Chapter 49

Insulin-like Growth Factors and the IGF Binding Proteins: Implications for Bone Biology

Clifford J. Rosen*

Division of Preventive Medicine, Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA

INTRODUCTION

It has been fifty years since Salmon and Daughaday first reported the presence of a soluble factor induced by growth hormone (GH) that had insulin-like properties and mediated somatic growth. The subsequent identification of the insulin-like growth factors (IGFs) has led to remarkable discoveries and therapeutic advances, particularly in relation to the skeleton. IGFs are 7 kDa peptides that are ubiquitous in nature and regulate cell growth and death (Daughaday *et al*., 1972). Outside the liver, bone is the richest source of IGF-I and IGF-II in the mammalian body, and these 'local' IGFs play a predominant role in skeletal modeling and acquisition. IGFs are also highly conserved across species; hence the physiology of these peptides can be studied in numerous animal models. Although GH has been recognized as the major determinant of circulating IGF-I, the balance between skeletal and serum IGF-I has also been clarified, particularly with the relatively recent introduction of genomic engineering.

The role of the GH/IGF system in aging has undergone intense scrutiny in the last two decades. Biological aging is a normal physiological process, part of the continuum from growth to death. Like other organ systems, skeletal homeostasis is maximized during the second and third decades of life, and IGFs are essential for that process. However, trabecular bone loss also begins by the third decade, even though we still do not understand how this happens. The hypothalamic-pituitary axis is profoundly affected by aging. GH secretion is reduced, resulting in lower levels of circulating IGF-I and IGF-II, but higher levels of IGF binding proteins, IGFBP-1, -2, and -4 (Kelijman, 1991; Rudman *et al*., 1981). Early attempts to link age-related bone loss to a suppressed GH-IGF-I axis, or enhanced IGFBP expression, spawned considerable interest in GH and/or IGF-I as therapeutic tools for osteoporosis. The advent of recombinant gene technology propelled synthetic growth factors into an ever-expanding therapeutic domain, particularly in regard to short stature. Another therapeutic venue for GH has been in its potential utility for the frail elderly. The paradigm that a "somatopause," or GH deficiency state with aging, produces discrete musculoskeletal changes, has never been firmly defined, nor whether these changes can be reversed with GH. On the other hand, GH is indicated for individuals with pituitary insufficiency, and long-term studies suggest a major benefit can be realized in respect to bone mineral density (BMD) and quality of life. Regardless, more attention has focused on understanding the IGF regulatory system (i.e., IGFs, IGFBPs, Type I, II IGFR, and proteases that cleave IGFBPs) in relation to both bone acquisition and maintenance (Rudman *et al*., 1990). In this chapter, we will review the cellular and systemic actions of the IGFs, in order to more fully understand the functional integration of IGF regulatory components with other skeletal and systemic factors. As such, a thorough overview of the physiology of the IGF system, from GH to receptor signaling, is warranted.

THE IGF REGULATORY SYSTEM AND ITS RELATIONSHIP TO THE SKELETON

IGF-I, -II, and Their Receptors (IGFRs)

The IGFs are single-chain polypeptides. IGF-I consists of 70 amino-acid residues and IGF-II has 67 amino acids.

Principles of Bone Biology, 3rd Edition

They have B, C, and A domains similar to proinsulin, but a D domain that is not found in proinsulin. This D domain may sterically hinder the interaction of the IGFs with the insulin receptor (IR), leading to only weak ligand binding of the IGFs to the IR. A number of post-transcriptional and post-translational variants of the IGFs have also been described (Slootweg *et al*., 1990). These IGFs have variable affinities for IGFBPs and the IGFRs. *In vitro,* these growth factors may have significantly greater activity than native IGF-I or IGF-II, especially those that exhibit weak binding to the IGFBPs.

IGF-I and IGF-II differ in their abilities to promote tissue growth due in part to the presence of distinct IGFRS, IGF-IR and IGF-IIR (Le Roith *et al*., 1997) (see Fig. 1). IGF-IR is a tetramer consisting of two identical extracellular α-subunits (conferring ligand binding specificity) and two identical transmembrane β-subunits (possessing tyrosine kinase activity). IGF-IR resembles the IR, and shares amino acid sequence homology (Zeslawski *et al*., 2001). IGF-II and insulin also bind to the IGF-IR but with 2- to 15-fold and 1,000-fold lower affinities, respectively (D'Ercole, 1996). It has an intrinsic tyrosine kinase activity critical for specific second message generation and indeed, ligand binding to the extracellular domain of the IGF-IR results in autophosphorylation and tyrosine phosphorylation of IGF-IR substrates. Tyrosine-phosphorylated IRS-1 and SHC bind different effector proteins involved in interconnecting pathways, including Ras/Raf-1/mitogen-activated protein kinase (MAPK, also known as extracellular signal-regulated kinase, ERK) and phosphatidylinositol 3-kinase (PI3K)/ phosphoinositide-dependent kinase-1 (PDK-1)/Akt (Maroni *et al*., 2004). Activation of the Ras/Raf-1/MAPK pathway is considered to be critical for cell proliferation whereas the PI3K/PDK-1/Akt pathway is considered to be important for cell survival. The protein encoded by the phosphatase and tensin homologue gene deleted on chromosome 10 (PTEN) is a lipid phosphatase that decreases the activation of Akt by dephosphorylating phosphatidylinositol-3,4,5-triphosphate (PIP3) and phosphatidylinositol-3,4-biphosphate (PIP2). Therefore, PTEN acts as an off switch for the PI3K/PDK-1/Akt pathway as well as a tumor suppressor. This tumor suppressor gene is deleted or mutated in various types of human cancers (Zhao *et al*., 2004; Sansal *et al*., 2004). On the other hand, the monomeric IGF type II receptor (IGF-IIR) does not bind insulin but binds IGF-II, with a 500-fold increased affinity compared to IGF-I (Khandwala, 2000).

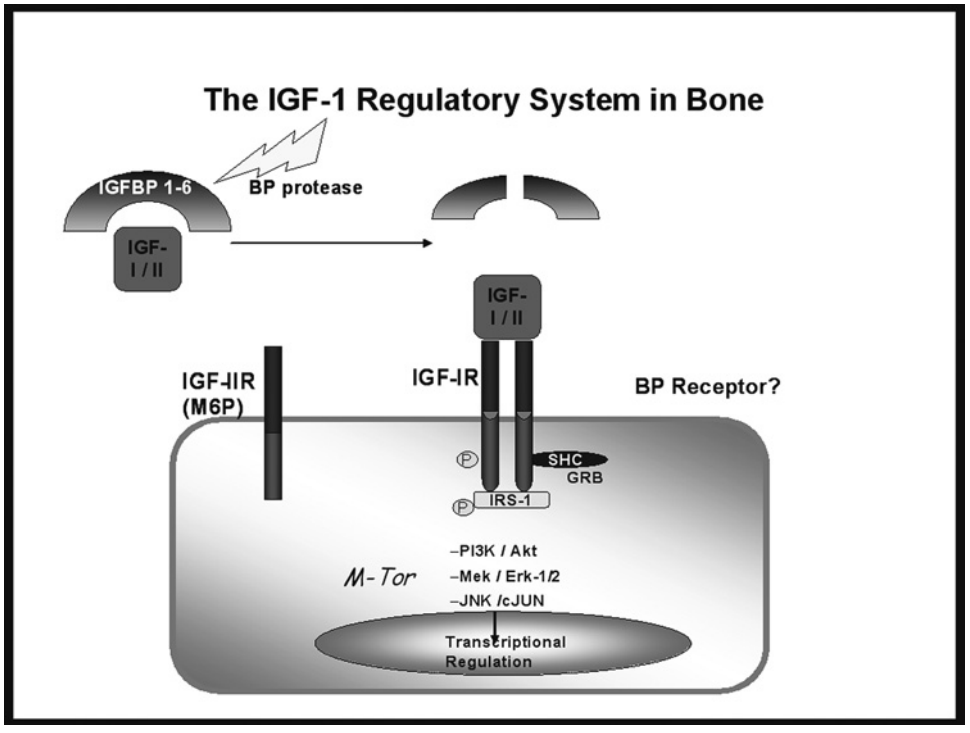

FIGURE 1 The IGF regulatory system contributes to bone formation through activation of the IGF type I receptor on osteoblasts. The downstream signaling is via three pathways 1-PI3 kinase/Akt/mTor, 2-MAP kinase/ERK, and 3-JNK/Jun. PI3K/mTor regulates cell differentiation, while the MAP/ERK and JNK/Jun impact cell growth. The IGFBPs carry IGFs to the receptor; several proteases can cleave IGFs for binding to the type I receptor. The type II IGF receptor can bind IGF-II and generally is a clearance mechanism for IGF-II and serves also as mannose 6 phosphate binding site. Finally, IGFBP receptors have been theorized as possible IGF independent signaling factors but none have been proven. However, it is likely that IGFBPs could bind to other receptors (e.g., EGF) and affect cell growth and differentiation.

The IGF-IIR exhibits no intrinsic kinase activity but is structurally very similar to the mannose 6-phosphate receptor, which is involved in targeting lysosomal enzymes intracellularly (Le Roith *et al*., 1997; Sell *et al*., 1995). Interestingly, it is now clear that in most tissues, except the liver, there are hybrid IGF-IR/IR receptors leading to significant cross-utilization between two rather distinct peptides. Hybrid receptors may also explain the growth-promoting activity of insulin, even in skeletal tissue, as well as the hypoglycemic effects of recombinant human IGF-I (rhIGF-I) when administered parenterally.

The IGFs possess tremendous growth potential as endocrine, autocrine, and paracrine factors. However, adequate nutrition is required for the full expression of IGFs' biologic activity, including its critical role in linear growth. For example, during states of malnutrition, GH production increases but hepatic IGF-I generation is severely impaired. Resistance at the hepatic GH receptor (GHR) reduces serum IGF-I and impairs GH bioactivity. The mechanism surrounding these nutrient-sensitive changes has not been clarified although message stability is clearly reduced by undernutrition. For malnourished children, the result is cessation of linear growth. GH resistance, to lesser degrees, occurs in other conditions such as diabetes mellitus, acute catabolic stresses, and renal insufficiency.

IGFs are produced in virtually every tissue (Rosen *et al*., 1994). However, the main source of circulating IGFs is the liver. Other sources of IGF-I include the skeleton and adipose tissue (Rosen *et al*., 1994; Mohan *et al*., 1990). Together these three sites contribute more than 95% to the circulating IGF-I pool. With acute or chronic hepatic insufficiency, both serum IGF-I and IGF-II levels are markedly decreased. In the circulation, IGFs are bound to serum IGFBPs, with a relatively small but detectable amount of 'free' IGF-I, which does circulate, but has a very short half-life. GH treatment increases total and free IGF-I levels in a dose-dependent manner, but rhIGF-I increases 'free' IGF-I considerably more than rhGH. The clinical significance of increases in 'free' IGF-I, versus that bound to the IGFBPs is not known.

The distribution of IGFs in the serum pool is determined by the relative saturation of the IGFBPs. This may explain why treatment with IGF-I may have different tissue effects than treatment with GH. Infusions of IGF-I produce a transient rise in free IGF-I and suppression of IGF-II, insulin, and endogenous GH (Ebeling *et al*., 1993). During the course of an IGF-I infusion, however, IGF-I is partitioned into several pools. This is due to the unsaturated nature of the lower molecular weight IGFBPs, and the presence of a large (150-kDa) circulating ternary IGF binding complex. This complex, composed of IGF-I (or -II), IGFBP-3 (or IGFBP-5), and an acid labile subunit (ALS), is the major circulatory reservoir for both IGFs. Normally, the majority of circulating IGF is bound to this saturated intravascular complex. However, with rapid IGF-I infusions, some IGF-I goes into the lower (50-kDa) unsaturated IGFBP fractions where transport into the extravascular space is possible. Partitioning of IGFs into various binding pools is critical to the biologic activity of both GH and IGF-I.

IGF-Binding Proteins (IGFBPs)

In the circulation and in tissues there are six IGFBPs. IGFBPs 1–6 belong to the same gene family and several features distinguish these known IGFBPs from one other (Rajaram *et al*., 1997). Just as the IGFBPs serve important regulatory functions within the circulation, their role at the tissue level is also critical for the full biologic expression of IGFs. Binding of IGFBPs to IGFs normally blocks the interaction between IGFs and IGF-IR and consequently suppresses IGF actions (Kelley *et al*., 1996; Collett-Solberg *et al*., 1996). Nevertheless, binding of IGFBPs to IGFs can also protect IGFs from proteolytic degradation, and consequently enhances the IGF actions by augmenting their bioavailability in local tissues (Kelley *et al*., 1996; Collett-Solberg *et al*., 1996). Therefore, most of the IGFBPs function in a bipotential manner, and their impacts on IGFs depend to a large extent on the post-translational modification of IGFBPs by phosphorylation and proteolysis (Kelley *et al*., 1996; Collett-Solberg *et al*., 1996; Coverley *et al*., 1997; Claussen *et al*., 1997). Some IGFBPs also exhibit IGF-independent effects (Kelley *et al*., 1996; Mohan *et al*.,1996).

The predominant binding protein in serum (and bone) is IGFBP-3, a 43-kDa glycosylated peptide. It is present in large concentrations in the serum and is easily measurable by radioimmunoassay (RIA). As noted earlier, IGFBP-3 is part of a larger saturated ternary complex including IGF-I (or -II) and an 80-kDa ALS. The association of these three proteins requires the presence of either IGF-I or IGF-II. In turn, this complex prolongs the half-life of the IGFs and provides a unique storage site.

The level of circulating IGFBP-3 is principally controlled by GH (Martin *et al*., 1988). However, IGFBP-3 synthesis outside of the liver is regulated by other endocrine and paracrine factors. At a cellular level, IGFBP-3 has stimulatory or inhibitory effects on IGF-I depending on both the cell type and the physiologic milieu. IGFBP-3 action at the cell is characterized by its interaction with IGF-I or -II. *In vitro,* coincubation of IGFBP-3 with IGF-I can block IGF access to the IGF-IR (Rosen *et al*., 1994; Conover, 1991). Conversely, preincubation of IGFBP-3 in certain cell systems facilitates receptor binding of the ligand by attaching to the cell membrane at a site remote from the receptor. In addition, very recent data suggest that IGFBP-3 may have IGF-independent actions on cell action. Although a putative IGFBP-3 receptor has not been cloned, IGFBP-3 has been shown to downregulate cell proliferation in certain cell lines and to enhance p53 production.

Further regulation of IGF-I by IGFBP-3 can occur in the extracellular space if IGFBP-3 undergoes proteolysis. Enzymatic degradation of IGFBP-3 produces low-molecular-weight IGFBP-3 fragments that differ in their affinities for the IGFs (Cohen *et al*., 1992; Mohan, 1993). There are numerous IGFBP-3 proteases, which are produced by various cell types, that can be found in the intra- and extravascular space, and are regulated by both endocrine and paracrine factors. Prostate-specific antigen (PSA) is a serine protease that cleaves IGFBP-3 and may be important in defining skeletal metastases with prostate cancer (Nunn *et al*., 1997).

IGFBP-1, -2, -4, and -5 are also important systemic and local regulators of IGF bioactivity. In contrast to IGFBP-3, these IGFBPs are not fully saturated and they easily translocate from the circulation into the extracellular space. IGFBP-1 is a 30-kDa peptide produced primarily in the liver. Serum IGFBP-1 levels correlate inversely with circulating insulin and, in poorly controlled insulin-dependent diabetes mellitus (IDDM), serum IGFBP-1 levels are quite high (Brismar *et al*., 1988). Hepatic IGFBP-1 production is tightly regulated by insulin and substrate availability. However, unsaturated IGFBP-1 could also serve as a reservoir of binding activity for unbound IGF or as the initial binding site for cell-secreted IGF, prior to transfer to the more stable, GH-dependent 150-kDa complex. Shifts in the levels of IGFBP-1 may alter the distribution of the IGFs among the other IGFBPs and thus affect the relative distribution of the IGFs between the intra- and extravascular space. This mechanism could be critical in controlling metabolic and mitogenic activities of the IGFs (Arany *et al*., 1994). In relation to the skeleton there is some *in vitro* suggestion that IGFBP-1 is synthesized by osteoblast and could inhibit IGF actions in bone during states of high IGFBP-1 production, such as starvation, and IDDM.

Human IGFBP-2 is a 31-kDa protein that preferentially binds to IGF-II (Christiansen *et al*., 1991). It is the major IGFBP in cerebrospinal fluid and is likely produced by neural cells. Insulin and dexamethasone have been shown to decrease production of IGFBP-2 in rat osteoblasts (Schmid *et al*., 1992). Excess rhIGFBP-2 inhibits IGF-I stimulated bone cell proliferation, bone collagen synthesis, and bone formation. Skeletal concentrations of IGFBP-2 are not nearly as high as IGFBP-3, -4, or -5 levels. Interestingly, IGFBP-2 concentrations increase with GHD and malnutrition as well as during aging. These changes are likely associated with its inhibitory properties. Yet, in puberty, there is a spike in IGFBP-2 production, predominantly from the liver. Khosla *et al*. (1998) reported that pro-IGF-II coupled to IGFBP-2 is present in the circulation of patients with osteosclerosis due to hepatitis C infections, suggesting that IGFBP-2 may have a permissive role in enhancing skeletal turnover, and in binding, through its heparin binding domain, to extracellular matrices. In addition, animal studies using IGF-II and IGFBP-2 in a complex have demonstrated that this combination can prevent disuse- and ovariectomy-induced bone loss (Conover *et al*., 2002). Recently, IGFBP-2 null mice have been shown to have low bone mass as well.

IGFBP-4 is a glycosylated 24-kDa binding protein. It is one IGFBP that is consistently inhibitory for the IGFs in numerous cell systems. It was originally isolated from skeletal tissue and was found to inhibit IGF-mediated bone cell proliferation (Mohan *et al*., 1989; Scharla *et al*., 1993). The expression of IGFBP-4 in bone cells is regulated by cyclic adenosine monophosphate (AMP), parathyroid hormone (PTH), and 1,25-dihydroxyvitamin D. In addition, IGF-I stimulates IGFBP-4 proteolysis through the target enzyme, pregnancy-associated plasma protein-A (PAPP-A), thereby providing an autocrine/paracrine loop between the ligand and its binding protein (Durham *et al*., 1994). PAPP-A deficient mice have been shown to have a growth phenotype with a reduced body size and a low bone mass, suggesting a complex role for this autocrine-paracrine loop, particularly in the skeleton.

Preliminary evidence suggests that circulating levels of IGFBP-4 may reflect local bone cell regulation. Rosen *et al*. (1992) have shown high serum levels of a 24-kDa IGFBP (likely to be IGFBP-4) in elderly women with hip and spine fractures. The relative ligand binding of IGFBP-4 in serum from osteoporotic women is closely correlated with circulating concentrations of PTH, suggesting that serum changes mirrored local skeletal activity (Rosen *et al*., 1992). More recent data from Mohan *et al.*, utilizing a specific RIA for IGFBP-4, have shown an age-related increase in this binding protein and a relatively strong correlation between PTH and IGFBP-4 (Honda *et al*., 1996). The age-related changes in IGFBP-4 have been confirmed in a larger study from the Framingham cohort, although those investigators did not find a relationship between PTH and IGFBP-4 (Karasik *et al*., 2003). More recently, it has been reported that IGFBP-4 null mice are smaller and have a reduced BMD, suggesting IGFBP-4 may serve as a reservoir for IGF-I and that the relative proportions of IGF-I and IGFBP-4 are critical to define its function.

IGFBP-5 is a nonglycosylated 31-kDa IGFBP produced by osteoblasts and numerous other cell types. It is found in relatively high concentrations, both in bone and in serum, where it can be measured by RIA (Nicolas *et al*., 1994). IGFBP-5 is the most abundant IGFBP stored in the bone, where it is bound to hydroxyapatite and extracellular matrix proteins (Nicolas *et al*., 1995; Mohan *et al*., 1995). IGFBP-5 is the only IGFBP that has been shown to consistently stimulate osteoblast cell proliferation *in vitro*, thus increasing the number of osteoblasts. Recent studies suggest that the mitogenic effects of IGFBP-5 may in part be independent of IGFs and mediated through rhIGFBP-5's own signal transduction pathway (Mohan *et al*., 1995; Andress *et al*., 1991; Schmid *et al*., 1996; Slootweg *et al*., 1996; Richman *et al*., 1999). IGFBP-5 has the unique capacity

to bind extracellular matrices, particularly hydroxyapatite. IGFBP-5 can also bind the ALS and IGF-I/IGF-II in the circulation, providing an alternative ternary complex. *In vitro,* IGFBP-5 enhances IGF bioactivity, especially in bone. Yet, *in vivo*, IGFBP-5 action can be either inhibitory or stimulatory depending on the relative concentration of IGF-I and its mode of administration (Salih *et al*., 2005). Its synthesis is increased by PTH and other cyclic AMP analogs (Conover *et al*., 1993). Intact IGFBP-5 can be found circulating in the extracellular space, attached to extracellular matrices, or cleaved into lower molecular weight protein fragments. Intact IGFBP-5's major role in the skeleton may be as a storage component for the IGFs because both IGF-I and IGF-II have very low binding affinity for hydroxyapatite, but bind avidly to IGFBP-5 (Rosen *et al*., 1994). During remodeling, resorption enhances proteolytic cleavage of IGFBP-5. In addition, during formation and mineralization, synthesis and release of IGFBP-5 by bone cells facilitates attachment of IGFs to the newly mineralized matrix (Koutsilieris *et al*., 1992).

IGFBPs are composed of three domains of approximately equal sizes (Baxter, 2000). The amino- and carboxyl-terminal domains are each internally disulfide-linked and share a high degree of sequence homology across the family (Neumann *et al*., 1999). However, little homology is exhibited among their central L-domains. The disulfide linkages of the amino-domain of IGFBP-6 differ from those of other IGFBPs, whereas the carboxyl-domain disulfides are the same for all IGFBPs so far studied (Neumann *et al*., 1999; Forbes *et al*., 1998; Chelius *et al*., 2001). IGFBP-6 differs functionally from other IGFBPs in binding IGF-II with 20- to 100-fold higher affinity than IGF-I, whereas IGFBPs 1–5 do not have a marked IGF binding preference (Headey *et al*., 2004). Therefore, IGFBP-6 constitutes a relatively specific IGF-II inhibitor (Bach, 1999).

Proteases that Cleave IGFBPs

IGF bioactivity is regulated transcriptionally by hormones and paracrine factors. Tissue activity of the IGFs is also controlled by their respective binding proteins. Tissue specific proteases provide another form of regulation of IGFs at a post-translational level. Binding protein targeted proteases have been identified in serum and in various tissues including bone. These proteases alter the binding capacity of IGFs for the IGFBPs, thereby freeing the IGFs to bind to their respective IGFRs (Rosen, C. J. 1994). PSA and PAPP-A represent two of the most important circulating serine proteases.

Bone is a rich source of binding protein proteases. Proteases that cleave IGFBP play a pivotal role in determining the regulatory effects of IGFBPs on IGF actions. There are three categories of known proteases that proteolyze IGFBPs: 1) kallikreins; 2) neutral and acid-activated cathepsins; and 3) matrix metalloproteinases (MMPs) (Cohen et al., 1992; Cohen *et al.,* 1994; Conover *et al.,* 1995; Fowlkes *et al.,* 1994a). PSA is the first serine kallikrein IGFBP protease found to proteolyze both IGFBP-3 and IGFBP-5 into several lower molecular weight fragments and is regulated at least to some extent by testosterone and other androgens (Collett-Solberg *et al*., 1996; Cohen *et al*., 1992; Koutsilieris *et al*., 1992). Its role in mediating the enhanced bone formation found in the lumbar spine of metastatic prostate cancer patients remains to be determined. However, it is likely to be one of several mechanisms whereby IGFs can stimulate mitogenic activity of both cancer and bone cells.

The concept of 'soil and seed' implies that the inherent bioactivity of the IGFs, whether bound or free, could stimulate growth of neoplastic tissue after there is homing of cancer cells to bone. Further studies are underway to define the nature of skeletal IGFs, the IGFBPs, and the proteases in this process, and the relationship of these to underlying morbidity associated with metastatic bone disease. A kallikrein-like IGFBP protease, 7S γ-subunit nerve growth factor, is found to cleave both IGFBP-4 and IGFBP-6, Cathepsin D is an acid-activated lysosomal protease, which is able to cleave all the six IGFBPs. MMPs are able to proteolyze a spectrum of IGFBPs, including IGFBP-2, IGFBP-3, IGFBP-4, and IGFBP-5 (Collett-Solberg *et al*., 1996; Fowlkes *et al*., 1994b; Rajah *et al*., 1996; Claussen *et al*., 1997; Marinaro *et al*., 1999; Braulke *et al*., 1995; Manes *et al*., 1999). PAPP-A, which is not specific for IGFBP-4, is activated by IGFs and is found within skeletal tissue as well as in other organs. Particularly for PAPP-A, it is clear that the IGFs can regulate tissue-specific proteases, thereby establishing a complex regulatory loop in which the ligand (i.e., IGF) controls its own bioavailability through transcriptional and nontranscriptional means (Arany *et al*., 1994). Global deletions of PAPP-A result in smaller mice with reduced bone mass, while targeted transgenic overexpression of PAPP-A in muscle causes hypertrophy and increased body weight (BW). IGF-I or -II can regulate PAPP-A, but GH does not regulate PAPP-A or other proteases (Angelloz-Nicoud *et al*., 1995; Skjaerbaek *et al*., 1998). Insulin and estrogen may also affect IGFBP protease activities (Bereket *et al*., 1995; Bang *et al*., 1998; Kudo *et al*., 1996).

The IGF System Relative to Lineage Determination

Bone formation and remodeling requires integration of multiple signaling pathways, which in turn regulate the activities of osteoblast lineage-specific master genes as well as their cellular substrates. Despite the importance of the IGFs in cell growth and maintenance (i.e., cell cycling and apoptosis), their precise role in osteoblast and osteoclast differentiation

is still a matter of debate. In part this relates to the complex yet developmentally sensitive and finely orchestrated process that drives mesenchymal stem cells into the bone lineage. Not unexpectedly, this pathway involves multiple transcription factors and cytokines, as well as the IGFs. The most notable transcription factors that control osteoblast fate are runt-related transcription factor 2 (Runx2) and osterix (Osx). Runx2, core binding factor 1 (Cbfa1)/polyoma enhancer binding protien 2a (Pebp2A) a transcription factor that belongs to the Runx family is the α subunit of a heterodimeric transcription factor, PEBP2/CBF, which is composed of α and β subunits (Ito, 1999). Runx2 is involved in osteoblast differentiation and bone formation. In particular, Runx2 is required for early commitment of mesenchymal stem cells into osteoprogenitors, and also functions later in osteoblast differentiation to regulate the formation of the extracellular matrix (Ducy *et al*., 1999). IGF-I can be shown to influence Runx2 through IGF-1 activation of PI3K, Pak1, and ERK (Xiao *et al*., 2000; Qiao *et al*., 2004).

Schnurri-3 (Shn3), a large zinc finger protein that functions as an adapter protein in the immune system (Oukka *et al*., 2002), has been shown to control the protein expression level of Runx2 through promoting Runx2 degradation by recruitment of the WW domain containing E3 ubiquitin ligase1 (WWP1) to Runx2. It is a novel regulator of postnatal bone mass. Mice lacking Shn3 display adult-onset osteosclerosis with increased bone mass due to an augmented osteoblast activity (Jones *et al*., 2006). Further studies are needed to elucidate whether IGF-I could influence Shn3 expression, or, could influence the Shn3 control of Runx2 degradation.

Osx is a master zinc-finger-containing transcription factor of osteoblast lineage progression that is highly specific to osteoblasts *in vivo*, which acts downstream of bone morphogenetic protein (BMP)-2 Smad signaling (Xiao *et al*., 2000; Qiao *et al*., 2004; Nakashima *et al*., 2002). The Osx amino acid sequence predicts three C2H2-type zinc fingers that have a high degree of identity to similar DNA-binding domains in the transcription factors Sp1, Sp3, and Sp4. The expression of Osx is more specific to osteoblasts than Runx2 (Nakashima *et al*., 2003). Because no Osx transcripts are detected in skeletal elements of Runx2-null mice, Osx must be downstream of Runx2 in the pathway of osteoblast differentiation (Nakashima *et al*., 2002). Both IGF-I and BMP-2 are shown to upregulate Osx expression during early osteoblast differentiation (Celil *et al*., 2005). In mesenchymal stem cells, it appears that both MAPK and PKD signaling pathways serve as points of convergence for mediating the IGF-I- and BMP-2-induced effects on Osx expression (Celil *et al*., 2005). IGF-I-mediated Osx expression required all three MAPK components (Erk, p38, and JNK), whereas BMP-2 required p38 and JNK signaling, and the synergistic interactions of BMP-2 and IGF-I were also disrupted by PKD inhibition (Celil *et al*., 2005).

It should be noted that Runx2-independent pathways of ossification may exist, including 1) the Wnt signaling pathway; 2) Msx2-dependent vascular ossification pathway; and 3) Osx induction via Dlx5, a homeobox transcription factor, which acts downstream of BMP-2 (Kato *et al*., 2002; Cheng *et al*., 2003; Lee *et al*., 2003). These studies suggest additional pathways may act in parallel to, or independent of, Runx2 to regulate Osx expression during osteogenic lineage progression. Indeed, in the canonical Wnt signaling pathway, it is becoming apparent that there is some crosstalk with the IGF pathway. For example, β-catenin binds to insulin receptor substrate-1 (IRS-1), as well as other factors, to enhance its transport from the cytoplasm into the nucleus where it can affect a whole series of downstream target genes.

In sum, IGFs can serve to enhance differentiation of mesenchymal stem cells. Their mitogenic role in the skeleton is relatively limited. However, IGF-I may also be important in lineage allocation or in promoting adipogenesis within the marrow niche independent of key transcription factors. Moreover, IGF-I is essential for adipogenic differentiation and likely is downstream of peroxisome proliferator-activated receptor gamma (PPARG) activation. Because mesenchymal stem cells can enter several distinct lineages, the precise timing of IGF-I action and other factors, some undefined, that are active in the marrow niche, ultimately determine cell fate (Fig. 2). The details of this coordination have still not been defined.

PHYSIOLOGY OF THE GH/IGF/IGFBP SYSTEM

GHRH

In order to appreciate the complexity and redundancy inherent in the IGF regulatory system in bone, an overview of the physiologic aspects of IGF-I regulation is required. Although IGF-I is regulated by genetic, nutritional, hormonal (insulin and thyroxine), and environmental factors, growth hormone is the major controller of IGF-I expression in tissues and in the circulation. That process begins in the hypothalamus and ends at the tissue level (Fig. 3).

The regulation of GH secretion from the pituitary is complex and involves elaboration of discrete neurosecretory peptides from the hypothalamus. Hypothalamic-releasing factors were postulated to exist for more than five decades, but the exact structure of GH-releasing hormone (GHRH) was not elucidated until extracts of pancreatic islet cell tumors from two patients with ectopic acromegaly were characterized. Subsequently, two different GHRH peptides, one of 40 amino acids and the other of 44, were isolated from the hypothalamus.

GHRH is a hypothalamic hormone that is essential for normal expansion of the somatotrope lineage during pituitary development (Frohman *et al*., 2002). GHRH, via binding to GHRH receptor (GHRHR), acts on somatotropes to

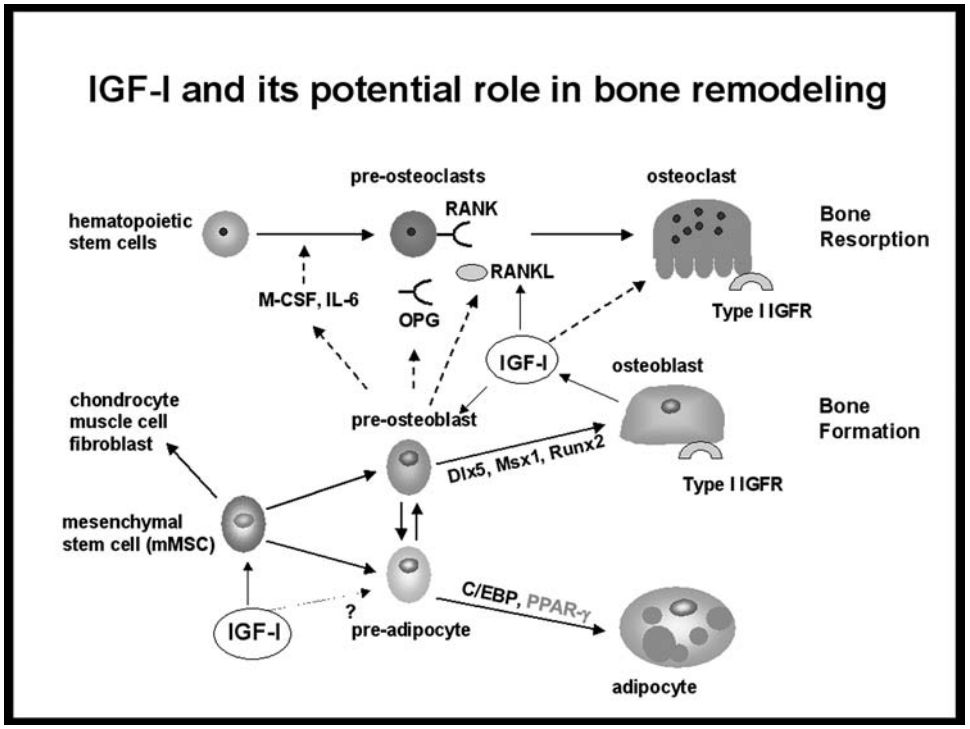

FIGURE 2 IGF-I serves as both a mitogen, albeit weak, and a differentiation factor for marrow stromal cells as they enter the osteoblast lineage. In addition, IGF-I can enhance osteoclast differentiation by stimulating RANKL production from stromal cells. There may be a direct effect of IGF-I on osteoclasts, because these cells express the type IGF-1 receptor and signal through IRS-2. IGF-I can also enhance adipocytes differentiation, and its role in promoting marrow adipogenesis is an area of recent investigations. Overall, IGF-I represents a coupling factor for bone remodeling.

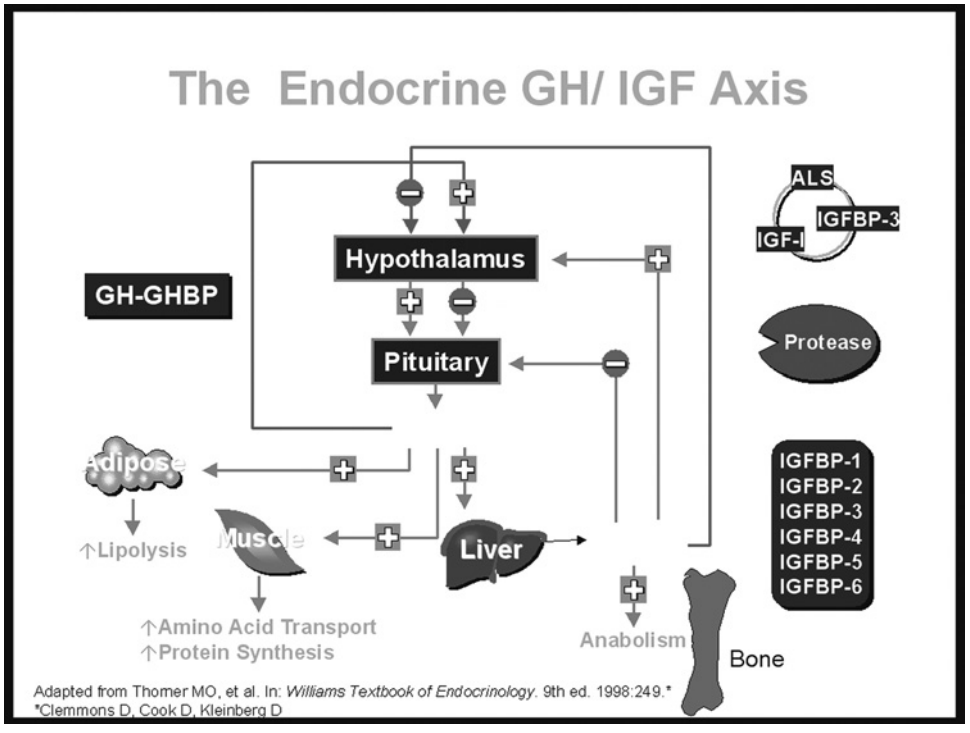

FIGURE 3 IGF-I is an endocrine and paracrine/autocrine growth factor. It is regulated by GH via hypothalamic GHRH. The primary source of circulating IGF-I is liver, although bone is a very rich source of IGF-I and IGF-II. Target tissues for IGF endocrine action include fat, muscle, and bone. IGF binding proteins (IGFBPs) circulate in excess of IGFs, but there is a ternary circulating IGF complex that includes the acid labile subunit (ALS) and IGFBP-3. GHBP is growth hormone binding protein, a circulating GH receptor. The balance between circulating and skeletal IGF-I during growth and maintenance determines the overall effect of this peptide on bone.

increase GH biosynthesis and secretion, and is thought to cause somatotroph proliferation (Petersenn *et al*., 2000). Release of GHRH is episodic, which accounts for the pulsatile release of GH from the pituitary. A decrease in GHRH is associated with somatotrope hypoplasia, whereas an increase in GHRH is associated with somatotrope hyperplasia (Frohman *et al*., 2000).

GHRH is a potent stimulus for GH release, and synthetic analogs are now undergoing clinical trials for both diagnostic and therapeutic purposes in patients with hypothalamic-pituitary disorders. Preliminary investigations examining the utility of these GH-releasing peptides in elders have also recently been initiated.

GHRHR

GHRHR is a G-protein-coupled receptor with seven hydrophobic transmembrane domains. The human GHRHR gene spans 15 kb and is composed of 13 exons. The open reading frame was shown to extend 1269 bp and encodes a protein of 423 amino acids with a predicted molecular weight of 47-kDa. After release from the hypothalamus, GHRH binds to the GHRHR predominantly located on the pituitary somatotrope (Lin-Su *et al*., 2002). GHRHR activation leads to the opening of a sodium channel in the somatotrope, which causes its depolarization. The resultant change in the intracellular voltage in turn opens a voltage-gated calcium channel, allowing for calcium influx, which directly causes the release of premade GH stored in secretory granules (Petersenn *et al*., 2000). The cAMP elevation stimulates protein kinase A, which phosphorylates and activates the transcription factor cAMP response element binding protein (CREB), which then stimulates de novo GH production (Petersenn *et al*., 2000; Muller *et al*., 1999; Mayo *et al*., 1995). Autosomal recessive mutations in the GHRHR can result in near total absence of GH, and lead to short stature in humans, and the *little* phenotype in mice.

Somatostatin

Somatostatin (SMS) is a small (14-amino-acid) but ubiquitous polypeptide that inhibits GH synthesis and release. In concert with GHRH, SMS regulates GH secretion through a dual control system; one stimulatory, the other inhibitory. Several molecular forms of somatostatin, distinct from the native 14-amino-acid peptide, have been isolated. In addition to inhibition of GH release, SMS also inhibits secretion of thyrotropin as well as several pancreatic hormones, including glucagon and insulin. The SMS receptor has been localized to various cell types, especially those of neuroendocrine origin. Localization of this receptor suggests that SMS acts as both an endocrine and a paracrine regulator in diverse tissues. A highly potent synthetic analog of SMS, octreotide, has been used therapeutically in acromegaly and diagnostically (in a radiolabeled form) for scintigraphic visualization of neuroendocrine tumors.

Secretion of GH from the Pituitary

Mechanism of GH Secretion

GH is an anabolic polypeptide hormone produced by the somatotropes of the anterior pituitary gland. GH is also lipolytic, which activates lipase and leads to mobilization of fat from the adipose tissue, and plays an important role in carbohydrate metabolism (Liu *et al*., 2004; Heffernan *et al*., 2001). Deletion of the GHR gene results in a small mouse with low IGF-I but enhanced insulin sensitivity (Liu *et al*., 2004). GH and its receptor belong to the cytokine superfamily of receptors and ligands. GH is secreted under the influence of three hypothalamic hormones: 1) GHRH, which acts via the GHRHR 2) GHS (also known as Ghrelin), which acts through the GHS receptor; and 3) SMS, which acts on the pituitary to suppress basal and stimulated GH secretion, but is not believed to affect GH synthesis (Petersenn *et al*., 2000; Lin-Su *et al*., 2002).

GH secretion is pulsatile (due to the episodic release of GHRH) and circadian with the highest pulse amplitude occurring between 02:00 and 06:00 (Ho *et al*., 1990). Puberty has a dramatic effect on the amplitude of GH pulses, due to changes in the hypothalamic milieu as a result of rising sex steroid concentrations (Jansson *et al*., 1985). Through binding directly to GHR, GH has profound effects not only on linear bone growth, but also bone metabolism and bone mass. The GHR is found on the cell surface of osteoblasts and osteoclasts, but not on mature osteocytes (Andreassen *et al*., 2001). Although GH can act on cells directly through specific receptors, most of its anabolic actions are mediated through IGF-I (Mathews *et al*., 1988). GH stimulates the secretion of IGF-I, largely from the liver, which then acts in an endocrine fashion (Daughaday, 1989). GH also stimulates IGF-I locally in target tissues such as bone, where it may act in a paracrine or autocrine fashion. Perturbations of the GH-IGF-I axis may predispose to the development of osteoporosis.

Effects of Gonadal Status on GH-IGF-I Axis

Not surprisingly, the pattern of GH secretion in animals and humans depends highly on age and sex (Ho *et al*., 1990; Jansson *et al*., 1985). Both factors strongly influence the frequency and amplitude of GH pulses, which in turn determines GH basal secretory rates, and the levels of serum IGF-I. Characteristic changes during puberty in rats parallel pubertal changes in humans (Jansson *et al*., 1985). GH secretion in male and female rats is identical after birth but at puberty, a sexually differentiated pattern of secretion appears with male rats displaying high-amplitude, low-frequency pulses, and with female rats displaying pulses of

high frequency but low amplitude (Jansson *et al*., 1985). This sexual dimorphism can be altered by manipulating the gonadal steroid environment, suggesting that sex steroids are important modulators of GH secretion.

In humans, sexual differences in GH secretion during puberty are less pronounced, even though administration of gonadal steroids to prepubertal children increases GH pulses and mimics the pubertal milieu of the hypothalamus. Various sampling techniques (profiles vs. stimulatory tests) and assays with different sensitivities have produced disparate findings. However, spontaneous and stimulated GH peaks in humans are enhanced during puberty. Matched for age and body mass index, young girls were found to have higher integrated GH concentrations (IGHC) than boys (Ho *et al*., 1990). Other secretory characteristics, including pulse amplitude, frequency, and the fraction of GH secreted as pulses (FGHP), were similar in both sexes of the same age. In a preliminary study, black adolescents (males and females) had higher GH secretory rates than age-matched white adolescents (Wright *et al*., 1995). Higher GH secretion rates in adolescent blacks could lead to a greater acquisition of bone mass.

Gonadal steroids affect GH secretion in perimenopausal women. IGHC mean pulse amplitude of GH and FGHP are lower in older women than premenopausal women. GH secretory indices in postmenopausal women correlate with serum estradiol, but not with total serum androgen levels. During menopause, GH secretion is reduced (Ho *et al*., 1990). However, oral administration of estradiol (or conjugated equine estrogens) increases GH secretion as a result of reduced hepatic generation of IGF-I (Ho *et al*., 1990; Dawson-Hughes *et al*., 1986). On the other hand, transdermal administration of 17-β estradiol increases serum IGF-I concentration, suggesting that suppression of IGF-I by oral estrogens is due to a "first-pass" hepatic effect. Impaired IGF-I generation in the liver removes a key component of negative feedback on the hypothalamus, resulting in increased GH release.

Effects of Age on the GH/IGF-I/IGFBP System

The GH-IGF-I axis undergoes changes over a life span so that elders have lower spontaneous GH secretion rates and serum IGF-I levels than younger people (Kelijman, 1991; Rudman *et al*., 1981; Donahue *et al*., 1990). Most of these age-related differences are a function of an altered hypothalamic-pituitary set point due in part to changes in lifestyle and nutrition. The GH secretory response to common stimuli such as GHRH, clonidine, L-dopa, physostigmine, pyridostigmine, hypoglycemia, and met-enkephalin, but not arginine, is reduced by aging. Somatotrope responsiveness to GHRH and arginine does not vary with age, implying that the maximal secretory capacity of somatotropic cells is preserved in elderly people (Corpas *et al*., 1993).

In sum, circulating IGF-I concentrations decline with advancing age as a result of reduced GH secretion, lower energy intake, altered gonadal status, and other factors. These changes have been causally linked to the frailty of aging in respect to musculoskeletal function. However, large cross-sectional studies have demonstrated only a weak association (i.e., correlation coefficient of r = 0.2–0.4) between diminished serum IGF-I and age-related bone loss, or between serum IGF-I and BMD (Rudman *et al*., 1981; Nicolas *et al*., 1994; Donahue *et al*., 1990; Corpas *et al*., 1993; Langlois *et al*., 1998). In one large cohort study, the lowest serum IGF-I quartile was associated with a significantly greater risk of hip fractures (Garnero *et al*., 2000). On the other hand, skeletal concentrations of IGF-I, IGF-II, and IGFBP-5 in femoral cortical and trabecular bone decline significantly with age and these have been associated with low BMD (Rudman *et al*., 1981; Nicolas *et al*., 1994; Donahue *et al*., 1990; Corpas *et al*., 1993; Langlois *et al*., 1998). In contrast to the multitude of studies linking serum IGF-I to age-related frailty and muscle performance, differences in GH secretion are difficult to determine due to its normal pulsatility. There is only one study in older postmenopausal women relating changes in 24-hour GH levels with BMD (Dennison *et al*., 2003).

GH exerts a multitude of biological effects on various tissues through the GHR. Regulation of GH bioactivity occurs at several pre- and postreceptor levels. GHBP is a plasma binding protein identical to the extracellular domain of the tissue GHR. GHBP binds exclusively to GH and most, if not all serum GH, is bound to this carrier protein. Measurements of GHBP in serum are relatively stable and reflect the endogenous status of the GH receptor in responsive tissues (Baumann *et al*., 1989). With advanced age, GHBP concentrations increase substantially.

GH/IGF ACTIONS ON THE SKELETON

GH-IGF-I Effects on Longitudinal Growth

GH has distinct effects on the skeleton in terms of both linear growth and bone remodeling. However, it has been extremely difficult to ascertain a role for IGF-I independent of GH. The interaction of GH and IGF-I in bone during growth is complex and has been labeled a "dual-effector" process. Indeed, in double GH/IGF-I knockout mice there is significant growth retardation suggesting that each of these two growth factors contribute equally but distinctly to longitudinal growth (Lupu *et al*., 2001). Interestingly, in those studies, only 17% of the growth in these mice could be attributed to non-GH and non IGF-I determinants (Lupu *et al*., 2001).

Longitudinal growth results from the activity of GH on the skeleton, particularly at the cartilaginous growth plate. In human bone, proliferating chondrocytes express IGF-IRs and are responsive to paracrine IGFs secreted by differentiated cartilage cells (Isaksson *et al*., 1987). The target

for GH in the growth plate is the differentiated chondrocyte that synthesizes IGF-I in response to GH. Proliferating chondrocytes respond to locally produced IGF-I by differentiation, which in turn leads to cartilage expansion and linear growth. Thus, GH's stimulatory properties on the endochondral growth plate are mediated by induction of IGF-I.

GH may have its own effect on linear growth, independent of IGF-I. For example, GH stimulates longitudinal bone growth in normal rats but rhIGF-I does not (Schmid *et al*., 1991). Similarly, transgenic mice that overexpress GH grow to twice their normal size, even though administration of IGF-I to normal mice does not provoke a similar growth response. These effects are almost certainly a result of distinct GHRs on osteoblasts and marrow stromal cells. The presence of both GHR and IGFRs on bone cells complicate interpretation of GH's action but recent Cre/loxP technology for targeted *in vivo* and *in vitro* deletion or overexpression has allowed investigators to clarify the anabolic activity of GH and IGF-I in bone. *In vitro,* GH stimulates osteoblastic proliferation, differentiation, and matrix mineralization (Ernst M *et al*., 1990; Maor *et al*., 1989). GH also induces the synthesis and release of IGFBP-3, -4, and -5 in rodent calvarial cells. The response to GH in human bone cells (hOB) is very dependent on specific cell culture conditions. For subconfluent cultures, GH stimulates cell proliferation, while in confluent hOB cultures, GH induces cell differentiation (as measured by cell alkaline phosphatase and procollagen type I propeptide synthesis) (Kassem *et al*., 1993).

GH and IGF-I Actions on the Skeleton: Local vs. Systemic

Local Skeletal Actions of the GH/IGF-I Axis

The effects of GH on bone remodeling are complex, in part because there are both local and circulating IGF-I complexes directly induced by GH. Several *in vivo* studies have shown that skeletal IGFs are critical in mediating the GH skeletal response. Remodeling is the sum of several distinct events beginning with activation of lining cells, followed by osteoclast recruitment, osteoblast differentiation, and osteocyte formation. Induction of IGF-I synthesis by GH in osteocytes, mature osteoblasts, or lining cells is one potential mechanism for activation of remodeling. Several lines of evidence showing that IGFs are critical to the remodeling sequence (and not just osteoblastic activity) are derived from clinical and basic studies. First, large quantities of growth factors [e.g., IGFs, transforming growth factor (TGF)-beta, fibroblast growth factors (FGFs)] are stored in bone and released during active resorption, suggesting that local growth factors could couple formation to resorption (Mohan *et al*., 1991). Second, IGFs stimulate the differentiation and activation of osteoclasts, possibly in concert with cytokines such as receptor activator of nuclear factor Kappa β ligand (RANKL), and macrophage colony-stimulating factor (M-CSF) (Slootweg *et al*., 1992; Mochizuki *et al*., 1992). Third, administration of IGF-I enhances bone formation and bone resorption to a similar degree (Ebeling *et al*., 1993). Fourth, bone marrow stromal cells that produce osteoclast-activating cytokines are also rich sources of IGFs and IGFBPs. Fifth, several proteases including PAPP-A and MMP-9 are physiologically active at low pH (Conover *et al*., 1994). The acidic pH necessary for protease activation is approximately the same pH present within the microenvironment of the osteoclast during its active proton secretion phase. This raises the possibility that bone resorption activates proteolytic cleavage, which permits the IGFs to become free of the IGFBPs, and allows for further recruitment of both osteoblasts and osteoclasts.

In vitro, GH, IGF-I, and IGF-II all have modest mitogenic effects on bone cell growth (Canalis *et al*., 1989; Mohan *et al*., 1988). This suggests that GH could act through the IGFs to activate skeletal remodeling. Indeed, GH-induced cell proliferation can be blocked by simultaneous addition of a specific monoclonal antibody to IGF-I (Mohan *et al*., 1991). IGF-II, on the other hand, stimulates mitogenesis independent of GH and even if high doses of IGF-I are coadministered. This implies that IGF-II could regulate osteoblastic proliferation via the IGF-IIR (Mohan, *et al*., 1989a). *In vitro*, both IGF-I and IGF-II are mitogenic to rodent preosteoblasts, and both rapidly increase mRNA expression of the proto-oncogene, c-*fos,* 20- to 40-fold in less than 30 minutes (Merriman *et al*., 1990). The IGFs also stimulate type I collagen synthesis, alkaline phosphatase activity, and osteocalcin in more differentiated human osteoblast-like cells (Mohan *et al*., 1989; Schmid *et al*., 1984). Taken together, the IGFs are important for osteoblast activity but the effects are almost certainly dose and time dependent.

Zhang *et al*. (2002) demonstrated the critical importance of IGF-I in the process of mineral apposition, which is a late osteoblast function. These investigators used a Cre/loxP system to delete the IGF-IR in mature osteoblasts and found that those mice with the deletion had a significant impairment in mineralization lag time. Similarly, targeted overexpression of IGF-I in osteoblasts resulted in mice with increased osteoblast function, but no change in the number of osteoblast precursors. These findings are reinforced by *in vitro* studies showing that IGF-I can increase type I collagen synthesis, alkaline phosphatase activity, and osteocalcin production in osteoblasts (Schmid *et al*., 1992). IGF-I also acts as a potent anti-apoptotic factor, particularly for differentiated osteoblasts and osteocytes, probably via the PI3's kinase signaling pathway. On the other hand, Rowe *et al.* used timed micro array technology with a green fluorescent protein (GFP) Col3.6 promoter to show that during marrow stromal cell recruitment, IGF-I expression

declines, particularly as these cells finally enter the osteoblast lineage.

In addition to regulating osteoblast function, several groups have shown that skeletal IGF-I can stimulate osteoclast recruitment and differentiation either directly through the IGF-IR or via RANKL expression (Mochizuki *et al*., 1992; Rubin *et al*., 2002). This would place IGF-I in the category of a "coupler" for bone remodeling. Indeed, IGF-I null mice are growth retarded, and most die after birth. Those that survive are very small, have developmental defects in brain, muscle, bone, and lung, and are infertile. However, their skeletal phenotype is particularly striking and is characterized by very little cortical bone but an increased trabecular bone volume fraction (Bikle *et al*., 2001; Bikle *et al*., 2006). Recently, it has been demonstrated both *in vivo* and *in vitro* that the absence of IGF-I impairs osteoclast recruitment and activity, although the exact mechanism is unknown (Wang *et al*., 2006).

Effects of Systemic GH-IGF-I Axis on the Skeleton

Although skeletal IGF-I is essential for bone growth, it is also apparent that the circulating IGF-I may play an important role in modulating skeletal development and acquisition. Liu *et al*. (1993) were the first to report that newborn mice homozygous for a targeted disruption of *Igf1* exhibit a growth deficiency similar in severity to that previously observed in viable *Igf2* null mutants (i.e., 60% of normal birth weight). Depending on the genetic background, Liu found that some of the *Igf1*(-/-) dwarfs died shortly after birth, whereas others survived and reached adulthood (Liu *et al*., 1993). On the contrary, null mutants for the *Igf1R* gene die invariably at birth, of respiratory failure and exhibit a more severe growth deficiency (45% normal size) compared to wild-type animals. In addition to generalized organ hypoplasia in *IgfR*(-/-) embryos, including the muscles and developmental delays in ossification, deviations from normalcy were found in the central nervous system as well as epidermis. *Igf1* -/- /*Igf1R*(-/-) double mutants did not differ in phenotype from *Igf1R*(-/-) single mutants, while in *Igf2(-)/Igf1R*(-/-) and *Igf1(-/-)/Igf2*(-) double mutants, which are phenotypically identical, dwarfism was further exacerbated (i.e., 30% normal size).

To investigate the role of IGF-I in normal development, Powell-Braxton *et al.* generated mice with an inactive *Igf1* gene by homologous recombination in embryonic stem cells. Heterozygous *Igf1*(+/-) mice appear healthy and fertile; however, they are 10–20% smaller than wild-type littermates and have lower than normal levels of IGF-I (Powell-Braxton *et al*., 1993). The size reduction is attributable to a decrease in organs and BMD. This was recently confirmed by studies from the Kream laboratory (He *et al*., 2006). These investigators showed that heterozygous IGF-I null mice had reduced OB function, as well as impaired osteoclast activity *in vitro*.

As previously noted, at birth homozygous mutant *Igf1* (-/-) mice are less than 60% BW of wild-type and greater than 80% of the pups die perinatally. The survivors are sometimes compromised in terms of several homeostatic processes but the compensatory mechanisms in the survivors are interesting. For example, Bikle *et al*. (2001) analyzed the structural properties of bone from mice rendered IGF-I deficient by homologous recombination using histomorphometry, peripheral quantitative computerized tomography (PQCT), and micro-computerized tomography. The knockout mice were 24% the size of their wild-type littermates at the time of study (four months). The knockout tibias were 28% and L_1 vertebrae were 26% the size of wild-type bones. Bone formation rates (BFR) of knockout tibias were 27% that of the wild-type littermates. They have shown that the bone formation rate was reduced by 77% in the tibia of *Igf1-/-* mice compared with corresponding littermates (Bikle *et al*., 2001). The bones of knockout mice responded normally to GH (1.7-fold increase) and supranormally to IGF-I (5.2-fold increase) with respect to BFR. Cortical thickness of the proximal tibia was reduced 17% in the knockout mouse. However, trabecular bone volume (bone volume/total volume [BV/TV]) in knockout mice compared with wild-type controls was increased 23% in male mice and 88% in female mice as a result of increased connectivity, increased number, and decreased spacing of the trabeculae. Thus, absence of IGF-I leads to the development of a smaller bone that may be more compact, almost certainly due to reduced osteoclastic activity as noted earlier. The structural consequences of these bones in respect to fracture have not been studied.

To further separate the role of endocrine and paracrine IGF-I in skeletal development, Yakar *et al*. (1999) used the Cre/loxP recombination system whereby mice with loxP-flanked *Igf1* gene were mated with albumin-Cre transgenic mice expressing the Cre recombinase exclusively in the liver. Liver-specific *Igf1* gene-null mice were macroscopically normal, suggesting that autocrine/paracrine IGF-I could support normal postnatal growth and development (Yakar *et al*., 1999). Nevertheless, more extensive developmental phenotyping of the liver-specific *Igf1* gene-null mouse revealed a marked reduction in bone volume, periosteal circumference, and medial lateral width, consistent with the hypothesis that circulating IGF-I had an important role in bone modeling (Yakar *et al*., 2002). Moreover, recent studies from Yakar *et al*. have shown that ALS knockout mice also have reduced cortical thickness and enhanced trabecular bone, consistent with an endocrine effect of the circulating IGF complex on skeletal acquisition. Finally, the double ALS and IGF-I knockout mice have a major growth phenotype as well as markedly reduced BMD, despite normal expression of skeletal IGF-I (Yakar *et al*., 2006). Thus, it seems likely that both local and circulating IGF-I concentrations are essential for peak bone acquisition and maintenance.

ROLE OF GH/IGF/IGFBPs IN OSTEOPOROSIS

Effects of GH-Deficiency on Bone Metabolism

GHD in childhood is associated with growth failure and short stature. However, the effects of GHD on BMD in prepubertal children have been more difficult to quantify, in part because of the mixed hypopituitary syndromes that often accompany GHD. Thus there are a paucity of studies examining BMD status in GH-deficient children. By single photon absorptiometry (SPA) of the wrist, children with GHD have been found to have a low BMD (Wuster *et al*., 1992). Serum concentrations of osteocalcin are also reduced in children with GHD, but the response of osteocalcin to GH administration does not correlate with linear growth (Delmas *et al*., 1986). In several cross-sectional studies of adults with GHD, lumbar spine BMD is reduced compared to that in age-matched controls (Wuster *et al*., 1991; Johansson *et al*., 1992; Hyer *et al*., 1992; Rosen *et al*., 1993; Bing-You *et al*., 1993; DeBoer *et al*., 1994). In one group of adult GHD patients, the lowest spinal BMD was found in people who were previously treated with rhGH during childhood (Wuster *et al*., 1991; Wuster *et al*., 1993). This degree of osteopenia was not due to cortisone or thyroxine substitution because the BMDs of patients on hormonal substitution did not differ from those without hormone replacement (Wuster *et al*., 1993). In that same study, Wuster *et al.* (1991) showed an increased prevalence of vertebral osteoporotic fractures among GH-deficient adults. Kaufman *et al.* (1992) confirmed low BMD in GHD adults with or without hormonal deficiencies. However, Kann *et al.* (1993) found no difference in the apparent phalangeal ultrasound transmission velocity of GHD patients compared to age- and sex-matched controls. De Boer *et al*. (1994) noted that low BMD was partly explained by reduced body height, but with correction for body mass index, BMD was still significantly reduced compared to age- and sex-matched controls (Wuster *et al*., 1992).

The cause of low BMD in adult GHD has been thought to be due to insufficient bone acquisition during the adolescent years (DeBoer *et al*., 1994). This hypothesis is supported in one study by bone histomorphometry. In 36 men with GHD (primarily of juvenile onset), there were increased eroded surfaces, increased osteoid thickness and increased mineralization lag time, all indicative of delayed mineralization probably due to changes in the timing of puberty (DeBoer *et al*., 1994; Bravenboer *et al*., 1994). In support of those histomorphometric changes, low serum levels of osteocalcin have been detected in some adult GHD patients (Delmas *et al*., 1986). This is in sharp contrast to patients with normal GH secretion but multiple pituitary hormone deficiencies, where serum osteocalcin levels are normal but there is markedly increased urinary pyridinoline excretion (de la Piedra *et al*., 1988).

Although an inadequate acquisition of BMD during childhood may be one explanation for the osteopenia of GHD, the role of gonadal steroids in this process has not been completely clarified. Furthermore, there are no data on hip fractures in GHD adults, and evidence that spinal fractures are more prevalent in GHD is still preliminary. Only longitudinal studies of GHD patients will be able to determine the precise cause of osteopenia in the acquired GHD syndrome.

Effects of GH Excess on Bone Mass and Bone Turnover

Chronic GH excess in adults (i.e., acromegaly) has been a surrogate model for studying the effects of GH on the skeleton. However, this disease is complicated by changes in vitamin D metabolism and gonadotropin secretion (Bouillon, 1991). Increased bone turnover has been reported in acromegaly by biochemical markers and histomorphometric studies (de la Piedra *et al*., 1988; Ezzat *et al*., 1993). However, bone mass determinations in acromegaly vary according to the site of measurement. Cortical BMD is increased compared to age-matched controls and is directly related to the degree of GH excess (Diamond *et al*., 1989). Trabecular BMD, however, can be high, normal, or low (Ezzat *et al*., 1993; Diamond *et al*., 1989; Seeman *et al*., 1982). In one study, computed tomography (CT) measurements of the lumbar spine revealed that trabecular BMD was elevated in only 1 of 14 patients with active acromegaly (Ezzat *et al*., 1993). This may have been due to hypogonadism in the acromegalics. Wuster *et al.* (1993) recently studied five patients with active acromegaly treated with octreotide for five years. All had achieved normal IGF-I levels during therapy. Spinal BMD was initially decreased in all five patients but normalized in three of them with octreotide. All patients remained eugonadal throughout follow-up.

As noted earlier, biochemical markers of bone turnover are altered in acromegaly. Many of these changes can be related to alterations in gonadal status during the disease and its treatment. However, changes in bone turnover with acromegaly reflect persistent coupling of the remodeling cycle with increased resorption and formation. Serum osteocalcin and skeletal alkaline phosphatase are increased in acromegaly as are urinary calcium and hydroxyproline excretion (de la Piedra *et al*., 1988; Ezzat *et al*., 1993). Although serum calcium, total alkaline phosphatase, and phosphorus are usually normal, there may also be increased synthesis of 1,25-dihydroxyvitamin D. This results from significant intracellular phosphate shifts due in part to an increased circulating IGF-I. The consequence of this change, however, is not entirely clear.

Changes in the GH-IGF-1 Axis in Patients with Osteoporosis

For several years, attempts have been made to link GH secretory status with a low BMD and osteoporosis. As noted previously, efforts to find a relationship between GH secretion and age-related bone loss have been conflicted at best. However, other investigators have examined the relationship of GH to BMD in the immediate menopausal period. These efforts gained prominence in the 1980s when it was reported that GH secretion in patients with osteoporosis was reduced even after stimulation with L-arginine. Low serum IGF-I, IGF-II, and IGFBP-3 levels (by RIA) were noted in 98 females with postmenopausal osteoporosis compared to 59 normal controls and 91 patients with osteoarthritis or degenerative bone disease (Wuster *et al*., 1993). In a cross-sectional study of a large cohort of older postmenopausal women from Framingham, Langlois *et al*. (1998) reported very strong correlations between the lowest quintile of IGF-I and BMD at the spine hip and radius. Bauer *et al*. reported that in the Study of Osteoporotic Fractures (SOF), women in the lowest quartile for serum IGF-I had a 60% greater likelihood of hip or spine fractures, even when controlling for BMD (Bauer *et al*., 1997). Gamero *et al*. (2000) noted that low serum levels of IGF-I were associated with a significantly greater risk of hip fractures among a large cohort of older postmenopausal women in France. In a study of 61 community-dwelling men over the age of 27, who were randomly selected from the Calgary cohort of 1,000 subjects in the Canadian Multicentre Osteoporosis Study, IGF-I was found to be a significant predictor of BMD at the total hip, femoral neck, and femoral trochanter neck ($p \leq 0.001$). Szulc *et al*. (2004) evaluated the correlation of BMD with serum IGF-I in a large cohort of 721 men aged 19–85 taking into account age, BW, 17 β-estradiol, free testosterone, and PTH. Serum IGF-I decreased with age ($r = -0.44$, $p = 0.0001$). IGF-I correlated positively with BMD at the whole body and at the third lumbar vertebra. BMD of the total hip was 6% higher in men in the highest quartile of IGF-I than in men in the lowest quartile. However, others have not found a relationship between serum IGF-I and BMD in patients with fractures, in postmenopausal osteoporosis or in otherwise healthy subjects (Kassem *et al*., 1994; Lloyd *et al*., 1996; Rudman *et al*., 1994).

In male osteoporotics, serum IGF-I as well as IGFBP-3 concentrations were reported to be low and correlated with lumbar BMD (Ljunghall *et al*., 1992). Comparable results have been noted for IGF-I by at least two other groups (Nakamura *et al*., 1992). Johannsen *et al*. (1994) reported that among healthy males, IGFBP-3 was the best predictor of femoral BMD. Kurland, E.S. *et al*. (1997) reported that younger males with idiopathic osteoporosis had low serum levels of IGF-I in relation to age-matched controls. Moreover, these men also had low rates of bone turnover by histomorphometry but normal GH dynamics (Kurland *et al*., 1998). Of potential pathophysiological importance is the observation that patients with osteoarthritis have higher concentrations of IGF-II than normal controls (Wuster *et al*., 1993; Mohan *et al*., 1991). Other studies have related serum IGFBP-4 and IGFBP-5 due to aging and to a low bone mass, although causality was not established (Karasik *et al*., 2002). Also, Dennison and colleagues reported that low 24-hour GH profiles were associated with low BMD of the lumbar spine in older British women (Dennison *et al*., 2003). Further longitudinal studies will be required to determine the precise relationship among the IGFs, GH, and osteoporosis.

GH AND IGF-I AS TREATMENTS FOR BONE DISORDERS

Anti-resorptive agents have been considered as cornerstone therapeutics for osteoporosis (Agnusdei *et al*., 2005). Anabolic agents can directly stimulate bone formation, which might have greater potential than the anti-resorptives to increase bone mass and to decrease fractures. Therefore, there is an emerging interest in developing anabolic agents including PTH, GH, and IGF-I to treat osteoporosis (Rubin *et al*., 2002).

GH Treatment for Skeletal Disorders

GH has direct and indirect effects on bone, depending on age and skeletal maturity. Indirectly, GH can enhance bone mass through its effects on muscle mass and calcium transport in the gut, as well as suppressing adipocyte differentiation (Fleet *et al*., 1994). In addition, GH can directly stimulate bone remodeling and increase endochondral growth through its actions on the osteoblast. Overall, GH is considered essential for both the growth and maintenance of skeletal mass. Moreover, it is established that for virtually all cohorts of GHD subjects, whether onset is in childhood or adulthood, male or female, there is reduced areal BMD. In some but not all studies, volumetric BMD, measured either by computed tomography (CT) or areal-adjusted algorithms, was reduced in children with GHD (Baroncelli *et al*., 1998). In the largest observational trial of GHD subjects to date, i.e., KIMS, GHD was associated with a marked increase in fracture risk, particularly when compared to age-matched normals (Rosen *et al*., 1997; Wuster *et al*., 2001). Hence, there is a strong rationale to treat GHD in children.

Substantial differences between the direct and indirect (i.e., via IGF-I) effects of GH on the osteoblast, the marrow stromal cell precursor, and the osteocyte, may partially explain changes in skeletal responsiveness to GH and IGF-I. For example, exogenous GH stimulates longitudinal growth in normal rats, but rhIGF-I does not (Schmid *et al*., 1991).

Similarly, transgenic mice who overexpress GH grow to twice their normal sizes whereas exogenous administration of IGF-I is far less efficient in stimulating long bone growth. Thus, despite the fact that GH induces IGF-I production in the skeleton and elsewhere, treatments with GH and with IGF-I are not equivalent. In general, skeletal responsiveness to GH and IGF-I depend on the species, the GH status of the animal, and the mode of administration. Even the systemic side effects of rhGH and rhIGF-I therapy may differ substantially.

GH Treatment for Children with Growth Impairment

Early clinical experiences with rhGH in GHD children provided investigators with a model for studying skeletal responsiveness to somatotropin. Intermittent (daily or three times weekly) injections of rhGH resulted in a prolonged and sustained GH profile with resultant catch-up growth evident during the first year of treatment (Rappaport *et al*., 1993). This increase in skeletal growth was accompanied by a rise in serum levels of type I procollagen peptide. Although dosage schemes varied between the United States and Europe (0.1 mg/kg/tiw[U.S.] to 0.7 U/kg/week[Europe]), there was a strong dose-related growth response to rhGH (de Muinck Keizer-Schrama *et al*., 1992). Indeed, most studies of pre-adolescent GHD children have shown significant improvements in areal BMD with GH replacement. However, the skeletal response to GH depends on several factors including: 1) GH secretory status; 2) pretreatment IGF-I levels; 3) pretreatment height velocity; and 4) GH dosage (de Muinck Keizer-Schrama *et al*., 1992). The rate of change in serum IGF-I (rather than the absolute level of IGF-I attained by GH treatment) is a relatively nonspecific predictor of growth as are procollagen I and osteocalcin concentrations (Delmas *et al*., 1986; de Muinck Keizer-Schrama *et al*., 1992). Serum procollagen III levels correlate with growth rates during GH treatment (Delmas *et al*., 1986).

Linear growth is a measurable response to exogenous GH, but changes in BMD in children are more difficult to quantify. In some studies, bone mineral content (BMC) is increased during GH treatment to a greater extent than expected for change in bone size (Inzucchi *et al*., 1994). In one of the longest intervention trials to date, 26 GHD children were given rhGH (0.6 IU/kg per week) for 12 months (Saggese *et al*., 1993). Baseline radial BMC *Z*-scores (corrected for their chronological, statural, and bone ages) were significantly reduced as were serum osteocalcin and procollagen peptide levels. Treatment with rhGH six times per week increased BMC and normalized *Z* scores of the radius in nearly 50% of the subjects. Serum levels of procollagen peptide during the first week of treatment were positively related to growth velocity at 6 and 12 months and radial BMC at 12 months. In another nonrandomized trial 32 children with GHD aged 7–16 were treated for nearly 1 year with rhGH and found to have significant improvements in areal BMD and final adult height (Saggese *et al*., 1996). In adolescent GHD subjects, GH replacement has variable effects on peak bone acquisition. Even with higher rhGH doses, significant changes in volumetric BMD in these subjects have not been found, nor has acceleration in skeletal maturation (Baroncelli *et al*., 2004; Mauras *et al*., 2000; Kamp *et al*., 2002). Controversy continues as to whether GH treatment impacts BMD in children with idiopathic short stature or children born small for gestational age (SGA). Arends *et al*. (2003) demonstrated that prepubertal SGA children given 33 ug/kg/d of rhGH for three years had significant increases in height, areal BMD, and areal adjusted spine BMD. However, rhGH to children with idiopathic short stature who had low volumetric BMD did not result in further increases in BMD, despite significant changes in lean body mass and bone turnover indices (Hogler *et al*., 2005). In cerebral palsy children (aged 4–15 years), 18 months of rhGH (50 μg/day) in a randomized placebo-controlled trial RPCT, increased areal BMD significantly, as did height, IGF-I, IGFBP-3, and osteocalcin (Ali *et al*., 2007). In sum, rhGH improves adult height, and areal BMD in prepubertal GHD children treated for at least one year. These changes are accompanied by favorable effects on body composition, muscle strength, and overall quality of life. It is still not certain, however, how beneficial these GH-induced effects are in late adolescent GHD subjects in non-GHD states, or whether true volumetric BMD is significantly improved by long-term GH therapy.

GH Administration for Healthy Adults

Although there were striking differences between longitudinal growth in children and remodeling in adults, criteria that determine rhGH responsiveness in children may be relevant for older individuals. It has already been established that biochemical and histomorphometric responses to rhGH in children may differ according to their GH secretory status. The same principle probably holds for adults treated with GH. Three adult populations have been studied before and after GH treatment in order to examine predictors of skeletal responsiveness: 1) healthy adults, 2) GHD adults, and 3) elderly men and women with/without osteoporosis.

Initial studies with rhGH in adults focused primarily on changes in body composition. Short-term treatment with rhGH leads to a decrease in adiposity and an increase in lean body mass (Crist *et al*., 1988). There is also a marked shift in extracellular water (Holloway *et al*., 1994). Detailed analysis of skeletal markers during GH treatment was first reported by Brixen *et al*. (1990). Twenty male volunteers (ages 22–31) were given a relatively large dose (0.1 IU/kg) of rhGH twice daily for seven days. Serum

osteocalcin increased after two days of treatment and remained elevated for six months. Bone alkaline phosphatase decreased initially (during the seven days of GH treatment) but then increased slightly over six months (Brixen *et al*., 1990). Serum calcium and phosphate increased but only during the seven-day treatment phase. Like bone formation indices, urinary markers of bone resorption (urinary Ca/Cr and hydroxyproline/creatinine) rose during treatment and remained elevated for up to four weeks after discontinuation of therapy.

Treatment with rhGH stimulates bone remodeling. More importantly, the anabolic effect on bone may persist well beyond discontinuation of GH. Early (two-day) and late (two-week) osteocalcin responses imply that GH can stimulate existing osteoblasts and enhance recruitment of new osteoblasts. Still, it is uncertain if those effects are mediated through IGF-I. For example, Brixen *et al*. (1990) were unable to find a significant correlation between the rise in serum IGF-I and an increase in osteocalcin or bone alkaline phosphatase. The absence of a significant correlation between bone formation markers and serum IGF-I, however, may be due to the low skeletal specificity of serum IGF-I.

Skeletal resistance to GH has been considered a possible cause for postmenopausal osteoporosis. However, on the basis of one double-blinded rhGH trial in postmenopausal women, this is unlikely. Kassem *et al.* (1994) noted that administration of rhGH (0.2 IU/kg/day) for three days increased serum IGF-I, osteocalcin, and procollagen type I C-terminal propeptide (PICP) to the same extent in 15 women with severe postmenopausal osteoporosis as in 15 age-matched control women. Serum and urinary markers of bone resorption also did not differ between the two groups. *In vitro* studies of marrow stromal cells from osteoporotic women demonstrate full GH responsiveness. Therefore, it is unlikely that the osteoporotic skeleton is resistant to rhGH therapy.

GH Treatment for GHD Adults

GHD can be documented by provocative stimuli (GHRH, insulin, glucagon) and serial GH measurements. The majority of adult patients treated with rhGH have either idiopathic GHD or a history of previous central nervous system (CNS)/pituitary-hypothalamic tumors. Early trials with rhGH replacement therapy examined changes in muscle mass, muscle strength, and body fat. Daily administration of subcutaneous rhGH to GHD patients produced a marked rise in serum IGF-I and an increase in muscle mass and basal metabolic rate (Jorgensen *et al*., 1991). Some of those anabolic changes were noted soon after the initiation of rhGH. For example, mean nitrogen retention during the first 15 days of rhGH treatment was as much as 2.8 g per day (approximately 20 g of muscle mass) (Valk *et al*., 1994). GH treatment can also increase the total cross-sectional area of thigh muscles and quadriceps as well as improve hip flexors and limb girdle strength (Jorgensen *et al*., 1991; Valk *et al*., 1994). At least one group has suggested that rhGH can increase the number of type II muscle fibers. Total fat mass, however, consistently decreases during rhGH treatment (Jorgensen *et al*., 1989; Jorgensen *et al*., 1991). Based on these and other studies, the U.S. FDA approved the use of rhGH in patients with established GH.

Several biochemical parameters reflect the pharmacologic action of GH on the skeleton. Serum calcium, osteocalcin, and urinary hydroxyproline all increase, while PTH declines slightly during rhGH treatment. Newer and more sensitive markers of bone turnover also reflect changes during rhGH treatment. Urinary deoxypyridinoline increases threefold and the amino-terminal propeptide of type III procollagen doubles during four months of daily rhGH (Christiansen *et al*., 1991; Johansen *et al*., 1990). After cessation of rhGH treatment, deoxypyridinoline excretion decreases but type III procollagen levels remain higher than controls for several months(Johansen *et al*., 1990). Serum osteocalcin and procollagen 1 N-terminal propeptide (P1NP) markers of bone formation also increase significantly with rhGH therapy in adults, not unlike the change noted in children.

If prolonged, GHD in adults results in profound changes in the musculoskeletal system, then GH replacement would be expected to enhance muscle performance and subsequently BMD. The first waves of studies with rhGH for adults were uncontrolled observational trials. Fourteen GHD adults given a nightly dose of rhGH (0.5 IU/kg/week) showed increases in exercise capacity, maximum oxygen consumption, and alkaline phosphatase even though quadriceps strength and spinal BMD did not change over one year (Whitehead *et al*., 1992). When 0.25 IU/kg/week of rhGH was administered to 12 GHD adults for one year, there was a marked increase in trabecular BMD (measured by single and dual energy QCT of the spine) at 6 and 12 months. At 12 months proximal and distal forearm BMC increased, mid-thigh muscle area was greater, and fat cross-sectional area decreased. Because the rise in spine BMD was noted with both single and dual energy CT measurements of the spine, it is possible that the enhancement in BMD was significant and not related to the reduction in marrow fat. However, more studies are needed to define the response of the bone marrow, and particularly the marrow adipocytes, to rhGH treatment. New BMD studies using magnetic resonance imaging (MRI) to quantify changes in the skeleton are likely to generate data on the response of marrow fat to systemic rhGH use.

Several groups have performed longer, although not randomized, trials with rhGH in the GHD syndrome. Changes in BMD were not significant at 12 months, however by 24 and 36 months BMD has been reported to increase by as much as 5–8% in the spine (Janssen *et al*., 1998; Baum *et al*., 1996; Papadakis *et al*., 1996).

In addition, other investigators have reported a concomitant increase in muscle strength after two years of rhGH treatment. It appears from those studies that individuals with earlier onset of GHD, as well as those with the lowest BMD, had the greatest likelihood of showing significant changes in BMD with rhGH. More recently, four RPCTs have been conducted in adult GHD subjects treated with rhGH for at least 18 months. In one of the studies of men only, BMD increased in the lumbar spine by 5.1% and in the femoral neck by 2.4% (Baum *et al*., 1996). In another study of both men and women, there were no significant differences in BMD after 18 months between the group treated with rhGH and those taking placebo (Sneppen *et al*., 2002). In the third trial, men but not women showed increases in spine BMD after 24 months of rhGH compared to no therapy. The most definitive and most recent study was a true randomized placebo-controlled trial using physiologic rather than pharmacologic doses of rhGH in GHD patients. In contrast to the three previous studies, changes in serum IGF-I were titrated within the normal range, rather than to the superphysiologic levels achieved with higher doses of rhGH. Interestingly, in that study of 67 men and women, spine BMD increased after 18 months by nearly 4% in men, which was statistically different than the placebo control, but increased much less in women, and those changes were not statistically different than placebo (Snyder *et al*., 2007). Neither gender showed a significant change in hip BMD in response to rhGH, in doses that were up to 12 μg/kg/day. In sum, there are clear gender- and dose-dependent effects of rhGH on BMD in GHD subjects treated for at least 18 months. There are no studies showing fracture risk reduction with rhGH treatment in GHD subjects.

GH Administration to Elderly Men and Women

As previously noted, elderly people have lower GH secretory amplitudes and reduced serum levels of IGF-I and IGFBP-3 compared to younger adults (Kelijman, 1991; Rudman *et al*., 1981; Donahue *et al*., 1990). Moreover, the pulse frequency for GH is less in the elderly population. Based on these data, it was assumed that skeletal responsiveness to GH in elders would be identical to that seen in GHD patients. In elderly men, one group reported a blunted serum IGF-I response to 0.1 mg/kg GH (36% lower) compared to that in younger men or adults with GHD (Lieberman *et al*., 1994). However, Rosen *et al*. (1999) and others have noted that generation of IGF-I after various doses of rhGH to frail elders was not associated with significant GH resistance. Based on some recent data it appears that GH replacement for adult GHD or for pharmacologic treatment results in similar IGF-I responses independent of age. Side effects such as fluid retention, gynecomastia, and carpal tunnel appear to be more common in the elderly given rhGH compared to young adults with GHD.

The most widely publicized GH RPCT in elders involved 21 men over age 65, randomized to receive 0.03 mg/kg of rhGH three times per week (as a subcutaneous injection), or placebo. Twelve men received rhGH while nine men served as observational controls. The men were selected on the basis of a low serum IGF-I (<350 IU/liter) concentration (Rudman *et al*., 1990). The rhGH produced a threefold rise in circulating IGF-I, an increase in lean body mass (as measured by ^{40}K analysis), and a decline in total adipose mass. BMD of the lumbar vertebrae (L_1–L_4) as measured by dual-energy x-ray absorptiometry (DXA) increased 1.6% after six months in the treatment group while no change was noted in controls. Biochemical markers of bone turnover were not examined and no changes in BMD were detected in the mid- or distal radius or three areas of the hip. Furthermore, the spinal BMD changes at six months were not sustained at one year.

Marcus *et al.* studied the effects of rhGH in 16 men and women over age 60 (Marcus *et al*., 1990). Daily doses of rhGH (0.03, 0.06, or 0.12 mg/kg BW/day) were randomly assigned to each subject and administered once daily for seven days. Serum IGF-I, osteocalcin, PTH, and calcitriol concentrations all increased during treatment. In this short-term study, there was also a significant rise in urinary hydroxyproline and urinary calcium excretion with a concomitant decline in urinary sodium excretion.

Holloway *et al.* conducted a longer double-blind RPCT of daily rhGH for one year in 27 healthy elderly women, 8 of whom took a stable dose of estrogen throughout the study (Holloway *et al*., 1994). Thirteen women completed six months of treatment and 14 women completed six months in the placebo group. Side effects prompted a 50% reduction in the original dose of rhGH (from 0.043 mg/kg BW or approximately 0.3 mg rhGH/kg/week to 0.02 mg/kg/day) and led to several dropouts in the treatment group. Fat mass and percentage body fat declined in the treatment group but there were no changes in BMD at the spine or hip at 6 or 12 months in other groups (Holloway *et al*., 1994). Although BMD did not change, there were changes in some biochemical parameters. In particular, urinary markers of bone resorption (e.g., hydroxyproline and pyridinoline) increased after six months of rhGH treatment. The response of bone formation markers was more variable. Osteocalcin increased but type I procollagen peptide levels did not change. For women taking estrogen replacement therapy, indices of bone turnover (both formation and resorption) were blunted.

Rosen *et al*. (1999) reported that there was a dose-dependent decrease in total body BMD after one year of rhGH in frail elderly men and women. This occurred despite striking increases in osteocalcin and serum IGF-I with the highest doses of rhGH (0.01 mg/kg/day). In part, the absence of a GH effect on BMD is not surprising because resorption is coupled to formation and GH activates the entire remodeling sequence. Moreover, the skeletal

response was only measured after one year of treatment; this was probably inadequate to determine the true effect of rhGH on BMD as noted from earlier studies in GHD. Not surprisingly, in the same trial of 132 frail elderly subjects by Rosen and colleagues, urinary N-telopeptide and osteocalcin both rose to the same extent suggesting that total bone turnover, not just bone formation, was increased by rhGH therapy. The relatively high incidence of acute side effects (weight gain, carpal tunnel syndrome, edema, glucose intolerance) in GH trials, especially in the frail elderly, has remained particularly troublesome even with titrating doses. Moreover, high serum IGF-I levels for long periods of time may predispose individuals to certain malignancies. Thus, there is limited enthusiasm for rhGH or rhGHRH treatments in the frail elderly.

GH Treatment for Osteoporotic Patients

Short nonrandomized clinical trials with GH in osteoporosis were attempted well before GH replacement therapy was considered. As early as 1975, two patients with osteogenesis imperfecta and one patient with involutional osteoporosis were treated with GH. Histomorphometric parameters of increased bone formation and resorption were noted. Subsequent studies employed GH with and without antiresorptive agents. Aloia *et al.* (1977) administered between 2 and 6 U/day of GH for 12 months to 8 patients with postmenopausal osteoporosis (the first 6 months of treatment featured low-dose GH; the last 6 months consisted of high-dose GH (6 U/day). Radial BMC dropped slightly and histomorphometric parameters did not change during treatment. However, severity of back pain decreased considerably in several people. Daily GH injections (4 U/day) combined with alternating doses of calcitonin produced an increase in total body calcium (measured by neutron activation analysis) but a decline in radial bone mass after 16 months. In a separate trial, 14 postmenopausal women were given two months of GH then three months of calcitonin in a modified form of coherence therapy. Total body calcium increased 2.3%/year and there were few side effects, but there were no changes in BMD or histomorphometric indices. One study administered 16 U of rhGH every other day along with daily sodium fluoride to six women with postmenopausal osteoporosis. On histomorphometric analysis, there was a significant increase in the number of osteoblasts and osteoclasts but BMD was unchanged.

Johansson et *al.* (1994) conducted a crossover double-blinded RPCT of rhGH and with idiopathic osteoporosis. In this seven-day trial with rhGH 2 IU/m^2, procollagen peptide and osteocalcin levels increased after treatment as did urinary markers of bone resorption. The changes in osteocalcin were relatively small and were not sustained after discontinuation of GH treatment.

There are no GH trials (past or present) that have examined spinal fractures as a therapeutic end point. Therefore it is difficult to judge the potential efficacy of GH in the treatment of osteoporosis. However, GH stimulates bone remodeling activity, thereby leaving open the possibility that GH can be coupled to anti-resorptive agents. This thesis was tested in a two-year randomized trial by Holloway and colleagues (Holloway *et al.*, 1997). In that study, rhGH and nasal calcitonin increased spine BMD by approximately 2%. This, however, was not much different than the use of CT alone, and certainly less than what has been seen in very large randomized trials with anti-resorptive agents. Once again, there were several side effects that produced limited enthusiasm for rhGH as a primary treatment for osteoporosis. In another combination trial that was larger and longer, 80 osteoporotic postmenopausal women on hormone replacement therapy (HRT) (estrogen with or without progestin) were administered rhGH ten 2.5 U/day or placebo for 18 months, and then open label rhGH for another 18 months. These women were then followed for an additional 24 months. Women given GH and HRT had a marked increase in total body and spine BMD compared to placebo, which was maintained to year 3, but disappeared by year 5 (Landin-Wilhelmsen *et al.*, 2003). This trial suggested that combination therapy of an anabolic and an antiresorptive could be used in postmenopausal osteoporosis. A similar result was noted in a seven-year follow-up of 30 men and women who received rhGH for four years and then were treated with alendronate for an additional three years. BMD increased significantly versus a control group after three years, especially in the males, and the addition of alendronate further enhanced spine BMD at year 7 (Biermasz *et al.*, 2004). Therefore, it is likely that GH may induce small but significant changes in BMD that over an extended period could translate into fewer spine fractures. In the meantime, several very small trials have looked at the effects of GH-releasing analogs on bone turnover and BMD. Not unlike rhGH, however, these studies have been small, and the results somewhat conflicting. However, in contrast to rhGH, GH-releasing analogs are not associated with the significant side effects of weight gain and carpal tunnel syndrome. Hence, further trials may continue with these analogs.

IGF-I for the Treatment of Osteoporosis

Overview

In the late 1980s, clinical trials with rhIGF-I for diabetes mellitus were begun. The availability of this recombinant peptide and the absence of other treatments to stimulate bone formation accelerated animal and human studies of rhIGF-I in metabolic bone diseases. Theoretically, there are potential benefits for rhIGF-I compared to rhGH. These include: 1) more direct stimulation of bone formation; 2) bypass of skeletal GH resistance; and 3) reduction in GH-induced side effects such as carpal tunnel and diabetes

mellitus. There are, however, considerably fewer animal and human studies using rhIGF-I than rhGH. Therefore, these advantages have either yet to be fully realized or have not been validated.

IGF-I is not a potent mitogen in most tissues and bone is no exception (see Chapter 8 by Canalis). There are high-affinity receptors for IGF-I expressed on osteoblasts and IGF-I can stimulate preosteoblast replication and provoke resting cells to proceed through their growth cycles. IGF-I maintains the differentiated osteoblast phenotype, stimulates collagen synthesis, and prevents collagen degradation. Theoretically, therefore, despite its relatively weak mitogenic properties, IGF-I could have significant anabolic activity on the skeleton.

Animal Studies with IGF-I

In hypophysectomized rats, growth can be fully restored by administration of either GH or IGF-I but not IGF-II (Schoenle *et al*., 1985). A similar growth response occurs after rhIGF-I in streptozotocin-diabetic rats but not in sex-linked dwarf-mutant chickens (Schoenle *et al*., 1985; Tixier-Boichard *et al*., 1992). In normal rats, rhIGF-I administrated either systemically or locally (hind limb infusions), does not stimulate longitudinal bone growth. In the spontaneously diabetic BioBreeding (BB) rat, rhIGF-I treatment does not result in changes in epiphyseal width, osteoblast surfaces, or osteocalcin concentration (Verhaeghe *et al*., 1992).

The skeletal response to rhIGF-I is determined by the GH/IGF-I status of the animal. For example, IGF-I does not increase bone formation in normal rats, whereas it stimulates bone growth and normalizes type I procollagen mRNA levels in hypophysectomized rats (Schmid *et al*., 1989; Spencer *et al*., 1991; Tobias *et al*., 1992). Similarly, in the spontaneous mouse mutant (*lit/lit*), the absence of GHRs results in very low levels of IGF-I and skeletal dwarfism. IGF-I treatment restores growth and increases total body water but does not enhance BMD in these mice (Donahue *et al*., 1993). These findings are somewhat similar to the effects of GH on the skeleton in GHD animals. However, rhIGF-I and rhGH differ in their actions on the circulatory IGF regulatory system. GH stimulates hepatic production of both IGF-I and IGFBP-3 while rhIGF-I administration increases the total circulating pool of IGF-I but suppresses hepatic production of IGFBP-3, primarily through feedback inhibition of GH secretion. It is conceivable that variations in IGF-I biological activity (between direct IGF-I administration and endogenously produced IGF-I as a result of GH treatment) may be due to the relative proportion of IGF-I bound to IGFBP-3.

Several experimental paradigms have been employed to study the effects of IGF-I on bone turnover in animals. These include: 1) oophorectomy, 2) diabetes mellitus (spontaneous or induced), and 3) immobilization. In each situation, bone remodeling is markedly altered prior to IGF-I treatment in order to study growth factor actions on bone resorption and formation. These experimental models provide useful clinical information since IGF-I has been considered a potential therapeutic agent in conditions similar to those produced experimentally.

In oophorectomized rats, administration of rhIGF-I has variable effects on bone remodeling, BMD, and bone strength. Kalu reported partial restoration of trabecular bone volume after oophorectomy in adult rats treated with rhIGF-I. In older oophorectomized rats, rhIGF-I increased mid-shaft tibial BMD and enhanced periosteal bone apposition (Ammann *et al*., 1996). Six weeks of rhIGF-I (delivery by mini-osmotic pump) to older rats caused a dose-dependent increase in BMD in the lumbar spine and proximal femur although bone strength and stiffness did not change. Muller reported that subcutaneous administration of rhIGF-I to adult oophorectomized rats stimulated bone formation as evidenced by increased osteoid surfaces, osteoblast surfaces, and mineral apposition rates. At high doses of rhIGF-I, osteoclast surface and osteoclast number also increased. In contrast, Tobias *et al*. (1992) found that rhIGF-I (200 mg/kg) administered for 17 days to 15-week-old rats increased longitudinal and periosteal growth but suppressed trabecular bone formation in both oophorectomized and control rats. Bone resorption was also slightly suppressed during rhIGF-I treatment, although not to the extent that bone formation was inhibited.

IDDM is associated with decreased cortical BMD. Although the pathophysiology of diabetic osteopenia remains unknown, it appears that the duration of diabetes, the extent of diabetic control, and the timing of disease onset are each associated with higher risks of low BMD (McNair, 1988). Serum markers of bone formation are reduced in type I diabetics, suggesting a possible defect in osteoblastic activity (Verhaeghe *et al*., 1992). Serum IGF-I levels are either normal or low in IDDM, but often are reduced in patients with poor diabetic control. In these same people, serum IGFBP-1 levels are quite high. This has led investigators to believe that changes in the IGF regulatory system during poor metabolic control contribute to impaired growth.

Spontaneously diabetic BB rats exhibit osteopenia and therefore provide a useful model for studying the effects of IGF-I on bone remodeling. Even though bone formation is lower in BB than control rats (as measured by serum markers), administration of rhIGF-I does not increase bone epiphyseal width, osteoblast surfaces, or serum osteocalcin (Verhaeghe *et al*., 1992). Thus, despite evidence that circulating levels of IGF-I are reduced in some patients with type I IDDM, preliminary animal studies have failed to show that IGF-I administration can correct any inherent defect in bone formation.

Chronic immobilization inhibits bone formation and leads to significant bone loss. The pathophysiology of immobilization caused by bedrest, hind quarter elevation, or space flight is unknown, but the bone remodeling unit is uncoupled due to a transient decrease in bone formation

and a marked rise in bone resorption (Heaney, 1962). Some investigators have proposed that reduced bone formation during immobilization results from resistance to skeletal IGF-I. Immobilization in rats by the hind limb elevation method causes cessation of bone growth (Bikle *et al*., 1994). Paradoxically, mRNA levels for IGF-I and the IGF-IR are substantially increased in the proximal tibia and distal femur of hind limb elevated rats (Bikle *et al*., 1994). Infusion of rhIGF-I (200 mg/day) during hind limb elevation does not reverse the cessation in linear growth induced by immobilization, even though growth and bone formation resume relatively soon after immobilization is stopped (Bikle *et al*., 1994). This would suggest that there may be, at least transiently, resistance to IGF-I bioactivity.

Other investigators have reported contrasting results during hind limb elevation. Machwate *et al*. (1994) continuously infused rhIGF-I (1.3–2.0 mg/kg/day) for 14 days to 5-week-old hind limb elevated rats. The decline in BMD of the proximal femur with unloading was blunted by infusions of IGF-I. At the tibial metaphysis of IGF-infused animals, bone formation rate and trabecular number were markedly increased. Marrow stromal cells from unloaded rats exhibit decreased proliferative characteristics, but addition of IGF-I greatly increased alkaline phosphatase positive cell proliferation. The rhIGF-I also enhanced serum alkaline phosphatase activity and osteocalcin levels in immobilized rats.

Alternate ways of exploiting the anabolic properties of IGF-I in bone have been proposed. IGF-I has been administered by intra-arterial infusion or coupled to IGFBP-3. Infusion of rhIGF-I continuously into the arterial supply of the right hind limb of ambulatory rats for 14 days leads to a 22% increase in cortical and trabecular bone formation in the infused limb (Spencer *et al*., 1991). By histomorphometry the number of osteoblasts, but not osteoclasts, increases.

Using an alternative model, Bagi *et al*. (1994) administered rhIGF-I or a complex of IGF-I-IGFBP-3 to 16-week-old oophorectomized rats. The IGF-I-IGFBP-3 complex (7.5 mg/kg/day) increased bone formation more than did IGF-I alone, even though both treatments increased longitudinal bone growth. The highest doses of rhIGF-I and rhIGF-I-GFBP-3 enhanced trabecular thickness in the lumbar vertebrae and femoral epiphyses and increased bone resorption but only in the femoral metaphysis. A similar study contrasting IGF-I with IGF-I-GFBP-3 was performed in 22-week-old oophorectomized rats (Brommage *et al*., 1993). BMD increased in both groups but fewer than 10% of the rats treated with IGF-I-IGFBP-3 complex developed hypoglycemia, compared to nearly 50% with rhIGF-I alone.

Human Studies of IGF-I and BMD

There is one published study of bone markers that employed rhIGF-I to healthy young postmenopausal women. Doses of rhIGF-I from 30 to 180 mg/kg/day were administered daily by subcutaneous injection for six days to older postmenopausal women without fractures and normal BMD (Rajaram *et al*., 1997). Very significant dose-dependent increases in serum PICP, osteocalcin, and urinary deoxypyridinoline were reported. Although the rise in PICP was greater than the increase in collagen breakdown (measured by deoxypyridinoline), it is uncertain whether this meant that formation was stimulated more than resorption. For the two highest doses of rhIGF-I (120 and180 mg/kg/day), orthostasis, weight gain, edema, tachycardia, and parotid discomfort were noted. At lower doses (30 and 60 mg/kg/day) fewer side effects were reported, but less discrete changes in PICP were noted. As noted later, high and low doses of rhIGF-I were also administered for 28 days to elderly postmenopausal women and the results are somewhat different in that bone formation was stimulated by lower doses of rhIGF-I.

