild-type mice decreases bone formation and bone volume (Sato *et al.,* 2007).

Most importantly, ICV infusion of NMU in *ob/ob* mice decreases bone volume as in wild-type mice but ICV infusion of leptin in NMU-/- mice cannot decrease bone mass, demonstrating that NMU is a mediator for leptin's action on bone formation (Sato *et al.,* 2007). Furthermore, treatment of NMU-deficient mice with the β-agonist isoproterenol does not decrease their bone mass, indicating that NMU is involved in the SNS regulation of bone remodeling. Additional analyses demonstrated that hypothalamic NMU only affects the leptin-dependent negative regulation of bone formation by the molecular clock (Sato *et al.,* 2007). Given the lack of an obesity phenotype in mice deficient for the NMU receptor (NMUR2) (Zeng *et al.,* 2006), and provided that this pathway is conserved in human NMU antagonists might become good candidates to treat bone-loss disorders without inducing undesirable effect on body weight.

Sympathetic Nervous System

One of the many abnormalities displayed by the *ob/ob* mice is a low sympathetic activity (Bray and York 1998) suggesting that the sympathetic nervous system (SNS) could mediate leptin's regulation of bone mass. In support to this hypothesis restoring sympathetic activity in *ob/ob* mice by treating them with an adrenergic agonist leads to a dramatic decrease in bone mass (Takeda *et al.,* 2002). Also consistent with a role of the sympathetic nervous system in mediating leptin's antiosteogenic action on bone mice deficient in dopamine β-hydroxylase (DBH), an enzyme necessary to produce norepinephrine and epinephrine, the catecholamine ligands produced by the SNS, have a high bone mass and this high bone mass persists upon leptin ICV infusion (Takeda *et al.,* 2002). A further demonstration that the central effect of leptin on bone remodeling is mediated by the sympathetic nervous system instead of a circulating factor is based on cross-circulation experiments between *ob/ob* animals. In pairs of parabiosed *ob/ob* mice where one mouse was implanted with a pump infusing leptin centrally, bone mass dropped significantly only in the mouse receiving leptin ICV (Takeda *et al.,* 2002). Although this result does not rule out the existence of a short-lived humoral mediator, it strongly suggests the existence of a neuronal mediation of leptin antiosteogenic function.

An extensive gene expression analysis determined that the only adrenergic receptor expressed in osteoblasts is the β2 adrenergic receptor ($Adr\beta_2$) (Takeda *et al.,* 2002). In the light of this specificity and of the fact that they have normal body and fat pad weights and none of the endocrine abnormalities observed in *ob/ob*, *db/db,* or Dbh-/- mice Adrβ2-/- mice are the most accurate model to elucidate whether and how sympathetic signaling in bone cells regulates bone mass. Histomorphometric analysis of Adrβ2-deficient mice revealed that they have high bone mass phenotype (Takeda *et al.,* 2002). This phenotype is cell-autonomous as transplantation of bone marrow cells (BMCs) from wild-type mice into irradiated Adrβ2-/- mice normalizes their bone formation parameters whereas transplantation of Adrβ2-/- BMCs into irradiated wild-type mice significantly increases bone formation (Elefteriou *et al.,* 2005). Importantly the bone phenotype observed in Adrβ2-deficient mice cannot be rescued by leptin ICV infusion demonstrating that the sympathetic nervous system, via Adrβ2 mediates leptin regulation of bone mass (Takeda *et al.*, 2002; Elefteriou *et al.*, 2005). Because Adrβ2-/- mice have no overt endocrine abnormalities this experiment also formally establishes that the high bone mass observed in absence of leptin signaling is not secondary to any metabolic perturbations.

The bone phenotype of the Adrβ2-/- mice originates from both an increase in bone formation and a decrease in bone resorption. Indeed, these mice have an increase in osteoblast number because of an increase in these cells' proliferation ability. At the molecular level this phenotype is caused by a dual mechanism: On the one hand, sympathetic signaling acts on AP-1 genes to favor osteoblast proliferation, and on the other hand, it inhibits osteoblast proliferation by affecting, through the molecular clock, both *D type cyclin* and *AP-1* gene expression (Fu *et al.,* 2005). The Adrβ2-/- mice also show a significant decrease in number of tartrate-resistant acid phosphatase (TRAP)-positive multinucleated osteoclasts caused by a defect in osteoclast differentiation, and therefore a decrease in urinary elimination of Dpd (Elefteriou *et al.,* 2005). This phenotype can also be observed in wild-type mice transplanted with Adrβ2-/- bone marrow cells indicating that it is cell autonomous. It is caused by an increase in *Rankl* expression

by osteoblast progenitor cells following protein kinase A phosphorylation of ATF4, a cell-specific CREB-related transcription factor essential for osteoblast differentiation and function (Yang *et al.*, 2004; Elefteriou *et al.*, 2005). Neither bone formation nor bone resorption phenotypes can be corrected by leptin ICV infusion, indicating that leptin signaling can regulate both arms of bone remodeling via the SNS (Takeda *et al.*, 2002; Elefteriou *et al.*, 2005).