One indication for rhIGF-I, which has been approved in the United States, Sweden, and other countries, is the GH-resistant short stature syndrome (Laron dwarf). Patients with the Laron dwarf syndrome lack functional GHRs and thus do not respond to GH; their IGF-I levels are very low, growth is slow, and circulating GH levels are high (due to a lack of negative feedback on GH by IGF-I) (Bondy *et al*., 1994). Underwood treated one such boy (age 9) with two weeks of continuous intravenous rhIGF-I (Bondy *et al*., 1994). Urinary calcium excretion increased while urinary phosphate and sodium decreased. After a two-week continuous infusion of rhIGF-I, the patient was treated with twice daily sc rhIGF-I (120 mg/kg) for two years. Growth occurred at a rate of 10 cm/year, compared to 5 cm for the three years prior to treatment. Subsequently, Underwood and colleagues have treated eight patients in this manner without hypoglycemia while Laron and his group have treated five children (Bondy *et al*., 1994; Laron *et al*., 1992). More recently, a child with an IGF-I deletion mutation in exon 5 has been reported. This patient had very short stature, mental retardation, and other abnormalities along with very low levels of circulating IGF-I (Woods *et al*., 1996). The rhIGF-I treatment led to a marked increase in linear growth and a huge increase in spinal bone mass. However, when corrected for changes in size of the bone, the incremental changes in volumetric bone mass were much less impressive (Camacho-Hubner *et al*., 1999). Hypoglycemia was avoided in these cases by having children eat three to four hours after their IGF-I injection, although several children had selective growth of adenoidal tissue.

Two unique aspects about these IGF-I data challenge previous concepts about the role of GH in skeletal homeostasis. First, IGF-I can act as a classical endocrine hormone stimulating longitudinal growth independent of GH; second, GH may not be absolutely essential for statural growth; i.e., the stimulatory effect of GH on chondrocytes that permits skeletal responsiveness to IGF-I may not be

as critical as once perceived. However, caution must be undertaken in examining the effects of rhIGF-I on BMD in children because most of the changes in the skeleton relate to linear growth and periosteal enhancement, both of which can contribute to two-dimensional changes in BMD as measured by DXA, but lesser changes when corrected for size (Bachrach *et al*., 1998).

Idiopathic osteoporosis in men is an ill-defined syndrome of low bone mass and spinal fractures without associated hypogonadism. By histomorphometry, these men often have low bone turnover, suggesting a possible defect in bone formation. Several groups of investigators have suggested that this syndrome is related to low serum IGF-I levels (Ljunghall *et al*., 1992; Kurland *et al*., 1997; Kurland *et al*., 1998). Because the therapeutic options in males with osteoporosis are somewhat limited and treatment for low bone turnover states, in general, is frustrating, the therapeutic potential for anabolic agents like IGF-I in this condition should be quite high. In one male with idiopathic osteoporosis and low serum IGF-I, Johansson *et al.* (1994) administered subcutaneous rhIGF-I (160 mg/kg/day) for seven days. Bone alkaline phosphatase, osteocalcin, and the PICP all increased more than 40% over baseline. However, urinary calcium/creatinine and hydroxyproline excretion rose during treatment. In a recent trial rhIGF-I (at a dose of 80 mg/kg/day) and rhGH (2 IU/m^2/day) in 12 men, serum osteocalcin, serum procollagen peptide, and urinary deoxypyridinoline excretion all increased following seven days of rhIGF-I treatment (Holloway *et al*., 1997). Although there were slight differences in the response of certain biochemical markers to IGF-I and GH, both forms of therapy produced significant increases in bone resorption.

Anorexia nervosa is a condition that is characterized by amenorrhea, profoundly low BMD (due either to low peak bone mass or rapid bone loss), as well as reduced body weight, low circulating IGF-I, resistance to GH, and a marked propensity for fractures. Hence, rhIGF-I might be considered an ideal therapeutic option for this group of adolescents and young adults with severe bone disease, particularly because oral contraceptive pills (OCPs) have virtually no effect on BMD in these patients. Grinspoon *et al*. (2003) studied 60 anorexic women with low BMD in a RPCT of nine months' duration using rhIGF-I 30 ug/kg/d, with or without OCPs. The group of women receiving rhIGF-I and OCPs had the greatest increase in spine BMD (+1.8%); rhIGF-I alone also increased BMD (+1.1%) while bone loss occurred in the group receiving placebo or OCPs alone. Interestingly, there were virtually no side effects in the anorexic women, and serum IGFBP-2 was inversely correlated with the changes in hip BMD. Although the increase in BMD was relatively modest, considering the lack of other available therapies, these changes are encouraging and suggest further studies are needed.

Clinical trials provide evidence that IGF-I acts by increasing the birth rate of remodeling osteons, thereby promoting bone resorption and formation. This action might be ideal for older individuals, because one characteristic of age-related osteoporosis is suppressed bone formation. However, concerns about dosing and side effects have limited enthusiasm for this approach. Yet, it is conceivable that low doses of rhIGF-I (<30 mg/kg/day) could differentially stimulate bone formation. In one trial of 16 healthy elderly women, 60 ug/kg/day(high dose) and 15 mg/kg/day(low dose) of rhIGF-I were tested for 28 days. The high dose rhIGF-I increased markers of bone resorption and formation. However, low doses of rhIGF-I caused increases in serum osteocalcin and PICP, but had no effect on total pyridinoline excretion (Ghiron *et al*., 1995). These data would support the thesis that low doses of rhIGF-I may directly increase osteoblastic function with only a minimal increase in bone resorption. However, further studies will be needed to assess the future therapeutic role of low doses of rhIGF-I in osteoporosis.

Recently, novel approaches to enhancing IGF-I action in bone have been proposed. One strategy is to administer a bone-specific agent that stimulates bone mass such as PTH. Intermittent hPTH increases trabecular bone by stimulating osteoblasts to synthesize IGF-I and other growth factors (Rosen and Donahue, 1998). Another strategy is to administer IGF-I along with an IGFBP. Bagi *et al*. (1994) previously reported that IGF-I/IGFBP-3 complex could enhance bone mass in the metaphysis and epiphysis of rats. One very small randomized trial utilized subcutaneous infusions of IGF-I/IGFBP-3 in 24 older women with hip fractures. Bone loss in the contralateral hip was reduced considerably after six months (i.e., from 6% to 1.5%) in those subjects who were given the complex versus those receiving saline (Geusens *et al*., 1998; Boonen *et al*., 2002). Accompanying that change in BMD was also an increase in grip strength in those that received the active agent, while no significant side effects were reported.

Limitations to the Clinical Use of Recombinant Human IGF-I

IGF-I treatment has its limitations (Zofkova, 2003). The impacts of serious sequelae of long-term administration of IGF-I remain to be evaluated. During IGF-1 treatment, undesirable metabolic manifestations may develop hypoglycemia (in particular after large intravenous doses) and hypophosphatemia with subsequent hypotension (Zofkova, 2003). A more frequent incidence of gynecomastia was also observed. The use of IGF-I/IGFBP-3 complex seems to be very useful and safe in women who are older and who have a recent hip fracture (Agnusdei *et al*., 2005). Furthermore, the combination of an anabolic agent with an anti-resorptive drug (such as calcitonin or alendronate) could be more potent than either agent alone. However, therapeutic effects of such combined approach on BMD at different skeletal sites have been controversial (Agnusdei *et al*., 2005).

SUMMARY

Several lines of evidence point to the importance of local IGF-I in skeletal turnover. Systemic IGF-I, regulated by GH, the IGFBPs, and several proteases, as well as the IGF receptors, also must be important for full linear growth and peak skeletal acquisition. Recent work suggests that recombinant growth factors may be anabolic for the skeletal remodeling unit. First, both GH and IGF-I stimulate osteoblastic differentiation and *in vivo* models using targeted deletion or overexpression of IGFs or the IGF-IR support a critical role for this regulatory circuit in peak bone acquisition. Second, in animal models, GH and IGF-I treatments stimulate longitudinal growth, bone formation, and BMD. Third, in GHD children, rhGH and rhIGF-I both enhance trabecular and cortical BMD. However, rhGH needs to be continued for several years in order to see a positive skeletal response in adults; the response is greater in men than women, and the potential long-term risks of elevating IGF-I as well as the availability of other less expensive therapies, precludes major development of these peptides. Therefore, unless more favorable responses in properly controlled clinical trials are seen with rhGH or rhIGF-I, these drugs are not recommended for the treatment of postmenopausal osteoporosis.

Chapter 50

Platelet-Derived Growth Factor and the Skeleton

Ernesto Canalis
Saint Francis Hospital and Medical Center, University of Connecticut School of Medicine, Hartford, Connecticut

INTRODUCTION

Platelet-derived growth factor (PDGF), a polypeptide with a molecular mass of 30-kilo Daltons (kDa), was originally isolated from human platelets. PDGF is composed of two polypeptide chains that form a homo- or heterodimer. The chains are the products of distinct but related genes. There are four members of the *pdgf* gene family: *pdgf a*, *pdgf b*, *pdgf c*, and *pdgf d* (Fredriksson *et al.*, 2004). In addition, vascular endothelial growth factor (VEGF) shares a high degree of sequence homology with members of the *pdgf* gene family, which is often referred as the PDGF/VEGF family (Ferrara and Davis-Smyth, 1997). The *pdgf a* gene is localized to chromosome 7 and the mature peptide shares 56% sequence homology with PDGF B (Betsholtz *et al.*, 1986). The *pdgf b* gene shares extensive sequence homology with *p28-sis*, the oncogene product of the simian sarcoma retrovirus (Doolittle *et al.*, 1983). *Pdgf* genes encode a highly conserved cytine knot motif, and *pdgf c* and *d* have a Clr/Cls, urchin endothelial growth factor, bone morphogenetic protein (BMP)-1 or CUB domain linked to the cystine knot core motif, by a hinge domain (Bergsten *et al.*, 2001; Gilbertson *et al.*, 2001; LaRochelle *et al.*, 2001; Reigstad *et al.*, 2005). The proteolytic release of the PDGF C and D core from the CUB domain is required for the activation of the growth factor, although activity for the full-length peptide and independent activity for the CUB domain have been reported. PDGFs must form homo- or heterodimers to exhibit activity, and they can form PDGF AA, BB, AB, CC, or DD dimers (Reigstad *et al.*, 2005).

Although PDGF was initially isolated from human platelets, its presence was subsequently found in selected tissues, including bone. In the circulation, PDGF is transported in platelet granules, where its composition is 70% PDGF AB heterodimer, 25% PDGF BB, and 5% PDGF AA homodimer (Hammacher *et al.*, 1988; Hart *et al.*, 1990). *Pdgf* genes are expressed in normal and malignant cells, where they act as local regulators of cell growth. The various *pdgf* genes are conspicuously expressed during development and in adult tissues. Transcripts for the *pdgf a*, *pdgf b,* and *pdgf c* genes can be detected in osteoblasts, but the basal level of PDGF expression is relatively low (Betsholtz *et al.*, 1986; Ding *et al.*, 2000; Reigstad *et al.*, 2005; Rydziel *et al.*, 1994). *Pdgf d* is expressed by myocardial and vascular cells, but not by the osteoblast (Ponten *et al.*, 2005).

SYNTHESIS OF PDGF BY SKELETAL CELLS

The major source of PDGF is the systemic circulation, and skeletal cells become exposed to PDGF following platelet aggregation. Skeletal cells express the *pdgf a*, *pdgf b,* and *pdgf c* genes, indicating that PDGF isoforms may act as autocrine regulators of skeletal cell function (Table I) (Ding *et al.*, 2000; Rydziel *et al.*, 1992; Rydziel *et al.*, 1994). The expression of the *pdgf a* gene in osteoblasts is regulated by other growth factors and TGF β as well as PDGF induce *pdgf a* expression, suggesting that an autoregulatory mechanism is in place to maintain local levels of the growth factor (Rydziel *et al.*, 1992; Rydziel *et al.*, 1994). This autoregulation of the *pdgf a* gene is not unique to the osteoblast, as it also occurs in nonskeletal fibroblasts and mesangial cells (Bhandari *et al.*, 1994). Furthermore, growth factor autoregulation is not specific to PDGF, and other growth factors, such as TGF β1, and insulin-like growth factors (IGF) are autoregulated (Kim *et al.*, 1989). Mechanisms involved in the expression of *pdgf a* in osteoblasts have not been established, but in nonskeletal cells they involve transcriptional control (Kavanaugh *et al.*, 1988; Starksen *et al.*, 1987). Post-transcriptional regulation of the *pdgf a* gene in skeletal cells has not been reported, and its rapid induction by PDGF and TGF β1 suggests that transcriptional mechanisms are involved in osteoblasts. The promoter region of the *pdgf a* gene contains multiple Sp-1 and Egr-1-binding sites, and negative regulatory or silencer elements (Lin *et al.*, 1992; Lin *et al.*, 1993; Takimoto *et al.*, 1991). A serum response element appears to be responsible

TABLE I Factors Inducing PDGF Gene Expression in Osteoblasts

TGF β			
Phorbol esters			

for the autoregulation of *pdgf a* (Lin *et al.*, 1992). The use of alternate promoters, alternative splicing, and multiple polyadenylation signals results in the expression of multiple species of *pdgf a* transcripts (Rorsman *et al.*, 1988; Rorsman *et al.*, 1992). In contrast to the regulation of the *pdgf a* gene by selected growth factors in osteoblasts, systemic hormones do not modify its synthesis in skeletal cells (Rydziel *et al.*, 1992).

TGF β1 increases the expression of *pdgf b* gene transcripts in a time- and dose-dependent fashion in osteoblasts (Rydziel and Canalis, 1996). Other growth factors and systemic hormones do not regulate *pdgf b* gene expression in skeletal cells. TGF β induces *pdgf b* expression in osteoblasts and nonskeletal cells, where it acts at the transcriptional level (Daniel and Fen, 1988). The *pdgf b* gene promoter contains a classic TATA box, Sp-1-binding sites, and a transcriptional silencer region (Jin *et al.*, 1993; Pech *et al.*, 1989). The regulation of *pdgf a* and *b* gene expression in skeletal cells is analogous to their regulation in nonskeletal cells, indicating that there are no specific transcription factors responsible for the regulation of *pdgf a* or *b* in osteoblasts. Because both TGF-β and PDGF regulate *pdgf a* and *b* gene expression, and because TGF β and PDGF are present in platelets, their release following platelet aggregation should act as a central step in the control of PDGF synthesis in the skeleton. This may prove critical for fracture healing. The subsequent induction of PDGF by TGF β and PDGF in the bone microenvironment may be a mechanism to ensure adequate and more constant levels of PDGF in skeletal tissue following platelet aggregation. Under basal conditions there may be no need for skeletal cells to be exposed to significant concentrations of PDGF, and its levels are low (Rydziel *et al.*, 1992; Rydziel *et al.*, 1994).

IN VITRO ACTIONS OF PDGF ON SKELETAL CELLS

PDGF AA, BB, and AB are the isoforms studied more extensively in skeletal cells. They have similar biological actions, although PDGF BB is more potent than PDGF AA, and PDGF AB has intermediate activity (Centrella *et al.*, 1991). PDGF stimulates bone cell replication and DNA synthesis, both in intact calvariae and in isolated rat osteoblasts. It appears that the primary effect of PDGF in bone is related to its mitogenic activity (Table II) (Canalis *et al.*, 1989). As a consequence of this effect, PDGF has the potential to increase a pool of cells of the osteoblastic lineage, which could differentiate and express the osteoblastic phenotype. The mitogenic effect of PDGF is observed primarily in the periosteal layer, a zone rich in fibroblasts and preosteoblasts. It is possible that preosteoblastic cells, replicating under the influence of PDGF, differentiate into mature osteoblasts. However, PDGF inhibits the differentiation of stromal cells into cells of the osteoblastic lineage (Tanaka and Liang, 1995). This would indicate that the dividing cells affected by PDGF could remain in a proliferative undifferentiated state. Some cells may respond to other local signals, and differentiate toward a mature functional osteoblast. It is important to note, that in accordance with the impaired differentiation of cells of the osteoblastic lineage, PDGF inhibits the expression of the mature osteoblastic phenotype, and decreases mineral apposition rate, a marker of osteoblastic function and bone formation (Canalis *et al.*, 1989; Centrella *et al.*, 1992; Hock and Canalis, 1994). PDGF may have direct and indirect effects on skeletal cells because it inhibits the synthesis of bone morphogenetic proteins (BMP) and IGF-I and II; factors that enhance the differentiation and the function of the osteoblast (Table III) (Canalis *et al.*, 1993; Gabbitas *et al.*, 1994). PDGF causes a time- and dose-dependent inhibition of IGF I and II mRNA and polypeptide levels (Canalis *et al.*, 1993; Gabbitas *et al.*, 1994; Gangji *et al.*, 1998), and inhibits BMP-4 expression in osteoblasts (Pereira *et al.*, 2000).

TABLE II Effects of PDGF on Skeletal Cells

Increases cell replication
Inhibits the differentiated function of the osteoblast
Decreases collagen synthesis and type I collagen expression
Decreases bone formation
Increases bone resorption
Increases collagen degradation and collagenase 3 expression
Decreases osteonectin expression
Increases osteopontin expression

TABLE III Effects of PDGF on Cytokine Expression in Osteoblasts

Decreases IGF I and IGF II synthesis
Increases IGF I receptor binding
Decreases IGFBP-5 synthesis
Decreases BMP-4 expression
Increases IL-6 transcription
Increases HGF/SF expression

The inhibition of IGF I and II and BMP-4 expression by PDGF correlates with its inhibitory effects on the differentiated function of the osteoblast, although this does not prove that the decrease in IGF I and II or BMP-4 mediates the effect of PDGF on osteoblastic function. Some of the effects of PDGF on the osteoblast, such as the inhibition of type I collagen transcription, occur following a short exposure to PDGF, suggesting direct effects on the differentiated function of the osteoblast. However, persistent or chronic exposure of skeletal cells to PDGF could result in a significant reduction of IGF and BMP levels, which may be ultimately responsible for a decrease in osteoblastic function and bone formation. The inhibitory effect of PDGF on IGF expression is not directly related to its mitogenic activity. In addition to the decrease in IGF I and IGF II synthesis, PDGF inhibits the transcription of IGF-binding protein (IGFBP) 5, a protein reported to regulate bone cell growth and bone formation (Canalis and Gabbitas, 1995). The interactions of PDGF with IGF I in skeletal cells appear relevant to the effects of PDGF in bone. PDGF modifies the synthesis of IGF I and II and of IGFBP-5, and opposes the effects of IGF I on bone collagen synthesis (Canalis *et al.*, 1989).

By increasing the number of osteoclasts, PDGF enhances bone resorption. In accordance with its effects on bone resorption, PDGF increases the synthesis of matrix metalloproteinase (MMP)-13 or collagenase 3 by the osteoblast (Holliday *et al.*, 1997; Varghese *et al.*, 1996). MMP-13 is a proteinase capable of initiating the degradation of type I collagen at neutral pH, and is required for bone resorption (Zhao *et al.*, 1999). Mice with a mutation of the *collagenase 3* or of the *type I collagen* gene that causes resistance to collagenase 3 cleavage, fail to resorb bone following exposure to parathyroid hormone (Zhao *et al.*, 1999). However, other proteases, particularly those biologically active at acid pH, are relevant to the bone resorptive process.

PDGF enhances collagenase 3 expression by transcriptional and post-transcriptional mechanisms, an effect mediated by the activator protein-1 (AP-1) family of transcription factors (Varghese *et al.*, 1996). Targeted mutations of an AP-1 binding site in the promoter region of the *collagenase 3* gene decrease the basal and PDGF BB-induced transcriptional activity (Varghese *et al.*, 1996). Electrophoretic mobility shift assays reveal enhancement of AP-1 nuclear protein complexes by PDGF BB, and PDGF-dependent interactions of c-Fos, Fos B, Fra-2, c-Jun, Jun B, and Jun D with AP-1 sequences present in the *collagenase 3* gene. The mechanism involves a rapid induction of these transcription factors by PDGF (Rydziel *et al.*, 2000). The elements and cytosolic proteins responsible for the post-transcriptional regulation of *collagenase 3* have not been reported.

The induction or activation of members of the AP-1 family of transcription factors by PDGF BB is consistent with the mitogenic activity of the growth factor and with its stimulatory effects on bone resorption (Angel and Karin, 1991). c-Fos is essential for osteoclast differentiation and mice with null mutations of *c-fos* exhibit osteopetrosis and decreased bone remodeling (Grigoriadis *et al.*, 1994). PDGF may have direct and indirect effects on bone resorption, as it increases the transcription of *interleukin (IL)-6* in osteoblasts, and IL-6 enhances the recruitment of osteoclasts and is critical to the process of bone resorption (Jilka *et al.*, 1992). The effect of PDGF on *IL-6* transcription, like that on *collagenase 3*, is mediated by members of the AP-1 family of transcription factors (Franchimont *et al.*, 1999). Changes in IL-6 expression could play a role not only in the actions of PDGF in bone resorption, but also in its effects on collagenase 3 expression and matrix breakdown, as IL-6 is an inducer of *collagenase 3* expression in osteoblasts (Franchimont *et al.*, 1997).

PDGF RECEPTORS AND BINDING PROTEINS

PDGF can interact with either one of two PDGF receptors, namely the PDGF receptor (PDGFR) α and β. These receptors have differential binding specificity for the various PDGF dimers (Claesson-Welsh *et al.*, 1989; Gronwald *et al.*, 1988; Seifert *et al.*, 1989; Yarden *et al.*, 1986). PDGFR α ligates PDGF A, B, and C chains, and PDGFR β binds PDGF B and D chains (Fredriksson *et al.*, 2004; Reigstad *et al.*, 2005). The two PDGF receptors are structurally and functionally related, and PDGF binding results in receptor dimerization and the formation of PDGF $\alpha\alpha$, $\beta\beta$, and $\alpha\beta$ receptor dimers (Reigstad *et al.*, 2005). For receptor activation, PDGF AA and PDGF CC require PDGFR $\alpha\alpha$, or $\alpha\beta$ dimers, PDGF DD requires PDGFR $\beta\beta$, or $\alpha\beta$ dimers, whereas PDGF AB and PDGF BB can activate PDGFR $\alpha\alpha$, $\alpha\beta$, or $\beta\beta$ dimers. Cells of the osteoblastic lineage express PDGF α and β receptors. PDGF binding to its osteoblast receptor results in receptor dimerization, and activation of tyrosine kinase activity, leading to activation of protein kinase C, and intracellular calcium signaling pathways (Claesson-Welsh, 1994; Heldin *et al.*, 1989).

PDGF activity in osteoblasts can be regulated by changes in PDGF receptor number and affinity. In rodent, but not in human osteoblasts, IL-1 increases PDGF α receptor

transcripts and the binding and mitogenic activity of PDGF AA (Centrella *et al.*, 1992; Gilardetti *et al.*, 1991; Tsukamoto *et al.*, 1991). Fibroblast and epidermal growth factors increase PDGF α receptor expression in osteoblastic cell lines (Tsukamoto *et al.*, 1991). TGF-β decreases PDGF binding, and hormones have no effect on PDGF binding to osteoblasts (Kose *et al.*, 1996). Information on the activity of PDGF CC and PDGF DD and receptor regulation in skeletal cells is limited. PDGF CC interacts with PDGF αα and αβ receptor dimers, and has potent mitogenic activity for mesenchymal cells, as well as angiogenic properties (Gilbertson *et al.*, 2001). These properties of PDGF CC could be important during the vascularization of endochondral bone formation, as it has been reported for VEGF. PDGF DD interacts with PDGF β receptors, has mitogenic activity for vascular cells and induces tissue fibrosis, but its effects on the skeleton are not known (Ponten *et al.*, 2005).

Although there is considerable information about the existence and function of specific binding proteins for many growth factors, including IGFs and TGF β, less is known about specific PDGF binding proteins. PDGF BB binds to α_2-macroglobulin and osteonectin or secreted protein acidic and rich in cysteine (SPARC), and PDGF is stored in the extracellular matrix by its association to osteonectin, as well as to other extracellular matrix proteins (Crookston *et al.*, 1993; Kelly *et al.*, 1993; Lane and Sage, 1994; Raines *et al.*, 1992). The interactions between PDGF and osteonectin may be important, as osteonectin, by binding PDGF B chains, may modify its binding to specific receptors and activity or may prolong its half-life. Skeletal cells secrete substantial amounts of osteonectin, and osteonectin plays a role in bone remodeling and angiogenesis. *Osteonectin* null mice exhibit decreased bone formation and decreased osteoblast number, leading to decreased bone remodeling with a negative bone balance and osteopenia (Delany *et al.*, 2000). The activity of PDGF in the *osteonectin* null state has not been tested. It is possible that changes in the expression of osteonectin in skeletal cells play a role in the regulation of PDGF activity. In chondrocytes, PDGF increases osteonectin expression, whereas in osteoblasts, PDGF BB and fibroblast growth factor 2 (FGF 2) decrease the expression of this matrix protein (Chandrasekhar *et al.*, 1994; Delany and Canalis, 1998). FGF 2 acts by destabilizing osteonectin transcripts, but the mechanisms involved in the action of PDGF on osteonectin expression have not been explored.

IN VIVO ACTIONS OF PDGF ON THE SKELETON

Although there is considerable knowledge about the actions of PDGF *in vitro*, information about its effects on the skeleton *in vivo* is limited. Consistent with its mitogenic effects, the systemic administration of PDGF BB to ovariectomized rats prevents bone loss, and increases the number of osteoblasts and as a consequence bone formation (Mitlak *et al.*, 1996). This suggests that, *in vivo*, the mitogenic effects of PDGF on preosteoblasts result in an increased number of osteoblasts, which are capable of forming bone. Osteoclast number was not altered by systemically administered PDGF. This is in contrast to the stimulatory effects of PDGF on osteoclastogenesis *in vitro*, but may be related to the model used because ovariectomy causes a substantial increase in bone resorption and remodeling. This would preclude an additional effect by PDGF on bone resorption. Topical application of PDGF to craniotomy defects in rodents stimulates soft tissue repair, but not osteogenesis (Marden *et al.*, 1993). The effects of PDGF on endothelial cell proliferation and angiogenesis probably contribute to the process of wound healing (Deuel *et al.*, 1991). PDGF induces the expression of hepatocyte growth factor/scatter factor (HGF/SF) in osteoblasts, and HGF/SF plays a role in tissue repair (Blanquaert *et al.*, 1999; Blanquaert *et al.*, 2000; Strain, 1993). Consequently, its induction by PDGF may also be relevant to the process on wound healing.

Studies of gain and loss of function mutations in mice have provided important information on the physiological role of PDGF during development and after birth. Null mutations of *pdgf b*, *pdgf* α and β receptors are lethal before birth, and *pdgf a* null deletions cause prenatal and perinatal death (Betsholtz, 2004). Because of their lethality, these models have not allowed for the study of the function of PDGF in the adult skeleton. *Pdgf b* and *pdgf* β receptor null mice exhibit vascular defects and absent renal mesangial cells (Leveen *et al.*, 1994; Soriano, 1994). *Pdgf a* and *pdgf* α receptor null mutants display defective alveolar formation leading to emphysema, and reduced intestinal villi, thin dermis, and spermotogenic arrest, but *pdgf a* null mutants do not manifest a skeletal phenotype (Fruttiger *et al.*, 1999; Tallquist and Soriano, 2003). *Pdgf c* null mice exhibit neonatal lethality and various skeletal developmental abnormalities, including cleft palate and spina bifida (Ding *et al.*, 2004). Similar defects are observed in *pdgf* α receptor null mice, which exhibit a phenotype characterized by embryonic lethality, cleft face, spina bifida, and vascular and skeletal defects (Fruttiger *et al.*, 1999; Tallquist and Soriano, 2003). Although PDGF B can interact with the PDGF α receptor, loss of function mutations of the *pdgf b* gene do not resemble the *pdgf* α receptor null phenotype, indicating that the functions of the PDGF α and β receptors are not redundant (Leveen *et al.*, 1994; Soriano, 1994). The phenotype of the *pdgf d* gene deletion has not been reported, but overexpression of PDGF DD, like that of PDGF CC, results in tissue fibrosis (Campbell *et al.*, 2005; Ponten *et al.*, 2005).

ROLE OF PDGF IN SKELETAL FUNCTION

The mitogenic activity of PDGF and its release by platelets suggests a role in wound healing and fracture repair. This

is supported by the demonstration of *pdgf a* and *b* gene expression at fracture sites, and the effects of PDGF on endothelial cell proliferation and angiogenesis. However, the effects of PDGF on wound healing are short-lived, and there is limited information regarding the possible effectiveness of PDGF in fracture repair. Because the *pdgf a* and *b* genes are expressed by a variety of malignant cells, including osteosarcoma, PDGF may play a role in tumorigenesis, a possibility supported by the near identity of the *pdgf b* gene and *p28-sis*. In addition, the Wilms tumor gene product WT1 represses transcription of the *pdgf a* gene, and a loss of WT1 or related represser activities could contribute to the pathogenesis of Wilms tumors (Gashler *et al.*, 1992). PDGF does not appear to play a role in the maintenance of bone mass in view of its inhibitory effects on the differentiated function of the osteoblast. Systemic administration of PDGF to estrogen-deficient rats prevents vertebral bone loss (Mitlak *et al.*, 1996). However, the mitogenic activity of PDGF and the fact that its systemic administration causes soft tissue fibrosis would limit its use. Topical application of PDGF to rat craniotomy defects results in increased soft tissue repair, but not increased osteogenesis, also placing limitations on the potential use of PDGF (Marden *et al.*, 1993).

FIBROBLAST GROWTH FACTORS AND BONE

Studies have demonstrated an important role for members of the heparin-binding fibroblast growth factor (FGF) family and their receptors in normal limb development, bone growth, and fracture repair and the inherited human osteo- and chondrodysplastic syndromes with their attendant skeletal abnormalities. FGF-1 and FGF-2 are potent agonists with stimulatory effects on bone resorption and both stimulatory and inhibitory effects on bone formation. The inhibitory effects on collagen synthesis have been demonstrated in cell and organ culture and appear to involve inhibition of transcription of the collagen gene and to be independent of effects on cell replication. The resorptive effects of FGFs appear to be both prostaglandin dependent and independent and also involve the replication and differentiation of osteoclasts. *In vivo*, exogenous FGF-1 and FGF-2 increase bone formation by multiple mechanisms. The effects of FGF may be mediated in part by transforming growth factor β (TGF β), bone morphogenetic protein-2 (BMP-2), and prostaglandins (PGs), because the production of these factors can be regulated by FGFs. These studies emphasize the important effects of FGFs on the control of skeletal cells (Hurley *et al.*, 2002; Marie *et al.*, 2002). Extensive studies demonstrate an important role for FGF23 in phosphate transport and this topic is reviewed in a separate chapter.

EXPRESSION OF FGF RECEPTORS IN BONE

The expression of FGFs and FGF receptors (FGFRs) is regulated temporally and spatially during skeletal development. Several FGF members are expressed during early stages of development in mammals (Yamaguchi and Rossant, 1995; Niswander, 1996), and their expression is related to skeletal development (Johnson and Tabin, 1997; Naski and Ornitz, 1998). During intramembranous bone formation, FGF-2 transcripts are found in mesenchymal cells and osteoblasts (Mehrara *et al.*, 1998; Rice *et al.*, 2000), together with FGF-9 (Kim *et al.*, 1998). During skeletal development, FGF-1 is expressed in proliferating and hypertrophic chondrocytes; FGF2 is present in resting and proliferating chondrocytes whereas FGF17 and 19 are widely expressed (Krejci *et al.*, 2007). FGFs 2, 7,18 and 22 are expressed in postnatal growth plate (Lazarus *et al.*, 2007). In the developing bone, FGF-2, -9, -18, and -20 are expressed in the calvaria and limbs (Hajihosseini and Heath, 2002). FGF-2 is produced by and stored in the extracellular matrix (Globus *et al.*, 1989; Hurley *et al.*, 1994).

FGF's actions are dependent on the expression and interactions with FGFRs. During skeletal tissue development, the spatiotemporal pattern of FGFR-1, -2, and -3 expression differs (Hughes *et al.*, 1997; Orr-Urtreger *et al.*, 1991; Wanaka *et al.*, 1991; Peters *et al.*, 1992; Patstone *et al.*, 1993; Wilke *et al.*, 1997; Delezoide *et al.*, 1998). During endochondral development, FGFR-1 transcripts are expressed in the mesenchyme and later in hypertrophic cartilage and osteoblasts, whereas FGFR-2 is expressed at sites of ossification and later in cartilage, perichondrium, and periosteum (Peters *et al.*, 1992; Delezoide *et al.*, 1998).

In contrast, FGFR-3 transcripts are found mainly in proliferating and prehypertrophic chondrocytes (Naski *et al.*, 1998) and are not found in mesenchymal cells or perichondral or periosteal cells until late stages of development (Peters *et al.*, 1993; Delezoide *et al.*, 1998). Consistently, the expression of FGFR-3 increases during the development of chondrogenesis *in vitro* (Szebenyi *et al.*, 1995; Molténi *et al.*, 1999a). FGF/FGFR3 signaling also has an essential role in mandibular skeletogenesis by facilitating the elongation of Meckel's cartilage, development of osteogenic condensations, and appositional growth of mandibular bones (Mina *et al.*, 2007).

In the human cranial vault, FGFR-1 immunostaining is localized in proliferating mesenchymal cells and preosteoblasts, whereas FGFR-2 and FGFR-3 immunostaining is found mainly with FGF-2 in preosteoblasts and osteoblasts (Delezoide *et al.*, 1998). In the mouse, FGFR-2 transcripts are present at the osteogenic fronts of the cranial suture (Iseki *et al.*, 1997; Kim *et al.*, 1998, Johnson *et al.*, 2000), and FGFR-2 expression is associated with endogenous FGF-2 expression (Mehrara *et al.*, 1998; Most *et al.*, 1998; Rice *et al.*, 2000). *In vitro*, FGFR-1 and FGFR-2 immunostaining is also found in neonatal rat calvaria cells (Molténi *et al.*, 1999a) and in human calvaria osteoblastic cells (Debiais *et al.*, 1998). Interestingly, FGFR1 and FGFR2 expression is age-related in calvaria cells (Cowan *et al.*, 2003). Although the spatiotemporal pattern of expression of FGF and FGFRs suggests that skeletal development is controlled by FGF/FGFR interactions, the FGF effects on bone cells may be modulated by the various affinity and specificity of FGF binding to the various alternative splice forms of FGFRs (Ornitz *et al.*, 1996).

FGF RECEPTORS AND HUMAN CHONDRODYSTROPHIES

FGFs have profound effects on chondrocyte development, proliferation and differentiation. The effects span stages of chondrocyte biology from chondrogenesis through the final steps of chondrocyte hypertrophy. Not surprisingly the effects of FGFs are complex and incompletely understood. The emerging data demonstrate that FGFs can both stimulate and suppress chondrocytes, depending on the stage of differentiation (Bobick and Kulyk, 2006; Bobick *et al.*, 2007; Mancilla *et al.*, 1998).

A number of human skeletal dysplasias, including chondrodysplasias and craniosynostosis syndromes have been linked genetically to mutations in FGFR1, FGFR2 and FGFR3 (Ornitz, 2005; Lajeunie *et al.*, 1999). Mutations in FGFR3 cause achondroplasia and others chondrodysplasias and dwarfism in humans. The mechanisms underlying these disorders are now better understood (Chen and Deng, 2005; Ornitz, 2005). The constitutive FGFR3 activation was found to be related to increased ligand stabilization, prolonged signaling, ligand-independent receptor activation or altered receptor conformation, resulting in constitutive activation of the receptor (Hart *et al.*, 2001; Sorokin *et al.*, 1994; Mohammadi *et al.*, 1996). In humans, mutations in FGFR-3 cause constitutive activation of FGFR-3, resulting in chondrodysplasia syndromes, including achondroplasia, the most common form of dwarfism, hypochondroplasia, and thanatophoric dysplasias (Wilkie, 2005), which demonstrates a role for FGFR-3 in the control of long bone cartilage growth. Several FGFR-3 mutations cause abnormal chondrogenesis in the mouse (Chen *et al.*, 1999; Segev *et al.*, 2000). Dwarfism induced by activating mutations in FGFR3 is associated with STAT activation, resulting in inhibition of proliferation of growth plate chondrocytes (Chen *et al.*, 1999; Li *et al.*, 1999). These skeletal abnormalities induced by FGFR3 activation result from abnormal activation of STAT1, STAT5 and p21 (Su *et al.*, 1997); Legeai-Mallet *et al.*, 1998; Sahni *et al.*, 1999; Yoon *et al.*, 2006). Additionally, FGFR3 mutants activate ERK1/2 signaling (Lievens *et al.*, 2005). Inhibition of MAPK pathway was found to rescue achondroplasia induced by FGFR3 activation in mice (Yasoda *et al.*, 2004). Additionally, pRb family members and PI3-kinase contribute to the effects of FGF receptor 3 on chondrocyte proliferation (Priore *et al.*, 2006; Raucci *et al.*, 2004). Stimulation of cultured chondrocytic cells with FGF causes rapid hypophosphorylation of the pRb family protein, p107. With slower kinetics, p130 and pRb are also dephosphorylated (Dailey *et al.*, 2003). Dephosphorylation of the Rb proteins inhibits proliferation by binding to E2F proteins and subsequently inhibiting expression of E2F target genes required for proliferation (Dailey *et al.*, 2003). Significantly, both the MAP kinase and PI3-kinase pathways regulate the dephosphorylation of pRb family proteins in response to FGF (Dailey *et al.*, 2003; Raucci *et al.*, 2004), suggesting that signals transmitted by FGF receptor 3 converge at this point.

Also, constitutive activation of FGFR-3 induced by the R248C mutation triggers premature apoptosis, which is mediated by activation of the STAT1 signaling pathway (Legeai-Mallet *et al.*, 1998). Human FGFR3 mutant chondrocytes also display increased apoptosis (Legeai-Mallet *et al.*, 1998) and treatment with IGF-1 can prevent the apoptosis induced by FGFR3 mutation through PI3K and MAPK pathways (Koike *et al.*, 2003). Thus, several mechanisms induced by FGFR3 signaling appear to be involved in the control of endochondral ossification (Ornitz, 2005).

Our understanding of how FGF signaling integrates with other cytokine signaling pathways during endochondral bone development is expanding. Of particular interest is the interaction of FGF and C-type natriuretic peptide (CNP). CNP is an essential regulator of endochondral bone development, as evidenced by the dwarfism resulting from disruption of the CNP gene of mice (Chusho *et al.*, 2001) or inherited mutations of the CNP receptor in humans (Bartels *et al.*, 2004). CNP regulates skeletal growth in part by antagonizing FGF signaling. This has been demonstrated both

in vivo and *in vitro*. Acting through natriuretic peptide receptor B, CNP inhibits the activation of MAP kinases by FGFs. In this way, CNP reverses the dwarfing condition caused by an activated FGFR-3 (Yasoda *et al.*, 2004). Cell culture experiments have corroborated these findings. Through blockade of MAP kinase activation, CNP repressed the inhibition of proliferation caused by FGF (Krejci *et al.*, 2005; Ozasa *et al.*, 2005). Interestingly, CNP may also moderate the effects of FGF on chondrocyte differentiation. This is supported by data showing that CNP partially blocked the induction of matrix metalloproteinases caused by FGF-2 (Krejci *et al.*, 2005).

FGFs also interact directly with the Wnt signaling cascade. This is demonstrated by results showing that the expression of certain FGFs like FGF-18 requires canonical Wnt signaling. The Wnt pathway increases the levels of the transcription co-activator β-catenin. β-Catenin induces FGF18 expression through binding to TCF-Lef transcription factors localized to the transcription start site (Reinhold and Naski, 2007). Significantly, canonical Wnt signaling inhibits chondrocyte development and differentiation (Chimal-Monroy *et al.*, 2002; Enomoto-Iwamoto *et al.*, 2002; Hartmann and Tabin, 2000, 2001; Stott *et al.*, 1999). Because FGFs are induced by Wnt signaling and FGFs inhibit early chondrogenesis (Bobick *et al.*, 2007; Buckland *et al.*, 1998; Moftah *et al.*, 2002), the inhibitory actions of Wnt may be a consequence of FGF induction. Consistent with this, the inhibitory effects of a Wnt mimetic on chondrocyte proliferation were abrogated in bone rudiments from FGFR-3 null mice (Kapadia *et al.*, 2005). In the future, it will be important to know which of the broader activities of Wnt signaling are mediated through the induction of FGFs and signaling via FGFRs.

FGF RECEPTORS AND HUMAN CRANIOSYNOSTOSIS

The important role of FGFRs during cranial development is supported by genetic evidence that FGFR mutations induce abnormal ossification of the cranial sutures (craniosynostosis) in humans (Lajeunie *et al.*, 1999; Ornitz and Marie, 2002; Wilkie, 2005). Several mutations in FGFR 1 or FGFR2 induce craniofacial abnormalities, causing Apert, Crouzon, Pfeiffer, and Jackson-Weiss syndromes (Wilkie, 2005). Genetic analyses indicated that mutations in the Ig III domain or in the linker between the Ig II and Ig III domain of FGFR-1 and FGFR-2 induce constitutive activation of the receptor (Neilson and Friesel, 1995, 1996; Robertson *et al.*, 1998; Plotnikov *et al.*, 2000). In Crouzon syndrome, the C342Y mutation in FGFR-2 results in the activation of FGFR-2 signaling and decreased binding of FGF-2 to the receptor (Mangasarian *et al.*, 1997). In Apert syndrome, FGFR-2 mutations enhance receptor occupancy by FGF ligands, prolongation of the duration of receptor signaling (Park *et al.*, 1997; Anderson *et al.*, 1998), enhancement of ligand binding (Ibrahami *et al.*, 2001, 2004) or loss of ligand binding specificity to FGFR2 (Yu *et al.*, 2000). A clue to the cellular and molecular mechanisms underlying the phenotype induced by FGFR genetic mutations came from studies in humans with FGFR2 mutations (Marie *et al.*, 2002). FGFR-2 mutations in Apert syndrome accelerate subperiosteal osteogenic differentiation without affecting cell proliferation (Fragale *et al.*, 1999; Lomri *et al.*, 1998; Lemonnier *et al.*, 2000; Tanimoto *et al.*, 2004), a phenotype also found in human nonsyndromic craniosynostosis (DePollack et al 1996; Fragale *et al.*, 1999). Apert mutations of FGFR-2 constitutively increase osteoblast marker genes in calvaria preosteoblasts in part through activation of PKC expression, phosphorylation and activity (Fragale *et al.*, 1999; Lemonnier *et al.*, 2000), resulting in increased N-cadherin–mediated cell-cell adhesion (Lemonnier *et al.*, 2001a). The S252W Apert FGFR2 mutation also downregulates the expression and activity of Src family members Fyn and Lyn in human osteoblasts, which contributes to the premature differentiation phenotype (Kaabeche *et al.*, 2004). This phenotype and underlying signaling mechanisms are consistent with the *in vivo* phenotype in fused cranial sutures in humans (Marie *et al.*, 2002; Wilkie, 2005).

In mice, activating FGFR mutations induce variable phenotypes. *In vitro* analyses showed that activating FGFR2 mutations stimulate calvaria bone cell proliferation, but inhibit mineralization (Mansukhani *et al.*, 2000; Ratisoontorn *et al.*, 2003). *In vivo*, unchanged or increased osteoblast proliferation and differentiation were reported in mice expressing FGFR1 or FGFR2 mutations (Zhou *et al.*, 2000; Chen *et al.*, 2003). Also, activating Apert and Crouzon FGFR2 mutations increase cell proliferation and decrease osteoblast differentiation in mice (Mansukhani *et al.*, 2005). However, conditional inactivation of FGFR2 affects the proliferation of osteoprogenitors, but not the differentiation, of mature osteoblasts in mice (Yu *et al.*, 2003). Moreover, the cell phenotype induced by FGFR2 activation varies with the sutures examined (Wang *et al.*, 2005). Although there are discrepancies in the phenotype induced by point mutations in mice and natural mutations in humans, which may relate to the distinct environmental factors or genetic background, the resulting effect is increased osteogenesis (Marie *et al.*, 2002; Wilkie, 2005).

Several data suggest that the accelerated osteogenesis induced by activation of FGFR signaling may result in part from increased expression of Runx2. Activating FGFR1 and FGFR2 mutations, or a gain-of-function mutation in FGFR2c in the mouse causes premature osteoblast differentiation associated with increased expression of Runx2 (Zhou *et al.*, 2000; Baroni *et al.*, 2004; Eswarakumar *et al.*, 2004). The P253R and S252W FGFR2 mutations were also found to increase Runx2 expression in human calvarial osteoblasts from Apert patients (Tanimoto *et al.*, 2004; Baroni *et al.*, 2005) and increased FGFR2 expression also correlates with Runx2 expression in human cranial

osteoblasts (Guenou *et al.*, 2005). Other transcription factors may however be involved downstream of FGFR signaling. For example, FGFR2 activating mutations increase Sox2 expression in murine osteoblasts (Mansukhani *et al.*, 2005). Recent analysis of cell signaling in murine osteoblasts expressing Apert or Crouzon FGFR2 mutations revealed that activation of FGFR downregulates Wnt target genes (Mansukhani *et al.*, 2005) suggesting that Wnt signaling may also be involved in the phenotype induced by FGFR2 activation. Although this may provide a molecular mechanism for the premature osteoblast differentiation and cranial suture ossification induced by FGFR2 signaling, the role of transcription factors or Wnt signaling in human syndromic craniosynostosis is unknown.

Another issue in FGFR signaling is the role of FGFR downregulation in the control of skeletal cells. Constitutive activation of FGFR2 in Apert syndrome accelerates FGFR downregulation in mutant osteoblasts *in vitro* and *in vivo* (Lemonnier *et al.*, 2000), which is consistent with the decreased expression of FGFR-2 in Crouzon syndrome (Bresnick *et al.*, 1995). The ubiquitin ligase Cbl was found to control FGFR1 degradation after ligand activation (Wong *et al.*, 2002). Similarly, FGFR2 activation in Apert syndrome induces Cbl-mediated FGFR2 proteasome degradation, as well as Src protein downregulation, which results in increased expression of early markers of osteoblast differentiation (Kaabeche *et al.*, 2004). Activated FGFR2 also shows increased binding to the adaptor protein FRS2 (Hatch *et al.*, 2006), an important molecule involved in the negative feedback mechanism induced following FGFR stimulation (Eswarakumar *et al.*, 2006). Uncoupling between the docking protein FRS2 alpha and activated Crouzon-like FGFR2c mutant results in normal skeletal development in mice (Eswarakumar *et al.*, 2006). These studies emphasize the role of FRS2 alpha and Cbl in the attenuation of signals induced by FGFR activation. In marked contrast, activated FGFR3 in achondroplasia escapes Cbl-mediated ubiquitination and lysosomal degradation, resulting in amplification of the FGFR3 signal in the growth plate (Cho *et al.*, 2004). The kinase activity of mutant FGFR3 affects receptor trafficking, resulting in increased signaling capacity (Lievens *et al.*, 2005).

FGFR2 mutations also promote apoptosis in mature osteoblasts *in vitro* and *in vivo*. Constitutive activation of FGFR2 signaling by the C342Y Crouzon and the S252W Apert FGFR-2 mutations promote apoptosis in mouse or human cranial osteoblasts (Chen *et al.*, 2003; Mansukhani *et al.*, 2000; Lemonnier *et al.*, 2001b; Kaabeche *et al.*, 2005). The increased apoptosis in Apert osteoblasts is mediated by increased IL-1 and Fas expression, activation of caspase-8 and increased Bax/Bcl-2 levels (Lemonnier *et al.*, 2001b). FGFR2 activation also results in Cbl-mediated alpha 5 integrin ubiquitination and degradation, which contributes to osteoblast apoptosis (Kaabeche *et al.*, 2005). It is unclear whether the increased apoptosis is a cause or a consequence of the increased osteogenesis. The upregulation of apoptosis by constitutive FGF signaling may be a significant mechanism controlling osteoblast number and osteogenesis. Alternatively, apoptosis in mature osteoblasts may be a necessary event compensating for the accelerated osteoblast differentiation induced by FGFR2 signaling (Lemonnier *et al.*, 2001b). Further studies are required to determine the precise role of apoptosis induced by FGFR signaling during cranial suture formation. Microarray analyses revealed that apoptotic genes are altered by FGFR2 activation in human (Lomri *et al.*, 2001) and murine osteoblasts (Mansukhani *et al.*, 2005), but it is not known whether these genes are involved in the observed phenotype.

FGF AND CARTILAGE

FGF-2 is expressed in chondrocytes *in vivo* (Twal *et al.*, 1994) and may be an autocrine growth factor (Luan *et al.*, 1996). Exogenous FGF-2 stimulates chondrocyte cell growth and inhibits chondrocyte differentiation (Kato *et al.*, 1990; Wroblewski *et al.*, 1995), *In vitro*, several FGF members stimulate chondrocyte proliferation (Praul *et al.*, 2002). Recent data indicate that FGF-18 stimulates the proliferation of cultured chondrocytes through activation of FGFR3 (Liu *et al.*, 2007) and p38 MAPK signaling (Shimoaka *et al.*, 2002). *In vivo*, FGF-2 overexpression induces chondrodysplasia and shortening of long bones in mice (Coffin *et al.*, 1995; Lightfoot *et al.*, 1997; Sobue *et al.*, 2005). Consistently, FGFRs were shown to be key regulators of endochondral bone growth *in vivo*. Although FGFR1 induces a mitogenic signal in cultured chondrocytes, activated FGFR1 signaling *in vivo* suppresses growth plate chondrocytes mitogenesis, resulting in achondroplasia-like dwarfism *in vivo* (Wang *et al.*, 2001). Recent data indicate that the mesenchymal FGFR-3c isoform is responsible for controlling chondrocyte proliferation and differentiation that mediate normal skeletal development, whereas the epithelial FGFR-3b isoform does not contribute toward this process (Eswarakumar and Schlessinger, 2007). The negative role of FGFR-3 in endochondral growth is emphasized by the finding that FGFR-3 −/− mice show excessive long bone growth, associated with increased chondrocyte proliferation (Colvin *et al.*, 1996; Deng *et al.*, 1996). Overexpression of activated FGFR-3 in mice reduces chondrocyte cell proliferation (Naski *et al.*, 1998; Ornitz, 2000), showing that activated FGFR-3 signaling inhibits chondrocyte proliferation and decreases differentiation (Li *et al.*, 1999; Rozenblatt-Rosen *et al.*, 2002). The expression in the growth plate of Ihh and BMP4 was found to be downregulated in mice overexpressing FGFR-3 and increased in mice lacking FGFR-3, suggesting that FGFR-3 may act on multiple signaling molecules to control endochondral bone growth (Naski *et al.*, 1996; Ornitz, 2000b). Conversely, BMPs antagonize FGF

signaling pathways in chondrocytes (Yoon *et al.*, 2006). The balance between proliferating and differentiating chondrocytes is likely to be controlled by interactions between FGF and BMP signaling (Minina *et al.*, 2002).

FGFs have far-reaching effects on cartilage, and these effects vary depending on the stage of differentiation. A principal example is the effect of FGFs on chondrocyte proliferation. During formative stages of cartilage development FGFs stimulate chondrocyte proliferation (Liu *et al.*, 2007), whereas during later stages FGFs inhibit proliferation. A number of studies using cultured chondrocytes, which probably represent early or immature chondrocytes , show that FGFs stimulate proliferation. For example FGF-2 is expressed in chondrocytes *in vivo* (Luan *et al.*, 1996) and when added to cultured chondrocytes stimulates cell replication (Kato *et al.*, 1990; Wroblewski *et al.*, 1995). Other FGFs including 4, 9, and 18 also strongly induce chondrocyte proliferation (Praul *et al.*, 2002; Shimoaka *et al.*, 2002). These data compare with the effects of FGFs in the established epiphyseal growth plate where signaling through FGFR-3 clearly inhibits proliferation. Overexpression of FGF-2 induces a dwarfing condition that in many respects phenocopies that caused by an activated form of FGFR-3 (Coffin *et al.*, 1995; Lightfoot *et al.*, 1997; Naski *et al.*, 1998a; Ornitz, 2000). Further evidence that FGFR-3 inhibits chondrocyte proliferation comes for studies of FGFR-3 null mice that show enhanced chondrocyte proliferation and excessive long bone growth (Colvin *et al.*, 1996; Deng *et al.*, 1996). These effects are dictated almost exclusively by the FGFR-3c isoforms that results from alternative splicing the C-terminal portion of the extracellular domain (Eswarakumar and Schlessinger, 2007). FGFs also directly affect the postproliferative stages of chondrocyte development. Chondrocyte hypertrophy is inhibited by FGF signaling. This is shown both in *ex vivo* chondrocyte cultures (Kato *et al.*, 1990) and in mouse models expressing activated FGFRs (Naski *et al.*, 1998; Li *et al.*, 1999). The FGF-dependent pathways that regulate chondrocyte hypertrophy are incompletely understood and require further investigation. However, several studies show genetic or biochemical interactions of FGF with BMP- or CNP-dependent processes (Li *et al.*, 1999; Yoon *et al.*, 2006; Minina *et al.*, 2002; Yasoda *et al.*, 2004). These complex interactions are likely to form a self-regulating circuit that adjust the rate of differentiation in step with chondrocyte proliferation.

FIBROBLAST GROWTH FACTOR PRODUCTION AND REGULATION

Although there are 23 members of the fibroblast growth factor family (Fig. 1), only FGF-1, FGF-2, FGF-18, and FGF 23 have been studied extensively in bone. FGF-2

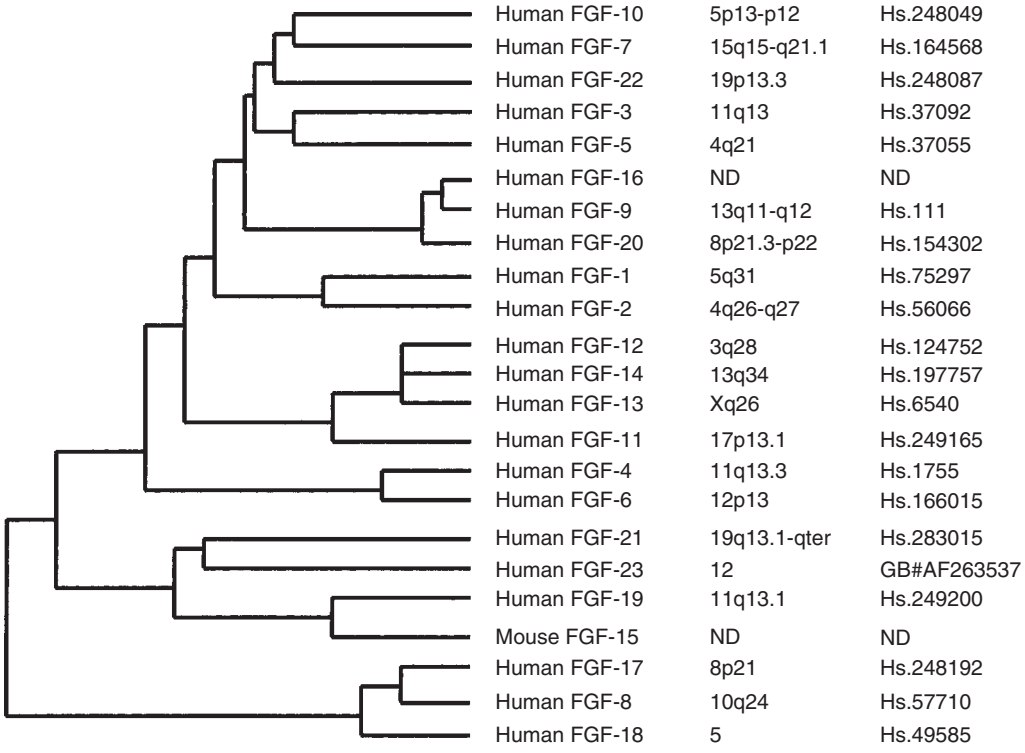

FIGURE 1 The human FGF gene family is made up of 23 genes. A dendrogram depicting the sequence relationship between members of the family is shown along with their human chromosomal location and corresponding unigene number. For FGF-15, no human homologue has been published, and the chromosomal location of FGF-16 has not yet been determined.

and FGF-1 are found in the bone matrix (Hauschka *et al.*, 1986) and are produced by bone cells, with FGF-2 being 10-fold higher than FGF-1 when measured by radioimmunoassay (Seyedin *et al.*, 1985; Globus *et al.*, 1989). FGF 23 has been shown to be an important regulator of phosphate homeostasis (reviewed by Fukimoto and Yamashita, 2007). FGF 23 mRNA was detected in many fetal and adult tissues, with the highest expression observed in adult calvariae, femurs, and incisors. Immunoreactive FGF2 23 was primarily found in osteoblasts, cementoblasts, and odontoblasts, although sporadic labeling was detected in chondrocytes, osteocytes, and cementocytes as well as osteoclasts (Yoshiko *et al.*, 2007).

There are few data on the regulation of FGF expression in bone. In cultures of mouse osteoblastic MC3T3-E1 cells, exogenous FGF-2 increases its own mRNA (Hurley *et al.*, 1994). TGF-β also increases FGF-2 mRNA and protein in MC3T3-E1 cells (Hurley *et al.*, 1994). TGF-β increases FGF-2 protein in both the cytoplasm and the nucleus. However, there is no measurable FGF-2 in the conditioned medium. The significance of TGF-β regulation of FGF-2 in osteoblasts is not clear. Amplification of the responses to both FGF and TGF-β could occur by an increase in endogenous FGF. In addition, parathyroid hormone (PTH; Hurley *et al.*, 1999) and prostaglandins (Sabbieti *et al.*, 1999) increase FGF-2 mRNA and protein levels in bone cells, suggesting that anabolic factors for bone may act in part by stimulating endogenous FGF-2 in osteoblasts. Impaired bone formation (Hurley *et al.*, 2006)and hypercalcemic response (Okada *et al.*, 2003) to PTH in Fgf2 null mice support an important role for endogenous FGF-2 in the actions of PTH in bone. Interestingly, FGF-2 is an immediate-early gene induced by mechanical stress in osteoblasts, an effect that results in activation of the PKA and MERK1/2 pathways, suggesting that FGF-2 may mediate some of the osteogenic effects induced by mechanical forces (Li *et al.*, 2006).

Studies have shown that $1,25(OH)_2D_3$ increased FGF23 expression in fetal rat calvarial cell cultures (Yoshiko *et al.*, 2007).

A DISTINCTIVE TRANSLATION INITIATION MECHANISM MEDIATES EXPRESSION OF FGF-2 AND FGF-3

Although all FGFs are encoded by single copy genes, multiple isoforms of both FGF-2 (Florkiewicz and Sommer, 1989; Prats *et al.*, 1989) and FGF-3 (Dickson and Acland, 1990) have been detected. The novel mechanism by which this occurs distinguishes these FGFs from all other known growth factors and ultimately may prove to be a critical point from which FGF-2 and FGF-3 gene expression is qualitatively regulated. Each of the multiple isoforms is a primary translation product with no precursor–product relationship. The larger isoforms are colinear amino-terminal extended versions of the shorter isoforms. Moreover, translation of each of the four high-molecular-weight (HMW) human FGF-2 isoforms (22, 23, and 24 kDa) is initiated with an unconventional CUG translation initiation codon; a 34-kDa isoform of FGF-2 has also been described (Arnaud *et al.*, 1999). In contrast, translation of the 18-kDa isoform is initiated with a classical AUG codon located downstream of the four CUG codons. Multiple HMW isoforms of rodent FGF-2 also initiate translation with CUG codons (Powell and Klagsbrun, 1991). Curiously, the rainbow trout FGF-2 gene appears to encode only an 18-kDa translation product, even though preferential CUG translation initiation from transfected human cDNA expression vectors does occur (Hata *et al.*, 1997). Likewise, the larger isoform of FGF-3 (31.5 kDa) utilizes a CUG codon, whereas the 28.5-kDa isoform uses an AUG codon to initiate translation (Dickson and Acland, 1990). In the case of FGF-2, CUG-initiated HMW isoforms are not minor translation products, and in some cases the HMW isoforms are expressed at levels equal to or greater than the 18-kDa isoform (Coffin *et al.*, 1995). Thus, the unusual utilization of CUG codons to initiate the translation of HMW FGF-2 effectively diversifies this single copy gene.

The uncommon use of CUG codons to initiate FGF-2 translation prompted speculation that selecting a CUG as opposed to AUG translation initiation codon may represent a physiologically relevant mechanism regulating FGF-2 gene expression. Three observations support this possibility. The first is that the CUG-initiated translation products of FGF-2 and FGF-3 localize to the nucleus preferentially, whereas their respective AUG-initiated isoforms are predominantly cytosolic or extracellular (Florkiewicz *et al.*, 1991). Second, the HMW isoforms of FGF-2 are expressed in a tissue-specific pattern distinct from the 18-kDa isoform that is maintained in transgenic model systems (Coffin *et al.*, 1995), as well as during development of the central nervous system (Giordano *et al.*, 1992). Third, partially purified HMW and 18-kDa FGF-2 isoforms have similar *in vitro* extracellularly mediated mitogenic activities (Florkiewicz and Sommer, 1989), but when synthesized in continuously expressing transfected cells, the HMW isoforms are transforming whereas the 18-kDa isoform is not (Quarto *et al.*, 1991). Although FGF-2 appears to be widely expressed when detected by immunohistochemical techniques and *in situ* hybridization, it is likely that the different molecular isoforms are expressed in a spatially and temporally restricted manner. Therefore, in order to put the complete FGF-2 picture into perspective, it will be necessary to determine the qualitative, as well as quantitative, patterns of expression.

As noted previously, the HMW isoforms of human FGF-2 initiate translation from CUG codons that are differentially recognized in a *de novo* pattern that is tissue specific. Regulating translation is one mechanism by

which eukaryotic cells control gene expression, including start site selection followed by formation of a highly ordered translation initiation complex (Hershey *et al.*, 1996). In most circumstances, ribosomes arrive at the site of translation initiation after establishing contact and assembling at the 5′ end of eukaryotic mRNAs and then scan 3′ until encountering the most favorable combination of mRNA structure and sequence to initiate protein synthesis. However, in some cases, ribosomes recognize translation initiation sites directly without scanning, termed internal ribosome entry (Le and Maizel, 1997). The CUG-mediated translation initiation of FGF-2 HMW isoforms is an example of internal ribosome entry that is also maintained in a tissue-specific manner (Creancier *et al.*, 2000; Vagner *et al.*, 1995). A number of factors are likely to be involved in this process (Kevil *et al.*, 1995; Touriol *et al.*, 2000). Although the sophisticated cellular mechanism mediating CUG-initiated translation of HMW FGF-2 is being elaborated, their physiological significance remains an enigma. Interestingly, it is proposed that age-related changes in FGF2 isoform expression might affect osteogenesis. Studies in primary osteoblasts derived from calvariae of neonatal and adult rats demonstrated that adult osteoblasts produced more FGF2 and preferentially translated the 22-kDa isoform (Cowan *et al.*, 2003). Ultimately, selected expression in transgenic animal model systems will be necessary for a thorough analysis. In addition to the isoform-specific phenotypes reported previously, other publications show that 24-kDa FGF-2 modulates interleukin-6 promoter activity (Delrieu *et al.*, 1999) and cell migration (Piotrowicz *et al.*, 1999).

EXPORT OR SECRETION OF FGFs?

FGFs are known to be released from cells by two clearly distinct intracellular pathways: one that is or likely to be endoplasmic reticulum (ER)/Golgi dependent (FGF-3 through 10 and 15 through 23) and another that is ER/Golgi independent (FGF-1 and -2). Although considered to be prototypic members of the FGF family, FGF-1 and FGF-2 are distinctive in that they are found extracellularly but do not possess hydrophobic signal peptide sequences. Historically, this has been one of the most intriguing features of FGFs because their signal-transducing receptors are extracellular (Rifkin and Moscatelli, 1989). In contrast, with the exception of FGFs 11–14, the other FGFs contain typical or noncleaved internal hydrophobic amino acid signal sequences that function as ER-targeting motifs. Consequently, FGF-3 through 10 and 15 through 23 are secreted proteins. However, an alternative exocytic ER/Golgi-independent trafficking pathway must also exist because FGF-1 and FGF-2 are detected routinely on the cell surface or in the extracellular matrix (Bashkin *et al.*, 1992; Florkiewicz *et al.*, 1991; Folkman *et al.*, 1988; Gonzalez *et al.*, 1990), in vitreous fluid (Baird *et al.*, 1987), in cell culture media (Florkiewicz *et al.*, 1995), and in the urine (Nguyen *et al.*, 1994) and serum (Dietz *et al.*, 2000) of patients with cancer. Several key publications have demonstrated unequivocally the existence of an energy- and plasma membrane–dependent "export" pathway for FGF-2 pictured in Figure 2 (Florkiewicz *et al.*, 1991, 1995; Mignatti *et al.*, 1992). Evidence has also been presented for the involvement of a heat shock response mechanism in the export of FGF-1 (Jackson *et al.*, 1992). A number of proteins have been characterized as functional components of the intracellular trafficking "export" pathway for FGF-2 and FGF-1 (Friesel and Maciag, 1999). In addition, a critical FGF-1 and FGF-2 targeting signal(s) that mediates trafficking through the export pathway has been identified (Shi *et al.*, 1997). It is particularly interesting to note that interleukins 1α and β, which share structural homology with the FGF family, are also exported through a yet to be defined ER/Golgi-independent pathways (Muesch *et al.*, 1990). In any instance, it is likely that the export pathway(s) of FGF-1, FGF-2, and the interleukins is clinically important and of therapeutic value. Inhibitors of export would be predicted to interfere with the bioavailability of these potent growth-promoting polypeptides (Florkiewicz *et al.*, 1995).

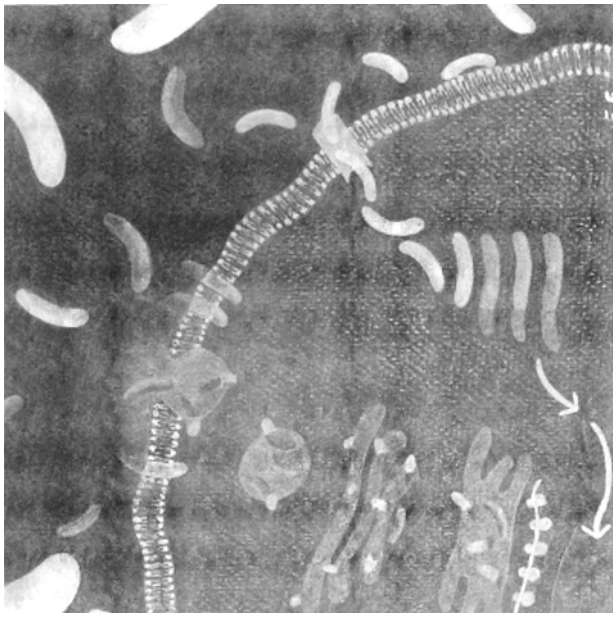

FIGURE 2 Two pathways traffic and release proteins from cells. One requires ER/Golgi, vesicular intermediates, and is signal sequence dependent. A second pathway exists for proteins without hydrophobic signal peptide sequences, such as 18-kDa FGF-2. These proteins are "exported" directly through a translocation apparatus located at the plasma membrane. The amino-terminally extended high-molecular-weight FGF-2 isoforms are targeted to the nucleus.

FIBROBLAST GROWTH FACTORS AND BONE FORMATION

Osteoblast Proliferation

FGF-1 and FGF-2 stimulate bone cell replication (Canalis 1980; Rodan *et al.*, 1987; Globus *et al.*, 1988, 1989; McCarthy *et al.*, 1989; Shen *et al.*, 1989). In osteosarcoma-derived ROS 17/2.8 cells, which express osteoblastic features, Rodan *et al.* (1989) found that FGF-2 stimulated cell proliferation when cells are seeded at low density in serum-free media but not when seeded at high density in the presence of serum. In contrast, in mouse osteoblastic MC3T3-E1 cells, FGF-2 stimulates cell proliferation in the presence of serum at both high and low density (Hurley *et al.*, 1993). FGF-1 and FGF-2 also activate the growth of rat and human stromal bone cells (Noff *et al.*, 1989; Pitaru *et al.*, 1993; Locklin *et al.*, 1995; Hanada *et al.*, 1997; Berrada *et al.*, 1995; Pri-Chen *et al.*, 1998). In human calvaria cells, FGF-2 also promotes cell proliferation at an early stage of differentiation (Debiais *et al.*, 1998). It is noteworthy that the mitogenic effect of FGF-2 on rat calvaria cells decreases with age (Kato *et al.*, 1995; Tanaka *et al.*, 1999). Recent data indicate that FGF-18, a novel member of the FGF family, stimulates the proliferation of cultured osteoblasts through activation of ERK signaling (Shimoaka *et al.*, 2002). Collective data suggest that FGF/FGFR signaling expands committed osteogenic population (Fakhry *et al.*, 2005).

Osteoblast Differentiation

In vitro FGFs inhibit markers of the osteoblast phenotype. FGFs reduce differentiation-related markers such as alkaline phosphatase (Rodan *et al.*, 1989; Shen *et al.*, 1989). FGF-2 inhibits parathormone responsive adenylcyclase activity (Rodan *et al.*, 1989). Type I collagen is the major product of the osteoblast, and FGF-2 affects its production. Both stimulatory and inhibitory effects of FGF-1 and FGF-2 on collagen synthesis in osteoblasts have been reported (Canalis *et al.*, 1988; McCarthy *et al.*, 1989; Shen *et al.*, 1989). Short-term treatment with FGF-2 results in the stimulation of collagen synthesis. However, continuous or chronic FGF treatment inhibits type I collagen synthesis. FGF-2 appears to have independent effects on osteoblast proliferation and differentiation. In bone organ cultures, the inhibitory effect of FGF-2 on collagen synthesis is similar in the presence or absence of aphidicolin, an inhibitor of cell replication (Hurley *et al.*, 1992b). Rodan *et al.* (1989) found that under conditions where FGF-2 had no effect on the proliferation of ROS 17/2.8 cells, there is a reduction in alkaline phosphatase activity, osteocalcin synthesis, and type I collagen mRNA. A similar dissociation is observed in chondrocytes where terminal differentiation and calcification are inhibited by FGF-2 independent of cell proliferation (Kato and Iwamoto, 1990).

The inhibitory effect of FGF-2 on collagen synthesis appears to be transcriptional (Rodan *et al.*, 1989; Hurley *et al.*, 1993) In studies in osteoblastic MC3T3-E1 cells, it has been shown that FGF-2 reduces the transcription of the type I collagen gene by nuclear run-on analysis (Hurley *et al.*, 1993). Studies on transcription of the collagen gene suggest that a DNA locus between −3.5 and −2.3 kb of the collagen promoter is negatively regulated by FGF-2 (Hurley *et al.*, 1993). The mechanism(s) by which FGF-2 negatively regulates collagen gene transcription is unknown.

FGF-2 also affects the expression of other bone matrix proteins. FGF-2 stimulates fibronectin expression through phospholipase C gamma, protein kinase C alpha, c-Src, NF-κB, and p300 pathway in osteoblasts (Tang *et al.*, 2007). FGF-2 also stimulates osteopontin and modulates osteonectin in rat osteosarcoma cells (Rodan *et al.*, 1989; Shiba *et al.*, 1995; Delany and Canalis, 1998a). Interestingly, osteonectin mRNA levels were reduced in osteoblasts from Fgf2 −/− and Fgf2 +/− mice (Naganawa *et al.*, 2006). Although FGF-1 inhibits osteocalcin expression in rat calvaria cells (Tang *et al.*, 1996), it enhances osteocalcin in bovine bone cells (Schedlich *et al.*, 1994) and directly affects osteocalcin transcription in mouse calvaria cells (Boudreaux *et al.*, 1996; Newberry *et al.*, 1996). In these cells, FGF-2 and cAMP have synergistic effects on osteocalcin expression, and some elements conferring FGF-2 responsiveness in the osteocalcin promoter have been identified (Schedlich *et al.*, 1994; Newberry *et al.*, 1997). FGF may also affect osteoblast function by acting on functional membranous proteins. FGFs downregulate the expression of connexin-43 associated with decreased gap junction-mediated communication (Shiokawa-Sawada *et al.*, 1997), and FGF-2 upregulates the expression of N-cadherin in osteoblasts (Debiais *et al.*, 2001).

Osteoblast Apoptosis

FGF signaling also controls osteoblast apoptosis. *In vitro*, FGF signaling protects from apoptotic effects induced by serum starvation (Hill *et al.*, 1997) and inhibits osteoblast death induced by peroxynitrite (Kelpke *et al.*, 2001). It was then found that FGF-2 induces osteoblast survival through a phosphatidylinositol 3-kinase-dependent pathway (Debiais *et al.*, 2004). Studies by Agas *et al.* (2007) showed that PGF2alpha increased osteoblast survival via endogenous FGF2/FGFR1 enhancement of Bcl-2/bax ratio. In contrast, FGF treatment induces apoptosis in more differentiated osteoblasts *in vivo* (Mathijssen *et al.*, 2001), and overexpression of FGF2 signaling in transgenic mice leads to increased apoptosis in mouse calvaria (Mansukhani *et al.*, 2000). Constitutive FGFR2 activation also induces apoptosis in more mature human calvaria osteoblasts (Lemonnier *et al.*, 2001b). This dual effect of FGF signaling on osteoblast apoptosis may be an important mechanism controlling osteoblastogenesis (Marie *et al.*, 2003).

FGF REGULATION OF GROWTH FACTORS IN BONE

FGF-2 has been shown to affect the production of several growth factors in osteoblasts. Continuous treatment with FGF-2 decreases IGF-I mRNA and protein levels in mouse osteoblastic MC3T3-E1 cells (Hurley *et al.*, 1992a) and rat bone cell cultures (Canalis *et al.*, 1993). This effect occurs independently of cell replication. Also, FGF-2 decreases the mRNA and protein levels for several IGF-binding proteins *in vitro*, in MC3T3-E1 cells (Hurley *et al.*, 1995a). In contrast to the studies of Chen *et al.* (1993), 24-hour treatment with FGF-2 does not inhibit IGF-binding protein mRNA in rat osteoblast-like cells. The inhibitory effects on IGFs and their binding proteins could play a role in the inhibition of bone formation by FGF. However, intermittent FGF-2 treatment increased bone nodule formation *in vitro* that was associated with increased IGF-1 expression (Zhang *et al.*, 2002). In addition, in ovariectomized rats, *in vivo* administration of FGF-2 caused a significant increase in IGF-I after 2 to 10 days of treatment (Power *et al.*, 2004).

Both FGF-1 and FGF-2 increase the production of TGFβ *in vitro* and *in vivo* (Noda and Vogel, 1989). In addition, TGFβ and FGF-1 and FGF-2 interact to modulate their mitogenic effects in osteoblasts (Globus *et al.*, 1989). In human calvaria cells, FGF-2 decreases TGFβ2 production in immature cells but increases TGFβ2 synthesis by more differentiated cells (Debiais *et al.*, 1998). However, FGF-2 increases vascular endothelial cell growth factor (VEGF) expression in rat and mouse calvaria cells independently of TGFβ synthesis (Saadeh *et al.*, 2000). FGF-2 also induces hepatocyte growth factor expression in osteoblasts (Blanquaert *et al.*, 1999), which may play a role in bone repair. Additionally, FGF-2 modulates the release of VEGF through Erk1/2, p38, and SAPK/JNK signaling in osteoblasts (Takai *et al.*, 2007). Overall, the data suggest that these factors may perhaps mediate some of the actions of FGF on osteogenesis.

BONE FORMATION *IN VITRO* AND *IN VIVO*

Studies have shown that FGF-2 has both stimulatory and inhibitory effects on bone formation *in vitro*. FGF-1 reduces bone nodule formation in the rat calvaria system (Tang *et al.*, 1996), whereas FGF-2 inhibits osteoblast differentiation markers in human marrow stromal cells (Rifas *et al.* 1995; Berrada *et al.*, 1995; Martin *et al.*, 1997). However, FGF-2 increases cell differentiation and matrix mineralization in rat bone marrow stromal cells (Noff *et al.*, 1989; Pitaru *et al.*, 1993) and in dexamethasone-treated rat (Locklin *et al.*, 1995) and human bone marrow stromal cells (Pri-Chen *at al.*, 2000). Recent data indicate that FGF-8 also promotes the differentiation of mesenchymal stem cells into osteoblasts (Valta *et al.*, 2006). In human calvaria cells, FGF-2 initially reduces osteocalcin synthesis, whereas a prolonged treatment increases both osteocalcin synthesis and matrix mineralization, indicating that the effects of FGF-2 are dependent on the osteoblast maturation stage (Debiais *et al.*, 1998). Therefore, FGF signaling appears to regulate osteoblast proliferation and differentiation positively in the long term *in vitro*.

Multiple studies showed that FGF signaling enhances bone formation *in vivo*. In the cranial vault, the proliferation and differentiation of skeletal cells is tightly modulated by endogenous FGF signaling (Greenwald *et al.*, 2001; Moore *et al.*, 2002). Local injection of FGF-1 also promotes calvaria bone formation (Mundy *et al.*, 1999). Consistently, implantation of FGF-2 or FGF-4 accelerates suture closure in mice (Iseki *et al.*, 1997; Kim *et al.*, 1998). Interestingly FGF-9 overexpression in cranial mesenchymal cells can promote chondrogenesis (Govindarajan and Overbeek, 2006). At the endosteal level, FGF-2 at low dose also stimulates bone formation in growing rats (Aspenberg *et al.*, 1991; Nakamura *et al.*, 1995; Kawaguchi *et al.*, 1994; Mayahara *et al.*, 1993; Nagai *et al.*, 1995). In normal rabbits, intraosseous application of FGF-2 increases bone formation and bone mineral density (Nakamura *et al.*, 1997). A comparative study of the bone restorative efficacy of PTH, FGF-2, and a selective agonist for prostaglandin E receptor subtype in aged ovariectomized rats revealed that FGF-2 was the most effective in reversing severe cancellous osteopenia, followed by PTH. EP4 and PTH caused a similar increase in cortical bone mass (Iwaniec *et al.*, 2007).

Exogenous FGF-1 and FGF-2 appear to act by increasing the recruitment of osteoblast precursor cells, which then differentiate into osteoblasts (Nakamura *et al.*, 1995). It is also possible that FGF-2 acts indirectly by increasing the expression of TGFβ in osteoblasts (Noda and Vogel, 1989; Nakamura *et al.*, 1995; Kawaguchi *et al.*, 1994). Additionally, FGF-2 enhances BMP-2- induced ectopic bone formation in mice by altering the expression of BMP receptors (Nakamura *et al.*, 2005), indicating that FGF-induced bone formation may be in part indirect.

Recent data point to an important role of FGF-18 in chondrogenesis and osteogenesis during skeletal development (Xiao *et al.*, 2004; Haque *et al.*, 2007). FGF-18 acts as a physiological ligand for FGFR3 in chondrocytes and through FGFR1/FGFR2 in osteoblasts (Liu *et al.*, 2002). FGF-18 deficiency in mice results in increased proliferation and differentiation, and conversely, decreases osteoblast proliferation and differentiation (Ohbayashi *et al.*, 2002). One mechanism of action appears to involve suppression of noggin expression and subsequent activation of BMP effects on chondrocyte differentiation (Reinhold *et al.*, 2004). Recent data indicate that FGF-18 may induce osteoblast recruitment through VEGF expression and subsequent neovascularization (Liu *et al.*, 2007). The positive

role of FGF-18 in osteogenesis is supported by the finding that FGF-18 is a direct target of Wnt signaling and Runx2, two important pathways controlling osteogenesis (Kapadia *et al.*, 2005; Reinhold and Naski, 2007).

There is evidence that FGF and BMP signaling cooperate to control osteogenesis. FGF acts with BMP4 to promote osteogenesis in rats (Kubota *et al.*, 2002). Moreover, FGF2 and FGFR2 inhibit the expression of noggin in the patent cranial suture, resulting in increased BMP4 activity and suture fusion (Warren *et al.*, 2003). It is likely that the biological activities of FGFs in bone is dependent on the presence of other signaling molecules such as BMPs.

Genetic evidence indicates that several FGFs are important factors controlling bone formation *in vivo*. Overexpression of FGF2 in mice induces abnormal long bone formation (Coffin *et al.*, 1995; Sobue *et al.*, 2005) whereas FGF2 invalidation inhibits it (Montero *et al.*, 2000), pointing to an important role of FGF2 in the control of osteogenesis. The role of FGFRs in the control of bone formation is much more complex. For example, the impact of FGFR1 inactivation depends on the cell type. Inactivation of FGFR1 in osteo-chondro progenitor cells increases proliferation and delays osteoblast maturation whereas inactivation in differentiated osteoblasts accelerates differentiation, possibly through increased expression of FGFR3 (Jacob *et al.*, 2006). Conditional inactivation of FGFR2 alters osteogenesis and bone mass in mice, as a result of defective proliferation of osteoprogenitor cells and anabolic function of mature osteoblasts, indicating that FGFR2 plays an essential role in osteoblastogenesis (Yu *et al.*, 2003). In mice, a secreted soluble dominant-negative FGFR-2 causes skull abnormalities resembling those induced by FGFR mutations (Celli *et al.*, 1998), suggesting that increased or decreased FGFR signaling induces skeletal abnormalities. Activation of FGFR3 inhibits chondrocyte proliferation and differentiation in mice (Wang *et al.*, 1999), whereas mice lacking FGFR3 exhibit skeletal overgrowth, indicating that FGFR3 acts as a negative regulator of endochondral bone growth (Colvin *et al.*, 1996). Osteoblasts express little FGFR3, but mice lacking FGFR3 display decreased bone density (Valverde-Franco *et al.*, 2004). Some FGFR3 mutation may also affect osteogenesis in addition to chondrogenesis (Guitz, 2005). FGFR1, FGFR2, and FGFR3 exist as two splice variants, IIIb and IIIc. The mesenchymal splice variant of FGFR2 (Fgfr2IIIc) is expressed in early mesenchymal condensates and later in sites of endochondral and intramembranous ossification where it interacts with FGF18 (Eswarakumar *et al.*, 2002). The recessive phenotype of Fgfr2IIIc(−/−) mice is characterized by decreased expression of Runx2 and retarded long bone ossification, suggesting that Fgfr2IIIc is a positive regulator of ossification (Eswarakumar *et al.*, 2002). Interestingly, FGFR2 and FGFR1 expression is markedly impaired in osteoblasts from Fgf2 null mice (Naganawa *et al.*, 2006).

Fibroblast Growth Factors in Fracture Repair

Fibroblast growth factors appear to play an important role in fracture repair in rats (Kawaguchi *et al.*, 1994) and in humans (Wildburger *et al.*, 1994). During fracture repair, FGF-1 and -2 are expressed in the granulation tissue (Bollander, 1992), suggesting that FGFs increase cell migration and angiogenesis at early stages of bone repair. At later stages, FGF-1 expression increases during callus formation, whereas FGF-2 expression is stable (Joyce *et al.*, 1991). Several studies indicate that exogenous FGF-2 can accelerate bone repair (Kawaguchi *et al.*, 2001; Komaki *et al.*, 2006). In various animal models of bone defects, FGF-2 at low doses was found to stimulate chondrogenesis and bone formation (Kato *et al.*, 1998; Tabata *et al.*, 1999; Zellin and Linde, 2000), suggesting that FGF may improve bone regeneration (Radomsky *et al.*, 1998). Part of the effects of FGF on bone repair may involve the release of HGF (Blanquaert *et al.*, 1999) or VEGF (Saadeh *et al.*, 2000) by osteoblasts. Because FGF2 expands mesenchymal cell progenitors *in vitro* (Solchaga *et al.*, 2005), this may be used to obtain a large number of cells for bone tissue repair (Bianchi *et al.*, 2003).

FGF Signaling in Bone Cells

The signaling mechanisms involved in the regulation of skeletal cells by FGF/FGFRs are complex because FGF signaling (Fig. 3) controls a large number of genes such as transcription factors, soluble factors, membranous and matrix proteins (Marie, 2003). The nature of the cellular response depends on the ligand, receptor, and integration of signaling pathways targeting specific genes in skeletal cells (Dailey *et al.*, 2005). Moreover, the cellular response to FGFR activation is dependent on the stage of osteoblast maturation (Debiais *et al.*, 2004; Mansukhani *et al.*, 2005). In the growth plate, a number of signaling events are activated by FGF signaling to coordinate chondrocyte growth arrest and differentiation (Laplantine *et al.*, 2002; Dailey *et al.*, 2003). FGF-mediated growth arrest of chondrocytes is mediated by ERK1/2 and p38 MAPK pathways (Raucci *et al.*, 2004). Additionally, FGF signaling and activating FGFR-3 mutations activate STAT1 signaling pathway, leading to growth arrest and apoptosis (Sahni *et al.*, 1999, 2001; Li *et al.*, 1999; Legeai-Mallet *et al.*, 1998; Su *et al.*, 1997).

In cultured osteoblasts, FGF-2 activates MAP kinase signal transduction and extracellular signal-regulated kinase 2 (ERK2; Hurley *et al.*, 1996b; Newberry *et al.*, 1997; Chaudhary and Avioli, 1997). Erk signaling pathway mediates the FGF-2 mitogenic effect and effects on procollagen, OP, OC, and VEGF expression in osteoblasts

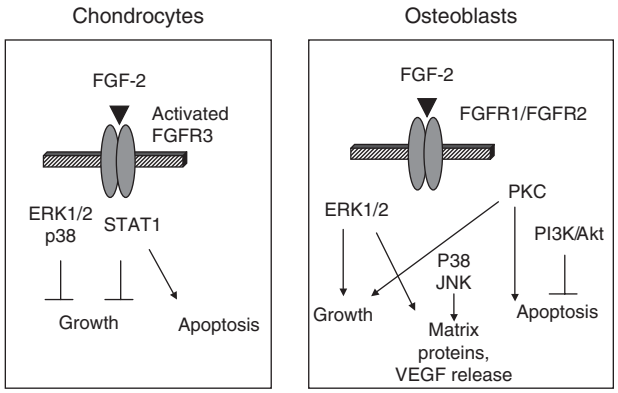

FIGURE 3 Signaling pathways involved in the response to FGF/FGFR in cartilage and bone. In chondrocytes, FGF-2-mediated growth arrest of chondrocytes is mediated by ERK1/2 and p38 MAPK pathways. FGF and activating FGFR-3 mutations activate the STAT1 signaling pathway, leading to growth arrest and apoptosis. In osteoblasts, ERK2 signaling mediates the FGF-2 effects on cell growth, matrix proteins (procollagen, OP, OC) and VEGF expression. p38 and JNK MAPKs also regulate FGF-2-stimulated VEGF release. The PKC and PI3K pathways are involved in osteoblast growth, differentiation or apoptosis induced by FGF2 or FGFR2 signaling (see text for details).

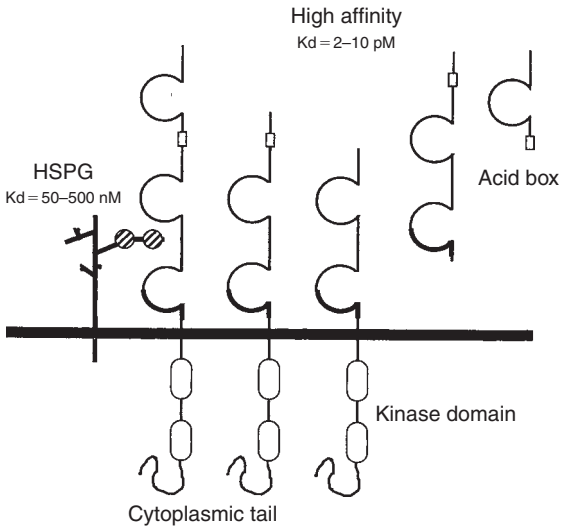

FIGURE 4 Cell surface FGF receptors. The low-affinity HSPG type, which protects and stabilizes FGF (hatched circles) in a conformationally dependent manner for presentation to its high-affinity receptor. Second, the high-affinity receptor containing two or three extracellular immunoglobulin-like loop structures. The characteristic location of an extracellular acid box is labeled (shaded box). Soluble splice variants of the high-affinity receptor without transmembrane domains are also diagrammed. Intracellularly, the high-affinity receptor contains a split tyrosine kinase domain and cytoplasmic tail. The third type, cysteine-rich receptor or MG-160, is found in the Golgi apparatus and is not shown here.

(Chaudhary and Avioli, 2000; Xiao *et al.*, 2002; Shimoaka *et al.*, 2002). Erk1/2, p38, and JNK MAPKs regulate FGF-2- stimulated VEGF release in osteoblasts (Takai *et al.*, 2007). The PKC pathway is another important pathway regulating FGF actions in osteoblasts. FGF-2 activates PKC activity in human osteoblasts, and this pathway is implicated in the expression of N-cadherin expression induced by FGF-2 (Debiais *et al.*, 2001). The PKC pathway is also involved in the growth response (Hurley *et al.*, 1996b), increased fibronectin expression (Tang *et al.*, 2007), and differentiation marker expression in osteoblasts (Lemonnier *et al.*, 2001a, 2001b) induced by FGF2 or FGFR2 signaling.

The effects of FGF signaling may be in part mediated by transcription factors. In mouse calvaria cells, FGF-2 and cAMP have synergistic effects on OC expression by acting on specific elements in the OC promoter (Schedlich *et al.*, 1994; Boudreaux *et al.*, 1996; Newberry *et al.*, 1996). Another direct effector of FGF signaling is Runx2 (Kim *et al.*, 2006). FGF2 increases Runx2 expression and activity in osteoblasts (Choi *et al.*, 2005; Kim *et al.*, 2006). FGF-2 also increases Runx2 protein nuclear accumulation in osteoblasts (Naganawa *et al.*, 2006). Moreover, Runx2 is phosphorylated and activated by FGF-2 via Erk1/2 (Xiao *et al.*, 2002), indicating that Runx2 is an important target of FGF signaling in osteoblasts.

Heparin sulfate proteoglycans are made by osteoblasts (Beresford *et al.*, 1987), and Globus *et al.* (1989) suggested that the FGF–heparin sulfate complex is released in an active form, resulting in osteoblast proliferation and new bone formation. Studies suggest a direct role for heparin in modulating the biological effects of FGF-1 and FGF-2 in bone (Simmons *et al.*, 1991; Hurley *et al.*, 1992b). Heparin enhances the mitogenic effect, in fetal rat long bone cultures (Simmons *et al.*, 1991). In contrast, heparin does not enhance the mitogenic effect of FGF-2 in fetal rat long bone or in fetal rat calvarial cultures (Simmons *et al.*, 1991; Hurley *et al.*, 1992b).

Low-affinity membrane-associated heparan sulfate proteoglycans (HSPGs) (Fig. 4) act as low-affinity co-receptors to modulate FGF actions (Ornitz, 2000a; Schlessinger *et al.*, 2000). Syndecans are cell surface proteoglycans that bind FGF via their heparin sulfate moieties and interact with FGF binding and signaling (David, 1993; Rapraeger, 1993; Bernfield *et al.*, 1993). During development, syndecan-1 is expressed in limb bud (Solursh *et al.*, 1990) and affects bone cell differentiation (Dhodapkar *et al.*, 1998). Syndecan-2 is abundant in prechondrogenic cells and is expressed in the perichondrium and periosteum at the onset of *in vitro* osteogenesis (Molténi *et al.*, 1999a). Syndecan-3 is expressed in mesenchymal cells during limb bud formation and is regulated by FGFs (Gould *et al.*, 1992). Thereafter, precartilage cells and immature chondrocytes express syndecan-3, which may control chondrocyte proliferation during endochondral ossification (Shimazu *et al.*, 1996). Syndecan-4 is strongly expressed in chondrocytes

(Kim *et al.*, 1994) and osteoblasts (Molténi *et al.*, 1999a) and is upregulated by FGF-2 (Song *et al.*, 2007). Coexpression of syndecans and FGFRs and functional analyses during osteogenesis suggests a role for these HSPGs in the control of bone formation. For example, rat chondrocytes coexpress FGFR-3, syndecan-2, and syndecan-4, and their expression decreases during *in vitro* differentiation. In contrast, rat calvaria osteoblasts express syndecan-1, -2, and -4 with FGFR-1 and FGFR-2, indicating that syndecans can interact with FGFRs to control FGF actions during *in vitro* chondrogenic and osteogenic differentiation (Molténi *et al.*, 1999a, 1999b; Jackson *et al.*, 2007), indicating that syndecans and other HSPGs may be important co-receptors modulating FGF/FGFR interactions in bone cells. Consistent with an important role of glycosaminoglycans in the control of FGFR signaling, it was found that specific GAGs can antagonize the overactive FGFR2 S252W mutation *in vitro* (McDowell *et al.*, 2005).

FIBROBLAST GROWTH FACTORS AND BONE REMODELING

FGF and Bone Resorption

FGF-1 induces bone resorption in fetal rat long bone via a prostaglandin-mediated mechanism (Shen *et al.*, 1989). FGF-2 is also a potent bone-resorbing agent in the fetal rat long bone model (Simmons *et al.*, 1991). However, in fetal rat long bones, the effects of FGF-2 on bone resorption appear to be independent of endogenous prostaglandin production (Simmons *et al.*, 1991). In contrast to the report by Shen *et al.* (1989), Simmons *et al.* (1991) reported that FGF-1 induces calcium release only in the presence of heparin and that this effect is not blocked by indomethacin. FGF-2 increases bone resorption in neonatal mouse calvariae, which is partially blocked by indomethacin, suggesting that the resorptive effects of FGF-2 are mediated in part by prostaglandins. In the presence of both an inhibitor of DNA synthesis and prostaglandin production, FGF-2-induced bone resorption is completely blocked. These results suggest that FGF-2 has direct effects on resorption through its effects on osteoclasts precursor proliferation and an indirect effect that is mediated by prostaglandin (Kawaguchi *et al.*, 1995a). These findings are important because prostaglandins are potent local regulators of bone metabolism (Kawaguchi *et al.*, 1995b).

FGF Regulation of the Collagenase Gene in Bone

FGF may also modulate bone matrix degradation by regulating collagenase expression and activity. Interstitial collagenase is required to initiate the degradation of type I collagen (Delaissé *et al.*, 1988), and inhibitors of metalloproteinases inhibit bone resorption (Delaissé *et al.*, 1988). In rat calvaria bone cells, FGFs increase interstitial collagenase-1 and -3 expression by a prostaglandin- and PKC-dependent pathway (Varghese *et al.*, 1995; Tang *et al.*, 1996). In contrast, in mouse cells the effects of FGF-2 on the collagenase gene are not affected by either indomethacin or staurosporine (Hurley *et al.*, 1995b). Similar to FGF-2, FGF-1 also upregulates the collagenase gene (M. M. Hurley, unpublished observation). FGF-2 transcriptionally regulates collagenase gene expression in mouse calvaria cells, and the tyrosine kinase inhibitors genistein and herbimycin A completely block the effect of FGF-2 on the collagenase promoter (Hurley *et al.*, 1995b). FGF response elements in the collagenase promoter have been identified (Newberry *et al.*, 1997). FGF-2 stimulates collagenase-3 gene transcription through an effect on the AP-1 site on the promoter (Varghese *et al.*, 2000) and induces the expression of tissue inhibitors of metalloproteinases (TIMP) 1 and 3 (Varghese *et al.*, 1995), which regulate collagenase activity. Although FGF-2 decreases stromelysin-3 mRNA stability, it increases gene transcription (Delany and Canalis, 1998b), which may contribute to the control of the bone matrix degradation.

FGF and Osteoclastogenesis

Histologic examination reveals that FGF-1 treatment increases osteoclast number in fetal rat long bones (Shen *et al.*, 1989) and in 21-day fetal rat calvariae (Hurley *et al.*, 1992b), suggesting a role for FGFs in osteoclastogenesis. Osteoclasts are derived from a hematopoietic precursor that is common to the granulocyte and the macrophage. The immediate progenitor of the osteoclast is the CFU-GM (colony-forming unit for granulocytes and macrophages; Mundy and Roodman, 1995), and studies show that FGF-2 stimulates the formation of CFU-GM in human marrow cultures (Gabrilove *et al.*, 1994). The production of osteoclasts from progenitor cells is regulated by cytokines and requires or is enhanced by interactions between marrow progenitor cells and either osteoblastic or stromal cells (Suda *et al.*, 1992). Interestingly, FGF-2 is a potent mitogen for stromal cells (Oliver *et al.*, 1990), which are multipotential mesenchymal cells in the marrow environment that are the precursors of osteoblasts, chondroblasts, fibroblasts, and other connective tissue cells in bone. FGF-2 is produced by bone marrow stromal cells (Brunner *et al.*, 1993) and hence may be autostimulatory.

FGF-2 has been found to increase the formation of multinuclear-resorbing osteoclast-like cells in mouse bone marrow cultures, an effect mediated by PGE_2 production (Hurley *et al.*, 1998; Kawaguchi *et al.*, 2000). Indeed, FGF-2 stimulates PGE_2 production rapidly in mouse calvaria cells through the transcriptional regulation

of PGHS-2 (Kawaguchi *et al.*, 1995a). FGF-2 also increases osteoclast formation by a mechanism involving COX-2 stimulation and prostaglandin formation, leading to increased osteoclast differentiation factor (ODF) production (Nakagawa *et al.*, 1999). Apart from this indirect effect of FGF-2 through osteoblastic cells, FGF-2 acts directly on mature osteoclasts to stimulate bone resorption (Kawaguchi *et al.*, 2000) through the activation of FGFR-1 and MAPK activation (Chikazu *et al.*, 2000). Similar to FGF1 and FGF-2, FGF-18 also induces osteoclast formation through receptor activator of nuclear factor-κB ligand and COX-2 (Shimoaka *et al.*, 2002). Interestingly, in the absence of endogenous FGF-2, PTH, RANKL, and interleukin-11 induced osteoclastogenesis is markedly impaired (Okada *et al.*, 2003).

HEPARIN, FIBROBLAST GROWTH FACTORS, AND OSTEOPOROSIS

In humans, the prolonged use of heparin is associated with the development of clinical osteoporosis and spontaneous fractures (Megard *et al.*, 1982). Heparin is the predominant glycosaminoglycan in mast cells and may play a role in the osteoporosis often seen in mast cell disease (Chines *et al.*, 1991). The bone marrow of postmenopausal women who are osteoporotic show increased numbers of heparin-rich mast cells (Frame and Nixon, 1968). *In vivo* studies in rats treated with heparin for 33 to 65 days reveal significant reduction in bone mineral mass (Thompson, 1973). In studies in bone organ culture, heparin decreases collagen synthesis (Hurley *et al.*, 1990), and this effect is reversed by exogenous IGF-I (Hurley *et al.*, 1992a). Heparin also potentiates the inhibitory effect of FGF-2 on collagen synthesis and procollagen mRNA levels in fetal rat calvariae (Hurley *et al.*, 1992b). In bone, heparin augments FGF-1 and FGF-2-induced bone resorption (Simmons *et al.*, 1991). Studies by Thompson *et al.* (1990) revealed that heparin infusion into rabbits results in an increase in FGF-2-like activity in plasma. The mechanisms by which heparin induces osteoporosis are not known. It is possible that modulation of the availability or action of local factors such as IGF-I and FGF-2 is important in heparin-induced osteoporosis.

The role of fibroblast growth factors in the development of osteopenia and postmenopausal osteoporosis in humans has not been defined. However, the studies of Montero *et al.* (2000) clearly documented a role for FGF-2 in bone remodeling and maintenance of bone mass (Figs. 5 through 8, Table I). These studies show that disruption of the Fgf 2 gene in mice results in decreased osteoblast replication, decreased mineralized nodule formation in bone marrow cultures, and decreased new bone formation *in vivo*.

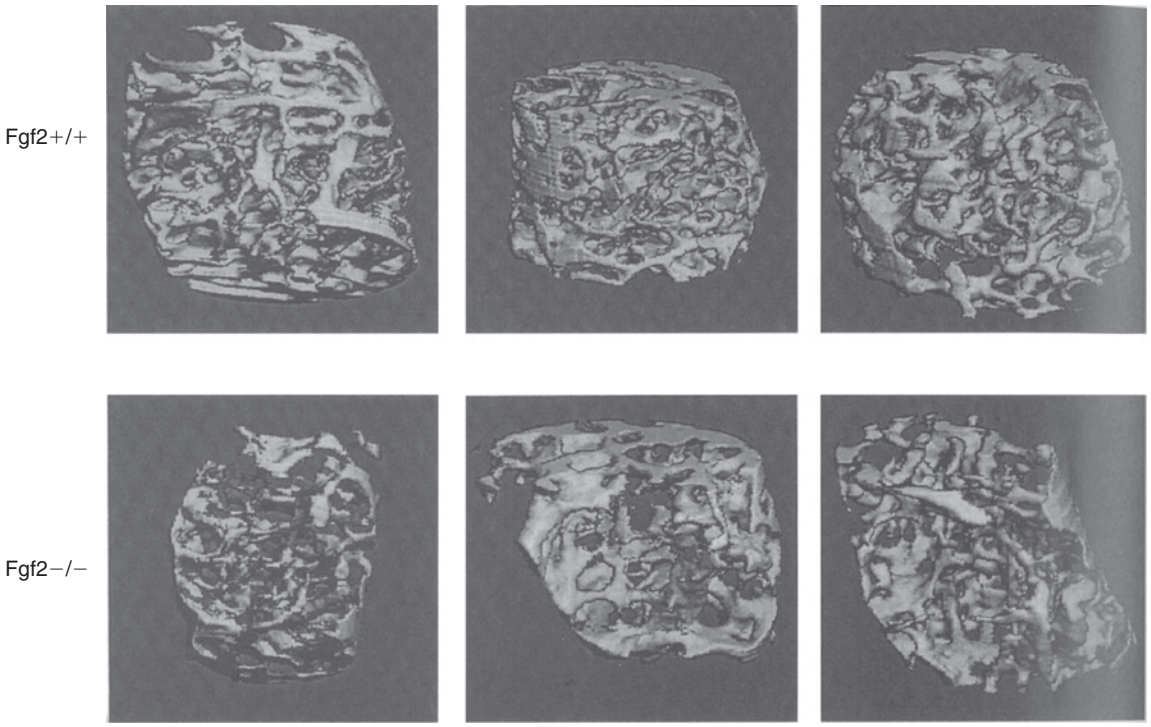

FIGURE 5 Morphological study by micro-CT scanning of trabecular bone of femurs of 4.5-month-old Fgf2 +/+ and Fgf2 −/− mice. The three-dimensional trabecular bone architecture of distal femoral metaphysis of 4.5-month-old male Fgf2 +/+ and Fgf2 −/− mice was analyzed by micro-CT. Note that the plate-like architecture of the trabecular bone is reduced markedly and the connecting rods of trabeculae are disrupted in Fgf2 −/− mice compared with Fgf2 +/+.

TABLE I Three-dimensional Parameters of Micro-CT of Femora from 8-Month-Old Fgf2+/+ and Fgf2−/− Mice

Genotype	*n*	Bone volume (%)	Trabecular number (mm^{-1})	Trabecular thickness (μm)	Trabecular separation (μm)
Fgf2+/+	3	22.0 (4.8)	3.9 (0.3)	57.0 (11.1)	203 (22)
Ffg2−/−	3	7.4 (2.4)[a,b]	1.8 (0.7)[a,b]	41.7[a,b] (3.2)	564[a,b] (190)

[a]$P < 0.05$, *significantly different from Fgf+/+ group, Mann−Whitney U test.*

[b]$P < 0.05$, *significantly different from Fgf+/+ group, Tukey−Kramer multiple comparison test* (ANOVA).

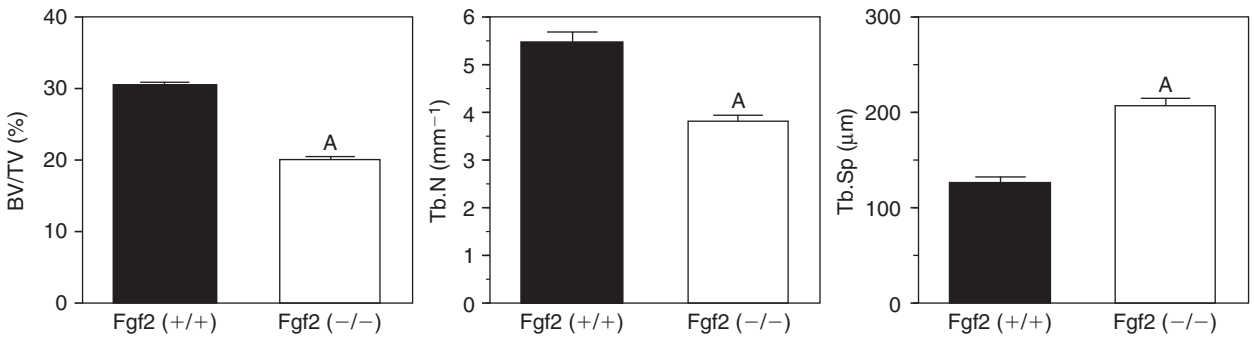

FIGURE 6 Three-dimensional microstructural parameters calculated using two-dimensional data obtained from micro-CT of femoral bones from 4.5-month-old Fgf2 +/+ and Fgf2 −/− mice. Calculated morphometric indices included bone volume density [bone volume (BV)/trabecular volume (TV)] trabecular number [Tb.N = (BV/TV)/Tb.Th], and trabecular separation [Tb.Sp = (1/Tb.N) – Tb.Th]. [A]Significantly different from Fgf2 +/+ group; $P < 0.05$, Tukey–Kramer multiple comparison test (ANOVA).

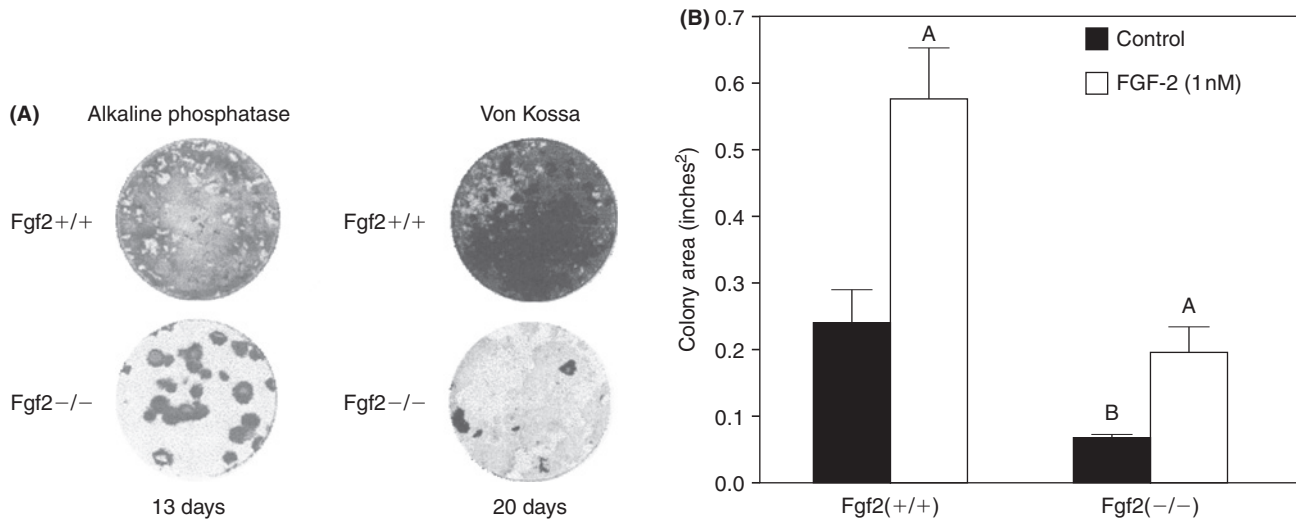

FIGURE 7 **(A)** Comparison of the ability to form ALP colonies and mineralized nodules as determined by von Kossa staining in mouse bone marrow cultures from Fgf2 +/+ and Fgf2 −/− mice. Cells were plated at a density of 20 million cells per well in αMEM containing penicillin/streptomycin and 10% heat-inactivated fetal calf serum (FCS). On day 3, media were changed and cells were cultured in differentiation media (αMEM, 10 n*M* dexamethasone, 10% FCS, 8 m*M* β-glycerophosphate, 50 μg/mL ascorbic acide) for the indicated times. (See also color plate) **(B)** Effect of FGF-2 on colony area in mouse bone marrow cultures from Fgf2 +/+ and Fgf2 −/− mice. Cells were plated at a density of 1 million cells per well in αMEM containing penicillin/streptomycin and 10% heat-inactivated FCS in the absence or presence of FGF-2 (10 n*M*). On day 3, media were changed and cells were cultured in differentiation media (αMEM, 10 n*M* dexamethasone, 10% FCS, 8 m*M* β-glycerophosphate, 50 μg/ml ascorbic acid) for another 11 days. [A]Significantly different from control cultures; $P < 0.05$. [B]Significantly different from Fgf2 +/+; $P < 0.05$.

TABLE II Effects of FGF/FGFR Interactions in Skeletal Cells

Chondrogenesis	Bone Formation	Bone Resorption/Degradation
Modulate chondroblast proliferation	Increase osteoblast proliferation	Promote osteoclast formation
Inhibit chondrocyte differentiation	Decrease collagen synthesis	Promote osteoclast formation
Promote chondrocyte apoptosis	Inhibit alkaline phosphatase	Regulate collagenase-1 and −3
	Modulate osteopontin, osteonectin, and osteoclacin	Promote TIMP 1and 3
	Downregulate connexin-43, upregulate N-cadherin	
	Increases Na-dependent P_i transport	
	Increase osteogenesis by marrow osteoprogenitors	
	Promote osteoblast apoptosis	
	Increase bone formation and promote bone repair *in vivo*	

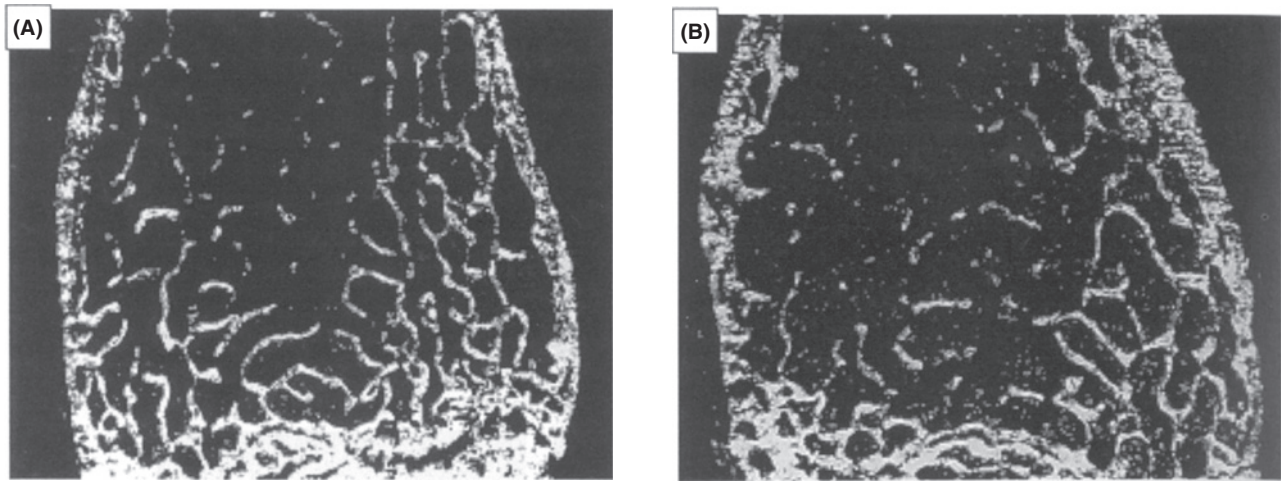

FIGURE 8 Undecalcified sections of the distal femur of **(A)** an 8-month-old Fgf2 + /+ mouse and **(B)** a FGF − /− mouse (dark-field illumination). Trabecular number is decreased in the secondary spongiosa of the Fgf2 − /− mouse.

There was a progressive decrease in trabecular number and trabecular bone volume as these mice aged. These data are the first to demonstrate an important role for endogenous FGF-2 in maintaining bone mass, as well as bone formation. These data further suggest that the redundancy of members of the FGF family cannot compensate to prevent bone loss when the Fgf 2 gene is disrupted in mice.

A therapeutic role for FGFs in osteopenic states is suggested by studies in animal models. In osteopenic mice, FGF-2 stimulates endocortical bone modeling (Nagai *et al.*, 1999). In ovariectomized rats, FGF-1 or FGF-2 administration also stimulates bone formation and restores bone volume (Nakamura *et al.*, 1997; Dunstan *et al.*, 1999; Liang *et al.*, 1999). The mechanism of this effect has not been studied. Studies are needed to examine the effects of menopause as well as oophorectomy on FGF expression in bones.

CONCLUSION

Multiple experimental and genetic evidence indicates that FGFs and FGFRs play important roles in the control

of endochondral and intramembranous bone formation (Table II). However, the cellular and molecular effects of FGF and FGFRs in bone cells are not fully understood. Identification of the signal transduction pathways that are activated by FGF/FGFR interactions and that lead to the expression of specific genes in skeletal cells may help to better understand the regulatory effects of FGFs during osteogenesis *in vivo*, and may allow for the development of therapeutic approaches to stimulate bone formation and to improve bone regeneration.

Chapter 52

Vascular Endothelial Growth Factor and Osteogenic-Angiogenic Coupling

Dwight A. Towler*

Department of Medicine, Center for Cardiovascular Research, Division of Bone and Mineral Diseases, Washington University in St. Louis, Missouri 63110

INTRODUCTION

Bone never forms without vascular interactions. However, the complex and enlightening biology behind this simple statement of fact has only recently been studied in detail. Studies from the fields of developmental biology, molecular genetics, and clinical pharmacology have converged to highlight the central role of the vasculature in bone physiology. The vasculature provides the conduit for calcium, phosphate, hematopoietic, hormonal, and nutrient flux necessary for matrix synthesis, mineralization, and calcium mobilization. It provides the organizational structure and rate-limiting "point-of-reference" for Haversian bone formation, remodeling, and repair (Eriksen *et al.*, 2007). Moreover, the vasculature provides a sustentacular niche and source of adult mesenchymal stem cells, including osteoprogenitors (Shi and Gronthos, 2003). During fracture repair, paracrine endothelial-mesenchymal signaling interactions are activated (Bouletreau *et al.*, 2002), recapitulating features of the epithelial-mesenchymal interactions that drive bone morphogenesis during embryonic development (Bandyopadhyay *et al.*, 2006). BMP2 and BMP4 stimulate the production of vascular endothelial growth factor (VEGF) by osteoblasts (Deckers *et al.*, 2002; Huang *et al.*, 2004) and placental growth factor (PlGF) by mesenchymal progenitors (Marrony *et al.*, 2003; Raida *et al.*, 2006), while VEGF actions on the endothelium enhance production of BMP2 and E-series prostaglandins (Bouletreau *et al.*, 2002; Kaigler *et al.*, 2005). Furthermore, recent evidence suggests that circulating, marrow-derived endothelial progenitor cells (EPCs) may be delivered by the vasculature to sites of bone formation—and contribute not only to mature endothelial populations, but also to microvascular smooth muscle cells and osteoblast lineages during skeletal growth and fracture repair (Eghbali-Fatourechi *et al.*, 2005, 2007; Matsumoto *et al.*, 2006). A better understanding of mechanisms coupling bone and vascular physiology will provide insights useful for devising novel strategies to address the mounting unmet needs in bone and mineral disease (Towler, 2007).

We know relatively little about how the vasculature integrates and conveys signals during skeletogenesis. However, vascular endothelial growth factor-A (VEGF, or VEGF-A) has emerged as the prototypic osteogenic-angiogenic coupling factor for bone-vascular interactions. In the previous edition of this volume, Harada and Thomas provide an outstanding, comprehensive overview of the VEGF family biochemistry and molecular biology (Bilezikian *et al.*, 2002). The reader is referred to that earlier edition, and recent reviews by Shibuya (Takahashi and Shibuya, 2005) and Claesson-Welsh (Olsson *et al.*, 2006), for a detailed foundation in VEGF molecular biology. Only a very brief overview and update will be given; in this edition, the focus will be on VEGF bone biology (Maes *et al.*, 2002, 2004, 2006; Wang *et al.*, 2007; Zelzer *et al.*, 2002)—incorporating selected but critical aspects of PlGF bone biology (Maes *et al.*, 2006)—to highlight the roles and regulation of VEGF receptor signaling during bone development, osteogenic-angiogenic coupling, matrix remodeling, fracture repair, and skeletal mineral metabolism.

VEGF MOLECULAR BIOLOGY

The VEGF gene is encoded on human chromosome 6; approximately 15 kb encompasses 5′ and 3′ regulatory elements, eight exons, and seven introns (Takahashi and Shibuya, 2005). Alternative splicing generates at least nine subtypes in humans: VEGF121, VEGF145, VEGF148,

*Corresponding author: Dwight A. Towler, MD, PhD, Washington University School of Medicine, Internal Medicine—Bone and Mineral Diseases, Barnes-Jewish North Campus Box 8301, 660 South Euclid Avenue, St. Louis, MO 63110; phone: 314-454-7434, fax: 314-454-8434, email: dtowler@im.wustl.edu

VEGF162, VEGF165, VEGF165b, VEGF183, VEGF189, and VEGF206. VEGF121, VEGF165, and VEGF189 predominate, and VEGF165b is an inhibitory form of VEGF, which binds to VEGFR2 with affinity approximating that of VEGF165. In the mouse, the three major isoforms are one amino acid shorter—namely, VEGF120, VEGF164, and VEGF188—encoded on mouse chromosome 17. (Unless otherwise stated, the human isoform numbering will be preferentially used.) VEGF165 is the major soluble isoform that is secreted and circulates as a homodimer of apparent molecular weight of 46 kDa. Like VEGF189, VEGF165 also binds to heparin and heparan sulfate proteoglycans such as glypican (Gengrinovitch *et al.*, 1999) and collagen XVIII/endostatin (Moulton *et al.*, 2004; Pufe *et al.*, 2005; Sipola *et al.*, 2006). However, VEGF189 is not soluble and very tightly associates with extracellular matrix proteoglycans—requiring proteolysis, heparanolysis, or heparin displacement for release (Houck *et al.*, 1992; Robinson *et al.*, 2006). By contrast, VEGF121 lacks the two heparan sulfate binding domains encoded by exons 6 and 7; this isoform is thus also found in the circulation. The details of how VEGF splicing is regulated with development and disease are poorly understood, but it is clearly important to determine them.

Embryonic lethality is observed in mice lacking even one copy of the VEGF gene (Carmeliet *et al.*, 1996; Ferrara *et al.*, 1996). Mice capable of expressing only VEGF120 (VEGF120/120 mouse) survive to birth but die shortly thereafter from ischemic cardiomyopathy (Carmeliet *et al.*, 1999) and pulmonary hypoplasia (Galambos *et al.*, 2002; Zelzer *et al.*, 2002). By contrast, VEGF165/165 mice are phenotypically normal, whereas VEGF188/188 mice are dwarfed and have aberrant retinal vascularization (Maes *et al.*, 2004).

In the absence of any VEGF, bone never forms. When VEGF120, VEFG164, or VEGF188 are present, murine intramembranous and endochondral bone formation can ensue. However, VEGF120/120 (Zelzer *et al.*, 2002) mice and VEGF188/188 (Maes *et al.*, 2004) mice have skeletal defects, highlighting the importance of VEGF164 to skeletal growth and development. In the VEGF120/120 mouse (Zelzer *et al.*, 2002), early embryonic lethality is bypassed, but profound delay in mid-diaphyseal vascular invasion and primary ossification center formation. In VEGF188/188 mice (Maes *et al.*, 2004), formation of primary ossification centers occurs; the process of MMP9-dependent matrix turnover in the remodeling primary spongiosa is posited to liberate sufficient VEGF to recruit endothelial cells and osteoprogenitors for metasphyseal mineralization (Engsig *et al.*, 2000; Gerber *et al.*, 1999; Heissig *et al.*, 2002). However, secondary ossification centers are profoundly deficient in VEGF188/188 mice; there is severe reduction in bone marrow cavity and long bone length. Skeletal hypoxia—revealed by pimonidazole administration and hypoxic adduct immunolocalization with EF5—was expanded throughout the epiphysis (Maes *et al.*, 2004). Epiphyseal chondrocyte hypertrophy is completely absent, with subsequent concomitant ablation of secondary ossification centers. Abnormalities in epiphyseal maturation resulted in joint dysplasia and arthritis (Maes *et al.*, 2004). A large, hypocellular core segment extending from the developing long bone joint surface to the metaphysis was seen due to apoptosis in VEGF188/188 skeletons (Maes *et al.*, 2004). Because conditional deletion of cartilaginous VEGF results in epiphyseal chondrocyte apoptosis (Zelzer *et al.*, 2004), this gap in VEGF188/188 mice indicates that diffusible VEGF isoforms mediate this important epiphyseal survival signal. Without this signal, epiphyseal dysplasia and joint dysplasia ensue (Maes *et al.*, 2004).

VEGF165b is a very recently identified variant produced by multiple cell types and also circulates in human plasma (Bates *et al.*, 2002; Konopatskaya *et al.*, 2006; Woolard *et al.*, 2004). This variant is generated by alternative splicing within exon 8 that alters only the last six C-terminal amino acid residues (CDKPRR → SLTRKD). VEGF165b is not angiogenic, but rather inhibits VEGF165-dependent angiogenesis. VEGF165b binds to VEGFR2/Flk1 with affinity identical to that of VEGF165 and antagonizes VEGFR2-dependent angiogenesis. Moreover, VEGF165b expression is decreased in malignant prostate tissue relative to benign prostate issue (Bates *et al.*, 2002; Konopatskaya *et al.*, 2006; Woolard *et al.*, 2004). Regulation and bioactivity in bone cell physiology have yet to be characterized. Whether VEGF165b inhibits TNFR2-dependent activation of VEGFR2 via the Bmx/Etk kinase pathway is as yet unknown also see later discussion).

As compared to the complexity of VEGF gene splicing, the transcriptional regulation of the VEGF is relatively simple. Transcriptional regulators of the hypoxia induced factor (HIF) family are critical determinants of VEGF gene expression. HIF-dependent transcription is covered in detail elsewhere in this volume (Chapter 34). Briefly, there are three HIF family members, HIF-1α, HIF-2α, and HIF-1β, that bind to DNA via their basic helix–loop–helix domains. Heterodimerization between alpha and beta subunits is required for function. HIF heterodimers recognize the DNA cognate TACGTG, which in the VEGF gene is located at basepairs −947 to −939 relative to the transcription initiation site (Forsythe *et al.*, 1996). Transcriptional coactivators of the CBP/p300 and p160/SRC1 family are then recruited; these proteins not only acetylate histones to open VEGF chromatin structure, but also recruit the megadalton, multiprotein complexes that orient and phosphorylate RNA polymerase II as necessary for VEGF transcription initiation (Cho *et al.*, 2007; Fath *et al.*, 2006). The main stimulus for HIF activation and VEGF transcription is hypoxia (Semenza, 2001). Prolyl hydroxylation of HIF-alpha subunits in oxygen sensing domains regulates ubiquitination and HIF turnover; under conditions of low oxygen tension, HIF subunits are not hydroxylated

and are stabilized in an active form (Jaakkola *et al.*, 2001). Intriguingly, it appears that most of the physiologic stimuli relevant to bone formation—including osteoanabolic growth factors and mechanical stimuli—function as "secretagogues" for VEGF production by the osteoblast (Towler, 2003). Moreover, as occurs with hypoxia, VEGF transcriptional induction by these other stimuli utilize HIF-alpha signaling for robust VEGF induction in osteoblasts (Akeno *et al.*, 2001, 2002). However, other Sp1-like binding cognates have now been described that convey responses to EP2 and EP4 prostaglandin receptor agonists in smooth muscle, and EGF receptor/Akt-dependent pathway induction in breast cancer cells (Abdelrahim and Safe, 2005; Bradbury *et al.*, 2005). Whether PGEs utilize specific Sp1 family members to support VEGF expression in osteoblasts is as yet unknown (Harada *et al.*, 1994). The tumor suppressor WT1 has been identified as one zinc-finger transcription factor that recognizes and represses VEGF expression via these Sp1 binding cognates (Hanson *et al.*, 2007). However, expression of VEGF in hypertrophic chondrocytes during endochondral bone formation requires Runx2/Cbfa1 (Himeno *et al.*, 2002; Zelzer *et al.*, 2001). Clearly, a detailed study of the protein − DNA interactions supporting VEGF gene transcription during chondrocyte and osteoblast development needs to be undertaken. Nonetheless, the recent data of Clemens and co-workers (Wang *et al.*, 2007) elegantly demonstrates that HIF-alpha will be the primary determinant of VEGF in normal osteoblasts, and the subsequent osteogenic/angiogenic coupling (Fig. 1).

Post-transcriptional regulation of VEGF expression also occurs; besides the alternatively splicing noted earlier, translation of the VEGF mRNA and stability of the mRNA transcript have been studied, although seldom in cells types immediately relevant to bone biologists (Yoo *et al.*, 2006). Both VEGF120 and VEGF164 transcripts are upregulated

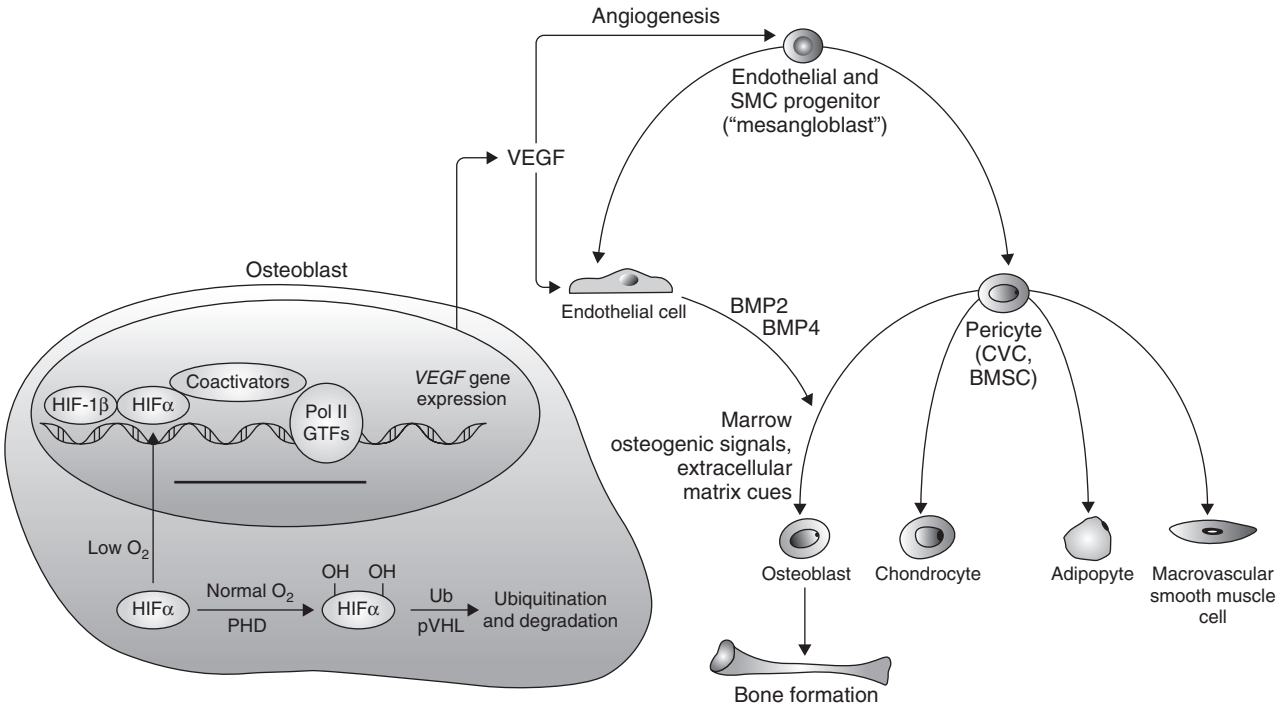

FIGURE 1 Working model of osteogenic-angiogenic coupling in trabecular bone. Recent data from multiple laboratories have indicated that microvascular smooth muscle cells known as pericytes represent osteoprogenitors capable of bone formation when placed in the correct microenvironment. Pericytes (Dellavalle *et al.*, 2007; Doherty *et al.*, 1998) appear to arise from a vessel-associated stem cell progenitor (mesoangioblast; Esner *et al.*, 2006; Tagliafico *et al.*, 2004)—and during the process of mesoderm growth and angiogenesis, this VEGFR2-expressing stem cell undergoes expansion. Not shown is the capacity of VEGF (or PlGF) to induce proliferation and osteogenic differentiation of mesenchymal progenitors via VEGFR1 (Maes *et al.*, 2006). Clemens and colleagues (Wang *et al.*, 2007) recently demonstrated that osteoblast HIF-alpha subunits, transcriptional regulators of VEGF expression, represent rate-limiting components of osteogenic-angiogenic coupling and trabecular bone formation. Augmentation of osteoblast HIF-alpha expression and bone formation was achieved by conditionally deleting Vhl, the gene encoding pVHL—the E3 ubiquitin ligase necessary for HIF-alpha degradation. Bone formation requires VEGF-mediated paracrine signals in bone that stimulated angiogenesis. Because VEGF can expand VEGFR2-expressing mesoangioblast numbers during angiogenesis (Brunelli *et al.*, 2004; Cossu and Bianco, 2003), this process may drive the increase in osteoblast numbers that promotes massive trabecular bone formation in the osteogenic marrow environment. PHD enzyme activity is required for HIF-alpha degradation, oxidatively "tagging" HIF-alpha for recognition by pVHL. In addition to low oxygen levels (as shown here), mechanical stimuli, TNF-alpha, and reactive oxygen species can also upregulate HIF-alpha expression. See text for details. in bone with fracture healing (Pufe *et al.*, 2002). LaFage-Proust and colleagues demonstrated that mechanical strain controls splicing of VEGF isoforms in MG63 human osteosarcoma cells (Fuare *et al.*, 2006); a low-frequency regimen (0.05 Hz for 150 min) stimulated soluble VEGF 121 and 165 production, whereas a high-frequency regimen (5 Hz for 1.5 min) stimulated matrix-bound VEGF 145, 165, 189, and 206 isoform production (Fuare *et al.*, 2006). Reactive oxygen species control VEGF translation in renal proximal tubule in response to angiotensin (Feliers *et al.*, 2006). Reactive oxygen species may control VEGF expression in osteoblasts via HIF-alpha signaling that is independent of hypoxia (Kim *et al.*, 2002), but this remains to be studied in detail.

VEGF RECEPTORS IN BONE BIOLOGY

Three classic VEGF receptors have been described—VEGFR1 (Flt1), VEGFR2 (Flk1), and VEGFR3—that are all members of the receptor tyrosine kinase superfamily. In addition, other "co-receptors"—namely, neuropilin 1, neuroplin 2, and glipican 1—have been identified that augment VEGF signaling in a ligand-specific, VEGFR-specific, and cell type–specific fashion (see later discussion). Detailed review of the combinatorial complexity of this receptor signaling system is beyond the scope of this chapter but has been recently reviewed (Takahashi and Shibuya, 2005). However, given the prominent contributions of VEGFR2 and VEGFR1 to skeletal physiology, those functional relationships and the ligands clearly relevant to the signaling of these receptors will be presented. The structural features of VEGFR structure and ligand-dependent signaling has been well discussed by Harada and Thompson (Bilezikian *et al.*, 2002); the reader is referred to the previous edition for this excellent overview.

VEGFR1

VEGFR1 is also known as Flt1 and, for simplicity, will be referred to as VEGFR1. The VEGFR1 is a 1338-amino-acid-long receptor tyrosine kinase, encoded in 30 exons spanning about 150 kbp of genomic DNA. The major ligands of VEGFR1 directly germane to bone biology are VEGF and PlGF—but PlGF and VEGF-B are VEGFR1-specific ligands. In addition to homodimerization, VEGFR1 forms ligand-induced heteromeric complexes with VEGFR2 and neuropilin; the signaling properties of these heteromers are poorly understood (Pan *et al.*, 2007b). However, neuropilin-1 enhances VEGF165 binding affinity for VEGR1 at least 10-fold (Fuh *et al.*, 2000), and. Mice completely null for the VEGFR1 gene are embryonic lethal around E8.5; this arises from abnormal vascular morphogenesis without impairment of endothelial cell differentiation; indeed, the VEGFR1 −/− embryo exhibits increased endothelial cell proliferation numbers in the yolk sac and nascent endomyocardium (Fong *et al.*, 1999). This may relate to the important role of the extracellular domain of VEGFR1 to bind and sequester VEGF and PlGF; indeed, a soluble, secreted form of VEGFR1 is elaborated during development, and is thought to be central to the pathobiology of preeclampsia (Ahmad and Ahmed, 2004; Koga *et al.*, 2003; Levine *et al.*, 2004). It had been appreciated that VEGFR1 was highly expressed in the osteoclast lineage, and that VEGF could replace M-CSF/CSF-1 in the development and activation of osteoclasts in concert with RANKL *in vitro* (Niida *et al.*, 1999). These contributions were robustly established via the analysis of VEGFR1(TK−/TK−) mice. Because the extracellular domain of VEGR1 is biologically active in the absence of intracellular tyrosine kinase domain (see earlier discussion), Shibuya and colleagues characterized a mutant form of the VEGFR1 gene in which the intracellular kinase domain was compromised without affecting the coding of the extracellular domain. This mouse, known as the VEGFR1(TK−/TK−) mouse, is a hypomorph that survives into adulthood (Niida *et al.*, 2005). No major defects in vasculogenesis or angiogenesis with development were observed; however, postnatal reductions in the chemotaxis of monocytes/macrophages to VEGF were noted with reductions in inflammation in VEGFR1(TK−/TK−) mice in arthritic disease models (Murakami *et al.*, 2006). Because monocytes and macrophages strongly express VEGFR1, it was suggested that this lineage—including the osteoclast—might be affected. Osteoclast numbers were modestly reduced in VEGFR1(TK−/TK−) mice; however, severe osteoclast abnormalities became clearly evident when VEGFR1(TK−/TK−) genotype was superimposed on the CSF-1 deficiency of the osteopetrotic op/op mouse. Thus, the VEGFR1 signaling system is clearly important to the regulation of bone-resorbing osteoclast physiology.

Other functions of VEGFR1 signaling relevant to bone marrow stromal cell physiology also emerged in these early studies. Marrow fibrosis was a significant finding in the VEGFR1(TK−/TK−) mice on the op/op background (Niida *et al.*, 2005), prompting the investigative team to propose that VEGFR1 signaling participates in other aspects of bone marrow function. These notions have now been confirmed. Recently, Nakamura and colleagues showed that bone mass, bone strength, and bone formation rates were reduced in VEGFR1(TK−/TK−) mice (Otomo *et al.*, 2007). Intriguingly, although osteoblast numbers were not increased, mineralizing surface, bone formation rate, and mineral apposition rates were reduced. No significant change in osteoclast surface was noted, although the trend was downward, consistent with coupling. Cultured bone marrow stromal cells exhibited reduced nodule mineralization in culture, suggesting that at least part of the deficit was cell autonomous (Otomo *et al.*, 2007). Thus,

VEGFR1 may play an important role in mature osteoblast synthetic function, maintaining synthetic activity necessary for optimal bone mass accrual and bone strength.

Carmeliet and colleagues very recently identified another aspect of VEGFR1 biology that reflects activation by placental growth factor (PlGF), a highly selective ligand for VEGFR1 (Maes *et al.*, 2006). Like VEGF, PlGF is spliced to form four variants denoted as PlGF1 (PlGF131), PlGF2 (PlGF152), PlGF3 (PlGF203), and PlGF4 (PlGF 224). Although PlGF −/− mice are developmentally viable (Carmeliet *et al.*, 2001), detailed studies subsequently demonstrated that PlGF potentiates the actions of VEGF, augmenting VEGFR1 signaling postnatally during wound repair and tumor angiogenesis (Carmeliet *et al.*, 2001; Maes *et al.*, 2006). Of note, treatment of mesenchymal stem cell with the powerful bone morphogen BMP2 upregulates PlGF expression (Marrony *et al.*, 2003; Raida *et al.*, 2006). PlGF recruits mesenchymal VEGFR1+ stem cells from the marrow environment to promote fracture healing (Maes *et al.*, 2006). In a definitive series of experiments, Carmeliet and colleagues demonstrated that PlGF deficiency compromises fracture healing in mice (Maes *et al.*, 2006). Moreover, the turnover of calcified cartilage—a component of fracture healing necessary for lamellar bone formation—is also severely compromised in VEGFR1(TK–/TK–) mice, to the extent that nonunion occurs (Niida *et al.*, 2005). In some aspects, this phenotype resembles that of mesenchymal BMP2 deficiency ($BMP2^{cko/cko}$; Prx1::cre); importantly, BMP2 is a potent stimulus that sustains PlGF1 and PlGF2 production by mesenchymal stem cells (Marrony *et al.*, 2003; Raida *et al.*, 2006). Thus, *in toto*, the results of Carmeliet, Shibuya, and colleagues indicate that VEGFR1 activation by PlGF not only is important in bone mass accrual via osteoblast synthetic activity, but also is critical to the bone metabolic processes necessary for fracture repair and other pathologic responses (Maes *et al.*, 2006; Murakami *et al.*, 2006; Niida *et al.*, 2005).

VEGFR2

VEGFR2 is critical to the developmental organization of vascular endothelial cells (Shalaby *et al.*, 1995). Mice completely null for the VEGFR2 gene are embryonic lethal around E8.0 to E8.5 because of lack of vasculogenesis and blood island formation that are dependent on the hemangioblast—a VEGFR2+ progenitor of both endothelial and hematopoietic cells (Choi *et al.*, 1998). Like VEGFR1, this 1356-amino-acid receptor tyrosine kinase possesses (a) seven immunoglobulin-like extracellular domains, (b) a transmembrane domain, (c) a tyrosine kinase with an about 70-amino-acid kinase insert domain; and (d) a carboxy-terminal effector domain that interacts with PLC-gamma and other signal transducing molecules (Takahashi and Shibuya, 2005). VEGFR2 also associates with the co-receptor neuropilin dependent on VEGF165 ligand-induced binding; mice with transgenic augmentation of neuropilin-1 (NRP1) exhibit embryonic lethality with excess capillary growth (Kitsukawa *et al.*, 1995). The glycosaminoglycan modification of NRP1 modulates VEGFR2 signaling in a modification-specific and cell type specific fashion (Shintani *et al.*, 2006). Activation of PI3K cell survival signals, ERK/MAPK-dependent mitogenicity, and the focal adhesion kinase pathways necessary for cell migration are also provided by the VEGFR2 carboxy-terminal domain. Moreover, VEGF recruitment of EPCs to sites of injury and active angiogenesis is dependent on VEGFR2 signaling (Li *et al.*, 2006).

VEGFR2 is classically activated by ligand-induced homodimerization that activates receptor tyrosine kinase activity, leading to VEGFR2 autophosphorylation and recruitment of cytosolic signaling adapters that elaborate second messengers (Takahashi and Shibuya, 2005). Ligands important for VEGFR2 action in bone include VEGF and VEGF-E, with plasmin-activated VEGF-C and VEGF-D also contributing (McColl *et al.*, 2003; Rissanen *et al.*, 2003) as VEGF-A actions are truncated (Roth *et al.*, 2006). Unlike VEGF, the parapoxivirus protein VEGF-E is a ligand specific to VEGFR2; VEGF-E can activate angiogenesis with much less edema and inflammation (Ogawa *et al.*, 1998). The fact that VEGF-E has little if any direct effect on osteoblasts has been taken to indicate that the expression of VEGFR2 on the osteoblast surface is of questionable consequence (Mayr-Wohlfart *et al.*, 2002). However, by promoting VEGFR1-mediated phosphorylation and activation of VEGFR2, PlGF binding to VEGFR1 can recruit active signaling via VEGFR2 (Autiero *et al.*, 2003). Moreover, elegant work by Min, Alitalo, and colleagues has identified another mechanism for activation of VEGFR2 signaling—via TNFR2 activation (He *et al.*, 2006; Luo *et al.*, 2006; Pan *et al.*, 2002; Zhang *et al.*, 2003). TNF-alpha activation of TNFR2 activates Etk/Bmx, a tyrosine kinase that phosphorylates VEGFR2 at Tyr-1175 and Tyr-801, residues necessary for PI3K/Akt signaling that promote endothelial cell migration, survival, and vascular permeability (Luo *et al.*, 2006; Zhang *et al.*, 2003). The TNFR2-Bmx/Etk pathway appears to be critical for angiogenic responses in response to tissue ischemia. In both Tie2-Cre;$Bmx^{CKO/CKO}$ (He *et al.*, 2006) and TNFR2–/– mice (Goukassian *et al.*, 2007), arteriogenesis and capillary formation necessary for hindlimb recovery following ischemia were markedly impaired; in the absence of endothelial and marrow TNFR2 → Bmx→ VEGFR2 signaling, limbs could not generate adequate angiogenic responses to ischemia, and limb necrosis and autoamputation ensued.

Because of the critical importance of vascular supply to tumor growth, VEGFR2 signaling has been successfully targeted to improve survival in patients with colorectal and renal malignancies (Dallas *et al.*, 2007). Moreover, sunitinib—a kinase inhibitor that targets VEGFR2,

PDGFR-beta, and c-kit—has proven useful in the treatment of gastrointestinal stromal cell tumors (Dallas *et al.*, 2007; Takahashi and Shibuya, 2005). However, mechanism-based toxicity to bone health and fracture may occur as well, dependent on the physiological demands placed on the patient's skeleton. In the growing skeleton, VEGF-VEGFR2 signaling is critical to the vascular invasion of growth plate cartilage necessary for endochondral bone formation (Gerber *et al.*, 1999; Maes *et al.*, 2002, 2004; Peng *et al.*, 2005; Zelzer *et al.*, 2002). As noted earlier, expression of VEGF—regulated by Runx2/Cbfa1 in hypertrophic chondrocytes—depends on the activity of the osteochondrogenic transcription factor, Runx2 (Zelzer *et al.*, 2001). Inhibition of VEGF bioactivity using a faux receptor-soluble fragment of VEGFR1 inhibits growth plate vascularization, decreases hypertrophic chondrocyte mineralization, reduces chondroclast recruitment and primary spongiosa remodeling, and thus impairs trabecular bone formation (Gerber *et al.*, 1999). VEGF expression and bioactivity figures prominently in fracture repair, whether occurring via endochondral or intramembranous ossification mechanisms. Gerstenfeld, Einhorn, and colleagues studied angiogenic responses in detail in distraction osteogenesis, a model of fracture repair where intramembranous ossification is stimulated by mechanical tension; little if any significant endochondral bone forms. In this model VEGF is upregulated in the distraction gap by the graded mechanical stimuli that promote intramembranous repair. Although the precise mechanisms are as yet unclear, HIF-alpha, a critical regulator of osteogenic-angiogenic coupling via paracrine VEGF production (Wang *et al.*, 2007), is also upregulated with appropriate mechanical distraction (Carvalho *et al.*, 2004; Mori *et al.*, 2006). Moreover, recent QTL mapping of loci contributing to bone anabolism response to mechanical load identified a region on mouse chromosome 17 that encompasses VEGF (and Runx2) genes (Kesavan *et al.*, 2007).

Neuropilin 1, Neuropilin 2

Neuropilins are transmembrane proteins initially identified as receptors for the semaphorin family of axonal guidance molecules, and VEGF itself does indeed participate in axonal guidance processes (Kolodkin *et al.*, 1997; Schwarz *et al.*, 2004). However, as outlined throughout the text, neuropilin 1 (NRP1; VEGF165R) and 2 (NRP2) are critical components of the receptor complexes that mediated VEGF and PlGF signaling during physiological and pathological angiogenesis (Staton *et al.*, 2007). Mice lacking either NRP1 or NRP2 exhibit profound abnormalities in vasculogenesis, and disruption of both genes results in very early embryonic lethality with completely avascular yolk sacs (Takashima *et al.*, 2002). Lowik and colleagues first identified that NRP1 is expressed by the KS483 osteoprogenitor cell line, with mRNA accumulation peaking at the point of maximal mineralization in culture (Deckers *et al.*, 2002). However, because soluble VEGFR1—a ligand for both VEGF and PlGF—did not inhibit mineralization of this cell culture model (Deckers *et al.*, 2002), the role and regulation of NRP1 in osteoblast cell physiology has yet to be clarified *in vivo*. Since NRP1 regulation of VEGF receptor signaling is cell-type specific and completely dependent on the type of NRP1 glycosaminoglycan modification (Shintani *et al.*, 2006), comprehensive studies must include an analysis of NRP1 post-translational modifications during osteoblast differentiation.

Recently, data from Watts and colleagues (Pan *et al.*, 2007b) and Neufeld and colleagues (Shraga-Heled *et al.*, 2007) have identified that a direct role for VEGF121 interactions with NRP1—independent of VEGFR2 bridging—is important for endothelial cell migration and capillary sprouting. An inhibitor antibody designed to selectively target NRP1 (Pan *et al.*, 2007a) not only inhibited VEGF165 binding and signaling, but antagonized VEGF121 actions (Pan *et al.*, 2007b); the latter was not expected, because the original working models of NRP1 signaling posited that NRP1 would facilitate VEGR2 signaling by ligands such as VEGF165. Indeed, NRP1 does enhance VEGF165—but not VEGF121—binding to VEGFR2 in surface plasmon resonance assays (Pan *et al.*, 2007b). However, residues encoded by VEGF amino acids 109 to 121 mediate direct interactions between VEGF and NRP1 that is independent of the NRP1–VEGF heparin binding domain interactions of VEGF165. This tail region, present in both VEGF165 and VEGF121, has been called Tuftsin and directly binds NRP1 (von Wronski *et al.*, 2006). Thus, VEGF121—independent of NRP1-VEGFR2 bridging—mediates key components of paracrine VEGF signaling via NRP1. Early data suggests that both NRP1 and NRP2 can enhance VEGF121-induced phosphorylation of VEGFR2 (Shraga-Heled *et al.*, 2007). The intracellular signaling mechanisms conveying NRP-VEGF121 activation of VEGFR2 have yet to be elucidated.

VEGF RECEPTOR SIGNALING AND SKELETAL REPAIR: SUMMARY AND FUTURE DIRECTIONS

The biological mechanisms whereby VEGFR signaling promotes bone mass accrual and restores skeletal health following injury are better understood—but is by no means comprehensive. Osteogenic-angiogenic coupling (see Fig. 1) is necessary for skeletal growth and repair (Gerber *et al.*, 1999; Maes *et al.*, 2006; Peng *et al.*, 2005; Street *et al.*, 2002; Zelzer *et al.*, 2002). The actions of VEGF and PlGF signaling on tissue angiogenesis (VEGFR2), recruitment of mesenchymal progenitors (VEGFR1), recruitment of multipotent EPCs capable of endothelial as well as osteogenic cell fates (VEGFR2, VEGFR1), and inhibition of osteoblast apoptosis (VEGFR2) have much to do with the

skeletal benefits of activating VEGF signaling (Li *et al.*, 2006; Maes *et al.*, 2006) in preclinical models of fracture nonunion. Studies by Huard and colleagues demonstrated synergistic enhancement of osteogenic differentiation and bone repair in critical calvarial defect models (Peng *et al.*, 2002). An optimal ratio of BMP4 to VEGF was required to ensure efficient cartilage induction, followed by VEGF-dependent vascularization and endochondral bone formation. Street and colleagues made similar observations in a rabbit radius gap defect model, and highlighted that VEGF promotes bone repair by promoting angiogenesis, remodeling, and ossification of fracture the callus. Inhibition of VEGF and PlGF actions with soluble VEGFR1 impaired fracture healing (Street *et al.*, 2002). Krebsbach and colleagues subsequently showed that radiation-induced compromise of surgically induced calvarial defects was also reversed by local VEGF administration on biodegradable scaffolds; recovery of bone formation closely tracked recovery of blood flow (Kaigler *et al.*, 2005, 2006). Of note, with skeletal growth and following fracture, circulating CD34+ EPCs with osteogenic potential increase; Khosla and colleagues first proposed that these EPCs would be recruited to sites of skeletal injury and thus accelerate bone repair (Eghbali-Fatourechi *et al.*, 2005). Asahara and co-workers directly demonstrated this fact; they showed that human CD34+ EPCs enhanced angiogenesis and osteogenesis—and promoted femoral fracture healing when transplanted intravenously in a xenograft-tolerant nude rat model of fracture nonunion (Matsumoto *et al.*, 2006). Since VEGFR1 and VEGFR2 are required to recruit circulating EPCs to sites of angiogenesis (Li *et al.*, 2006), the local production of VEGF elaborated during fracture is likely to be critical to rapid repair and remodeling of the injured skeleton.

VEGFR signaling—including VEGFR1, VEGFR2, and NRP1—is central to the cross-talk between cells of endothelial, mesenchymal, and histocyte lineages (Fig. 2) that give rise to the endothelium, osteoblasts, and osteoclasts in the bone remodeling compartment (Eriksen *et al.*, 2007). Propelled by the seminal data of Harada, Rodan, and Rodan (Harada *et al.*, 1994), recent data from multiple laboratories have now clearly established the important

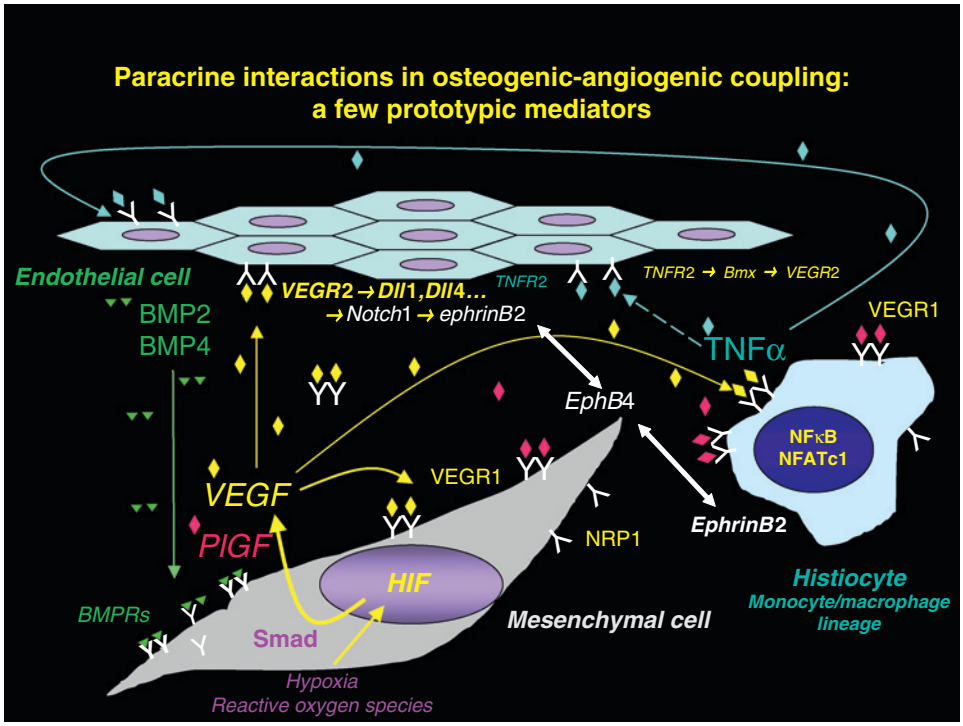

FIGURE 2 The central role of VEGF receptor signaling in osteogenic-angiogenic coupling. Recent studies of orthotopic and heterotopic mineral deposition have established that functional interactions between endothelium, mesenchyme (pericytes, bone marrow stromal cells, osteoblasts), and tissue histiocytes (monocytes, macrophages, osteoclasts) coordinate the deposition and removal of extracellular calcified matrix. Paracrine signals provided by VEGF and PlGF (Autiero *et al.*, 2003; Li *et al.*, 2006; Maes *et al.*, 2006; Marrony *et al.*, 2003; Raida *et al.*, 2006) convey and control osteogenic morphogens such as BMPs, Delta-Notch, and bidirectional ephrinB2–EphB4 signaling (Erber *et al.*, 2006; Hainaud *et al.*, 2006; Scehnet *et al.*, 2007; Thurston *et al.*, 2007; Zhao *et al.*, 2006) that control bone formation in the bone remodeling compartment (Eghbali-Fatourechi *et al.*, 2007; Eriksen *et al.*, 2007). Not shown are the numerous other paracrine signals—e.g., those provided by Wnt, FGF, Ihh, prostaglandin, or matrix cytokines—that are necessary for intramembranous and endochondral bone metabolism. See text for details. (See plate section)

role for VEGF signaling in all aspects of bone physiology (Gerber *et al.*, 1999; Maes *et al.*, 2006; Zelzer *et al.*, 2002). Enlightened by this knowledge, novel strategies for enhancing bone formation under conditions of impaired wound healing have emerged. Because between 10% and 15% of fractures exhibit impaired healing and nonunion, strategies that augment VEGF and PlGF—with diminished inflammatory responses—may accelerate fracture repair in these therapeutically difficult settings (Damany *et al.*, 2005; Kalra *et al.*, 2006). Low-turnover bone disease—a serious complication in a subset of patients with end-stage kidney disease that increases risk for avascular necrosis—might be addressed in part via augmentation of PlGF-dependent EPC and osteoclast lineage activation (Kalra *et al.*, 2006). Future studies will no doubt address how pharmacologic manipulation of VEGFR1, VEGFR2, and NRP1 signaling cascades can address the burgeoning unmet clinical needs in musculoskeletal medicine (Towler, 2007).

It is important to note that strategies useful for reducing VEGF signaling in neoplasia (Takahashi and Shibuya, 2005) will compromise skeletal reparative potential to varying extents—dependent on drug, dose, disease, and skeletal metabolic status. Because the high-dose aminobisphosphonates utilized in patients with malignancy suppress angiogenesis and accumulate in the skeleton (Wood *et al.*, 2002), some cases of osteonecrosis of the jaw following dental procedures in these patients may in fact reflect drug-induced impairment of osteogenic angiogenic coupling (Khosla *et al.*, 2007). This notion has yet to be rigorously tested. The effects of more specific VEGF-VEGFR2 signaling inhibitors on skeletal homeostasis in patients have not been reported; based on the impaired fracture healing observed with VEGF antagonism in preclinical models, these therapeutics may also compromise skeletal reparative capacity in cancer patients. Better modalities are necessary to functionally image bone metabolism and blood flow in all skeletal venues (Leitha *et al.*, 1996; Schmitz *et al.*, 2002; Yang *et al.*, 2002). As our fundamental understanding of osteogenic-angiogenic coupling in specific physiological contexts becomes more comprehensive, personalized strategies will emerge for optimizing clinical outcomes and skeletal health to the benefit of our patients.

TGFβ SUPERFAMILY

Transforming growth factor beta-1 (TGFβ-1) is the prototype and founding member of the TGFβ superfamily. This family has grown to include more than 40 members, including the TGFβ isoforms, activins and inhibins, Mullerian inhibitory substance, growth and differentiation factors (GDFs), and an ever-increasing number of bone morphogenetic proteins (BMPs) (for reviews see Chang *et al.*, 2002; Chen *et al.*, 2004; Alliston *et al.*, 2008). Members of this superfamily appear to mediate many key events in growth and development and have been maintained evolutionarily from fruit flies to mammals. TGFβ superfamily members are structurally related dimeric molecules. They share a set of conserved cysteine residues that, through disulfide bonding, form a three-dimensional "cysteine knot structure." These proteins are produced as precursor molecules that contain a signal sequence, prodomain and C-terminal mature growth factor domain. Their actions are mediated primarily through a family of serine/threonine kinase transmembrane receptors. Members of the TGFβ superfamily have important regulatory roles in a number of cellular functions, including proliferation, differentiation, chemotaxis, apoptosis, and tumor suppression. Many members of this superfamily also have profound effects on skeletal tissues, both during development and postnatally (reviewed in Janssens *et al.*, 2005; Alliston *et al.*, 2008).

ISOFORMS OF TGFβ

The mammalian TGFβ isoforms include TGFβs 1 through 3, which are closely related and are thought to have arisen by duplication of a common ancestor gene. Much greater homology exists between the mature growth factor regions of the molecules as compared with their precursor regions, suggesting that the propeptides are under less selection pressure and/or that the precursor regions may provide distinct functions. The isoforms of TGFβ have often been "lumped" together and their effects on bone generalized, which must be kept in mind when reviewing the literature in this field. However, in spite of their similarity, the TGFβs1 through 3 are expressed differentially in mammalian tissues. Each binds with different affinities to TGFβ receptors and appears to have slightly different biological effects in *in vitro* assays. Gene knockout studies of the different isoforms have revealed major differences in their phenotypes, emphasizing their nonoverlapping *in vivo* functions (see Section X).

The dramatic differences in tissue distribution of the three mammalian TGFβ isoforms suggest specific functions for each isoform. For example, 80% to 90% of TGFβ in bone is the TGFβ-1 isoform (reviewed in Bonewald, 1999), but the major form produced by kidney glomerular mesangial cells (approximately 50%) is TGFβ-2 (Marra *et al.*, 1996). Prostate produces 30 to 70 times more TGFβ-2 than 1 (Dallas *et al.*, 2005). Even within the skeleton, the expression of the different isoforms is highly regulated, with unique but overlapping expression patterns for each isoform (reviewed in Alliston *et al.*, 2008). Accordingly, the promoter regions for TGFβ-1, TGFβ-2, and TGFβ-3 show little similarity (Kim *et al.*, 1989; Lafyatis *et al.*, 1990; Malipiero *et al.*, 1990). TGFβ genes also appear to be regulated post-transcriptionally, which may account for the lack of correlation between mRNA expression and protein secreted from some cell types.

In addition to having different expression patterns, the TGFβ isoforms have different functions. In many of the *in vitro* assays in which the isoforms have been tested, small variations in biological effects have been observed (reviewed in Centrella *et al.*, 1994). However, the different TGFβ isoforms can have very different effects *in vivo*,

which may depend on tissue and receptor expression. An example of different opposing effects of the isoforms can be found in the cranial suture of rat calvaria, where removal of TGFβ-3 results in obliteration of the suture, but this is prevented by removing TGFβ-2 (Opperman *et al.*, 1999). Similarly, in models of wound healing, reduced scarring is observed following inhibition of TGFβ-1 and -2, but the same effect can be achieved by addition of TGFβ-3 (reviewed in Ferguson and O'Kane, 2004). On the other hand, TGFβ isoforms can exhibit some functional redundancy, as shown by the observation that defective fusion of the palatal shelves in organ cultures from TGFβ-3 null mice can be partially rescued by application of TGFβ-1 and TGFβ-2 (Taya *et al.*, 1999).

The various TGFβ isoforms bind with different affinities to TGFβ receptors. Investigators are now involved in unraveling the specificity of each isoform for each receptor by determining the three dimensional structures of the ligands and receptors in their bound and free states (for review, see Lin *et al.*, 2006). The TGFβ-2 tertiary structure was determined by x-ray crystallography (Daopin *et al.*,1992) and the structure of TGFβ-1 by nuclear magnetic resonance imaging (Hinck *et al.*, 1996). The shape of TGFβ isoforms has been described as resembling an outstretched hand with curled fingers. Hydrophobic patches are on the "heel" of the "hand" and on the "fingertips." When the two TGFβ monomers bind together to form the homodimer, the hydrophobic "heel" of one molecule touches the hydrophobic "fingers" of the other molecule. The central core of the hydrophobic molecule also contains four molecules of water of unknown function. The further analysis of the three-dimensional structure of the ligand and its receptors should lead to the production of agonists and antagonists for pharmaceutical use in diseases in which TGFβ is misregulated (see Section XI).

PROCESSING AND LATENCY OF TGFβ

Control of TGFβ latency, activation and deposition in the extracellular matrix are all critical steps in the regulation of TGFβ in the skeleton. TGFβs are secreted by most cells in one or more biologically latent forms (reviewed in Annes *et al.*, 2003; Hyytiainen *et al.*, 2004). Release of the mature TGFβ 25kDa homodimer from these latent complexes is necessary for TGFβs to bind to receptors and exert their effects on target cells. Of the three TGFβ isoforms, TGFβ-1 has been the most widely studied. The insights gained into its processing, storage and activation may form a paradigm for the other isoforms and possibly other members of the superfamily.

TGFβ-1 is produced as a 390 amino acid precursor (prepro-TGFβ-1), which consists of a 29-amino-acid signal peptide, a 249-amino-acid propeptide (also known as latency-associated peptide, or LAP), and a 112-amino-acid mature growth factor peptide. A series of post-translational modifications occur as summarized schematically in Fig. 1. First, the signal peptide is cleaved off, then two monomers dimerize through disulfide bonding at positions 223 and 225 in the propeptide and position 356 in the mature growth factor. Following dimerization the precursor is cleaved by furin at position 278 to produce the mature 25-kDa TGFβ homodimer and the 75-kDa LAP. After cleavage, the mature TGFβ and LAP remain associated noncovalently, forming a complex known as the small latent TGFβ complex (SLC), in which the TGFβ is inactive and unable to bind to its receptors. Activation of TGFβ requires dissociation of the mature dimeric growth factor from its propeptide (see Section IV).

Most cells secrete the majority of their TGFβ as a "large latent complex" (LLC) in which proteins called latent TGFβ-binding proteins (LTBPs) are linked to LAP. This linkage occurs via disulfide bonding between cysteine 33 of the LAP and the third 8-cysteine repeat domain of the LTBP. LTBPs do not appear to be required for latency, as the small latent complex is, by itself, latent (Gentry and Nash, 1990). However, these proteins can facilitate the correct folding and secretion of TGFβ (Miyazono *et al.*, 1991) and they appear to play a major role in targeting latent TGFβ for storage in the extracellular matrix (Taipale *et al.*, 1994; Dallas *et al.*, 1995; Olofsson *et al.*, 1995). To date, four LTBP isoforms (LTBPs 1–4) have been identified, ranging in size from 125 to 240 kDa (for reviews see Hyytiainen *et al.*, 2004; Rifkin, 2005).

Although most cell types secrete TGFβ predominantly as part of the large latent complex, containing LTBPs, bone cells are unique in that they are the only known cell type that secretes a significant proportion (approximately 50%) of their TGFβ in the small latent complex form (Bonewald *et al.*, 1991; Dallas *et al.*, 1994). The SLC may therefore have a unique function in bone, perhaps by acting as a soluble, more readily activated form.

ACTIVATION OF LATENT TGFβ

Because both TGFβ and its receptors are ubiquitously expressed and TGFβ has such potent effects on many cell types, activation of the latent forms must be tightly controlled and is likely one of the major mechanisms for regulation of TGFβ functions in skeletal and other tissues. Latent TGFβ can be activated physicochemically by transient acidification or alkalinization, by the action of chaotropic agents, or by heat treatment (Lawrence *et al.*, 1985; Pircher *et al.*, 1986; Brown *et al.*, 1990) . These treatments presumably induce conformational changes in the LAP that destabilize the complex, releasing the mature growth factor. Although the precise physiological mechanisms by which TGFβ is activated *in vivo* remain unclear, several potential mechanisms have been proposed, based mainly on *in vitro* studies using purified native or recombinant

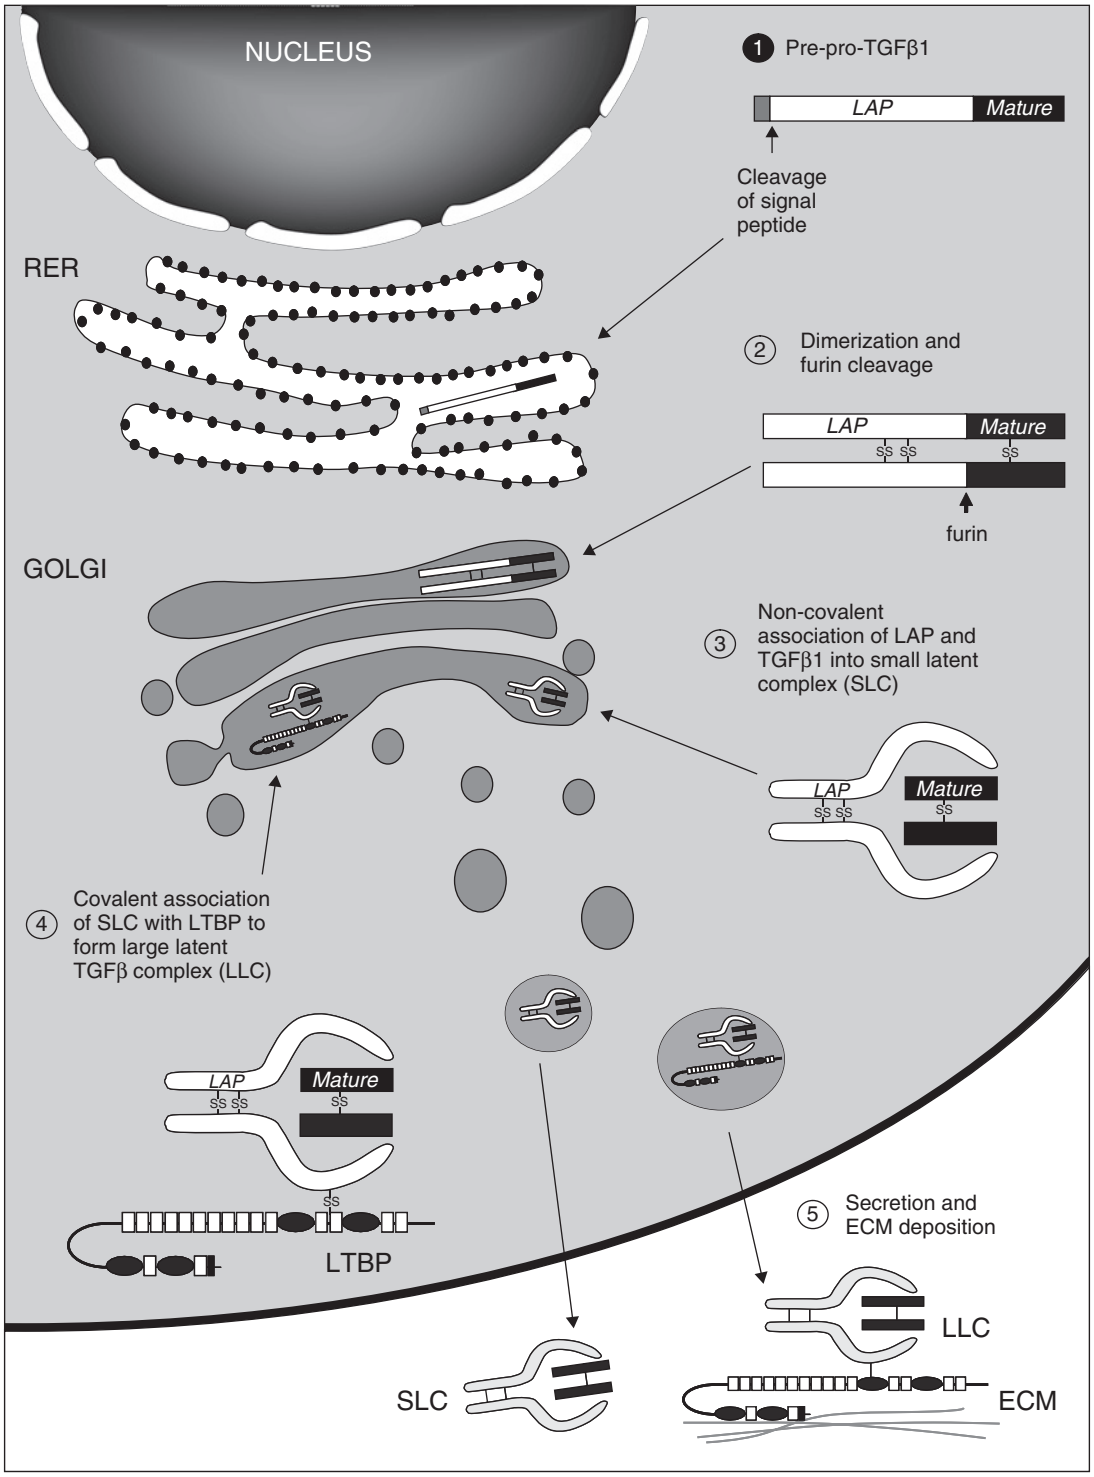

FIGURE 1 Schematic diagram depicting the major steps in the synthesis, processing and secretion of TGFβ-1. (1) TGFβ-1 is synthesized as a 390 a.a. precursor (prepro-TGFβ-1), consisting of 29 a.a. signal peptide, a 249 a.a. propeptide (also known as latency-associated peptide, or LAP), and a 112 a.a. mature growth factor peptide. A series of post-translational modifications occur as it traffics through the rough endoplasmic reticulum (RER) and Golgi and is secreted into the extracellular space. First, the signal peptide is cleaved off, and (2) two TGFβ-1 monomers dimerize through disulfide bonding at positions 223 and 225 in the propeptide and position 356 in the mature growth factor. Following dimerization, the precursor is cleaved by furin at position 278 to produce the mature 25-kDa TGFβ homodimer and the 75-kDa LAP homodimer. (3) After cleavage, the mature TGFβ and LAP remain associated noncovalently, forming a complex known as the small latent TGFβ complex (SLC), in which the TGFβ is inactive and unable to bind to its receptors. (4) Proteins called latent TGFβ-binding proteins (LTBPs) are linked to LAP via disulfide bonding between cysteine 33 of the LAP and the third 8-cysteine repeat domain of the LTBP to form the "large latent TGFβ complex" (LLC). (5) Once secreted from the cell, the LLC binds to the extracellular matrix, primarily through binding of the N terminus of LTBPs to ECM components. Bone cells also secrete significant amounts of SLC, which may represent a soluble, more readily activatable form. Modified from Janssens *et al.* (2005). *Endocr. Rev.* **26**, 743–744.

proteins and/or cell culture systems (reviewed in Annes *et al.*, 2003; Rifkin, 2005). When reviewing the literature it is important to consider the source of the TGFβ being activated (i.e., SLC versus LLC, recombinant versus native protein) as well as whether the latent TGFβ is in solution or may be bound to the matrix.

Proposed *in vivo* activation mechanisms fall into three main categories, any or all of which may be relevant in bone: (1) proteolytic degradation of the LAP, resulting in release of mature TGFβ, (2) induction of a conformational change in LAP (e.g., through interaction with cell surface integrins or thrombospondin), resulting in destabilization of the complex; or (3) disruption of the noncovalent interactions between LAP and mature TGFβ. It also seems likely that these mechanisms may work in combination, for example a conformational change, followed by proteolytic cleavage at a previously cryptic site. Other steps, such as conversion of matrix-bound LLC into soluble form(s) of LLC, may also be key events in the activation pathway.

Lyons and colleagues were the first to demonstrate proteolytic activation of recombinant SLC by plasmin, which cleaves LAP at multiple sites (Lyons *et al.*, 1990). Plasmin-mediated activation of latent TGFβ was also shown in cocultures of pericytes and smooth muscle cells (Sato and Rifkin, 1989), and subsequently, matrix metalloproteinases (MMPs) 2 and 9 were reported to activate latent TGFβ *in vitro* (Yu and Stamenkovic, 2000). Not only is LAP a target for proteolysis, but the protease-sensitive hinge regions of LTBPs are also potential targets for protease action to release from the matrix a soluble form of LLC containing a cleaved fragment of LTBP. This released LLC presumably then requires further processing for activation. Several studies have confirmed that proteases including plasmin, elastase, and MMPs can cleave LTBP1 to release LLC from the matrix (Taipale *et al.*, 1995; Dallas *et al.*, 2000, 2002). In the case of plasmin, the concentrations required to release bone matrix bound LLC appear to be 10- to 100-fold less than those required to activate the SLC (Dallas *et al.*, 2002), suggesting that a more physiological function of plasmin may be to release the latent complex from the matrix rather than to activate soluble forms. Elastase will cleave matrix-bound LTBP1 (Taipale *et al.*, 1995; Dallas *et al.*, 2002) but does not appear to activate the SLC (Dallas *et al.*, 2002). Whereas both MMP-9 and MMP-2 activate SLC (Yu and Stamenkovic, 2000), MMP-9, but not MMP-2, appears to be able to cleave LTBP1 (Dallas *et al.*, 2002). Other studies have shown that stromelysin-1 (MMP3) can cleave LTBP1 and release LLC from the matrix for subsequent activation by other proteases (Maeda *et al.*, 2002). Together, these observations suggest that combinations of proteases may be involved in the activation of TGFβ, i.e., activation may occur via a series of sequential proteolytic cleavage events that may be different in specific tissues.

Thrombospondin-1 (TSP-1) is a matricellular protein that activates both small and large latent TGFβ by inducing a conformational change in LAP (reviewed in Murphy-Ullrich and Poczatek, 2000). This occurs via a two-step process involving binding of TSP-1 to LAP, followed by release of active TGFβ. A KRFK amino acid motif in the type I repeats of TSP-1 binds to a conserved LSKL sequence in the N terminus of LAP. A synthetic KRFK peptide by itself can activate latent TGFβ (Schultz-Cherry *et al.*, 1995) and, conversely, a synthetic LSKL peptide acts as an antagonist to prevent TSP-1 activation of latent TGFβ. There are obvious potential therapeutic applications for such inhibitory or stimulatory peptides in diseases of TGFβ misregulation (see Section XI). A recent study showed that the LSKL sequence in LAP is also essential for LAP binding to TGFβ (Young and Murphy-Ullrich, 2004). Presumably, the mechanism by which TSP-1 activates latent TGFβ is by occupying this site, thereby preventing TGFβ and LAP from forming a stable complex. In support of an *in vivo* role for TSP-1 in TGFβ activation, the TGFβ-1 null and TSP-1 null mice share a partially overlapping phenotype (Crawford *et al.*, 1998). Furthermore, treatment of TSP-1 null mice with the KRFK peptide that activates TGFβ rescues several of the abnormalities in these mice. Although TSP-1 is known to be expressed in skeletal tissues, future studies are needed to determine whether it contributes to TGFβ activation in the skeleton.

Another proposed mechanism for TGFβ activation *in vivo* is via interactions with cell surface integrins (reviewed in Sheppard, 2005). Munger and colleagues identified the $\alpha_v\beta_6$ integrin as an activator of TGFβ (Munger *et al.*, 1999), and Mu *et al.* (2002) reported activation of latent TGFβ by $\alpha_v\beta_8$ integrins through a mechanism that also requires MT1-MMP activity. In the case of $\alpha_v\beta_6$, the activation occurs through binding between the RGD sequence in the TGFβ-1 LAP and the $\alpha_v\beta_6$ integrin. This would theoretically allow TGFβ to be activated in a spatially restricted manner that would prevent the free diffusion of the activated growth factor away from the cell surface (Sheppard, 2001). These authors also generated mutant forms of the β_6 subunit that bound LAP efficiently but did not activate the latent complex, suggesting that integrin ligation alone is not sufficient for latent TGFβ activation. They presented evidence that the cytoskeleton is required. One possibility is that, after binding of LAP to cell surface integrins, a mechanical force may be applied to LAP via the actin cytoskeleton in a manner analogous to the mechanical stretching of fibronectin during its assembly on the cell surface (Pankov *et al.*, 2000). This may induce a conformational change in LAP to allow activation of the growth factor. In support of an *in vivo* role for $\alpha_v\beta_6$ integrins in TGFβ activation, integrin β_6 null mice showed greatly reduced lung fibrosis compared to wild-type animals, presumably due to less activation of TGFβ (Munger *et al.*, 1999). However, as $\alpha_v\beta_6$ integrin expression is limited to epithelia, this activation mechanism may be cell-type specific. Although an integrin-mediated TGFβ activation mechanism seems

likely in skeletal tissues, the specific integrins that may be involved in such a mechanism have yet to be determined.

The mechanisms for activation of TGFβ in bone are not yet fully understood, and much work remains to be done to define these important pathways. Isolated avian osteoclasts upon treatment with retinol were shown to activate latent TGFβ (Oreffo *et al.*, 1989), but this activation was not dependent on plasmin (Bonewald *et al.*, 1997). Similarly, Oursler (1994) showed that avian osteoclast-like cells produced and activated latent TGFβ but saw no significant inhibition of activation using a series of protease inhibitors, including those that block plasmin. However, a combination of five protease inhibitors significantly blocked activation, suggesting a potential role for proteases. Osteoclasts also appear to be able to cleave LTBP1 via the action of serine proteases and/or MMPs to release a soluble LLC from bone ECM, which may facilitate activation of bone matrix bound TGFβ (Dallas *et al.*, 2002). Interestingly, bone is one of the few tissues for which an acid-mediated activation mechanism may be physiological. A mild acid pH (4.5) is sufficient for activation of latent TGFβ (Lyons *et al.*, 1988), which is similar to the pH generated within the osteoclast resorption lacunae (Silver *et al.*, 1988). Thus, resorbing osteoclasts may be able to activate latent TGFβ within their acidic microenvironment (Oreffo *et al.*, 1989). Much less is known concerning the mechanisms of latent TGFβ activation in osteoblasts. Human osteoblast-like cells treated with glucocorticoids activate latent TGFβ (Oursler *et al.*, 1993). Parathyroid hormone-treated osteoblast-like cells, UMR-106–01 cells, and neonatal mouse calvarial cells appear to activate latent TGFβ using the plasminogen activator system (Yee *et al.*, 1993). Karsdal and colleagues have shown that TGFβ activation via MT1-MMP expressed on the cell surface of osteoblasts may play a role in maintaining their viability during the transition from osteoblast to osteocyte (Karsdal *et al.*, 2002). A noncellular mechanism has been described in cartilage in which latent TGFβ is activated by extracellular organelles called matrix vesicles that are associated with matrix calcification (Boyan *et al.*, 1994). Alone, these organelles have no effect on latent TGFβ; however, upon pretreatment of matrix vesicles with $1,25(OH)_2D_3$, both recombinant latent TGFβ-1 and TGFβ-2 are activated. Matrix vesicles contain proteases, such as plasminogen activator, and therefore one of the nongenomic effects of $1,25D_3$ on the membranes of these organelles may be the release of TGFβ-activating proteases

To date, there does not appear to be an extensive literature on potential isoform-specific differences in activation of latent TGFβ complexes. However, a recent study has shown that prostate-specific antigen (PSA) preferentially activates latent TGFβ-2 but not latent TGFβ-1 (Dallas *et al.*, 2005). In the same study, PSA was shown not to cleave LTBP1 or release bone matrix-bound latent TGFβ. Clearly, further studies are needed to better define the complex and potentially tissue-specific and isoform-specific *in vivo* activation mechanisms for TGFβ in the skeleton, as well as in other cell systems, as this may represent a key step in the regulation of these potent growth factors.

LATENT TGFβ-BINDING PROTEINS (LTBPs)

The TGFβs may be unique among growth factors because of their intimate association with and regulation by the LTBPs (see Fig. 1). The LTBPs are a family of four extracellular glycoproteins ranging in size from 125 to 240 kDa. They share homology and structural similarities with the fibrillins and are therefore grouped together as members of a larger superfamily including the fibrillins 1–3 and LTBPs 1–4 (reviewed in Hyytiainen *et al.*, 2004; Todorovic *et al.*, 2005). LTBPs are well established as major regulators of TGFβ actions and appear to exert control at multiple levels in the TGFβ growth factor pathway. Thus, LTBPs may facilitate secretion of latent TGFβ from the cell (Miyazono *et al.*, 1991), provide a mechanism for targeting of TGFβ to the matrix (Taipale *et al.*, 1994; Dallas *et al.*, 1995; Olofsson *et al.*, 1995), and may also provide a mechanism for release of the latent growth factor through proteolytic cleavage of LTBP (Dallas *et al.*, 1995, 2002; Taipale *et al.*, 1995). LTBPs have also been shown to play a role in latent TGFβ activation in certain cell systems (Flaumenhaft *et al.*, 1993; Annes *et al.*, 2004). In particular, ECM targeting of TGFβ, via LTBPs, appears to be essential for latent TGFβ activation via $\alpha_V\beta_6$ integrins on the cell surface (Annes *et al.*, 2004; Fontana *et al.*, 2005).

Independent of their role in regulation of TGFβ, the LTBPs may have other functions. For example, it is now known that, unlike the other LTBP isoforms, LTBP2 does not interact with TGFβ (Gleizes *et al.*, 1996; Saharinen *et al.*, 1996). Therefore its role may be primarily as an extracellular matrix protein. Ninety percent of the LTBP1 in osteoblasts is produced without association with TGFβ, and LTBP1 colocalizes with fibrillin-1 in microfibrillar structures (Dallas *et al.*, 2000). Therefore, independent from its association with TGFβ, LTBP1 appears to function as an extracellular matrix protein required for new bone formation. Both antibodies and antisense oligonucleotides to LTBP1 inhibit the formation of bone-like nodules by fetal rat calvarial cells (Dallas *et al.*, 1995), which cannot be mimicked by antibodies to TGFβ.

The LTBPs, like the fibrillins, have a repeating domain structure consisting predominantly of cysteine-rich repeats of two types. These include 6-cysteine (EGF-like) repeats, similar to motifs found in epidermal growth factor (EGF) precursor, and 8-cysteine repeats (termed "TB repeats"). The TB repeats are unique to the LTBPs and fibrillins and importantly, the site for binding with LAP is located within the third TB repeats in LTBPs 1, 3, and 4 (Gleizes *et al.*, 1996; Saharinen

et al., 1996). Specificity for LAP binding is conferred by a four-amino-acid intervening sequence between the sixth and seventh conserved cysteines in the third TB repeat (Saharinen and Keski-Oja, 2000), which is not present in LTBP2. LTBP4 binds more weakly than LTBPs 1 and 3, which is likely due to sequence differences in this four amino acid motif (Saharinen and Keski-Oja, 2000; Chen *et al.*, 2005).

Although all four LTBP isoforms are widely expressed, they do have different tissue distributions, and LTBPs 1 and 3 may be particularly important in bone. In the skeleton, LTBP1 is expressed in early and late differentiated osteoblasts and colocalizes with fibrillin-1 in osteoblast extracellular matrix *in vitro* (Dallas *et al.*, 2000). *In vivo* it is present in cartilage matrix and is colocalized with fibrillin-1 in the periosteum and perichondrium (Dallas *et al.*, 2000). LTBP3 is expressed in osteoblasts, periosteal cells, chondrocytes, and perichondrial cells of the developing skeleton, as well as in articular cartilage and within the presumptive growth plate (Yin *et al.*, 1995). As will be described later in this chapter, gene deletion of LTBP3 results in skeletal abnormalities.

TGFβ RECEPTORS

Members of the TGFβ superfamily signal through a receptor system consisting of two type I and two type II transmembrane receptors with serine/threonine kinase activity. Type III receptors have also been identified that may indirectly regulate signaling through modulation of ligand binding specificity. The TGFβ receptor structure and signaling serves as a model for the rest of the TGFβ family, including BMPs, GDFs, and activins, each of which also plays important roles in the skeleton.

Essentially all cells express receptors for TGFβ (reviewed in Heldin *et al.*, 1997; Hu *et al.*, 1998), and all three TGFβ receptor types are expressed throughout the skeleton, including in cells of the osteoblast and osteoclast lineages (Horner *et al.*, 1998; Kaneda *et al.*, 2000). The type II receptor (TβRII) is responsible for binding to the TGFβ1, TGFβ2, or TGFβ3 ligands. The ligand-bound TβRII then recruits type I receptors to form a heterotetrameric complex, which mediates downstream signaling. Of the three type I receptors that can interact with the TGFβ/TβRII complex (ten Dijke and Hill, 2004), only Alk5 (called TβRI) has yet been implicated in TGFβ signaling in bone. In addition to the type I and II receptors, both of the known type III receptors, betaglycan and endoglin, are present in bone (Segarini *et al.*, 1989).

The TGFβ receptors are transmembrane glycoproteins with a conserved protein structure. Both type I and type II receptors have short extracellular domains with a long cytoplasmic region that mainly consists of a serine/threonine kinase domain. TGFβ binds directly to the type II receptor, which is a constitutively active kinase. The ligand-bound TβRII is then recognized by the type I receptor. These form a complex in which the type II receptor phosphorylates the type I receptor, initiating its kinase activity. Phosphorylation propagates signaling to downstream substrates. For example, phosphoserines in the conserved SGSGSGLP motif of the type I receptor bind Smad proteins. TβRI then phosphorylates Smads, resulting in their release and the subsequent activation of the TGFβ signaling cascade (Attisano *et al.*, 1994).

The type III receptor, betaglycan, can bind to all three TGFβ isoforms and may play a role in presenting TGFβ to the type II receptor (Lopez-Casillas *et al.*, 1993). Glycosylation of the extracellular domain of betaglycan is regulated and likely affects whether these receptors promote or antagonize TGFβ signaling. Glycosylated type III receptor facilitates the presentation of ligand to TβRII. This appears to be particularly important for the TGFβ2 isoform, which cannot efficiently bind to TβRII independently of betaglycan (Stenvers *et al.*, 2003). However, addition of certain glycosaminoglycan chains to betaglycan can inhibit formation of TβRI/TRII complexes (Eickelberg *et al.*, 2002). Betaglycan has a short intracellular domain with no kinase activity. This domain binds β-arrestin following phosphorylation by TβRII, and this interaction is thought to mediate receptor endocytosis, thereby downregulating TGFβ signaling (Chen *et al.*, 2003). The other type III receptor, endoglin, binds TGFβ1 and β3 in the presence of the type II receptor and may also regulate TGFβ signaling (Cheifetz *et al.*, 1992). Mice null for endoglin show a phenotype with many similarities to the TGFβ-1 and TβR11 knockout mice, suggesting an important role in TGFβ signaling *in vivo* (Bourdeau *et al.*, 1999). Further research is needed to fully understand the regulation and role of type III receptors in TGFβ signaling in bone.

The ratio and expression of the different TGFβ receptors can be modified by osteotropic factors. Studies on bone cells using crosslinking of radiolabeled TGFβ showed that PTH and BMP enhanced, whereas glucocorticoids reduced the binding of TGFβ to TβRI (Centrella *et al.*, 1991, 1995). The authors suggested that downregulation of the TGFβ receptor might be essential for osteoblast differentiation. At least part of this regulation has been explained at the transcriptional level. The osteoblast-specific transcription factor, Runx2, binds to the TβRI promoter and confers glucocorticoid dependent regulation of TβRI (Chang *et al.*, 1998; Ji *et al.*, 1998). Because Runx2 integrates signals from several osteotropic pathways, including estrogen, parathyroid hormone, and BMPs, this mechanism may couple TGFβ signaling to the progression of osteoblast differentiation (Chang *et al.*, 1998; McCarthy *et al.*, 2003).

TGFβ SIGNALING PATHWAYS

TGFβ family receptors have multiple signaling effectors. Among the direct substrates for TGFβ type I receptors,

the Smad family of intracellular signaling molecules appear to play a central role in TGFβ signaling and have been investigated most extensively (reviewed in Shi and Massague, 2003; ten Dijke and Hill, 2004). Additionally, TGFβ activates signaling by Smad-independent pathways, including signaling via MAP-kinase (MAPK), ERK, p38 MAPK and G protein-mediated pathways to regulate AP-1 and other downstream effectors in osteoblast differentiation (for review, see de Caestecker *et al.*, 2000). Many other proteins that bind TGFβ receptors or Smads facilitate TGFβ crosstalk with other signaling pathways, which may also be important in the intricate cellular regulation of the skeleton. However, this discussion focuses on proteins that participate directly in the TGFβ signaling pathway, with particular emphasis on those that have been shown to impact bone.

The Smad proteins are widely viewed as the major effectors of TGFβ signaling. These proteins are highly conserved and share structural homology through two domains called MH-1 and MH-2. Of the receptor-activated Smads (R-Smads), TβRI specifically phosphorylates and activates Smads 2 and 3. These two R-Smads bind to Smad4, a common mediator Smad (Co-Smad), to form a trimeric complex that can translocate to the nucleus to regulate the transcription of target genes (Feng and Derynck, 2005). Smad4 appears to be the only co-Smad available for TGFβ signaling and genome-wide searches have failed to identify any new Smad family members (Attisano *et al.*, 2001). TGFβ signaling is negatively regulated by the inhibitory Smads (I-Smads), Smad6 and Smad7 (Shi and Massague, 2003). I-Smads can compete with R-Smads for binding to the TGFβ receptor, but can also inhibit signaling via other mechanisms, including the recruitment of ubiquitin ligases to degrade components of the TGFβ signaling pathway.

The expression level, tissue localization, subcellular distribution, and stability of R-Smads, co-Smads, and I-Smads are tightly regulated (ten Dijke and Hill, 2004). The expression of Smads during skeletogenesis mirrors sites and times of known TGFβ family function (Sakou *et al.*, 1999). Both Smad2 and Smad3 are present in osteoblasts and osteoclasts and are required for normal skeletogenesis. Once activated, the R-Smads, in complex with Smad4, translocate to the nucleus to activate or repress gene transcription. The nuclear translocation of Smads is regulated in part by LEMD3, an inner nuclear membrane protein (Hellemans *et al.*, 2004; Lin *et al.*, 2005). In humans, loss of LEMD3 function causes osteopoikilosis, a skeletal dysplasia characterized by symmetric but unequal distribution of hyperostotic bone (Hellemans *et al.*, 2004).

In the nucleus, Smad DNA binding occurs with relatively low affinity and specificity. Therefore, Smads typically interact with other sequence-specific transcription factors to confer TGFβ-responsive gene transcription. For example, Smad3 interacts specifically with the vitamin D nuclear receptor, VDR, at a VDR consensus DNA binding site. Activation of TGFβ signaling results in a Smad3-mediated enhancement of VDR-dependent transcription (Yanagi *et al.*, 1999; Yanagisawa *et al.*, 1999). This cooperative activity may have implications for bone growth and remodeling, because TGFβ and $1,25(OH)_2D_3$ have been shown to synergistically increase alkaline phosphatase activity in cultured osteoblasts (Bonewald *et al.*, 1992; Wergedal *et al.*, 1992).

Abundant evidence, including the fact that cells lacking Smad4 can still respond to TGFβ, supports the existence and importance of Smad-independent TGFβ signaling pathway(s) (Sirard *et al.*, 1998; Dai *et al.*, 1999). In studies using a mutated TβRI that was defective in recruitment of Smads, activation of the MAPK pathway was observed in response to TGFβ (Yu *et al.*, 2002; Itoh *et al.*, 2003). In mammary epithelial cells, this mutant receptor was able to activate p38 and stimulate apoptosis but was not sufficient to induce epithelial to mesenchymal transition (Yu *et al.*, 2002). Further support for a role for the MAPK pathway comes from studies in which various TGFβ-induced responses were impaired by inhibiting components of the MAPK pathway, either using inhibitors or dominant negative expression constructs (reviewed in Janssens *et al.*, 2005). TGFβ activation of MAPK pathways has been shown to lead to ERK, c-Jun N-terminal kinase (JNK) and p38 MAPK activation and subsequent phosphorylation of components of the Jun, Fos and ATF family of transcription factors (reviewed in Mulder, 2000). TGFβ activated kinase (TAK1) is a member of the MAPK family that is also activated in response to TGFβ (Yamaguchi *et al.*, 1995). Mice null for its binding protein, TGF-beta activated kinase-1 binding protein-1 (TAB1) exhibit delayed ossification, bony malformations and reduced TGFβ responsiveness (Komatsu *et al.*, 2002). Other substrates for the type I receptor have been reported, including FKBP12, WD40, and farnesyl transferase (for review see Derynck and Zhang, 2003). However, the signaling function of these pathways is less clear than the Smad pathway.

In osteoblasts and osteoblast-like cell lines, TGFβ activation of MAPK signaling is required for several critical events, including; changes in cell morphology (Karsdal *et al.*, 2001), type I collagen and collagenase 3 expression (Palcy and Goltzman, 1999; Selvamurugan *et al.*, 2004), inhibition of osteocalcin, alkaline phosphatase and mineralization (Lai and Cheng, 2002; Sowa *et al.*, 2002), and osteoblast to osteocyte transition (Karsdal *et al.*, 2002). In osteoclasts, TGFβ-induced osteoclastogenesis (Karsdal *et al.*, 2003) and osteoclast chemotaxis (Pilkington *et al.*, 2001) have both been shown to be dependent on MAPK. Some of these events may be dependant on dual signaling through both the MAPK and Smad-dependent pathways.

Crosstalk occurs between the Smad and MAPK pathways, which increases the complexity of the signaling response. This may occur through physical interactions between molecular components of the two pathways

(reviewed in Janssens *et al.*, 2005). For example, JNK has been shown to phosphorylate Smad3, enhancing its activation (Engel *et al.*, 1999). However, such crosstalk can also have antagonistic effects. For example, TGFβ-activated c-Jun enhanced the interaction of Smad2 with a co-repressor, thus inhibiting Smad2 signaling (Pessah *et al.*, 2001).