As for leptin's regulation of bone remodeling, several clinical observations indicate that the SNS function on bone mass is conserved in human. For instance, patients with reflex sympathetic dystrophy, a disease characterized by localized high sympathetic activity, develop a severe and localized osteoporosis that can be treated by β-blockers (Kurvers, 1998). Likewise, multiple epidemiologic studies reported beneficial effects of β-blocker administration on BMD and/or fracture risk in women. In a population of 1,344 postmenopausal women (Geelong Osteoporosis Study) it was found that a higher BMD at the total hip (2.5%, $p = 0.03$) and ultradistal forearm (3.6%, $p = 0.04$) as well as a decreased fracture risk (odds ratio for fracture associated with β-blocker use = 0.68) associates with β-blockers use (Pasco *et al.*, 2004). Subsequent analyses also reported that β-blocker use was associated with a decrease in serum CTx levels (Pasco *et al.*, 2005). A case-control analysis using the UK General Practice Research Database (GPRD) showed that compared to patients who did not use them, the odds ratio for current use of β-blockers was 0.77 (Schlienger *et al.*, 2004). Another study of 158 women taking β-blockers and 341 age-matched controls showed that the odds ratio for fracture (at all sites) in the β-blocker user group was 0.56. In this study β-blocker use was associated with a higher BMD at the femoral neck (+4.2%, $p < 0.05$) and L1–L4 (+3.2%, $p < 0.05$) while proximal femur scans revealed significantly higher cortical width (+3.6%, $p < 0.05$) at the femoral neck of patients under β-blockers (Bonnet *et al.*, 2007). A small prospective case-control study in elderly patients showed that bone mineral density was significantly greater at the total hip and spine sites of beta-blocker users compared with nonusers (Turker *et al.*, 2006). More generally, a systematic computerized search of MEDLINE, EMBASE, and LILACS databases from 1966 to December 2005 for case-control and cohort studies of associations between exposure to antihypertensive agents and fracture outcomes showed that β-blockers induce a statistically significant protection against fractures (pooled relative risk = 0.86), especially relevant to hip fractures (28% relative risk fracture reduction); in contrast, the use of α-blockers did not appear to protect against fractures (Wiens *et al.*, 2006).

A few studies also reported less conclusive evidence of a beneficial effect of β-blockers on bone mass in human patients. For instance, no difference in BMD could be found between men with severe myocardial infarction taking or not taking cardioselective β-blockers. Likewise, in U.S. women enrolled in the Study of Osteoporotic Fractures (SOF) total hip BMD was greater among β-blocker users but adjustment for body weight or other parameters eliminated the difference. Nevertheless, there was a protective effect of β-blockers against hip fracture (hazard ratio for hip fracture associated with β-blocker use was 0.76) (95% CI 0.58–0.99) (Reid *et al.*, 2005). The discrepancy between the results of these and the studies cited earlier could have many origins. Among the most likely is the specificity of the β-blocker used. Indeed, it was recently shown that although mouse osteoblasts do not normally express the adrenergic receptor 1 (Adrβ1) and Adrβ1-deficient mice do not show a bone phenotype, Adrβ1-/-; Adrβ2-/- double mutant mice deficient display a low bone mass phenotype (Pierroz *et al.*, 2006). This result suggests that the Adrβ1 receptor could, via an osteoblast-independent mechanism, counteract the effect of Adrβ2 on bone remodeling. If this mechanism is conserved in human this observation implies that patients treated with non-Adrβ2 specific β-blockers could display either a low or a normal BMD. Differences of doses of β-blockers could be another significant factor of variability between studies. Administration of 0.1, or 5, or 20 mg/kg of the β-blocker propranolol in ovariectomized rats showed that the best preventive effect against bone loss was obtained with the lowest dose, the highest dose being ineffective (Bonnet *et al.*, 2006). It is therefore most likely that only long-term prospective randomized trials taking into account at least the specificity and dosage of the β-blocker(s) evaluated will provide the most accurate demonstration of the protective effect of this class of molecules in human.

Cannabinoid Receptors

An unexpected role of the endocannabinoid system, which is known to regulate analgesia, energy balance, and appetite, in the regulation of bone mass has been revealed in mice and some of these findings have been validated in human (Di Marzo *et al.*, 2004). There are two highly homologous cannabinoid receptors, CB1 and CB2, which are similarly activated by endocannabinoids but yet show functional differences (Bisogno *et al.*, 2005). CB1 is predominantly expressed in the brain and peripheral neurons, where it is responsible for the psychotropic action of cannabinoids, but it is also expressed in peripheral tissues including immune cells, the reproductive system, the gastrointestinal tract, and the lung (Di Marzo *et al.*, 2004). CB2 is not expressed in the brain; it is mainly expressed in immune cells (Di Marzo *et al.*, 2004).

Mice with a targeted deletion of CB1 have an increase in bone mass in both an ADH and a CD1 genetic background (Idris *et al.*, 2005; Ofek *et al.*, 2006; Tam *et al.*, 2006), although bone formation and resorption parameters are normal in these latter mice (Tam *et al.*, 2006).

Surprisingly, the same mutation, this time in the C57Bl/6J genetic background, causes a low bone mass phenotype associated with a decrease in bone formation rate and, in females only, an increase in osteoclast number (Tam *et al.,* 2006). The bases of this difference of phenotype between strains of mice are still unclear. Four single nucleotide polymorphisms (SNPs) have been identified in the human CB1 gene but no statistically significant differences of allele or genotype distributions were found between postmenopausal osteoporotic patients and age- and sex-matched controls (Karsak *et al.,* 2005).

In contrast, CB2 appears to be involved in regulating bone remodeling in both rodent and human species. CB2-deficient mice display a low bone mass phenotype characterized by an increase in bone formation rate as well as a sharp increase in osteoclast number (Ofek *et al.,* 2006). In a population of 168 postmenopausal osteoporotic women and 220 ethnically, age- and sex-matched controls, several CB2 SNPs show a significant difference of allele frequencies between cases and controls (Karsak *et al.,* 2005). These results are consistent with an involvement of the CB2 locus in human osteoporosis.