A major mechanism by which TGFβ regulates osteoblast function may be through its effects on the transcription factor, Runx2, which occur through both Smad-dependent and Smad-independent TGFβ signaling pathways (reviewed in Ito and Miyazono, 2003). Whereas BMP-activated Smads 1 and 5 bind and activate Runx2 in osteoblasts, the TGFβ responsive Smad3 represses Runx2 function (Zhang and Derynck, 2000; Zhang *et al.*, 2000). Specifically, Smad3 binds and represses Runx2 transactivation of the Runx2 and osteocalcin promoters (Alliston *et al.*, 2001). This occurs by recruitment of transcriptional co-repressors, HDACs 4 or 5, to the Smad3/Runx2 complex (Kang *et al.*, 2005). In contrast to Smad3, Smad2 does not repress Runx2 function, but may act to enhance it (Alliston *et al.*, 2001; Selvamurugan *et al.*, 2004). These interactions may be greatly facilitated by the targeting of Smads and Runx2 to the same intranuclear foci through Runx2 binding to the nuclear matrix (Zaidi *et al.*, 2002). Additionally, the transcriptional co-regulator, menin, further modulates the activity of BMP- and TGFβ-activated Smad/Runx2 complexes to help control the progression of osteoblast differentiation (Sowa *et al.*, 2003).

In addition to the Smad-dependent pathway discussed above, TGFβ also regulates Runx2 function by Smad-independent mechanisms. Thus, the balance between these two pathways may be critical for the progression of osteoblast differentiation. For example, whereas TGFβ-activated Smad3 represses Runx2 function, TGFβ activation of ERK 1 and 2 and p38 MAPK enhances Runx2 phosphorylation and function (Selvamurugan *et al.*, 2004). Additionally, TGFβ increases Runx2 longevity by inducing p300-dependent acetylation of Runx proteins to prevent their association with the Smurf ubiquitin ligases and their subsequent degradation (Jin *et al.*, 2004). Whether or not Smads are required for TGFβ-dependent Runx2 acetylation remains unknown.

Because TGFβ can regulate Runx2 function by several mechanisms, and because Runx2 is a key regulator of TβRI expression, TGFβ and Runx2 form a regulatory feedback loop that may control the progression of osteoblast differentiation. Both the TGFβ pathway and Runx2 integrate information from multiple signaling pathways to modulate their respective activities. For example, in mesenchymal stem cells, TGFβ crosstalks with the Wnt signaling pathway by inducing the translocation of β-catenin in a Smad3-dependent manner (Jian *et al.*, 2006). Smad3 is also implicated in the PTH-dependent increase in osteoblast β -catenin levels (Tobimatsu *et al.*, 2006).

Overall, the delicate balance of Smad and non-Smad-mediated signaling, together with the crosstalk of TGFβ with other signaling pathways, may explain the ability of TGFβ to promote some aspects of osteoblast differentiation while inhibiting others. Furthermore, the subtleties of this regulation may be difficult to replicate *in vitro,* which likely explains some differences across studies of TGFβ action in bone, as will be discussed in the following section. Genetically modified animal models are powerful tools that will likely be the major approach for the future elucidation of the physiologically relevant signaling pathways in bone and other tissues (see Section X).

IN VITRO EFFECTS OF TGFβ ON BONE CELLS

TGFβ is a potent multifunctional cytokine whose major effects in the body appear to be as a regulator of cell growth, a stimulator of matrix production, and an inhibitor of the immune system. TGFβ is also a key player in several human diseases, including fibrotic disorders (reviewed in Sheppard, 2006; Leask, 2007), aortic aneurisms (Loeys *et al.*, 2005; Pannu *et al.*, 2005), and various types of cancer, where TGFβ has been implicated as a tumor suppressor (Buck and Knabbe, 2006; Jakowlew, 2006). Clearly, the actions of TGFβ are widespread; however, here we will focus on the effects of TGFβ in bone cells.

The discovery of large amounts of TGFβ stored in bone matrix led to reports from several laboratories that TGFβ is a major player in bone remodeling. Numerous *in vitro* studies have examined the actions of TGFβ on bone cells, and the data appear to be somewhat contradictory. Upon reviewing these studies, it becomes apparent that the effects of TGFβ in different bone cell culture systems depend upon factors such as the differentiation stage of the cells, the cell density, culture conditions, and concentrations of TGFβ. However, it is clear that TGFβ has dramatic effects at every stage of the bone remodeling process, affecting both bone resorption and bone formation (reviewed in Janssens *et al.*, 2005). A general consensus from the literature is that TGFβ, released and activated by resorbing osteoclasts, stimulates subsequent bone formation by recruiting osteoblast precursors and stimulating them to proliferate, thereby expanding the pool of committed osteoblasts. Thus, TGFβ has been viewed as a "coupling factor" that links bone resorption to subsequent bone formation. TGFβ also stimulates osteoblasts to synthesize extracellular matrix proteins. However, if TGFβ is not downregulated during later phases, it will actually inhibit the later phases of osteoblast differentiation and mineralization. Some of the key studies providing evidence for the involvement of TGFβ at the various stages of bone remodeling are summarized in the following section.

In contrast to BMPs, TGFβ does not induce uncommitted mesenchymal cell lines to differentiate along the osteoblastic pathway (Katagiri *et al.*, 1994). However,

once these cells have become committed to the osteoblastic lineage, TGFβ can act as a potent chemotactic factor to recruit osteoblast precursors to sites of bone formation (Lucas, 1989; Pfeilschifter *et al.*, 1990; Hughes *et al.*, 1992). A chemotactic epitope of TGFβ has been identified at residues 368 to 374 (Postlethwaite and Seyer, 1995), which induces the chemotactic migration of neutrophils, monocytes, and fibroblasts. However, this peptide has yet to be tested on osteoblast precursors. Many studies using cell lines, osteoblast-enriched cell cultures or bone organ cultures have reported that TGFβ has a mitogenic effect on osteoblast precursors (Centrella *et al.*, 1986; Robey *et al.*, 1987; Hock *et al.*, 1990; Chen and Bates, 1993). In contrast, other studies have suggested a growth inhibitory effect of TGFβ on osteoblasts (Noda and Rodan, 1986; Antosz *et al.*, 1989). The differences in results are probably due to biphasic effects of TGFβ at high versus low concentrations, as well as the culture conditions and differentiation state of the cells.

TGFβ is well known as a potent stimulator of ECM protein expression in numerous cell types and often also inhibits expression of proteases that degrade ECM proteins, leading to an overall accumulation of ECM (Roberts, 1998). However, published reports have shown both stimulatory and inhibitory effects of TGFβ on type I collagen production in osteoblasts (reviewed in Bonewald and Dallas, 1994; Janssens *et al.*, 2005). Similarly, conflicting data have been reported concerning the effects of TGFβ on fibronectin, osteopontin, osteonectin, and decorin expression as well as on expression of alkaline phosphatase (reviewed in Bonewald and Dallas, 1994; Janssens *et al.*, 2005). The stimulatory effects are generally seen in the earlier stages of osteoblast differentiation. In contrast, the effects of TGFβ in late osteoblasts and on the mineralization process are mostly inhibitory. It has been shown to suppress markers of the calcified matrix, such as osteocalcin, in fetal rat calvarial cells and ROS 17/2.8 osteoblast-like cells (Noda and Rodan, 1989; Harris *et al.*, 1994). Although TGFβ stimulates the formation of osteoid, it actually appears to suppress mineralization of the osteoid (reviewed in Bonewald and Dallas, 1994; Janssens *et al.*, 2005). For example, TGFβ suppresses the mineralization of fetal rat calvarial cells (Harris *et al.*, 1994). One potential reason for the differential effects of TGFβ on early versus late osteoblasts is that there appears to be a decrease in expression of TβRI and TβRII during the transition from pre-osteoblasts to maturing osteoblasts (Centrella *et al.*, 1995; Takeuchi *et al.*, 1996). This may be mediated by TGFβ downregulating expression of its own receptors (Centrella *et al.*, 1996; Gebken *et al.*, 1999). Additionally, many of the effects of TGFβ on bone formation are likely mediated via Runx2, and in later stages of differentiation, TGFβ antagonizes the effects of BMP2 on Runx2 (Spinella-Jaegle *et al.*, 2001). This may be mediated by physical interaction of TGFβ-activated Smad3 with Runx2 to inhibit its binding to Runx2-responsive elements, including one within the Runx2 promoter itself (Alliston *et al.*, 2001).

In vitro studies examining the effects of TGFβ on osteoclast activity are equally complex and many studies again appear to be contradictory. This is partly due to the variety of different culture models used, some of which examine formation of osteoclasts from mononuclear precursors, in either the presence or absence of supporting cells, and some of which examine bone resorption by mature osteoclasts. Spleen cells, bone marrow cells, and peripheral blood mononuclear cells from various species have all been used as sources of osteoclast precursors and/or mature osteoclasts for these studies. An overall consensus from the literature is that TGFβ regulates all the stages in osteoclast resorption, including recruitment of osteoclast precursors to the resorption site, differentiation into the mature osteoclast, bone resorption, and osteoclast apoptosis. Similar to other modulators of osteoclastic activity, these effects of TGFβ on osteoclasts either may represent direct actions of the growth factor on osteoclasts or their precursors or may be mediated indirectly via actions on osteoblasts and/or stromal cell populations.

In bone marrow cultures, which are heterogeneous populations containing both osteoclast precursors and osteogenic cells, TGFβ has biphasic effects. At concentrations in the picogram range, TGFβ stimulates the formation of osteoclast-like cells, but at nanogram concentrations TGFβ is inhibitory (reviewed in Fox and Lovibond, 2005; Janssens *et al.*, 2005). This appears to be mediated via modulation of expression of RANKL, OPG, and M-CSF in the stromal cell populations, because low concentrations of TGFβ increase the ratio of RANKL to its inhibitor, OPG, and increase expression of M-CSF, all of which act to enhance osteoclast formation (Takai *et al.*, 1998; Karst *et al.*, 2004). In contrast, at higher concentrations of TGFβ, expression of RANKL and M-CSF is reduced and OPG is increased (Karst *et al.*, 2004).

In cultures of isolated osteoclasts grown in the presence of RANKL and M-CSF (i.e., without supporting stromal cells), many investigators have reported stimulation of osteoclast-like cell formation by TGFβ (reviewed in Fox and Lovibond, 2005; Janssens *et al.*, 2005). These osteoclastogenic effects are likely due to direct actions of TGFβ on osteoclast precursors to upregulate their expression of RANK, the receptor for RANKL, as well as NFκB. Clearly, the situation *in vivo* is more complex than in these isolated cell culture systems, where the responses of stromal cells and immune cells to TGFβ also affect the process of osteoclastogenesis.

In studies that have examined the effects of TGFβ on bone resorption, again the outcome depends on the type of culture model used and the presence of other cell types. When the assay requires differentiation of osteoclasts from their mononuclear precursors, as in the fetal rat long bone

resorption assay, TGFβ is usually found to be inhibitory, consistent with its inhibitory effects on osteoclastogenesis (Pfeilschifter *et al.*, 1988; Dieudonne *et al.*, 1991; Hattersley and Chambers, 1991). In contrast, when the assay starts with already formed osteoclasts, such as in the calvarial resorption assay, TGFβ has almost invariably been found to be stimulatory (Tashjian *et al.*, 1985; Lerner, 1996). These stimulatory effects may be mediated by the generation of prostaglandins by TGFβ (Tashjian *et al.*, 1985), possibly via induction of prostaglandin synthase II in osteoblasts (Pilbeam *et al.*, 1993).

Another important level at which TGFβs may control bone resorption is by inducing the apoptosis of mature osteoclasts (Hughes *et al.*, 1996). TGFβ regulates apoptosis or programmed cell death in a number of tissues, such as liver, uterine epithelial cells, and hemopoietic cell lines, and will cause cell death of various tumor cell lines, such as prostate, liver, and kidney tumors (reviewed in Bursch *et al.*, 1992). TGFβ also induces programmed cell death in osteoclasts and antagonizes the effects of cytokines such as IL-6 that promote osteoclast survival (Hughes *et al.*, 1996). Because active TGFβ is thought to be released from the bone matrix during osteoclastic resorption (Pfeilschifter and Mundy, 1987), an intriguing theory is that TGFβ promotes osteoclast apoptosis as a negative feedback mechanism to limit the extent of bone resorption within a healthy bone. Theoretically, this would be achieved via its actions on osteoclasts to induce apoptosis and on osteoblasts to reduce RANKL expression (reviewed in Fox and Lovibond, 2005). This negative feedback mechanism would then presumably be overridden in pathological states by a strong stimulus to promote osteoclast survival, such as IL-6 or IL-1.

In summary, the use of *in vitro* culture systems has been and will continue to be a powerful tool to identify the cellular and molecular pathways involved in mediating the effects of TGFβ on osteoblasts and osteoclasts. However, care must be taken when interpreting the results of these *in vitro* studies, and the strengths and limitations of the various assays should always be considered when making conclusions.

IN VIVO EFFECTS OF TGFβ ON BONE

TGFβ will induce new bone formation if injected in close proximity to bone. However, unlike the bone morphogenetic proteins, TGFβ does not stimulate bone formation when injected into ectopic sites. Early *in vivo* experiments in which TGFβ was injected over the calvaria of mice showed conclusively that TGFβ stimulates new mineralized bone formation (Noda and Camilliere, 1989; Mackie and Trechsel, 1990; Marcelli *et al.*, 1990). TGFβ has also been shown to initiate chondrogenesis and osteogenesis when applied to the rat femur (Joyce *et al.*, 1990). Soon after these studies were performed, it was shown that a single injection of TGFβ1 can induce bone closure of a nonhealing skull defect (Beck *et al.*, 1991). Several independent studies have confirmed the usefulness of TGFβ1 in repair of large bone defects (Kamakura *et al.*, 2001; Dean *et al.*, 2005; Srouji *et al.*, 2005) and in implant fixation (Lin *et al.*,2001; Sumner *et al.*, 2006). When TGFβ is combined with demineralized bone matrix, an acceleration of osteoinduction is observed, together with increased resorption of the demineralized bone matrix carrier (Kibblewhite *et al.*, 1993). Prostaglandins may be important for some of the effects of TGFβ on osteogenesis (Mackie and Trechsel, 1990; Marcelli *et al.*, 1990).

Systemic administration of TGFβ stimulates cancellous bone formation in both juvenile and adult rats (Rosen *et al.*, 1994), in the hindlimb unloaded rat (Machwate *et al.*, 1995), and in the aging mouse model (Gazit *et al.*, 1999). However, Kalu and co-workers (1993) did not find significant effects of TGFβ2 on cancellous bone loss after ovariectomy. Even though no significant effect was observed on bone loss, TGFβ2 did prevent the increase in TRAP(+)-multinucleated cells and caused a decrease in the number of trabecular osteoclasts. These studies suggest that bone loss in these different systems is mediated through different mechanisms and that TGFβ treatment may be more efficacious in some conditions of bone loss as compared to others. Perhaps in the ovariectomized rat model, resorption is accelerated greatly beyond the levels of formation so that TGFβ has little effect on bone loss. Interestingly, from *in vivo* models examining the effects of injections of TGFβ over murine calvaria (see earlier discussion), it was only after the injections of TGFβ had ceased that the osteoid became mineralized. Together these data suggest that TGFβ may be required to initiate new bone formation, but that it must be removed before mineralization can proceed.

Agents that regulate bone formation or resorption appear to alter the amount of TGFβ in bone. For example, bones from ovariectomized rats have less TGFβ than normal rats (Finkelman *et al.*, 1992), vitamin D-deficient rats have less TGFβ than vitamin-replete animals (Finkelman *et al.*, 1991), and studies using intermittent treatment with parathyroid hormone showing increased bone mass also show increased TGFβ (Pfeilschifter *et al.*, 1995). The only other factor that appears to share this characteristic with TGFβ is insulin-like growth factor.

BONE PHENOTYPES OF TRANSGENIC AND KNOCKOUT MICE WITH ALTERATIONS IN TGFβ ISOFORMS, LTBPs, AND COMPONENTS OF THE TGFβ SIGNALING PATHWAY

Loss-of-function and gain-of-function genetically modified mouse models have provided key insights into the role of

TGFβ signaling *in vivo*. Transgenic mice have been generated with targeted gene deletions of all three TGFβ isoforms, their binding proteins, LTBPs 3 and 4, and the type I and II TGFβ receptors, as well as their signaling effectors, Smads 2, 3, and 4. Except in the case of LTBP4, all of these knockout mouse models either are embryonic lethal prior to skeletogenesis or show bone defects ranging from moderate to severe, underscoring the critical importance of TGFβ signaling in both the embryonic and postnatal skeleton.

Mice with targeted gene deletions for each of the TGFβ isoforms have different phenotypes, suggesting that each isoform has specific nonoverlapping expression patterns and/or functions (i.e., deletion of a particular isoform of TGFβ in knockout animals cannot be compensated for by the other isoforms). Deletion of the TGFβ-1 gene results in premature death due to inflammatory disease (Shull *et al.*, 1992; Kulkarni and Karlsson, 1993; Boivin *et al.*, 1995). The mice appear normal until after weaning, when massive infiltration of lymphocytes and macrophages into multiple organs occurs, leading to organ failure and death. Interestingly, the reason for the appearance of this phenotype after weaning appears to be because TGFβ-1 can be transferred across the placenta and through the milk from the heterozygous mother to her offspring, leading to a maternal rescue prior to weaning (Letterio *et al.*, 1994).

To eliminate the effects of multifocal inflammation, TGFβ-1 null mice were generated on a severe combined immunodeficiency (SCID) background (Diebold *et al.*, 1995). Although inflammation is absent in these mice, due to the lack of T and B cells, and they do survive into adulthood, they are 50% to 80% of the size of their TGFβ-1-expressing littermates, show a lack of vigor, and do not thrive. Geiser and colleagues examined the skeletons of TGFβ1 deficient mice maintained on an immunosuppressive drug and showed that the width of the growth plate, their longitudinal bone growth, and total mineral content as well as the elastic properties of the bone were reduced (Geiser *et al.*, 1998). A subsequent study examined the properties of bones from TGFβ-1-null mice by histology and Fourier transformed infrared microscopy (Atti *et al.*, 2002). These authors showed a reduction in mineral content, mineral crystallinity, and collagen maturity in the cortical bone. There was also a dramatic depletion of osteoblasts on the trabecular bone surfaces, leading to an imbalance in modeling versus bone resorption. Together, the results of these studies are consistent with a potential role for TGFβ-1 in bone quality and in bone modeling.

Mice that lack the TGFβ-2 isoform show a perinatal lethal phenotype and exhibit a wide range of developmental defects, including cardiac, lung, eye, ear, and urogenital defects (Sanford *et al.*, 1997). The skeletal abnormalities include craniofacial defects as well as defects in the ribs, sternum, vertebrae, mandible, and long bones. The craniofacial defects include decreased size and reduced cranial ossification, agenesis of the alisphenoid and occipital bones, and mandibular abnormalities. Cleft palate was also observed but was not fully penetrant. The noncranial skeletal manifestations included limb laxity, bifurcation of the sternum, rib deformities, shortened radius and ulna, absence of specific muscle attachment sites, and vertebral defects resembling spina bifida occulta.

Mice lacking TGFβ-3 also show a perinatal lethal phenotype, probably due to delayed lung development (Kaartinen *et al.*, 1995). These mice show failure of the palatal shelves to fuse, resulting in cleft palate. No other craniofacial abnormalities were observed, suggesting that the effect of TGFβ-3 on palatal shelf fusion is not just a general defect in craniofacial development (Kaartinen *et al.*, 1995; Proetzel *et al.*, 1995). These studies corroborate those of Brunet *et al.* (1995), who found that antibody and antisense oligonucleotides to TGFβ-3 but not TGFβ-1 or TGFβ-2 prevented normal embryonic palate fusion in the mouse. Blavier *et al.* (2001) have further shown that TGFβ-3 deficient mice showed abnormalities in expression of MMPs and their inhibitor, TIMP-2, which may be responsible for the cleft palate phenotype. These studies implicate TGFβ-3 in the complex epithelial-mesenchymal interactions that facilitate correct positioning of the palatal shelves, remodeling of the extracellular matrix, and fusion of the palatal shelves.

Because a large proportion of TGFβ is found in association with LTBPs 1, 3, or 4, absence of or mutations in one of these proteins would also be expected to affect TGFβ processing, storage, and/or activation. Dabovic and co-workers have successfully deleted the gene for LTBP3 in mice (Dabovic *et al.*, 2002, 2005). Postnatally, these mice develop craniofacial skeletal abnormalities, including rounding of the cranial vault, overextension of the mandible, and ossification of the synchondroses. The animals also show reduced body size and kyphosis and develop osteosclerosis as well as severe osteoarthritis with age. Mice lacking LTBP4 exhibit lung emphysema, cardiovascular abnormalities, and colorectal cancer, but skeletal abnormalities have not been reported (Sterner-Kock *et al.*, 2002). As the phenotypes of these mice resemble those associated with perturbed TGFβ signaling, the abnormalities in both the LTBP3 and LTBP4 knockout mice have been interpreted as being primarily due to misregulation of TGFβ. Recent evidence supports this in the case of LTBP4 (Koli *et al.*, 2004), underscoring the importance of TGFβ interactions in the biology of these extracellular matrix proteins.

Deletion of TGFβ receptors results in embryonic lethality, precluding examination of their roles in skeletogenesis in conventional knockout models (reviewed in Chang *et al.*, 2002). However, the importance of TGFβ signaling in the skeleton has become apparent from humans and mice harboring mutations or tissue-specific deletions of TGFβ receptors. Humans with mutations in the TβRI and

TβRII genes exhibit craniosynostoses and cleft palate, as well as other soft-tissue abnormalities (Loeys *et al.*, 2005). Through these types of studies, the TGFβ pathway has emerged as a central regulator of palatogenesis, because targeted mutations in TGFβ-3, TβRI, TβRII, Smad2, or sometimes TGFβ-2 in mice all result in cleft palate (Proetzel *et al.*, 1995; Sanford *et al.*, 1997; Nomura and Li, 1998; Dudas *et al.*, 2004; Cui *et al.*, 2005). Conditional deletion of TβRII in Col2a-expressing cells using the Cre/lox recombinase system revealed that TβRII is also required for axial skeletal patterning (Baffi *et al.*, 2004, 2006). The size and spacing of the vertebrae were altered in these mice, and there were defects in closure of the neural arches. Intervertebral disks (IVDs) were either missing or incomplete. Mice that survived postnatally showed changes in the length of specific bones. The vertebral malformations in these mice are likely due to loss of TβRII expression in the sclerotome, which gives rise to the axial skeleton. Expression of a dominant negative TβRII later in osteoblast differentiation using the osteocalcin promoter showed that TβRII signaling is required for crosstalk between osteoblasts and osteoclasts (Filvaroff *et al.*, 1999). Loss of osteoblast TGFβ signaling in these mice resulted in decreased bone resorption and increased bone mass, showing that TGFβ participates in the homeostatic control of bone mass.

Gene deletions of the effectors of TGFβ signaling, the Smads, would be expected to produce phenotypes that overlap with knockouts of the ligands and their receptors. Because Smad4 is the only known co-Smad for all TGFβ superfamily members, it is not surprising that conventional knockout of Smad4 is early embryonic lethal (Sirard *et al.*, 1998; Yang *et al.*, 1998). However, mice with a conditional deletion of Smad4 in the chondrocytes showed dwarfism, associated with a disorganized growth plate in which the resting zone of chondrocytes was expanded and the proliferative zone was reduced (Zhang *et al.*, 2005). There was also increased hypertrophic differentiation and ectopic bone was observed in the perichondrium.

Homozygous or heterozygous deletion of Smad2 results in embryonic lethality, but Smad2 heterozygous embryos die later in development and exhibit abnormal mandibular development (Nomura and Li, 1998). Smad3-deficient mice are viable and exhibit an osteopenic phenotype (Borton *et al.*, 2001; Yang *et al.*, 2001). This is apparently because loss of Smad3 causes premature osteocyte apoptosis, which impairs production of bone matrix and alters its material properties (Borton *et al.*, 2001; Balooch *et al.*, 2005). Although Smads2 and 3 have 95% sequence homology, the differences in their knockout phenotypes suggest that they have nonoverlapping functions *in vivo.* They also appear to activate different sets of target genes and have different mechanisms of transcriptional activation, again suggesting the nonredundancy of their function (Yang *et al.*, 2003).

Transgenic mice overexpressing active TGFβ-2 driven by the osteocalcin promoter have been described as osteoporotic (Erlebacher and Derynck, 1996). These mice overproduce a constitutively active form of TGFβ2, which is therefore not regulated through the normal physiological control mechanisms of latency, matrix storage, and activation. Conversely, when the osteocalcin promoter is used to drive overexpression of the dominant-negative TGFβ type II receptor, the mice show increased bone mass (Filvaroff *et al.*, 1999). Together, these studies implicate TGFβ as a factor that couples bone resorption to bone formation. If excess amounts of TGFβ are present, then bone remodeling may become uncoupled. Thus, the osteoporotic and osteopetrotic phenotypes of these mouse models likely result from disruption of this coupling mechanism. Although the overall phenotypes appear to contradict many of the observations concerning TGFβ function outlined in the previous paragraphs, in part because of the pathological levels of TGFβ signaling in these transgenic models, such contradictions highlight the importance of the tight regulation of TGFβ expression and activation in bone. It must be expressed and activated at the appropriate time and location and then must be removed or inactivated. For example, excess amounts of TGFβ in mature osteoblasts, as occurs in the TGFβ2 overexpression model, actually appear to inhibit mineralization in the later stages of osteoblast maturation. Bone diseases can potentially result from an imbalance in TGFβ isoforms and their bioavailability, as will be discussed in the following section.

ROLE OF TGFβ IN HUMAN SKELETAL DISEASES

TGFβ has been implicated in a number of disorders of the skeletal system. A particularly exciting recent discovery was that mutations in the TGFβ-1 gene are responsible for Camurati-Engelmann disease (CED; reviewed in Janssens *et al.*, 2006). This is a rare autosomal progressive skeletal dysplasia characterized by hyperostosis and osteosclerosis that mainly affects the diaphyses of the long bones as well as the base of the skull (Fig. 2). Patients experience limb pain, muscular weakness, and a waddling gait and are easily fatigued. They may also have complications such as anemia, leukopenia, and hepatosplenomegaly. Several studies have shown that the genetic defect underlying this condition is mutation of the TGFβ1 gene. The majority of the mutations are in exon 4 in the region coding for the propeptide (LAP), and the Arg218 residue is a particular hot spot for mutations (reviewed in Janssens *et al.*, 2006). In general these mutations are close to cysteine residues 223 and 225 and are thought to cause premature activation of the latent TGFβ complex by destabilizing the disulfide bridging of the LAP homodimers, thereby reducing their ability to associate with mature TGFβ-1 (Saito *et al.*, 2001;

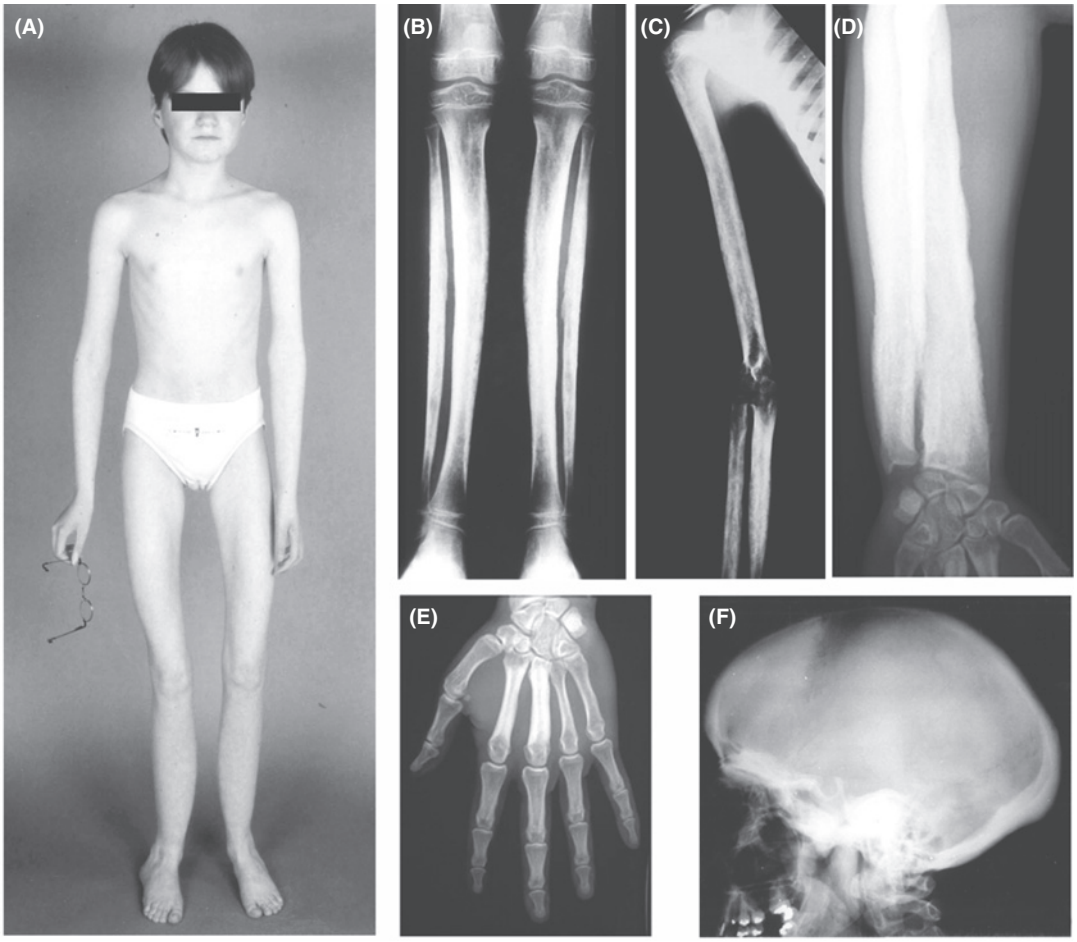

FIGURE 2 Clinical features of CED. (**A**) Clinical picture of a CED patient at the age of 15. Note the absence of subcutaneous fat (weight 27 kg), muscle hypotrophy, and valgus deformity of the knees and feet. Muscle weakness restricts her maximum walking distance to 20 to 50 m. Secondary sex characteristics (breast development, menstruation) were delayed. (**B**) AP radiographs of both lower legs of a CED patient. Note that there is cortical thickening and a severe modeling defect in the diaphyses of both tibiae and fibulae. (**C**) Radiograph of the right arm (AP view) of a CED patient, showing thickening of the cortex of the diaphyseal portion of the humerus, ulna, and radius, resulting in narrowing of the medullary canal. Note also the modeling defect of the long bones, which is most extensive at the diaphysis of the ulna. (**D**) Radiograph of the forearm of a CED patient. Marked cortical thickening at the diaphysis of the ulna and radius can be observed, causing obliteration of the medullary cavity and hypertrophy of the long bones. Note extension of the cortical sclerosis toward the distal metaphysis of the radius. (**E**) Radiograph of the left hand (AP view) of a CED patient, showing cortical sclerosis, cortical thickening, and medullary cavity obliteration at the diaphysis of metacarpals 2 and 3. (**F**) Radiograph of the skull (lateral view) of a CED patient. Sclerosis of the calvaria, the tympanic portion of the skull base, and the ascending ramus of the mandible is visible. Note relatively small frontal and sphenoidal sinuses resulting from adjacent sclerosis of the frontal bone and upper part of the face. The maxillary sinuses are spared. Images and figure legends reproduced with permission from Janssens *et al.* (2006), *Journal of Medical Genetics*, **43**, 1–11.

Janssens *et al.*, 2003). Other mutations in exon 1 impair secretion, leading to intracellular retention of the molecule. All the mutations investigated to date appear to increase the activity of TGFβ.

Because TGFβ1 and its receptors are widely expressed, it is surprising that the disease phenotype in CED is predominantly localized in the skeleton. Janssens and colleagues (2006) proposed that a potential reason for the skeletal predominance of the phenotype is that osteoblasts are one of the few cell types to secrete large amounts of their TGFβ as the small latent TGFβ complex, lacking LTBPs (Bonewald *et al.*, 1991; Dallas *et al.*, 1994). The presence of LTBP in the latent complexes of other cell types may have a protective effect so that stability of the complex is less affected by the CED mutations.

Recently, misregulation of TGFβ has been proposed to underlie many of the phenotypic features of Marfan syndrome, a disorder associated with mutations in the gene for fibrillin-1 reviewed in Judge and Dietz (2005) and Mizuguchi and Matsumoto (2007). The most serious clinical feature of this disease is the cardiovascular abnormalities that can lead to aortic dissection. However, these patients also exhibit skeletal abnormalities including tall stature due to overgrowth of the long bones, arachnodactyly, joint hypermobility, scoliosis, and pectus excavatum. Although fibrillin does not appear to directly bind TGFβ,

LTBP1 is structurally related to fibrillins and colocalizes with fibrillin-1 in cultured osteoblasts and in the periosteum (Dallas *et al.*, 2000). Fibrillin-1 binds to the C terminus of LTBP1 and may therefore indirectly regulate the bioavailability of TGFβ (Isogai *et al.*, 2003). Chaudhry and co-workers have recently shown that application of a fibrillin-1 peptide encoded by exons 44–49 causes release of TGFβ1 from the extracellular matrix. This appears to occur via inhibition of the association of the C terminus of LTBP1 with the N terminus of fibrillin-1 (Chaudhry *et al.*, 2007). Neptune and co-workers showed misregulation of TGFβ in the lungs of fibrillin-1-deficient mice and showed dramatic improvement of the lung phenotype by treatment with TGFβ neutralizing antibodies (Neptune *et al.*, 2003). The pharmacological manipulation of TGFβ has therefore now become a major avenue of research for the treatment of Marfan-related disorders. Interestingly, women with Marfan syndrome have increased osteopenia (Kohlmeier *et al.*, 1995). A potential explanation for this may be due to altered TGFβ signaling.

In addition to these genetically inherited disorders, TGFβ has been implicated in joint degenerative diseases, such as osteoarthritis (OA) and rheumatoid arthritis (RA). TGFβ expression is upregulated in synovial tissue from patients with OA and RA (Lafyatis *et al.*, 1989; Taketazu *et al.*, 1994; Szekanecz *et al.*, 1995). Through its anti-inflammatory properties, TGFβ is thought to protect against the development of RA (Lafyatis *et al.*, 1989). In particular, interleukin-1 (IL-1) may be one of the major mediators of cartilage degeneration in RA. TGFβ appears to antagonize its proinflammatory effects in chondrocytes (Takahashi *et al.*, 2005) and in synovial fluid from diseased joints (Lotz *et al.*, 1990). Another mechanism by which TGFβ antagonizes the effects of IL-1 may be by inhibiting expression of its receptor in articular chondrocytes (Redini *et al.*, 1993). Although the anti-inflammatory properties of TGFβ are beneficial, TGFβ also appears to have detrimental effects by promoting fibrosis and/or the formation of osteophytes. For example, Scharstuhl and colleagues showed that inhibition of TGFβ in a mouse model of OA prevented osteophyte formation but impaired cartilage repair (Scharstuhl *et al.*, 2002). In order to develop more effective therapies to treat RA and OA, there is clearly a need for agents that stimulate cartilage repair while at the same time inhibiting breakdown of the cartilaginous matrix. A potential approach for separating out the beneficial effects of TGFβ on cartilage repair from its negative effects on fibrosis was recently reported (Blaney Davidson *et al.*, 2006). In an animal model of IL-1-induced OA, adenoviral overexpression of TGFβ and Smad7 was used to show that overexpression of Smad7 reduced the amount of synovial fibrosis induced by TGFβ but did not reduce the beneficial effects of TGFβ on cartilage repair. This type of approach may therefore provide new opportunities for treatment of these debilitating diseases, and TGFβ is being actively explored as a potential therapeutic agent for joint degenerative diseases (reviewed in Grimaud *et al.*, 2002).

Although increased expression of TGFβ appears to occur in OA as a protective response against inflammation, in some cases downregulation of TGFβ signaling may play a causal role in the development of joint degenerative diseases. Disruption of Smad3 in mice is associated with an OA phenotype (Yang *et al.*, 2001). Further support for a role for TGFβ in the development of OA comes from studies showing that mice lacking the gene for LTBP3 developed OA (Dabovic *et al.*, 2002). These investigators interpreted the phenotype as being due to decreased TGFβ signaling (Dabovic *et al.*, 2005).

In addition to its role in the diseases discussed earlier, TGFβ has been implicated in osteoporosis. Thus, polymorphisms in TGFβ1 genes have been associated with increased risk of osteoporosis and alterations in TGFβ responsiveness or amounts of bone matrix-stored TGFβ have been reported in animal models of osteoporosis (reviewed in Fromigue *et al.*, 2004). However, the literature in this field is somewhat controversial and it is beyond the scope of this chapter to provide an extensive review on this topic. Several good reviews on this subject have been recently published, and the reader is referred to Chapters 73, 74, and 80 of this book for further information on osteoporosis.

TGFβ has been implicated as a tumor suppressor and TGFβ signaling appears to play a major role in many other steps in the progression to malignancy (reviewed in Pardali and Moustakas, 2007). Of particular significance in relation to skeletal biology is the established role of TGFβ as a key mediator of cancer–bone cell interactions in cancers that metastasize to bone, such as breast and prostate cancers (reviewed in Guise *et al.*, 2005)). Again, an extensive discussion of this topic is beyond the scope of the current chapter, and the reader is referred to Chapter 61 of this book for further information on bone metastatic cancers.

SUMMARY

The drive and determination to discover osteoinductive factors were responsible for the initial discovery of the TGFβs and other members of this superfamily in bone. However, with their discovery has come the challenge of unraveling their function in bone and the challenge to control the therapeutic use and delivery of these factors. Nature has developed a surprisingly complex system of regulation from latency and activation of the TGFβ molecule to an intricate system of receptors and a vast array of regulatory molecules that either enhance or inhibit the activity of this factor. Although in the past decade great advances have been made toward our understanding of the function and regulation of this growth factor in the skeleton, there are still many unanswered questions: What are the physiological mechanisms for activation of TGFβ in skeletal tissues?

How is TGFβ regulated by ECM proteins, and what are the specific roles and signaling pathways of the different isoforms? A greater understanding of TGFβ, its effects, and its regulation will be the key to developing its potential for use as a therapeutic in disorders of skeletal metabolism.

INTRODUCTION

BMPs influence all cell types that reside within the skeleton, but the information they provide to skeletal cells is highly context-specific. Here we discuss the current understanding of how BMPs work to regulate bone formation during skeletal development and postnatal skeletal growth, in maintaining bone mass, and during bone repair.

DISCOVERY OF BONE MORPHOGENETIC PROTEINS

The discovery of bone-inducing molecules, bone morphogenetic proteins (BMPs), came directly from the pioneering work of Dr. Marshall Urist, who was the first to report that protein extracts from demineralized bone matrix were able to induce bone formation at ectopic sites in rodents. Because the process initiated by the implantation of these extracts closely resembled the cellular events seen during endochondral bone formation and fracture healing, he characterized this activity as morphogenetic (Urist, 1965; Fig. 1). Dr. Urist's work led to the identification of the first BMP genes in 1988 and to the realization that BMP activity within bone is the sum of the activities of several BMP genes (Wozney *et al.,* 1988). We now know that at least five related BMPs (BMP2, BMP4, BMP5, BMP6, and BMP7; see Chapter 51, Fig. 1) are deposited into bone matrix and have osteoinductive activity (Celeste *et al.,* 1990; Kingsley, 1994a; Luyten *et al.,* 1989; Ozkaynak *et al.,* 1990, 1992; Sampath and Reddi, 1981; Sampath *et al.,* 1987; Urist *et al.,* 1973; Wang *et al.,* 1988, 1990; Wozney *et al.,* 1988).

BMP THERAPEUTICS AID BONE REPAIR

The success of preclinical studies evaluating the ability of bone-derived BMPs and recombinant human (rh) BMPs to induce *de novo* bone formation led the way for clinical trials in which the safety and efficacy of rhBMP2 or rhBMP7 (Osteogenic protein-1, OP-1) was examined. BMPs have been shown to be safe and effective alternatives to autogenous bone grafts, and rhBMP2 received FDA approval for use in spine fusion in 2002 (Valentin-Opran *et al.,* 2002; Carlisle and Fischgrund, 2005; Villavicencio *et al.,* 2005; Singh *et al.,* 2006; Slosar *et al.,* 2007), to augment tibial fracture repair in 2006 (Govender *et al.,* 2002; Jones *et al.,* 2006; Swiontkowski *et al.,* 2006), and most recently to aid in bone regeneration in the oral cavity (Boyne *et al.,* 2005; Fiorellini *et al.,* 2005). OP-1 (BMP7) has been granted a Humanitarian Device Exemption (intended to benefit patients with conditions that are manifested by fewer than 4000 individuals in the United States per year), allowing use in patients as an alternative to autograft for treatment of recalcitrant long-bone nonunions (Brown *et al.,* 2006; Ronga *et al.,* 2006). In these indications, BMPs are typically applied with a matrix or carrier that aids in defining the shape and volume of the new bone produced, and also helps to retain BMP at the site of application.

Although human clinical studies have proven that BMPs are safe and efficacious bone-inducing agents when added exogenously to sites undergoing repair, we know very little about the normal physiological roles endogenous BMPs play in skeletal tissues. Next we highlight our current understanding of the skeletal actions of endogenous

*Corresponding author: Vicki Rosen, Department of Developmental Biology, Harvard School of Dental Medicine, Boston, MA 02115, Phone: 617-432-5910, Fax: 617-432-3246, E-mail: Vicki_rosen@hsdm.harvard.edu

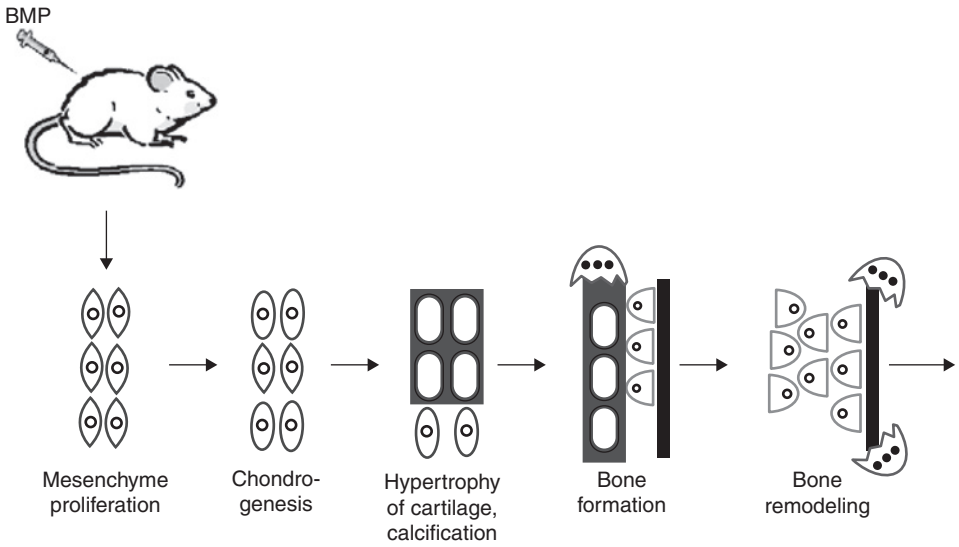

FIGURE 1 Implantation of BMP at ectopic sites in rodents induces *de novo* bone formation. Mesenchymal progenitors condense at the site of BMP implantation and differentiate into chondrocytes; chondrocyte hypertrophy occurs and a mineralized matrix is laid down; new vessels arrive at the site bringing bone marrow elements including osteoclasts that remove the calcified cartilage; and, osteoblast differentiation by mesenchymal cells at the site results in bone formation.

BMPs and discuss how this understanding will define new clinical roles for BMPs.

BMPS ARE PRODUCED BY AND ACT ON SKELETAL CELLS

Individual BMPs, like other members of the transforming growth factor-β (TGF-β) superfamily, are transcribed as large precursor molecules with amino-terminal signal sequences and prodomains of variable size and heterogeneity. These BMP precursors dimerize and are cleaved at RXXR consensus cleavage sites at the time of secretion, releasing a mature BMP dimer that consists of 110–140 amino acids with seven absolutely conserved cysteines. The three-dimensional conformation that results from the location of six of the seven cysteines makes BMPs highly resistant to heat, denaturants, and extremes of pH. Although these unique properties were of fundamental importance in the initial separation of BMPs from bone, we still do not know if native BMPs found in bone exist as homodimers, heterodimers, or combinations of both, because the methods used to purify BMPs destroy their native conformation (Aono *et al.,* 1995; Israel *et al.,* 1996).

In skeletal tissues, BMPs are made *de novo* by osteoblasts, chondrocytes, and their progenitors (Rosen and Wozney, 2002), and are also secreted by invading macrophages and vascular endothelial cells that participate in fracture repair (Csiszar *et al.,* 2005; Sipe *et al.,* 2004; Rosen and Wozney, 2002). When BMPs are secreted from cells, they have one of several fates: They should immediately exert their actions locally through interactions with BMP receptors on the surface of target cells; they may be bound up and prevented from acting by extracellular antagonists present at the site of BMP secretion; or, they may interact with extracellular matrix proteins that serve to sequester or enhance BMP activity by anchoring it to the matrix where it is more available for target cell interactions (Arteaga-Solis *et al.,* 2001; Ohikawara *et al.,* 2002; Lanain *et al.,* 2001). Within the skeleton, target cells for BMPs are located in the perichondrium, periosteum, growth plate, articular cartilage, newly formed bone, and bone marrow stroma (Abe *et al.,* 2000; Brunet *et al.,* 1998; Devlin *et al.,* 2003; Enomoto-Iwamoto *et al.,* 1998; Rountree *et al.,* 2004; Wu *et al.,* 2003; Kobayashi *et al.,* 2005). At each of these sites, changing BMP activity can alter cell proliferation, influence cell fate decisions by pluripotent progenitors, or change extracellular matrix production and its subsequent mineralization.

BMPs exert their effects through transmembrane serine/threonine kinases known as type I and type II receptors (see Chapter 51). These closely related proteins are composed of a short cysteine-rich extracellular domain, a single transmembrane-spanning domain, and an intracellular domain with serine and threonine kinase regions (Franzen *et al.,* 1993; Lin *et al.,* 1992). BMPs can bind to both type I and type II receptors alone with low affinity (Liu *et al.,* 1995). High-affinity binding of BMPs is achieved only when both receptors are present. Although some differences exist with regard to receptor preferences, osteogenic BMPs utilize the same type I (Alk2, Alk3, and Alk6) and type II receptors (BMP RII, ActRII, ActRIIb; Aoki *et al.,* 2001; Miyazono, 2002), and the signal transduced by each osteogenic BMP appears to be identical in skeletal

target cells (Korchynskyi *et al.,* 2003; ten Dijke *et al.,* 2003; Peng *et al.,* 2003; Noth *et al.,* 2003). Comparison of results from many labs using a variety of cell and animal models of bone formation points to the conclusion that osteogenic BMPs are interchangeable in their ability to activate the osteoblast phenotype in osteoprogenitor cells, induce ectopic bone formation at nonskeletal sites (Wang *et al.,* 1990; Gitelman *et al.,* 1994; Franceschi *et al.,* 2000), enhance fracture repair (Yasko *et al.,* 1992; Cook *et al.,* 1994; Cho *et al.,* 2002), and activate osteoblast differentiation in primary populations of bone marrow stromal cells (Abe *et al.,* 2000; Locklin *et al.,* 2001), primary and clonal cell lines derived from bone (Yamaguchi *et al.,* 1991; Thies *et al.,* 1992; Hughes *et al.,* 1995; Roman-Roman *et al.,* 2003), and C2C12 muscle cells (Katagiri *et al.,* 1994; Ebisawa *et al.,* 1999; de Jong *et al.,* 2002; Yeh *et al.,* 2002). In addition to activation of the canonical Smads 1, 5, and 8, BMPs have also been shown to activate MAPK and AKT pathways, and based on current published information, each of the osteogenic BMPs appears to have the same capacity to activate these signaling pathways as well (Zuzarte-Luis *et al.,* 2004; Aubin *et al.,* 2004).

BMP ACTIVITY IS PRECISELY REGULATED

Once secreted, the availability of BMPs for receptor interactions is mediated by the presence of extracellular antagonists that bind to BMP proteins and prevent their subsequent interaction with BMP receptors (Dionne *et al.,* 2001). Developmental analysis of the function of BMP antagonists suggests that they guard against excessive BMP activity during formation of the skeleton. For example, inactivation of the gene for the potent BMP antagonist noggin results in hyperplasia of cartilage condensations and failure of joint formation due to increased BMP activity (Brunet *et al.,* 1998). This phenotype is reminiscent of that seen in humans with missense mutations in *Noggin*. Both proximal symphalangism and multiple synostosis syndromes, autosomal-dominant disorders, are characterized by joint fusion caused by the union of two individual bones (Gong *et al.,* 1999). Gain-of-function studies in the chick limb have shown that too much noggin, the opposite situation, blocks BMP activity and inhibits normal skeletal chondrogenesis (Capdevila and Johnson, 1998; Pathi *et al.,* 1999). Mice engineered to over-express noggin in the skeleton display osteopenia and severe bone fragility, highlighting the importance of precisely regulating BMP activity to normal skeletal function (Tsumaki *et al.,* 2002). Another potential regulator of BMP activity in the skeleton is chordin. Cysteine-rich (CR) domains in the chordin molecule provide high-affinity binding sites for BMPs, sequestering them and making them unavailable to their receptors (Holley *et al.,* 1993). Chordin expression patterns in the skeleton place it at sites of BMP activity (Piccolo *et al.,* 1996), and when chordin is overexpressed during chick limb development, there is a substantial delay in chondrocyte maturation and a negative effect on endochondral ossification (Zhang *et al.,* 2002). The control of skeletal BMP activity by chordin is likely to be affected by another BMP binding protein, Tsg, that interacts with both BMP-7 and chordin and enhances the ability of chordin to antagonize BMPs (Zakin *et al.,* 2005). Connective tissue growth factor (CTGF), a secreted protein found in ECM, can also antagonize BMP activity. CTGF contains CR domains similar to those found in chordin, and these domains provide binding sites for BMP-4 and TGF-β. Whereas CTGF binding to BMP-4 serves to antagonize BMP activity, CTGF binding to TGF-β enhances TGF-β receptor binding. Transgenic mice that overexpress CTGF under regulation of a Col-XI promoter show decreased bone density within a few months after birth, establishing CTGF as a negative regulator of bone formation (Abreu *et al.,* 2002). Whether this is due to the ability of CTGF to bind BMPs and inhibit their activities remains to be determined. Follistatin may also regulate the availability of BMP activity in bone by binding to BMPs or through modulation of activin signaling (Merino *et al.,* 1999). In addition to a role in antagonizing BMP activity, it is conceivable that at least some of these BMP-binding proteins regulate the diffusion of BMPs through the extracellular matrix. A similar activity has been identified for short gastrulation (sog), the *Drosophila* homologue of chordin (Ashe and Levine, 1999). Furthermore, these proteins may play direct roles in modulating BMP interactions with the extracellular matrix. For example, sog has been shown to physically interact with integrins (Araujo *et al.*, 2003).

Once the BMP signaling cascade is activated in skeletal cells, there appear to be many feedback loops whose purpose is to modulate the BMP effect. To date, BMP signaling has been shown to intersect with the mitogen-activated protein kinase (MAPK) pathway in osteoblasts, the Indian Hedgehog (Ihh)–parathyroid hormone related peptide (PTHrP) pathway in chondrocytes and osteoblasts, the Wnt pathway during limb development and bone formation, fibroblast growth factor (FGF) pathway during limb patterning, and with the TGF-β and activin pathways in bone cells (Centrella *et al.,* 1991; Chung *et al.,* 2001; Lanske *et al.,* 1996; Alvarez *et al.,* 2002; Chen *et al.*, 2007; Gori *et al.,* 2001; Rawadi *et al*., 2003; Yoon *et al.,* 2006).

AMOUNT OF BMP ACTIVITY OR ACTION OF INDIVIDUAL BMPs?

Our ability to remove specific BMPs and observe skeletal development in mice has shown that in most instances, loss of any individual BMP can be compensated for by the other BMPs present. For example, lack of BMP5 (Green,

1958; Kingsley *et al.,* 1992; DiLeone *et al.,* 1998), BMP6 (Solloway *et al.,* 1998), or BMP7 (Dudley *et al.*, 1995; Luo *et al.,* 1995; Dudley and Robertson, 1997) has little consequence on the embryonic skeleton, and elimination of either BMP2 or BMP4 from the limb prior to the start of endochondral ossification does not affect skeletal development (Tsuji *et al.,* 2006; Bandyopadhyay *et al.,* 2006). However, mice in which combinations of osteogenic BMPs have been removed display a variety of phenotypes, ranging from normal bone formation (Kim *et al.,* 2001; Zhao, 2003) to absence of osteoblast differentiation (Bandyopadhyay *et al.,* 2006), raising the possibility that based on expression levels, some BMPs may be more important than others. BMP3 is one of the most abundant BMPs in demineralized bone matrix (Wozney and Rosen, 1993). Most surprisingly, however, examination of the phenotype of BMP-3 null mice revealed that the loss of BMP-3 during embryogenesis results in increased bone density, with a doubling of trabecular volume at 5 to 6 weeks of age (Daluiski *et al.,* 2001). Although the cellular basis for this phenotype is currently under investigation, preliminary data suggest that BMP-3 can antagonize osteogenic BMPs by binding to a subset of type II BMP receptors (Gamer *et al.,* 2005).

BMPs AND THE ADULT SKELETON

BMP activity is required to maintain normal bone function in the adult skeleton because generalized loss of BMPs through overexpression of BMP antagonists by osteoblasts leads to osteopenia, bone fragility, and spontaneous fracture (Gazzerro *et al.,* 1998, 2005; Wu *et al.,* 2003). How much BMP activity is required, how BMPs affect bone remodeling, and which specific BMPs are the endogenous mediators of bone formation in the postnatal skeleton remain open questions. BMP activity found in bone declines with age (Syftestad and Urist, 1982; Fleet *et al.,* 1996; Moerman *et al.,* 2004), and this decrease correlates with the observation that osteoprogenitors are less effective at replicating, differentiating into osteoblasts, and laying down bone matrix in older animals. It appears that BMPs 4, 5, and 6 are not required for bone remodeling, because mice lacking any one of these BMPs maintain normal bone mass (Kingsley *et al.,* 1992; DiLeone *et al.,* 1998; Solloway *et al.,* 1998; Tsuji and Rosen, unpublished observations). In contrast, mice lacking BMP2 are unable to maintain their bone mass as they age and undergo spontaneous fracture with 100% penetrance (Tsuji *et al.,* 2006). When BMP3, a negative regulator of bone formation is removed, mice have increased bone mass as they age (Daluiski *et al*., 2001), another indication that BMP activity and postnatal bone mass are intimately linked.

Bone remodeling, the removal of existing bone and its replacement by new bone, is carried out in a highly controlled manner and requires the differentiation of both osteoblasts and osteoclasts from precursors located in the bone marrow environment (Manolagas and Jilka, 1995). The exact nature of the signals that control remodeling remains to be established, but it is likely that both osteoblast and osteoclast precursors are affected by systemic and local signals and by mechanical stimulation (Rodan, 1998). BMPs have been proposed to be among the local signals that induce commitment of mesenchymal stem cells resident in bone marrow into osteoprogenitors and osteoblasts (Abe *et al.,* 2000; Manolagas and Weinstein, 1999). Several lines of evidence make this hypothesis an attractive one. Many data exist to show that BMPs are present in bone matrix in a form that allows for their release or presentation to marrow stromal cells, cells that can differentiate into osteoblasts in response to BMPs (Rosen *et al.,* 1996). Osteoblasts have also been shown to synthesize and secrete BMPs both *in vitro* and *in vivo,* suggesting that once BMPs initiate MSC differentiation, a positive feedback loop is created, allowing for the production of additional BMP signals (Suzawa *et al.,* 1999). In addition, BMPs are thought to regulate the transcription of several osteoblast-specific transcription factors, which in turn may regulate transcription of RANK ligand, a signal important for the differentiation of hematopoietic progenitors into osteoclasts (Manolagas and Weinstein, 1999). These tantalizing links between BMPs and bone remodeling have become the focus of much research and may lead to new therapeutic approaches to osteopenia. In designing treatments that utilize site-specific activation of endogenous BMPs, it is fundamentally important to identify which BMPs are available to affect bone remodeling and which cell types at each step of the remodeling process are the targets of these signals. If BMPs are effectors of remodeling, it will be necessary to determine whether factors that are known to change the balance in remodeling toward formation or resorption do so through effects on these BMPs. *In vitro* studies have shown that estrogens and glucocorticoids, two agents known to affect remodeling, increase BMP-6 synthesis by osteoblasts (Boden *et al.,* 1997; Ricard *et al.,* 1998). However, mice lacking BMP6 have no apparent skeletal defects and do not develop osteopenia, suggesting that identifying the roles that BMPs play in remodeling will require an understanding of the influence of individual BMPs in this process (Solloway *et al.,* 1998).

It will also be of great interest to determine whether the decrease in MSC present in bone marrow that occurs with aging is related to the changes in levels of specific BMPs found in bone matrix in older animals (D'Ippolito *et al.,* 1999). If BMPs are required for MSC survival, as well as MSC differentiation, changing the BMP content of bone matrix and bone marrow may have important clinical benefits. A hint that this may be the case has been provided by the production of transgenic mice in which noggin, a potent BMP antagonist, is overexpressed using the bone-specific

osteocalcin promoter. These mice have osteopenia and are prone to fracture, suggesting that a reduction in osteogenic BMPs available to the postnatal skeleton reduces overall bone formation and bone healing (Devlin *et al.,* 2003). The discovery that the genetic defect in fibro-ossificans dysplasia progressiva (FOP) is an activating mutation of Alk2, a type I BMP receptor (Shore *et al.,* 2006), and the report that conditional inactivation of another type I BMP receptor, Alk3, regulates the size of the hematopoietic stem cell niche in mice (Zhang *et al*., 2003) points to an important role for BMP signaling in mesenchymal stem cell differentiation.

New bone formation also occurs in the adult skeleton during the process of fracture repair, where osteoblast precursors resident in marrow and periosteum differentiate into osteoblasts in a highly regulated manner. BMPs have been shown to be present at fracture repair sites, and several lines of evidence support the role of BMPs in this process. First, all of the cell types that synthesize new bone during fracture healing have been shown to be targets for BMPs *in vitro* and to possess BMP receptors *in vivo* (Bostrom *et al.,* 1995). Recent studies using mice in which BMP2 is inactivated only in the limb skeleton have identified BMP2 as required for periosteal activation, a critical initiation step for fracture repair (Tsuji *et al.,* 2006). The availability of animal models in which specific BMPs, BMP receptors, and BMP antagonists have been removed should allow us to address this issue and to begin to understand what regulates endogenous BMP production during fracture healing.

Another circumstance in which the adult skeleton produces new bone is during distraction osteogenesis, a method of bone lengthening that takes advantage of the inherent capacity of bone to repair after breaking (Paley, 1988). We are just beginning to understand the molecular and cellular events that form the basis of distraction osteogenesis, and from these initial studies, it seems likely that BMPs are important mediators of bone formation at the distraction site. Data from a rat model of distraction osteogenesis link the mechanical stress/tension needed for successful distraction osteogenesis with BMP gene expression (Sato *et al.,* 1999). The precise link between mechanical stress and BMP gene expression remains to be discovered, as do the other signaling pathways that must interact with BMPs to produce the cascade of events that results in temporally delayed bone formation. Understanding what regulates the temporal differences in bone formation seen between distraction osteogenesis and normal fracture healing, which are thought to be BMP-mediated events, should provide insight into how BMPs affect the rate of repair.

Finally, new bone formation in adults is also found in several instances of chronic joint disease, of which osteoarthritis (OA) is by far the most common. BMPs have been localized in both normal and arthritic joints, and polymorphisms in the BMP2 gene and in asporin, an ECM protein that is able to regulate the activity of both BMP-2 and TGF-β, have been associated with arthritis (Kizawa *et al.,* 2005; Lories and Luyten, 2005; Yamada *et al.,* 2007). Mice lacking expression of the Bmpr1a gene specifically in developing joints show articular cartilage erosion after birth that resembles human OA (Rountree *et al.,* 2004). Greater understanding of the requirements for BMP signaling in the maintenance of synovial joints may allow for the design of novel OA therapies.

CONCLUSIONS

In the 20 years since the identification of the BMP genes, it has become clear that BMPs are involved in almost every aspect of bone biology. Our increasing understanding of how BMPs exert their effects on skeletal cells coupled to the realization that BMP activity is tightly regulated to restrict its action provide entrance points for investigating the physiological significance of BMP activity in the skeleton. Several important questions remain to be addressed, including why BMP therapeutics must be used in microgram amounts in the clinic whereas endogenous BMPs are active at far lower levels, and how BMP signals are integrated with other kinds of signals, in particular, Wnts and FGFs to maintain skeletal homeostasis.

INTRODUCTION: BMPs

Bone morphogenetic proteins (BMPs) were originally identified as proteins that induce the formation of bone and cartilage tissues when implanted at ectopic sites in rats (Wozney *et al.,* 1988; Reddi, 1998). *In vitro,* BMPs have potent effects on the regulation of growth and differentiation of chondroblast and osteoblast lineage cells. Moreover, BMPs have been shown to be multifunctional cytokines with a wide range of biological activities in various cell types, including epithelial cells, mesenchymal cells, endothelial cells, monocytes, and neuronal cells (see Chapter 50).

BMPs belong to a larger family, known as the transforming growth factor-β (TGF-β) family, which includes TGF-βs, activins and inhibins, nodal, myostatin, and Müllerian inhibiting substance (MIS, also known as anti-Müllerian hormone). More than a dozen molecules have been identified in the BMP subfamily; these can be classified into several subgroups based on similarities in structure and function. BMP-2 and BMP-4 are highly similar and form one subgroup (BMP-2/4 group). BMP-5, BMP-6, BMP-7 (also termed osteogenic protein-1; OP-1), and BMP-8 (OP-2) form another subgroup (OP-1 group). Growth and differentiation factor-5 (GDF-5, also termed cartilage-derived morphogenetic protein-1, CDMP-1), GDF-6 (CDMP-2, also termed BMP-13), and GDF-7 (BMP-12) belong to a third subgroup (GDF-5 group), and BMP-9/GDF-2 and BMP-10 form a fourth subgroup (BMP-9 group; Fig. 1; Kawabata and Miyazono, 2000). Most of the members of the BMP-2/4, OP-1, and BMP-9 groups have been shown to induce formation of bone and cartilage tissues *in vivo,* whereas those of the GDF-5 group induce cartilage and tendon-like tissues. In contrast, certain other BMPs and GDFs, including BMP-3 and myostatin (also termed GDF-8), do not induce formation of bone and cartilage tissues *in vivo.* Evaluation of osteogenic activities of 14 different BMPs/GDFs by adenoviral gene transfer *in vitro* revealed that BMP-2, BMP-6, and BMP-9 were most potent in the induction of alkaline phosphatase activity and osteocalcin expression in C3H10T1/2 cells, and that they play critical roles in inducing differentiation of mesenchymal progenitor cells into osteoblasts (Cheng *et al.,* 2003).

In this chapter, mechanisms for the signal transduction by BMPs on mesenchymal progenitor cells, are described and compared to the TGF-β signaling system. Although the signaling mechanisms of serine-threonine kinase receptors and Smads have been intensively studied in invertebrates, i.e., in *Drosophila* and *Caenorhabditis elegans* (Zimmerman and Padgett, 2000; Raftery *et al.,* 2006), BMP signaling pathways in mammals will be the principal focus of this chapter.

BMP RECEPTORS

Serine-Threonine Kinase Receptors

Members of the TGF-β family bind to two distinct types of serine-threonine kinase receptors, termed type I and type II receptors (Heldin *et al.,* 1997; Shi and Massagué, 2003). Both type II and type I receptors are essential for signal transduction. TGF-β and activin ligands bind to type II receptors independently of type I receptors, whereas type I receptors can bind these ligands only in the presence of type II receptors. In contrast, BMPs bind to type I receptors in the absence of type II receptors, whereas they bind to type II receptors only weakly in the absence of

Principles of Bone Biology, 3rd Edition

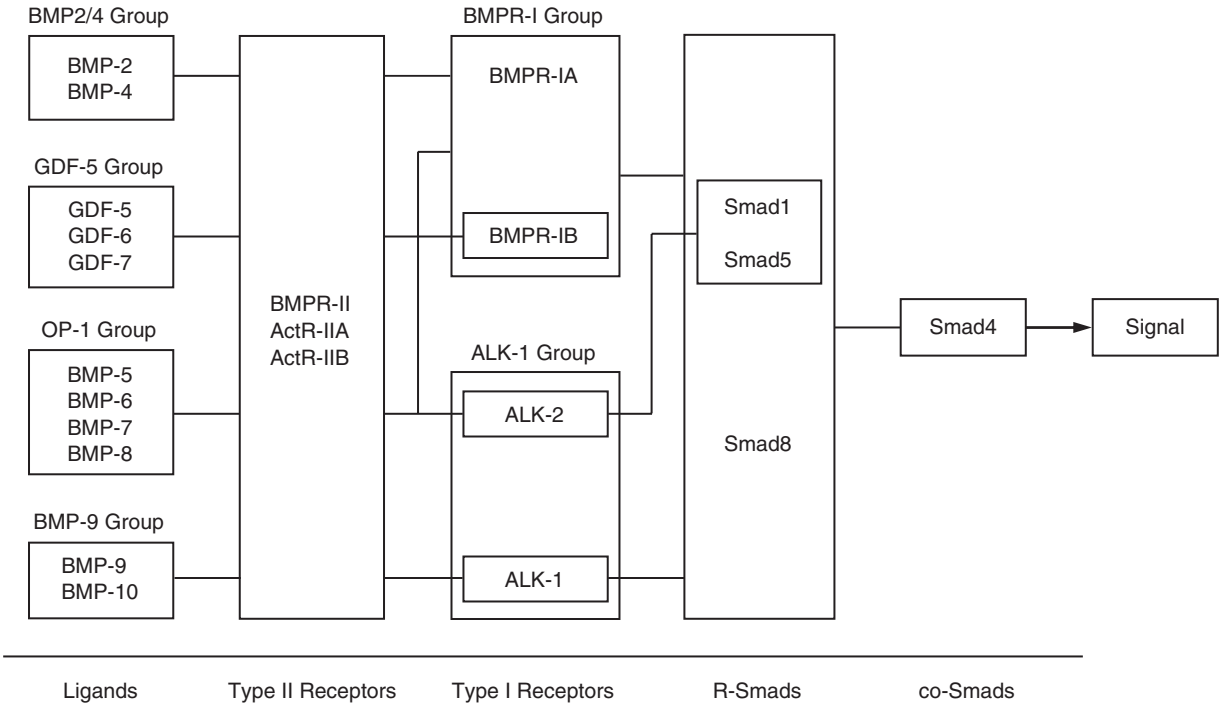

FIGURE 1 Relationships between BMPs, type II and type I receptors, and Smad proteins in signal transduction. Among the receptors of the ALK-1 group, ALK-2 serves as a receptor for the BMPs in the OP-1 group, whereas ALK-1 serves as a receptor for those in the BMP-9 group. Similarly, BMPR-IB, but not BMPR-IA, preferentially functions as a type I receptor for GDF-5. Of the BMP-R-Smads, Smad1, and Smad5 are activated by ALK-2, whereas all three BMP-R-Smads are activated by BMPR-IA and BMPR-IB.

type I receptors, and their binding affinity is dramatically increased when both types of receptors are present (see later discussion; Liu *et al.,* 1995; Rosenzweig *et al.,* 1995). The binding affinities of BMP-2 to BMP type I receptors are 1 to 11 n*M*, while those to type II receptors are 50 to 100 n*M* (see later discussion). The type II receptor kinase transphosphorylates the type I receptor, which transmits specific intracellular signals.

The structures of the type I and type II receptors are schematically shown in Figure 2A. They have a relatively short extracellular domain, a single membrane-spanning domain, and an intracellular domain containing a serine-threonine kinase domain. The extracellular domains have several conserved cysteines, which are important for the formation of characteristic three-dimensional structures (Greenwald *et al.,* 1999; Kirsch *et al.,* 2000a). In addition to the serine-threonine kinase domain, the intracellular domains of type I receptors, but not those of type II receptors, have a characteristic GS domain (glycine- and serine-rich domain) located N-terminal to the serine-threonine kinase domains. In the kinase domain, type I receptors have a characteristic structure, denoted L45 loop, between kinase subdomains IV and V. The C-terminal tails of type I receptors are very short (less than 9 amino acids), whereas those of type II receptors are more than 24 amino acids long. The C-terminal tail of BMPR-II is much longer (530 amino acids) than other type II receptors. Although the functional importance of the C-terminal tail of BMPR-II is not fully known, several molecules have been shown to interact with the C-terminal tail of BMPR-II, and mutations in this domain have been found in some patients with pulmonary arterial hypertension (see later discussion; IPPH Consortium, 2000; Deng *et al.,* 2000; Morrell, 2006).

BMP Type I Receptors

Seven type I receptors, termed activin receptor-like kinases (ALKs) 1 through 7, have been identified in mammals. ALKs can be classified into three subgroups, i.e., the BMPR-I group, the ALK-1 group (see Fig.1), and the TβR-I group (Kawabata and Miyazono, 2000). ALK-3 and ALK-6 are very similar to each other (BMPR-I group) and are also denoted BMP type IA and type IB receptors (BMPR-IA and BMPR-IB), respectively. The kinase domains of BMPR-IA and BMPR-IB have 85% amino acid sequence identity. Functional differences between the intracellular domains of BMPR-IA and BMPR-IB have not been fully determined. ALK-5, ALK-4, and ALK-7 are structurally similar to each other (TβR-I group), and ALK-5 and ALK-4 serve as TGF-β and activin/nodal type I receptors (TβR-I and ActR-IB), respectively. ALK-7 and ALK-4 have been reported to bind nodal (Reissmann *et al.,* 2001). ALK-1 and ALK-2 are structurally similar to each other

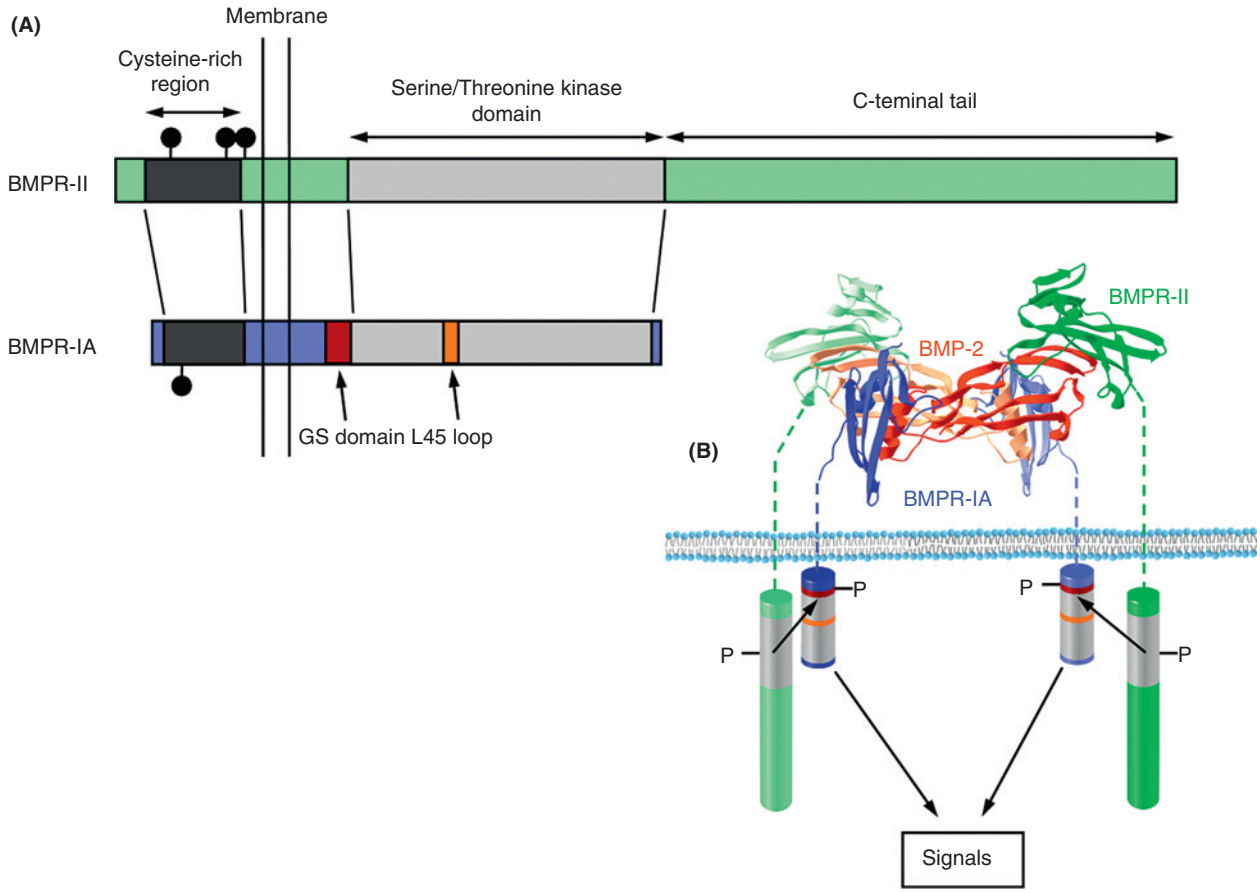

FIGURE 2 BMP type II and type I receptors. (**A**) Structure of BMPR-II and BMPR-IA. ActR-IIA and ActR-IIB have similar structures, but shorter C-terminal tails than BMPR-II. BMPR-IB and ALK-1/2 have overall structures similar to that of BMPR-IA. Closed circles indicate N-glycosylation sites. (**B**) BMP-2 has an elongated structure and binds to BMPR-IA and BMPR-II through wrist and knuckle epitopes, respectively. The ribbon diagram of hypothetical BMP-2-BMPRIA-BMPR-II ternary complex in the cell membrane is shown. The structure of BMPR-II was superposed onto that of ActR-II in the ternary complex containing BMP-2, BMPR-IA, and ActR-II (Protein Data Bank entry 2GOO). Subunits of the BMP-2 dimer are shown in red. The extracellular domains of BMPR-IA and BMPR-II are shown in blue and green, respectively. In the intracellular parts, BMPR-II transphosphorylates the GS domain of BMPR-IA, and BMPR-IA kinase transduces intracellular signals. (See plate section)

(ALK-1 group), and they are distantly related to the other type I receptors. Despite the low degree of similarity between the receptors of the ALK-1 group and those of the BMPR-I group, they transduce similar intracellular signals.

BMPR-IA is expressed in various types of cells, including human foreskin fibroblasts, MC3T3-E1 osteoblasts, C2C12 myoblasts, and ROB-C26 osteoprogenitor cells (ten Dijke *et al.,* 1994; Nishitoh *et al.,* 1996; Ebisawa *et al.,* 1999). ALK-2 is also widely expressed in various cells, including human foreskin fibroblasts, MC3T3-E1 cells, and C2C12 cells. In contrast, expression of BMPR-IB is restricted to certain cell types, including ROB-C26 cells and glioblastoma cell lines, and that of ALK-1 is limited to endothelial cells and certain other cells. In the postimplantation mouse embryos, BMPR-IA and ALK-2 are nearly ubiquitously expressed, whereas BMPR-IB shows a more restricted expression profile and is observed in mesenchymal precartilage condensations, premuscle masses, central nervous system, and some other tissues (Dewulf *et al.*, 1995; Verschueren *et al.*, 1995). ALK-1 is expressed in several different tissues and organs, but its expression is highest in blood vessels, mesenchyme of the lung, and submucosal layer of gastrointestinal tracts (Roelen *et al.*, 1997).

Members of the BMP subfamily bind with different affinities to BMPR-IA, BMPR-IB, ALK-1, and ALK-2, expressed in mammalian cells. Under physiological conditions, BMP-2 and BMP-4 bind to BMPR-IA and BMPR-IB (ten Dijke *et al.,* 1994). In contrast, BMP-6 and BMP-7 bind strongly to ALK-2 and weakly to BMPR-IB (Ebisawa *et al.,* 1999). GDF-5 preferentially binds to BMPR-IB, but not to other receptors (Nishitoh *et al.,* 1996). BMP-9 and BMP-10 bind to ALK-1 in the presence of BMPR-II (Brown *et al.*, 2005; David *et al.,* 2007; Scharpfenecker *et al.*, 2007). Moreover, TGF-β binds to TβR-I as well as ALK-1 in endothelial cells (Oh *et al.,* 2000; Goumans

et al., 2003). In addition to members of the BMP family, MIS binds to ALK-2, BMPR-IA and BMPR-IB in the presence of its specific type II receptor, MISR-II (Gouédard *et al.,* 2000; Zhan *et al.,* 2006). Thus, BMP type I receptors are shared by certain other members of the TGF-β family.

Truncated forms of BMPR-IA and BMPR-IB, lacking the intracellular domains, or kinase inactive forms with mutations in the ATP-binding sites, have been widely used to study the functions of BMPs. BMPs induce differentiation of C2C12 cells into osteoblast-like cells, but in the presence of the truncated form of BMPR-IA, cells fail to become osteoblasts, differentiating instead into mature myocytes (Namiki *et al.,* 1997).

The two unique structures in the intracellular domain, i.e., the GS domain and L45 loop, are observed only in type I receptors, but not in type II receptors. Mutations in the GS domains (see later discussion) lead to constitutive activation of type I receptors. The constitutively active BMP type I receptors, including those of the BMPR-I group and the ALK-2 group, stimulate osteoblast differentiation *in vitro* (Fujii *et al.,* 1999). The L45 loop located between kinase subdomains IV and V of type I receptors is most important for the determination of intracellular signaling.

BMP Type II Receptors

Three receptors, i.e., BMPR-II, ActR-II, and ActR-IIB, serve as type II receptors for BMPs. BMPR-II is specific for BMPs, whereas ActR-II and ActR-IIB are shared by activins and BMPs. In contrast to type I receptors, these type II receptors appear to bind most BMPs.

Two alternatively spliced variants of BMPR-II have been identified (Rosenzweig *et al.,* 1995; Liu *et al.,* 1995). The long form of BMPR-II is composed of 1038 amino acids, and includes the long C-terminal tail rich in serines and threonines. The short form lacks the long C-terminal tail, but its expression is rare in most tissues. Although the long and short versions have been reported to be functionally indistinguishable in *Xenopus* assays (Ishikawa *et al.,* 1995), nonsense mutations in the C-terminal tail have been found in some patients with familial pulmonary arterial hypertension, indicating that this region plays an important role in signaling activity (IPPH Consortium, 2000; Deng *et al.,* 2000).

BMPR-II binds ligands only weakly by itself, but its ligand-binding affinity is increased in the presence of type I receptors. ActR-II and ActR-IIB bind activins and BMPs, but the binding affinities of ActR-II and -IIB to BMPs are lower than those to activins (Yamashita *et al.,* 1995). ActR-II and -IIB bind activins with high affinity in the absence of type I receptors. Similar to BMPR-II, however, ActR-II and -IIB bind BMPs with high affinity only in the presence of type I receptors (Rosenzweig *et al.,* 1995; Liu *et al.,* 1995). Moreover, type II receptors affect the binding preferences of BMPs for type I receptors (Yu *et al.,* 2005).

BMPR-II, ActR-II, and ActR-IIB are widely expressed in various tissues. BMPR-II is expressed in skeletal muscle, heart, brain, and lung, and plays an important role in mesoderm formation during early embryogenesis (Beppu *et al.,* 2000).

Co-receptors for BMPs

Although type II and type I receptors are sufficient for transduction of intracellular signaling by TGF-β family proteins, signaling activity of certain members is regulated by co-receptors, including Cripto for nodal signaling, and βglycan and endoglin for TGF-β signaling. Glycosylphosphatidylinositol (GPI)-anchored proteins of the repulsive guidance molecule (RGM) family, including RGMa, DRAGON/RGMb, and hemojuvelin/RGMc, serve as co-receptors for BMP-2 and BMP-4, and enhance BMP signaling (Samad *et al.,* 2005; Babitt *et al.,* 2005, 2006). They interact with BMP type I receptors and bind selectively to BMP-2 and BMP-4, but not to BMP-7 or TGF-β1 .

BMPs play a key role in metabolism in hepatocytes, in which hemojuvelin and hepcidin function as downstream components in the BMP signaling pathway and regulate iron homeostasis. Acting as a BMP co-receptor, hemojuvelin induces the expression of hepcidin in hepatocytes upon BMP stimulation, and hepcidin in turn decreases iron absorption by the intestine and iron release from macrophages (Babitt *et al.,* 2006). Mutations in the *hemojuvelin* gene as well as in the *hepcidin* gene cause juvenile hemochromatosis, which is characterized by accumulation of iron in various organs.

Molecular Mechanism of BMP Receptor Activation

BMP Binding to Receptor Extracellular Domains

The extracellular domains of BMP type I receptors interact with ligands even in the absence of type II receptors. Because a soluble form of BMPR-IA lacking the transmembrane and intracellular domains binds BMPs in the absence of type II receptors, it may be useful as an antagonist of BMPs (Natsume *et al.,* 1997). The binding affinity of BMP-2 for soluble BMPR-IA is about 1 n*M*, and that for BMPR-IB is about 11 n*M* (Kirsch *et al.,* 2000b). In contrast, binding affinities for the extracellular domains of BMPR-II and ActR-II are only 100 and 50 n*M*, respectively.

Several studies solved the structures of binary complexes containing ligands and receptor extracellular domains, i.e. BMP-2-BMPR-IA (Kirsch *et al.*, 2000a), BMP-7-ActR-II (Greenwald *et al.*, 2003), and activin-ActR-IIB (Thompson

et al., 2003). A ternary structure has been reported for BMP-2 in the complex with BMPR-IA and ActR-II (Allendorph *et al.*, 2006). The structure of the BMPR-II extracellular domain has also been determined (Mace *et al.*, 2006).

Two receptor-binding motifs have been identified in BMP-2 (Kirsch *et al.,* 2000b; see Fig. 2B). A large epitope 1 (termed *wrist epitope*) is a high-affinity binding site for BMPR-IA, and a smaller epitope 2 (termed *knuckle epitope*) is a low-affinity binding site for BMPR-II. The BMP-2/BMPR-IA interface of the complex structure consists of one BMPR-IA molecule containing both BMP-2 monomers, and the wrist epitopes from both monomers contribute to binding to BMPR-IA, whereas the knuckle epitope from only one monomer is involved in the binding to BMPR-II. The wrist and knuckle epitopes are very closely located to each other. Certain BMP-2 mutants in the knuckle epitope (e.g., Ala-34 and Leu-90), but not in the wrist epitope, function as antagonists of BMP-2, because these mutants bind to BMPR-IA with the wrist epitope, but fail to interact with BMPR-II through the mutated knuckle epitope.

The extracellular domain of ActR-II has a structure termed the *three-finger toxin fold*, composed of three pairs of β-strands projecting from the palm domain with a conserved scaffold of disulfide bridges (Greenwald *et al.,* 1999). The extracellular domains of ActR-II and BMPR-IA have very similar three-dimensional configurations but with some differences (Kirsch *et al.,* 2000a). The BMPR-IA extracellular domain consists of two β-sheets and one α-helix (helix α1); the latter is missing in ActR-II and may serve as a key element in type I receptors for specific ligand-binding.

Activation of Serine-Threonine Kinases

Small fractions of type II and type I receptors are present as preexisting homodimers as well as heterodimers on the cell surface in the absence of ligand stimulation (Gilboa *et al.,* 2000). All BMP receptors form oligomers, including type II/type I heteromers (BMPR-II/BMPR-IA and BMPR-II/BMPR-IA) and type II/type II and type I/type I oligomers (BMPR-II/BMPR-II, BMPR-IA/BMPR-IA, BMPR-IB/BMPR-IB, and BMPR-IA/BMPR-IB). Ligand-binding increases hetero- and homo-oligomerization of the receptors, except for BMPR-II homodimers. Receptor oligomerization may also induce conformational alterations of these receptor molecules.

The type II receptor kinase is constitutively active in the absence of ligand. Upon ligand binding, the type II receptor kinase transphosphorylates the GS domain of type I receptor, resulting in the activation of type I receptor kinases (see Fig. 2B). The intracellular substrates are then activated by the type I kinase (Wrana *et al.,* 1994).

Phosphorylation of the GS domain is a critical event in signal transduction by the serine-threonine kinase receptors. Crystallographic analysis of the intracellular domain of TβR-I revealed that the inactive conformation of the TβR-I kinase is maintained by physical interaction between the GS domain, the N-terminal lobe, and the activation loop of the kinase (Huse *et al.,* 1999). Upon phosphorylation of the GS domain by TβR-II, the TβR-I kinase is converted to an active conformation. Mutations of Thr-204 in TβR-I and the corresponding Gln in BMP type I receptors to acidic amino acids (Asp or Glu) lead to constitutive activation of the type I receptors (Wieser *et al.,* 1995). The constitutively active type I receptors transmit intracellular signals in the absence of ligands or type II receptors, indicating that type I receptors are a downstream component of the type II receptor signaling pathways and that they determine the specificity of the intracellular signals. However, truncation of the C-terminal tail of BMPR-II was found in some familial pulmonary arterial hypertension patients, suggesting that certain non-Smad signals may be transduced through BMPR-II (IPPH Consortium, 2000; Deng *et al.,* 2000).

In a yeast two-hybrid screening using TβR-I as a bait, FKBP12, a binding protein for immunosuppressants such as FK506 and rapamycin, was obtained (Wang *et al.,* 1994). FKBP12 binds to the Leu-Pro sequence in the GS domain of type I receptors, and negatively regulates the activity of type I receptors (Wang *et al.,* 1996; Chen *et al.,* 1997). FKBP12 thus prevents spontaneous activation of type I receptors by type II receptors.

The L45 loop of the N lobe in the type I receptor protrudes from the kinase domain (Huse *et al.,* 1999) and specifically interacts with intracellular substrates, e.g., Smads (Feng and Derynck, 1997). Amino acid sequences of the L45 loop are conserved in each type I receptor subgroup, but diverge between different subgroups. The L45 loop of the BMPR-I group is more similar to that of the TβR-I group than that of the ALK-1 group; however, receptors of the BMPR-I and ALK-1 groups activate a similar set of Smads, whereas those of the TβR-I group activate a distinct set of Smads.

Pseudoreceptor: BAMBI

Xenopus BAMBI is a pseudoreceptor for serine-threonine kinase receptors with a high degree of sequence similarity to the human *nma* gene product (Onichtchouk *et al.,* 1999). BAMBI/Nma is structurally related to type I serine-threonine kinase receptors, but the former does not have the intracellular domain. BAMBI stably interacts with various type I and type II receptors and inhibits signaling by these receptors. Since the expression of BAMBI and *nma* is induced by BMP and TGF-β (Onichtchouk *et al.,* 1999; Akiyoshi *et al.,* 2001), BAMBI/Nma may regulate BMP and TGF-β signaling via a negative feedback loop. Expression of BAMBI is also induced by Wnt-β-catenin signaling (Sekiya *et al.,* 2004).

Mutations of BMP Receptors *in Vivo*

Phenotypes of BMP Receptor-Deficient Mice

BMPs play essential roles during embryogenesis, and mice lacking BMP-2 or BMP-4 exhibit defects in mesoderm formation during early embryonic stages. Similarly, gene targeting of *Bmpr1a* or *Bmpr2* leads to defects in mesoderm formation. Homozygous *Bmpr1a* mutant mice die by E9.5 due to defects in mesoderm formation during gastrulation (Mishina *et al.,* 1995). *Bmpr2* null mice also die by E9.5, and their phenotype is very similar to that of *Bmpr1a*$^{-/-}$ mice (Beppu *et al.,* 2000). BMP signaling mediated by ALK-3/BMPR-IA is essential for hair follicle renewal in adult skin (Andl *et al.,* 2004; Yuhki *et al.,* 2004).

BMPR-IB-deficient mice are viable, but exhibit short limbs and abnormal digit cartilage, similar to *Gdf5* null mice (Baur *et al.,* 2000; Yi *et al.,* 2000). Analysis of *Gdf5*; *Bmpr1b* double mutant mice revealed that GDF-5 is a physiological ligand for BMPR-IB *in vivo,* although other receptors may also be involved in the GDF-5 signaling pathway. In addition, analysis of *Bmp7*; *Bmpr1b* double knockout mice revealed that BMP-7 and BMPR-IB may act in part in overlapping pathways. BMPR-IB is also essential for female fertility; *Bmpr1b*-null mice exhibit defects in cumulus cell expansion (Yi *et al.,* 2001).

Some, but not all, ActR-II-deficient mice exhibit hypoplasia of the mandible and other skeletal abnormalities (Matzuk *et al.,* 1995). Defects in the reproductive system and decrease in the secretion of follicle stimulating hormone (FSH) are also observed in these mice. ActR-IIB-deficient mice exhibit complicated cardiac defects, and abnormalities in lateral asymmetry and vertebral patterning (Oh and Li, 1997). ActR-II and ActR-IIB also play important roles in the formation of the endocrine pancreas (Kim *et al.,* 2000).

Human Diseases Induced by Mutations of BMP Receptors

Primary pulmonary arterial hypertension is characterized by stenosis of precapillary pulmonary arteries. Proliferation of endothelial cells and smooth muscle cells is observed in the pulmonary arteries of pulmonary arterial hypertension and leads to high pulmonary artery pressure. Familial pulmonary arterial hypertension occurs as an autosomal dominant disorder with reduced penetrance. Mutations in the human *BMPR2* gene are found in some familial pulmonary arterial hypertension patients (IPPH Consortium, 2000; Deng *et al.,* 2000). Mutations can be observed in various regions of this gene, including the extracellular domain, transmembrane domain, intracellular domain, and even the C-terminal tail. BMP signaling may thus play an important role in the maintenance of vascular integrity in the pulmonary arteries.

Mutations in human *ALK3/BMPRIA* as well as those in *SMAD4/MADH4* have been found in some patients with an autosomal dominant syndrome juvenile polyposis (Howe *et al.*, 2001; Zhou *et al.*, 2001). Although perturbations of TGF-β signaling are known to lead to development of gastrointestinal cancers, BMP signaling also plays a key role in the control of growth of gastrointestinal epithelium and development of cancers.

Mutations in human *ALK1* gene as well as those in *ENG* gene (encoding endoglin) cause hereditary hemorrhagic telangiectasia (HHT, also known as Osler-Weber-Rendu disease), an autosomal dominant vascular disorder characterized by skin and mucosal telangiectasia, pulmonary, cerebral, and hepatic malformations, and bleeding due to these vascular abnormalities (McAllister *et al.*, 1994; Johnson *et al.*, 1996).

A mutation in *ALK2/ACVR1* causes fibrodysplasia ossificans progressiva (Shore *et al.*, 2006), an autosomal dominant disorder of skeletal malformations and progressive ossification in muscular tissues. A heterozygous single nucleotide mutation (617G-> A; Arg-206 to His) was found in individuals with this disorder. Since Arg-206 is located in the GS domain of ALK-2, the mutation may induce destabilization of the GS domain, leading to hyperactivation of the ALK-2 kinase.

Brachydactyly (BD) type A2 is an autosomal dominant malformation characterized by short and laterally deviated index fingers and shortening and deviation of the first and second toes. Mutations in the GS domain or kinase domain of the *BMPR1B/ALK6* gene, which act in a dominant-negative manner, are responsible for the malformation (Lehmann *et al.*, 2003).

GDF-5 preferentially binds to BMPR-IB, whereas it binds to other type I receptors only weakly (Nishitoh *et al.*, 1996; Nickel *et al.*, 2005). A mutation of Arg-438 to Leu in GDF-5 (R438L mutant) is responsible for proximal symphalangism, characterized by fusion of carpal and tarsal bones and ankylosis of the proximal interphalangeal joints. The R438L mutant of GDF-5 acquires an ability to bind to BMPR-IA with a high binding affinity, indicating that the GDF-5 mutant exhibits biological activity similar to BMP-2 (Seemann *et al.*, 2005; Nickel *et al.*, 2005).

As described earlier, mutations in the human *Hemojuvelin* gene, encoding a BMP co-receptor hemojuvelin/RGMc, were identified in patients with juvenile hemochromatosis, which is characterized by accumulation of iron in various organs (Babitt *et al.*, 2006).

INTRACELLULAR SIGNALING

Signaling by Smad proteins

Structure of Smads

Three Classes of Smads

Smads are the major signal transducers for the serine-threonine kinase receptors (Heldin *et al.,* 1997; Miyazono *et al.,* 2000; Shi and Massagué, 2003). Activated type I

receptor kinases phosphorylate receptor-regulated Smads (R-Smads). R-Smads then form a complex with common-partner Smads (co-Smads) and translocate to the nucleus. The oligomeric Smad complexes regulate the transcription of target genes through interaction with various transcription factors and transcriptional coactivators or co-repressors. Inhibitory Smads (I-Smads) negatively regulate the action of R-Smads and/or co-Smads.

Eight different Smads have been identified in mammals. They can be classified into three subclasses as described earlier, i.e., R-Smad, co-Smad, and I-Smad. R-Smads are subdivided into those activated in BMP signaling pathways (BMP-specific R-Smads) and those in TGF-β/activin signaling pathways (TGF-β/activin-specific R-Smads). BMP-specific R-Smads include Smad1, Smad5, and Smad8, whereas Smad2 and Smad3 are TGF-β-specific R-Smads. Smad4 is the only co-Smad in mammals, shared by both BMP and TGF-β/activin signaling pathways. Smad6 and Smad7 are I-Smads. Smad1 and Smad5 have been shown to induce the differentiation of C2C12 myoblasts into osteoblasts, a process facilitated by the addition of Smad4 (Fujii *et al.,* 1999). Moreover, osteoblast differentiation by Smad1/5 requires nuclear translocation induced by receptor activation.

Smads have highly conserved N- and C-terminal regions termed Mad homology (MH) 1 and MH2 domains, respectively, which are bridged by a linker region of variable length and amino acid sequence (Fig. 3). MH2 domains are found in all three classes of Smads, whereas MH1 domains are conserved only in R-Smads and co-Smads. The N-terminal regions of I-Smads highly diverge from those of the other Smads. R-Smads have a characteristic Ser-Ser-X-Ser sequence (SSXS motif) at the C-terminal ends. The SSXS motif is phosphorylated by the type I receptors, resulting in the activation of R-Smads for signaling.

Smad1, Smad5, and Smad8 are structurally highly similar to each other, and the functional differences between them are unknown. However, Smad1 and Smad5, but not Smad8, are activated by BMP-6 and BMP-7 (Ebisawa *et al.,* 1999), whereas all three BMP-specific R-Smads are activated by BMP-2 (Aoki *et al.,* 2001). Smad1 and Smad5 are activated by TGF-β in endothelial cells and some other cells through activation of ALK-1 (Goumans *et al.,* 2003).

MH2 Domain

The MH2 domain, composed of about 200 amino acids, has various important functions. It is responsible for (1) interaction with receptors, (2) binding to SARA (Smad anchor for receptor activation), (3) oligomer formation with other Smads, (4) interaction with various DNA-binding proteins, and (5) transcriptional activation. In the absence of receptor activation, the MH2 and MH1 domains physically interact with each other and repress each other's function. Upon phosphorylation of the SSXS motif by receptors, this interaction is eliminated, and R-Smads become activated.

A region composed of 17 amino acids, termed the *L3 loop*, protrudes from the surface of the molecule and interacts with the L45 loop of type I receptors (Chen *et al.,* 1998; Shi *et al.,* 1997; Wu *et al.,* 2000). The amino acid sequences of the L3 loop are conserved in BMP-specific R-Smads and in TGF-β/activin-specific R-Smads, but diverge between these two groups. In addition to the L3 loop, the α-helix H1 in the MH2 domain, composed of eight amino acids, is also required for the interaction of BMP-specific R-Smads with type I receptors of the ALK-1 group (Chen and Massagué, 1999; see Fig. 3).

MH1 Domain

The MH1 domains, composed of approximately 130 amino acids, are responsible for (1) binding to specific DNA sequences, (2) interaction with certain DNA-binding proteins, (3) nuclear translocation, and (4) repression of the function of MH2 domains. The direct-DNA binding of Smads occurs through an 11-amino-acid "β-hairpin loop," which protrudes from the surface of the molecule (Shi *et al.,* 1998). The structure of the β-hairpin loop is conserved in R-Smads and co-Smad in mammals, and Smad4 and Smad3 bind to the characteristic Smad-binding elements (SBEs; AGAC or GTCT sequence) through this domain (Zawel *et al.,* 1998). BMP-specific R-Smads bind

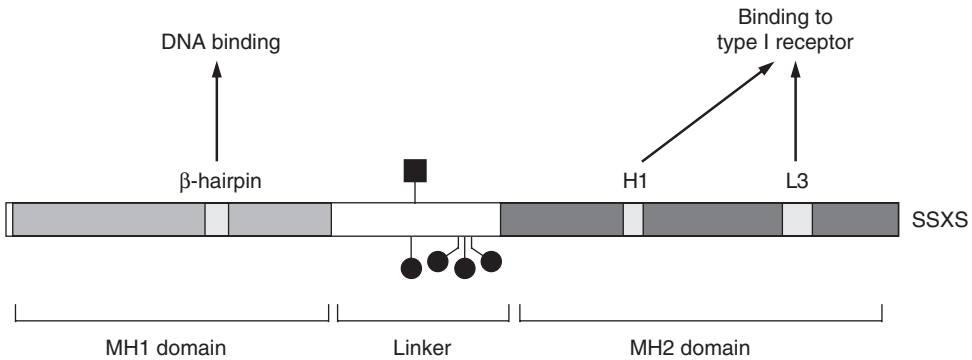

FIGURE 3 Structure of R-Smads. Circles in the linker region indicate the PXS/TP (or S/TP) motif, and the square indicates the PY motif.

to the AGAC/GTCT sequence only weakly, whereas they bind to GC-rich sequences with relatively high affinity (Kim *et al.,* 1997; Kusanagi *et al.,* 2000).

Linker Region

The linker regions of R-Smads contain four copies of PXS/TP (or S/TP) motifs that are phosphorylated by MAP (mitogen-activated protein) kinases (Kretzschmar *et al.,* 1997). When these motifs are phosphorylated, R-Smads become unable to translocate into the nucleus.

The PPXY sequence (known as the PY motif) interacts with proteins containing WW domains. A PY motif is found in all Smads except Smad4 and Smad8. Certain members of the HECT family E3 ubiquitin ligases, including Smurf1 and Smurf2, interact with Smad1 and Smad5 through the PY motif and degrade them in a ligand-independent manner (Zhu *et al.,* 1999).

An alternatively spliced variant of Smad8, lacking 37 amino acids in the linker region, has been observed (Watanabe *et al.,* 1997). Whether there is a functional difference between the long and short versions of Smad8 remains to be determined.

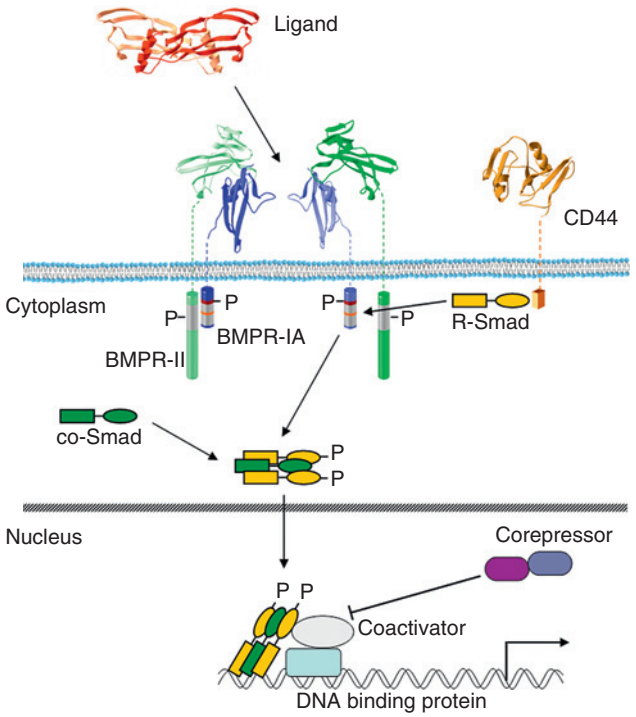

FIGURE 4 Mechanism of activation of Smad signaling pathway. R-Smads exist in the cytoplasm through interaction with membrane anchoring proteins, e.g., CD44 and endofin. Upon phosphorylation by type I receptors, R-Smads form complexes with co-Smad (Smad4), translocate into the nucleus, and regulate transcription of target genes through interaction with transcription factors (DNA binding proteins) and transcriptional coactivators. Transcriptional co-repressors inhibit the transcription induced by transcriptional coactivators. (See plate section)

Smad Signaling in the Cytoplasm

R-Smads are anchored at the cell membrane by interacting with various cytoplasmic proteins, including SARA and other molecules (Fig. 4). SARA binds to Smad2/3, but not to BMP-specific R-Smads (Tsukazaki *et al.,* 1998), whereas endofin interacts with Smad1 as well as Smad4 and enhances BMP signaling (Shi *et al.*, 2007; Chen *et al.*, 2007). dSARA in *Drosophila* was shown to interact with Mad, the *Drosophila* homologue of Smad1/5/8 (Bennett and Alphey, 2002).

SARA and endofin contain a phospholipid interaction domain, termed the FYVE domain, which targets them to the plasma membrane. SARA presents R-Smads to type I receptors and facilitates their activation (Tsukazaki *et al.,* 1998). R-Smads transiently interact with and become phosphorylated by activated type I receptors. In addition to SARA and endofin, Smad1 was shown to interact with the cytoplasmic domain of CD44, a receptor for hyaluronan (Peterson *et al.,* 2004). In chondrocytes, Smad1 is anchored at the plasma membrane by CD44 and presented to the BMP receptors for activation. Disruption of interaction between hyaluronan and CD44 leads to inhibition of Smad1 phosphorylation induced by BMPs.

The interaction between type I receptors and R-Smads is determined by the L45 loop of type I receptors and L3 loop and α-helix HI of the MH2 domains of R-Smads (see Fig. 3; Wu *et al.,* 2000). Phosphorylation occurs at the last two serine residues in the SSXS motif of the R-Smads. R-Smads then form heteromeric complexes with co-Smads, possibly composed of two or one molecule(s) of R-Smads and one molecule of co-Smad (Kawabata *et al.,* 1998; Shi, 2006).

Smad Signaling in the Nucleus

In the nucleus, Smads regulate transcription of target genes through (1) direct binding to DNA, (2) interaction with other DNA-binding proteins, and (3) recruitment of transcriptional coactivators and/or co-repressors (see Fig. 4).

In addition to the characteristic GTCT/AGAC sequence specific for Smad3 and Smad4, BMP-specific R-Smads bind to GC-rich sequences (GCCGnCGC motif) found in the promoter region of *Smad6* (Ishida *et al.*, 2000). BMP-specific R-Smads bind to other GC-rich sequences, e.g., bre7 (TGGCGCC sequence) in *Bambi*, *Vent2*, and *Smad7*. In the promoter of *Id1* gene, both SBEs and GC-rich boxes are most important for efficient transcriptional activation (Lopez-Rovira *et al.*, 2002; Korchynskyi and ten Dijke, 2002).

Smads interact with various DNA-binding proteins, and this interaction may be a critical event in the exhibition of specific effects of TGF-β family proteins in different types of cells. In certain BMP target genes, Smads may regulate transcription through indirectly binding to DNA with other transcriptional factors. Many DNA-binding proteins, including Runx, Menin, OAZ, MyoD, Vent2, Hoxc-8, and Msx1, interact with BMP-specific R-Smads (Miyazono *et al.*, 2005).

Runx is a family of transcription factors that regulate various biological events, including hematopoiesis and osteogenesis (Ito and Miyazono, 2003). Three mammalian isoforms of Runx, Runx1 through 3, interact with R-Smads. Mice lacking the *Runx2* gene (also termed *Cbfa1* or polyomavirus enhancer binding protein-αA; *PEBP2αA*) exhibit complete loss of bone formation. Haploinsufficiency of *RUNX2* in human is responsible for the development of the autosomal dominant bone disease cleidocranial dysplasia. Expression levels of Runx2 are low in undifferentiated mesenchymal cells. BMP facilitates expression of Dlx5 (Miyama *et al.*, 1999; Lee *et al.*, 2003), which in turn induces expression of Runx2 in osteoprogenitor cells. BMP-specific R-Smads physically interact with Runx2 upon activation by BMP receptors (Hanai *et al.,* 1999; Zhang *et al.,* 2000), and they cooperatively activate the transcription of target genes, leading to facilitation of the osteoblast differentiation.

Menin, the product of the *MEN1 (multiple endocrine neoplasia 1)* gene, may be required for mesenchymal stem cells to differentiate into the osteoblast lineage. Menin physically interacts with BMP-specific R-Smads and Runx2 in mesenchymal stem cells and facilitates transcriptional activity induced by BMP-specific R-Smads and Runx2 in the early stage of osteoblast differentiation (Sowa *et al.,* 2004).

In addition to the transcription factors that positively regulate the transcription of target genes, certain DNA-binding proteins act as transcriptional repressors in the absence of BMP/TGF-β stimulation, and this repression may be relieved after interaction with Smads upon ligand stimulation (Miyazono *et al.,* 2000). A homeodomain protein Hoxc-8 binds to the promoter region of the *osteopontin* gene and represses its transcription. Upon BMP stimulation, Smad1 interacts with Hoxc-8, which then dissociates from the DNA-binding element (Shi *et al.,* 1999).

p300 and CBP (CREB binding protein) have histone acetyltransferase (HAT) domains, which upregulate gene transcription by loosening nucleosomal structure and by increasing the accessibility to the general transcription machinery. p300 and CBP interact with various transcription factors; they interact with Smad1, -2, and -3 upon ligand stimulation and enhance Smad-dependent transcription of target genes (Miyazono *et al.,* 2000; Massagué and Wotton, 2000). Transcriptional complexes containing Smad1, 5, and 4 and CBP have been shown to bind to the promoter of colony-stimulating factor-1 (CSF-1) and increase the expression of CSF-1 in C2C12 cells (Ghosh-Choudhury *et al.*, 2006). In addition to Smads, p300 interacts with Runx proteins and stimulates Runx-dependent transcription. Runx3 is acetylated on lysine residues by p300 upon stimulation by TGF-β, leading to prevention of ubiquitin-dependent degradation of Runx by Smurf and stabilization of the transcriptional complex containing Runx3 and p300 (Jin *et al.*, 2004; see later discussion). GCN5 and P/CAF are transcriptional coactivators, which belong to the GNAT (GCN5-related N-acetyltransferase) superfamily. Similar to p300 and CBP, GCN5 interacts with BMP-specific R-Smads and enhances BMP-induced transcriptional activity (Kahata *et al.*, 2004).

Transcriptional co-repressors, including c-Ski, SnoN, and Evi-1, recruit histone deacetylases (HDACs) to Smad complexes (Miyazono, 2000). In contrast to p300 and CBP, they induce nucleosomal condensation, and consequently repress the transcription of target genes (see later discussion).

Target Genes for BMPs

Through DNA microarray analyses, many BMP target genes have been identified in various cells (Korchynskyi *et al.*, 2003; Clancy *et al.*, 2003; Peng *et al.*, 2003; Kowanetz *et al.*, 2004; de Jong *et al.*, 2004). Early mesenchymal cells, e.g., C2C12 cells, have been widely used for identification of BMP target genes during osteoblastic differentiation, and numerous BMP-early response genes have been identified in these cells. BMP-early response genes can be subdivided into immediate early (2 hours after BMP stimulation), intermediate early (6 hours after BMP-2 stimulation), and late early response genes (24 hours after BMP stimulation; de Jong *et al.*, 2004). Genes that are involved in signal transduction have mainly been identified as immediate early genes, including *Id1-3, Smad6, Smad7, OASIS, Prx2, TIEG,* and *Snail*. The intermediate and late early response genes are involved in osteoblast differentiation processes, and transcription factors involved in Notch and Wnt signaling, e.g., *Hey1* (also known as *HesR1* and *Herp2*) and *Tcf7,* respectively, are induced by BMP-2 treatment. In addition, some negative regulators of BMP signaling, including Smad6 and Smad7, are induced by BMPs in most cell types.

Synexpression groups are sets of genes that show similar expression profiles in certain biological processes. The BMP-4 synexpression group in the early stages of *Xenopus* embryos includes eight members, *BMP4* and *BMP7, BMPR-II, BAMBI, Smad6, Smad7, Tsg,* and *Vent2*, which encode components of the BMP signaling cascade (Karaulanov *et al.*, 2004).

Among the various BMP target genes, Id (inhibitor of differentiation or inhibitor of DNA binding) genes are induced by BMP in various types of cells and are one of the most important targets of BMPs (Ogata *et al.*, 1993). Id proteins inhibit cell differentiation and stimulate cell proliferation (Miyazono and Miyazawa, 2002). The four isoforms of Id proteins (Id1 through 4) exhibit similar, but not identical, biological activities. The ubiquitously expressed basic helix-loop-helix (bHLH) transcription factors, including E2A gene products, associate with tissue-specific bHLH transcription factors, including MyoD and myogenin in muscle, and activate transcription of genes containing E-box sequences in their promoters. Id proteins have an HLH dimerization domain, but lack the basic region responsible

for DNA binding. Through interacting with and sequestering ubiquitously expressed bHLH transcription factors, they antagonize the transcription induced by bHLH transcription factors. Id proteins induced by BMP repress transcription induced by bHLH heterodimers containing MyoD/myogenin, resulting in the inhibition of myogenesis.

Regulation of Smad Signaling

I-Smads

I-Smads, i.e., Smad6 and Smad7, function as antagonists of R-Smad/co-Smad signaling (Fig. 5). I-Smads interact with type I receptors activated by type II receptors through their MH2 domains. Unlike R-Smads, however, they do not dissociate from type I receptors, and thus prevent the activation of R-Smads (reviewed in Miyazono *et al.,* 2000). Smad6 has also been reported to form a complex with Smad1 and compete with Smad4 for oligomer formation. As a third mechanism, Smad6 has been reported to interact with a transcription factor Hoxc-8, and thereby inhibit the interaction between Smad1 and Hoxc-8 and repress the transcription of the *osteopontin* gene induced by Smad1 (Bai *et al.,* 2000). Smad7 inhibits both TGF-β and BMP signaling, whereas Smad6 preferentially represses BMP, but not TGF-β or activin, signaling.

In mammalian cells, Smad7 is located in the nucleus, and exported to the cytoplasm upon TGF-β stimulation (Itoh *et al.,* 1998). I-Smads are also exported to the cytoplasm by Smurf proteins, leading to association of I-Smads with type I receptors (see later discussion).

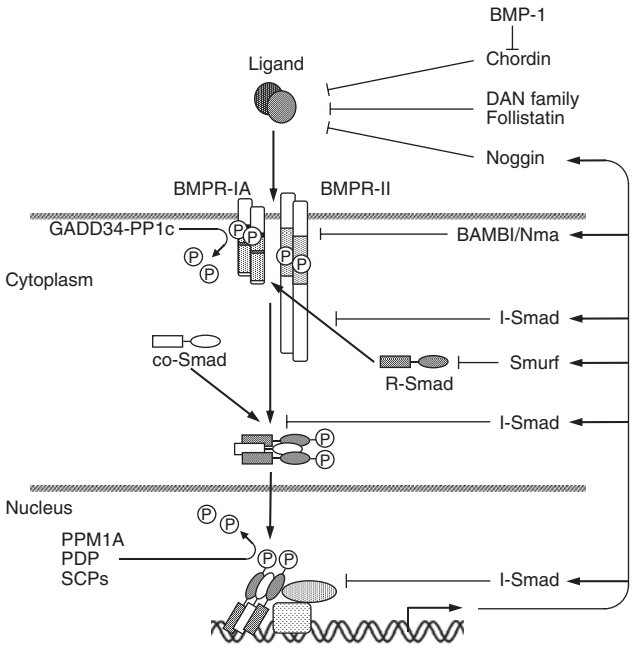

FIGURE 5 Regulation of BMP signaling pathways. BMP signaling is negatively regulated by extracellular antagonists, pseudoreceptor BAMBI/Nma, E3 ubiquitin ligase Smurf, I-Smads, and phosphatases, including PP1c, PPM1A, PDP, and SCPs. Expression of some of these regulatory molecules is induced by BMP or TGF-β signaling.

Expression of I-Smads is regulated by various stimuli, including growth factors, mechanical stress, interferon-γ, and NF-κB signaling (reviewed in Miyazono, 2000). Expression of I-Smads is strongly induced by TGF-β/activins and BMPs; transcription of Smad7 and Smad6 has been shown to be induced by direct effects of TGF-β-specific R-Smads and BMP-specific R-Smads (Nagarajan *et al.,* 1999; Ishida *et al.,* 2000). R-Smad/co-Smad and I-Smad thus form a negative feedback loop for regulation of TGF-β family signaling. I-Smads are strongly induced by BMP during osteoblastic differentiation in a biphasic fashion. I-Smads are transiently induced by BMP within 2 hours, followed by gradual, sustained induction after 2 days during the osteoblastic maturation phase (Maeda *et al.*, 2004). Endogenous TGF-β is activated during this period and induces the expression of I-Smads. Osteoblastic differentiation of mesenchymal progenitor cells at the maturation phase can thus be enhanced by a small molecule TGF-β type I receptor kinase inhibitor SB431542 (Maeda *et al.*, 2004).

In addition, expression levels of I-Smads are decreased by some E3 ubiquitin ligases, including Arkadia (Koinuma *et al.*, 2003) and Jab1/CSN5 (Kim *et al.*, 2004). AMSH (associated molecule with the SH3 domain of STAM) binds to Smad6 upon BMP stimulation and antagonizes Smad6 by interfering with the association of Smad6 with BMP type I receptors and with Smad1 (Itoh *et al.*, 2001).

Proteasome-Dependent Degradation of Smads

R-Smads are degraded by the ubiquitin–proteasome pathway in ligand-independent and ligand-dependent fashions (Miyazono, 2000). Protein ubiquitylation is triggered by E1 ubiquitin-activating enzyme, E2 ubiquitin-conjugating enzyme, and E3 ubiquitin-ligases. Of these, E3 ligases are most important for specific recognition and degradation of target proteins. HECT type E3 ligases Smurf1 and Smurf2 physically associate with R-Smads (Zhu *et al.*, 1999; Zhang *et al.*, 2001; Lin *et al.*, 2000). This interaction occurs between the WW motif in Smurfs and the PY motif in the linker region of R-Smads. Smurfs degrade BMP-specific R-Smads in a ligand-independent fashion. Smurfs thus regulate the intracellular pool of R-Smads and inhibit TGF-β family signaling.

Smurfs also interact with I-Smads (Kavsak *et al.*, 2000; Ebisawa *et al.*, 2001). Smurfs induce nuclear export of I-Smads and facilitate the interaction of I-Smads with type I receptors. The enhanced interaction of I-Smads with type I receptors results in suppression of TGF-β family signaling. Moreover, Smurfs induce degradation of the receptors, leading to a decrease in the number of cell surface receptors. Smurf1 also induces the degradation of Runx2 and reduces alkaline phosphatase activity and production of osteocalcin in osteoprogenitor cells (Zhao *et al.*, 2003). Transgenic mice overexpressing Smurf1 in osteoblasts thus show reduction in bone formation (Zhao *et al.*, 2004).

After nuclear translocation and transcriptional activation, R-Smads may be degraded by the ubiquitin-proteasome pathway (Lo and Massagué, 1999; Fukuchi *et al.,* 2000). This ligand-dependent degradation of R-Smads may be important for termination of TGF-β family signaling.

Dephosphorylation of Receptors by Protein Phosphatase 1 (PP1)

In addition to Smurfs, Smad7 interacts with GADD (growth arrest and DNA damage protein) 34, a regulatory subunit of the PP1 holoenzyme (Shi *et al.*, 2004). Smad7 recruits the catalytic subunit of PP1 (PP1c) through GADD34 to TβR-I and induces its dephosphorylation. SARA also interacts with PP1c. dSARA recruits PP1c to *Drosophila* BMP type II receptor PUNT, resulting in suppression of Dpp signaling by dephosphorylating type I receptors (Bennett and Alphey, 2002).

Smad Phosphatases

Several phosphatases have been shown to dephosphorylate the SSXS motif of R-Smads. PPM1A/PP2C, the prototype of PPM (metal ion-dependent protein phosphatase) family phosphatases, interacts with Smad1 and Smad2/3 and dephosphorylates the phospho-SSXS motif (Duan *et al.,* 2006; Lin *et al.,* 2006). PPM1A dephosphorylates the C-terminal SSXS motif, but not the linker region. Other phosphatases, including PDP (pyruvate dehydrogenase phosphatase; Chen *et al.,* 2006) and the SCPs (small C-terminal domain phosphatases; Knockaert *et al.,* 2006), decrease the level of phospho-Smad1 and suppress BMP signaling in mammals, *Xenopus*, and *Drosophila*.

Transcriptional Co-repressors

Transcriptional co-repressors, including c-Ski, SnoN, and Evi-1, repress Smad signaling (Miyazono, 2000). Ski was originally identified as the oncogene of the avian Sloan-Kettering retrovirus. SnoN is structurally closely related to c-Ski. c-Ski and SnoN interact with Smads as well as with N-CoR and mSin3A and recruit HDACs to the Smad complexes (Liu *et al.,* 2001). c-Ski and SnoN interact with Smad2/3 at the N-terminal regions, whereas they interact with Smad4 through the middle portions (Mizuide *et al.,* 2003; Wu *et al.,* 2002; Qin *et al.,* 2002). c-Ski and SnoN repress BMP signaling both *in vitro* and *in vivo* through interaction with Smad4 (Wang *et al.,* 2000; Takeda *et al.,* 2004).

Evi-1 is a sequence-specific transcriptional repressor, which is highly expressed in some human myeloid leukemias and myelodysplastic syndromes. Evi-1 binds to Smad2, Smad3, and Smad1 and represses TGF-β as well as BMP signaling (Kurokawa *et al.,* 1998; Alliston *et al.,* 2005). Evi-1 interacts with a transcriptional co-repressor CtBP, and decreases acetylation of histones upon ligand stimulation (Palmer *et al.,* 2001; Alliston *et al.,* 2005).

Other BMP Signaling Regulators

Some other molecules, including Tob, SANE (Raju *et al.,* 2003), and CIZ (Shen *et al.,* 2002), interact with BMP-specific R-Smads and regulate BMP signaling through various mechanisms.

Tob (transducer of ErbB2) is a member of the antiproliferative gene family, which inhibits growth of NIH3T3 cells and T lymphocytes. Tob-deficient mice show osteosclerosis with an increased bone mass later in their lives (Yoshida *et al.,* 2000). Tob inhibits BMP signaling in osteoblasts through interaction with BMP-specific R-Smads. In addition, Tob associates with I-Smads, and inhibits BMP signaling through interaction with BMP type I receptors (Yoshida *et al.,* 2003).

Crosstalk with Other Signaling Pathways

BMP signaling is regulated negatively and positively by various signaling pathways (Herpin and Cunningham, 2007). The Erk MAP kinase pathway is activated by peptide growth factors. Erk phosphorylates the serines and threonines in the PXT/SP (or T/SP) motif, four copies of which are present in the linker regions of R-Smads. R-Smads phosphorylated by Erk are unable to translocate into the nucleus, and thus signaling by BMPs and TGF-β is inhibited by peptide growth factors through the action of Erk MAP kinase (Kretzschmar *et al.,* 1997). Phosphorylation of the linker region of BMP-specific R-Smads also facilitates the interaction with and degradation by Smurf1 (Sapkota *et al.,* 2007). In contrast to the antagonistic effects, MAP kinase signaling enhances BMP signaling under certain conditions, e.g., activation of Erk MAP kinase pathway by FAK (focal adhesion kinase; Tamura *et al.,* 2001).

Leukemia inhibitory factor (LIF) and BMP-2 synergistically induce astrocytic differentiation of neuroepithelial cells (Nakashima *et al.,* 1999). LIF activates STAT3 through gp130 and JAKs, and BMP-2 activates BMP-specific R-Smads. Although direct interaction between STAT3 and BMP-specific R-Smads is not observed, they are indirectly associated through binding to p300, which results in cooperative transcriptional activation of target genes.

Notch encodes a transmembrane receptor that is proteolytically cleaved upon binding of ligands. The cleaved product, the Notch intracellular domain (NICD), translocates into the nucleus, where it associates with the transcription factor CSL/RBP-Jκ/CBF-1. The NICD-CSL complexes induce transcription of target genes, including *Hey* and *Hes,* which encode bHLH transcriptional regulators. Both synergy and antagonism have been observed between the Notch and BMP signaling pathways. Expression of Hey1 and Hes1 is induced by BMP in various cells, including osteoprogenitor cells, and it is required for inhibition of myogenic differentiation induced by BMP-4 (Dahlqvist *et al.,* 2003). Smad1 physically interacts

with NICD and activates the transcription of *Hey1*. In contrast, Hey1 induced by BMP-2 has been reported to negatively regulate osteoblast maturation by suppressing the transcriptional activity of Runx2 (Zamurovic *et al.,* 2004).

BMP and Wnt signaling pathways act synergistically on various biological processes. Wnt signaling induces the stabilization and accumulation of β-catenin, resulting in the interaction with the Lef1/Tcf family transcription factors and transcription of target genes. BMP-dependent activation of Msx2 is mediated by cooperative binding of Smad4 and Lef1 to the Msx2 promoter (Hussein *et al.,* 2003). Tcf7, a downstream effector of Wnt signaling, is induced by BMP-2 and inhibits myogenic differentiation through suppression of the expression of myogenin and MyoD (de Jong *et al.,* 2004).

In Vivo Abnormalities Associated with Smad Genes

Mutations of the human *SMAD4/DPC4* gene are frequently found in pancreatic cancer, biliary tract cancer, metastatic colon cancer, and juvenile polyposis (reviewed in Miyazono *et al.,* 2000). *Smad4* null mice die before E7.5 with gastrulation defects and an abnormal visceral mesoderm, which are similar to the phenotypes of BMP-4- and BMPR-IA-deficient mice (Sirard *et al.,* 1998). Homozygotic loss of the *Smad4* gene together with *Apc* mutations results in progression of intestinal tumors (Takaku *et al.,* 1998). *Smad4* heterozygous mice develop gastric polyposis 6 to 12 months after birth, which eventually progresses to gastric cancer as a result of loss of heterozygosity (Takaku *et al.,* 1999; Xu *et al.,* 2000).

Smad5-deficient mice exhibit abnormalities in angiogenesis with dilated vessels and decreased number of smooth muscle cells surrounding vessels (Yang *et al.,* 1999; Chang *et al.,* 1999). The phenotype of *Smad5*-null mice is similar to that of the *Alk1*-null mice as well as those of TGF-β-, TβR-II-, or endoglin-deficient mice. Because ALK-1 binds TGF-β in endothelial cells and activates BMP-specific R-Smads (Oh *et al.,* 2000; Goumans *et al.*, 2003), Smad5 might be an important signal transducer for TGF-β in endothelium. Smad5 is also required for development of left–right asymmetry (Chang *et al.,* 2000). Targeted disruption of the mouse *Smad1* gene demonstrates an essential role for Smad1 in chorioallantoic fusion and primordial germ cell formation (Lechleider *et al.,* 2001; Tremblay *et al.,* 2001). Smad8-deficient mice do not exhibit overt abnormalities during embryogenic or postnatal development (Hester *et al.,* 2005; Arnold *et al.,* 2006).

Smad6-null mice exhibit cardiac defects with abnormal valve formation and outflow tract septation (Galvin *et al.,* 2000). Some *Smad6*-null mice survive through adulthood, but exhibit aortic ossification and elevated blood pressure, indicating that Smad6 is required for development and homeostasis of the cardiovascular system.

Transgenic mice expressing Smad6 in chondrocytes exhibit dwarfism with osteopenia and delayed chondrocyte hypertrophy (Horiki *et al.,* 2004). Transgenic mice expressing Smurf1 in chondrocytes do not show significant abnormalities, but double transgenic mice expressing Smad6 and Smurf1 in chondrocytes show more delayed ossification than the Smad6 transgenic mice (Horiki *et al.,* 2004). Smurf1-deficient mice exhibit age-dependent increase of bone mass, due to enhanced osteoblast activity induced by activation of MEKK2 and the JNK signaling cascade (Yamashita *et al.,* 2005).

Non-Smad Pathways

In addition to the Smad pathways, BMP-2 and GDF-5 have been shown to activate the p38 MAP kinase pathway (Iwasaki *et al.,* 1999; Nakamura *et al.,* 1999; Kimura *et al.,* 2000). The p38 MAP kinase activated by BMPs induces neurite outgrowth from PC12 pheochromocytoma cells, chondrocyte differentiation of ATDC5 mouse teratocarcinoma cells, and apoptosis in mouse hybridoma MH60 cells. Erk MAP kinases have also been shown to be activated by BMP-2 in certain cells. These non-Smad pathways activated by BMPs may play important roles in modulation of effects of Smads on cellular proliferation and differentiation.

TAK1 has been reported to act as a downstream component of BMP and TGF-β and activate the SAPK/JNK and p38 MAP kinase pathways. BMPR-IA directly interacts with XIAP, which activates TAB1-TAK1. However, activation of TAK1 by TGF-β or BMPs may occur only under certain conditions; under physiological conditions, TAK1 may serve as a downstream target of interleukin-1 (Ninomiya-Tsuji *et al.,* 1999).

The C-terminal tail of BMPR-II interacts with LIM kinase 1 (LMK1), Tctex1, Src, and Tribbles-like protein 3 (Trb3). LMK1 regulates actin dynamics through phosphorylation and inactivation of cofilin. BMPR-II has been reported to inhibit the ability of LIMK1 to phosphorylate cofilin through interaction with its C-terminal tail (Foletta *et al.*, 2003). LIMK1 has also been reported to be activated by BMPR-II binding and Cdc42, and to modulate BMP-dependent regulation of neurite formation (Lee-Hoeflich *et al.*, 2004). Tctex1 is a light chain of the motor complex dynein (Machado *et al.,* 2003). BMPR-II induces phosphorylation of Tctex, resulting in movement of Tctex along the microtubules and the efficient activation of downstream signal mediators. The C-terminal tail of BMPR-II also interacts with c-Src and decreases c-Src-activating phosphorylation at Tyr-418 in pulmonary smooth muscle cells upon ligand stimulation (Wong *et al.*, 2005). In addition to regulating the non-Smad pathways, the C-terminal tail may also regulate the Smad signaling pathway. Trb3 is associated with the BMPR-II C-terminal tail and is released from BMPR-II upon ligand binding. Trb3 then induces degradation of Smurf1, leading to stabilization of BMP-specific R-Smads and facilitation of the Smad signaling pathway (Chan *et al.*, 2007).

EXTRACELLULAR REGULATORS OF BMPs

BMP Antagonists

The biological activities of BMPs are tightly regulated by extracellular antagonists (see Fig. 5). A wide variety of extracellular antagonists of the TGF-β family exist and are divided into two different types: those that directly bind ligands (ligand-binding antagonists) and others that compete with ligands for binding to specific receptors (pseudoligand-type antagonists) (Miyazono, 2000). Lefty-1, Lefty-2, and zebrafish Antivin are typical pseudoligand-type antagonists, which interfere with binding of nodal and activin-like factors to activin type II receptors.

Most of the antagonists of BMPs are ligand-binding type antagonists, including Noggin, Chordin, Cerberus and its related proteins, Sclerostin, ectodin/uterine sensitization-associated gene-1 (USAG-1), Follistatin, and nephroblastoma overexpressed (Nov; Canalis *et al.*, 2003). Cerberus and its related proteins, including Gremlin, Caronte, and DAN, contain a conserved cystine-knot motif, and are collectively referred to as the DAN family. Sclerostin and USAG-1 are small secreted proteins with a cystine-knot structure similar to those in DAN family proteins. Nov is a member of the CCN family of cysteine-rich secreted proteins including connective tissue growth factor (CTGF) and cysteine-rich 61 (Cyr 61; Rydziel *et al.*, 2007).

These BMP antagonists have distinct expression profiles and different affinities with various BMP isoforms. Noggin associates with BMPs, including BMP-2, BMP-4, GDF-5, GDF-6, BMP-5, and BMP-6. Caronte functions as an antagonist of BMP-4, BMP-7, and nodal. Noggin competes with Cerberus, Gremlin, and DAN for binding to BMP-2, indicating that the binding sites in BMPs are shared by these antagonists (Hsu *et al.*, 1998). Cerberus binds to several cytokines, including BMPs, nodal-like factors, and Wnt, through independent binding sites in its molecule (Piccolo *et al.*, 1999). Follistatin is a potent antagonist of activins, but also antagonizes certain BMPs both *in vitro* and *in vivo.*

Limb development is regulated by various BMP antagonists, including Noggin, Chordin, Gremlin, and Follistatin (McMahon *et al.*, 1998; Merino *et al.*, 1999). Noggin is abundantly present in joint-forming spaces, and mutations in the human Noggin *(NOG)* gene are associated with skeletal dysplasia syndromes, such as proximal symphalangism (SYM1; Gong *et al.*, 1999). Noggin is also expressed in the follicular mesenchyme and involved in hair-follicle induction (Botchkarev *et al.*, 1999). In *Xenopus* embryos, Noggin and Chordin are expressed in Spemann's organizer and induce neural tissues and dorsalize ventral mesoderm. These BMP antagonists may thus play a central role in the formation of morphogen gradients during early embryogenesis.

Mutations of human Sclerostin *(SOST)* gene are responsible for sclerosteosis, a recessive autosomal sclerosing bone dysplasia characterized by progressive skeletal overgrowth (Balemans *et al.*, 2001; Brunkow *et al.*, 2001). Sclerostin was reported to interact with BMPs, interfere with the binding of BMPs to their receptors, and inhibits BMP-stimulated bone differentiation (Kusu *et al.*, 2003; Winkler *et al.*, 2003). However, recent data suggested that primary function of sclerostin in suppression of bone morphogenesis is induced by modulation of Wnt signaling (van Bezooijen *et al.*, 2004) through interaction with Wnt receptor LRP5/6, rather than BMP signaling (Li *et al.*, 2005; Semenov *et al.*, 2005).

Certain BMP antagonists may exert their effects through a negative feedback loop. Expression of Noggin is induced by BMPs in osteoprogenitor cells (Gazzero *et al.*, 1998). Other cytokines, including TGF-β, also induce expression of Noggin, indicating that expression of BMP antagonists is regulated by BMP signaling itself, as well as through crosstalk of signals.

BMP-1 Is a BMP Activator

BMP-1 does not belong to the TGF-β family but is a procollagen C-proteinase that cleaves procollagens and induces accumulation of extracellular matrix (Kessler *et al.*, 1996). BMP-1 homologues are present in *Drosophila (Tolloid)* and in *Xenopus (Xolloid);* studies of Tolloid and Xolloid suggest that BMP-1 may be an activator of BMPs, because it releases active BMPs from inactive complexes by cleavage of Chordin (Piccolo *et al.*, 1996; Marques *et al.*, 1997). The proteinase activity of BMP-1 is suppressed by Frizzled-related proteins, including Ogon/Sizzled, which results in stabilization of Chordin (Lee *et al.*, 2006). BMP-1 also cleaves latent TGF-β binding protein, leading to consequent activation of latent TGF-β by metalloproteinases, e.g. MMP2 (Ge and Greenspan, 2006). In addition, BMP-1-like proteinases activate the latent form of myostatin by cleavage of its prodomain (Wolfman *et al.*, 2003).

CONCLUSION

BMPs play multiple roles in various tissues including bone, cartilage, neurons, heart, kidney, liver, and lung. Signaling by BMPs is transduced by serine-threonine kinase receptors and Smad proteins. BMP signaling is tightly regulated by various mechanisms including extracellular antagonists, pseudoreceptors, and I-Smads. BMPs thus exhibit a diverse array of biological activities in various tissues. Further understanding of the BMP signaling pathways can aid the pharmacological regulation of biological activities of BMPs in various tissues.

Chapter 56

Colony-Stimulating Factor-1

W. Hofstetter*
Department Clinical Research, University of Bern, Murtenstrasse 35, 3010 Bern, Switzerland

INTRODUCTION

Bone and bone marrow exist in a close anatomical relationship, and several lines of evidence suggest a reciprocal interaction between the two tissues. Bone provides the microenvironment that is critical for the development of the hemopoietic stem cells, from which all the cells of the mammalian immune system derive (Arron and Choi, 2000; Walsh *et al.,* 2006). In the bone marrow reside the precursors of the cell lineages accounting for the cellular base of bone remodeling. Osteoclasts, the cells dissolving bone, originate from hemopoietic progenitors, the colony-forming unit granulocyte/macrophage (CFU-GM; Kurihara *et al.*, 1990; Hagenaars *et al.,* 1991; Hattersley *et al.,* 1991a, 1991b). Osteoblast lineage cells, the cells elaborating the extracellular matrix of bone and regulating its mineralization, are derived from mesenchymal progenitors of the marrow stroma, the colony-forming unit fibroblasts (CFU-Fs; Owen, 1985; Owen and Friedenstein, 1988).

The interactions between hemopoietic and bone cells are complex and occur at different levels. Immunoregulatory cytokines of hemopoietic origin modulate the development and activity of bone cells. In developing bone, osteoclasts resorb and invade the calcified cartilage rudiment. As a result, the primitive marrow cavity is formed and hemopoiesis is initiated. Bone cells take part in hemopoiesis by synthesizing growth factors essential for the proliferation and differentiation of hemopoietic cells. In the bone marrow, hemopoietic stem cells proliferate and differentiate into lineage-restricted progenitors that eventually give rise to the terminally differentiated cells of the lymphoid and myeloid series. This differentiation process is directed by a group of lineage-specific growth factors, the colony-stimulating factors (CSFs; Metcalf and Nicola, 1984). The hemopoietic CSFs are glycoproteins that were initially characterized by their ability to stimulate *in vitro* the clonal proliferation of hemopoietic multipotential stem cells and/or mono- or bipotential progenitors in semisolid (agar or methylcellulose) medium. Furthermore, CSFs, which include interleukin-3 (IL-3, also named multi-CSF), granulocyte-macrophage-CSF (GM-CSF), granulocyte-CSF (G-CSF), and colony-stimulating factor-1 (CSF-1; also named macrophage-CSF, M-CSF) will induce the activity of mature, specialized myeloid cells and are required for their survival.

CSFs are ideal candidate factors for being synthesized by osteogenic cells to modulate at the local level osteoclast recruitment and marrow hemopoiesis. In this chapter, the role of CSF-1 is described in modulating osteoclast development and activity. Functions outside of bone are only mentioned, without detailed elaboration. Other cytokines and interleukins besides CSF-1 do have intrinsic and/or synergistic effects on hemopoiesis and osteoclast development. Their respective roles in the local control of bone cell physiology are described in detail in other chapters of this book.

CSF-1 is the lineage-specific growth factor for cells of the mononuclear phagocyte system (MNPS) and for osteoclasts. The cytokine binds to a single class of high-affinity cell-surface receptors that are encoded by the proto-oncogene c-*fms* and belong to the receptor tyrosine kinase family. Expression of c-*fms* is considered a marker for the cells of the MNPS (Felix *et al.,* 1994; Stanley, 1994). Within this chapter, the effects of the cytokine on the cells of this lineage as well as the involved mechanisms are discussed.

MOLECULAR BIOLOGY AND BIOCHEMISTRY OF CSF-1

CSF-1 is the product of a single-copy gene, size and structure are well conserved between different species. The gene spans approx. 120 kb and is composed of 10 exons, 8 of which encode the translated sequence. Several transcripts,

*Corresponding author: Willy Hofstetter, PhD, Group for Bone Biology, Department of Clinical Research, University of Bern, Murtenstrasse 35, 3010 Bern, Switzerland, Phone: +41 31 632 8786, Fax: +41 31 632 3297, E-mail: hofstetter@dkf.unibe.ch

derived from a common RNA precursor by alternative splicing, encode either a secreted or a membrane-bound form of the cytokine (for review, see Sherr and Stanley, 1990).

All translation products contain an amino-terminal signal peptide of 32 amino acids. A hydrophobic 23-amino-acid region is followed by a charged "stop transfer" sequence, characteristic for many membrane-spanning proteins. The CSF-1 peptide is cotranslationally glycosylated and remains integrated in the membrane of the endoplasmic reticulum, the amino-terminal end facing the lumen. In the Golgi, the protein is O-glycosylated, the N-linked carbohydrate molecules are further processed, and eventually the cytokine can be modified by the attachment of a glycosaminoglycan side chain (Price *et al.*, 1992; Suzu *et al.*, 1992; Felix *et al.*, 1996). The secreted cytokine is synthesized as a 554-amino-acid precursor, which is processed to yield a disulfide-linked homodimer of 223 amino acids per chain, whereas the membrane-bound form is synthesized as a precursor protein of 256 amino acids, which subsequently is processed to a homodimer of 150 amino acids per chain.

THE ROLES OF SECRETED AND MEMBRANE-BOUND CSF-1

The osteopetrotic mouse strain *op* was the first animal model found to be deficient in a hemopoietic growth factor (Felix *et al.*, 1990b; Wiktor-Jedrzejczak *et al.*, 1990). The phenotype of these mice was characterized by a strong reduction in tissue macrophages and a virtual absence of osteoclasts (Marks and Lane, 1976). Thus, CSF-1 was described as the first obligate growth factor for osteoclasts, its activity being a prerequisite for functional bone resorption. The contributions of the molecular forms of CSF-1 to bone resorption and their regulation were the subject of intense study. The cytokine could be a constitutive part of the hemopoietic microenvironment in bone, essential but continuously present and not exerting regulatory functions. As a second possibility, CSF-1 may be involved in the acute regulation of bone resorption and as a consequence will be modulated by osteotropic hormones and cytokines. The aforementioned fact that CSF-1 is synthesized either as a secreted or as a membrane-bound molecule further complicated the elucidation of the cytokine's role in bone biology. In cell culture experiments, the membrane-bound form of CSF-1 was found to be more efficient than soluble CSF-1 in promoting osteoclast formation (Takahashi *et al.*, 1991). At that time, this was attributed to the proximal relationship of other membrane-associated factors regulating osteoclastogenesis, a hypothesis that was subsequently confirmed with the characterization of the osteoclastogenic growth factor RANKL (receptor activator of NF-κB ligand; Kong *et al.*, 1999).

The dependence of osteoclastogenesis and bone development on the biological activity of CSF-1 was further confirmed in animals lacking *c-Fms* (Dai *et al.*, 2002). The phenotype of the *c-fms*$^{-/-}$ mice closely resembled the phenotype of the *op* animals, including the osteopetrotic, hemopoietic, tissue macrophage and reproductive phenotypes. Furthermore, the osteopetrotic phenotype is resolved in the *c-fms*$^{-/-}$ animals with aging, as was previously reported for *op* animals. Further information on the spatial and temporal roles of *c-Fms* will be derived from the experimental use of conditional *c-fms* knockouts (Li *et al.*, 2006).

CSF-1 has been shown to be expressed by numerous cell types, such as activated macrophages and T cells, epithelial and mesenchymal cells, but the major source of circulating CSF-1 is endothelial (Metcalf *et al.*, 2001; Pixley and Stanley, 2004). *In vitro*, CSF-1 secretion by osteoblast lineage cells is stimulated by parathyroid hormone (PTH), interleukin-1 (IL-1), and tumor necrosis factor-α (TNFα) (Sato *et al.*, 1986; Felix *et al.*, 1988). In contrast to the rather ubiquitous expression *in vitro*, expression of the cytokine is tightly controlled *in vivo*. Levels of CSF-1 are dramatically increased in mice during early pregnancy (Bartocci *et al.*, 1986), the cytokine being induced by 17β-estradiol and progesterone in uterine glandular epithelial cells (Pollard *et al.*, 1987; Daiter *et al.*, 1992). In bone, expression of CSF-1 is correlated temporally and spatially with osteoclast formation and bone resorption (Hofstetter *et al.*, 1995). Although a considerable body of data has been collected, little is known about the transcriptional and translational regulation of the expression of CSF-1 *in vivo*. Deficiency in estrogen will cause a release of TNFα by bone marrow (Kimble *et al.*, 1996) and T cells (Roggia *et al.*, 2001, 2004) which in turn will affect osteoclastogenesis by direct or indirect actions on osteoblast and osteoclast lineage cells (Bertolini *et al.*, 1986; Fuller *et al.*, 2002; Nanes, 2003) or which will cause expansion of a subpopulation of stromal cells high in CSF-1 production (Kimble *et al.*, 1996).

The osteopetrotic mouse strain *op*, described earlier as deficient in active CSF-1, represents an ideal model to investigate the biological roles of the cytokine (Felix *et al.*, 1990b; Wiktor-Jedrzejczak *et al.*, 1990). The lack of biologically active CSF-1 was found to be caused by a point mutation within the coding region of the CSF-1 gene (Yoshida *et al.*, 1990). Treatment of newborn *op/op* animals with daily injections of recombinant human CSF-1 induced osteoclast formation and bone resorption, proving the deficiency in CSF-1 to be the cause of the osteopetrosis in this strain (Felix *et al.*, 1990a; Kodama *et al.*, 1991). Transgenic animals, in which CSF-1 expression was reconstituted within the *op* background, were instrumental in the elucidation of the specific roles of the molecular forms of CSF-1. Expression of the full-length cytokine, under control of a 3.13-kb fragment of the CSF-1 promoter, fully reversed the *op* phenotype (Ryan *et al.*, 2001). The correction of essentially all the defects of the *op* strain demonstrates

that in these animals all the observed alterations are due to CSF-1 and not due to an unknown secondary defect. In contrast to the restoration of a normal phenotype in *op* animals expressing the soluble CSF-1, exclusive expression of the membrane bound molecule was sufficient for a partial phenotypic rescue only (Dai *et al.,* 2004), although low levels of circulating CSF-1, shed from the membrane, could be detected (Ovadia *et al.,* 2006). Despite the restoration of tooth eruption, reproductive functions, and F4/80$^+$ tissue macrophages of some tissues, macrophages of other tissues failed to develop, and some residual osteopetrosis and abnormal hemopoietic parameters were found in these mice. The two models demonstrated that soluble CSF-1 is sufficient for a complete reversal of the phenotype, whereas the membrane-bound molecule enables partial recovery. Whether this deficiency is due to specific effects of the molecular forms or whether it is caused by limited availability at specific sites remains an open question.

Because osteopetrosis is a major phenotype in *op* mice, it could be hypothesized that osteoblast-derived CSF-1 might affect the bone disease. Indeed, forced expression of soluble CSF-1 in osteoblasts in transgenic *op* mice carrying the CSF-1 gene under the control of the osteocalcin promoter restored osteoclastogenesis and as a consequence resolved the osteopetrotic phenotype (Abboud *et al.,* 2002).

The analysis of these animal models supports the hypothesis that the different molecular forms of CSF-1 may indeed induce different responses in the target cells, be it in concert with other ligands and receptors (i.e., RANKL/RANK) or by inducing different signal transduction cascades in their respective target cells. The availability of the soluble cytokine at sufficient levels, however, seems to allow for virtually full function and for the mediation of the full array of biological effects.

REGULATION OF CSF-1 EXPRESSION

Different functions of the secreted and the membrane-bound forms of CSF-1 suggest differential regulation. Indeed, various research groups described hormones, e.g., PTH, 1,25$(OH)_2$ vitamin D_3, and dexamethasone, cytokines such as TNFα, or mechanical stimuli to stimulate expression either of both molecular forms of CSF-1 or of the membrane-bound form of cytokine only (Rubin *et al.,* 1996, 1997, 1998; Yao *et al.,* 1998; Saunders *et al.,* 2006). Because the transcripts encoding CSF-1 are derived from a common hnRNA precursor by differential splicing, the regulation of the expression of membrane-bound and secreted CSF-1 occurs at the post-transcriptional level. The mechanisms that allow for this regulation, however, are not well understood.

A considerable effort was devoted to the elucidation of the transcriptional control of CSF-1 expression. The promoter of the murine CSF-1 gene was found to contain consensus sequences for numerous transcription factors (Harrington *et al.,* 1991). *In vitro*, TNFα was most effective in regulating CSF-1 expression through activation of the NF-κB signaling pathway, in cells of the osteoblast lineage. The relevance of the members of the NF-κB family of signaling molecules in bone metabolism was evident when double knockout mice, deficient in the NF-κBs p50 and p52, expressed an osteopetrotic phenotype caused by the absence of osteoclasts (Iotsova *et al.,* 1997). The dependence of CSF-1 expression on NF-κB was also demonstrated with osteoblastic cells derived from mice deficient in p50. In contrast to cells from wild-type controls, CSF-1 levels were not increased in p50-deficient osteoblasts upon treatment with TNFα (Yao *et al.,* 2000). Somewhat contradictory, however, was the finding that the NF-κB consensus sequence of the CSF-1 promoter did not affect the stimulation of CSF-1 expression by TNFα (Isaacs *et al.,* 1999; Rubin *et al.,* 2000) or that TNFα may (Kimble *et al.,* 1996) or may not (Balga *et al.,* 2006) increase CSF-1 transcript levels in primary osteoblasts. A further transcription factor shown to take part in the transcriptional regulation of CSF-1 is AP-1 (Konicek *et al.,* 1998).

In conclusion, the expression of the cytokine in different cell types is governed by general and by cell-type-specific *trans*-acting factors, allowing for a tight temporal and spatial regulation. As mentioned, however, it is still not clear whether CSF-1 is involved in the acute regulation of bone resorption or whether the growth factor acts as a constitutive and essential component of the hemopoietic microenvironment. Support for the latter comes from studies in which IL1, IL3, IL6, IL7, IL10, GM-CSF, G-CSF, bFGF, and TGFβ did not effect CSF-1 expression by cultured human bone marrow stromal cells (Besse *et al.,* 2000).

CSF-1 IN POSTMENOPAUSAL OSTEOPOROSIS

Peripheral blood monocytes from osteoporotic women (Pacifici *et al.,* 1987) or from women after oophorectomy (Pacifici *et al.,* 1991) were found to secrete elevated levels of IL-1 and TNFα. An increase in the production of these cytokines, and their critical role in increased bone loss, was confirmed in various animal studies (Ammann *et al.,* 1997; Kimble *et al.,* 1997; Roggia *et al.,* 2001). CSF-1 was first implicated in bone loss after estrogen deficiency, when it was found that after ovariectomy, under the influence of IL1 and TNFα, a subpopulation of stromal cells developed that synthesized increased levels of CSF-1 (Kimble *et al.,* 1996). Further studies on the mechanism of action of IL1 and TNFα on the expression of CSF-1 demonstrated the involvement of the early response gene *egr-1*. Under estrogen deficiency, *Egr-1* becomes phosphorylated.

In its phosphorylated state, *Egr-1* cannot interact with the transcription factor SP-1, causing an excess of free SP-1 to stimulate CSF-1 production via the SP-1 site in the CSF-1 promoter (Srivastava *et al.,* 1998). Consequently, in mice deficient in *Egr-1,* bone turnover is high, but estrogen deficiency fails to stimulate bone resorption any further (Cenci *et al.,* 2000). Furthermore, evidence has been presented suggesting a differential expression of the molecular forms of CSF-1 under estrogen deprivation. In cultures of human bone marrow cells (Sarma *et al.,* 1998) and in ovariectomized rats (Lea *et al.,* 1999), the expression of the membrane-bound form of CSF-1 was increased under estrogen deficiency, an effect that was reversed by the treatment with the hormone.

CSF-1 AND OSTEOIMMUNOLOGY

In the recent past, the crosstalk between cells of the immune defense and bone has attracted increased interest, and the term *osteoimmunology* has been coined (Arron and Choi, 2000; Walsh *et al.,* 2006). Immunomodulatory cytokines affect both cells of bone and of the immune system in physiological and pathophysiological conditions, and bone active diseases such as postmenopausal osteoporosis, inflammatory joint diseases such as rheumatoid arthritis, or clinical complications such as loosening of orthopedic implants are caused by identical sets of cytokines and cells and thus are governed by similar mechanisms. Activated T cells were supporting osteoclast formation by secreting the essential growth factor RANKL *in vitro* (Horwood *et al.,* 1998) and *in vivo* (Kong *et al.,* 1999). Most interesting, osteoclastogenesis induced by T cells is counteracted by interferon-γ, another T-cell product (Takayanagi *et al.,* 2000). The T cell–bone connection, however, not only is important in inflammatory and immunologic situations, but has been shown to be relevant in estrogen deficiency as well. Thus, not only may cells of the monocyte/macrophage lineage mediate the effect of estrogen deficiency on bone by the production of TNFα and IL1, but T lymphocytes contribute to bone loss through the synthesis of TNFα as well (Cenci *et al.,* 2000). The critical role of T cells in this process, however, is somewhat controversial. Athymic nude mice (Cenci *et al.,* 2000) and *Rag1*$^{-/-}$ mice that are deficient in both T and B lymphocytes (Medina *et al.,* 2000) were demonstrated to be protected from bone wasting after OVX, whereas others reported a failure of protection in T cell-deficient mice (Lee *et al.,* 2006). In all these cases, CSF-1 is postulated to represent a component of the hemopoietic environment, expression levels being increased by TNFα (Kimble *et al.,* 1996) and by estrogen deficiency (Srivastava *et al.,* 1998), and thus contributing to the stimulation of osteoclast development and activation. Furthermore, levels of CSF-1, among other inflammatory cytokines, were suggested to be increased in conditions of aseptic loosening of orthopedic implants caused by wear particles or metal ions (Pioletti and Kottelat, 2004; Jost-Albrecht and Hofstetter, 2006).

THE ROLE OF CSF-1 IN THE FORMATION OF OSTEOCLASTS

The role of CSF-1 in the development of osteoclasts *in vivo* and in physiological bone resorption has been extensively investigated and was described in detail earlier. For the elucidation of the detailed mechanisms of CSF-1 action in osteoclastogenesis, investigations in cell and organ culture systems were most rewarding, and the dependence of osteoclast formation on CSF-1 was confirmed and could be further elucidated. In cultures of ^{45}Ca-prelabeled fetal metatarsals, CSF-1 stimulated osteoclastogenesis and the release of ^{45}Ca. This effect was blocked by irradiation of the bone rudiments, indicating an action of CSF-1 on proliferating osteoclast precursors. The cytokine was not found to exert an effect on bone resorption in cultured fetal radii, a system in which bone resorption depends on the activation of mature osteoclasts (Corboz *et al.,* 1992). These data suggested an effect of CSF-1 on recruitment of osteoclasts rather than on the activation of mature cells. In cultures of ^{45}Ca-prelabeled fetal metatarsals from *op/op* mice, CSF-1 alone exerted only a slight effect on the release of ^{45}Ca. Bone resorption was stimulated, however, when the rudiments were cultured in the presence of CSF-1 plus PTH and 1,25(OH)$_2$D$_3$ (Morohashi *et al.,* 1994). In this system, CSF-1 was required but not sufficient for the formation of osteoclasts. Although it was not clear at that time, with present knowledge it can be concluded that the process of osteoclast formation is initiated by CSF-1 through the induction of the proliferation of osteoclast precursors, whereas PTH and 1,25(OH)$_2$D$_3$ induce osteoblastic and stromal cells to express RANKL supporting the late steps of osteoclastogenesis.

In vitro, osteoclasts are formed in cocultures of osteoblasts or stromal cells and hemopoietic precursor cells in the presence of 1,25(OH)$_2$D$_3$ (Takahashi *et al.,* 1988). The coculture system can be divided into an early proliferative phase and a late differentiation and fusion phase. Whereas 1,25(OH)$_2$D$_3$ is essential only during the second phase of the culture, CSF-1 was found to be required during both the proliferation and differentiation/fusion phases (Tanaka *et al.,* 1993). Neutralizing antibodies against GM-CSF did not affect osteoclast formation. Precursor cells grown in the presence of GM-CSF or interleukin-3, however, are capable of forming osteoclasts in coculture with osteoblasts (Takahashi *et al.,* 1991; Lari *et al.,* 2007). These cytokines may therefore support proliferation of early precursors, but are not able to replace CSF-1 at later stages of development. Somewhat contradictory was the finding that fusion

of osteoclast precursors in long-term bone marrow cultures is not blocked by anti-CSF-1 antibodies, demonstrating that this step in osteoclast formation does not depend on the cytokine (Biskobing *et al.,* 1995). The notion that the late stages of osteoclast formation and of bone resorption are independent of the presence of CSF-1 was supported by some *in vivo* data. To induce osteoclast formation in osteopetrotic *op* mice, a single injection of the growth factor proved to be sufficient (Kodama *et al.,* 1993). In these experiments, however, the actual temporal availability of the cytokine cannot be assessed accurately, and conclusions on the cellular differentiation stages affected by CSF-1 should be drawn carefully.

The actions of hemopoietic growth factors are not restricted to the differentiation and activation of the target cells, but they are required for survival as well. Accordingly, CSF-1 is no exception to the rule and provides support for survival of osteoclast lineage cells (Fuller *et al.,* 1993). Indeed, enforced expression of Bcl-2, the protein blocking programmed cell death, in *op* mice restored macrophage development and resolved the osteopetrotic phenotype (Lagasse and Weissman, 1997). In mature osteoclasts, CSF-1 was found to cause an increase in the intracellular pH under involvement of the electroneutral Na/HCO_3 cotransporter NBCn1, intracellular acidification frequently being linked to apoptosis (Bouyer *et al.,* 2007). Other investigators reported a concomitant decrease in bone resorptive activity and increase of osteoclast life spans upon prevention of acidification (Karsdal *et al.,* 2005).

Data similar to those obtained with the *op* mouse were obtained with the osteopetrotic rat *tl* mutant. Phenotypically, *tl* rats and *op* mice are similar; in both cases the osteopetrotic phenotype is caused by the virtual absence of osteoclasts. Because the *tl* rat was not cured by marrow transplantation, and based on the phenotypic characteristics, the osteopetrosis was proposed to be caused by a deficiency in CSF-1, and indeed a frame-shift mutation in the CSF-1 gene could be demonstrated in this strain (Van Wesenbeeck *et al.,* 2002). Upon injection of CSF-1 into *tl/tl* rats, osteoclastogenesis was induced and bone resorption was restored (Marks *et al.,* 1992). Furthermore, osteoclast formation was induced in neonatal metatarsals from *tl/tl* rats when cultured in the presence of CSF-1, PTH, and $1,25(OH)_2D_3$ (Peura and Marks, 1995), as was described previously for the murine *op/op* mutant (Morohashi *et al.,* 1994).

EXPRESSION OF THE CSF-1 RECEPTOR IN BONE

Osteoclast precursors and mature osteoclasts are among the target cells for CSF-1, because these cells were shown to express transcripts encoding the receptor (Hofstetter *et al.,* 1992; Weir *et al.,* 1993), as well as to bind the cytokine (Hofstetter *et al.,* 1995). Expression of *c-Fms* is reliant on the transcription factor PU.1 (DeKoter *et al.,* 1998). PU.1 controls the development of granulocytes, macrophages, and B and T lymphocytes. Granulocytic precursors deficient in PU.1 cannot differentiate along the macrophage/monocyte lineages with CSF-1 because of the lack of *c-Fms* expression; hence the osteopetrotic phenotype in PU.1 null mice due to osteoclast deficiency (Tondravi *et al.,* 1997).

RESOLUTION OF THE OSTEOPETROTIC PHENOTYPE IN *op* MICE

Osteopetrotic *op/op* mice (Marks and Lane 1976; Wink *et al.,* 1991; Begg *et al.,* 1993) as well as mice deficient in *c-Fms* (Dai *et al.,* 2002) undergo an age-dependent hemopoietic recovery, the marrow cavity and cellularity being comparable to normal at 22 weeks of age. Because both mutant mice will not recover genetically during life, osteoclasts must develop via a pathway independent of CSF-1. However, based on the complex post-transcriptional processing of CSF-1 transcripts, an incomplete penetration of the phenotype, due to a leaky mutation causing a delay in normal development, could not be excluded (Hume and Favot, 1995). The recovery of the *c-Fms* null mice, however, renders this possibility rather unlikely. If, on the other hand, CSF-1 would be partially redundant, a candidate growth factor to replace CSF-1 may be GM-CSF. Injections of GM-CSF alone did not reverse the osteopetrotic phenotype in *op/op* animals (Wiktor-Jedrzejczak *et al.,* 1994), but in combination with IL-3, GM-CSF corrected the osteopetrotic phenotype (Myint *et al.,* 1999). Furthermore, bone resorption and hemopoietic recovery proceeded with the same kinetics in *op/op* mice and in GM-CSF/CSF-1 double-knockout animals (Nilsson *et al.,* 1995), negating an essential role of GM-CSF in the recovery process, and nonadherent osteoclast precursors that were grown in the presence of GM-CSF could differentiate into osteoclasts only when the cells were subsequently cultured in the presence of CSF-1 and RANKL (Lari *et al.,* 2007). Thus, the formation of osteoclasts and the reconstitution of bone resorption in growing *op/op* animals require proliferation, differentiation, and activation of macrophages and osteoclasts by alternative pathways, independent of CSF-1 and GM-CSF.

A step toward the elucidation of the mechanisms leading to the resolution of the osteopetrotic phenotype in *op/op* mice was achieved when a single injection of vascular endothelial growth factor (VEGF) was found to resolve the osteopetrotic phenotype (Niida *et al.,* 1999). The authors suggest that VEGF is produced in *op/op* mice at levels sufficient for the survival and functioning of mature osteoclasts, but not for the recruitment of these cells at maximal levels,

resulting in an osteopetrotic phenotype that is resolved with time. Consequently, mice with an *op* background containing a tyrosine-kinase defective VEGFR-1 (Flt-1) fail to recover, the osteopetrosis persists, and the animals are characterized by fibrotic bone marrow and extramedullary hemopoiesis (Niida *et al.,* 2005). The potential role of VEGF in the regulation of bone resorption was further strengthened by the finding that the factor acts chemotactically on osteoclasts and their precursors (Engsig *et al.,* 2000). Because VEGF is synthesized by hypertrophic chondrocytes (Gerber *et al.,* 1999), is integrated in the extracellular matrix of bone and cartilage, and can be released by metalloproteinases (Bergers *et al.,* 2000), location, availability, and release of the factor seem to be suited to act as a growth factor for the cells of the osteoclastic lineage.

EFFECTS OF CSF-1 ON MATURE OSTEOCLASTS AND SIGNAL TRANSDUCTION

Upon ligand binding, the tyrosine kinase receptor *c-Fms* dimerizes and autophosphorylates on specific tyrosine residues, which act as binding sites for SH2 and PTB domain-containing proteins that start specific signaling cascades (Hamilton, 1997). Subsequently, the receptor becomes internalized, dephosphorylated, multiubiquinylated, and degraded (Lee *et al.,* 1999). Depending on the differentiation and cell cycle states of the target cells, the CSF-1 dependent response may differ and may result in cell proliferation, survival, differentiation and cytoskeletal reorganization (Ross and Teitelbaum, 2005).

The effects exerted by CSF-1 on macrophages have been extensively studied, as have the mechanisms involved in signal transduction in these cells (Feng *et al.,* 2002). Ligand activation of the receptor kinase serves as the proximal signal that eventually elicits the mitogenic response. CSF-1 is required by mononuclear cells during the G1 phase of the cell cycle to enter the S phase, but the growth factor is not necessary during S, G2, and M phases. Withdrawal of the growth factor induces the cells to enter a quiescent state and leads to cell death. In osteoclasts, CSF-1 induces, as in macrophages, cell spreading. The cytokine increases the migration of osteoclasts, in this way decreasing the number of resorbing cells and as a consequence decreasing total resorptive activity (Fuller *et al.,* 1993). In addition to inducing migration of osteoclasts, CSF-1 induces the fusion of mature cells (Amano *et al.,* 1998). In summary, CSF-1 supports proliferation, differentiation, fusion, and survival (Karsdal *et al.,* 2005) of progenitors and mature osteoclasts. The cytokine, however, does not activate the bone-resorptive activity of the mature cells (Jimi *et al.,* 1999).

As mentioned above, binding of CSF-1 induces cell spreading both in macrophages and in osteoclasts. This effect is brought about by cytoskeletal rearrangements, involving c-*Src*-dependent tyrosine phosphorylation (Insogna *et al.,* 1997) and translocation of phosphatidylinositol-3-kinase (PI-3 K) from the cytoplasm to the cell membrane (Grey *et al.,* 2000; Palacio and Felix, 2001; Golden and Insogna, 2004). Although the cell spreading can be blocked by the specific PI-3 K inhibitor wortmannin (Amano *et al.,* 1998), deficiency in the monocyte-specific PI-3 K isoform PI-3Kβ does not affect the bone phenotype (Hirsch *et al.,* 2000). In c-*Src*-deficient mice, which are characterized by an osteopetrotic phenotype due to an osteoclastic failure to form a ruffled border (Boyce *et al.,* 1992), the autophosphorylation of *c-Fms* is not affected, whereas the phosphorylation of an as yet unidentified protein of 85 to 90 kDa is significantly reduced, suggesting an abnormal phosphorylation of downstream targets (Insogna *et al.,* 1997).

Other signal transduction pathways induced by CSF-1 involve *Cbl* (Lee *et al.,* 1999; Ota *et al.,* 2000), which is important for degradation of c-*Fms.* Furthermore, mitogen-activated protein kinases and phosphatases (Valledor *et al.,* 1999; Lee and States, 2000) are activated, finally leading to regulation of cell cycle progression by cyclins (Dey *et al.,* 2000).

The profound effects of CSF-1 on cytoskeletal rearrangement, which is required for motility, fusion, and cellular activity in osteoclasts, drew the attention to the combined actions of CSF-1 with integrin receptors binding to components of the extracellular matrix. The vitronectin receptor, $\alpha_v\beta_3$ integrin (Athanasou *et al.,* 1990), not only serves as an attachment site, but the integrin's capability to transmit matrix-derived signals to the cell interior is equally important. The failures in cytoskeletal rearrangements in mice deficient in *c-Src* (Soriano *et al.,* 1991), the non-receptor tyrosine kinase *Syk* (Mocsai *et al.,* 2004), or *Vav3* (Faccio *et al.,* 2005), a member of the family of guanine nucleotide exchange factors, result from impaired signaling through *c-Fms* and $\alpha_v\beta_3$ integrin.

This short summary of signal transduction pathways induced by CSF-1 upon binding to c-*Fms* indicates the complexity of signaling that is required to enable the multiple roles the growth factor exerts on the cells of the osteoclast lineage.

CSF-1 IN TUMOR METASTASIS

Certain cancers such as breast and prostate cancer metastasize preferentially to bone (Mundy, 1997). The response in bone toward the two primary cancers differs dramatically, prostate cancer generally inducing an osteoblast response, resulting in osteosclerotic lesions, whereas mammary cancer triggers preferentially an osteoclastic response with the consequence of osteolytic lesions. In mouse models of tumor metastasis, osteolytic tumors were found to express PTHrP (PTH-related protein) and CSF-1,

both potent stimulators of bone resorption (van der Pluijm *et al.,* 2001). These studies were corroborated by the finding that only cell lines inducing osteolytic lesions in bone express osteoclastogenic cytokines such as PTHrP, CSF-1, and IL-8 (Schwaninger *et al.,* 2007). The data suggest an ability of metastasizing tumor cell lines to generate their own niche in bone, CSF-1 being one of the factors stimulating the accompanying bone resorption and contributing to the development of a suitable microenvironment for the tumors.

CONCLUDING REMARKS

From the original description of CSF-1 as an essential growth factor for osteoclast-lineage cells to the present state of knowledge, a huge body of information has been accumulated, describing many detailed aspects of the function and the mechanisms of the growth factor. CSF-1 and RANKL are the only growth factors that under physiological conditions are indispensable for functional osteoclastogenesis. Deficiency in these factors or their receptors leads to osteopetrosis due to the absence of osteoclasts. The dependence of osteoclast development on CSF-1, however, is not absolute, because an age-dependent resolution of the osteopetrotic phenotype was observed, and VEGF was found to restore osteoclastogenesis in CSF-1 deficient animals. In recent years our understanding on the complex processes regulating development and activation of osteoclasts has become more complete. In particular, the analysis of the interactions of signaling pathways in osteoclasts allowed for a dissection of the various effects exerted by the secreted and membrane-bound forms of CSF-1 on the respective target cells. Also, the understanding of the functional proximity of bone and the innate and specific immune systems opened up the exciting field of osteoimmunology, CSF-1 being a relevant player on this area.

Chapter 57

Local Regulators of Bone

IL-1, TNF, Lymphotoxin, Interferon-γ, the LIF/IL-6 Family, and Additional Cytokines

Mark C. Horowitz* and Joseph A. Lorenzo

Departments of Orthopaedics and Rehabilitation, Yale University School of Medicine, New Haven, Connecticut; and the Department of Medicine, The University of Connecticut Health Center, Farmington, Connecticut

The bone remodeling cycle is highly regulated by a variety of factors (i.e., hormones, cytokines, growth factors, and physical force). These are produced both locally and systemically and act in concert to direct local rates of bone turnover. Many studies of the mechanisms regulating bone remodeling have concentrated on the role of cytokines because these factors appear to have crucial roles in both normal and pathological bone cell function. A variety of cytokines that were originally identified by their ability to regulate immune and hematopoietic cells are believed to be produced in the bone microenvironment either spontaneously or in response to specific stimuli. It has become apparent that during both health and disease, the production of cytokines by cells in the bone microenvironment and the responses of bone cells to these cytokines are regulated in a highly ordered manner. It is hypothesized that the spectrum of cytokines that are produced in bone defines the responses of bone cells to a particular state and predicts the subsequent development of normal or pathological bone remodeling. Diseases of bone where cytokines are believed to play an important role include osteoporosis, Paget's disease, periodontal disease, and the effects of malignancy on bone. Studies of the production of cytokines in bone and the responses of bone cells to these cytokines provide insights into the mechanisms that regulate the development of these diseases and could lead to new therapies for these conditions. The following is a broad overview of the actions of a number of cytokines on bone and the mechanisms by which bone cells respond to these cytokines.

EFFECTS OF INTERLEUKIN-1 ON BONE

Interleukin-1 (IL-1) is a multifunctional cytokine with a wide variety of activities. It is a family of two active peptides (IL-1α and IL-1β) that are encoded by two separate gene products. Both forms of IL-1 have identical activities and potencies (Dinarello, 1991). IL-1 is the first polypeptide mediator of immune cell function that was shown to regulate bone resorption (Gowen *et al.*, 1983; Lorenzo *et al.*, 1987) and formation (Canalis, 1986), and it is the major activity that had been identified as osteoclast-activating factor (OAF) (Dewhirst *et al.*, 1985). IL-1 is the most potent stimulator of bone resorption yet identified (Lorenzo *et al.*, 1987). It also increases prostaglandin synthesis in bone (Lorenzo *et al.*, 1987), an effect that may account for some of its resorptive activity because prostaglandins themselves are potent resorption stimuli (Klein and Raisz, 1970). The ability of IL-1 to stimulate bone resorption *in vivo* and *in vitro* requires that inducible nitric oxide synthase be present (Van't Hof *et al.*, 2000). Like a variety of other resorption stimuli, IL-1 increases receptor activator of nuclear factor κB ligand (RANKL) production in stromal/osteoblastic cells (Hofbauer *et al.*, 2001) by a mechanism that may require STAT3 activation (O'Brien *et al.* 1999). It also paradoxically stimulates osteoprotegerin (OPG) production in a human osteosarcoma cell line (Vidal *et al.*, 1998) by a mechanism that depends on activation of p38 and ERK MAP kinases (Lambert *et al.*, 2007). However, it is reported to decrease OPG production in primary rat osteoblasts (Tanabe *et al.*, 2005). IL-1 directly enhances the resorptive activity of mature osteoclasts (Jimi *et al.*, 1999) by a mechanism that may involve activation of nuclear factor κB (NF-κB) (Miyazaki *et al.*, 2000).

Direct stimulation of osteoclastogenesis by IL-1 in mixed murine stromal and hematopoietic cell cultures

Principles of Bone Biology, 3rd Edition

depends on RANKL expression in the stromal/osteoblastic cells, but not tumor necrosis factor (Ma *et al.*, 2004). Expression of myeloid differentiation factor 88 (MyD88), but not Toll/interleukin-1 receptor domain-containing adaptor inducing interferon-beta (TRIF) was necessary for IL-1 to stimulate RANKL production in osteoblasts and prolong the survival of osteoclasts (Sato *et al.*, 2004). Survival of osteoclasts by treatment with IL-1 appears to require PI3-kinase/AKT and ERK (Lee *et al.*, 2002). IL-1 receptor-associated kinase M (IRAK-M) is an inhibitor of IL-1 signaling, which, if deleted, leads to enhanced osteoclastogenic activity (LI *et al.*, 2005).

IL-1 stimulates osteoclast-like multinucleated giant-cell formation in cultured bone marrow through a prostaglandin-dependent mechanism (Akatsu *et al.*, 1991). Hence, IL-1 may be involved in the differentiation of osteoclasts from hematopoietic progenitor cells, and this appears to be an additional mechanism by which it regulates bone resorption. IL-1 is a potent bone resorption stimulus *in vivo* (Sabatini *et al.*, 1988). Its effects on bone formation appear to be mainly inhibitory (Canalis, 1986), although it does stimulate DNA synthesis in both bone organ cultures and primary cultures of human bone cells (Canalis, 1986; Gowen *et al.*, 1985).

IL-1 is produced by bone organ cultures. However, the cells responsible for this production are not clearly identified (Lorenzo *et al.*, 1990b). It appears that both hematopoietic and mesenchymal/osteoblastic cells can produce IL-1 and its production is enhanced when both cell types are cocultured together (Haynes *et al.*, 1999). Macrophages are a likely source of IL-1 in bone marrow (Horowitz *et al.*, 1989), and osteoblast-like cells from human adult bone can also produce IL-1β *in vitro* (Keeting *et al.*, 1991).

A natural inhibitor to IL-1 has been identified (Arend *et al.*, 1990). This peptide, IL-1 receptor antagonist (IL-1ra), is an analogue of IL-1 that binds but does not activate IL-1 receptors. IL-1ra blocks the ability of IL-1 to stimulate resorption and prostaglandin E2 (PGE_2) production in bone organ cultures (Seckinger *et al.*, 1990). Increased release of IL-1ra has recently been shown in the conditioned medium of cultured peripheral blood monocytes (PBMs) from either normal or osteoporotic postmenopausal women when levels are compared with cultures of PBM from premenopausal women or postmenopausal women who are treated with estrogen (Pacifici *et al.*, 1993).

There are two known receptors for IL-1, type I and type II (Dinarello, 1993a, b). All known biological responses to IL-1 appear to be mediated exclusively through the type I receptor (Sims *et al.*, 1993). Postreceptor signaling through the type I receptor involves sphingomyelin breakdown and production of ceramide (Kolesnick and Golde, 1994) in addition to activation of NF-κB (Jimi *et al.*, 1996). The type II IL-1 receptor appears to have little or no agonist activity, rather it functions as a decoy receptor that prevents the activation of IL-1 type I receptor (Colotta *et al.*, 1993). In addition, type II IL-1 receptor can be released and circulate in serum as a soluble binding protein that inhibits IL-1 interactions with the type I receptor (Dinarello, 1993a, b). Type II IL-1 receptor may also synergize with IL-1ra to inhibit activation of the type I IL-1 receptor by IL-1 (Burger *et al.*, 1995). One recent report found a decrease in the bone mass of mice that were deficient in the bioactive type I IL-1 receptor (Bajayo *et al.*, 2005); however, this has not been our experience (Vargas *et al.*, 1996).

Production of IL-1 appears to be involved in the development of osteoporosis. Increased IL-1 bioactivity has been found in the conditioned medium of PBM from some patients with a high-turnover form of this disease (Pacifici *et al.*, 1987). One group has found that *in vivo* estrogen treatment reduced the amount of IL-1 that was released from cultured PBM (Pacifici *et al.*, 1989). However, not all studies have confirmed this finding (Hustmeyer *et al.*, 1993; Stock *et al.*, 1989). In a related study, greater bone-resorbing activity was found in lipopolysaccharide (LPS)-stimulated, PBM-conditioned medium from ovariectomized women than in PBM-conditioned medium from premenopausal or estrogen-treated postmenopausal women (Cohen-Solal *et al.*, 1993). Neutralization studies showed that this activity results from both IL-1 and tumor necrosis factor (TNF)-α production *in vitro*. Measurements of IL-1 in the serum of pre- and postmenopausal women have produced conflicting results. One study showed that IL-1 levels were increased 30 days after ovariectomy (Fiore *et al.*, 1994), but others failed to find a correlation between serum IL-1α, IL-1β, or IL-1ra levels and indices of bone turnover in either pre- or postmenopausal women (McKane *et al.*, 1994) or between osteoporotic women and normal subjects (Khosla *et al.*, 1994). Because modulation of cytokine production and/or responses in the bone marrow microenvironment may be the key mechanism by which estrogens modulate bone cell function, recent studies have focused on the ability of estrogen withdrawal to regulate IL-1 production in bone marrow. Increased production of a number of cytokines including IL-1α has also been identified in the conditioned medium of bone marrow cultures from postmenopausal women who had discontinued estrogen replacement within 1 month compared with similar studies of premenopausal controls (Bismar *et al.*, 1995). Two groups have demonstrated in mice that IL-1α biological activity in bone marrow serum increases after ovariectomy but levels of IL-1α protein do not (Miyaura *et al.*, 1995; Kawaguchi *et al.*, 1995).

In vivo administration of IL-1ra inhibited the bone loss that occurred in ovariectomized rats (Kimble *et al.*, 1994). This effect was most pronounced after 4 weeks and was much less at earlier times. A trend demonstrating similar effects in the excretion of urinary type 1 collagen breakdown products (a measure of bone resorption) was also seen in postmenopausal women who were withdrawn from estrogen therapy and administered IL-1α

(Charatcharoenwitthaya *et al.*, 2007). In addition, treatment of mice for 2 weeks after ovariectomy with IL-1ra decreased the ability of marrow cell cultures to form osteoclasts *in vitro* and inhibited the excretion of pyridinoline cross-links (a marker of *in vivo* bone resorption) (Kitazawa *et al.*, 1994).

In humans polymorphisms in the gene for IL-1α were not associated with an increased risk of fractures (Knudsen *et al.*, 2007). However, a polymorphism in the IL-1β gene was associated with low bone mass (Moreno *et al.*, 2005) by one group. Interestingly, other groups did not find an association of bone mass with polymorphisms in the IL-1β gene but did with the gene for IL-1ra (Kim *et al.*, 2006; Langdahl *et al.*, 2000).

IL-1 has also been implicated as one mediator of the hypercalcemia that accompanies some forms of cancer. Production of IL-1 occurs in myeloma cells that are cultured *in vitro* (Carter *et al.*, 1990) and correlates with their ability to stimulate bone resorption and hypercalcemia *in vivo*. In addition, the uncoupling of bone resorption and bone formation, which is characteristic of the lytic bone lesions in myeloma, is reproduced by local *in vivo* infusions of IL-1 (Boyce *et al.*, 1989).

EFFECTS OF TUMOR NECROSIS FACTOR ON BONE

Like IL-1, TNF is a family of two related polypeptides (α and β) that are products of separate genes (Beutler and Cerami, 1986; Paul and Ruddle, 1988). TNF-α and -β have similar biological activities and are both potent stimulators of bone resorption (Bertolini *et al.*, 1986; Lorenzo *et al.*, 1987) and inhibitors of bone collagen synthesis (Bertolini *et al.*, 1986; Canalis, 1987).

As with IL-1, TNF binds to two cell surface receptors, the TNF-receptor 1 or p55, and the TNF-receptor 2 or p75 (Fiers, 1993). In contrast to IL-1, both receptors transmit biological responses. There appear to be interactions between the TNF-receptor 1 and TNF-receptor 2 (Tartaglia *et al.*, 1993), and for many responses, activation of both receptors is necessary to produce a full biological effect (Vandenabeele *et al.*, 1995). However, some effects can be induced by selective activation of either receptor (Sheehan *et al.*, 1995). Mice deficient in the TNF-receptor 1 and TNF-receptor 2 have been made (Rothe *et al.*, 1993; Erickson *et al.*, 1994). These animals appear healthy and breed normally, but lack normal immune responses and apoptotic mechanisms.

In vivo, TNF-α injections increased the serum calcium of mice (Tashjian *et al.*, 1987), and similar effects were seen with TNF-β (Garrett *et al.*, 1987). In a more detailed study, Chinese hamster ovary (CHO) cells that were genetically engineered to release large amounts of active TNF-α peptide were injected into nude mice (Johnson *et al.*, 1989). These animals became hypercalcemic within 2 weeks. Bone histomorphometry demonstrated a 10-fold increase in the number of osteoclasts in their bones compared with controls (animals injected with CHO cells that contained an empty vector). In addition, the percentage of the bone surface undergoing active resorption was similarly increased in animals receiving the TNF-producing cells.

The effects of TNF on resorption appear to be mediated by its effects on osteoclasts because osteoclast number increased after TNF treatment of bones (Johnson *et al.*, 1989) and because resorption stimulated by TNF was inhibited by calcitonin (Stashenko *et al.*, 1987). Like IL-1, TNF-stimulated induction of osteoclast-like cells formation in bone marrow culture (Pfeilschifter *et al.*, 1989) is mediated by increases in RANKL expression (Hofbauer *et al.*, 1999). However, in addition to increasing RANKL expression TNF also stimulates OPG in osteoblastic cell models (Hofbauer *et al.*, 1998).

TNF, either alone or in combination with IL-1 and transforming growth factor (TGF)-β, was shown by a variety of investigators to directly stimulate osteoclast formation in an *in vitro* culture system. This response appears to be direct and independent of RANK, because, in combination with IL-1 and TGF-β, it occurred in cells from RANK-deficient mice (Azuma *et al.*, 2000; Kim *et al.*, 2005; Kobayashi *et al.*, 2000). However, the significance of these *in vitro* findings is questionable because administration of TNF to RANK-deficient mice produced only an occasional osteoclast in one study and no osteoclasts in another (Li *et al.*, 2000, 2004). The ability of TNF to stimulate osteoclast formation in mixed stromal cell/osteoclast precursor cell cultures was dependent on the production of IL-1 (Wei *et al.*, 2005) as is the ability of TNF to induce joint damage in mice (Zwerina *et al.*, 2007). TNF-induced osteolysis in induced arthritic lesions in mice was also found to be dependent on macrophage colony-stimulating factor (M-CSF) production (Kitaura *et al.*, 2005). CD44 also appears involved in TNF-mediated arthritis in mice because arthritis produced by TNF was more severe in CD44-deficient mice (Hayer *et al.*, 2005).

TNF inhibits bisphosphonate-induced osteoclast apoptosis by upregulating the antiapoptotic molecules Ets-2 and Bcl-xL in osteoclasts (Zhang *et al.*, 2005). It also directly affects putative osteoclast precursor cells. It increased expression of the osteoclastogenic cofactor paired Ig-like receptor A (PIR-A), which enhances responses of these cells to RANKL (Ochi *et al.*, 2007) and it increases the circulating pool of $CD11b^{(high)}$ peripheral blood cells that can differentiate into osteoclasts (Li *et al.*, 2004). The latter effect appears to depend on upregulation of c-FMS expression, which is the receptor for M-CSF (Yao *et al.*, 2006).

The synergistic effects of TNF on RANKL-stimulated osteoclastogenesis are mediated by activation of the TNF-receptor 1 (p55) (Zhang *et al.*, 2000). TNF-receptor 1 also mediates the ability of TNF to stimulate RANKL expression

in stromal cells (Abu-Amer *et al.*, 2004). RANKL, in turn, can induce TNF production in the osteoclast precursor cell model, RAW 264.7 and primary cultures, through its ability to enhance the transcriptional activity of the TNF gene (Nakao *et al.*, 2007; Zou *et al.*, 2005). TNF-induced osteoclastogenesis is associated with induction of the mitogen-activated protein kinases, p38, ERK, and JNK, as well as p21 (WAF1/Cip1), an inhibitor of cyclin-dependent kinase (Kwak *et al.*, 2005).

In bone organ cultures, TNF stimulates DNA synthesis (Canalis, 1987). However, in an osteoblast-like osteosarcoma cell line, ROS 17/2.8, TNF did not stimulate DNA synthesis but did inhibit collagen synthesis (Nanes *et al.*, 1989). Furthermore, addition of hydroxyurea, an inhibitor of DNA synthesis, to primary rat osteoblast-enriched cultures did not alter the inhibitory effects of TNF on collagen synthesis (Centrella *et al.*, 1988). Hence, the effects that TNF has on cell replication do not appear to be linked to its effects on collagen synthesis. *In vitro*, TNF directly inhibits the differentiation of osteoblast precursor cells into mature osteoblasts (Gilbert *et al.*, 2000). This effect appears to involve production of nitric oxide and peroxynitrite (Hikiji *et al.*, 1997, 2000). Osteoblast apoptosis (programmed cell death) can also be stimulated by TNF (Jilka *et al.*, 1998) and this response also may be mediated by nitric oxide production (Damoulis and Hauschka, 1997). TNF-receptor 1 mediates the ability of TNF to inhibit osteoblast differentiation (Gilbert *et al.*, 2005) and this effect depends, at least in part, on the ability of TNF to activate SAPK/JNK signaling (Mukai *et al.*, 2007).

In contrast to the inhibitory effects that continuous treatment with TNF has on collagen synthesis in bone, transient treatment with TNF for 24 hours causes a rebound increase in collagen synthesis in primary cultures of osteoblast-like cells from rat calvaria (Centrella *et al.*, 1988). Post-transcriptional regulation of message may also be involved in the effects that TNF has on collagen synthesis (Centrella *et al.*, 1988). TNF-α is produced by human osteoblast-like cell cultures (Gowen *et al.*, 1990) and its production is stimulated by IL-1, granulocyte-macrophage colony-stimulating factor (GM-CSF), and lipopolysaccharide but not by parathyroid hormone (PTH), 1,25$(OH)_2$ vitamin D_3, or calcitonin. Like RANKL, effects of TNF on osteoblastic cells are mediated by stimulation of NF-κB activity (Ali *et al.*, 1999; Yao *et al.*, 2000).

TNF production in bone may be involved in the development of postmenopausal osteoporosis. Estrogens are reported to modulate TNF production *in vitro* in human osteoblast cultures by one group (Rickard *et al.*, 1992). However, another group failed to find an effect of estrogen treatment on TNF protein production in human osteoblast-like cell cultures (Chaudhary *et al.*, 1992). Spontaneous production of TNF-α in cultured peripheral monocytes from women who had recently undergone ovariectomy was increased compared with levels from cells that were assayed preovariectomy (Pacifici *et al.*, 1991). Bone-resorbing activity in LPS-stimulated PBM-conditioned medium (CM) is increased in cultures from postmenopausal women when compared with CM from premenopausal or postmenopausal women that were treated with estrogen and this effect relies on TNF in the CM to some degree (Cohen-Solal *et al.*, 1993). Kimble *et al.* (1994) found that, like the effect of *in vivo* administration of IL-1ra, treatment of mice with soluble TNF receptor, an inhibitor of TNF action, reduced the ability of ovariectomy to decrease bone mass (Kimble *et al.*, 1995a, b). Interestingly, the most potent inhibition of the effects of estrogen withdrawal on bone mass was seen in rats that were treated with both IL-1ra and soluble TNF receptor. In a related study, it was demonstrated that mice overexpressing soluble TNF receptor 1, which binds TNF and inhibits its action, did not have increased bone loss after ovariectomy (Ammann *et al.*, 1995). Most recently it was shown that administration of soluble type 1 TNF receptor (an inhibitor of TNF action) significantly reduced the increase in urinary type 1 collagen breakdown products (a measure of bone resorption) that occurred in postmenopausal women who were withdrawn from estrogen therapy (Charatcharoenwitthaya *et al.*, 2007).

Recently, mice lacking mature T lymphocytes were found to not lose bone mass after ovariectomy and this effect appeared to be related to T lymphocyte-mediated production of TNF (Cenci *et al.*, 2000). However, this hypothesis is controversial because similar experiments using nude rats (Sass *et al.*, 1997) and nude, RAG2- or TCR-α-deficient mice (all of which lack functional T lymphocytes) demonstrated that OVX-induced trabecular bone loss in these models was equivalent to that seen in wild-type mice (Lee *et al.*, 2006). Curiously, loss of cortical bone with OVX was different between T-cell-deficient and wild-type models and dependent on the bone that was examined (Lee *et al.*, 2006). These results suggest that there may be compartmental and bone-specific effects of T-cell depletion on OVX-induced bone loss. Additional experiments will be required to determine how T cells are involved in this response of bone.

Estrogen can also directly suppress transcriptional activity of the TNF gene (Srivastava *et al.*, 1999). Increased follicle-stimulating hormone (FSH) production, which occurs after sex steroid withdrawal, can also stimulate TNF-α production in immune cells, which may enhance the ability of sex steroids withdrawal during the menopause to cause osteoporosis (Iqbal *et al.*, 2006).

Production or response to TNF has been linked to a number of human diseases. Polymorphisms in the gene for TNF-receptor 2 (p75) was associated with differences in bone density in women and may represent a risk factor for the development of osteoporosis (Mullin *et al.*, 2007; Tasker *et al.*, 2004). Production of TNF and RANKL by mononuclear cells at sites of failing hip implants was

positively associated with bone loss, suggesting that these events are related (Holding *et al.*, 2006). Cherubism in children results from a gain-of-function mutation in the SH3BP2 gene, which, when expressed in a mouse model, produces inflammation, increased bone turnover, very large osteoclasts, and macrophages that express high levels of TNF-α (Novack *et al.*, 2007; Ueki *et al.*, 2007).

TNF-β has been implicated as one cause of the effects that hematological malignancies have on bone (Garrett *et al.*, 1987). A tumor cell line was established from a patient with multiple myeloma who had developed hypercalcemia and osteolytic bone lesions. This cell line was found to contain detectable steady-state levels of TNF-β mRNA and to produce TNF-β *in vitro*. Furthermore, an antibody to TNF-β blocked some but not all of the *in vitro* bone-resorbing activity that was present in the conditioned medium from these cells and from other established myeloma cell lines. Like IL-1, TNF stimulates bone resorption while inhibiting bone formation and mimics the *in vivo* responses of bone to hematological malignancy (Bertolini *et al.*, 1986).

TNF has also been linked to the resorptive effects that nonhematological malignancies have on bone. In one report, a squamous carcinoma cell line was shown to release a factor that stimulated monocyte cultures to produce TNF-α. This tumor did not itself produce TNF. However, implantation of the tumor into nude mice stimulated bone resorption, hypercalcemia, and leukocytosis that were reversed by a specific anti-TNF-α antibody (Yoneda *et al.*, 1991).

EFFECTS OF INTERFERONS ON BONE

Interferons are generally divided into two types. Type I interferons include interferon-α and -β (IFN-α and IFN-β). Interferon-γ (IFN-γ) is the only type II interferon. All interferons are regulatory cytokines with a wide variety of biological activities.

INF-α and INF-β are typically produced in response to invading pathogens (Takayanagi *et al.*, 2005). Mice deficient in the INF α/β receptor component IFNAR1 have a reduction in trabecular bone mass and an increase in osteoclasts (Takayanagi *et al.*, 2002). RANKL induces INF-β in osteoclasts, and INF-β, in turn, inhibits RANKL-mediated osteoclastogenesis by decreasing c-fos expression (Takayanagi *et al.*, 2002). INF-α has also been shown to inhibit bone resorption although its mechanism of action is not as well studied as that of INF-γ and -β (Avnet *et al.*, 2007). *In vivo*, INF-α had no effect on bone turnover (Goodman *et al.*, 1999).

Activated T lymphocytes and NK cells typically produce IFN-γ. *In vitro* it inhibits resorption (Gowen and Mundy, 1986; Peterlik *et al.*, 1985). This effect appears to be more specific for the response to IL-1 and TNF because lower concentrations of IFN-γ inhibit the maximum activity of these factors compared with resorption stimulated by PTH or $1,25(OH)_2$ vitamin D_3 (Gowen *et al.*, 1986). The actions of IFN-γ on *in vitro* resorption appear to be mediated by its effects on osteoclast progenitor cells. IFN-γ inhibits the ability of $1,25(OH)_2$ vitamin D_3, PTH, IL-1, and RANKL to stimulate the formation of osteoclast-like cells in cultures of human bone marrow (Takahashi *et al.*, 1986; Fox and Chambers, 2000). This effect is mediated at least in part by the ability of IFN to stimulate degradation of TRAF-6 (Takayanagi *et al.*, 2000), an intermediate in RANK signaling (Wong *et al.*, 1999). INF-γ is also reported to have stimulatory effects on resorption through its ability to stimulate RANKL and TNF-α production in T lymphocytes (Gao *et al.*, 2007).

IFN-γ is an inhibitor of other hematopoietic functions including erythropoiesis (Mamus *et al.*, 1985). However, it does not affect the resorptive activity of mature osteoclasts (Hattersley *et al.*, 1988). IFN-γ can synergistically augment IL-1- or TNF-stimulated nitric oxide (NO) production by cultured osteoblasts (Ralston *et al.*, 1995). NO appears to be a biphasic regulator of osteoclast-mediated bone resorption that stimulates at low concentrations and inhibits at high concentrations (Ralston *et al.*, 1995). It is possible that part of the inhibitory effects of IFN-γ on IL-1- and TNF-mediated resorption results from effects on NO synthesis. IFN-γ together with IL-1 or TNF synergistically stimulates NO production to high levels in bone, which inhibits osteoclast-mediated resorption by inducing apoptosis of osteoclast progenitors and inhibiting osteoclast activity (Van't Hof and Ralston, 1997).

The *in vitro* effects of IFN-γ on collagen synthesis are also inhibitory. In bone organ culture, IFN-γ decreases both collagen and noncollagen protein synthesis (Smith *et al.*, 1987). This effect was not dependent on prostaglandin synthesis (Smith *et al.*, 1987). The effects of IFN-γ on collagen synthesis in the osteoblast-like ROS 17/2.8 cell line are similar to those seen in organ cultures (Nanes *et al.*, 1989).

IFN-γ also inhibits DNA synthesis in bone organ cultures (Smith *et al.*, 1987), in human cultured bone cells with osteoblast characteristics, and in the ROS 17/2.8 cells (Nanes *et al.*, 1989). It also inhibits the stimulatory effects that TNF and IL-1 have on cell replication in bone cultures (Smith *et al.*, 1987) and that TNF has in human osteoblast-like cells (Gowen *et al.*, 1988) and the ROS 17/2.8 osteosarcoma cell line (Nanes *et al.*, 1989). Effects of IFN-γ on osteoblast function appear to involve nitric oxide production (MacPherson *et al.*, 1999).

The effects of IFN-γ on bone *in vivo* are markedly different from its actions *in vitro*. In rats, i.p. injection of IFN-γ for 8 days induced osteopenia (Mann *et al.*, 1994). In patients who have osteopetrosis and produce defective osteoclasts, administration of IFN-γ stimulates bone resorption and appears to partially reverse the pathology of the disease. These effects are possibly because of the

ability of IFN-γ to stimulate osteoclast superoxide synthesis (Key *et al.*, 1992, 1995) or osteoclast formation *in vivo* (Vignery *et al.*, 1990).

ADDITIONAL CYTOKINES THAT ARE PRODUCED IN BONE OR HAVE EFFECTS ON BONE CELL FUNCTION

Interleukin-7

IL-7 is a cytokine that has diverse effects on the hematopoietic and immunological systems and is best known for its nonredundant role in supporting B and T lymphopoiesis. Studies have demonstrated that IL-7 also plays an important role in the regulation of bone homeostasis (Miyaura *et al.*, 1997; Weitzmann *et al.*, 2002); however, the precise nature of how IL-7 affects osteoclasts and osteoblasts is controversial, because it has a variety of actions in different target cells. Systemic administration of IL-7 upregulated osteoclast formation in human peripheral blood cells by increasing osteoclastogenic cytokine production in T cells (Weitzmann *et al.*, 2000), and IL-7 did not induce bone resorption and bone loss in T-cell-deficient nude mice *in vivo* (Toraldo *et al.*, 2003). In addition, treatment of mice with a neutralizing anti-IL-7 antibody inhibited ovariectomy-induced proliferation of early T-cell precursors in the thymus, demonstrating that ovariectomy upregulates T-cell development through IL-7. This latter effect may be a mechanism by which IL-7 regulates ovariectomy-induced bone loss (Ryan *et al.*, 2005). The interpretation of results from *in vivo* IL-7 treatment studies, however, are complicated by secondary effects of IL-7, which result from the production of bone-resorbing cytokines by T cells (Weitzmann *et al.*, 2000; Toraldo *et al.*, 2003).

IL-7 directly inhibited osteoclast formation in murine bone marrow cells that were cultured for 5 days with M-CSF and RANKL (Lee *et al.*, 2003). In IL-7-deficient mice, osteoclast number was markedly increased and trabecular bone mass was decreased compared with wild-type controls (Lee *et al.*, 2006). In addition, trabecular bone loss after ovariectomy was similar in wild-type and IL-7-deficient mice (Lee *et al.*, 2006). Curiously, IL-7 mRNA levels in bone increase with ovariectomy and this effect may be linked to alterations in osteoblast function with estrogen withdrawal (Weitzmann *et al.*, 2002; Sato *et al.*, 2007). Addition of IL-7 to the medium of newborn murine calvaria cultures inhibited bone formation, as did injection of IL-7 above the calvaria of mice *in vivo* (Weitzmann *et al.*, 2002).

IL-8 and MCP-1

A variety of additional cytokines have been shown to either be produced by bone cells or to have effects on bone cell function. Interleukin-8 (IL-8) and monocyte chemotactic peptide-1 (MCP-1) are members of the chemokine family of cytokines, which is named for the ability of its members to direct the migration of cells to sites of inflammation. Both are produced in bone cells in a regulated manner (Chaudhary and Avioli, 1995; Takeshita *et al.*, 1993; Zhu *et al.*, 1994). More than 20 different chemokines have been described. In addition to IL-8 and MCP-1, these include macrophage inflammatory proteins 1α, 1β, and 2 (MIP-1α, MIP-1β, and MIP-2) and RANTES (Regulated on Activation Normal T-cell Expressed and Secreted) (Horuk, 1994). All contain four conserved cysteine residues and are classified into two categories depending on whether the first two conserved cysteine residues are separated by an intervening amino acid (CXC) or not (CC). IL-8 is a member of the CXC chemokine group whereas MCP-1 belongs to the CC group. IL-8 has specific neutrophil chemotactic activity. It is produced by human osteoblast-like cells, the human osteosarcoma cell line MG-63, human bone marrow stromal cells, and human osteoclasts (Chaudary and Avioli, 1995; Chaudary *et al.*, 1992; Rothe *et al.*, 1998). Production of IL-8 in these cells was augmented by treatment with either IL-1 or TNF and was synergistically increased by their combination. Dexamethasone decreased the production of IL-8 in the cells in response to treatment with IL-1 or TNF. However, *in vitro* estrogen treatment had no effect.

MCP-1, which was originally called JE in mice, is a potent monocyte chemoattractant that is produced by stimulated osteoblasts (Zhu *et al.*, 1994). Like IL-8, IL-1 and TNF strongly stimulated its production in human and murine osteoblastic cells (Takeshita *et al.*, 1993; Zhu *et al.*, 1994; Graves *et al.*, 1999).

The function of IL-8 and MCP-1 in bone remains to be defined. However, MCP-1 does not appear to be involved in regulating the development or activity of osteoclasts because it did not stimulate the maturation of osteoclast-like cells in bone marrow cultures (Zhu *et al.*, 1994) nor did it affect bone resorption rates in organ cultures (Williams *et al.*, 1992) or in isolated osteoclasts that were cultured on bone slices (Fuller *et al.*, 1995). However, it is possible that it regulates the migration of a common monocyte-osteoclast progenitor cell from the blood or bone marrow to sites of osteoclast development at the bone surface.

Of the other members of the chemokine family that have been examined for their effects on bone cells, MCP-1α and IL-8 were found to stimulate the motility but suppress the resorptive rate of isolated osteoclasts whereas MIP-1β, MIP-2, and RANTES were without effect (Fuller *et al.*, 1995). However MIP-1α is a potent stimulator of bone resorption that may be involved in the effects of multiple myeloma on bone (Choi *et al.*, 2000).

Interleukin-10

Interleukin-10 is produced by activated T and B lymphocytes (Moore *et al.*, 2001). It is a direct inhibitor of osteoclastogenesis (Owens *et al.*, 1996; Xu *et al.*, 1995) and osteoblastogenesis (Van Wlasselaer *et al.*, 1993). This

effect is associated with increased tyrosine phosphorylation of a variety of proteins in osteoclast precursor cells (Hong *et al.*, 2000). The direct effects of IL-10 on RANKL-stimulated osteoclastogenesis are associated with decreases in expression and translocation into the nucleus NFATc1 (Evans *et al.*, 2007) as well as suppressed c-Fos and c-Jun expression (Mohamed *et al.*, 2007). Administration of IL-10 may have utility as a therapy to control wear-induced osteolysis (Carmody *et al.*, 2002).

Treatment of bone marrow cell cultures with IL-10 suppressed the production of osteoblastic proteins and prevented the onset of mineralization (Van Wlasselaer *et al.*, 1993). IL-10 also inhibited the formation of osteoclast-likecells (OCLs) in bone marrow cultures without affecting macrophage formation or the resorptive activity of mature osteoclasts (Owens *et al.*, 1995). This effect appears to involve the production of novel phosphotyrosine proteins in osteoclast precursor cells (Hong *et al.*, 2000). IL-10 also stimulates a novel inducible nitric oxide synthase (Sunyer *et al.*, 1996).

4-1BB is an inducible T-cell costimulatory molecule that interacts with 4-1BB ligand. Treatment of RANKL-stimulated osteoclast precursor cells *in vitro* with 4-1BB ligand enhanced IL-10 production. In addition, expression of IL-10 was greater in RANKL-stimulated wild-type osteoclast precursor cell cultures than in cultured cells from 41-BB-deficient mice (Shin *et al.*, 2006). These results imply that some effects of IL-10 on osteoclasts may be mediated through interactions of 4-1BB with 4-1BB ligand.

Interleukin 12

Interleukin 12 (IL-12) is a cytokine that is produced by myeloid and other cell types. It induces T lymphocytes to express INF-γ (Hsieh *et al.*, 1993). IL-12 has an inhibitory effect on osteoclastogenesis. However, the mechanisms by which this effect occurs *in vitro* is controversial. Some authors have demonstrated direct inhibitory effects of IL-12 on RANKL-stimulated osteoclastogenesis in purified primary osteoclast precursors and RAW 264.7 cells (Amcheslavsky *et al.*, 2006). This effect was associated with inhibition of the expression of NFATc1 in the osteoclast precursor cells. Interestingly, the inhibitory effects of IL-12 on osteoclastogenesis were absent in cells that were pretreated with RANKL (Amcheslavsky *et al.*, 2006). In contrast, others have found that the inhibitory effects of IL-12 on osteoclastogenesis are indirect. One group demonstrated that the inhibitory effects of IL-12 are mediated by T lymphocytes and do not involve production of INF-γ (Horwood *et al.*, 2001). However, a second group disputes this and found inhibition of osteoclastogenesis by IL-12 in cells from T-lymphocyte-depleted cultures and in cells from T-lymphocyte-deficient nude mice (Nagata *et al.*, 2003). The latter authors also found that antibodies to INF-γ blocked some of the inhibitory effect of IL-12 on RANKL-stimulated osteoclast formation.

Interleukin 15

Interleukin 15 (IL-15), like IL-7, is a member of the interleukin 2 superfamily and shares many activities with IL-2 including the ability to stimulate lymphocytes. It has been shown to enhance osteoclast progenitor cell number in culture (Ogata *et al.*, 1999). Production of IL-15 by T lymphocytes has been linked to the increased osteoclastogenesis and bone destruction seen in the bone lesions of rheumatoid arthritis (Miranda-Carus *et al.*, 2006).

Interleukin 17 and Interleukin 23

Interleukin 17 (IL-17) is a family of related cytokines that are unique and contain at least six members (A to F) (Weaver *et al.*, 2007). IL-17E is also called interleukin 25 (Fort *et al.*, 2001). These cytokines are central for the development of the adaptive immune response and the production of a subset of CD4 T lymphocytes with a unique cytokine expression profile.

IL-17A was initially identified as a stimulator of osteoclastogenesis in mixed cultures of mouse hematopoietic cells and osteoblasts (Kotake *et al.*, 1999). It stimulated osteoclastogenesis by inducing prostaglandin synthesis and RANKL. Production of IL-17A in rheumatoid arthritis appears involved in the production of activated osteoclasts and bone destruction in involved joints (Kotake *et al.*, 1999; Lubberts *et al.*, 2000, 2003). Effects of IL-17 on osteoclastogenesis and bone resorption are enhanced by TNF-α, which is also produced in inflamed joints in rheumatoid arthritis (Van bezooijen *et al.*, 1999). Inhibition of IL-17A in an antigen induced arthritis model inhibited the joint and bone destruction that is characteristic and decreased production of RANKL, IL-1β, and TNF-α in the involved lesions (Koenders *et al.*, 2005).

Interleukin-23 (IL-23) is an IL-12-related cytokine composed of one subunit of p40, which it shares with IL-12, and one subunit of p19, which is unique (Kastelein *et al.*, 2007). It is critical for the differentiation of the IL-17-producing subset of T lymphocytes (TH17) along with TGF-β and IL-6 (Bettelli *et al.*, 2006). IL-23 appears to be most important for expanding the population of TH17 T lymphocytes. These are a subset of T lymphocytes that have a high osteoclastogenic potential (Sato *et al.*, 2006). Using a LPS-induced model of inflammatory bone destruction, Sato *et al.* (2006) found markedly decreased loss of bone in mice that were deficient either in IL-17 or IL-23. Hence, production of both IL-23 and IL-17 is involved in the bone loss in this model.

Interleukin 18

Interleukin-18 (IL-18) is similar to IL-1 in its structure and a member of the IL-1 superfamily (Orozco *et al.*, 2007). IL-18 synergizes with IL-12 to induce INF-γ production

(Okamura *et al.*, 1995) and its levels are increased at sites of inflammation such as in joints that are affected by rheumatoid arthritis (Yamamura *et al.*, 2001). It is expressed by osteoblastic cells and inhibits osteoclast formation through a variety of mechanisms. These include its ability to stimulate GM-CSF, which is produced by T cells in response to IL-18 treatment (Horwood *et al.*, 1998). It also stimulates INF-γ production *in vivo* in bone (Kawase *et al.*, 2003), and its inhibitory effects on osteoclastogenesis are enhanced by cotreatment with IL-12 (Yamada *et al.*, 2002). Finally, it has been shown to increase production of osteoprotegerin (Makiishi-Shimobayashi *et al.*, 2001). In IL-18 overexpressing transgenic mice osteoclasts were decreased; although, curiously, so was bone mass. These results indicate that there also may be effects of IL-18 on bone growth (Kawase *et al.*, 2003). IL-18 has been shown to indirectly stimulate osteoclastogenesis through its effects on T lymphocytes (Dai *et al.*, 2004). IL-18 is also a mitogen for osteoblastic cells *in vitro* (Cornish *et al.*, 2003).

Macrophage Migration Inhibitory Factor

Macrophage Migration Inhibitory Factor (MIF) was initially identified as an activity in conditioned medium from activated T lymphocytes that inhibited macrophage migration in capillary tube assays (Baugh *et al.*, 2002). Once purified and cloned (Weiser *et al.*, 1989), it became available for functional studies and was shown to have a variety of activities. In addition to T lymphocytes, it is produced by pituitary cells and activated macrophages. Mice that overexpress MIF globally have high-turnover osteoporosis (Onodera *et al.*, 2006). In contrast, MIF-deficient mice failed to lose bone mass or increase osteoblast or osteoclast number in bone with ovariectomy (Oshima *et al.*, 2006). Hence, MIF appears to be another mediator of the effects of estrogen on bone. Estrogen downregulates MIF expression in activated macrophages (Ashcroft *et al.*, 2003) and a similar response may occur in bone or bone marrow to mediate some of the effects of ovariectomy on bone mass. MIF is made by osteoblasts (Onodera *et al.*, 1996) and its production by these cells is upregulated by a variety of growth factors including TGF-β, FGF-2, IGF-II, and fetal calf serum (Onodera *et al.*, 1999). *In vitro* MIF increases MMP9 and MMP13 expression in osteoblasts (Onodera *et al.*, 2002) and inhibits RANKL-stimulated osteoclastogenesis (Lee *et al.*, 2006).

EFFECTS OF IL-4 AND IL-13 ON BONE

IL-4 is a 19-kDa pleotropic cytokine secreted by activated TH2 cells and mast cells (Howard *et al.*, 1982). Its major functions include the growth and survival of T-helper cells, the activation and growth of B cells, increased expression of class II MHC molecules, and the inhibition of macrophage function (Hart *et al.*, 1989; Stuart *et al.*, 1988). Although IL-4 is not a member of the LIF/IL-6 subfamily of cytokines, it uses a two-chain plasma membrane-expressed receptor similar in many ways to the LIF and IL-11 receptors. Ligand binds to the 140-kDa IL-4 receptor, which is a single-polypeptide chain of 800 amino acids that confers both specificity and determines signaling (Idzerda *et al.*, 1990). The IL-4 receptor heterodimerizes with the common γ-chain of the IL-2 receptor to form a complete and functional receptor (Russell *et al.*, 1993). Binding of IL-4 results in the phosphorylation on tyrosine of cellular substrates. The IL-4 receptor has no intrinsic kinase activity. As is the case for the LIF receptor, Jak1 and Jak3 are tyrosine phosphorylated in response to IL-4, as is Stat 6 (Witthuhn *et al.*, 1994). Jak3 associates with the common γ-chain, suggesting that the IL-4 receptor-specific chain associates with Jak1. It is assumed that the phosphorylation of cellular substrates is mediated by the Jak kinases. IL-4 binding does cause the tyrosine phosphorylation of ligand-specific substrates such as insulin receptor substrates 1 and 2. Activation of these unique substrates is likely to be part of how different ligands confer specific activities to their targets.

IL-4 appears to inhibit bone remodeling. In organ culture, IL-4 antagonized the resorption inducing activity of IL-1, tumor necrosis factor, 1,25-dihydroxyvitamin D_3, and PGE_2 without affecting basal resorption (Watanabe *et al.*, 1990). Addition of IL-4 or IL-13 to calvarial organ cultures suppressed ^{45}Ca release following stimulation with a variety of cytokines (i.e., OSM, IL-1, TNF, and IL-6), PTH, and 1,25-dihydroxyvitamin D_3 (Palmqvist *et al.*, 2006). As mentioned previously, IL-4 inhibits macrophage function. Osteoclasts are in the macrophage lineage, suggesting that at least one of the targets for IL-4 is mature osteoclasts or more likely osteoclast precursors. Addition of IL-4 to cultures of bone marrow cells (source of osteoclast precursors) and stromal cells causes the inhibition of osteoclastogenesis (Shioni *et al.*, 1991). In this system, osteoclastogenesis induced by PTH, PTH-related peptide (PTHrP), 1,25-dihydroxyvitamin D_3, IL-1, and PGE_2 was inhibited by the addition of IL-4 (Lacey *et al.*, 1995). By using this same system, bone marrow macrophages were substituted for unfractionated bone marrow cells with similar results, suggesting that the target for the IL-4 inhibitory activity was the osteoclast precursor. IL-4 and IL-13 decreased RANKL and RANK mRNA and increased OPG mRNA in mouse calvariae (Palmqvist *et al.*, 2006). Induction of RANKL mRNA and a decrease in OPG mRNA induced by vitamin D_3 in osteoblasts were reversed by treatment with IL-4 and IL-13. Osteoclast differentiation from spleen or bone marrow precursors induced with RANKL and M-CSF were decreased by IL-4 and IL-13 treatment (Palmqvist *et al.*, 2006). No inhibition of osteoclast differentiation was seen by using precursors from Stat6 -/- mice. These data suggest that a Stat6-dependent pathway mediates at least part of the action of IL-4 and IL-13. In addition, effects

of IL-4 on osteoclastogenesis were demonstrated to occur through direct actions on the peroxisome proliferator-activated receptor gamma 1 (Bendixen *et al.*, 2001).

In vivo bone resorption in mice that were transplanted with a PTHrP- and IL-1-secreting tumor was inhibited by continuous infusions of IL-4 (Nakano *et al.*, 1994). In addition, IL-4 delivery by adenovirus vector was shown to suppress RANKL and IL-17 production and prevent bone resorption in an *in vivo* collagen-induced arthritis mouse model (Lubberts *et al.*, 2000). At least part of this inhibitory effect could be related to the ability of IL-4 to block local prostaglandin synthesis in bone cells (Kawaguchi *et al.*, 1996; Onoe *et al.*, 1996). Further evidence for the role that IL-4 may play in the control of bone remodeling is provided by IL-4-overexpressing transgenic mice (Lewis *et al.*, 1993). These mice have pronounced cortical thinning in the long bones and vertebrae. Although IL-4-overexpressing mice have normal numbers of osteoclasts, their function appeared altered as measured by a decrease in tartrate resistant acid phosphotase (TRAP) activity. Interestingly, these animals have a marked reduction in bone formation. Both the number of cells lining the bone surface and the function of these cells was decreased. IL-4 treatment also decreased bone turnover in ovariectomized mice (Okada *et al.*, 1998).

Hence, osteoblasts, as well as osteoclasts, appear to be a target of IL-4. IL-4 induces the secretion of M-CSF from the murine osteoblast-like cell line MC3T3-E1 as well as primary osteoblasts in a dose-dependent manner (Lacey *et al.*, 1994; Ohara *et al.*, 1994). MC3T3 cells express IL-4 receptors that can be upregulated by treatment with 1,25-dihydroxyvitamin D_3 (Lacey *et al.*, 1993). Primary human osteoblast-like cells and the human osteosarcoma MG-63 also express IL-4 receptors (Riancho *et al.*, 1993; Ueno *et al.*, 1992). Furthermore, IL-4 stimulated the proliferation of human osteoblast-like cells *in vitro* as well as their expression of alkaline phosphatase.

EFFECTS OF THE LIF/IL-6 SUBFAMILY OF CYTOKINES ON BONE

Abundant data have accumulated demonstrating that the LIF/IL-6 subfamily of cytokines has important effects on the regulation of the normal and pathological remodeling cycles. These factors are related based on sequence homology, chromosome location, and receptors (Rose and Bruce, 1991). This subfamily is composed of leukemia inhibitory factor (LIF), oncostatin-M (OSM), IL-6, IL-11, ciliary neurotrophic factor (CNTF), cardiotrophin-1 (CT-1), cardiotrophin-like cytokine (CLC), and neuropoietin (Derouet *et al.*, 2004). The data known about these cytokines as they relate to bone are variable. Information is known about which bone cells secrete LIF and IL-6. Receptor expression for all of the cytokines is better described and some of the biological consequences of that binding are known. Substantial information is available on LIF, OSM, IL-6, and IL-11; less is available on CNTF and CT-1; and little is known about CLC and neuropoietin and their receptor expression (Bellido *et al.*, 1997; Elias *et al.*, 1995; Girasole *et al.*, 1994; Horowitz *et al.*, 1994; Jay *et al.*, 1996). Although information is available about the receptors for these cytokines and some of the downstream events that occur following ligand binding in skeletal cells, the signal transduction pathways used by some of these cytokines have been elucidated (Bellido *et al.*, 1994; Horowitz *et al.*, 1996; Levy *et al.*, 1996). These cytokines may interact with their receptors in two settings, both of which can result in signal transduction. The first and more conventional setting is when ligand binds to its appropriate plasma membrane-expressed receptor component. This interaction initiates receptor component assembly, culminating in a functional receptor capable of transmitting a signal to the interior of the cell. This form of ligand–receptor interaction can occur for all of the cytokine subfamily members. The second setting, which involves the interaction between ligand and soluble receptor, is limited to specific members of the subfamily (IL-6, IL-11, and CNTF).

Originally known as differentiation-inducing factor, LIF is a pleotropic cytokine exerting multiple effects in bone. Its effects on bone resorption *in vitro* are variable and, like other members of the group, depend on the model system that is used. LIF is secreted as a diffusible molecule and in an immobilized form associated with the extracellular matrix as a result of alternate promoter usage, again suggesting an important developmental control mechanism (Rathjen *et al.*, 1990). LIF mRNA is found in various rodent and human immortalized cell lines and primary fetal rat calvarial cells (Marusic *et al.*, 1993). It induces bone resorption in cultured mouse calvaria via a prostaglandin-mediated mechanism (Reid *et al.*, 1990). However, in fetal rat and mouse long-bone cultures it inhibits resorption (Lorenzo *et al.*, 1990a; Van Beek *et al.*, 1993). Mice injected with a hematopoietic cell line overexpressing LIF developed cachexia and increased bone turnover with marked bone formation (Metcalf and Gearing, 1989). LIF can either potentate or inhibit the expression of alkaline phosphatase and type I collagen synthesis depending on the cells or assay used, suggesting a role for LIF in osteoblast development (Lorenzo, 1991). Continuous treatment of fetal rat calvarial cell cultures with LIF resulted in inhibition of bone nodule formation (Malaval *et al.*, 1995, 1998). This effect was dependent on the stage of differentiation of the cells. Addition of LIF to the cultures early, during the proliferative stage (days 1 to 4) did not affect nodule formation. However, addition of LIF later, during the differentiation stage (days 1 to 7) resulted in marked inhibition of nodule formation (Malaval *et al.*, 2005). Osteoblasts and adipocytes, arising from a common progenitor, are closely related. Therefore, it was likely that LIF may affect adipocyte differentiation. This is supported by the data showing overexpression of LIF in *in vivo* results in mice with

cachexia. Treatment of rat calvarial cells with rosiglitazone (thiazolidinediones, PPARγ agonist) induces increased adipogenesis (Falconi *et al.*, 2007). These data suggest a LIF-regulated switch from osteoblastogenesis to adipogenesis. In contrast, ovariectomized C57BL/6 mice injected with LIF experienced a significant decrease in white fat, serum leptin, and brown fat mass, but had no effect on trabecular bone mineral density (BMD) (Jansson *et al.*, 2006). LIF had variable effects on osteoblast-like cell proliferation. LIF had no effect on the proliferation of the human osteosarcoma cell line MG-63, induced a 40% increase in proliferation in murine MC3T3-E1 cells, and had no effect on authentic murine calvarial osteoblasts (Bellido *et al.*, 1997). The addition of LIF to MC3T3-E1 cells inhibited apoptosis induced by either serum starvation or addition of TNF (Jilka *et al.*, 1998). Treatment of MC3T3-E1 cells with PTH results in the increased transcription of LIF and IL-6 but not 14 other cytokines including IL-1, GM-CSF, and TGFβ-1 (Greenfield *et al.*, 1993) Similarly, treatment of a rat osteosarcoma cell line with PTH resulted in IL-6 secretion (Horowitz *et al.*, 1990). This suggests that some of the effects of PTH may be mediated by LIF and PTH (Grey *et al.*, 1999). Because murine osteoblasts respond to LIF, they must express cell surface receptors. LIF induced signal transduction in non-skeletal cells results in protein tyrosine phosphorylation.

Therefore, appropriate substrates should also be phosphorylated in bone cells. Treatment of the murine osteoblast cell line MC3T3-E1 with LIF resulted in tyrosine phosphorylation of Jak1, Jak2, gp130, and what appears to be the LIFR (Lowe *et al.*, 1995). The fact that osteoblasts respond to LIF and secrete LIF indicates that it is a true autocrine growth factor. However, few data are available on the effects of LIF on primary human osteoblast-like cells, effects that may be particularly important because osteoblast-like cells derived from patients 60 years and older fail to respond to LIF as measured by the induction of phosphoproteins (M. Horowitz, unpublished observation). Whether this reflects an intrinsic unresponsiveness in these cells or is related to other processes is unknown. It is tantalizing to speculate that if this failure were age related, it could account for the onset of osteopenia and possibly osteoporosis. This idea is supported by the observation that mice rendered LIFR negative by homologous recombination develop severe osteopenia with increased osteoclastic activity (Ware *et al.*, 1995). Loss of the LIFR in humans results in Stuve–Wiedemann/Schwartz–Jampel type 2 syndrome (SWS). SWS, which is a severe autosomal recessive condition characterized by bowing of the long bones, cortical thickening, irregularities of the chondro-osseous junction, with rare, thick, and irregular trabeculae, increased numbers of osteoclast and camptodactyly (Dagoneau *et al.*, 2004; Cormier-Daire *et al.*, 1998).

OSM, which is structurally similar to LIF, is a 28-kDa glycoprotein originally isolated from media of phorbal 12-myristate 13-acetate (PMA)-stimulated U937 human histiocytic leukemia cells (Zarling *et al.*, 1986). OSM is secreted by phytohemagglutinin-stimulated T cells, lipopolysaccharide-activated monocytes, and cell cultures from AIDS-related Kaposi's sarcoma for which OSM is a growth factor. OSM mRNA is also found in bone marrow cells. Its expression in bone, however, is currently unknown. OSM, like LIF, induces murine osteoblasts to proliferate and secrete matrix proteins and, of the family members, it is the most potent stimulator of IL-6 (Jay *et al.*, 1996; Bellido *et al.*, 1997). However, it inhibits alkaline phosphatase activity and bone resorption (Jay *et al.*, 1996). OSM has also been reported to inhibit the proliferation of MG-63 cells (Bellido *et al.*, 1997). Anti-Fas antibody-induced apoptosis in MG-63 cells was inhibited by OSM (Jilka *et al.*, 1998). OSM activation of MG-63 cells leads to transcriptional activation of the p21WAF1,CIP1,SDI1 gene, which has been shown to be important in protecting against apoptosis and could explain the antiapoptotic effects of OSM (Lacey *et al.*, 1997; Wang *et al.*, 1996). Transgenic mice that overexpress bovine OSM develop osteopetrosis (Malik *et al.*, 1995). Although the overall syndrome is similar to the picture seen in the LIF-overexpressing mice, it does not have the associated increase in bone resorption. In fact, the osteopetrosis seen in both the LIF- and the OSM-overexpressing mice is just the opposite picture to that seen in the LIFR knockout mice. Continuous treatment of fetal rat calvarial cells with mOSM caused a significant reduction in bone nodule formation similar to LIF (Malaval *et al.*, 2005). In contrast to LIF, treatment of rat calvarial cells with OSM during the early proliferative phase of *in vitro* culture resulted in a marked increase in nodule formation. This effect appears to be mediated through the OSM-specific receptor (OSMR). OSM treatment of the rat osteosarcoma cell line ROS17/2.8 or osteoblast from long-bone explants inhibited growth and differentiation (Chipoy *et al.*, 2004). This inhibitory effect was restricted to mature osteoblasts and differentiated osteosarcoma cells because OSM stimulated osteoblast differentiation in early but not late bone marrow mesenchymal stem cells. It should be noted that some of the differences in response to these cytokines may be caused by the anatomical source of the cells. The ability and type of response of calvarial cells (mouse or rat) to cells from long bones may be very different. Treatment of human adipose mesenchymal stem cells isolated from subcutaneous fat with OSM resulted in a decrease in adipocyte differentiation and an increase in osteoblast differentiation (Song *et al.*, 2007). OSM is the only member of the LIF/IL-6 family of cytokines that increases osteoprogenitor development, which may help to explain its anabolic effects *in vivo*. Mice deficient in the OSMR had a 75% increase in trabecular bone volume in the long bones and vertebrae with little change in cortical bone (Sims *et al.*, 2007). This was associated with a decrease in osteoclast number and bone resorption. Bone formation was also reduced as evidenced by a decreases in osteoid thickness, osteoblast surfaces,

and bone formation rate. Interestingly, marrow adipocytes were increased 4 fold (Sims *et al.*, 2007). Treatment of a mouse stromal cell line with OSM caused increased mineralization and a decrease in fat production. These data are, for the most part, consistent with the data from the OSMR null mice and that reported by Malaval *et al.* (2005).

Human OSM induces tyrosine phosphorylation in both primary human and mouse osteoblast-like cells. Three JAK family members (Jak1, Jak2, and Tyk2) are tyrosine phosphorylated in response to OSM in calvarial osteoblastic cells, a response similar to that observed in nonskeletal cells (Levy *et al.*, 1996). However, human osteoblast-like cells express a number of additional phosphoproteins in the 150- to 200-kDa range not found in the mouse. These differences may be caused by the mouse cell's use of the LIFR + gp130 and the alternate receptor, or of the OSMR + gp130 complex versus the human cell's use of only the OSMR, because human cells do not express the LIFR (Gearing and Bruce, 1992; Rose *et al.*, 1994; Hermanns *et al.*, 2000; Heinrich *et al.*, 2003). These data suggest that differences exist between the ability of these ligands to bind and activate osteoblasts, and the complexity may be increased by differences in species and age.

CT-1, a 21.5-kDa protein, was originally isolated from differentiated mouse embryonic stem (ES) cells (Pennica *et al.*, 1995a). The amino acid sequence of CT-1 is similar to LIF (24% homology) and CNTF (19% homology). mRNA for CT-1 is expressed in heart, liver, and kidney with less in brain and none in spleen. Its expression in bone is currently unknown, CT-1 is a potent inducer of myocyte hypertrophy, as are LIF, IL-11, and OSM, whereas IL-6 and CNTF are much less effective. CT-1 is inactive in the B9 assay (detects IL-6) and inhibits the differentiation of mouse ES cells (Pennica *et al.*, 1995b). CT-1 binds the LIFR directly and requires gp130 to effect signal transduction (Pennica *et al.*, 1995b). No α component of the receptor has been identified. Based on the receptor component composition, CT-1 should activate osteoblasts. Addition of CT-1 to calvarial osteoblastic cultures induces numerous tyrosine-phosphorylated proteins in a time-dependent manner (M. Horowitz, unpublished observation). Because CT-1 uses the LIFR + gp130, it seems reasonable that the defects observed in heart development in the gp130 knockout mouse owe, at least in part, to the failure of CT-1 to function. CT-1 must also be considered a candidate, as are LIF and OSM, for the cytokines contributing to the maintenance of normal bone remodeling, which is profoundly altered in the LIFR knockout mice.

The second setting for the interaction of ligand and receptor is restricted to IL-6, CNTF, and IL-11 by the ability of their receptors to be cleaved from the membrane and function in soluble form (sIL-6R, sCNTFR, and sIL-11R). It is these α components that confer a level of specificity to the interaction of ligand and cell. Soluble receptor can bind ligand, forming a complex that can interact with the appropriate β-subunits to trigger signaling. Addition of premixed sIL-6R plus IL-6 to murine calvarial osteoblasts results in their activation. This indicates that for IL-6 this interaction can occur in solution. This interaction can also occur on the cell membrane, as is the case for IL-11 and CNTF interacting with their receptor on calvarial osteoblasts. This is due to the presence of the α components for IL-11 and CNTF being expressed on the cell membrane whereas the IL-6 α component is absent. This type of interaction may induce signal transduction in cells that would not normally be responsive to these cytokines because of lack of the appropriate α components on their membrane surface. It is thought that the major effect of IL-6 is its colony-stimulating activity on osteoclast precursors (Roodman, 1992). This is an important issue because estrogen inhibits cytokine-induced IL-6 secretion by bone cells and osteoclastogenesis (Girasole *et al.*, 1992). Antibodies to IL-6 or estrogen blocked the increased formation of osteoclasts in ovariectomized mice (Jilka *et al.*, 1992). However, Tamura has reported that IL-6 does not directly induce osteoclast formation in coculture experiments (Tamura *et al.*, 1993). This failure can be overcome by the addition of sIL-6R. IL-11, OSM, and LIF (OSM > IL-11 > LIF); all directly induce osteoclast formation in this system. Because of the design of the studies, the target of the cytokines could not be determined. However, treatment of primary mouse osteoblast cultures with IL-11 resulted in the upregulation of RANKL gene expression (Yasuda *et al.*, 1998). Increased RANKL expression would explain the increase in osteoclast formation in coculture induced by all four cytokines. We have shown that IL-6 does not directly induce tyrosine phosphorylation in primary mouse or human osteoblasts, but this failure can be overcome by the addition of sIL-6R (Horowitz *et al.*, 1994). However, it has been demonstrated that treatment of murine osteoblastic cells with dexamethasone induced a marked increase in IL-6 receptor expression (Udagawa *et al.*, 1995). This suggests that osteoblastic cells may be the target for IL-6 under the appropriate conditions. Therefore, the target cell in bone for IL-6 remains ambiguous. The ambiguity over the role of IL-6 in bone is heightened by the differences reported in the ability of IL-6 to induce bone resorption (Ishimi *et al.*, 1990; al-Humidan *et al.*, 1991). Because osteoblasts secrete IL-6, it is possible that IL-6 may function as an autocrine or paracrine factor, but this could only occur in the presence of sIL-6R or an increase in cortisol levels. The fact that other members of the subfamily also induce osteoclast formation supports our hypothesis that these factors play an important role in the regulation of bone remodeling. Although the LIFR has no α component, LIFR can be detected in the circulation (Layton *et al.*, 1992). Unlike the agonist effect of sIL-6R + IL-6, sLIFR + LIF may have an antagonistic effect (Gearing, 1993). Whether this is because of α versus β receptor component usage or downstream events is unknown. Equally unknown is the effect of sLIFR + LIF on bone cells.

IL-11 is a 23-kDa stromal cell-derived cytokine that causes the maturation of hematopoietic precursor cells (Quesniaux *et al.*, 1993). The IL-11-specific receptor is 24% homologous with the IL-6R, suggesting that it also occurs in soluble form (Hilton *et al.*, 1994). IL-11, unlike IL-6, appears to function in the estrogen-replete state to induce osteoclast formation and bone resorption and therefore may regulate normal remodeling (Girasole *et al.*, 1994). We have demonstrated that IL-11 is secreted by primary human osteoblasts and induces tyrosine phosphorylation in primary mouse osteoblasts (Elias *et al.*, 1995; Horowitz *et al.*, 1994). This suggests that, unlike IL-6, but like LIF, IL-11 is a true autocrine factor for osteoblasts. This is supported by our demonstration that IL-11 induces IL-6 secretion by primary osteoblastic cells (Horowitz *et al.*, 1994). The IL-11 receptor, which is 32% and 30% identical by amino acid composition to the CNTF and IL-6 receptors, respectively, is expressed by day 9 in the developing embryo (Neuhaus *et al.*, 1994). The highest expression is in mesenchymal cells, particularly in regions containing chondro- and osteoprogenitors. However, no IL-11R mRNA was detected in mature osteoblasts, chondroblasts, odontoblasts, or osteocytes. This suggests that IL-11R is a marker of early bone development. MC3T3-E1 cells treated with IL-11 resulted in the phosphorylation of Jak1, Stat1, and Stat3, the inhibition of cellular proliferation, and stimulation of alkaline phosphatase activity (Shih *et al.*, 2000). Treatment of fetal rat calvarial cells with IL-11 inhibited bone nodule formation (Malaval *et al.*, 2005). IL-11 stimulated BMP through Stat3, leading to osteoblast differentiation, and inhibited adipogenesis in bone marrow stromal cells (Takeuchi Y *et al.*, 2002). Mice made null for both isoforms of the IL-11 receptor (IL-11Rα1 and IL-11Rα2) had significantly increased trabecular bone volume (Sims *et al.*, 2005). This was associated with decreased bone resorption and formation *in vivo*. Culture of IL-11R -/- bone marrow with RANKL and M-CSF to induce osteoclast differentiation resulted in fewer osteoclasts in the mutant bone marrow than in controls. In contrast, overexpression of IL-11 in transgenic mice resulted in stimulation of bone formation with increased cortical thickness and bone strength (Takeuchi *et al.*, 2002). Increased IL-11 expression did not affect osteoclast differentiation and bone resportion. Injection of IL-11 into 7-month-old ovariectomized mice that were actively losing bone restored BMD to sham levels and was as good as injected PTH (Ma *et al.*, 2006). Trabecular architecture, including trabecular number and trabecular separation, improved in the IL-11-treated mice. Cortical area increased by increasing periosteal and endocortical mineralizing surfaces and reducing endocortical bone resorption.

One way in which these ligands are related is by the use of a common receptor. This receptor is composed of multiple components and expression of different components allows the cell to discriminate between ligands. Therefore, a clear understanding of how this receptor functions cannot be separated from the significance of how multiple ligands sharing a common receptor regulate cell function. The receptor is composed of a set of proteins that are assembled in a defined order and that have specific functions. However, the members of the subfamily utilize different combinations of the receptor components. Each subfamily member appears to possess at least three receptor-binding sites. The first site binds the α component of the receptor. The receptors for IL-6, IL-11, and CNTF have ligand-binding α components whereas the receptors for OSM, LIF, and CT-1 lack this component (Davis *et al.*, 1991).

The other two binding sites on the ligand are required for interaction with the β1 and β2 components of the receptor. The β1 component is a transmembrane protein, which forms a complex with the ligand and the α component, or with the ligand alone, if the α component is absent. The β1 component has been found in the receptor of all subfamily members that have been examined. However, it is not necessarily the same molecule for every member. OSM, CNTF, and CT-1 use the same β1 molecule that was originally identified for LIF, known as LIFRβ or LIFR (Gearing *et al.*, 1992). LIFR is now known to be the low-affinity receptor for LIF (Fig. 1).

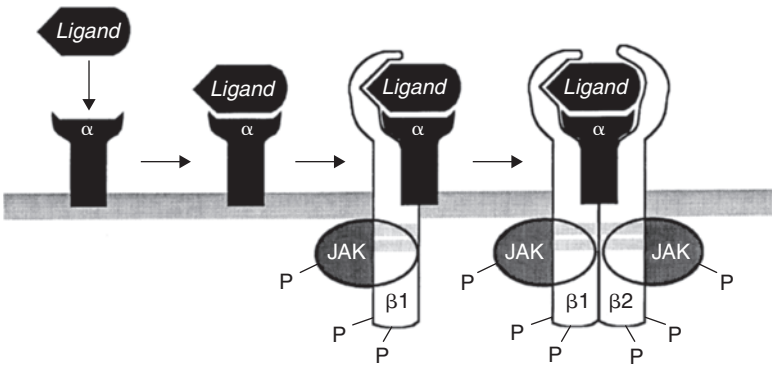

FIGURE 1 LIF/IL-6 cytokine receptor with component assembly including ligand, α component, β1 component, β2 component (gp130), and JAK kinase. P indicates tyrosine phosphorylation sites; cross-hatched portion in β component represents box 1 and 2 regions where JAK kinase is associated.

The β2 component has been identified as gp130. GP-130 was originally identified as a signal transducer for IL-6 and is now known to be a common and obligatory component of the receptor for all of the cytokines in the subfamily and is required for signal transduction (Ip *et al.*, 1992). GP-130 has been referred to as a high-affinity converting subunit. An example of this is cell activation with LIF, an event that requires LIF, LIFR, and gp130. LIF can bind LIFR and transmit a suboptimal signal. However, the presence of gp130 allows for high-affinity binding, optimal signal transduction, and cell activation. With the exception of OSM, it appears that gp130 is the last member of the receptor components to bind the ligand and form the completed and functional receptor. As can be seen in Table I, CNTF, LIF, OSM, and CT-1 use the LIFR subunit as the β1 component and gp130 as the β2 component. IL-6 and IL-11 use two gp130 molecules. Like LIF, OSM uses gp130 as a high-affinity converting subunit. However, unlike LIF, OSM binds gp130 preferentially. OSM may also use the OSM alternate receptor (OSMR), which is similar in structure to LIFR (32% homology) and requires gp130 for signaling (Mosley *et al.*, 1996). The OSMR is expressed on primary murine calvarial osteoblasts (Horowitz *et al.*, 1996). LIF does not bind the OSMR (Fig. 2).

It has been demonstrated in nonskeletal cells that signal transduction stimulated by this subfamily of cytokines is mediated by tyrosine kinases. With respect to bone cells, two major examples can be cited to demonstrate the importance of tyrosine phosphorylation in bone remodeling. Both examples involve altered bone remodeling because of genetic defects in some aspect of the process involving tyrosine phosphorylation. The first, as demonstrated by the oplop mouse, has a defect in the secretion of biologically active M-CSF, which can no longer signal through its receptor, c-fins, a receptor tyrosine kinase (Yoshida *et al.*, 1990). The second example involves c-src, a nonreceptor tyrosine kinase whose gene deletion by homologous recombination, like the oplop defect, results in osteopetrosis (Soriano *et al.*, 1991).

The JAK family (Janus or just another kinase) is associated with the receptors for the LIF/IL-6 subfamily and other cytokines including interferon-γ, erythropoietin, growth hormone, IL-3, and GM-CSF (Silvennoninen *et al.*, 1993). The JAK family presently includes five members: Jak1–4 and Tyk2, which range in size from 130 to 137 kDa. In mammals, Jak1, Jak2, Jak3, and Tyk2 are used. These kinases can be distinguished from other nonreceptor tyrosine kinases in that they have no SH2 or SH3 (src homology) domains and contain two catalytic domains, one being the classical kinase domain and the second, a kinase-related domain that is nonfunctional (Firmbach-Kraft *et al.*, 1990; Wilks *et al.*, 1991). Different JAK kinases are activated depending on cell type and ligand bound and may phosphorylate different substrates, representing a second level of discrimination by the cell (Stahl, 1994).

The LIF/IL-6 subfamily of cytokines uses Jak1, Jak2, and Tyk2. IL-12 uses a gp130-related receptor but not gp130 itself. Cytokines whose receptors are homodimers, such as growth hormone, prolactin, erythropoietin, and thrombopoietin, use Jak2. Signal transduction is initiated by ligand binding to its receptor, which causes receptor multimerization and an apparent conformational change in the receptor complex, allowing for activation of the associated JAK kinases and phosphorylation of three groups of proteins. The first group includes the β-chains of the receptor (LIFR, gp130, and OSMR). Second, the kinase itself becomes phosphorylated. The third group includes a family of cytoplasmic proteins. In both skeletal and nonskeletal cells some of these cytoplasmic proteins are transcription factors belonging to the STAT family (signal

TABLE I Cytokine Receptor Composition

Cytokine (ligand)	Subunit		
	α	β1	β2
IL-6	IL-6R	None	gp130
IL-11	Il-11R	None	gp130
LIF	None	LIFR	gp130
OSM	None	LIFR	gp130
OSM	None	OSMR	gp130
CNTF	CNTFR	LIFR	gp130
CT-1	None	LIFR	gp130
CLP	CNTF	LIFR	gp130
NP	CNTF	LIFR	gp130

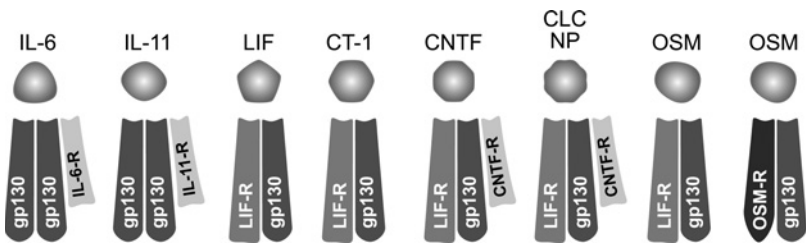

FIGURE 2 Receptor composition of the LIF/IL-6 family of cytokines.

transducers and activators of transcription). In addition to the STAT proteins, a group of adaptor proteins (i.e., Shc) may also become phosphorylated on tyrosine. Tyrosine phosphorylation of She is important because it provides the bridge between activated receptor chains and the mitogen-activated protein kinase (MAPK) pathway. Phosphorylated tyrosine residues and their flanking amino acids on the cytoplasmic domains of the receptor chains form docking sites where proteins like the STATs, She, and protein tyrosine phosphatases bind and become phosphorylated (Stahl *et al.*, 1995). These proteins recognize the phosphorylated tyrosine through their SH2 domains. Because the JAKs autophosphorylate, their phosphorylated tyrosines may also serve to dock additional proteins. JAK-deficient mice have been generated with multiple phenotypes (Neubauer *et al.*, 1998; Parganas *et al.*, 1998; Rodig *et al.*, 1998). Jak1-deficient mice show perinatal lethality, are small at birth, have defects in lymphopoiesis but not myelopoiesis, and fail to respond to the LIF/IL-6 subfamily of cytokines. Jak2 deficiency results in embryonic lethality because of the absence of erythropoiesis. Loss of Jak3 results in a SCID-like syndrome (Park *et al.*, 1995; Thomis *et al.*, 1995). Apparently, the skeletons of these mice have not been examined.

At the present time, six members of the STAT family have been described (Darnell *et al.*, 1994). Once phosphorylated, these proteins homo- or heterodimerize and translocate to the nucleus, by an unknown mechanism, and bind appropriate DNA sequences, resulting in gene transcription (Shuai *et al.*, 1993). A DNA promoter site in genes activated by IL-6 is similar to the IFN-γ-activated site (GAS), which mediates transcriptional induction of IFN-γ-responsive genes (Pearse *et al.*, 1993). Nonskeletal cells treated with IL-6 tyrosine phosphorylate Stat1 or related proteins with subsequent binding to GAS and IL-6 sites (Bonni *et al.*, 1993; Sadowski *et al.*, 1993). CNTF induces phosphorylation of STAT proteins with subsequent translocation to the nucleus (Bonni *et al.*, 1993). Because CNTF, as well as other family members, activates early-response genes, a comparison of promoter sequences was developed as a potential target sequence for STAT proteins. When nuclear extracts from CNTF-treated cells (nonskeletal) were incubated with oligonucleotides to the STAT protein-recognizing sequence, binding occurred as detected by DNA-protein mobility-shift assay. This binding did not occur in the absence of CNTF and could be blocked (super shift) by the addition of anti-p91 (anti-Stat1α) (Bonni *et al.*, 1993). At present, only limited data are available relating to phosphorylation of cytosolic transcription factors and subsequent gene activation in bone cells. We have shown by immunoprecipitation that OSM induces tyrosine phosphorylation of both Stat1 α and Stat3 in primary mouse osteoblastic cultures (Levy *et al.*, 1996). Stat1 α and Stat3 are also phosphorylated in MC3T3 cells in response to LIF (Lowe *et al.*, 1995). Expression of a dominant negative Stat3 in a stromal/osteoblastic cell line that normally supports osteoclastogenesis results in the failure of those cells to further support osteoclast formation (O'Brien *et al.*, 1999). The inhibition of osteoclastogenesis by the dominant negative Stat3 occurs following stimulation by OSM, IL-6 + sIL-6R, and IL-1 but not by parathyroid hormone or 1,25-dihydroxyvitamin D_3. In the same system the dominant negative Stat3 blocked the ability of OSM or IL-6 + sIL-6R to induce expression of RANKL, indicating an important role for Stat3 in gp130-mediated osteoclast formation. Stat3-deficient mice have a severe defect in development and die early in fetal life (Takeda *et al.*, 1997). A conditional knockout of Stat3 has been developed (Takeda *et al.*, 1998). These mice demonstrate the importance of Stat3 in IL-2, IL-6, and IL-10 signaling. Their bone phenolype(s), if any, have not been reported. Although the data are extremely limited at present, CNTF appears not to play a major role in bone cell activation. Of the family members, CNTF is the poorest at

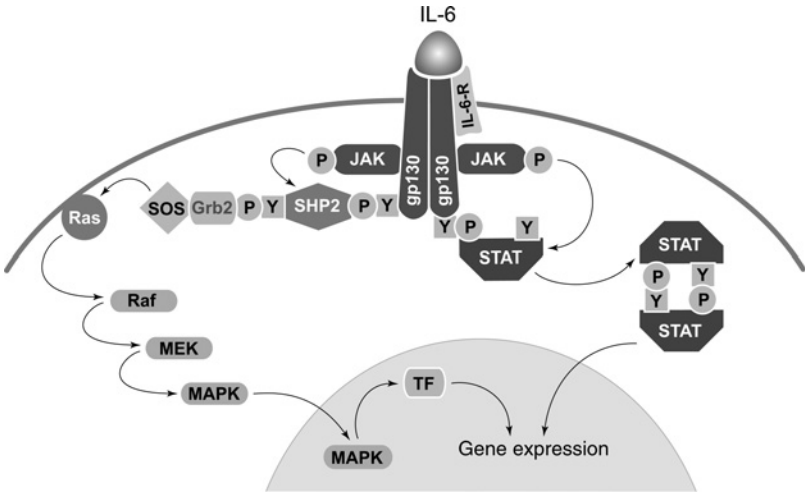

FIGURE 3 LIF/IL-6 cytokine signaling.

inducing IL-6 secretion from primary cultured osteoblastic cells (Horowitz *et al.*, 1994). However, CNTF did induce cell proliferation, increase alkaline phosphatase activity, and induce IL-6 secretion in MC3T3 cells (Bellido *et al.*, 1995). One pathway that has been shown to be activated by tyrosine phosphorylation in nonskeletal cells is Ras, a small GTP-binding protein that functions to relay signals to a group of kinases referred to as mitogen-activated protein kinases (MAPKs) or extracellular signal-regulated kinases (ERKs) (Bollag and McCormick, 1991). Activation of the MAPK cascade leads to the stimulation of transcription factors resulting in specific biological consequences. In nonskeletal cells it is known that OSM and IL-6 phosphorylate and activate MAPK (Amaral *et al.*, 1993; Kumar *et al.*, 1994). Our data show induction of a 43- to 45-kDa phosphorylated protein in human and mouse osteoblasts following OSM stimulation, which we have recently shown is MAPK (Horowitz and Levy, 1995). Tyrosine kinase pathways are linked to the Ras signaling pathway via Grb2, a small adaptor protein that contains domains referred to as src homology (SH2 and SH3), which are involved in protein–protein interactions. Grb2 associates with the guanine nucleotide exchange factor for Ras, SOS (the mammalian homologue of the *Drosophila* son of sevenless gene product), via interactions between its SH3 domain and proline-rich sequences in SOS. These Grb2–SOS complexes then associate with tyrosine kinase receptors through binding of the SH2 domain of Grb2 to tyrosine residues in growth factor receptors that become phosphorylated following ligand binding and cellular activation. The tripartite complex of receptor/Grb2/SOS aids in translocating SOS from the cytoplasm to the plasma membrane where it is placed in close proximity to its target, Ras, converting Ras from the GDP to the biologically active, GTP-bound state. Another adaptor protein, Shc, contains an SH2 domain that has been shown to bind to tyrosine-phosphorylated receptors in nonskeletal cells (Pelicci *et al.*, 1992). Shc also contains an additional phosphotyrosine-binding domain (PTB) that is capable of interacting with other phosphorylated proteins (Kavanaugh and Williams, 1995). Subsequent to cytokine binding, Shc becomes tyrosine phosphorylated and can interact with phosphorylated cytokine receptors, thereby enabling its interaction with Grb2 and activation of the Ras pathway. OSM stimulation of human osteoblasts results in tyrosine phosphorylation of Shc (Horowitz and Levy, 1995). The presence of tyrosine-phosphorylated MAPK supports the idea that family members may be stimulating the Ras pathway as well as the JAK/STAT signaling pathway. The tyrosine kinases that are responsible for phosphorylating Shc upon cytokine stimulation may be members of the JAK family or other cytoplasmic tyrosine kinases such as the src-family of tyrosine kinases.

As with other types of cytokine signaling, it is as important, if not more so, to turn off the signaling cascade as it is to turn it on. This can be accomplished by the activation, through phosphorylation on tyrosine residues, of protein tyrosine phosphatases. Once activated these proteins dephosphorylate other phosphorylated proteins, in particular, tyrosine kinases, resulting in deactivation. As mentioned previously, protein tyrosine phosphatases dock to phosphorylated tyrosine residues on the cytoplasmic domains of the cytokine receptor through their SH2 domains, resulting in phosphorylation of the phosphatase. Although there is clear evidence that protein tyrosine phosphatases are activated in response to the LIF/IL-6 family of cytokines (PTPase, Shp1) few if any direct data are available as to whether this negative regulation occurs in bone cells (Stahl *et al.*, 1995). In addition to the negative regulatory activity of phosphatases, a new family of proteins has been recently identified that can inhibit JAK-STAT signaling. The first member of this family (CIS/CIS1) inhibited the signaling of IL-3 and erythropoietin (Yoshimura *et al.*, 1995). A second member of the family was identified and is referred to as JAB (JAK-binding protein), SOCS1 (suppressor of cytokine signaling), or SSI-1 (STAT-induced STAT inhibitor) (Endo *et al.*, 1997; Naka *et al.*, 1997; Starr *et al.*, 1997) and is a negative regulator of IL-6 signaling. At present seven members of this family have been identified. In some cases (JAB and CIS3) inhibit the kinase activity by directly binding to the JAKs and in others cases (CIS/CIS1) the STATs are inhibited. Thus, ligand binding results not only in activation of the signaling pathway, but also in its inactivation by a negative feedback loop. Whether this family of proteins downregulates cytokine activation in bone cells remains to be determined.

Molecular Mechanisms of Metabolic Bone Disease

Chapter 59

Skeletal Effects of Nitric Oxide: Novel Agent for Osteoporosis

Sunil J. Wimalawansa*

Division of Endocrinology/Regional Osteoporosis Center, Department of Medicine, UMDNJ-Robert Wood Johnson Medical School, New Brunswick, New Jersey 08903, USA

INTRODUCTION

Nitric oxide (NO) is a water-soluble, gaseous radical molecule that moves freely across cell membranes. It is enzymatically produced by the oxidation and cleavage of one of the terminal nitrogen atoms of the amino acid L-arginine. The reaction is dependent on electrons donated by the cofactor NADPH and requires oxygen, yielding L-citrulline as a co-product (Fig. 1). Nitric oxide is involved in a variety of physiological and pathophysiological processes including vasodilatation, neurotransmission, the cytotoxic effects of various pathogens, and the genesis of inflammatory diseases. These broad-ranging actions are determined largely by the site, the rate, and the quantity of NO generated, and by the nature of the environment into which it is released. The reactivity of NO is influenced in particular by the presence of reactive oxygen intermediates and the activity of anti-oxidant defense systems (Moncada and Higgs, 1993; Knowles and Moncada, 1994; Gross and Wolin, 1995). Generation of NO from conversion of L-arginine to L-citrulline is illustrated in Fig. 1.

A family of three related enzymes, the nitric oxide synthases (NOS), regulates the synthesis of NO. These are characterized as a neuronal form (type 1; nNOS) originally isolated from brain, an endothelial form (type 3; eNOS) originally isolated from bovine aortic endothelial cells (Pollock *et al.*, 1991), and an inducible form (type 2; iNOS) originally isolated from murine macrophages (Xie *et al.*, 1992). Both eNOS and nNOS are expressed constitutively and are characterized by highly regulated, rapid but low-output NO production that has a tonic physiological function (Moncada and Higgs, 1993; Knowles and Moncada, 1994). For example, when a compound

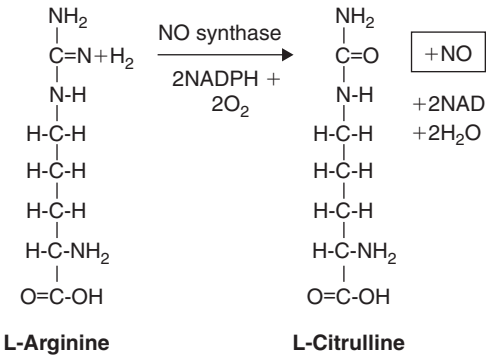

FIGURE 1 Generation of nitric oxide (NO) from L-arginine via nitric-oxide synthase enzyme.

that NOS is administered intravenously (e.g., L-NAME), one could observe an instant rise in blood pressure in animals (Yallampalli and Wimalawansa, 1998). Table I illustrates the differences and commonalities of three NOS isoenzymes.

Conversely, iNOS is generally not active under normal physiological conditions, but can be induced in a number of different cell types in response to infection, inflammation, or traumatic injury (Moncada and Higgs, 1993; Knowles and Moncada, 1994; Gross and Wolin, 1995). In contrast to rapid activation and deactivation of the constitutive enzymes eNOS and nNOS, iNOS expression is induced over several hours, requiring transcription of mRNA and *de novo* protein synthesis. Once activated, iNOS is capable of generating sustained high levels of NO locally over many hours (Gross and Wolin, 1995). In these circumstances NO can exacerbate the inflammatory response as seen in septic shock and rheumatoid arthritis, and it may also contribute to localized cell and tissue damage (Gross and Wolin, 1995).

Principles of Bone Biology, 3rd Edition

TABLE I Chromosomal and Cellular Localization of NOS Isoenzymes, and Their Activities[a]

NOS Type	Name	Chromosomal Location	Predominant Location	NO Output	Calcium-Dependent Activation
NOS-1	nNOS (bNOS) (*Constitute*)	12	Brain NANC neurons	Low	Dependent Cytosolic/membrane
NOS-2	iNOS inducible	17	Macrophages Neutrophils	High	Independent Cytosolic
NOS-3	eNOS (*Constitute*)	7	Endothelium Smooth muscles	Low	Dependent Membrane bound

[a]*Adapted from* Wimalawansa (2008).

Although nNOS, eNOS, and iNOS catalyze the same reaction to generate NO from L-arginine, they are distinct enzymes. Each is the product of a separate gene, and they share only 50% to 60% homology. In addition, each is subject to widely differing mechanisms of regulation (Moncada *et al.*, 1991; Hukkanen *et al.*, 1999). General characteristics of NOS isoenzymes are presented in Table I and in more detail in Table II. All three isoforms exhibit a bidomain structure containing consensus sequences along the C-terminal domain for binding for several cofactors including NADPH, FAD, FMN, and calmodulin. The arginine-binding site is retained within the N-terminal domain, which also contains a heme group and a consensus site for binding tetrahydrobiopterin. All cofactors are required for full activity and in their native, catalytically competent state, all three isoforms are homodimers (Griffith and Stuehr, 1995).

The activities of the constitutive NOS enzymes (nNOS and eNOS) are also dependent on mobilization of intracellular Ca^{2+}. Comparisons of sequence homologies reveal that NOS enzymes bear resemblance to cytochrome P450 reductase, sharing around 60% sequence similarity along their C-terminal domain (Bredt *et al.*, 1991; Griffith and Stuehr, 1995). This has been instrumental in elucidating the catalytic mechanism of NOS showing that the C-terminal domain, like cytochrome P450, is essentially an electron transporter. Bound calmodulin acts as a gate to regulate flow of electrons from the C-terminal domain to the N-terminal domain, where they are donated to the heme group, and their energy is used to drive the generation of NO (Griffith and Stuehr, 1995). Whereas the C-terminal domains of NO synthase isoenzymes are very similar, the N-terminal domains exhibit some variations. Most notably, eNOS possesses consensus sequences for myristoylation/palmitoylation at its N terminus and is important in determining its subcellular trafficking, locating the enzyme to membranes and in particular the caveolae (Garcia-Cardena *et al.*, 1996).

The molecular regulation of iNOS is particularly complex and occurs at several sites in the gene expression pathway with both transcriptional and post-transcriptional mechanisms (Ganster and Geller, 2000). Expression of iNOS can be induced by various "proinflammatory" cytokines including tumor necrosis factor alpha (TNF-α), interleukin 1-beta (IL-1β), and interferon-gamma (IFN-γ), and the effects of these inductive stimuli are mediated by the NF-κB and Jak-STAT signaling pathways (Damoulis and Hauschka, 1997; Ganster and Geller, 2000). Downregulators of iNOS expression include glucocorticoids such as dexamethasone, which inhibits cytokine-induced iNOS mRNA at the transcriptional level (Ganster and Geller, 2000). On the other hand, the cytokine TGF-β downregulates iNOS expression at the post-transcriptional level by inducing instability in iNOS mRNA. There is also evidence for a negative feedback loop whereby NO downregulates iNOS gene expression as well as inhibits the activity of iNOS protein (Ganster and Geller, 2000).

Although the eNOS gene is considered to be constitutively expressed, there are a number of additional factors that exert positive or negative effects on its expression. The activity of eNOS is stimulated by a number of agonists including estrogen, vascular endothelial growth factor (VEGF), and shear or mechanical stress (Klein-Nulend *et al.*, 1998; Fox *et al.*, 1996). In fact VEGF expression is stimulated by NO (Frank *et al.*, 1999). Also involved are activation of various signaling pathways, particularly those resulting in mobilization of intracellular Ca^{2+} and phosphorylation of eNOS (Gratton *et al.*, 2000). It is clear that in addition to stimulating the activity of eNOS protein, shear stress, estrogen, VEGF (Frank *et al.*, 1999), as well as TGF-β and fibroblast growth factor (FGF), upregulate eNOS expression at the level of transcription. Conversely, TNF-α and hypoxia downregulate eNOS gene expression by inducing instability in eNOS mRNA (Kleinert *et al.*, 2000).

Nitric oxide donors such as nitroglycerine and nitrates have been used as therapeutic agents for the past century, and the only significant adverse effect is headache. When the body cannot generate adequate amounts of NO for its biological homeostasis, administration of

TABLE II General Molecular and Biochemical Characteristics of NOS Enzymes and Their Association with Bone

	nNOS [NOS I]	iNOS [NOS II]	eNOS [NOS III]
Molecular weight (kDa)	160 Active form ~260 homodimer	130 Active form ~260 homodimer	135 Active form ~260 homodimer

exogenous NO or prolongation of the actions of endogenous NO are practical methods of supplementation. Examples of the former are patients with angina pectoris, coronary artery disease, hypertension, osteoporosis, or gastrointestinal motility disorders; an example for the latter is erectile dysfunction in men (use of phosphodiesterase 5 inhibitors). Postmenopausal NO deficiency is rectified by hormone replacement therapy, enhancing local production of NO (Wimalawansa, 2007). Declining local NO production secondary to estrogen deficiency in postmenopausal women and perhaps in older men could be one of the key reasons for age-related increased incidences of cardiovascular events and sexual dysfunction. Thus, in addition to supplementation of NO compounds in acute situations such as alleviating angina and erectile dysfunction, chronic NO therapy may potentially lead to a decrease in cardiovascular event rates and improvement in urogenital as well as skeletal health.

During the 1980s, NO was identified as a significant biological signaling molecule that regulates a wide range of important cellular physiological functions. Discovery of NO as the endothelium-derived relaxing factor has opened the door to a wide research arena (Angus and Cocks, 1989; Ignarro *et al.*, 1981; Moncada *et al.*, 1991). Nitroglycerine and nitrates are common heart medications that dilate blood vessels, decrease blood pressure, and improve circulation, and control angina and heart failure. Nitric oxide-donors are cost-effective and have beneficial effects in multiple body systems. Administration of exogenous NO donor compounds are a practical way to supplement NO.

Circulating NO products are significantly lower in postmenopausal women compared to premenopausal women (Stacey *et al.*, 1998; Rosselli *et al.*, 1995), and this is corrected after initiation of hormone replacement therapy (HRT; Rosselli *et al.*, 1995). Because menopause can lead to NO deficiency, there is a plausible biological basis for use of NO replacement or supplementation therapy in menopause. Studies have shown that the beneficial effects of estrogen on bone are predominantly mediated via NO (Wimalawansa *et al.*, 1996). Therefore, it makes sense to supplement NO directly for postmenopausal women, because HRT has potential (albeit small) adverse effects in postmenopausal women as reported from the Women's Health Initiative study.

NITRIC OXIDE BIOCHEMISTRY

Nitric oxide is synthesized in biological systems by a complex set of enzymes, the nitric oxide synthases (NOS; Bredt and Snyder, 1990; see Table 1). Smaller quantities of NO are also produced by non-enzymatic chemical reductions of inorganic nitrate and during acidic-reducing conditions (Weitzberg and Lundberg, 1998). Cyclic guanosine

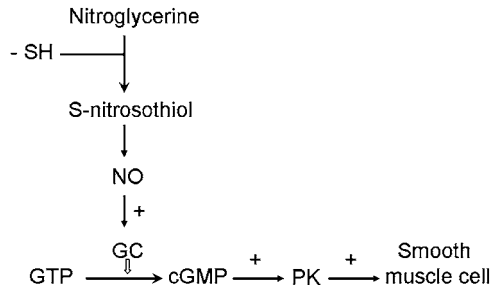

FIGURE 2 The necessity of the thiol group (–SH) in activation of the nitroglycerine molecule to release NO at target tissues.

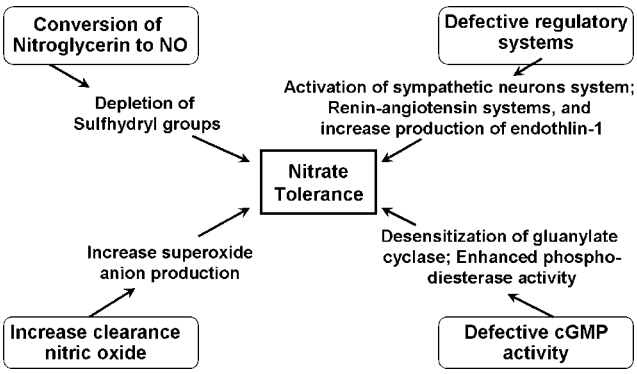

FIGURE 3 Potential methods of developing desensitization to nitroglycerine and nitrates (Wimalawansa, 2008).

monophosphate (cGMP) is synthesized from the nucleotide guanosine triphosphate (GTP) by the enzyme guanylate cyclase (Muscara *et al.*, 1998, Murad *et al.*, 1978). Cyclic GMP serves as the second messenger for several key compounds and peptides such as atrial natriuretic peptide (ANP) and NO, and it even elicits the light response by the rods in the retina. Some of the effects of cGMP are mediated through protein kinase G (PKG), a cGMP-dependent protein kinase that phosphorylates target proteins in cells.

Glyceryl trinitrate (GTN), or nitroglycerine, is one of the oldest synthetic drugs that are still widely used in clinical practice. It releases its active moiety NO or an NO-congener such as *S*-nitrosothiol (SNO), within or very close to the cell membranes of target cells such as vascular or penile smooth muscle cells. This results in activation of guanylate cyclase (GC) leading to smooth muscle cell relaxation (Munzel, 2001). Sulfhydryl groups (–SH) are essential for release of the NO moiety from nitroglycerine (Fig. 2). The sulfhydryl requirement for NO release in cell relaxation can explain in part nitrate tolerance: that is, the loss of clinical efficacy over a short period of time, especially with frequent administration of nitroglycerine (Carini *et al.*, 2001). This is a major problem for long-term use of nitrates (Munzel, 2001; Nakamura *et al.*, 1999) but can be overcome by intermittent dosing of nitrates. Figure 2 illustrates the requirement of thiol (–SH) groups containing compounds for activation of nitroglycerine to releasing NO at local target sites.

Figure 3 illustrates the several potential mechanisms involved in the development of nitrate tolerance in humans (i.e., losing its efficacy) *in vivo*. Attention to these factors is necessary to overcome this difficulty during longer-term administration of nitroglycerine to maintain its intended actions (efficacy).

The signaling functions of NO begin with its interactions with guanylate cyclase on cell membranes, or following diffusion into cells. The binding sites can be either a metal ion in the protein, or one of its sulfur atoms: e.g., on a cysteine (Wiesinger, 2001; Luo and Cizkova, 2000). In either case, binding triggers an allosteric change in the protein that in turn triggers the formation of a "second messenger" within the cell. The most common protein target for NO is guanylate cyclase, the enzyme that generates the second messenger cGMP (Murad *et al.*, 1978). In the presence of hemoproteins, such as hemoglobin or myoglobin, NO may promote or inhibit oxidative reactions, depending on the relative fluxes of O_2^-, H_2O_2, and NO (Jourd'heuil *et al.*, 1998). This balance can be a critical event in protection of tissue damages associated with a variety of pathological conditions, such as postischemic myocardial damage, chronic smoking, post-traumatic brain injury, hemorrhagic disorders, and chronic inflammation.

NO SIGNALING

Biology and Chemistry of NO

Although NO might be regarded chemically as a simple molecule, its biochemistry and its actions in biological systems are often complex, and this accounts in part for the wide range of biological processes that are influenced by NO. Nitric oxide products represent several related species, including its higher oxides and derived oxidants. For the purpose of this review it is necessary to consider only the NO-derived oxidant peroxynitrite, with all other actions generalized as NO.

Nitric oxide is eventually oxidized to nitrite and nitrate in biological systems. In aqueous buffers and culture conditions, nitrite is the principal oxidation product of NO (Ignarro *et al.*, 1993), whereas *in vivo* NO is in general almost completely oxidized to nitrate and excreted. These end products have proved to be useful markers for evidence of NO biosynthesis within biological samples (Wimalawansa, 2007). Nitrate and nitrite can be detected by the Greiss reaction, which relies on the reduction of nitrate to nitrite after the addition of the enzyme nitrite reductase or a metallic catalyst to the sample, the resultant color changes being then detectable spectroscopically (Green *et al.*, 1982; Stuehr and Marletta, 1987). This technique, however, is quite insensitive, requiring the accumulation of micromolar

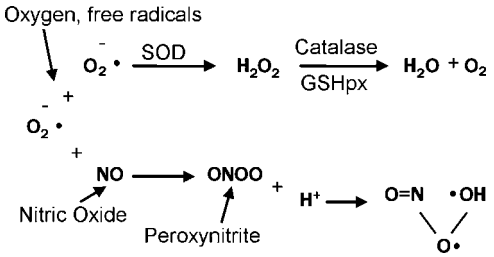

FIGURE 4 Generation of peroxynitrite from nitric oxide.

amounts of nitrite. For greater sensitivity, a chemiluminescence analyzer can be used to measure NO levels. In this assay, a strong reducing agent is used to reduce the nitrite or nitrate present in the sample of interest back to NO. The NO is then reacted with ozone, which results in the generation of light or chemiluminescence, with the amount of light being directly proportional to NO levels (Archer, 1993).

Perhaps one of the better-understood reactions of NO in biological systems is its combination with superoxide anion (O^{-}_{2}) to form peroxynitrite anion ($ONOO^{-}$; Beckman *et al.*, 1990). Both molecules show a high affinity for each other, the reaction proceeding several-fold more quickly than catalysis of superoxide anion dismutation by superoxide dismutase (SOD). Free radical NO itself is a potent oxidant (Freeman, 1994). Peroxynitrite is a very powerful oxidant and can either augment or abrogate some of the biological actions associated with NO (Beckman *et al.*, 1994a). Induction of iNOS together with the formation of peroxynitrite is thought to play an important part in osseous prosthetic failure (Hukkanen *et al.*, 1997). Figure 4 demonstrates the alternate path of NO metabolism leading to generation of peroxynitrite.

Cellular Targets of NO

NO does not require specific receptors to communicate its physiological actions; its small size and lipophilic nature allow it to traverse plasma membranes without the need for a specific transporter. In biological systems, the principal cellular targets for NO are proteins containing transition metal ions. Soluble guanylate cyclase is perhaps the most significant of these metal-ion proteins, with NO demonstrating high affinity for the heme moiety of the enzyme, forming a transient and reversible nitrosyl-heme group. Binding of NO induces a conformational change in the enzyme stimulating the catalysis of cGMP formation.

Nitric oxide is also rapidly bound to free hemoglobin, resulting in the formation of methemoglobin and nitrate and termination of the activity of NO. This quenching action explains in part the rise in blood pressure in patients following intravascular hemolysis. It has been proposed that hemoglobin acts as a biological "sink" for NO (Gross and Wolin, 1995), but Jia *et al.* (1996) reported that NO can

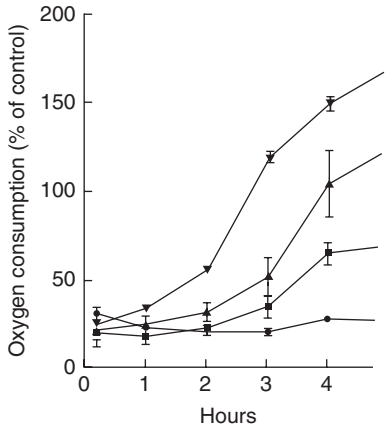

FIGURE 5 Effects of exposure to the NO donor, DETA-NO on oxygen consumption of J774 cells (Orsi *et al.*, 2000).

S-nitrosylate hemoglobin to form *S*-nitrosohemoglobin, and this, on the other hand, is important for preserving or potentiating the vascular actions of NO. *S*-Nitrosylation of proteins by NO is also an important intracellular signaling mechanism, activating for example the small G-protein $p21^{ras}$ and the ensuing MAP kinase cascade (Lander, 1997).

Nitric oxide will also bind and inhibit various iron-sulfur (Fe-S) cluster proteins (Hibbs *et al.*, 1990). Many Fe-S proteins play a significant role in energy metabolism as well as in growth, and NO therefore is able to affect cellular cytotoxicity and cytostasis (Freeman, 1994). In particular, NO inhibits key enzymes involved in mitochondrial respiration, including mitochondrial aconitase, NADH-ubiquinone oxidoreductase, and NADH-succinate oxidoreductase (Hibbs *et al.*, 1990; Stuehr and Nathan, 1989), as well as ribonucleotide reductase (Kwon *et al.*, 1991), which is the rate-limiting enzyme in DNA synthesis.

Following prolonged exposure to NO, cells exhibit a decrease in oxygen utilization as a consequence of two synergistic actions: persistent inhibition of mitochondrial oxygen consumption and production of a hypoxic microenvironment following extraction of oxygen from extracellular medium. It is uncertain whether or not these striking effects occur *in vivo,* but should they do so, they are likely to be associated with pathological effects (Beltran *et al.*, 2000; Orsi *et al.*, 2000; Fig. 5). However, this could in part explain how myocardial oxygen consumption is decreased (leading to improvements in angina and heart failure) following administration of therapeutic amounts of NO supplements to cardiac patients.

Nitric oxide and superoxide anion demonstrate a strong affinity, reacting to form peroxynitrite (Beckman *et al.*, 1990). Peroxynitrite is a powerful oxidant with the potential to cause tissue and cellular damage; its products are potent nitrating agents with a particular affinity for protein tyrosine residues (Beckman *et al.*, 1994a; Freeman, 1994) that is capable of interfering with tyrosine kinase signaling

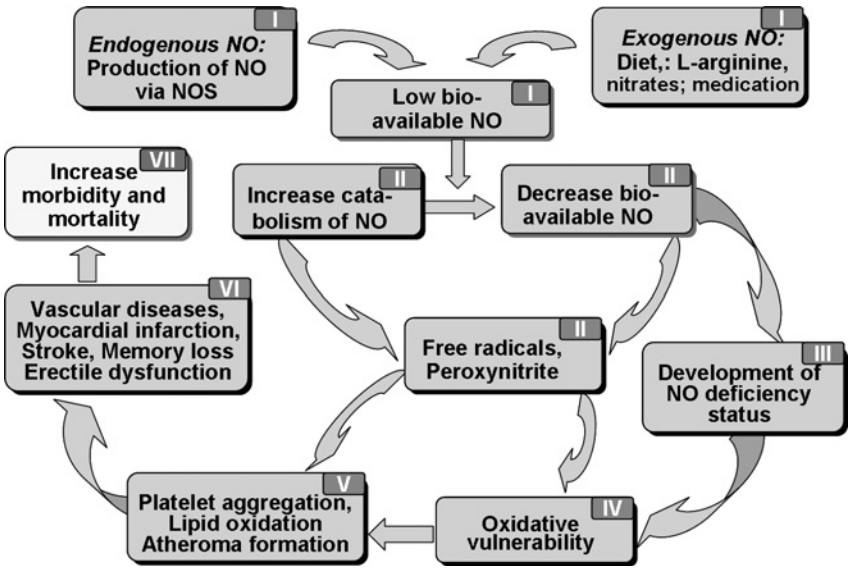

FIGURE 6 Cycle of disease vulnerability due to relative nitric oxide deficiency (production or bio-availability): Interactions and the balances between NO generation, free radicals, scavenging molecules, and disease statuses.

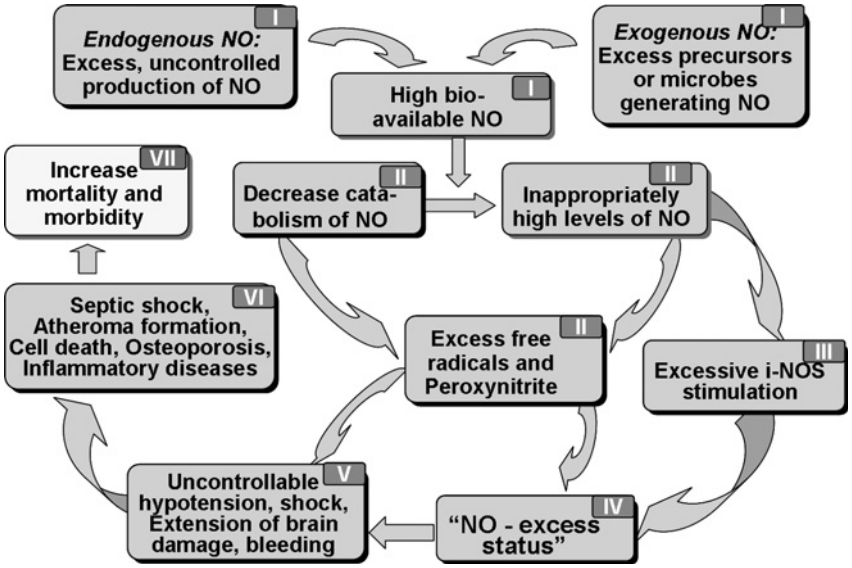

FIGURE 7 Vicious cycle of vulnerability to high levels of NO: diseases secondary to excessive generation, or synthesis of inappropriately high levels of NO. Figure also demonstrates the interactions and imbalances between NO productions and free radicals enhancement leading to development of serious disease statuses.

pathways. Evidence for endogenous peroxynitrite activity has been provided through the immunochemical (Beckman *et al.*, 1994b) and biochemical detection of nitrotyrosine species (Kaur and Halliwell, 1994) in tissues and fluids.

Nitric oxide or NO species, in particular peroxynitrite, can damage DNA bases, either by oxidation or by base deamination. This damage to DNA can directly stimulate the activation of the enzyme poly-ADP ribose polymerase (PARP), which facilitates DNA repair, by a process that utilizes both NADH and ATP (Zhang *et al.*, 1994). However, prolonged activation of PARP and in particular the continued consumption of NADH and ATP can lead to rapid energy depletion and result in cell death. This may be one mechanism by which generation of high levels of NO locally is able to induce cell death by enhanced apoptosis. Increased production of NO also correlates with increased expression of the proapoptotic proteins P53 and caspases and downregulation of bc12.

Over the years, the role of NO in disease status has been under-estimated. Figure 6 illustrates the interactions and the balance between NO generation, its bioavailability, free radicals, scavenging molecules such as free hemoglobin,

and disease statuses. Impairment of generation of NO, or its excessive degradation leading to sub-optimal levels of active No moiety can contribute to the development of several disease status.

Figure 7 illustrate the development of vicious cycle of disease processes secondary to excessive generation leading to inappropriately higher levels of NO (usually synthesized via NOS enzyme. Similar process can also be sustained via exogenous administration of high doses of nitrates. Figure also demonstrates the interactions and balances between NO productions, free radicals enhancement leading to development of serious disease statuses.

NITRIC OXIDE IN BONE

NOS Isoforms

A large number of antibodies and probes are now available to investigate the expression and localization of NOS enzymes. On the whole, many of the studies performed on bone tissues and cultured cells have resulted in similar descriptions of NOS expression and localization (Helfrich *et al.*, 1997). However, there has been some controversy, with some groups failing to find expression or localization where others had. In part, such discrepancies can be reconciled by the lack of standardization between studies. Many of the antibodies raised against different NOS enzymes may be species- or even tissue-specific, and some may be cross-reactive (Coers *et al.*, 1998). This is also confounded by variations in the cell lines studied, differences in culture conditions, or differences in the differentiation status of the cultures.

A number of RT-PCR and immunocytochemical investigations performed on whole bone preparations and cultured bone-derived cells from both human and rodents confirmed that eNOS and iNOS are the principal NOS isoforms expressed in bone (Helfrich *et al.*, 1997; Fox and Chow, 1998; MacPherson *et al.*, 1999). Although, some investigators have shown expression of nNOS mRNA in bone tissues by RT-PCR (Pitsillides *et al.*, 1995; Helfrich *et al.*, 1997), there is little evidence for the presence of nNOS protein in bone. However, nNOS gene knockout mice have specific bone phenotypes (Moradi-Bidhendi *et al.*). Whether this is due to the nNOS-containing nerves present within the bone regulating bone cell activity or bone blood flow has not been addressed yet. As discussed later, nNOS knockout mice also have altered responses to osteogenic hormones such as estrogen.

From the studies performed to date, there is consensus that under normal, physiological conditions eNOS is the predominant NOS enzyme expressed in the bone and is present in endothelial cells within the bone tissues, bone marrow stromal cells, osteoblasts, osteocytes, and osteoclasts (Brandi *et al.*, 1995; Helfrich *et al.*, 1997; Fox and Chow, 1998; MacPherson *et al.*, 1999). Expression of eNOS varies according to developmental stage, with eNOS mRNA and protein being most abundant in the bones of neonates and subsequently declining with age (Hukkanen *et al.*, 1999). Robust eNOS immunostaining has been demonstrated in cuboidal columnar osteoblasts lining trabecular and endosteal bone from neonates and to a lesser extent in osteocytes and multinuclear osteoclasts located in resorption lacunae.

Expression of NOS Isoforms

Expression of eNOS in osteoblasts, osteocytes, and osteoclasts becomes more diffuse with age. eNOS enzyme is also present in hypertrophic and degenerating chondrocytes of the epiphyseal growth plate of all ages, but particularly in the first 4 weeks of the neonatal period. Chondrocytes within the proliferation zone, however, are generally negative for eNOS expression and staining. NOS expression during fetal development in murine and human fetal long bones (mouse embryonic day 14 and human 8- to 12-week-old abortuses) has shown robust immunostaining, principally in hypertrophic and degenerating chondrocytes, but not in the proliferation zones. There is multiple evidence to suggest that NO is directly involved in osteoblast function and cell differentiation (Danziger *et al.*, 1997; Inoue *et al.*, 2000; Hikiji *et al.*, 1997; Wimalawansa, 2008). On the other hand, iNOS induced excess production of NO can lead to osteoblast apoptosis (Damoulis and Hauschka, 1997; Wimalawansa, 2007).

iNOS is generally not thought to be expressed in unstimulated bone cells and bone tissues, and expression is generally associated with pathological conditions. Nevertheless, some researchers have reported the presence of low levels of iNOS transcripts in unstimulated whole bone and cultured osteoblast-like cells by RT-PCR (Hukkanen *et al.*, 1995, 1999; Riancho *et al.*, 1995; Helfrich *et al.*, 1997), and others have described low-level iNOS expression in untreated cultures of a human preosteoclastic cell line (Brandi *et al.*, 1995). There is also evidence to indicate that in some tissues including bone, iNOS is expressed transiently and likely to have a physiological function. Immunostaining for iNOS protein was seen in sections of neonatal bone, but not in older animals, and localized to both osteoblasts and osteoclasts, where it was compartmentalized toward the ruffled border. A role for iNOS in regulating osteoclast activity was also suggested on the basis of *in vivo* administration of NOS inhibitors (Kasten *et al.*, 1994) that was subsequently supported by additional studies (Tsukahara *et al.*, 1996; Turner *et al.*, 1997).

iNOS is expressed in bone during the neonatal period. Expression of iNOS in bone later in life is usually associated with inflammatory stimulus. The expression of iNOS mRNA and protein have been demonstrated in cultured rodent and human osteoblast-like cells after cytokine stimulation (Ralston *et al.*, 1994, 1995; Hukkanen *et al.*, 1995). The level of expression of iNOS by osteoblasts is also quantitative and correlates with the type and combination of cytokine stimuli (Damoulis and Hauschka, 1994).

In general, combinations of two or more cytokines are more potent than single cytokines in stimulating iNOS activity. The synergism between IFN-γ, TNF-α, and IL-1β is particularly effective for iNOS induction in osteoblasts (Hukkanen *et al.*, 1997). Moreover, rodent osteoblasts seem to be more responsive to cytokine-stimulated iNOS induction than human osteoblasts.

Cytokines and iNOS

The evidence for cytokine-stimulated iNOS expression by osteoclasts is less definitive. Some researchers have shown marked iNOS expression in rodent and avian osteoclastic cell lines and comparatively weaker expression in a human preosteoclastic cell line after cytokine stimulation *in vitro* (Brandi *et al.*, 1995; Hukkanen *et al.*, 1995, 1997). Others have described marked cytokine-induced iNOS expression in an avian osteoclastic cell line (Sunyer *et al.*, 1996). Conversely, some failed to detect iNOS by *in situ* hybridization or immunocytochemistry in osteoclast cultures even after cytokine stimulation (Helfrich *et al.*, 1997). The reasons for such differences are unclear, but there are corollaries with other cells of leukocyte lineage. Induction of iNOS expression can be readily achieved in rodent monocyte macrophages after cytokine challenge, and the response is often exaggerated, whereas induction of iNOS in human monocyte macrophages is much more tempered (Sakurai *et al.*, 1995). Data from author's laboratory indicate that stimulated osteoblast cells can mediate osteoclastic iNOS induction. Others have reported that NO stimulated cGMP production in osteoclasts (Dong *et al.*, 1999). However, iNOS-induced higher local expression of NO together with cytokines is thought to be responsible for osteoblast apoptosis (Jilka *et al.*, 1998).

Human cells are also responsive to combinations of cytokines that are distinct from those described for rodent cells. One possible explanation for these idiosyncrasies, other than differences between cell lines or differentiation status, might lie with the "distinctness" of the human iNOS gene, which shares only 80% homology with the rodent gene. This has added relevance considering that the constitutive NOS isoforms (eNOS and nNOS) are very highly conserved, with greater than 93% homology between rodent and human.

Other important sites of iNOS expression include the articular joint, where iNOS is expressed and localized to chondrocytes, and the synovium of arthritic but not in normal subjects (Sakurai *et al.*, 1995), again suggestive of cytokine-driven expression of iNOS in chondrocytes. NO also activates cyclooxygenase enzymes (Salvemini *et al.*, 1993). Collectively, these observations demonstrate that NOS isoforms, in particular eNOS and iNOS, are widely expressed in bone tissue. These observations are consistent with that involvement of NO in many aspects of embryonic bone growth, modeling, and remodeling under both physiological and pathophysiological conditions.

NOS Gene-Deficient Mice

Gene knockout mice represent powerful tools for studying possible functions and targets of regulatory factors involved in physiological and pathological processes. Murine gene knockouts have been created for all three isoforms of NOS (Huang *et al.*, 1993, 1995; MacMicking *et al.*, 1995; Wei *et al.*, 1995). In all cases the mutant mice were found to be viable, fertile, and identical in general appearance but not behavior, to their wild-type counterparts.

Mice deficient in nNOS were the first knockouts to be created and revealed that the nNOS gene-deficient mice are largely resistant to brain damage induced by vascular stokes (Huang *et al.*, 1993), confirming the importance of nNOS-derived NO in mediating traumatic brain injury and stroke damage. It is also apparent that nNOS knockout male mice are aggressive (Nelson *et al.*, 1995). The observations of iNOS gene-deficient mice were also in keeping with what might have been expected, corroborating the participation of iNOS in mediating inflammatory responses with iNOS gene-deficient mice demonstrating attenuated microbicidal and tumoricidal responses (MacMicking *et al.*, 1995; Wei *et al.*, 1995).

The findings from mice deficient in eNOS are also in accord with what might have been expected. These mice had an elevated blood pressure, and aortic rings isolated from these animals did not display a relaxation response when challenged with acetylcholine. This demonstrated the important role of eNOS-derived NO in mediating vascular homeostasis (Huang *et al.*, 1995). Nevertheless, induction of a hypotensive effect following administration of a NOS inhibitor has been shown to be reversed by infusion of excess L-arginine (Huang *et al.*, 1995). This suggests that blockers of NO synthesis might have independent effects on the vasculature or that other isoforms of NO synthase contribute to the maintenance of blood pressure. The prime candidate for this is nNOS, which is known to be present in the vasomotor centers of the central nervous system and hence may be involved in neuronal regulation of blood pressure and in nerves supplying blood vessels.

NOS-Deficient Mice as a Model

NOS gene-deficient mice represent somewhat useful models for studying the role of NO in bone metabolism, circumventing the lack of isoform specificity of the current generation of NOS inhibitors and providing a rigorous test of previous proposed actions of NO on bone. It is inevitable that after inactivation of a NOS gene, there will be compensation by over-expression of other two NOS genes, clouding the interpretation from these knockout mouse models. Moradi-Bidhendi, *et al.* demonstrated that male nNOS knockout mice have a marked reduction in urinary nitrate (Fig. 8). In addition, female nNOS knockout mice fail to respond to the stimulatory effect of estrogen based on urinary nitrate

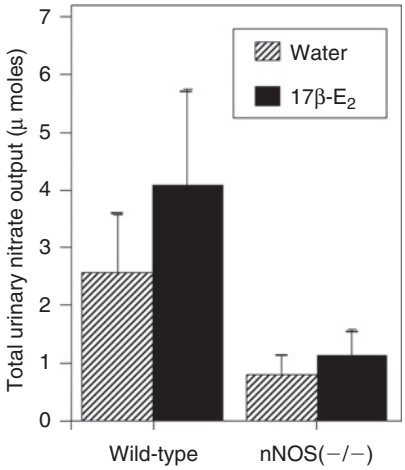

FIGURE 8 Marked difference of the total urinary nitrate output (mean) in c57/bI/6 wild-type mice versus nNOS null (–/–) knockout mice. nNOS(–/–) knockout mice showed a significantly lower nitrate output than wild-type controls. Animals were between 8 and 12 weeks of age and maintained on a low nitrate diet throughout the experiment. Values are mean±SEM, $n = 6$ ($^{**}p < 0.01$) using Student's t-test (Moradi-Bidhendi, Mancini, Forte, Cafferkey, Benjamin, and MacIntyre).

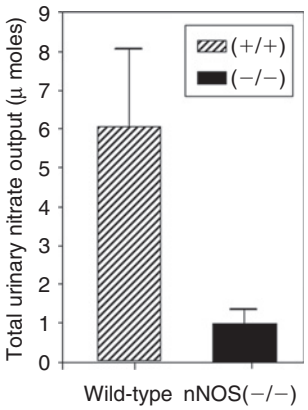

FIGURE 9 The mean urinary total nitrate output of c57/bI/6 wild-type and nNOS (–/–) knockout mice following administration of estrogen (administration of 10μg of 17/β-E_2), or placebo. Control c57/b1/6 mice showed a significant increase in urinary nitrate output in comparison to nNOS knockout mice, while there were change in the nNOS (–/–) mice. Animals were between 8 and 12 weeks of age and maintained on a low-nitrate diet throughout the experiment. Values are mean±SEM, $n = 6$ ($^{**}p < 0.01$) using Student's t-test.

measurements (Fig. 9). Interestingly, male eNOS knockouts have urinary nitrate outputs similar to wild-type controls, and females respond normally to estrogen with a cyclic increase in urinary nitrate excretion. These findings imply that nNOS is mainly responsible for urinary nitrate and that nNOS is stimulated by estrogen, thus explaining the normal increase in nitrate after administration of estrogen to eNOS knockouts. Further, it is conceivable that the aggressive behavior of nNOS knockouts resembles the effect of estrogen deficiency on cerebral nNOS.

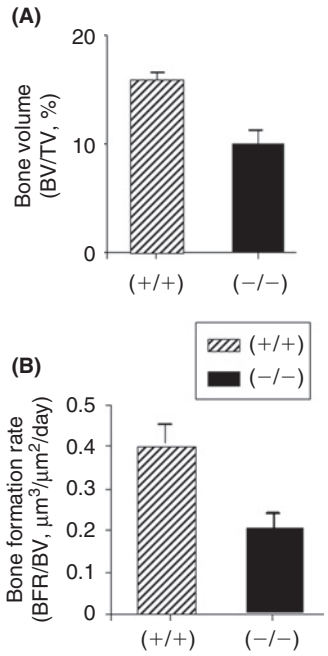

FIGURE 10 Histomorphometry analysis of femurs from 6-week-old eNOS gene knockout mice and age-matched wild types. Both bone formation rate and bone volume are significant reduced in eNOS knockouts. Values are mean±SEM, $n = 7$ ($^{*}p < 0.05$; $^{**}p < 0.01$).

eNOS knockout mice are viable and fertile, and in terms of gross physical appearance (stature, gait, and anatomy) are unremarkable, but aggressive behavior has been reported (Demas *et al.*, 1999). However, closer examination of the long bones demonstrated that both the femur and the tibia of eNOS knockouts were significantly shorter (1 to 2 mm) than the corresponding wild-type. Histomorphometry analysis of the same bones showed a marked reduction in bone formation rate as well as bone volume (Fig. 10). eNOS activity is likely to be required for the maintenance of physiological bone mass (Aguirre *et al.*, 2001; Armour *et al.*, 2001).

Interestingly, the consequences of eNOS gene deficiency were most pronounced in young (6- to 9-week-old) adults, and by 12 to 18 weeks bone phenotype was restored toward wild type. Regardless of eNOS expression, bone turnover was significantly higher in young mice than old mice, and similar observations have been made on rats and humans, demonstrating that bone modeling/remodeling activity is related to sexual maturity. Moreover, we have shown that eNOS expression correlates with skeletal development and is most abundant in the bones of neonates and young adults, decreasing markedly in older animals (Hukkanen *et al.*, 1999).

These data suggest that eNOS expression and activity is important during phases of rapid bone growth or turnover, such as in the period from neonate through to sexually mature adult and the attainment of peak bone mass. eNOS gene deficiency does not represent a severe or irreversible impediment

to skeletal growth. Upregulation of eNOS activity is important in mechanical load-induced bone growth (Pitsillides *et al.*, 1995; Turner *et al.*, 1996; Klein-Nulend *et al.*, 1995; Zaman *et al.*, 1999) and fracture healing (Corbett *et al.*, 1999a, , 1999b; Diwan *et al.*, 2000). Thus, eNOS knockout mice are likely to exhibit defective or protracted bone repair mechanisms following traumatic injury. NO also seems to involved in control of expression of tartrate-resistant acid phosphatase (TRAP). Inhibition of osteoclast acid phosphatase markedly decrease bone resorption (Zaidi *et al.*, 1989). Overexpression of TRAP is associated with increased bone turnover (Angel *et al.*, 2000), and TRAP-deficient mice have an osteopetrotic phenotype (Hayman *et al.*, 1996).

Bone Cell Biology of NOS Gene Knockout Mice

Osteoblasts from eNOS knockouts, unlike wild-type cultures, were unresponsive to the mitogenic effects of estradiol over a range of concentrations, providing further evidence that the eNOS-NO signaling pathway is important in mediating the osteogenic actions of estrogen (O'Shaughnessy *et al.*, 2000). Moreover, these cells demonstrated an attenuated chemotaxis response and failed to migrate along a TGF-β gradient (Aguirre *et al.*, 2001)—the latter is a potent cytokine in recruiting osteoblasts to remodeling sites (Pfeilschifter *et al.*, 1990). Taken together, these data illustrate that distinct components of the osteoblast phase of the bone remodeling cycle are altered in eNOS knockout mice, strongly implicating NO-dependent signaling via eNOS in the regulation of osteoblast growth, differentiation, recruitment, and extracellular matrix synthesis. Studies by Armour and coworkers (Armour *et al.*, 2001) also showed that ovariectomized eNOS knockout mice have a significantly diminished anabolic response to high doses of exogenous estrogen.

There is evidence that bone vasculature can modify bone formation through intraosseous pressure (Kelly and Bronk, 1990) and factors released from endothelial cells including NO can modulate bone cell function (Collin-Osdoby, 1994). The potential impact of the persistent hypertension associated with eNOS gene deficiency (Huang *et al.*, 1995) on bone turnover needs to be thoroughly evaluated.

Studies *in vitro* and *in vivo* using iNOS gene knockout mice (van't Hof *et al.*, 2000) demonstrated that IL-1-induced NO production by iNOS was important for promoting osteoclast formation and activity. Moreover, osteoblast-bone marrow cocultures revealed that osteoblasts were the principal source of NO regulating osteoclast activity, particularly in osteoclast precursors, and was dependent on NFκB translocation and DNA binding. Importantly, the defects in IL-1-induced bone resorption could be reversed by exogenous supply of the NO donor SNAP (van't Hof *et al.*, 2000). Initial studies on iNOS knockouts have revealed marked reductions in bone formation and volume similar to the abnormalities described in eNOS knockouts (Aguirre *et al.*, 2001). However, the underlying mechanism is distinct and appears to relate to increased osteoclast number and activity and support the NOS inhibitor (iNOS; Kasten *et al.*, 1994; Tsukahara *et al.*, 1996; Turner *et al.*, 1997). iNOS knockout mice have a three- to fourfold compensatory increase in eNOS mRNA expression in whole bone preparations. Such a phenomenon is expected and is not unusual in NOS gene knockouts (Huang and Fishman, 1996).

NO Donor Compounds and Osteoporosis

Unlike some other disease entities, osteoporosis can be easily diagnosed and treated. Because osteoporosis leads to fracture, the keys to preventing fractures are early detection of the disease by measuring bone mineral density (BMD), a bone-healthy lifestyle, avoiding medications that contribute to bone loss, elimination of secondary causes of bone loss, prevention of falls and injuries, and effective use of antiosteoporotic agents (Wimalawansa *et al.*, 1997).

In the past, many postmenopausal women relied on HRT after menopause to reduce the risk of heart disease and osteoporosis fractures. However, the Women's Health Initiative (WHI) study confirmed that although it is highly effective in preventing fractures, HRT could also slightly increase the risk of stroke, heart disease, and breast cancer in some patients. Another barrier to HRT treatment is the high cost, breakthrough bleeding, and breast tenderness, especially in older women. Thus, finding a cost-effective alternative therapy for osteoporosis with few or no adverse effects would be very useful. One such exciting opportunity is to use NO donor therapy such as nitroglycerine; the original postulation of the role of NO in bone was demonstrated in 1987 (Fig. 11; Wimalawansa, 1988).

Role of Nitric Oxide in Bone Metabolism

During the past decade, significant advances have been made in understanding cellular mechanisms involved in bone metabolism leading to identification of novel therapeutic agents. These include those with antiresorptive (also known as anticatabolic) and anabolic agents. However, it is essential to consider multiple interactions of these chemical entities *in vivo* for proper understanding as well as to develop new therapeutic agents. Key interactions between cytokines, hormones, and NO in bone are illustrated in Fig. 12.

Nitric oxide has been shown to regulate osteoclasts (Dong *et al.*, 1999; Inoue *et al.*, 1995), cells responsible for bone resorption that belong to the monocyte lineage. Bone formation and resorption are key processes in the constant remodeling that occurs in bone tissue in order to keep it healthy and to repair bone microdamage. Uniquely, the NO donor nitroglycerine has a beneficial effect on controlling

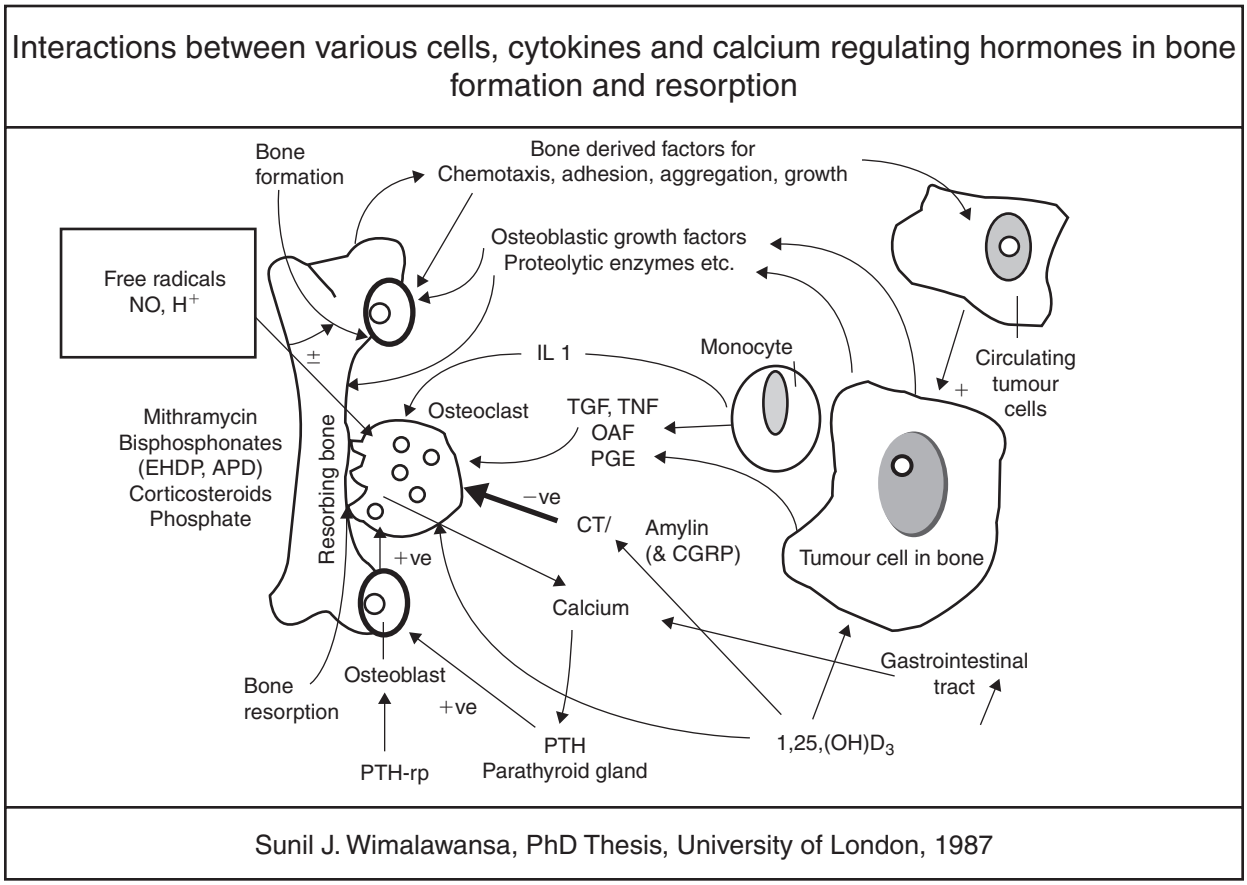

FIGURE 11 First postulation of involvement of NO in bone metabolism (Wimalawansa, 1988). NO = nitric oxide; PTH = Parathormone, PTH-rp = PTH related peptide; CT = calcitonin; PGE = Prostaglandin; CGRP = calcitonin gene-related peptide; D_3 = vitamin D; IL = interleukin; OAF = osteoclast activating factors.

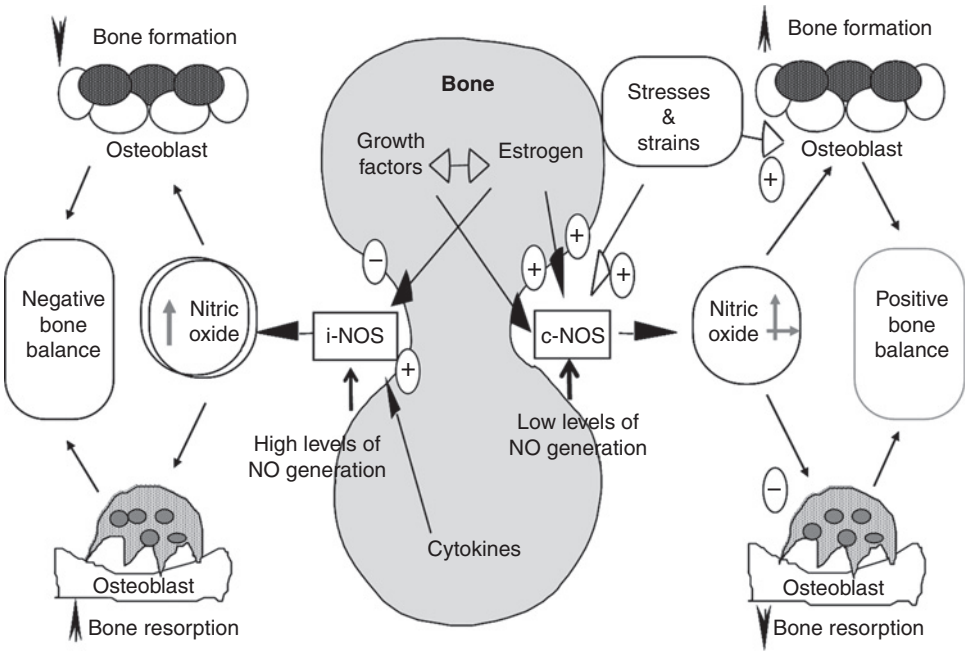

FIGURE 12 Key interactions between sex-steroid hormones, cytokines, and growth factors generating nitric oxide (NO) via iNO and c-NOS, and their effects on osteoblasts and osteoclasts (Wimalawansa, 2007).

bone resorption (decreased osteoclastic activity), while also having positive effects on bone formation (enhanced osteoblastic activity; Wimalawansa, 2007, 2008). For postmenopausal women who cannot tolerate or afford HRT treatment, nitroglycerine therapy may become an affordable and cost-effective option in the future (Wimalawansa, 2007).

Furthermore, supplementary studies demonstrated that nitroglycerine has beneficial additive effects on BMD when coadministered with some agents including vitamin D, calcitonin and bisphosphonates (Wimalawansa, 2008; D. Wimalawansa *et al.*, 2008). However, because the mechanism of action of these agents in bone cells is different from that of NO, it is not surprising that there is an added beneficial effect when any one of these agents are coadministered with a NO donor on the BMD. For example, the effects of statins on BMD reported to be additive to those of the bisphosphonate agent risedronate when these two agents are coadministered (Tanriverdi *et al.*, 2005). It appears that NO donors have the potential to treat bone loss and fragility in women (Wimalawansa *et al.*, 1996). Taken together, these data suggest that long-term therapy with NO will not only increase BMD (prevention of osteoporosis), but also likely decrease fracture rates (treatment of osteoporosis). Because the final common pathway of actions of sex-steroid hormones, in particular estrogen, and statins (Garrett *et al.*, 2001), as well as essential fatty acids, seems to be mediated via NO at least in bone cells, no such additive effect is expected. *In vitro* and *in vivo* animal data suggest positive effects of bone cell metabolism of estrogens and statins as well as essential fatty acids. Fig. 13 illustrates the postulated final common pathway of these quite different compounds on bone metabolism.

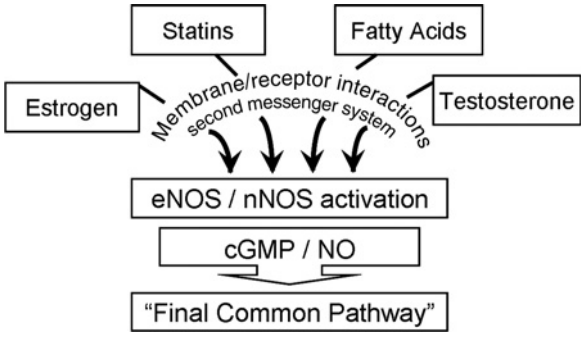

FIGURE 13 Proposed interactions and final common pathway of sex-steroid hormones, free fatty acids, and statins in bone (Wimalawansa, 2008).

Osteoclast Effects

Osteoclasts express both eNOS and iNOS (Brandi *et al.*, 1995; Sunyer *et al.*, 1996; Helfrich *et al.*, 1997; Fox and Chow, 1998; MacPherson *et al.*, 1999), and accordingly, these cells demonstrate sensitivity to low physiological levels of basal NO synthesis generated via eNOS and nNOS, as well as with higher levels of NO synthesis via iNOS following stimulation by cytokines (Evans and Ralston, 1996). The effects of NO on osteoclasts are also biphasic; NO can either suppress or stimulate osteoclast-mediated bone resorption (see Fig. 12).

Some researchers have demonstrated that exposure of cultured osteoclasts to NO-donor compounds inhibit cell spreading and caused profound inhibition of bone resorption measured by the bone slice assay (Brandi *et al.*, 1995; MacIntyre *et al.*, 1991). Although the concentrations of NO used were supraphysiological, these findings have subsequently been confirmed by several additional *in vitro* and *in vivo* studies. Chronic *in vivo* administration of the NOS inhibitor compounds in rats, in particular aminoguanidine, was accompanied by marked reductions in bone mass (Kasten *et al.*, 1994; Tsukahara *et al.*, 1996; Turner *et al.*, 1997). These data suggest that NO is an endogenous inhibitor of osteoclast activity, and hence they are consistent with the profound inhibitory effect of NO donors on osteoclastic bone resorption (Wimalawansa, 1988; MacIntyre *et al.*, 1991; Kasten *et al.*, 1994). These findings will have profound impact not only on our understanding bone cell biology, but also on future drug developments. Figure 14 demonstrate the effects of low and high doses of NO donors on osteoclast-mediated pit formation on bone slices in compression compared to osteoclasts cultured in control medium.

However, the reported selectivity of aminoguanidine for iNOS and the apparent absence of any significant effects following administration of other nonselective NOS inhibitors has led to the somewhat misleading suggestion that iNOS is the principal source of NO in the regulation of bone cells. Another potentially incorrect conclusion was made based on NOS inhibitor studies that iNOS might be expressed constitutively in bone. Some researchers have failed to elicit expression of iNOS in bone cells (Riancho *et al.*, 1995; Hukkanen *et al.*, 1995), which is against the inference just mentioned, but is consistent with studies demonstrating low-level expression of iNOS transcripts in unstimulated whole bone preparations and in bone cell cultures (Brandi *et al.*, 1995; Helfrich *et al.*, 1997).

Interactions of NO and Cytokines with Osteoclasts

Cytokines including IL-1β, TNF-α, and IFN-γ are powerful regulators of bone resorption (Mundy, 1993) and also are potent stimulators of iNOS (Ganster and Geller, 2000). It has been shown that cytokine-induced iNOS activity exerts marked effects on osteoclastic bone resorption (Lowik *et al.*, 1994; Brandi *et al.*, 1995; Riancho *et al.*, 1995; Ralston and Grabowski, 1996). Apparently, cytokine-induced NO synthesis can either stimulate or inhibit osteoclastic bone resorption and correlates with the apparent level of iNOS induction or activation (Ralston and

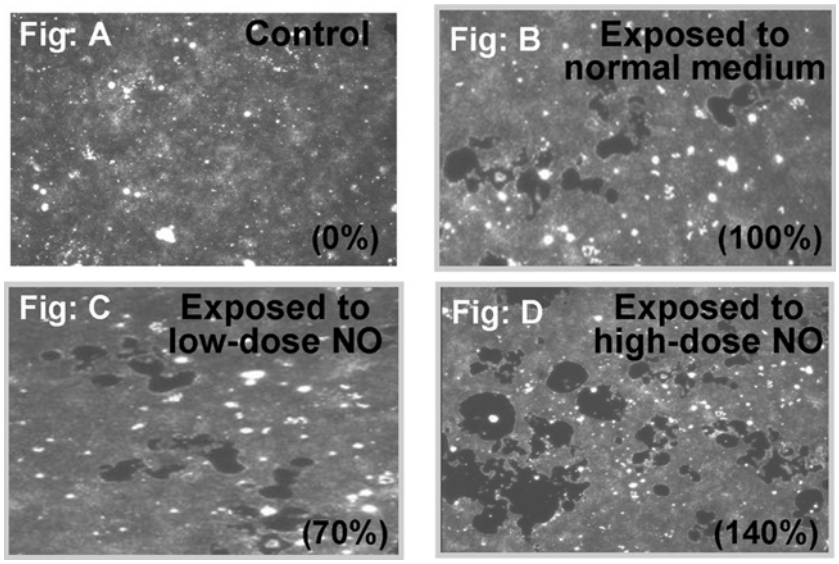

FIGURE 14 Bone slice-pit-resorption assay demonstrating the effects of adding low and high doses of NO donors to culture medium in comparison with a control (Wimalawansa, unpublished).

Grabowski, 1996). However, when added singly, these cytokines produce very different results. IL-1β and TNF-α exert a more modest inductive effect on iNOS expression and activity, and this is manifest by inhibition of the pro-resorptive effects of these cytokines by NOS inhibitors (Lowik *et al.*, 1994; Ralston *et al.*, 1995). These studies also demonstrated synergism between NO and prostaglandin E_2, another important regulator of bone resorption (Ralston *et al.*, 1995; Hukkanen *et al.*, 1999). This is consistent with recent observations on bone marrow cocultures from iNOS-gene-deficient mice, revealing that iNOS is essential for mediating the bone-resorptive effects of IL-1β (van't Hof *et al.*, 2000). IL-1β induced bone resorption as well as osteoclastic apoptosis is thought to be NO-dependent (perhaps in a dose-dependent fashion; van't Hof and Ralston, 1997; van't Hof *et al.*, 2000).

Expression of eNOS and the activity of this constitutive enzyme have been suggested to be associated with stimulating bone resorption (Brandi *et al.*, 1995; Ralston *et al.*, 1995). Supporting evidence was reported with the administration of a general NOS inhibitor to untreated neonatal rodent osteoclasts blocking resorption, suggesting that tonic release of NO or moderate induction of NO synthesis is an important facet of osteoclast resorptive function. Nevertheless, it is unlikely that this is the case; in fact, constitutive production of NO via eNOS (and nNOS) together with osteoprotegerin seems to be the key protective mechanism keeping excess osteoclastic activity under control (Wimalawansa, 2007). Furthermore, *in vivo* NOS inhibitors have shown to suppress adjuvant arthritis (Stefanovic-Racic *et al.*, 1993, 1994).

Although it is clear that NO has a key role in the regulation of osteoclastic bone resorption, the cellular source(s) that contribute to this process are still controversial. There is evidence to show that preosteoclastic and osteoclast cell lines have a low basal NO synthesis (Brandi *et al.*, 1995), which can be further stimulated by fluid shear stress (McAllister *et al.*, 2000). In response to cytokine stimulation, iNOS expression is induced in avian, rodent, and human osteoclastic cell lines (Brandi *et al.*, 1995; Sunyer *et al.*, 1996) and is accompanied by marked elevation in NO synthesis, as suggested by nitrite accumulation (Sunyer *et al.*, 1996). Such data would be consistent with an autocrine role for NO in osteoclast function. However, other investigators have argued against this after failing to detect appreciable levels of iNOS expression in osteoclasts even after cytokine stimulation (Helfrich *et al.*, 1997). Moreover, this same group of investigators have implicated the osteoblast as being the predominant source of inducible NO affecting osteoclast activity based on bone organ culture or osteoblast bone marrow coculture experiments (van't Hof and Ralston, 1997; van't Hof *et al.*, 2000).

Mechanisms of Action of NO in Osteoclasts

The mechanisms of action of NO on osteoclasts are quite varied and also dependent on the stage of cell development. Exposure to high levels of NO associated with iNOS activation is known to induce damage and death in a number of cell types. Consistent with this, cytokine-stimulated NO synthesis (i.e., high NO levels) initially will enhance activity of osteoclast, but later diminishes proliferation of preosteoclasts (Brandi *et al.*, 1995) and may involve induction of apoptotic cell death (van't Hof and Ralston, 1997). Although suggestive, the data are not convincing that osteoblasts are more resistant to NO-induced apoptosis in

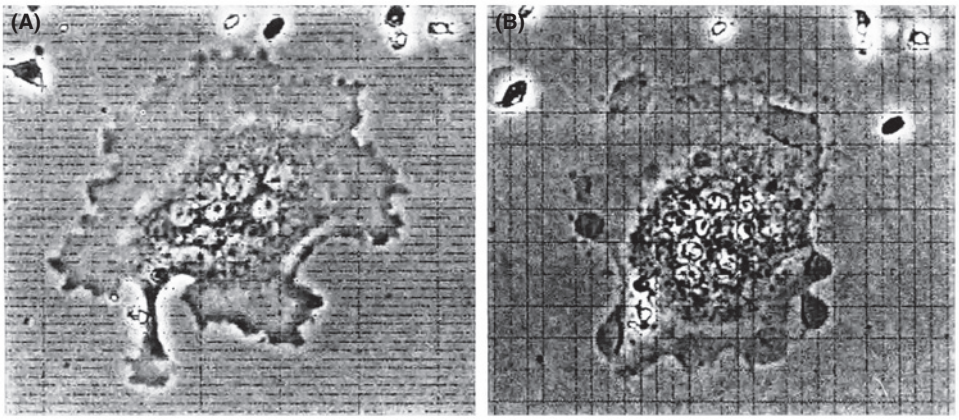

FIGURE 15 Video-microscope image of a primary rat osteoclast. **(A)** A typical rat osteoclast showing large cytoplasmic area and numerous nuclei. **(B)** The same cell after addition of a nitric oxide donor showing reduced cell area (MacIntyre, 2000).

comparison to osteoclasts (van't Hof and Ralston, 1997). In fact, data from author's laboratory suggest exactly the opposite. The upshot of this is that very high levels of NO *in vitro* may cause a reduction in the formation of mature osteoclasts and suppression of bone resorption. However, at higher levels of NO, virtually none of the osteoclasts or osteoblasts will survive. Finally, it is doubtful that such high levels of NO will ever be achieved *in vivo*, and this seems to be an *in vitro* pharmacologic artifact.

In mature osteoclasts NO has been shown to both stimulate and inhibit activity: a bidirectional effect (Brandi *et al.*, 1995) related to changes in the local concentration of NO. Exposure of mature osteoclasts to NO stimulates contraction and causes the cells to become detached from the underlying bone surface (MacIntyre *et al.*, 1991; Brandi *et al.*, 1995). This effect is illustrated in isolated rat osteoclasts (Fig. 15). The contraction of isolated osteoclasts is induced by fluxes in calcium ion concentration and appears to be mediated by a calcium-sensitive isoform, eNOS, because NOS inhibitors largely prevent the calcium-induced osteoclastic contraction (Brandi *et al.*, 1995). It is now known that this action of nitric oxide is largely mediated by cGMP (Wimalawansa, 2008), although this was not apparent in initial studies using slowly permeable cGMP analogues such as 8-bromo- or dibutyryl-cGMP (MacIntyre *et al.*, 1991). However, in more recent studies using rapidly permeable cGMP analogues, 8-pCPT-cGMP has been shown to produce a dramatic and rapid osteoclast contraction. This is also seen after exposure to NO donors and is largely, although not entirely, prevented by guanylate cyclase inhibitors (Mancini *et al.*, 1998). The calcium-stimulated effect of NO is highly likely to be physiological, and during osteoclastic bone resorption, in which periodic calcium-induced detachment occurs, this contracting and detaching effect likely forms an essential part of osteoclastic bone resorption and also is involved in osteoclast movement on bone surface.

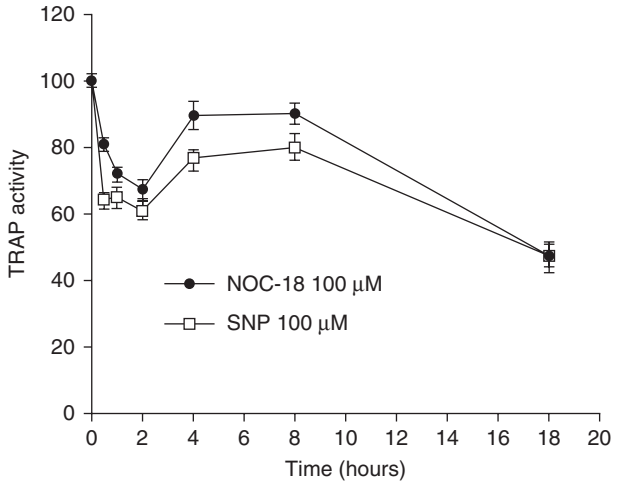

FIGURE 16 Effect of NO donors on human type 5 acid phosphatase activity. The two NO donors, SIN-1 and NOC-18, used in this experiment are both able to decrease TRAP activity over time, with a maximum reduction observed after 18 hours. Values are the mean of three different experiments and are expressed as percentage of control (Mancini L, Cox T, MacIntyre I).

NO inhibits the activity of recombinant tartrate-resistant acid phosphatase (Fig. 16), and this effect might contribute to the inhibitory action of NO on osteoclastic bone resorption. TRAP is mainly localized in resorption vacuoles, suggesting that it is secreted by the osteoclasts at the site of active resorption, although the mechanism by which it promotes bone resorption is still unclear. However, it is established that inhibition of acid phosphatase by chemical and immunological means can abolish osteoclastic bone resorption (Zaidi *et al.*, 1989). Further, acid phosphatase knockout mice have mild osteopetrotic phenotype, whereas genetically engineered mice overexpressing acid phosphatase have an increased bone turnover (Hayman *et al.*, 1996; Angel *et al.*, 2000). Thus, acid phosphatase seems to be important for bone resorption and osteoclast

activity and the finding that NO can inhibit TRAP activity, possibly by binding to the iron moiety of the protein; this could account for some of the inhibitory actions of NO on osteoclastic bone resorption.

Osteoblast and Osteocyte Effects

Synthesis of NO by cells of the osteoblast lineage came from studies in responses of these cells to cytokine stimulation. Several groups independently demonstrated induction of iNOS mRNA and protein expression in cultures of both rodent and human primary osteoblasts and osteoblast cell lines after cytokine challenge (Damoulis and Hauschka, 1994; Lowik *et al.*, 1994; Ralston *et al.*, 1994; Hukkanen *et al.*, 1995; Riancho *et al.*, 1995). Activity of iNOS and synthesis of NO by these cells was confirmed by marked increases in the accumulation of nitrite, one of the oxidation products of NO biosynthesis, in the culture medium. Furthermore, these studies revealed a rank order of potency for induction of iNOS by cytokines.

By including inhibitors of NOS activity in the culture medium during or after cytokine-induced NO production, it has been possible to examine the effects of NO on osteoblast function. However, the blanket conclusions that NO causes profound inhibition of cell proliferation and DNA synthesis (Ralston *et al.*, 1995; Hukkanen *et al.*, 1995; Evans and Ralston, 1996) and osteoblast cell apoptosis (Damoulis and Hauschka, 1997; Jilka *et al.*, 1998) may not be correct. One cannot conclude from any of these experiments that NO causes osteoblastic suppression, whereas NOS inhibitors as well as very high levels of NO produced following cytokine stimulation can accomplish both.

Because of the higher levels of NO generated, cytokine-induced NO synthesis by iNOS leads to reductions in the expression and activity of osteoblast differentiation as suggested by the decrease in osteoblastic markers alkaline phosphatase and osteocalcin (Ralston *et al.*, 1995; Hukkanen *et al.*, 1995), as well as formation of mineralized bone nodules (Buttery, Hughes and Hukkanen, unpublished observations; Fig. 17). NO donors also have been demonstrated to stimulate expression of cyclooxygenase 2 and prostaglandin (PGE_2) synthesis; this might be relevant to osteoblastic control of osteoblast-mediated bone resorption (Hughes *et al.*, 1999).

There are also some physiological processes that are stimulated by osteoblast/osteocyte constitutive NO synthesis by eNOS. Some have demonstrated basal, constitutive NO synthesis by osteoblasts, which promoted cell proliferation and could be augmented by 1,25-dihydroxy vitamin D_3 (Riancho *et al.*, 1995). NOS inhibitors also blocked the new bone formation induced by mechanical strain in rodent models (Fox *et al.*, 1996; Turner *et al.*, 1996). Furthermore, osteocytes and osteoblasts rapidly produce NO when exposed to mechanical strain or pulsatile fluid flow *in vitro* (Pitsillides *et al.*, 1995; Klein-Nulend *et al.*, 1995; Turner *et al.*, 1996), and this is now known to be dependent on the expression and activation of eNOS (Klein-Nulend *et al.*, 1998; Zaman *et al.*, 1999). This again confirmed that eNOS activation is physiological and indeed beneficial for the skeletal system.

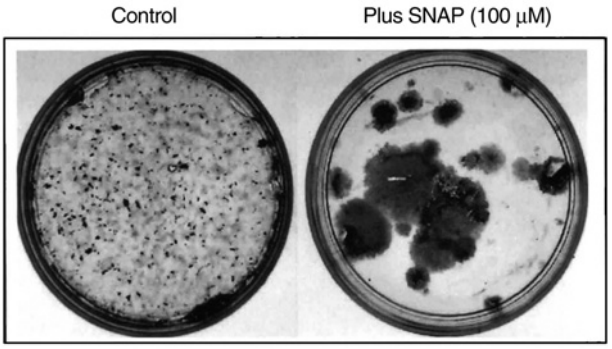

FIGURE 17 Effects of exogenous NO on rat osteoblast differentiation and formation of mineralized bone nodules. Exposure to SNAP (12 hours) at the time of cell seeding severely inhibited subsequent cell growth and differentiation (MacIntyre, 2000).

Such a role for eNOS in sensing and responding to mechanical loading or shear flow is consistent with the regulation of this enzyme (Kleinert *et al.*, 2000). More recently, McAllister and Frangos (1999) have examined the kinetics of NO release from osteoblasts exposed to both steady and transient fluid shear stress. The results demonstrated two distinct biochemical pathways with transient flow stimulating a burst of NO that was dependent on G-protein activation and calcium mobilization, whereas steady flow produced sustained NO release that was G-protein- and calcium-independent. Such studies are important because they not only confirm the involvement NO in transduction of osteogenic signals, but also provide an insight into how perturbations in this signaling pathway might contribute to bone physiology and pathology. There are ample *in vitro* (Danziger *et al.*, 1997) and *in vivo* animal data (Wimalawansa, 2000c, 2008; Wimalawansa *et al.*, 1996) as well as human data (Wimalawansa *et al.*, 2000a; Wimalawansa, 2007) to support a key role of NO in bone metabolism.

Estrogen and NO

NO generated by cells of the osteoblast lineage is important in mediating the anabolic effects of estrogen on bone (Wimalawansa *et al.*, 1996). Although the major effect of estrogen has been thought to be its ability to inhibit osteoclastic bone resorption, estrogen has also been shown to have a direct effect on osteoblast-like cells (Ernst *et al.*, 1989). The presence of functional estrogen receptors in cells of the osteoblast lineage (Eriksen *et al.*, 1988; Komm *et al.*, 1988) suggests that estrogen compounds such as

17β-estradiol (E_2) stimulate bone formation *in vivo* by a direct action on osteoblasts (Chow *et al.*, 1992a, 1992b; Tanko-Yamamoto and Rodan, 1990; Samuels *et al.*, 1999). Indeed, this independent anabolic effect of estrogen on osteoblast cells is one of the possible explanations of the additive effects on BMD observed when two classical anti-resorptive agents (e.g., estrogen and bisphosphonate) are administered to postmenopausal women (Wimalawansa, 1995, 1998). Estrogen enhances bone cell eNOS and nNOS activity, acting via estrogen alpha receptor in bone cells (Bonnelye and Aubin, 2005), while NO directly regulates bone metabolism (Chae *et al.*, 1997; Hikiji *et al.*, 1997).

Studies *in vitro* have shown that 17β-estradiol enhances both proliferation and differentiation of cultured osteoblasts (Qu *et al.*, 1998; Ernst *et al.*, 1988; Scheven *et al.*, 1992). Although a link between estrogen and stimulation of eNOS had been established in the vascular system (Hayashi *et al.*, 1995; Weiner *et al.*, 1994), the first studies to demonstrate a link between the osteogenic effects of estrogen and NO in bone were those of Wimalawansa and coworkers (Wimalawansa *et al.*, 1996). They demonstrated that the NO donor compound nitroglycerin, long used in the treatment of ischemic heart disease, could prevent and also reverse the bone loss induced by ovariectomy in a rat model (Wimalawansa *et al.*, 1996; Wimalawansa, 2000c).

The results of subsequent studies demonstrated upregulation of eNOS expression and activity in a human osteoblast cell line after stimulation by 17β-estradiol (Armour and Ralston, 1998). 17β-Estradiol dose-dependently stimulated osteoblast (primary human and rat osteoblast cultures) proliferation and differentiation as assessed by alkaline phosphatase activity and bone nodule formation (Hayashi *et al.*, 1995; O'Shaughnessy *et al.*, 2000; Fig. 18), and in particular the trabecular bone (Tanko-Yamamoto and Rodan, 1990). This is abolished in the presence of inhibitors of NOS.

Additionally, 17β-estradiol increased total eNOS enzyme expression in rat osteoblasts and stimulated increases in NO metabolite levels (Fig. 19); once again this could be abolished by NOS inhibitors. A final and important finding from these studies is the lack of response to 17β-estradiol in animals treated with NOS blockers (Wimalawansa *et al.*, 1996; Wimalawansa, 2000c) and in primary osteoblasts cultures from eNOS gene knockout mice. Collectively these observations suggest that the stimulatory effect of estrogen on osteoblast proliferation and differentiation relies on local production of NO by bone cells via the eNOS (and nNOS) isoforms (Wimalawansa, 2007).

Estrogen has immunomodulating as well as anti-inflammatory actions. Following natural menopause and after oophorectomy, serum IL-1, IL-6, IL-8, TNF-α, and GM-CSF levels increase (Pacifici *et al.*, 1991), while TGF-β level increase in bone (Finkelman *et al.*, 1992). Estrogen replacement therapy reverses these cytokine levels (Fig. 20).

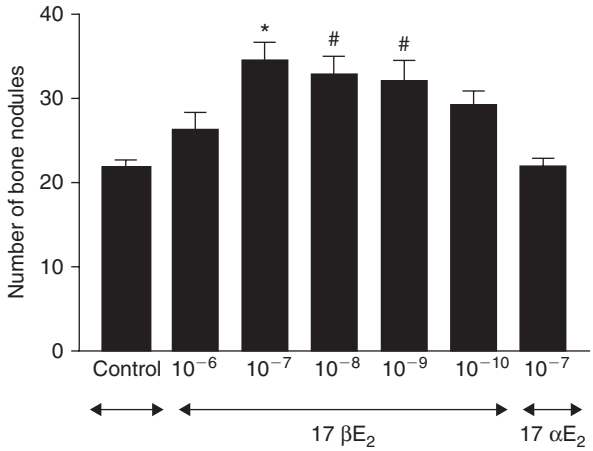

FIGURE 18 Quantitative assessment of rat osteoblast differentiation by *in vitro* formation of mineralized bone nodules. 17β-Estradiol has a dose-dependent effect on rat osteoblast differentiation. α-Estradiol did not have any effects on osteoblast differentiation (negative control). Values are means$\pm$SEM of six different experiments (**$p < 0.001$; *$p < 0.01$).

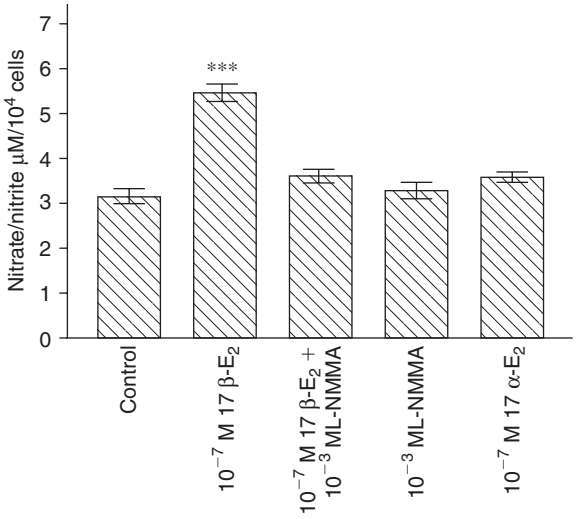

FIGURE 19 Analysis of NOS activity in osteoblasts by nitrite accumulation. Estradiol stimulates eNOS activity, which was blocked by the addition of the NOS inhibitor l-NMMA. Values are means$\pm$SEM of six different experiments (***$p < 0.01$ versus control).

Estrogen is known to increase TGF-β and stimulate eNOS and nNOS isoenzymes (Finkelman *et al.*, 1992; Ascroft *et al.*, 1997). This is in contrast to glucocorticoids that suppress the production of TNF-α as well as many other proinflammatory cytokines but do not prevent bone loss and, in fact, worsen bone loss. These data suggest that in addition to the production and suppressions of these cytokines, other second messengers must be involved *in vivo*. We proposed that NO is one such candidate for this (see Figs. 12 and 13).

Similar results to those just described are also seen after exogenous administration of NO donor compounds to osteoblast cultures. NO donors increase cGMP production,

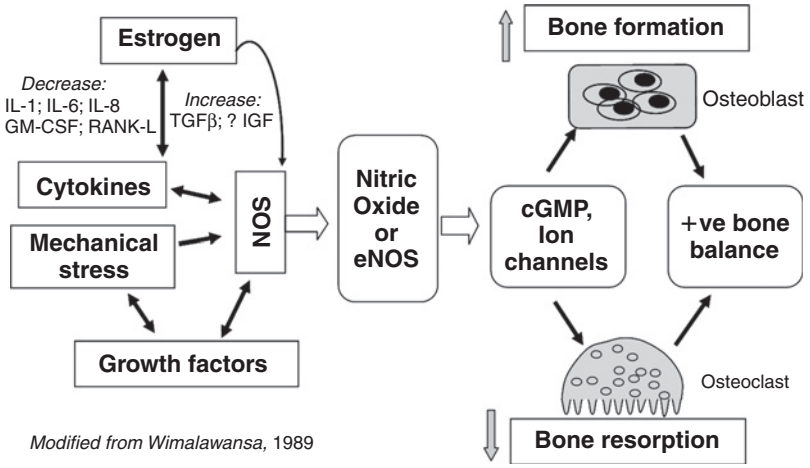

FIGURE 20 Schematic representation of interactions between estrogen, cytokines mechanical stress and growth factors on NO generation from eNOS/nNOS (physiological levels) and iNOS (pathological levels of NO); and their effects on skeletal homeostasis (Wimalawansa, 2007).

alkaline phosphatase activity, osteocalcin expression, and *in vitro* bone nodule formation (Chae *et al.*, 1997; Hikiji *et al.*, 1997; Otsuka *et al.*, 1998). Many researchers have found that whereas slow release and generation of low concentrations of NO stimulated osteoblast replication and alkaline phosphatase activity, rapid release and high concentrations of NO inhibited proliferation and induced apoptosis (Mancini *et al.*, 2000; Wimalawansa, 2007). These observations help to emphasize a fundamental aspect of the biological chemistry of NO, showing that alterations in the kinetics of NO synthesis, perhaps differential regulation of eNOS versus iNOS activity, can evoke profoundly different biological responses. These studies also demonstrated that the biphasic effects of NO on osteoblasts are mediated by the second messenger cGMP (Mancini *et al.*, 2000; Wimalawansa, 2007).

Interestingly, an estrogen-induced antioxidant effect is also due to suppression of superoxide anion production via release of NO (Arnal *et al.*, 1996). Estrogen indeed increases synthesis of eNOS (Thompson *et al.*, 2000; Hernandez *et al.*, 2000; Guetta *et al.*, 1997). Statins also activate protein kinase Akt, leading to an increased NO production by eNOS (Kureishi *et al.*, 2000). Furthermore, essential fatty acids and their metabolism enhance eNOS activity (see Fig. 13). Therefore the mechanism of all three of the compounds, estrogen, statins, and essential fatty acids, in improving skeletal health is likely to be mediated by augmenting eNOS activity. This is further supported by the fact that raloxifene, a selective estrogen receptor modulator (SERM), is also shown to dose-dependently increase the release of NO from endothelial cells (Simoncini and Genazzani, 2000). The data further support that eNOS activation and NO release from endothelial cells, osteoblasts, and osteocytes tonically inhibits osteoclastic activity. Unlike estrogen and NO donors, nitroglycerine and statins may have different paths of action on osteoblasts. So, the combination of these two agents at least in theory could have an added benefit on the skeleton.

Results confirm that NO is generated by osteoblasts via eNOS and iNOS and has an important role in osteoblast as well as osteoclast function. As a general rule of thumb, transient low-level production of NO regulated by eNOS is associated with stimulation of osteoblast activity and bone formation (see Fig. 20). whereas more sustained or high-output NO synthesis associated with iNOS expression and activity inhibits osteoblast function. The latter can lead to bone loss.

Bone tissue including bone marrow contains an abundance of endothelial cells that are capable of inducing eNOS activity. Similarly, some of the nerve terminals also contain nNOS. Many of these lie in proximity to osteoblasts and osteoclasts and so can influence their activity. Because of the sheer numbers of endothelial cells present in bone, it is conceivable that eNOS activity generated from these cells will have a constant homeostatic influence on bone cells.

The effects of NO on osteoblasts and osteoclasts are dependent on the local concentration of NO, and hence the level of stimulation of eNOS/nNOS and the iNOS. Therefore, we hypothesized that if these physiological amounts of NO can be delivered to bone cells via the bloodstream using NO donor therapies, the beneficial effects of NO on bone should be possible to obtain. Our data suggests that at low (physiological) concentrations, NO promotes osteoblast cell proliferation and activity and decreases bone-resorbing activity by osteoclasts. However, at higher concentrations (e.g., proinflammatory cytokine-induced iNOS stimulation and generation of higher levels of NO), NO enhances bone resorption and suppresses osteoblast activities (Wimalawansa, 2007).

NO Donors

NO donors can be used to characterize NO-mediated effects and provide a means of supplying "controlled" levels of NO from an exogenous source to mimic endogenous NO synthesis in *in vitro* or *in vivo* biological systems. The kinetics of NO release varies among NO donor compounds. Some release NO spontaneously in aqueous buffers, whereas others require active metabolic uptake, presence of thiol compounds, or degradation (see Figs. 2 and 3). Compound-specific susceptibility to changes in pH, oxygen, light, and temperature and formation of different by-products and metabolites during decomposition or metabolism also vary.

One of the most commonly used NO donor compounds is nitroglycerine (glyceryl trinitrate, GTN). It is an organic nitrate with more than 100 years of therapeutic use, particularly in cardiovascular disease (Wimalawansa, 2008). It appears to require active metabolic uptake and degradation by cells to release NO and to be biologically effective. Therein lies one of the drawbacks of its use, with cells potentially becoming tolerant after repeated exposure, requiring consistently higher dosages. Nitroglycerin does have several advantages; NO is a safe agent and has been used in clinical practice for several decades, it can readily be used *in vivo*, it is economical to use, and it has been shown to be effective in the prevention or reversal of estrogen-depleted bone loss in rodent models and osteopenia in human subjects (Wimalawansa *et al.*, 1996; Wimalawansa, 2000b, 2000c). Rapid-acting nitrates such as GTN and orally administered nitrates such as isosorbide dinitrate (ISDN, ISMN), although they may be effective, are associated with unacceptable incidences of headaches.

S-Nitroso-*N*-acetylpenicillamine (SNAP), *S*-nitrosoglutathione (SNOG), 3-morpholinosydnonomine (SIN-1), and sodium nitroprusside (SNP) are some of the other NO donor compounds that have been used in a number of *in vitro* experiments, including in cultured bone cells, and some *in vivo* experiments. All seem to liberate NO or NO adducts more or less spontaneously on contact with aqueous buffers. However, this can potentially "flood" the culture medium with NO, making difficult to quantify cellular responses. Careful adjustment of donor concentration may overcome this problem somewhat by creating a NO gradient that may mimic both physiological and pathophysiological responses *in vitro* (Damoulis and Hauschka, 1997; Otsuka *et al.*, 1998; Hughes *et al.*, 1999; O'Shaughnessy *et al.*, 2000; Aguirre *et al.*, 2001). These compounds are, however, too toxic to be administered in humans.

The final class of compounds, the diazeniumdiolates or NONOates, are perhaps the most useful for mimicking endogenous NO synthesis in *in vitro* studies. Although the NONOates release NO spontaneously, their rate of decomposition can be controlled. This enables the kinetics and concentrations of NO liberated into the culture medium to be more accurately predicated and adjusted to correlate more closely with the activity of eNOS or iNOS (Otsuka *et al.*,1998; Mancini *et al.*, 2000).

Nitroglycerine

Nitroglycerine is the preferred NO donor to be used for prevention and treatment of osteoporosis in humans. NO donors can be administered in many ways: tablets, sprays, gels, and creams, and also intravenously. Nitroglycerine is 1,2,3-propanetriol, an organic vasodilator nitrate. Nitroglycerine ointment has been on the market for more than 50 years, and the mild nature of its adverse effects has been well documented. It is supplied as a USP 2% in 60-g tubes (as the current market leader Nitrobid, Fougera Co., a division of Altana Pharmaceuticals). It is recommended to be stored between 15°C and 30°C (59–86°F). The chemical structure of nitroglycerine is illustrated in Fig. 21.

It is also important to note that ED_{50} of NO required for activation of each biological organ system is quite different (Wimalawansa, 2007). For example, the average nitroglycerine dose used in clinical practice to treat angina ranges

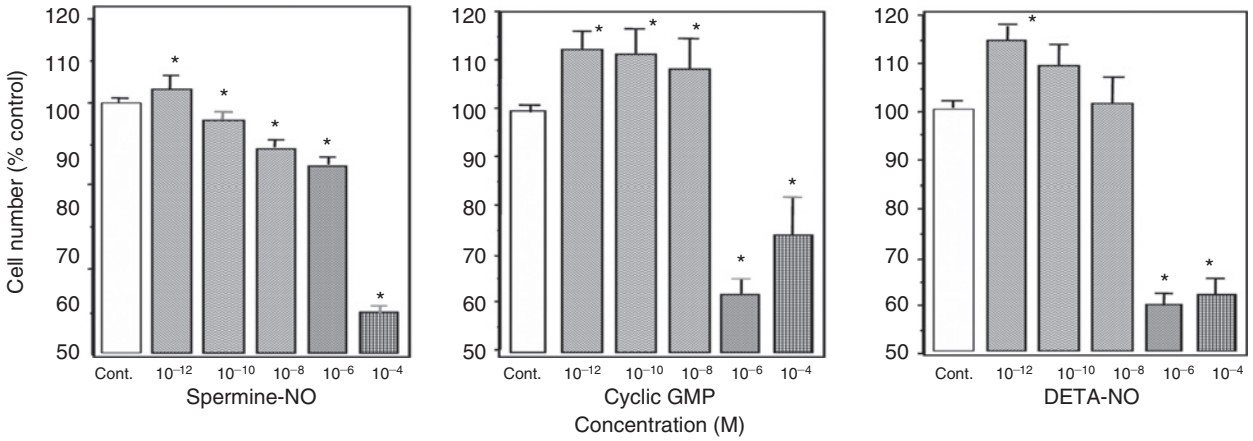

FIGURE 21 Dose-dependent cell-proliferation effect on various NO donor compounds (Wimalawansa, 2008).

from 15 to 30 mg, two to three times a day (i.e., over 60 mg of nitroglycerine daily, or its bioequivalent), whereas the dose of nitroglycerine required for skeletal health is only 15 to 25 mg, once a day, about one fourth of the standard dose use in clinical practice. Figure 22 illustrates data from a cross-sectional study demonstrating dose-effect of NO donor nitroglycerine on BMD in comparison to those who are not on nitrates.

Whereas doses below 30 mg equivalent of nitrates are beneficial for bones, doses over 40 mg of nitroglycerine/day, as demonstrated in Fig. 22, seem to be detrimental to skeletal tissues (Wimalawansa, 2007). The nitroglycerine dose used in the first human clinical study in 1997 demonstrated an equivalent efficiency of nitroglycerin to estrogen (Premarin; Wimalawansa, 2000b, 2007), and in the NOVEL clinical study (2002) about 20 mg nitroglycerine/day was utilized (Wimalawansa, 2007). That dosage represents about one fourth of the average dose that routinely used in cardiac patients with angina. The osteoporosis prevention studies just mentioned used once a day application of Nitro-Bid ointment containing 2% nitroglycerine that delivered about 20 mg nitroglycerine a day. If the efficacy is established, then use of nitroglycerine for prevention of bone loss will cost less than 10% of most of the currently approved anti-osteoporosis therapies (Wimalawansa, 2008).

Local NO levels can be raised either by supplements via an exogenous NO donor (e.g., nitroglycerine), or by preventing its rapid breakdown locally via inhibition of specific phosphodiesterase enzymes (Wimalawansa *et al.*, 2008). In fact, some inhibitors of phosphodiesterase have been shown to increase BMD by promoting bone formation (Kinoshita *et al.*, 2000). It may be possible in the future to target treatment to up-regulate osteoblast and osteocyte specific eNOS activity, enhancing its effectiveness completely eliminating its adverse effects. Expression of NOS isoenzymes are detailed elsewhere (MacPherson *et al.*, 1999; Kleinert *et al.*, 2000).

If nitroglycerine were eventually approved for prevention and treatment of osteoporosis, it would become the most cost-effective therapy for this disorder. The only significant adverse effect of nitroglycerine is the occurrence of mild headaches in about 20% of the subjects who use this ointment. This is comparable to the background incidence of headaches reported among U.S. adults over a period of time (*MMWR Morb. Mortal. Wkly Rep.* 55, 77 [2006]). However, with the orally administered nitrates, the incidence of headaches may be as high as 50% or more, and hence these are unlikely to have a practical utility. Therefore, for the use in chronic conditions such as osteoporosis, a percutaneous route seems to be the best choice.

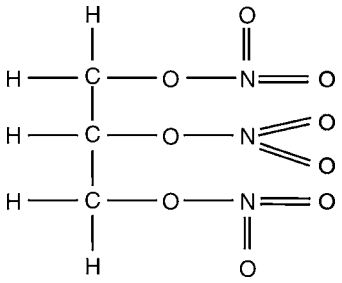

FIGURE 22 The structure of glyceryl trinitrate (GTN; nitroglycerine).

Inhibition of NO Synthesis

Research directed toward the controlling of NO synthesis (and hence NOS inhibitors) has flourished in the past decade, particularly in view of the roles that NO production may play in various pathophysiological states. Following the initial discovery that N^G-monomethyl-L-arginine (L-NMMA) could inhibit the synthesis of NO, a variety of N^G-substituted L-arginine derivatives and related compounds have been investigated as inhibitors of NO synthesis. Structures of couple of these NOS antagonistic compounds are illustrated in Fig. 23.

L-NMMA and N^G-N^G-dimethyl-L-arginine (ADMA) are naturally occurring inhibitors of NO synthesis with an equal affinity for the constitutive and inducible isoforms of NO synthase (Vallance *et al.*, 1992). Other commonly used inhibitors of NO synthesis include N^G-nitro-L-arginine (L-NNA), N^G-L-argininemethylester (L-NAME), N^G-iminoethyl-L-ornithine (L-NIO), and L-canavine. Some of these are reported to demonstrate rank-order specificity for particular isoforms (Knowles and Moncada, 1994). For example, L-NNA, L-NIO, and L-canavine are more selective for iNOS than for either nNOS or eNOS. Aminoguanidine (AG), has been much used as a somewhat selective inhibitor of iNOS including studies on bone (Kasten *et al.*, 1994; Tsukahara *et al.*, 1996) and is reported to be about 20-fold more selective for iNOS than the constitutive isoforms. However, none of these inhibitors

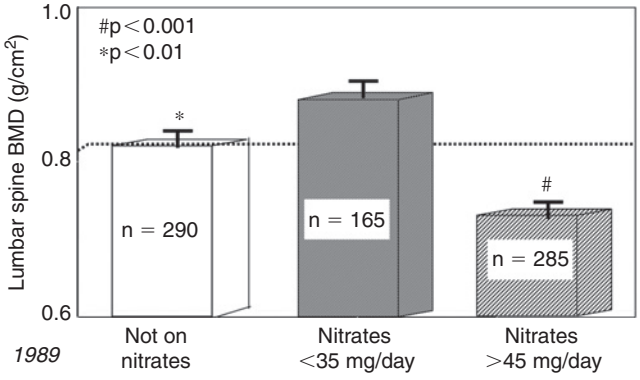

FIGURE 23 Effects of taking low or high doses of NO donors on BMD in comparison with a control group not taking nitrates or any other agents affecting bone metabolism (modified from Wimalawansa, 2007).

is sufficiently specific in its selectivity while also having effects independent of its NOS inhibition (Peterson *et al.*, 1992) to allow unequivocal assignment of a specific cellular function to a particular NOS isoform.

In Vitro Cell Biological Studies

Nitric oxide appears to play an autocrine and paracrine regulatory role in bone cell metabolism. In addition, NO modulates the activity of both osteoblasts and osteoclasts *in vitro*. Number of studies suggest that NO may have an anabolic effect on bone tissues and aid osteoblast-induced mineralization in all cultures (Wimalawansa, 2007). Thus, NO donors increase osteoclast cell proliferation, osteocalcin synthesis, and the formation of a mineralized matrix by osteoblasts *in vitro*. As expected, NOS inhibitors have an antiproliferative effect on osteoblastic cells *in vitro*. Also not surprisingly, the release of large amounts of NO from iNOS in cytokine-stimulated cells also has an antiproliferative effect on osteoblasts (Armour *et al.*, 2001), increases osteoblast apoptosis, and enhances osteoclast-mediated bone resorption (Lowik *et al.*, 1994; Armour *et al.*, 1999). Therefore, NO appears again to have a biphasic effect on bone forming cells (Brandi *et al.*, 1995): In low concentrations it promotes bone formation, whereas it may have an inhibitory effect at higher concentrations (Fig. 24).

Studies have demonstrated production of NO by osteoclasts in response to a rise in intracellular Ca^{2+}, leading to a retraction of cells and inhibition of bone resorption (Silverton *et al.*, 1999). Some authors have suggested that NO effects on bone cells are not mediated via cGMP (MacIntyre *et al.*, 1991), but overwhelming evidence suggests otherwise (Wimalawansa, 2007). Estrogen is known to regulate eNOS in osteoblasts (Armour and Ralston, 1998) and osteoblasts produce NO (Ralston *et al.*, 1994), whereas cytokine-induced inflammation (Hukkanen *et al.*, 1995) enhances iNOS activity (Armour *et al.*, 1999). NO compounds have been shown to decrease bone resorption *in vitro*, and similar effects have been demonstrated with L-arginine (Fini *et al.*, 2001). Furthermore, the inhibition of NOS activity leads to enhanced bone resorption (Broulik *et al.*, 2003; Kasten *et al.*, 1994; see Fig. 18).

Interestingly, TNF-α-dependent osteoclastic survival is thought to be iNOS-dependent (Lee *et al.*, 2004), although some researchers have suggested otherwise (Rogers *et al.*, 1996). Bone cells, in particular osteoclasts (Silverton *et al.*, 1999) but also osteoblasts (Ralston *et al.*, 1994) as well as bone marrow cells, produce NO (Punjabi *et al.*, 1992). Mechanical strain on cells also produces NO (Pitsillides *et al.*, 1995; Sterck *et al.*, 1998; Burger and Klein-Nulend, 1999; Turner *et al.*, 1996) . The nitric oxide-cGMP pathway also seems to be involved in the mechanism of bone resorption by cyclosporin as well (Wimalawansa *et al.*, 2000c).

Enhanced expression of NO via iNOS in inflammatory conditions, e.g., lipopolysaccharide-induced bone resorption, can be alleviated with NOS inhibitors. This inflammation-associated bone loss has been predominantly due to augmentation of cytokine-induced matrix metalloproteinase 1 (MMP-1) production in osteoblasts and subsequent activation of osteoclasts (Grabowski *et al.*, 1996; Lin *et al.*, 2003). *In vitro* studies using high doses of NO also led to rapid osteoclast cell death. Indeed, NO donors inhibit osteoclast formation in mouse bone marrow cultures, an experimental system frequently used to study factors regulating osteoclastogenesis. It is possible that this effect is mediated by the NO-induced apoptosis of osteoclast progenitors, perhaps via peroxynitrite (see Fig. 4) and/or diminished osteoclast requirement, at physiological levels of NO. Nevertheless, the inhibition of osteoclast activity seems to be the predominant effect of NO under normal conditions (Wimalawansa, 2007).

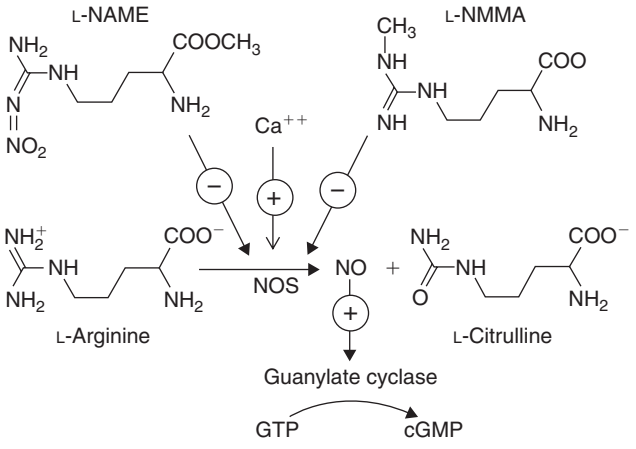

FIGURE 24 Structures of two commonly used NOS-antagonistic compounds *in vitro* cell culture and some *in vivo* animal research (Wimalawansa, 2008).

NO Is a Mediator in Mechanical Stimulation

Nitric oxide is a key mediator in osteoblastic stimulation following exercise, shear-strain and most mechanical stimulations (Rodan *et al.*, 1975; Fox and Chow, 1998; Fox *et al.*, 1996). Pulsating fluid flow simulating canaliculi and shear stress releases NO that leads to osteoblastic stimulation (Klein-Nulend *et al.*, 1995, 1998). In addition to releasing NO, fluid shear stresses also release prostaglandins (McAllister *et al.*, 2000), perhaps via preosteoclast cells (McAllister and Frangos, 1999).

Mechanical stimuli are important during growth and subsequent bone homeostasis. This is manifested by lower peak bone mass in children who are physically inactive, and by the decrease in bone mass in adults following bed rest, inactivity, or exposure to microgravity. The mechanisms

involved in the transduction of the effect of mechanical forces have not been elucidated, but data suggest the influence of prostaglandins and NO. Indeed, the inhibition of NO synthesis *in vivo* impairs the bone formation induced by mechanical loading of rat tibiae (Turner *et al.*, 1996). Furthermore, the exogenous NO donors can potentiate the osteogenic effect of loading.

In Vivo Studies with NO

In vivo studies suggest that the predominant effect of NO is on osteoclast cells, but anabolic effects on osteoblast cells are also important (Wimalawansa, 2007). Whereas NOS inhibitors such as aminoguanidine or L-NAME cause bone loss in rats, NO donors at physiological doses prevent ovariectomy-induced and glucocorticoid-induced bone losses (Wimalawansa, 2000b, 2000c) in rats and estrogen deficiency-induced bone loss in women. This further suggests physiological roles of NO in bone metabolism. Furthermore, eNOS- and/or nNOS-deficient mice have reduced bone formation (Aguirre *et al.*, 2001), whereas iNOS activation enhances bone resorption see Fig. 8). NO also seems to play a role in angiogenesis, particularly in vascular tissues in bone (Ziche, 2000).

NO also seems to mediate local vasoreactive activity during fracture healing (Corbett *et al.*, 1999b). Moreover, studies showed that although the NO-donor nitroglycerine by itself had no significant effect on the bone in adult rats (hormonally normal male or female rats), it prevented the loss of bone induced by methylprednisolone (Wimalawansa *et al.*, 1997; Wimalawansa and Simmons, 1998). These studies suggest that NO-releasing compounds may have a protective effect even on glucocorticoid-induced osteoporosis. The relevance of this to humans is yet to be studied.

We and others have demonstrated that nitroglycerine prevents both ovariectomy and corticosteroid-induced bone loss, as assessed by BMD, bone weight, and bone histomorphometry in rats (Wimalawansa *et al.*, 1997; Wimalawansa and Simmons, 1998; Wimalawansa, 2000b). Further, using the NO synthase inhibitor, L-NAME, using animal models of bone loss, it has been demonstrated that almost all beneficial effects of estrogen on bone can be blocked (Wimalawansa *et al.*, Figure 25).

Changes in the expression of eNOS have also been shown to influence growth plate chondrocytes as well as osteoblast activity in the metaphyses, especially in the lactation-induced bone loss model (Aguirre *et al.*, 2003). Using the adult ovariectomized (OVX) rat model, we and others have demonstrated positive effects of topically applied nitroglycerine (Fougera, NY 2% ointment) on indicators of bone metabolism including BMD, biochemical markers of bone turnover, and bone histomorphometry (Wimalawansa *et al.*, 1997). In these experiments, 17β-estradiol was used as positive control and compared its effects with nitroglycerine (Wimalawansa *et al.*, 1996). Data revealed that the skeletal effects of nitroglycerine are equivalent to those of estrogen in preventing as well as in treating OVX-induced bone loss.

Although applications of nitroglycerine once daily (0.2 mg/kg) were highly effective in the prevention of OVX-induced bone loss, multiple applications of the same dose were ineffective (Wimalawansa, 2007). The beneficial effects of nitroglycerine are biphasic and maximal between 0.2 and 0.5 mg/kg. Below 0.2 mg/kg as well as above 0.5 mg/kg the skeletal effects were not different from a placebo (i.e., relatively narrow therapeutic window for its skeletal benefits). Interestingly, nitroglycerine applied in the morning hours was more efficacious than when applied in

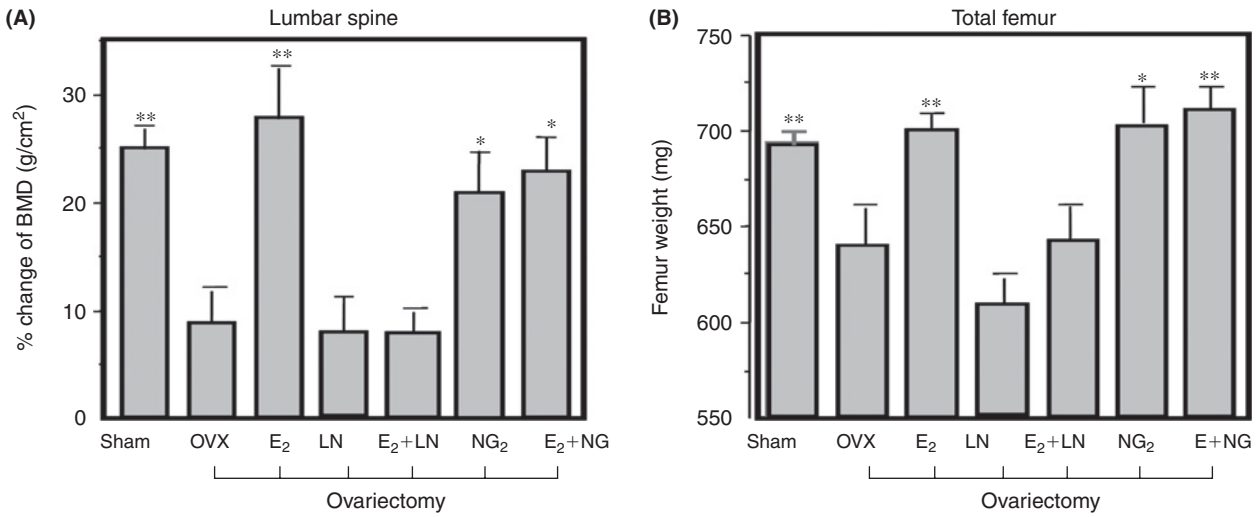

FIGURE 25 Effects of NO 17β-estradiol and NOS-antagonist l-NAMA on BMD in ovariectomized rats. Beneficial effects of estrogen are negated in the presence of l-NAME (NOS-blocks), suggesting that at least in part, estrogenic effects on bone are mediated via the NO/cGMP pathway (Wimalawansa *et al.*, 1996).

the evening. Figure 26 illustrates the dose- and Figure 27, frequency-dependent effects of nitroglycerine on BMD in female Wistar rats.

Our animal studies have demonstrated a similar efficacy of NO donor therapy in male rats. Among castrated rats, preservation of BMD by either testosterone or estrogen administration is blocked by concomitant administration of the NOS blocker L-NAME. These data suggests that NO therapy is also likely to help in males, especially those males suffering from hypogonadism and older males suffering from idiopathic bone loss. Accordingly, the use of nitroglycerine is likely to have advantages over estrogen replacement therapy or SERMs in postmenopausal women, and testosterone and selective androgen receptor modulators (SARMs) in men.

Another study demonstrated that nitroglycerine was superior to more than 10 other NO donors. Also shown were the additive effects on BMD when nitroglycerine was coadministered with vitamin D, calcitonin, and bisphosphonates (Wimalawansa *et al.*, 2008). Because the final common pathway is the same, no such additive effects were expected or seen when nitroglycerine was coadministered with sex-steroid hormones such as estrogen, progestogens, or testosterone.

Overall, the results indicate that at low doses, nitroglycerine has marked beneficial effects on bone metabolism. Cyclosporine A is known to cause bone loss (Movsowitz *et al.*, 1988). The interactions of cyclosporine A with the bone cellular nitric oxide–cGMP pathways has also been shown to induce bone loss (Wimalawansa *et al.*, 2000c). No donor therapy can prevent the glucocorticoid-induced bone loss (Wimalawansa *et al.*, 1997). The same authors also demonstrated that NO therapy can prevent the glucocorticoid-associated histomorphometric changes in bone (Figure 28).

Using the ovariectomized rat model we also demonstrated that estrogen and the NO donor therapy with nitroglycerine were also equally effective in restoring or maintaining bone strength. Figure 29 illustrates the femoral neck ultimate load [force/load (N); displacement(N/mm)] in four groups of rats (sham operated; ovariectomized placebo therapy; estrogen-treated; nitroglycerine-treated). Both estro gen and nitroglycerine therapy significantly improved the bone strength.

L-NAME, the NO synthase inhibitor, prevents synthesis and release of NO via a NOS enzyme, abrogating the beneficial effects of estrogen in bone (Wimalawansa *et al.*, 1996). These suggest that some part of the beneficial effects of estrogen in bone is mediated through NO. Furthermore, effects of NO on bone cells are highly dose dependent; at low concentrations activation of eNOS or nNOS promotes

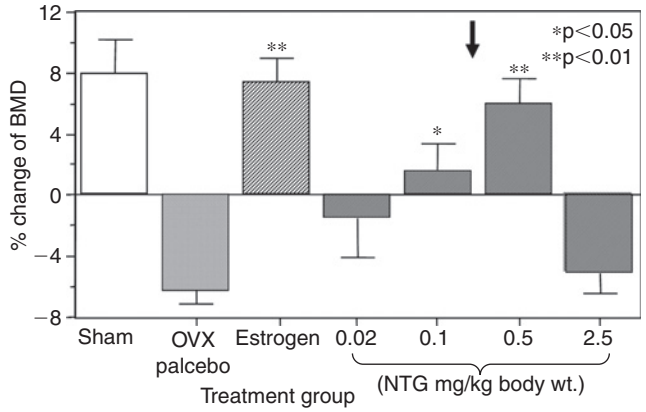

FIGURE 26 Dose-dependent effect of NO donor nitroglycerine on lumbar spine BMD in ovariectomized, female Wistar rats (Wimalawansa *et al.*, 2000a).

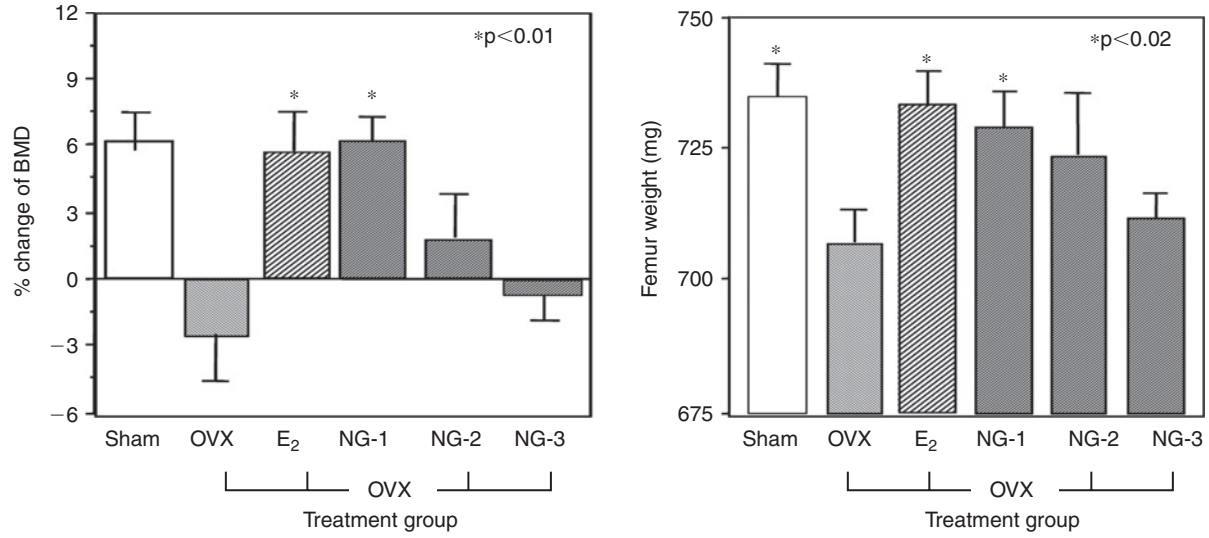

FIGURE 27 Frequency-dependent effect of NO donor nitroglycerine on lumbar spine BMD (trabecular bone) and femur weight (cortical bone) in ovariectomized rats (Wimalawansa *et al.*, 2000a).

osteoblast activity and cell proliferation and control of osteoclastic bone resorption, whereas at higher concentrations induction of iNOS activity with inflammatory cytokines leads to loss of osteoblastic activity and enhances osteoclastic activity leading to bone loss (Wimalawansa, 2007).

Potential Molecular Targets for the Action of NO in Bone Cells

NO signaling is able to activate various signal transduction pathways in different cell types. Despite this, there is a paucity of information of the detailed signaling mechanisms of NO in bone cells (Margolis and Wimalawansa, 2006). The guanylate cyclase-cGMP pathway is a classical target for NO, and there is a substantial body of evidence to show that the cGMP-dependent signaling is crucial to normal bone formation (Wimalawansa, 2007). Early studies demonstrated that cGMP was important in transducing the anabolic effects of mechanical loading (Rodan *et al.*, 1975) and more recently those of natriuretic peptides on bone formation (Suda *et al.*, 1996, Mericq *et al.*, 2000).

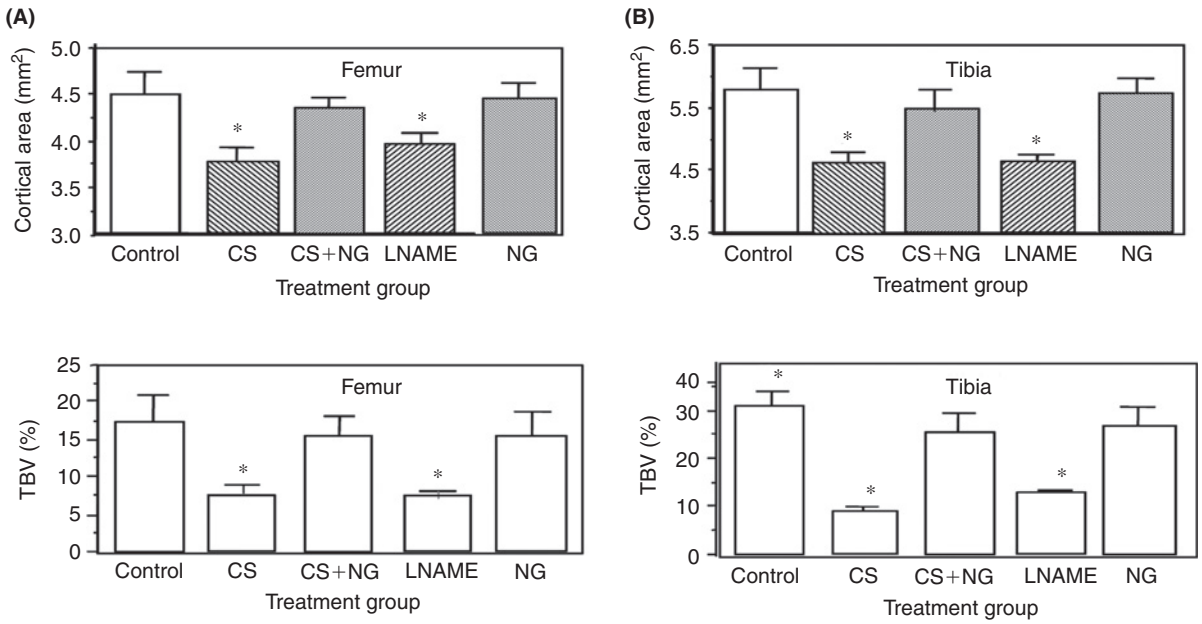

FIGURE 28 Effects of NO donor nitroglycerine on bone histomorphometry—cortical area and TV/BV% in comparison to control in glucocorticoid-treated rats. The effect of blocking the effects of NOS using the NOS inhibitor l-NAME is similar to that of glucocorticoid on the bone structure. Glucocorticoid-induced bone loss and associated histomorphometric changes can be prevented with appropriate doses of NO donor therapy in rats (Wimalawansa *et al.*, 1997).

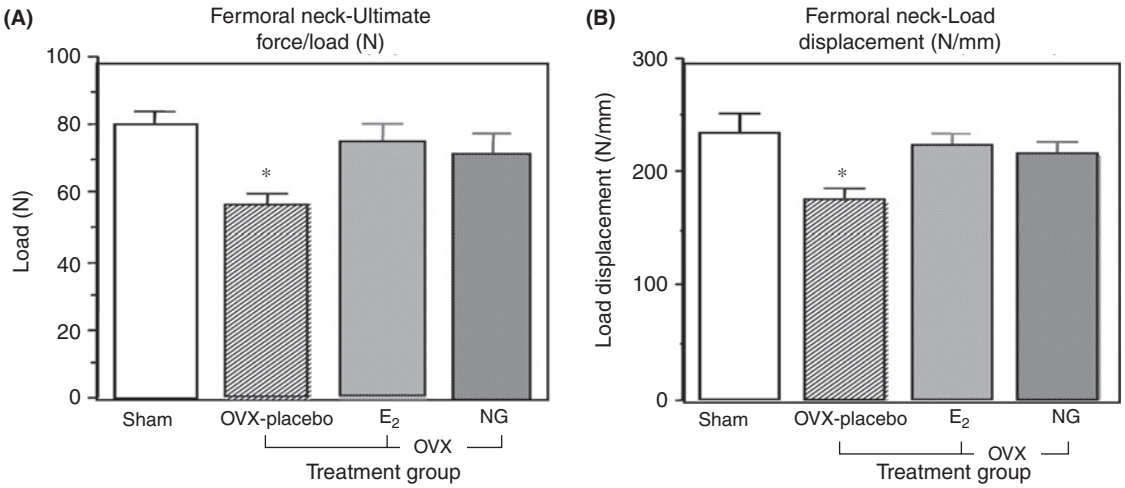

FIGURE 29 Effects of NO donor nitroglycerine on bone strength in comparison to 17β-estradiol (Wimalawansa, unpublished).

cGMP analogues increase the expression of markers of osteoblast differentiation alkaline phosphatase and osteocalcin and augment formation of mineralized bone nodule in rat calvaria cell cultures (Inoue *et al.*, 1995). The marked bone abnormalities and dwarfism seen in mice lacking protein G kinase type II is particularly compelling evidence for the role of cGMP, and a role for NO, in endochondral ossification (Pfeifer *et al.*, 1996). Osteoblast cultures stimulated with NO donors showed increased alkaline phosphatase activity, osteocalcin expression, and *in vitro* bone nodule formation that depended on cGMP synthesis (Chae *et al.*, 1997; Hikiji *et al.*, 1997; Otsuka *et al.*, 1998; Mancini *et al.*, 2000), demonstrating the association between NO and cGMP in bone cells.

The role of cGMP in mediating osteoclast function is less conclusive. Initial studies suggested cGMP production is not required for the functional modulation of osteoclasts by NO (MacIntyre *et al.*, 1991; Ralston and Grabowski, 1996). However, more recent studies using newer generation cGMP analogues and guanylate cyclase inhibitors have demonstrated that stimulation of cGMP by low concentrations of NO does regulate osteoclast function, increasing cell contraction and detachment from bone surfaces (Mancini *et al.*, 1998). In addition, Dong *et al.* (1999) showed that NO-dependent cGMP production reduced transport of HC1 osteoclast membranes and inhibited activity.

In addition to the cGMP pathway, NO is a potent stimulator of $p21^{ras}$ activity and MAP kinase signaling (Lander, 1997). Although there is no direct evidence for NO-dependent activation of this pathway in bone cells, it has been shown that the MAP kinases are involved in stimulating osteoblast proliferation and differentiation (Matsuda *et al.*, 1998) and in regulating expression of the osteoblast transcription factor Cbfa-1 (Xiao *et al.*, 2000). MAP kinase activation is also involved in RANK ligand-induced osteoclast differentiation (Matsumoto *et al.*, 2000).

Expression and activity of VEGF is fundamental to the process of endochondral ossification stimulating chondrocyte cell death, cartilage remodeling, and angiogenesis (Gerber *et al.*, 1999). However, there is no direct evidence to support the involvement of NO in mediating the actions of VEGF in bone, but there is evidence to suggest that NO facilitates the angiogenic effects of VEGF in other cell types (Papapetropoulos *et al.*, 1997; Frank *et al.*, 1999; Ziche, 2000). As such, NO-VEGF signaling might also be important in the angiogenic response (Frank *et al.*, 1999) that is crucial to fracture healing.

Phase II Studies Using NO Donor Compounds

The rationale for using NO compounds for osteoporosis has been developed after many *in vitro* and *in vivo* studies

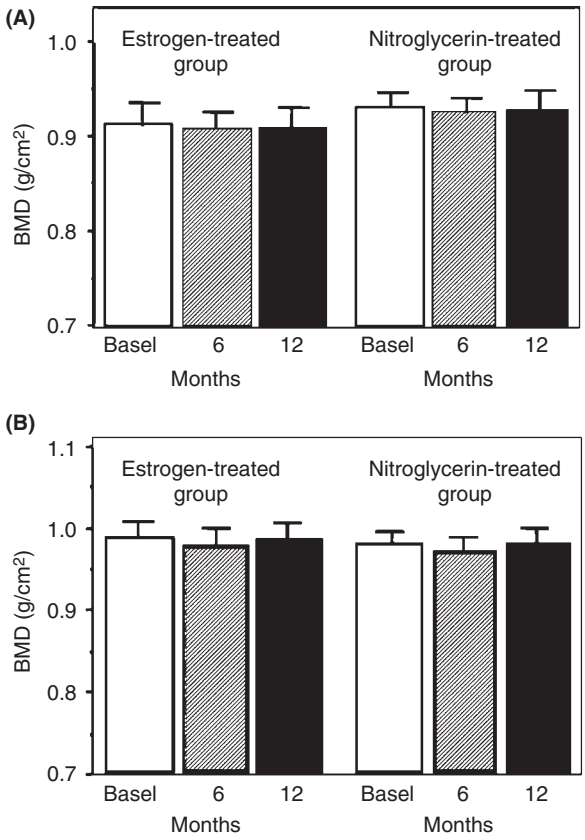

FIGURE 30 Comparable effects of NO donor nitroglycerine with estrogen (Premarin) in prevention of bone loss in oophorectomized women. Women were randomly allocated to receive either Premarin (standard therapy) or percutaneously administered nitroglycerine. BMD and the biochemical markers of bone turnover were examined at the baseline and at 6-month- and 12-month time points. There were no differences of BMD between the two groups, or from their respective baselines to 6- and 12-month time points in each treatment group (Wimalawansa, 2000b).

conducted over the past two decades (Wimalawansa, 1988, 2000b, 2000c, 2007; Wimalawansa *et al.*, 1997). Circulating nitrate levels increase in the presence of HRT (Rosselli *et al.*, 1994) and androgen replacement therapy (Wimalawansa, unpublished), as well as calcitonin therapy (Tas *et al.*, 2002). Circulating nitrate (NO) levels fluctuate according to the menstrual cycle (Cicinelli *et al.*, 1996), whereas administration of estradiol increases plasma NO levels (Cicinelli *et al.*, 1998). Results from these animal and human studies indicate that nitroglycerine has marked beneficial effects on bone metabolism. Some of these beneficial effects of established antiosteoporosis agents such as estrogen, testosterone, anabolic steroids, and SERMS as well as statins are likely to mediate via the cGMP/NO pathway (see Fig. 13).

The first human clinical study to evaluate the beneficial effects of the NO donor nitroglycerine in prevention of oophorectomy-induced bone loss was conducted in the mid-1990s (Wimalawansa, 2000b). Based on animal data,

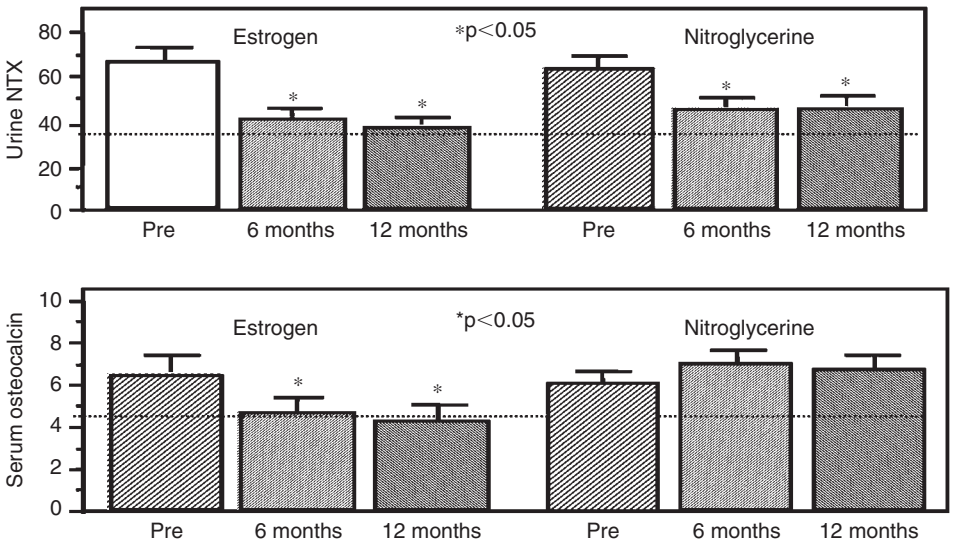

FIGURE 31 Changes of biochemical markers of bone turnover in response to estrogen (Premarin) versus topically administered nitroglycerine ointment (for the details of the experiment see the legend of Fig. 30). While a bone resorption marker (N-telopeptide) decreased as expected with any antiresorptive agent, the bone formation marker osteocalcin was suppressed only with estrogen therapy (as a coupling effect). This suggests that a dissociation of bone formation from resorption, which is favorable for gaining bone, occurred in the presence of the NO donor nitroglycerine (Wimalawansa, 2000b).

this 1-year controlled, randomized human study was conducted to assess the efficacy of topically administered nitroglycerine ointment in comparison with oral estrogen, using BMD and biochemical markers as endpoints. Data from this pilot study established an equipotent effect of nitroglycerine to estrogen HRT, preventing oophorectomy-induced bone loss in women; that is, NO donor therapy prevented accelerated bone loss in early menopause. Figure 30 illustrates the equipotency of NO with estrogen in maintaining the BMD in oophorectomized women.

Figure 31 illustrates the differential (i.e., an example of dissociation of bone resorption from bone formation) effects of NO versus estrogen in oophorectomized women. Note that whereas the bone resorption marker N-telopeptide is suppressed with both estrogen and NO, the bone formation marker osteocalcin is only suppressed with estrogen.

Supplementation with the NO precursor L-arginine may be effective (Visser and Hoekman, 1994), but the amount of L-arginine that must be ingested to achieve these biological effects is so high that it makes this approach impractical. A cross-sectional study also supported the role of NO in enhancing BMD (Jamal *et al.*, 1998). More importantly, a larger nationwide case-controlled study conducted in Denmark, studying 124,655 subjects with fractures in comparison to 373,962 gender-matched controls, revealed a 15% reduction of hip fractures in those using organic nitrates Fig. 32). The authors speculated that use of nitrate may protect against osteoporosis and its fractures.

Phase III Study with NO Donor Nitroglycerine

Based on the pilot study data described earlier, a single-center, large, randomized, double-blind, placebo-controlled clinical study funded by the National Institutes of Health was conducted to assess the effectiveness of topically administered nitroglycerine. This clinical trial, known as the NOVEL [**N**itroglycerine as an **O**ption: **V**alue in **E**arly bone **L**oss] study, was designed to resolve the questions: Can nitroglycerine stop bone loss in menopausal women? If so, can this be an alternative therapy for estrogen and HRT? The original study was designed to compare the effects of nitroglycerine with HRT and the SERM raloxifene. However, as a result of data available in the early 2000 from the WHI study, to minimize potential risks to study subjects the NOVEL protocol was modified to compare nitroglycerine with a group treated with inactive ointment together with calcium and vitamin D (Wimalawansa *et al.*, 2007).

If the results of the NOVEL study confirm efficacy of nitroglycerine and the hypothesis that estrogen works through NO on bone, then nitroglycerine therapy could become a highly cost-effective and attractive treatment option for prevention and treatment of postmenopausal osteoporosis. The role of combination therapies (Wimalawansa, 1995, 2000a; Wimalawansa and Simmons, 1998; Wimalawansa *et al.*, 2008) may have a place in the future and needs to be investigated, especially the combination of NO donors with bisphosphonate therapy (Wimalawansa, 2007). Figure 33 illustrates mechanism

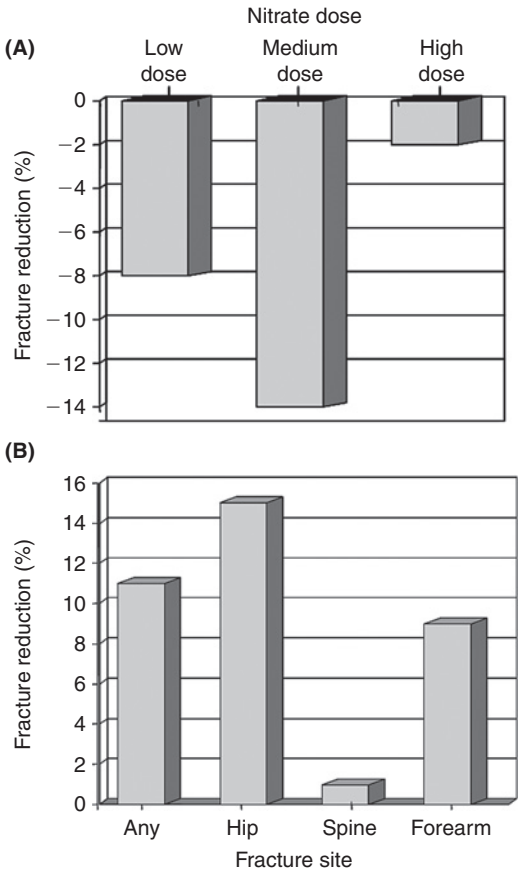

FIGURE 32 Diagrammatic representation of fracture reduction reported in a nationwide large epidemiology study in Denmark. (A) Overall effects of three broad dose categories of nitrates used, which demonstrated that the moderate dose of nitrates had the highest efficacy in fracture reduction, and at higher doses there is no effects on fracture prevention. (B) Percentage fracture reduction: any fractures, 0.89 (CI, 0.86–0.92); hip fractures, 0.85 (CI, 0.79–0.92); lumbar spine, 0.99 (CI, 0.85–1.16); and forearm, 0.91 (CI, 0.83–1.00). (Data adapted from Rejnmark *et al.*, 2006).

of activation of eNOS and nNOS leading to physiological actions in bone cells.

NO and Bone Pathology

Alterations or disruption to NO synthesis within the bone environment has been implicated in the genesis of a number of diseases. Inflammatory diseases such as rheumatoid arthritis, which is characterized by articular cartilage erosion together with juxta-articular bone loss, is associated with activation of iNOS and production of high local levels of NO and NO-related species including peroxynitrite (Farrell *et al.*, 1992; Stefanovic-Racic *et al.*, 1993; Kaur and Halliwell, 1994; Grabowski *et al.*, 1996). On the basis of data using NOS inhibitors and iNOS knockout mice, activation of iNOS and increased levels of NO production contribute directly to the tissue damage associated with rheumatoid arthritis (McCartney-Francis *et al.*, 1993; Stefanovic-Racic *et al.*, 1994).

There are several other inflammatory conditions associated with activation of iNOS and in which increased production of NO or NO-derived oxidants including peroxynitrite is implicated in pathological bone loss. Increased staining for iNOS and formation of peroxynitrite in macrophages associated with bone erosions adjacent to prosthetic hip implants has also been demonstrated (Hukkanen *et al.*, 1997), suggesting the involvement of activated iNOS in the process of loosening of the implant. iNOS activation and increased NO production has been reported as a contributory factor to the extensive bone loss seen in animal models of inflammation-induced arthropathy and osteoporosis (Armour *et al.*, 1999). The deleterious effects of iNOS activation in these animal models could be minimized by administration of a NOS inhibitor.

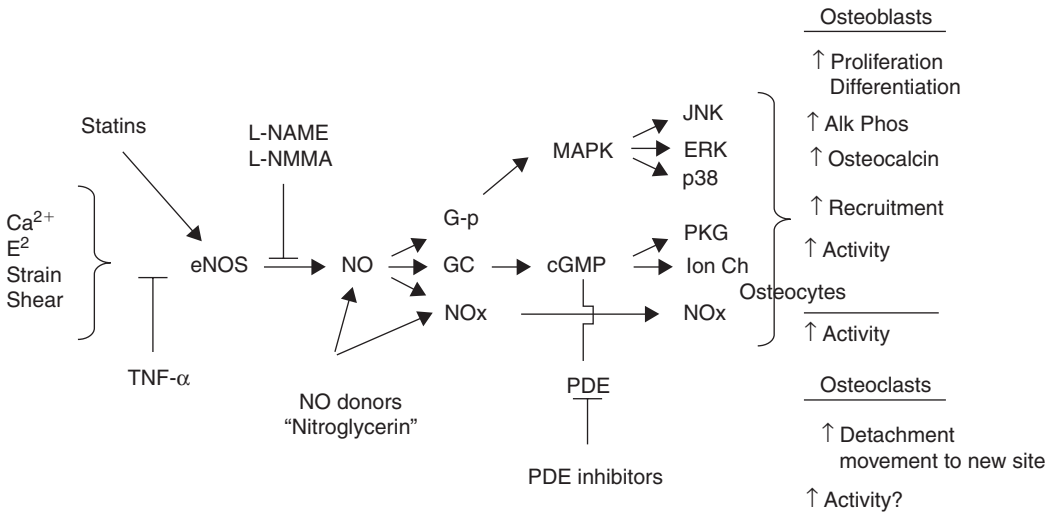

FIGURE 33 Diagrammatic overview of mechanism of eNOS activation and NO-mediated physiological signaling pathways in bone cells. For detailed discussion refer to main text. iNOS expression and staining has been demonstrated in osteoblasts, in osteoclasts, and in particular osteocytes in bone samples from osteonecrotic subjects. Interestingly, iNOS-positive cells correlated closely with the incidence of apoptotic cells and has led to the somewhat controversial suggestion that osteocyte apoptosis is induced by NO. These larger amounts of NO generated locally, together with osteoclast activation, might in fact be the underlying mechanism of the extensive bone destruction seen in inflammatory arthritis (Calder *et al.*, 2001). Figure 34 illustrates the pathological consequences following stimulation of iNOS activity on bone cells.

NO and Fracture Healing

There is evidence to show that NO is involved in various stages of fracture healing. Marked iNOS expression and activity within 24 hours after fracture in a rat model has been reported, which is consistent with the initial inflammatory phase of fracture healing (Corbett *et al.*, 1999a). In these experiments, iNOS was localized principally to endosteal osteoblasts. This expression was transient, and after 24 hours iNOS expression and activity were scarcely detectable. It is likely that this is a signal to attract osteoclasts to the site of injury and to activate the repair process starting with bone resorption; this is an essential part of the fracture healing process. During the first week after fractures there was a marked increase in expression and activity of calcium-dependent eNOS, which was localized, in particular, to cortical blood vessels and osteocytes (Corbett *et al.*, 1999a). This makes sense as the increase of blood supply that is necessary for the repair process.

Blood supply to a fracture site is critical for its proper healing. The presence of large numbers of vascular endothelial cells (Collin-Osdoby, 1994), and thus eNOS activity generating NO locally, plays a role in fracture healing (Corbett *et al.*, 1999b; Diwan *et al.*, 2000). This is supported by the demonstration of differential expression of NOS isoenzymes at the fracture sites. In addition, NO also activates other growth factors and cyclooxygenase enzymes (Salvemini *et al.*, 1993). The aforementioned is consistent with eNOS being involved in the vascular response and neovascularization that are crucial to successful fracture repair. Indeed, a further study on the same model demonstrated enhanced NO-dependent vasoreactivity around the fracture site, supporting a role for NO in the restoration of blood flow to the fractured bone (Corbett *et al.*, 1999b). Subsequent reports provided similar evidence for the involvement of NO in fracture healing (Diwan *et al.*, 2000). Of particular interest in that study was the finding that NOS inhibitors significantly impaired fracture healing, which could be reversed by local delivery of a NO donor.

Disrupted NO synthesis, whether too low or too high, is likely to be a significant factor in the postmenopausal, age-related as well as inflammation-associated bone loss associated with osteopenia. Estrogen-depletion osteoporosis induced by ovariectomy in animal models can be largely prevented or reversed by administration of NO donor compounds, notably nitroglycerin (Wimalawansa *et al.*, 1996, 2000c). This was extended to a human clinical trial showing that nitroglycerin is equally as effective as HRT in preventing or restoring postmenopausal bone loss (Wimalawansa *et al.*, 2000b).

Additional evidence for NO mediating the osteogenic effects of estrogen is provided by cyclic increases in plasma nitrite and nitrate levels (oxidation products of NO metabolism), which are highest at the mid-phase of the menstrual cycle, closely following estrogen levels

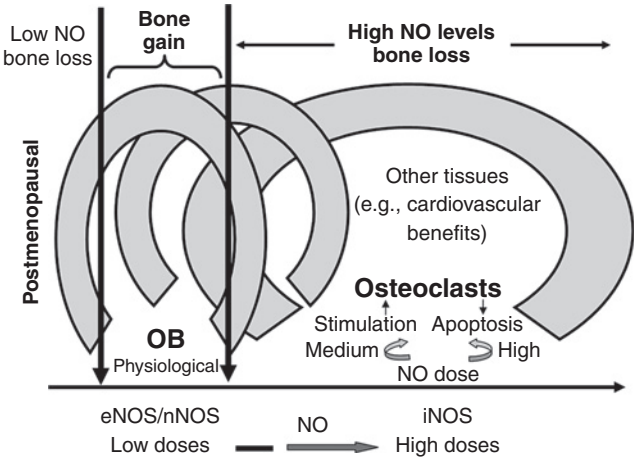

FIGURE 35 Schematic demonstration of dose-dependent effects of nitric oxide donor therapies on cellular and organ fractions. This also highlighted the relatively narrow therapeutic index for NO donor therapies in skeletal health.

(Cicinelli *et al.*, 1996). Postmenopausal subjects and amenorrheic athletes have reduced serum NO metabolites, which can be elevated following treatment with HRT (Rosselli *et al.*, 1995; Cicinelli *et al.*, 1998; Stacey *et al.*, 1998). Finally, *in vitro* studies on rodents, including eNOS knockouts, and human osteoblasts demonstrate that eNOS expression and activity are elevated by estrogen and correlate with increased osteoblast proliferation and differentiation (Armour and Ralston, 1998; O'Shaughnessy *et al.*, 2000; Aguirre *et al.*, 2001; Armour *et al.*, 2001).

Therapeutic Implications

It has been shown that NO has an estrogen-like effect and that nitric oxide can in part replace the beneficial effect of estrogen in bone (Wimalawansa, 1996; Wimalawansa *et al.*, 2000a; Armour and Ralston, 1998; Aguirre *et al.*, 2001; Armour *et al.*, 2001). Wimalawansa and coworkers (Wimalawansa *et al.*, 2000a) also demonstrated that a NO donor in humans is as effective as estrogen in inhibiting postmenopausal bone loss. Clearly this has important therapeutic implications in the treatment and prevention of osteoporosis. Further, it strongly suggests that a NO donor in combination with an osteoclast inhibitor—for example, calcitonin or bisphosphonates—can be useful in the treatment of osteoporosis. Nitroglycerine has a relatively narrow therapeutic window for treatment of osteoporosis, as illustrated in Figs. 21, 32, 35. At low doses NO promotes skeletal health, whereas at high doses (e.g., the doses of nitrates used in angina pectoris and other cardiovascular disease) it is likely to promote bone loss.

If NO or a NO donor can be administered directly to the fracture sites, it could conceivably augment fracture healing (Corbett *et al.*, 1999a, 1999b; Diwan *et al.*, 2000). There are, however, potential limitations on the use of NO donors. Cellular desensitization following prolonged use of organic-nitrate compounds such as nitroglycerin is a particular problem that has been encountered in the treatment of ischemic heart disease and requires increased dosages to reproduce the beneficial effects. However, this can be easily overcome by providing NO therapy intermittently, such as daily or less than daily administration (Wimalawansa *et al.*, 2000a; Wimalawansa, 2007).

OTHER VASOACTIVE AGENTS

These include the members of the calcitonin family, the prostaglandins, endothelin, natriuretic peptides and VEGF (Wimalawansa, 1996, 1997; Inoue *et al.*, 1995). The calcitonin family acts as osteoclast inhibitors (Zaidi *et al.*, 1991), whereas NO enhances the angiogenesis of avascular tissues (Ziche, 2000). Calcitonin is the most potent, whereas the other members of the group all share predominant vasoactive actions with weaker osteoclast inhibitory effects. Only calcitonin has been thoroughly studied for its action on bone, and this is well described (Wimalawansa and Cooper, 1997; Wimalawansa, 1989; Zaidi *et al.*, 1991). Osteoclasts each have about six million calcitonin receptors, making it the prime target for its actions. Briefly, calcitonin acts directly on the osteoclast to produce a marked inhibition primarily via activation of adenylate cyclase, but also involving an increase in intracellular calcium (Wimalawansa, 1991; Wimalawansa and MacIntyre, 1991).

Endothelin is a potent vasoconstrictor, influence bone metabolism by impairing blood supply to bones and also by inhibiting osteoclast cells (Alam *et al.*, 1992). It also inhibits osteoblast-dependent skeletal mineralization (Hiruma *et al.*, 1998) and thereby regulates bone cell metabolism (Kasperk *et al.*, 1996; Yasoda *et al.*, 1998; Alam *et al.*, 1992; Nelson *et al.*, 1999).

The prostaglandins have a complex but very important set of actions of bone. Interestingly, NO is know to activate cyclooxygenase and also increase prostaglandin synthesis (Salvemini *et al.*, 1993) and may be important in bone cell function (Hughes *et al.*, 1999). Endothelin has not been studied extensively in bone, but has been reported to have a weaker osteoclast inhibitory effect (Alam *et al.*, 1992; Zaidi *et al.*, 1993). The effects of endothelins on osteoblast function appear to be contradictory and, perhaps, species-specific. Endothelins inhibit osteoblast differentiation in rodent osteoblast cultures (Hiruma *et al.*, 1998; Inoue *et al.*, 2000), whereas in human cultures endothelins promote osteoblast differentiation and mineralization (Kasperk *et al.*, 1996; Nelson *et al.*, 1999).

C-type natriuretic peptide is significant in the physiological control of endochondral ossification and in osteoblast proliferation differentiation (Suda *et al.*, 1996; Yasoda *et al.*, 1998; Mericq *et al.*, 2000; Inoue *et al.*, 2000). This

peptide also regulate bone growth via cGMP (Mericq *et al.*, 2000) and osteoblast functions (Suda *et al.*, 1996). In some respects the actions of natriuretic peptide is not unlike those of NO. Calcitonin gene-related peptide (CGRP; a member of the calcitonin family) also has weaker antiosteoclastic effect, presumably via binding into calcitonin receptor in osteoclasts (Zaidi *et al.*, 1991; Wimalawansa and MacIntyre, 1991). Being the most potent vasodilator in humans and its wide network of distributions in the neuronal and vascular network in the bone, it is also likely to have a major effect on controlling nutrition supply to the skeleton (Wimalawansa, 1996, 1997). NO is a key factor for inductions of VEGF (Frank *et al.*, 1999). Finally, VEGF is an important vasoactive factor that plays a fundamental role in endochondral ossification (Gerber *et al.*, 1999), and angiogenesis during endochondral bone formation (Gerber *et al.*, 1999; Papapetropoulos *et al.*, 1997).

FUTURE PROSPECTS USING NO DONOR THERAPY FOR OSTEOPOROSIS

Alternatives to NO donors include delivering compounds that preserve the signaling actions of messenger molecules downstream of NO synthesis such as cGMP. Indeed, phosphodiesterase (PDE) inhibitors are able to increase bone mass by accelerating bone formation in mice (Kinoshita *et al.*, 2000). Consequently, specific PDE inhibitors may have some value in the treatment of osteoporosis and need further exploration. Other approaches for eliciting anabolic effects in the skeleton include the lipid-lowering drugs called statins (Wimalawansa *et al.*, 1997), as first reported by Wimalawansa in 2000 at the Bone and Tooth Society Meeting in London. Statins have been shown to stimulate new bone formation (Mundy *et al.*, 1999) and reduce the risk of hip fracture in elderly humans (Wang *et al.*, 2000). Interestingly, statins upregulate eNOS expression and downregulate iNOS expression ; i.e., favorable for skeletal health) at least in brain tissue and may also account for some the osteoprotective effects of these compounds. Some studies have shown an increase in BMD following the use of statins (Tanriverdi *et al.*, 2005; Kawane *et al.*, 2004; Maritz *et al.*, 2001). However, recent controlled clinical studies have failed to demonstrate any skeletal benefits of statins, e.g., atrovastatin at doses up to 80 mg per day. This is probably due to an inability to deliver adequate concentrations of statins to local bone cells.

Elevated production of NO following iNOS activation is a significant factor in the progression of various inflammatory conditions including rheumatoid arthritis. Consequently, inhibition of iNOS activity appears to be an attractive target in tempering inflammation-induced tissue damage. Although there are several reports to show that when NOS inhibitors (L-NAME, L-NMMA) are administered prophylactically, these compounds were able to suppress the onset of disease in animal models (McCartney-Francis *et al.*, 1993; Stefanovic-Racic *et al.*, 1994), not all iNOS activity is detrimental. Indeed, iNOS does have protective effects such that NOS inhibitors can exacerbate some tissue injury (Wimalawansa, 2008). In part this also relates to the fact that in virtually all the studies that have been performed using NOS inhibitors, none of the compounds used are sufficiently selective in their action and can often block the beneficial effects of constitutive NO activity. None of these are safe enough to give to humans.

It is possible that in adults, a low-grade expression of iNOS activity may be useful in normal bone physiology. Thus, although modulation of NOS activity has important therapeutic implications in bone biology and pathology, much research is still required at this stage. Continued investigation of NOS gene knockouts, together with developments in the generation of more selective NOS inhibitors and NO donor compounds, should provide more information on the cellular targets and mechanisms of action of NO.

CONCLUSIONS

The predominant NOS isoform expressed by bone tissues is eNOS. iNOS is expressed in inflammatory and other pathological situations in osteoblasts, osteocytes, and in osteoclasts. eNOS is also expressed widely in vascular tissues within the bone, and consequent generation of lower levels of NO is likely to interact with bone cells. Synthesis of NO by these cells is stimulated by a variety of signals including hormones, cytokines, growth factors, fluid shear stress, and mechanical loading, resulting in a number of distinct physiological and pathophysiological responses (see Figs. 12, 20, 33, and 34). Nitric oxide donor compounds such as nitroglycerin and nitrates are safe and highly cost-effective agents. These compounds have been clinically used in humans for decades and are well tolerated; headaches are the only demonstrable adverse effects, which depend on the dose and the route of administration.

Furthermore, NO has been shown to play a role in various physiological as well as pathological conditions. The most attractive novel indication for NO donor therapy is the prevention and treatment of osteoporosis in men and women. In this regard a phase III randomized, double blind, control clinical study has just been completed (NOVEL clinical study). Recent research and developments have created the possibility of using NO donor compounds and designing new complex NO compounds capable of delivering NO directly into target tissues or to the bloodstream more efficaciously in a controlled or pulsatile manner. If a NO donor is proved to be effective in prevention of bone loss and, perhaps reduction of fracture risks, it may become a widely used, safe, and quite cost-effective therapeutic agent to combat osteoporosis. Figure 36 summarizes the current knowledge of response of BMD to

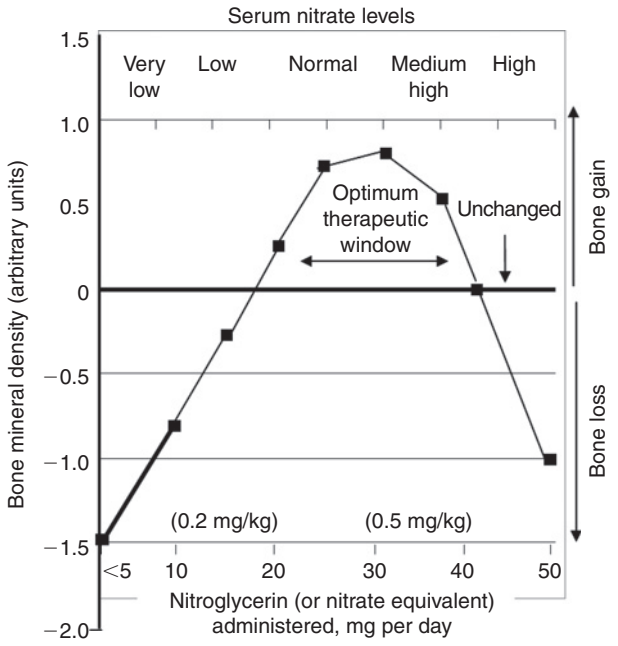

FIGURE 36 Diagrammatic representation of the BMD response to various doses of nitrates and nitroglycerine used in current clinical practice. This demonstrates the narrow therapeutic window for nitroglycerine and nitrates in general that should be used in enhancing human skeletal health (i.e., to improve BMD and decrease fractures).

various doses of nitroglycerine (or nitrate equivalents) in animals and in humans.

Physiology

At low concentrations NO, generally as a result of eNOS activity, stimulates osteoblast and osteocyte activity and keeps the osteoclast-mediated bone resorption under control. eNOS-dependent NO generation stimulates osteoblast replication and differentiation *in vitro*. Similar effects are evident *in vivo*, where NO facilitates fracture healing and is also involved as a second messenger in mechanical stress-induced bone formation. Perhaps most important, NO is significant in mediating the osteogenic effects of sex-steroid hormones, in particular estradiol (Wimalawansa, 2007). It is possible that NO also modulates osteocyte activities such as mechanical and shear-stress-induced bone formation.

Pathophysiology

Disruption of eNOS activity, as occurs following estrogen deficiency, can contribute to reduction in bone formation and enhanced bone resorption, leading to the development of osteoporosis. Inflammation-induced activation of iNOS expression and activity is also associated with the development and progression of cartilage and bone destruction that characterize inflammatory arthritis.

In summary, at physiological NO concentrations (i.e., premenopausal level), the balance of bone metabolism and bone homeostasis changes in favor of formation by stimulating osteoblast replication and differentiation, and in parallel, inhibiting osteoclast action. Lower concentrations of NO in bone tissue, as is the case in postmenopausal women, is likely to be one of the causes of bone loss that can be rectified with estrogen—or perhaps with NO replacement therapy, because the beneficial effects of estrogen in bone are mediated via NO/cGMP pathway (Wimalawansa *et al.*, 1996). High local concentrations of NO, on the other hand, whether it is endogenous (such as in rheumatoid arthritis where iNOS is induced) or exogenous (high doses of exogenous administered nitrates over a longer period of time), are likely to cause damage to bone and cartilage tissues. With this wide range of functions, there are multiple opportunities for therapeutic interventions using the NO-cGMP pathway. However, this has so far not been adequately investigated, in part because of the lack of safe NOS inhibitors, and, more important, the lack of funds to conduct research in the area. The latter is simply due to the fact that the NO donor therapies are relatively inexpensive, and thus pharmaceutical companies are not interested in developing these NO compounds as therapeutic agents for prevention and treatment of osteoporosis. As a result, though the modulation of NO synthesis or NO supplementation as a therapeutic agent for prevention and treatment of metabolic bone diseases such as osteoporosis (and arthritis) and for fracture healing, as well as for reducing the occurrence of osteoporotic fractures, seems feasible, these therapeutic interventions remain to be exploited.

INTRODUCTION

Over the past several years application of powerful molecular biology techniques has provided a wealth of new information and insights into the development of tumors. The purpose of this chapter is to review this new information as it relates to our understanding of parathyroid tumorigenesis. Parathyroid hyperfunction is found in several disease states including sporadic primary and secondary hyperparathyroidism and familial disorders such as the multiple endocrine neoplasia (MEN) syndromes.

Primary hyperparathyroidism is a common disorder characterized by hypercalcemia caused by an excessive secretion of parathyroid hormone (PTH). This is due to both an increased parathyroid gland mass and a resetting of the control of PTH secretion from the parathyroid cell by the ambient calcium concentration. Patients with primary hyperparathyroidism have one or more enlarged parathyroid glands with a single, benign adenoma occurring in almost 85% of cases; multiple hypercellular glands are present in about 15% of patients (Black and Utley, 1968; Castleman and Roth, 1978). In modern series, parathyroid carcinoma occurs in less than 1% of cases, and the ectopic secretion of PTH from nonparathyroid tumors is extremely rare.

The refractory state of secondary hyperparathyroidism, as seen, for example, in patients with uremia, and tertiary hyperparathyroidism (Galbraith and Quarles, 1994) are characterized by hyperfunctioning parathyroid tissue that no longer responds appropriately to physiological regulators such as ambient calcium and 1,25-dihydroxyvitamin D [1,25$(OH)_2$D].

Hyperparathyroidism may also occur as part of familial syndromes, such as multiple endocrine neoplasia types 1 and 2 (MEN1 and 2), the hereditary hyperparathyroidism and jaw tumor (HPT-JT) syndrome, and familial hypocalciuric hypercalcemia (FHH) and neonatal severe hyperparathyroidism (NSHPT).

MOLECULAR ONCOLOGY

Cancer cells contain genetic damage to key growth-regulating genes that directly contributes to the abnormal neoplastic phenotype. A cardinal feature of cancers is their clonal, or monoclonal, nature. They arise from a single precursor cell that has a selective growth advantage over normal cells and whose progeny outgrow them and ultimately make up the tumor. Typically, certain identical patterns of DNA damage are seen in each cell of such a tumor, indicating that important underlying genetic events occurred early before major proliferation or clonal expansion took place. The clonality of tumors also implies that these events occur only rarely in the large population of cells making up a tissue.

It is important to note the molecular heterogeneity underlying the development of neoplasia (Vogelstein and Kinzler, 2004). Generally, accumulating damage to several distinct genes, within the same cell, is required for the expression of the complete neoplastic phenotype. Whereas certain genes are implicated in tumors of only one or a few cell types, other genes may be involved in many different types of tumor. However, in most cases, no single gene will be both a necessary and a sufficient neoplastic agent. More commonly, the emergence of a particular tumor type may relate to disruption of specific biochemical pathways, which can be achieved by different combinations of mutated genes resulting in similar cellular and clinical consequences.

Clonal DNA damage in two groups of normal cellular genes contributes to the development of neoplasia. These are protooncogenes and tumor suppressor genes. Protooncogenes are often involved in the physiological

Principles of Bone Biology, 3rd Edition

control of cellular growth, proliferation, or differentiation. Conversion of a protooncogene to an "oncogene" is caused by a deregulation of the expression of its protein product or by formation of an intrinsically abnormal product. The products of tumor-suppressor genes normally restrain cellular proliferation and their gene inactivation contributes to neoplasia. Protooncogenes can be activated by a variety of mechanisms, including chromosome translocations or inversions, point mutations, proviral insertions, or gene amplification. Inactivation of tumor-suppressor genes can occur by point mutation or deletion, for example.

CLONALITY OF PARATHYROID TUMORS

The issue of the clonal status of parathyroid tumors was examined using an X-chromosome inactivation method, evaluating DNA polymorphisms, and by the direct demonstration of monoclonal DNA alterations in parathyroid adenomas (Arnold *et al.,* 1988). It was determined that most, if not all parathyroid adenomas are monoclonal (Arnold *et al.,* 1988; Arnold and Kim, 1989; Friedman *et al.,* 1989; Bystrom *et al.,* 1990; Orndal *et al.,* 1990), emphasizing that they are true neoplastic outgrowths of a single abnormal cell. This is consistent with the general experience that surgical removal of such tumors is curative of the disease. As would be expected, parathyroid carcinomas are also monoclonal (Cryns *et al.,* 1994b). In addition, monoclonal parathyroid tumors are seen in familial MEN1 (Friedman *et al.,* 1989; Thakker *et al.,* 1989; Bystrom *et al.,* 1990), in nonfamilial, sporadic, primary parathyroid hyperplasia (Arnold *et al.,* 1995), and in the refractory secondary or tertiary parathyroid hyperplasia of uremia (Arnold *et al.,* 1995; Falchetti *et al.,* 1993). Therefore, even in parathyroid hyperplasia, which begins with a stimulus for generalized, polyclonal, parathyroid cell proliferation affecting all of a patient's glands, monoclonal tumors can arise, at least in some of the glands. Such tumors may be more autonomous and exhibit a more marked dysregulation of PTH secretory control than the hyperplastic, polyclonal glands within the same patient.

An important goal is to identify the specific protooncogenes and tumor suppressor genes that are clonally activated or inactivated, respectively, in parathyroid tumors. Several successes in approaching this aim have already been achieved.

GENETIC DERANGEMENTS IN BENIGN PARATHYROID TUMORS

DNA rearrangements are some of the best characterized clonal oncogenic abnormalities, and they frequently involve juxtaposition of cellular protooncogenes with regulatory sequences of other genes. This then results in overexpression or deregulated expression of the protooncogene,

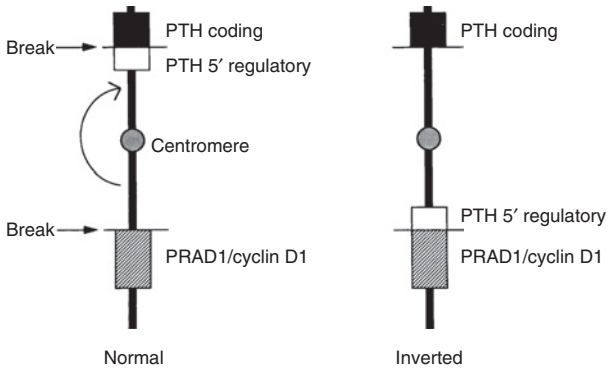

FIGURE 1 Schematic diagram of rearrangement of chromosome 11 in parathyroid tumors. In a subset of parathyroid adenomas a pericentrometric inversion of chromosome 11 is the most likely cause of the observed rearrangement involving the *PTH* gene and the *PRAD1* gene. Each tumor has another copy of chromosome 11 which bears a normal *PTH* gene. Reproduced with permission from Arnold (1993).

converting it to an oncogene. To date the only oncogene solidly implicated in parathyroid neoplasia is *cyclin D1/PRAD1*.

Cyclin D1/PRAD1

A subset of parathyroid adenomas contains a tumor-specific DNA rearrangement that separates the 5′ regulatory region of the *PTH* gene from its protein coding exons (Fig. 1). These tumor cells still possess one intact copy of the *PTH* gene, which accounts for expression of PTH by the tumor. The non-*PTH* gene sequences adjacent to the breakpoint were originally cloned from a genomic DNA library (Arnold *et al.,* 1989) and revealed a then-novel putative oncogene first called *PRAD1*, located on chromosome band 11q13. Currently, *PRAD1* is most often called *cyclin D1* or *CCND1* and is now fully established as a key human oncogene. The normal chromosomal *cyclin D1* gene contains five exons and four introns spanning approximately 15 kb and is transcribed in a centromeric to telomeric direction (Motokura and Arnold, 1993). In the cases of *PTH/cyclin D1* rearrangements characterized to date, the 11q13 breakpoints have occurred from 1 to 15 kb upstream of *cyclin D1* exon 1 with the *PTH* gene 5′ regulatory region and noncoding exon 1 placed upstream of the breakpoint (Friedman *et al.,* 1990; Rosenberg *et al.,* 1991) (Fig. 2). The overexpression of the *cyclin D1* gene is likely to be caused by its aberrant placement in close proximity to the strong tissue-specific enhancer elements of the *PTH* gene (Rosenberg *et al.,* 1993; Mallya *et al.*, 2005).

On the order of 5% of parathyroid adenomas have been shown to contain an activated form of the *cyclin D1* oncogene. However, rearrangement breakpoints on 11q13 associated with overexpression of *cyclin D1* in other tumors can occur more than 120 kb upstream of the gene (Williams *et al.,* 1993; Vaandrager *et al.,* 1996, 1997), and such rearrangement

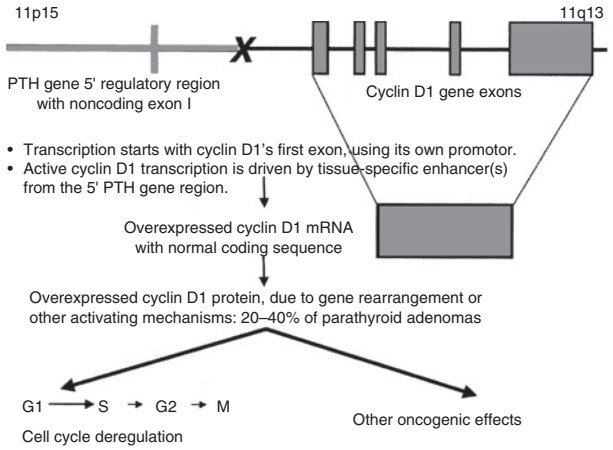

FIGURE 2 Diagram of directly observed molecular structure of the *PTH/cyclin D1 (PRAD1)* DNA rearrangement and its functional consequences. Modified with permission from Arnold (1993).

would have been missed by the Southern blot approach used in initial studies of parathyroid tumors. In addition, it seems likely that cyclin D1 expression could be deregulated in some parathyroid tumors by rearrangement with genes other than the *PTH* gene. Thus, previous studies may not have revealed the full frequency with which *cyclin D1* deregulation occurs in parathyroid neoplasia. Indeed, studies assessing the cyclin D1 protein product have revealed its overexpression in 20% to 40% of parathyroid adenomas (Hsi *et al.,* 1996; Vasef *et al.,* 1999; Tominaga *et al.,* 1999). This overexpression may occur more commonly by a *trans*-acting regulatory disturbance like that observed for *cyclin D1* overexpression in a variety of human cancer cells (Hosokawa and Arnold, 1998) rather than a clonal mutation in one gene allele. However achieved by the cell, such overexpressed cyclin D1 is a potent driver of abnormal parathyroid cell proliferation (Imanishi *et al.,* 2001; Mallya *et al.,* 2005).

Cyclin D1 is a 295-amino-acid protein homologous to various members of the cyclin family (Motokura *et al.,* 1991). Cyclins play important roles in regulation of cell cycle progression, and human cyclins have been grouped into several types based upon sequence similarities (Pestell *et al.,* 1999). Each cyclin appears to regulate the cell cycle at a specific time point by binding to and activating cyclin-dependent kinases (CDKs; Sherr, 1996). Expression of these cyclins is cell cycle phase-dependent and controlled by both transcriptional and posttranscriptional mechanisms. Cyclin D1 is a key regulator of the critical G1–S phase transition in the cell cycle. In so doing, its major cdk partners are cdk4 or cdk6, depending upon the tissue type examined. It may also be that cyclin D1 has other cellular functions, mediated through non-cdk-dependent pathways (Bernards, 1999; Arnold and Papanikolaou, 2005; Ewen and Lamb, 2004; Fu *et al.*, 2004).

Although genetic evidence for *cyclin D1*'s role as a parathyroid oncogene is incontrovertible, animal modeling has additionally provided direct experimental evidence that cyclin D1 overexpression is capable of driving parathyroid tumorigenesis. A transgenic mouse model for parathyroid neoplasia has been generated (Imanishi *et al.,* 2001) in which the *cyclin D1* gene is under the control of the regulatory region of the *PTH* gene, mimicking the rearrangement and resultant overexpression observed in human tumors. These mice develop parathyroid enlargement and increased serum calcium and PTH levels, and their study has illuminated the relationship in hyperparathyroidism between abnormal parathyroid proliferation and the biochemical phenotype (Imanishi *et al.,* 2001; Mallya *et al.,* 2005). Finally, cyclin D1 is being vigorously pursued as a target for antineoplastic therapy, primarily because of its major role in human breast cancer, lymphoma, and squamous cell cancers. If such efforts are successful, an anti-cyclin D1 agent would also be expected to have efficacy against the cyclin D1-driven subset of parathyroid tumors.

Tumor Suppressor Genes: MEN1

Inactivation of both alleles of a tumor suppressor gene, often by mutation or deletion, is required to completely deplete the gene's antineoplastic product. A common inactivation mechanism is somatic deletion of a substantial portion of chromosomal DNA that includes the relevant gene. This is revealed by a loss of heterozygosity of DNA markers in tumor DNA relative to normal DNA of the same individual. Identification of regions of chromosomes that are clonally and nonrandomly lost in parathyroid adenomas can indicate the general locations of tumor suppressor genes active in parathyroid cells. Our present state of knowledge in this regard shows that the overwhelming majority of parathyroid adenomas (and probably all) have at least one such clonal defect.

The MEN1 syndrome, which is inherited in an autosomal dominant fashion, is characterized classically by tumors of the parathyroids, pancreatic islets, and anterior pituitary. Several years ago, it was established by genetic mapping studies in families affected by MEN1 that the gene responsible is on chromosome 11q13 (Larsson *et al.,* 1988). Early evidence that the *MEN1* gene is a tumor suppressor gene was provided by the demonstration of somatic genetic alterations in MEN1 tumors that inactivate one allele of a gene region at 11q13 and so reveal the inherited *MEN1* mutation on the other allele (Fig. 3). In fact, allelic loss of polymorphic marker DNAs from this region of chromosome 11 has been found in the majority of MEN1-associated tumors including those of the parathyroid.

The *MEN1* gene was identified by positional cloning (Chandrasekharappa *et al.,* 1997; European Consortium on MEN1, 1997). More than 400 independent germline and somatic mutations scattered throughout the protein-coding

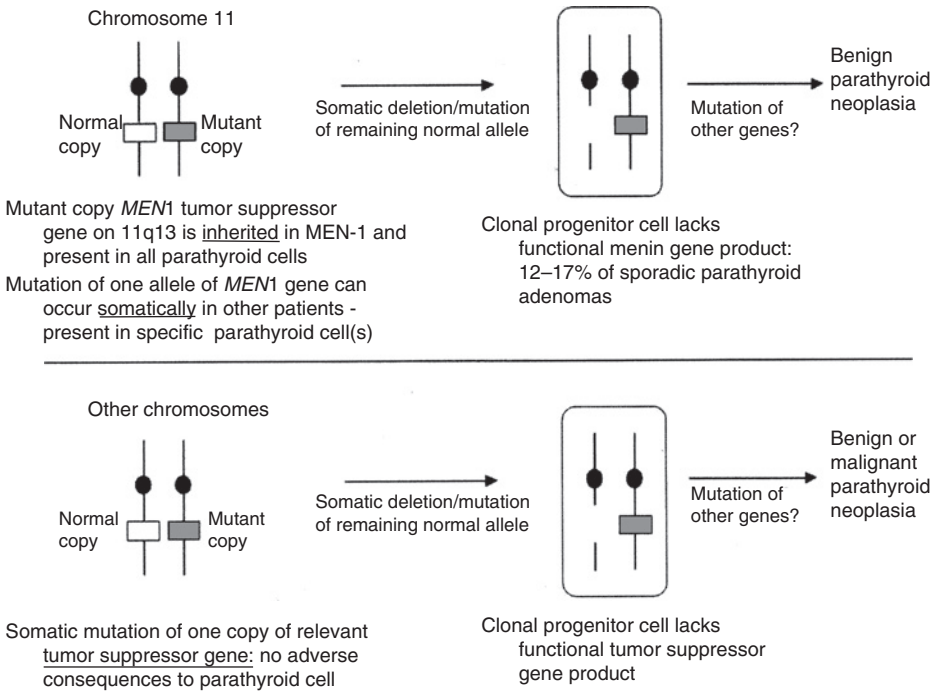

FIGURE 3 Schematic diagram illustrating the established (for *MEN1*) and hypothesized roles of inactivation of classic tumor suppressor genes as contributory mechanisms in parathyroid neoplasia. A similar scheme applies to the role of the *HRPT2* tumor suppressor gene in the pathogenesis of parathyroid carcinoma. Modified with permission from Arnold (1993).

region have been identified. There is no correlation between genotype, meaning the specific location of mutation within the gene, and phenotype. Somatic mutations have been found to a variable extent in parathyroid adenoma as well as gastrinoma, insulinoma, lung carcinoid, and anterior pituitary tumors. Over 80% of the mutations are clearly inactivating, leading to a truncated product. This would be consistent with *MEN1* acting as a tumor suppressor gene and a lack of the menin protein caused by the loss of both alleles leading to tumor development. The human gene encodes a 610-amino-acid protein. Two nuclear localization signal sequences are present at the COOH-terminal portion of the menin protein, which is predominantly located in the nucleus (Guru *et al.,* 1998; Kaji *et al.,* 1999). The first protein shown to be a menin-interacting protein was the activator protein 1 factor, JunD, with resultant downregulation of JunD-activated transcription (Agarwal *et al.,* 1999). Because JunD is antimitogenic, in contrast to other Jun and Fos family members, and menin is a tumor suppressor, this appeared to be paradoxical. Further studies *in vitro* have suggested that the functions of JunD as a growth suppressor require interaction with menin, and that JunD is a growth promoter if menin is absent or inactive (Agarwal *et al.*, 2003). The level of menin changes throughout the cell cycle. Pituitary cells synchronized at the G1–S-phase boundary express menin at a lower level than G0–G1-synchronized cells (Kaji *et al.,* 1999). The expression of menin increases as the cell enters S phase, at which time JunD expression also increases. Cells synchronized at the G2–M phase express lower levels of menin.

Menin upregulates the cyclin-dependent kinase inhibitors, p18 and p27, important for cell-cycle regulation (Karnik *et al.*, 2005; Milne *et al.*, 2005). Menin re-expression in *Men1*-deficient cells blocks the transition from G0/G1 to S phase of the cell cycle and increases apoptosis (Hussein et al, 2007). Mice dually deficient in p18 and p27 develop a range of endocrine tumors representing those found in MEN1 and MEN2 syndromes (Franklin *et al.*, 2000).

The frequency of *MEN1* mutations in several kindreds representing a variant of MEN1 in which only parathyroid and pituitary tumors develop is very low (~10%) versus typical MEN1 kindreds (~75%). In one case of this MEN1 variant, in which *MEN1* mutation was not detected, a germline mutation of the *CDKN1B* gene encoding p27 was identified (Pellegata *et al.*, 2006). However, examination of 34 index cases from several other MEN1 variant kindreds failed to identify further mutations in p27 (Ozawa *et al.*, 2007). Hence, the main causes of this MEN1 variant remain unknown.

Menin is a component of particular histone methyltransferase complexes that control *Hox* gene expression important for early development, and cell proliferation and differentiation (Hughes *et al.*, 2004; Milne *et al.*, 2005; Yokoyama *et al.*, 2004). It may be involved in telomere biology (Lin and Elledge, 2003; Suphapeetiporn *et al.*, 2002) and DNA replication and repair (Jin *et al.*, 2003; Sukhodolets *et al.*, 2003). Menin interacts with several transcription factors including Smads, JunD, and NF-κB and modulates their activities (see Poisson

et al., 2003; Balogh *et al.*, 2006; Dreijerink *et al.*, 2006, for further details of menin-interacting proteins). Menin is a Smad3-interacting protein, and inactivation of menin blocks transforming factor-beta (TGF-β) and activin signaling, antagonizing their growth inhibitory properties (as well as inhibition of prolactin expression) in anterior pituitary cells (Kaji *et al.*, 2001; Lacerte *et al.*, 2004). In cultured parathyroid cells, menin inactivation achieved by menin antisense oligonucleotides leads to loss of TGF-β inhibition of cell proliferation and PTH secretion (Sowa *et al.*, 2004). Moreover, TGF-β did not affect (decrease) the proliferation and PTH production of parathyroid cells from MEN1 patients (Sowa *et al.*, 2004; Naito *et al.*, 2006). Loss of various TGF-β signaling pathway components by genetic or epigenetic means is common in cancer and is likely to be important in MEN1 tumorigenesis (Hendy *et al.*, 2005) despite the fact that, thus far, no acquired clonal mutations, insertions, or microdeletions in the Smad3 gene have been detected in a series of sporadic parathyroid adenomas and enteropancreatic tumors (Shattuck *et al.*, 2002).

Mice heterozygous for genetic ablation of the *Men1* gene develop endocrine tumors similar to human MEN1 patients (Crabtree *et al.*, 2001; Bertolino *et al.*, 2003). Parathyroid gland-specific deletion of the mouse *Men1* gene results in parathyroid neoplasia and hypercalcemic hyperparathyroidism (Libutti *et al.*, 2003). In mice (and in humans) tissue expression of menin is widespread throughout development and into adult life and occurs early in fetal life. Therefore, menin expression is not restricted to those cells and tissues that are affected in MEN1, and haploinsufficiency of menin is well tolerated in many tissues. In mice, homozygous deletion of *Men1* is embryonic lethal. The affected fetuses die at mid-gestation with defects in multiple organs. This may reflect defective TGF-β signaling or Hox gene expression.

About 20% of the menin mutations are missense and, although found throughout the entire sequence, are prevalent within amino acids 149–218 encoded by exon 3. This is in a part of the molecule thought to be important for interaction with transcriptional regulators Smad3 and JunD but not NF-κB. Although it might have been anticipated that analysis of the missense mutations would provide insight into which few of the many proteins that menin interacts with are critical for MEN1-tumorigenesis, for the most part this promise has yet to be fulfilled. To a large extent, this is because the missense menin mutants are markedly unstable and are targeted to the ubiquitin-proteasome pathway (Yaguchi *et al.*, 2004; Canaff *et al.*, 2006).

Putative Oncogenes and Tumors Suppressor Genes

Comparative genomic hybridization—a molecular cytogenetic technique in which the entire tumor genome is screened for chromosomal gains and/or losses—has identified amplified regions on several chromosomes (most consistently 7, 16, and 19; Fig. 4). These observations suggest the presence of novel parathyroid oncogenes (Palanisamy *et al.*, 1998; Agarwal *et al.*, 1998; Farnebo *et al.*, 1999; Dwight *et al.*, 2002) in these locations, which remain to be identified.

Besides loci on chromosome 11, several other regions of nonrandom clonal allelic loss have been documented in parathyroid adenomas, pointing to the location of novel tumor suppressor genes. This finding of the involvement of multiple chromosomal regions, which include 1*p* (Cryns *et al.*, 1995; Williamson *et al.*, 1997), 1*q*, 6*q*, 9*p*, and 15*q* (Tahara *et al.*, 1996a, 1996b), emphasize the molecular heterogeneity of parathyroid adenomatosis.

Comparative genomic hybridization has confirmed the chromosomal losses identified by loss of heterozygosity analysis (allelotyping) (Palanisamy *et al.*, 1998; Agarwal *et al.*, 1998; Farnebo *et al.*, 1999; see Fig. 4). One common defect uncovered to date involves allelic loss on chromosome 1*p* (Cryns *et al.*, 1995). Interestingly, chromosome 1*p* loss occurs in several other neoplasms including medullary thyroid carcinomas and pheochromocytomas which occur in association with the MEN2A inherited cancer syndrome, of which parathyroid tumors are also a part. Benign parathyroid tumors are found in 10% to 20% of MEN2A patients. This pattern of allelic loss is consistent with the existence of a tumor suppressor gene(s) on 1*p*, whose loss or inactivation is pathogenetically important. Numerous candidate genes are present in this region, but the involvement of any of them in the development of parathyroid or other types of tumors remains to be established. Some candidates on 1*p*, such as genes for the *p*18 cyclin-dependent kinase inhibitor and *RAD54*, have been excluded as parathyroid tumor suppressors (Tahara *et al.*, 1997; Carling *et al.*, 1999a). Mutations of candidate genes within the 9*p* region for the *p*16 and *p*15 cyclin-dependent kinase inhibitors do not appear to be involved in parathyroid tumorigenesis (Tahara *et al.*, 1996b). A major goal for future work is the identification of the entire constellation of oncogenes and tumor suppressor genes that contribute to the development of parathyroid adenomatosis.

It had been assumed that primary parathyroid hyperplasia and uremic refractory secondary hyperparathyroidism involved polyclonal, nonneoplastic cellular proliferation. However, the monoclonal nature of a substantial number of the "hyperplastic" tumors from such patients was demonstrated by X-chromosome inactivation analysis (Arnold *et al.*, 1995). In addition, allelic loss of chromosome 11 markers and/or *MEN1* gene inactivation has been demonstrated in only a few of these tumors (Falchetti *et al.*, 1993; Arnold *et al.*, 1995; Imanishi *et al.*, 1997, 1999a). Furthermore, cyclin D1 overexpression does not appear to be common in these uremia-associated tumors (Vasef *et al.*, 1999; Tominaga *et al.*, 1999), nor is mutation of the

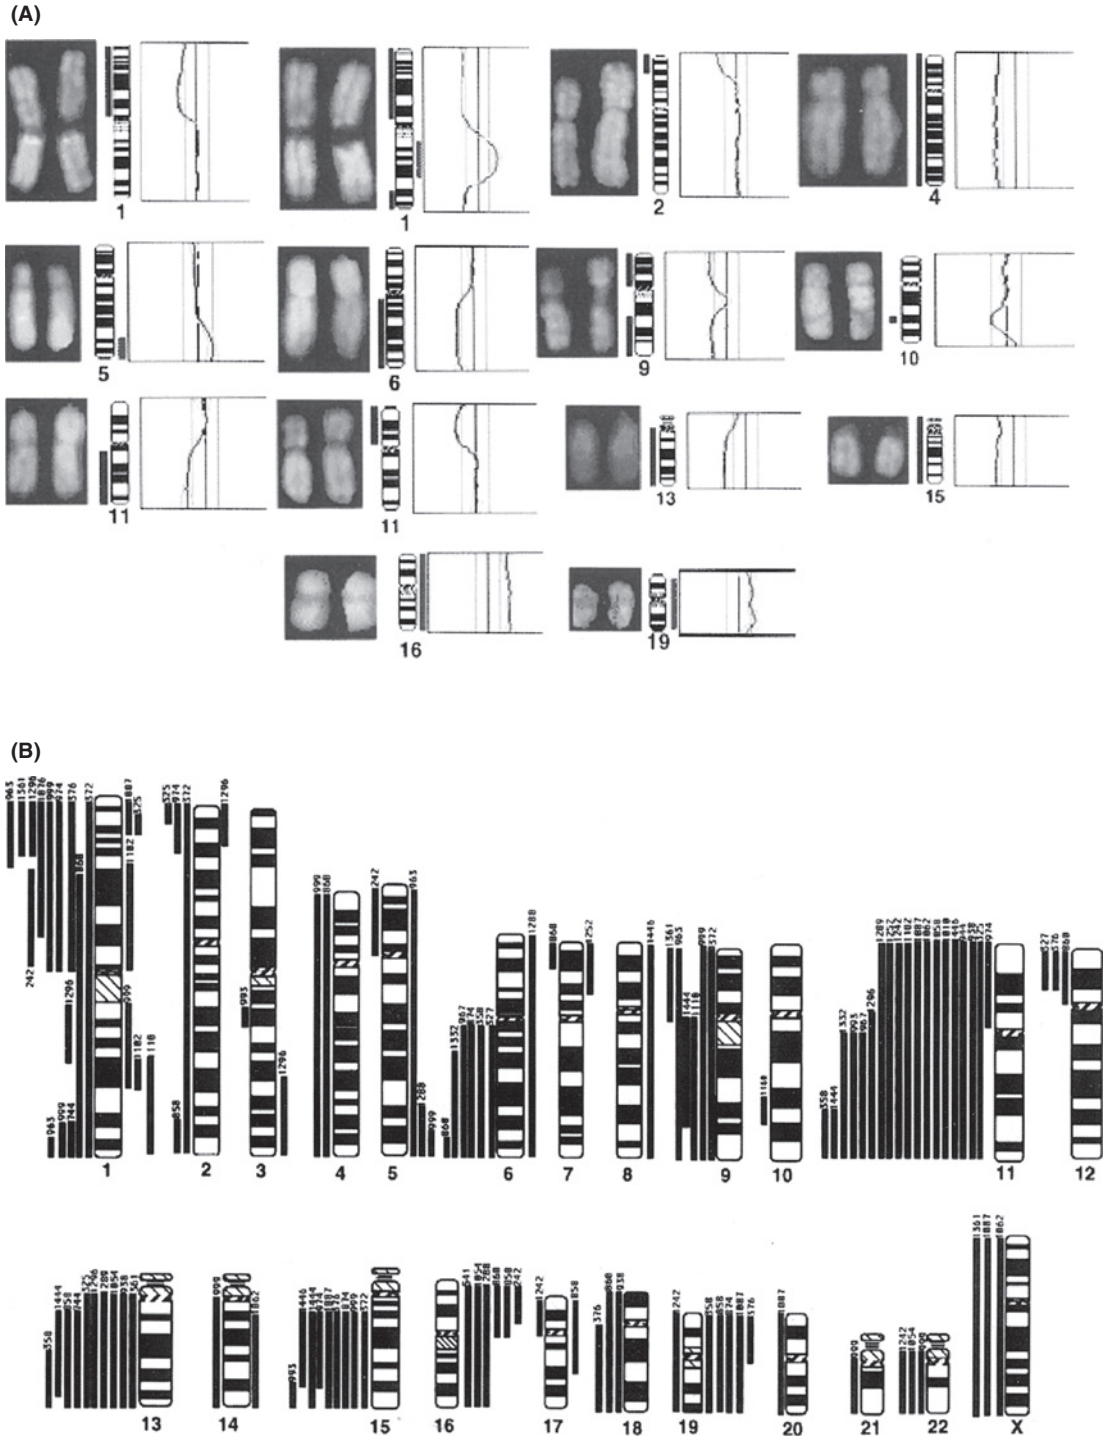

FIGURE 4 Novel chromosomal abnormalities identified by comparative genomic hybridization (CGH) in parathyroid adenomas. (**A**) Representative CGH results in parathyroid adenomas. Individual examples of fluorescent ratio profiles (*right*) and digital images (*left*) of chromosomes with recurrent gains or losses. The red vertical bar on the left side of a chromosome ideogram (*middle*) indicates the region of loss, and the green vertical bar on the right side of an ideogram indicates the region of gain. (**B**) DNA copy number changes in 53 parathyroid adenomas. Summary of all gains and losses detected by CGH. The vertical bars on the left side of the chromosome ideograms indicate losses, and those on the right side indicate gains of the corresponding chromosomal region for each individual tumor, as numbered. Adapted with permission from Palanisamy *et al*. (1998).

vitamin D receptor (*VDR*) gene, despite the low expression of this parathyroid cell antiproliferative factor in such tumors (Brown *et al.,* 2000). Neoplastic transformation of preexisting polyclonal hyperplasia involving genes not yet implicated in parathyroid tumorigenesis is thus likely to play an important role in these disorders.

Further Genetic Aspects

Some genes that play an important role in the pathogenesis of other tumor types might have been expected to be involved in the pathogenesis of benign parathyroid adenomas. However, candidate genes such as *ras* (Friedman *et al.,* 1990), *p53* (Yoshimoto *et al.,* 1992; Cryns *et al.,* 1994a; Hakim and Levine, 1994), and *RB* (Cryns *et al.,* 1994b) seem rarely, or not at all, to contribute to the development of benign adenomas. A target of the Wnt pathway, β-catenin, encoded by the *CTNNB1* gene that is implicated in other forms of tumorigenesis is a candidate for involvement in parathyroid neoplasia. Although one study reported stabilizing missense *CTNNB1* mutations in 3 of 20 parathyroid adenomas and increased β-catenin expression (Bjorklund *et al.,* 2007), this has not been found in other studies (Semba *et al.*, 2000; Ikeda *et al.*, 2002; Costa-Guda and Arnold, 2007). Therefore, the present view is that β-catenin's involvement in the initiation or early progression of parathyroid adenomatosis remains to be established (Simonds, 2007).

The development of primary hyperparathyroidism occurs with increased frequency in individuals exposed to ionizing radiation of the neck. Thus mutations in genes involved in DNA repair and recombination may contribute to parathyroid tumorigenesis irrespective of the actual involvement of irradiation. Such candidates include the *RAD51* and *RAD54* genes on chromosomes 15*q* and 1*p,* respectively, within regions that demonstrate allelic loss in parathyroid adenomas. However, no evidence for a role of somatic inactivation of these particular genes in parathyroid neoplasia has been found (Carling *et al.,* 1999a, 1999b). In some cases, those genes responsible for the rare inherited predisposition to a particular tumor also play a role in the development of the more common sporadic type. The *MEN1* gene, as detailed earlier, has proved to be such an example. Germline gain-of-function mutations in the *RET* protooncogene cause MEN2 (Eng *et al.,* 1996). This made the *RET* gene, which encodes a tyrosine kinase receptor, a candidate for involvement in nonfamilial hyperparathyroidism. However, although MEN2-type *RET* mutations have been implicated in the pathogenesis of some sporadic medullary thyroid carcinomas and pheochromocytomas, there is no evidence of these *RET* mutations in sporadic parathyroid adenomas (Padberg *et al.,* 1995; Pausova *et al.,* 1996; Williams *et al.,* 1996; Komminoth *et al.,* 1996; Kimura *et al.,* 1996). It was demonstrated that *RET* is expressed in both MEN2A parathyroid tumors and in sporadic adenomas (Pausova *et al.,* 1995, 1996; Kimura *et al.,* 1996). This suggests that parathyroid disease is an integral part of the MEN2A syndrome, but that MEN2 mutations in *RET* rarely, if ever, play a role in the pathogenesis of sporadic parathyroid tumors. Mutations within the coding region of glial cell-derived neurotrophic factor (GDNF), one of the RET ligands, do not appear to play a role in the genesis of MEN2 neoplasms or in sporadic neuroendocrine tumors such as parathyroid adenomas (Marsh *et al.,* 1997). An interesting candidate parathyroid tumor suppressor, *VDR*, is also lacking in evidence for a direct pathogenetic role by specific clonal mutation (Brown *et al.,* 2000; Samander and Arnold, 2006).

Familial hypocalciuric hypercalcemia (FHH), also known as familial benign hypercalcemia, is an autosomal dominant disorder that is characterized by enhanced parathyroid function due to reduced sensitivity to extracellular calcium (Marx *et al.,* 1981; Law et al., 1985). Mutations in the parathyroid calcium-sensing receptor (*CASR*) gene, located on chromosome 3*q*13.3-*q*21 (Janicic *et al.,* 1995a), are a primary cause of this disorder (Pollak *et al.,* 1993; Janicic *et al.,* 1995b; Hendy *et al.,* 2000; D'Souza-Li *et al.,* 2002; Pidasheva *et al.*, 2005, 2006). Moreover, individuals homozygous for such mutations present with neonatal severe hyperparathyroidism (NSHPT) with marked parathyroid hypercellularity (Pollak *et al.,* 1994), and members of some FHH kindreds atypically manifest hyperparathyroidism and surgical removal of the adenoma or hyperplastic glands is generally curative (Soei *et al.,* 1999; Carling *et al.,* 2000). Affecteds of some kindreds presenting with FIHP (with either frankly elevated serum PTH levels and/or hypercalciuria) are heterozygous for inactivating *CASR* mutations (Simonds *et al.*, 2002; Warner *et al.*, 2004). The apparent link between parathyroid calcium-sensing and proliferative pathways suggested that somatic alterations in the *CASR* gene could be tumorigenic in sporadic parathyroid tumors. However, several studies have failed to document somatic mutation of the *CASR* gene as a significant factor in parathyroid tumorigenesis (Hosokawa *et al.,* 1995; Thompson *et al.,* 1995; Degenhardt *et al.,* 1998; Cetani *et al.,* 1999). It has been reported that more than half of the parathyroid glands of patients with primary and severe uremic secondary hyperparathyroidism show reduced CASR expression (Kifor *et al.,* 1996; Farnebo *et al.,* 1997, 1998; Gogusev *et al.,* 1997; Chikatsu *et al.,* 2000). Thus, despite somatic mutation of the *CASR* gene rarely if ever contributing to the pathogenesis of sporadic parathyroid tumors, mutations in growth-deregulating genes may secondarily alter the calcium set point, perhaps in part by decreasing expression of the CASR. It can be noted that because *CASR* gene transcription is upregulated by $1,25(OH)_2D$ (Canaff and Hendy, 2002), and the clinical severity of FHH-affected individuals can be exacerbated by vitamin D deficiency (Zajickova *et al.*, 2007), reduced levels of the VDR observed in parathyroid tumors may contribute to the decreased CASR expression. A mutation

in a gene involved in calcium set-point control might secondarily stimulate proliferation until the serum calcium concentration surpasses the abnormal set point (Parfitt 1994). Data indicating that the growth rate of parathyroid tumors is generally low, but must have been higher earlier in their development (Parfitt *et al.,* 1994), are consistent with this hypothesis. Interestingly, calcium regulatory abnormalities found in transgenic mice with cyclin D1-driven hyperparathyroidism show that mutations in "set-point" genes need not be the primary instigators in this disease (Imanishi *et al.,* 2001; Mallya *et al.*, 2005).

The syndrome of hereditary hyperparathyroidism and jaw tumors (HPT-JT) is an uncommon autosomal dominant disorder inherited with incomplete penetrance and characterized by early-onset recurrent parathyroid tumors (90%) and fibrous ossifying tumors of the mandibula or maxilla (30%). Less frequent renal lesions (10%) include Wilms' tumor, hamartomas, and polycystic kidney disease (Jackson *et al.*, 1990; Chen *et al.*, 2003). Uterine tumors include adenosarcoma, but benign adenofibromas and leiomyomas are more common (Bradley *et al.*, 2005). Parathyroid carcinoma occurs at increased frequency (15%) in this syndrome. In contrast to the multiglandular enlargement typically found at presentation in other classical forms of inherited hyperparathyroidism, a solitary, enlarged, and often cystic gland may be found in an HPT-JT patient. Normocalcemia is often achieved after removal of the tumor; however, recurrence is well documented. In a large group of families the HPT-JT trait was linked to 1q21-32 (Szabo *et al.*, 1995; Hobbs *et al.*, 2002). The responsible gene, *HRPT2*, at 1q31.2, was identified by positional cloning and mutation analysis, and encodes a novel transcription factor, parafibromin, of 531 amino acids (Carpten *et al.*, 2002). Parafibromin is a widely expressed nuclear protein, and within the parathyroid gland it is reported to be in both the cytoplasmic and nuclear compartments (Woodward *et al.*, 2004). Functional analysis of the several potential nuclear localization signals (NLSs) in parafibromin is the subject of ongoing study (Hahn and Marsh, 2005; Bradley *et al.*, 2007; Lin *et al.*, 2007). Nuclear parafibromin has a proapoptotic activity (Lin *et al.*, 2007). Transfection experiments have demonstrated the ability of parafibromin to block cyclin D1 expression (Woodward *et al.*, 2004). Experimental overexpression of wild-type parafibromin in transformed cell lines inhibits cell proliferation and induces G1-phase cell-cycle arrest (Zhang *et al.*, 2006). Parafibromin HPT-JT mutants act in a dominant-negative manner to abolish the ability of wild-type parafibromin to inhibit cell growth (Zhang *et al.*, 2006). In mammalian cells parafibromin is part of an RNA polymerase II associated factor complex (Paf1) and has sequence homology to yeast Cdc73, a constituent of a protein multimer important for transcription initiation/elongation, histone methylation and RNA processing (Rozenblatt-Rosen *et al.*, 2005; Yart *et al.*, 2005). Parafibromin binds directly to the COOH-terminal part of β-catenin and transduces Wnt pathway signals into transcriptional initiation and elongation by RNA polymerase II (Mosimann *et al.*, 2006). However, because stimulation of Wnt pathway signals lead to cell proliferation, it is unclear how this proposed action of parafibromin fits with its role as a tumor suppressor.

Loss of heterozygosity (LOH) at chromosome 1q, particularly in carcinomas from HPT-JT kindreds, suggests that the two-hit hypothesis of Knudson applies to the *HRPT2* gene (Howell *et al.*, 2003; Shattuck *et al.*, 2003a; Cetani *et al.*, 2004). The most frequent genetic mechanism through which the second hit occurs—small intragenic mutations—differs from that of most other tumor suppressor genes (Weinstein and Simonds, 2003). Importantly, sporadic parathyroid carcinomas very commonly contain somatic mutations of the *HRPT2* gene (Howell *et al.*, 2003; Shattuck *et al.*, 2003a; Cetani *et al.*, 2004). Of note is the finding that some patients with apparently sporadic parathyroid carcinomas harbor germline mutations (Shattuck *et al.*, 2003a; also see later section on parathyroid carcinoma).

Familial isolated hyperparathyroidism (FIHP or HRPT1) has been defined as hereditary primary hyperparathyroidism without the association of other disease or tumors. Although listed as a distinct genetic entity, some cases presenting as FIHP have now been shown, by gene mutation analysis, to be variants of other monogenic diseases—FHH (Simonds *et al.*, 2002; Warner *et al.*, 2004), MEN1 (Carrasco *et al.*, 2004; Pannett *et al.*, 2003), or HPT-JT (Guarnieri *et al.*, 2007; Kelly *et al.*, 2006; Villablanca *et al.*, 2004; Simonds *et al.*, 2004). Despite the rarity of *HRPT2* mutations in FIHP, a personal or family history of parathyroid carcinoma in FIHP warrants consideration of germline *HRPT2* mutation status that will be useful for diagnosis and management. Identification of an *HRPT2* mutation can lead to detection and removal of potentially malignant parathyroid tumors (Kelly *et al.*, 2006; Guarnieri *et al.*, 2007).

For several other FIHP kindreds the causative gene is not known and the basis of familial hyperparathyroidism distinct from other described inherited disorders remains to be clarified. A genome-wide screen of several kindreds with FIHP has suggested a 1.7-Mb region of linkage on chromosome 2p13.3-14, and mutation analysis of candidate genes within this interval is ongoing (Warner *et al.*, 2006). In addition, one kindred has been described with apparent autosomal recessive inheritance of the hyperparathyroidism and large recurrent adenomas (Law *et al.,* 1983). The mode of inheritance in this family would set it apart from the other autosomal dominant disorders, although it may prove, with further study, to be autosomal dominant with decreased penetrance.

MOLECULAR PATHOGENESIS OF PARATHYROID CARCINOMA

As noted earlier, mutation of the *HRPT2* tumor suppressor gene was recently identified as a major contributor to parathyroid carcinoma. Such mutations are detectable in over

75% of parathyroid cancers (Shattuck *et al.*, 2003; Howell *et al.*, 2003; Cetani *et al.*, 2004), and because noncoding mutations are expected and would have escaped detection, most likely *HRPT2* inactivation occurs in essentially all cases. In addition, a sizable subset of patients with apparently sporadic parathyroid carcinoma bear unsuspected germline mutations in *HRPT2* (Shattuck *et al.*, 2003). Such patients may represent *de novo* examples, or lower penetrance variants, of the HPT-JT syndrome, and the potential opportunity for early diagnosis to prevent or cure parathyroid cancer in their family members has established a new role for genetic testing in this circumstance.

Because of the impressive genetic evidence for *HRPT2*'s role, parafibromin immunostaining is being evaluated as a potential clinical test for parathyroid carcinoma (Tan *et al.*, 2004; Gill *et al.*, 2006; Juhlin *et al.*, 2006; Cetani *et al.*, 2007). Several studies have reported virtually complete loss of nuclear immunostaining in most parathyroid carcinomas in comparison with positive staining in benign parathyroid tumors. However, because of technical and/or biological factors, not all studies yield such uniform results (Juhlin *et al.*, 2007), and the clinical use of parafibromin staining remains to be established. Interestingly, adenomas of kindreds with germline *HRPT2* mutations were also parafibromin negative, suggesting that allelic loss of parafibromin is a key step in progression to carcinoma.

The cyclin D1 oncoprotein, overexpressed in 20% to 40% of adenomas, was found to be overexpressed in 10 of 11 (91%) parathyroid carcinomas in one study (Vasef *et al.*, 1999) and in 2 of 3 in another (Hsi *et al.*, 1996). This observation raises the possibility that cyclin D1 may play a critical and consistent role in parathyroid cancers, and that patients with this disease might be considered for eventual inclusion in clinical trials once novel anti-cyclin D1 therapies have been developed. The tumor suppressor genes *p53* and *RB* have been examined for abnormalities in malignant, as well as benign, parathyroid tumors. Allelic loss of the *p53* gene has been found occasionally in parathyroid carcinomas, but direct mutations have not been described, and *p53*'s overall contribution to parathyroid cancer is minimal at best (Cryns *et al.*, 1994a; Hakim and Levine, 1994). In contrast, loss of chromosome region 13*q*, which contains *RB, BRCA2,* and other potential parathyroid tumor suppressors, is likely to be a key factor in the pathogenesis of many parathyroid carcinomas (Cryns *et al.*, 1994b; Dotzenrath *et al.*, 1996; Pearce *et al.*, 1996; Imanishi *et al.*, 1999b; Kytola *et al.*, 2000). However, the absence of detectable mutations in *RB* or *BRCA2* suggests that any role for these genes would be indirect rather than as classical tumor suppressors (Shattuck *et al.*, 2003b). Similarly, loss of putative tumor suppressor genes in genomic regions including 1*p,* 3*q,* 4*q,* and 21*q* may be involved as significant factors in malignant parathyroid tumors (Cryns *et al.*, 1995; Imanishi *et al.*, 1999b; Kytola *et al.*, 2000; Agarwal *et al.*, 1998). Specific chromosome regional gains, suggesting the involvement of oncogenes, have been found in parathyroid carcinomas by comparative genomic hybridization (Imanishi *et al.*, 1999b; Kytola *et al.*, 2000; Agarwal *et al.*, 1998), but the involved genomic locations show little consistency among the existing reports, and the results require confirmation by complementary methods. Identification of genetic lesions that are specific for the malignant phenotype are key in making a molecular diagnosis, which would aid in overcoming the well-known difficulties in distinguishing malignant versus benign parathyroid tumors histopathologically. Here, the new knowledge of *HRPT2* mutations and loss of parafibromin expression in parathyroid carcinoma represents a major step forward that could be enhanced by knowledge of additional genetic contributors to parathyroid malignancy.

ECTOPIC SECRETION OF PTH

The ectopic secretion of PTH by nonparathyroid tumors is an extremely rare cause of hyperparathyroidism. The use of modern immunometric assays for PTH that show no cross-reactivity with PTHrP, the major cause of the hypercalcemia of malignancy, combined, in some cases, with molecular analysis using specific human PTH gene probes (Hendy *et al.*, 1981; Vasicek *et al.*, 1983), has suggested or confirmed the occurrence of this syndrome in several cases (see VanHouten *et al.*, 2006, and references therein).

In one case of an ovarian carcinoma (Nussbaum *et al.*, 1990), the molecular basis for the aberrant expression of PTH was determined. This involved a rearrangement (Fig. 5) and amplification of the *PTH* gene, such that it was no longer under the control of upstream regulatory elements that may normally act to silence *PTH* gene expression in nonparathyroid tissue. This case provided strong documentation that the tumor was in fact the source of the high circulating PTH levels and the patient's hypercalcemia. In a case of severe hyperparathyroidism resulting from ectopic PTH production by a pancreatic malignancy, a mechanism of transactivation of the *PTH* gene was suggested by the finding of hypomethylation of the *PTH* gene promoter in tumor tissue (VanHouten *et al.*, 2006).

SUMMARY

Several advances have been achieved toward the goal of understanding the molecular basis of sporadic parathyroid tumorigenesis. The cyclin *D1/PRAD1* oncogene has been identified as a parathyroid oncogene, is overexpressed in 20% to 40% of parathyroid adenomas, and is also involved in the development of many additional tumor types. The gene responsible for MEN1 has been identified, and mutations in menin contribute in up to 20% of sporadic parathyroid adenomas. Mutations in the *RET* gene, the causal agent in MEN2, plus *CASR* and *VDR*, appear to contribute

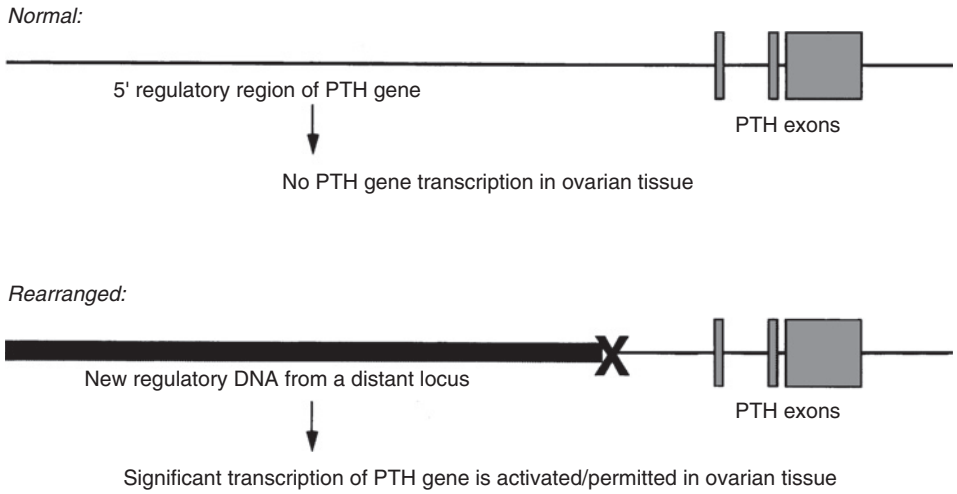

FIGURE 5 Molecular pathology of the ectopic production of PTH by an ovarian cancer. The bold **"X"** represents the breakpoint of the DNA rearrangement. Reproduced with permission from Arnold (1993).

rarely if ever to the development of sporadic parathyroid tumors. The identification of the tumor suppressor parafibromin encoded by the *HRPT2* gene has provided important insight into parathyroid disease, especially parathyroid carcinoma. Ultimately, a description of parathyroid tumorigenesis will need to account for such features as the rarity of parathyroid carcinoma, the increased incidence of tumors after neck irradiation, and the increased frequency of hyperparathyroidism in postmenopausal women. In addition, the relationship between excessive cellular proliferation and an altered set point in the mechanism linking extracellular calcium concentration to PTH secretion requires further dissection, and recently developed animal modeling of primary hyperparathyroidism may assist in this effort.

DISCOVERY AND INITIAL DESCRIPTION

Before the ready availability of inexpensive and accurate measurements of serum calcium concentration, the diagnosis of hypercalcemia was generally considered only when there were overt signs or symptoms to suggest it. Thus, most cases of hypercalcemia that were identified were severe, and patients presented with urolithiasis, nausea and vomiting, weight loss, or renal insufficiency (Albright and Reifenstein, 1948; Trigonis *et al.,* 1983). In the late 1960s, automated multichannel serum chemical analyzers became widely used in the United States and Western Europe, leading to "routine" measurement of serum calcium concentration in large numbers of adult medical patients, many having no specific symptoms. This large-scale screening of the population revealed a hitherto-unsuspected group of mildly to moderately hypercalcemic individuals, most of whom turned out to have primary hyperparathyroidism (1° HPT) (Heath *et al.,* 1980). Subsequently, the literature on mild 1° HPT has expanded enormously, and the syndrome of virtually asymptomatic 1° HPT is now recognized to be the most common form of the disease (Bilezikian *et al.,* 1991; Heath, 1991). Some forms of 1° HPT are inherited, such as in multiple endocrine neoplasia types 1 or 2A (Gagel, 1994; Metz *et al.,* 1994), the hyperparathyroidism-jaw tumor syndrome (Szabo *et al.,* 1995; Carpten *et al*, 2002), or isolated familial 1° HPT (Law *et al.,* 1983; Wassif *et al.,* 1993, 1999). However, investigators studying families in which hypercalcemia seemed to be transmitted as an autosomal dominant trait recognized about 40 years ago that some kindreds differed in important ways from those having inherited neoplastic parathyroid disease. Jackson and colleagues reported a hypercalcemic family (the WAL kindred) in which the clinical and biochemical characteristics shared certain features with 1° HPT, but in whom surgical exploration of affected individuals neither revealed parathyroid adenomas nor cured the hypercalcemia (Jackson and Boonstra, 1967). Those investigators recognized that this family might have a novel hypercalcemic syndrome (Jackson and Boonstra, 1966), but they did not give the disorder a specific name. Only in 1972 did Foley *et al.* offer the first detailed studies, clear description, and distinct name for this syndrome of benign, life-long hypercalcemia, familial benign hypercalcemia, which they postulated to be due to an abnormality of the receptor mechanism for calcium ion control and unassociated with clear-cut parathyroid hyperplasia or adenomatosis (Foley *et al.,* 1972). Subsequent studies (D. A. Heath, 1989; H. Heath, 1989; Heath, 1994; Law and Heath, 1985; Marx *et al.,* 1981a; Menko *et al.,* 1983) reinforced and extended Foley's original description, establishing the disorder as having the characteristics shown in Table I.

A related familial disorder occurring in neonates, characterized by severe hypercalcemia, bone demineralization, respiratory distress, and failure to thrive, had been described several decades earlier (Hillman *et al.,* 1964; Landon, 1932; Philips, 1948). Spiegel *et al.* were the first to recognize the relationship of this syndrome, now known as neonatal severe hyperparathyroidism (NSHPT), to familial benign hypercalcemia (Cooper *et al.,* 1986; Lillquist *et al.,*

TABLE I Comparison of Characteristic Features of Familial Benign Hypocalciuric Hypercalcemia (FBHH), Familial Isolated Primary Hyperparathyroidism (Familial HPT), and Sporadic Primary Hyperparathyroidism (Sporadic HPT).

Variable	FBHH	Familial HPT	Sporadic HPT
Age of onset	At birth	Variable	Usually >40 years
Symptoms	Usually none	Variable	—Asymptomatic in 80% —Cortical bone loss —Urolithiasis in 20%
Serum-plasma level			
Calcium	Elevated	Elevated	Elevated
Magnesium	Normal to increased	Variable	Variable
Phosphorous	Normal to mild decrease	Normal to very low	Normal to very low
$1,25(OH)_2D$	Normal	Normal to increased	Normal to increased
Intact PTH	Normal (80–85%) Elevated (15–20%)	Elevated in >80%	Elevated in >80%
Urinary excretion			
Cyclic AMP	Normal to mildly increased	High normal to increased	High normal to increased
Calcium	Normal to low	Low to elevated	Low to elevated
Ca:Cr clearance ratio	Generally <0.01	Generally >0.03	Generally >0.02
Magnesium	Low	Normal to high	Normal to high
Other findings	Possibly increased risk of chondrocalcinosis, gallstones	Typical findings of HPT	Typical findings of HPT

1983; Marx *et al.,* 1982, 1985; Matsuo *et al.,* 1982; Page and Haddow, 1987; Spiegel *et al.,* 1977; Steinmann *et al.,* 1984). Almost a decade before the molecular basis for these two related syndromes was identified, Marx *et al.* suggested that they represented the expression of homozygous and heterozygous abnormalities in calcium-sensing, respectively (Fujimoto *et al.,* 1990; Marx *et al.,* 1982, 1985).

FAMILIAL BENIGN HYPOCALCIURIC HYPERCALCEMIA

As just noted, Foley and colleagues provided the first full clinical description of this syndrome (Foley *et al.,* 1972) as well as the name familial benign hypercalcemia (FBH)—a simple but very descriptive and reassuring name. Later, investigators at the National Institutes of Health reported the same condition as familial hypocalciuric hypercalcemia (FHH) (Marx *et al.,* 1977), in recognition of the unexpectedly low urinary excretion of calcium in affected persons. The literature is substantially divided between the use of these two names, i.e., FBH or FHH, to describe this clinical entity (D. A. Heath, 1989; H. Heath, 1989; Heath, 1994; Law and Heath, 1985; Marx *et al.,* 1981a, 1977; Menko *et al.,* 1983). A unifying term describing the key features of the syndrome, familial benign hypocalciuric hypercalcemia (FBHH), was proposed by Heath (1989) and later adopted by Strewler (1994). This unifying term will be used in this chapter.

CLINICAL AND BASIC LABORATORY CHARACTERISTICS OF FBHH

The earliest kindreds reported to have FBHH usually had one family member who had been misdiagnosed as having 1° HPT and, therefore, had undergone surgical exploration, only to have either no histologic abnormality (the commonest finding) or subtle "hyperplasia" of the parathyroids identified (Davies *et al.,* 1981; D. A. Heath, 1989; Heath, 1994; Law and Heath, 1985; Marx *et al.,* 1981a, 1977; Menko *et al.,* 1983; Paterson and Gunn, 1981; Sereni *et al.,* 1982). In any event, even subtotal parathyroidectomy usually failed to normalize serum calcium levels. Subsequent investigations of other family members often revealed someone else with failed neck exploration and/or a large number of hypercalcemic, but asymptomatic, individuals of widely varying ages within a given kindred. Approximately 9% of patients referred to the National Institutes of Health in the 1970s with failed parathyroid surgery turned out to have FBHH (Marx *et al.,* 1980). As the syndrome of FBHH has become more widely recognized, it is often diagnosed before any family members have had unnecessary parathyroid surgery. The prevalence of classical FBHH was

estimated to be 1/78,000 in the west of Scotland (Hinnie *et al*., 2001).

THE FBHH SYNDROME IS CLINICALLY BENIGN

This uncommon, globally distributed hypercalcemic syndrome is inherited in an autosomal dominant fashion and is usually characterized by lifelong asymptomatic hypercalcemia, relative hypocalciuria, and absence of classical complications of hypercalcemia, including bone disease and renal stone disease. General morbidity and mortality appeared to be essentially normal in series from the Mayo Clinic and National Institutes of Health, as well as in studies by other investigators (D. A. Heath, 1989; H. Heath, 1989; Heath, 1994; Law and Heath, 1985; Marx *et al.,* 1977, 1981a; Menko *et al.,* 1983). Furthermore, almost all affected persons probably lack symptoms of hypercalcemia (Foley *et al.,* 1972; D. A. Heath, 1989; Law and Heath, 1985; Marx *et al.,* 1977; Menko *et al.,* 1983; Pearce *et al*., 1997; Hendy *et al*., 2000; Rose *et al*., 2001), although symptoms consistent with hypercalcemia have been described in some probands (Marx *et al.,* 1981a). The studies of Law and Heath (1985) suggested that selection, referral, and "coaching" biases could account for the presence of symptoms among probands; that is, the probands see physicians for various reasons that lead to biochemical screening and the incidental discovery of hypercalcemia. Probands may undergo repeated questioning about possible symptoms of hypercalcemia and be prompted inadvertently to answer in the affirmative. Thus, probands in typical FBHH kindreds may have a variety of symptoms, but affected family members detected by screening generally usually have no more symptoms than unaffected persons (see Associated Clinical Findings). However, atypical presentations such as severe hypercalcemia, hypercalciuria, nephrolithiasis and pancreatitis have been described. Indeed, genetic testing of families with some features of FBHH has led to the discovery of CaSR mutations in some families with isolated familial hyperparathyroidism (Simonds *et al.,* 2002; Warner *et al.*, 2004). In addition, some children/infants with heterozygous CaSR mutations can clearly present with symptomatic bone disease that can revert to more typical asymptomatic FBHH picture later (Pearce, *et al.* 1995b). The capacity to identify atypical FBHH families by genetic means may also bring additional unusual presentations to light as time goes by, such as stone disease in some Swedish families (Carling, *et al.,* 2000); or pancreatitis (Felderbauer *et al.,* 2003; Felderbauer *et al.,* 2006).

ASSOCIATED CLINICAL FINDINGS

Some observers have suggested that FBHH increases the risk of acute pancreatitis (Damoiseaux *et al.,* 1985; Davies *et al.,* 1981; Falko *et al.,* 1984; Robinson and Corall, 1990; Toss *et al.,* 1989; Pearce *et al.,* 1996) but others have questioned the validity of this claim (Stuckey *et al.,* 1990). Indeed, Stuckey *et al.* evaluated 10 cases with FBHH and pancreatitis: in 8/10 cases there were potential confounders for pancreatitis such as alcohol abuse ($n = 5$) and biliary pathology ($n = 3$) (Stuckey *et al.,* 1990). Clearly, there is a potential for ascertainment bias; that is, patients presenting with acute pancreatitis commonly are examined for hypercalcemia. Thus, hypercalcemia would be found incidentally in any patient with FBHH who developed pancreatitis for any reason. *Post hoc ergo propter hoc* reasoning would then lead the physician to conclude that FBHH caused the pancreatitis. Interestingly, the CaSR is expressed in pancreatic cells, raising the possibility for its role in patients with FBHH and pancreatitis (Bruce et al., 1999; Racz *et al.,* 2002). Subsequently, a Swedish group characterized a family with FBHH and a concomitant mutation in the pancreatic secretory tripsin inhibitor gene (SPINK1), a putative modifier or causative factor in chronic pancreatitis (Felderbauer *et al.*, 2003). The same group then screened 19 families ($n = 170$ members) with a history of chronic idiopathic pancreatitis, and showed another family member to have a simultaneous mutation in the CaSR and in SPINK1 (Felderbauer *et al.,* 2006). It is thus possible that under certain conditions the hypercalcemia of FBHH predisposes to or aggravates acute pancreatitis, mutations in the CaSR possibly being a potential genetic risk factor for pancreatitis.

There is one report of increased prevalence of chondrocalcinosis in FBHH families (Marx *et al.,* 1981a); and cholithiasis appeared to occur at increased frequency in FBHH kindreds (Law and Heath, 1985). The association of symptoms associated with FBHH was systematically studied by Law and Heath who administered an interview to 15 families with well-documented FBHH: 82 individuals were hypercalcemic and 52 were normocalcemic first-degree relatives. Whereas nocturia, arthritis, gallstones, and arterial hypertension were significantly more common in the index patients than in normocalcemic individuals, only gallstones were found to occur with increased frequency in patients found solely by family screening (Law and Heath, 1985). These associations require systematic reevaluation in a greater number of FBHH kindreds.

The skeleton in patients with FBHH generally appears to be normal histologically, radiographically, and by mineral densitometry (Abugassa *et al.,* 1992; Gilbert *et al.,* 1985; D. A. Heath, 1989; H. Heath, 1989; Heath, 1994; Law and Heath, 1985; Law *et al.,* 1984c; Marx *et al.,* 1977, 1981a; Menko *et al.,* 1983; Monfort-Gourand *et al*, 1993). Some case reports have described increased bone turnover on biopsy of FBHH patients (Alexandre *et al.,* 1982; Kristiansen *et al.,* 1987; Sereni *et al.,* 1982), but the data are very limited. As previously stated, serum alkaline phosphatase levels are normal in most patients with FBHH

(D. A. Heath, 1989; Marx *et al.,* 1977, 1981a; Menko *et al.,* 1983). It is not clear if the bone in patients with FBHH is altered in a manner similar to that described by others in patients with 1° HPT who exhibit increased or preserved iliac crest trabecular bone connectivity accompanied by cortical thinning (Christiansen *et al.,* 1992; Parisien *et al.,* 1990). While FBHH does not appear to threaten skeletal integrity, it does not confer immunity to osteoporosis; certainly, we have observed elderly members of some FBHH kindreds to have had osteoporosis that was clinically indistinguishable from that expected for their ages (Heath, H., III, unpublished observations). Indeed, occasional patients may have a bone density below that of controls (Abugassa et al., 1992) or even well into the osteoporotic range (Timmers et al., 2006).

Probably because of the relative hypocalciuria in patients with FBHH, nephrolithiasis is uncommon, but has, however, been described in a few cases (see Renal Function and Ion Excretion).

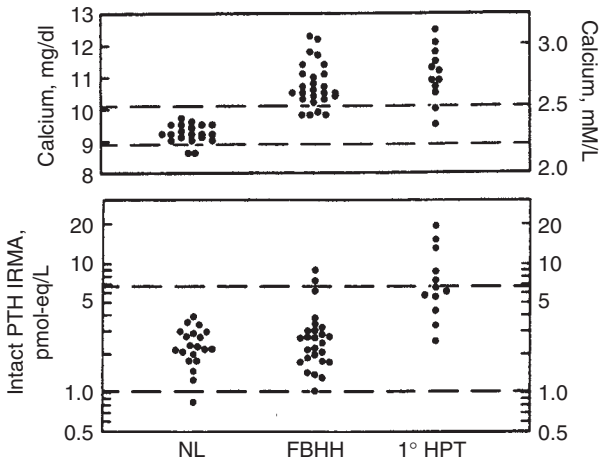

FIGURE 1 Serum calcium (top) and parathyroid hormone (PTH, bottom panel) concentrations in healthy adults (NL), patients with familial benign hypocalciuric hypercalcemia (FBHH), and patients with primary hyperparathyroidism (1 HPT) that was surgically verified. PTH was measured by a two-site immunoradiometric assay (Intact PTH, IRMA). Note the logarithmic scale for PTH. Normal ranges are indicated by horizontal dashed lines. BIOCHEMICAL FINDINGS IN FBHH

The biochemical picture in FBHH is also benign, but can be indistinguishable from that of mild-to-moderate 1° HPT (H. Heath, 1989). The only absolute finding is hypercalcemia, which represents a true elevation of serum and total ionized calcium; serum protein concentrations are normal, and calcium binding is normal (D. A. Heath, 1989; H. Heath, 1989; Heath, 1994; Law and Heath, 1985; Marx *et al.,* 1977, 1981a; Menko *et al.,* 1983). There is a variable degree of hypophosphatemia, and while this finding can occasionally be marked, absolutely low values for serum phosphorous are uncommon. Serum total magnesium levels are increased on average to about the upper limit of normal, being absolutely elevated in no more than half of affected individuals (Marx *et al.,* 1981a). Serum alkaline phosphatase activity has been reported as elevated in some cases (Marx *et al.,* 1981a), but is usually normal (D. A. Heath, 1989; H. Heath, 1989; Heath, 1994; Law and Heath, 1985; Menko *et al.,* 1983). Other markers of bone turnover (e.g., osteocalcin or pyridinium cross-links) have not been reported in FBHH.

PTH levels have been measured in the serum of FBHH patients (Fig. 1) by first-generation radioimmunoassay (Kent *et al.,* 1987; Marx *et al.,* 1978b), cytochemical bioassay (Allgrove *et al.,* 1984), extraction-cell-based bioassay (Rajala *et al.,* 1991), and two-site immunoradiometric (Rajala *et al.,* 1991) and immunochemiluminometric assays (Firek *et al.,* 1991). The findings from all these methods are in general agreement: most persons affected with FBHH have paradoxically normal serum PTH values, and many are in the lower half of the normal range. However, 10−20% of FBHH patients have absolutely elevated serum PTH values (Fig. 1) (Firek *et al.,* 1991; Rajala *et al.,* 1991). In addition, one kindred coded as $FBHH_{OK}$ had elevated serum PTH levels in affected individuals, especially the elderly (McMurtry *et al.,* 1992). Vitamin D deficiency may be the explanation for high PTH levels in some individuals with FBHH. Indeed, a recent report described a subject with FBHH, vitamin D deficiency, and frankly elevated intact PTH levels that decreased to within a range that is more characteristic of FBHH patients after vitamin D repletion (Zajickova *et al.,* 2007). In contrast, serum PTH values are supranormal in >85% of patients having 1° HPT (Firek *et al.,* 1991; Rajala *et al.,* 1991). One can imagine the ease with which mild to moderate hypercalcemia (say, 11.0 mg/dl), hypophosphatemia (perhaps 2.0−2.5 mg/dl), and slight elevation of serum intact PTH (70 pg/ml, as an example) could be mistakenly ascribed to 1° HPT in a patient who actually had FBHH.

RENAL FUNCTION AND ION EXCRETION

The characteristic urinary mineral profile in FBHH led to the term *familial hypocalciuric hypocalcemia* or FHH (Marx *et al.,* 1978a); however, most affected persons are not truly "hypocalciuric" (below the normal range), but rather excrete less calcium than expected for their degree of hypercalcemia (a finding that has been termed "relative hypocalciuria"). About 75% of affected persons excrete less than 100 mg of calcium daily (Law and Heath, 1985), and some excrete strikingly low amounts of calcium in the face of hypercalcemia; values as low as 5 mg/day have been noted. However, the physician must be aware that a few individuals with FBHH may excrete as much as 250 mg

of calcium daily (Law and Heath, 1985; Marx *et al.,* 1981a; Carling *et al.*, 2000). The relatively low urinary excretion of calcium in FBHH results from avid renal tubular reabsorption of calcium, as detailed in the following section. Similarly, urinary excretion of magnesium is unexpectedly low given that the serum level is in the upper part of the normal range or, in some cases, mildly elevated (Kristiansen *et al.,* 1985, 1986; Marx *et al.,* 1978a).

The excretion of calcium in suspected FBHH cases may be expressed either as an absolute amount (mg/day) or as a unitless calcium:creatinine clearance ratio (fractional excretion of calcium), as advocated by Marx and colleagues (1980): [UCaXSCr]/[SCaXUCr], where UCa is the urinary calcium concentration, SCr the serum creatinine concentration, SCa the serum calcium concentration, and UCr the urinary creatinine concentration, all in milligrams per deciliter. Most patients having FBHH have urinary Ca:Cr clearance ratios below 0.01 (Law and Heath, 1985; Marx *et al.,* 1980, 1981a). There is considerable overlap between the absolute values for total urinary calcium excretion and Ca:Cr clearance ratios among persons having FBHH, their unaffected family members, and unrelated patients having 1° HPT, as shown in Fig. 2. The ratio is most helpful in supporting a diagnosis of FBHH in a kindred, rather than in an individual patient, because the mean Ca:Cr clearance ratio generally will be less than 0.01 when averaged across affected members of the kindred. However, in an atypical family with FBHH with a mutation in the cytoplasmic tail of the CasR, Ca:Cr clearance ratio was above 0.01 in 7 of 10 affected members, and nephrolithiasis was present in two members (Carling *et al.,* 2000).

Calcium infusions have been used to compare renal calcium handling in FBHH and hyperparathyroidism (Attie *et al.,* 1983; Davies *et al.,* 1984; Kristiansen *et al.,* 1986; Stuckey *et al.,* 1987). In response to a rising filtered load of calcium, subjects with hyperparathyroidism increase their urinary calcium excretion more than FBHH patients do. This avid tubular calcium reabsorption persists even in FBHH patients who have been rendered surgically aparathyroid, pointing to a primary renal tubular abnormality in calcium reabsorption (Attie *et al.,* 1983; Davies *et al.,* 1984; Kristiansen *et al.,* 1986; Watanabe and Sutton, 1983). Renal function is well preserved in FBHH (D. A. Heath, 1989, H. Heath, 1989; Heath, 1994; Law and Heath, 1985; Marx *et al.,* 1977, 1981a; Menko *et al.,* 1983), and there appears to be no more than the usual age-related loss of glomerular filtration rate. Moreover, the hypercalcemia of FBHH does not appear to alter renal sensitivity to vasopressin as it does in 1° HPT. Marx and colleagues demonstrated convincingly that reduced maximal urinary concentrating ability occurs in 1° HPT but not in FBHH (Marx *et al.,* 1981b). As stated above, urolithiasis is rare in patients having FBHH, but has been reported (Marx *et al.,* 1981a; Menko *et al.,* 1983; Toss *et al.,* 1989). A Swedish family with a syndrome that presented as a hybrid between

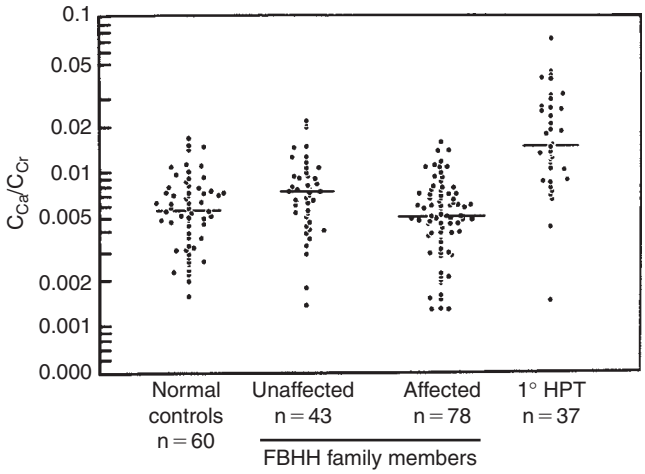

FIGURE 2 Ratios of calcium clearance to creatinine clearance in patients with familial benign hypocalciuric hypercalcemia (FBHH), unaffected family members, unrelated normal controls, and patients with surgically confirmed primary hyperparathyroidism (1° HPT). Note the logarithmic scale for C_{Ca}:C_{Cr} ratios. There is substantial overlap between FBHH and 1° HPT; however, a ratio of >0.02 is helpful in excluding FBHH. Reprinted with permission from Heath, H., III.

1° HPT and FBHH, with hypercalciuria that subsided after parathyroidectomy was reported by Carling *et al.* (2000).

In summary, the clinical and laboratory picture of FBHH is generally that of incidentally discovered hypercalcemia that bears no clear relationship to any of the patient's symptoms. The biochemical picture can be very similar to that of patients with asymptomatic 1° HPT, although elevation of serum PTH levels is much less common in FBHH than in 1° HPT (Allgrove *et al.,* 1984; Firek *et al.,* 1991; Kent *et al.,* 1987; Marx *et al.,* 1978b; Rajala *et al.,* 1991). While chondrocalcinosis, gallstones, and acute pancreatitis have been reported in FBHH, the relationship of these events to the FBHH remains uncertain. As for pancreatitis, specific environmental factors or interaction with other genetic mutations may be required (Felderbauer *et al.,* 2006) Hyperparathyroid bone disease, hyposthenuria, and urolithiasis are conspicuously absent. The greatest importance of the FBHH syndrome to clinicians is that it is so easily misdiagnosed as mild to moderate 1° HPT, leading to excessive testing and to inappropriate, unnecessary, and potentially harmful exploratory cervical surgery.

PATHOPHYSIOLOGIC STUDIES IN FBHH

Extensive clinical research studies have clarified the organ-level pathogenesis of FBHH. Because the molecular basis of the predominant form of FBHH is now known (detailed later), these studies now are mainly of value for providing a clear definition of the syndrome. Notably, they also suggested basic research leads that ultimately elucidated the molecular pathogenesis of one form of the syndrome.

PARAMETERS OF SYSTEMIC PLASMA CALCIUM REGULATION

PTH Dynamics

As previously stated, the hypercalcemia of FBHH is a "true" hypercalcemia, not an artifact of calcium binding. It is stable across time and usually is reduced little or not at all by subtotal parathyroidectomy (Law and Heath, 1985; Marx *et al.,* 1981a). However, total parathyroidectomy results in permanent hypocalcemia that responds to the usual therapeutic measures for hypoparathyroidism. The hypercalcemia of FBHH is, therefore, clearly PTH-dependent in a qualitative sense, but recent data show that this is also true in a quantitative sense (Firek *et al.,* 1991). Since the first application of PTH RIAs to the study of 1° HPT, a clear, direct relationship between the degree of hypercalcemia and the elevation of serum immunoreactive PTH has been evident (Arnaud *et al.,* 1971). Studies at the Mayo Clinic (Firek *et al.,* 1991) demonstrated a similar positive correlation between serum calcium and intact PTH levels in FBHH—but with a much shallower slope than the one described for hyperparathyroidism—and there was an inverse relationship between PTH and serum inorganic phosphorus levels. Clearly, hypercalcemia and hypophosphatemia are maintained in FBHH at lower levels of ambient PTH than in 1° HPT, suggesting that inappropriately high PTH levels result from abnormal calcium-sensing at the level of not only the parathyroid gland but also the kidney. Indeed, the latter contributes to the hypercalcemia through avid calcium reabsorption thus resulting in lower than anticipated PTH levels to achieve a given degree of hypercalcemia. The reduced responsiveness of the parathyroid glands to changes in serum calcium has been documented carefully in FBHH. Induction of relative hypocalcemia by infusion of ethylenediaminetetra acetic acid (EDTA) or of relative hypercalcemia by calcium infusion causes anticipated but only partial increments and decrements of serum PTH concentrations (Auwerx *et al.,* 1984; Heath and Purnell, 1980; Khosla *et al.,* 1993). The percent decrements of PTH are greater in FBHH than in 1° HPT—in fact, indistinguishable from normal, although they occur at a higher level of serum calcium than do the corresponding reductions in PTH in normal persons—and increases are less than in 1° HPT. Systematic evaluation of PTH dynamics in FBHH patients compared to normal controls using consecutive citrate and calcium infusions indicates a shift in the calcium−PTH relationship to the right, again consistent results with altered calcium-sensing (Fig. 3, authors' personal observations, Haden *et al.,* 2000). PTH secretion responds in the usual inverse manner to changes in serum calcium concentration, but is reset so as to maintain a higher-than-normal level of plasma calcium. Interestingly, Foley *et al.* presciently interpreted their 1972 findings on FBHH as being consistent with a genetic abnormality of parathyroid calcium sensing (Foley *et al.,* 1972).

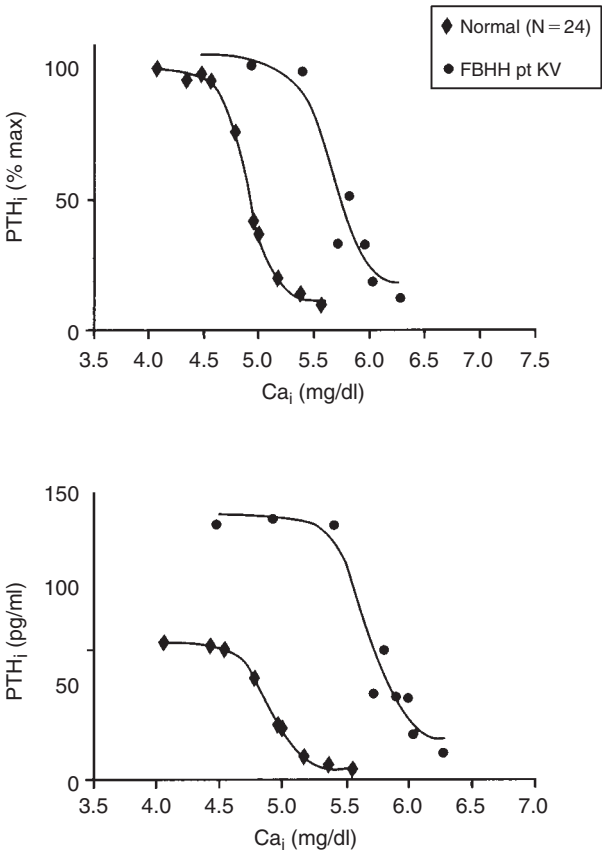

FIGURE 3 Inverse sigmoid curve between serum intact PTH and ionized calcium (Ca_i/PTH_I) in response to consecutive citrate and calcium infusions in patient KV with FBHH S. T. Haden, E. M. Brown, and G. El-Hajj Fuleihan, unpublished observation) in comparison to the Ca/PTH curve derived from 24 healthy subjects (adapted from Haden *et al.* (2000) *Clin. Endocrinol.* **52,** 329−338). There is a clear abnormality of PTH dynamics in the patient with FBHH compared to normal controls: a shift in the Ca/PTH curve to the right, increased PTH levels in response to hypocalcemia, and decreased suppression in response to hypercalcemia. The set-point, the calcium concentration at which there was 50% suppression in PTH levels, was 4.89 mg/dl in the curve derived from 24 healthy controls and 5.65 mg/dl in the patient with FBHH.

Parathyroid Glands

The histologic findings in parathyroid glands of patients having FBHH are variable, possibly because of mutation-specific effects. Most case and single-family reports have described unremarkable parathyroid tissue (Davies *et al.,* 1981; Paterson and Gunn, 1981; Sereni *et al.,* 1982, and reviewed in Law *et al.,* 1984b). These findings were corroborated by studies of large kindreds (Law and Heath, 1985; Menko *et al.,* 1983; Toss *et al.,* 1989). However, the two large histologic studies published to date focusing on parathyroid pathology yielded conflicting results. Thorgeirsson *et al.* reported that a highly variable parathyroid hyperplasia was typical in their examination of 55 parathyroid glands from 18 patients thought to have FBHH (Thorgeisson *et al.,* 1981). Conversely, Law *et al.* examined

28 parathyroid glands from 23 patients in 16 FBHH kindreds, quantifying fat-to-parathyroid-parenchymal ratios in comparison with 82 normal glands from 47 control patients, and they found no evidence to support the presence of parathyroid hyperplasia in FBHH (Law *et al.,* 1984b). The differences in the findings between these two large studies could be explained by referral bias or differences in the study populations. However, the most useful clinical point is that parathyroid histology is unremarkable or minimally abnormal in most cases of FBHH. In a few recent cases, lipohyperplasia of the parathyroid glands has been described in FBHH (Fukumoto *et al.,* 2001; Yamauchi *et al.,* 2002), although it is clearly distinctly uncommon. Of interest in this regard, however, Law *et al.* (1984b) found the percent parenchymal fat to be about 50% higher in parathyroid glands from patients with FBHH than in those with 1° HPT (30 vs. 21%, respectively). The significance of this observation is unclear at present.

Other Calciotropic Hormones

Plasma concentrations of 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D are normal in FBHH patients (Davies *et al.,* 1983; Gilbert *et al.,* 1985; Kristiansen *et al.,* 1985; Law *et al.,* 1984a; Law and Heath, 1985; Lyons *et al.,* 1986), as is intestinal calcium absorption (Kristiansen *et al.,* 1985; Law and Heath 1985; Menko *et al.,* 1983). Plasma calcitonin concentrations are inappropriately normal in FBHH for the degree of calcium elevation (Kristiansen *et al.,* 1985; Law and Heath, 1985; Menko *et al.,* 1983), but they exhibit a normal response to other secretagogues (Rajala *et al.,* 1991).

The Kidney

Two careful studies of small numbers of patients support an intrinsic defect of renal tubular reabsorption of calcium in FBHH (Attie *et al.,* 1983; Davies *et al.,* 1984). These patients, who were later recognized to have FBHH, had inadvertently been rendered totally aparathyroid during surgical explorations for parathyroid tumors. Comparisons with individuals who became hypoparathyroid after removal of typical sporadic parathyroid adenomas demonstrated greater PTH-independent renal tubular reabsorption of calcium and magnesium in the FBHH patients than in the hypoparathyroid controls (Attie *et al.,* 1983).

In summary, clinical studies of the FBHH syndrome are almost uniformly consistent with a genetic disorder of calcium sensing by the parathyroid glands paired with enhanced renal tubular reabsorption of calcium. PTH secretion persists at normal or slightly elevated values in the face of hypercalcemia, but without obvious disturbances of other calcium-regulating hormone concentrations. These pathophysiologic abnormalities are most parsimoniously explained by dominant mutations of a single calcium-sensing receptor expressed both in parathyroid glands and in kidneys.

GENETIC STUDIES IN FBHH

The FBHH trait is inherited in an autosomal dominant pattern (Foley *et al.,* 1972; D. A. Heath, 1989; H. Heath, 1989; Heath 1994; Law and Heath, 1985; Marx *et al.,* 1977; 1981a; Menko *et al.,* 1983; Jackson and Boonstra, 1966; Toss *et al.,* 1989). Across numerous families, the sex distribution is essentially 1:1, and about half of all persons at risk manifest hypercalcemia. There is a considerable variation in clinical manifestation, that is, in the extent of hypercalcemia (there being almost no other clinical marker). Several groups have observed that the "hypercalcemia breeds true"; that is, there are FBHH families with relatively high and those with relatively low serum calcium concentrations (Marx *et al.,* 1981a; Rajala and Heath, 1987). There is, however, considerable variability of serum calcium values even within kindreds (Fig. 4). We have had the opportunity to follow affected women whose husbands were normocalcemic through three pregnancies and deliveries. Hypercalcemia was present in all three infants at birth, with serum calcium levels of up to 18 mg/dl observed in cord blood and during the first few days of life; subsequently, serum calcium declined by age 3−4 years to values similar to the affected mother's (unpublished results).

The FBHH syndrome is genetically heterogeneous: in the majority of cases (over 85%) the FBHH phenotype links to a region of chromosome 3 that contains the calcium-sensing receptor sensor gene (CaSR), a disease subtype called $FBHH_{3q}$ (Heath *et al.,* 1993; Pearce *et al.,* 1995b). In two thirds of $FBHH_{3q}$ families, specific inactivating mutations of the CaSR were found (Fig. 5). The remainder presumably have CaSR mutations outside of the coding region, perhaps reducing expression of an otherwise normal CaSR. In a smaller number of families the linkage of the trait was to markers on the short arm of chromosome 19 (Heath *et al.,* 1993), thus termed $FBHH_{19p}$ (Heath, 1994; Heath *et al.,* 1996; Strewler, 1994). Trump and colleagues carried out genetic linkage studies in the FBHH kindreds described by Whyte *et al.* (Trump *et al.,* 1995), and found linkage neither to chromosome 3*q* nor to chromosome 19*p* markers, establishing that there are three genetically distinct forms of the FBHH syndrome (R. V. Thakker, 2004): $FBHH_{3q}$ (FBHH type 1 or HHC1, OMIM 145980), $FBHH_{19p}$ (FBHH type 2 or HHC2, OMIM 145981), and $FBHH_{OK}$ or $FBHH_{19q}$ (FBHH type 3 or HHC3, OMIM 600740); "OK" stands for Oklahoma, the family's state of residence (Trump *et al.,* 1995, Lloyd *et al.,* 1999).

The Molecular Basis of $FBHH_{3q}$: Mutations in the CaSR

Chou *et al.* achieved the first linkage of the FBHH trait to markers on chromosome 3 (Chou *et al.,* 1992), specifically, 3*q*21−*q*24. This linkage coincided with the cloning of the bovine parathyroid calcium-sensing receptor by Brown

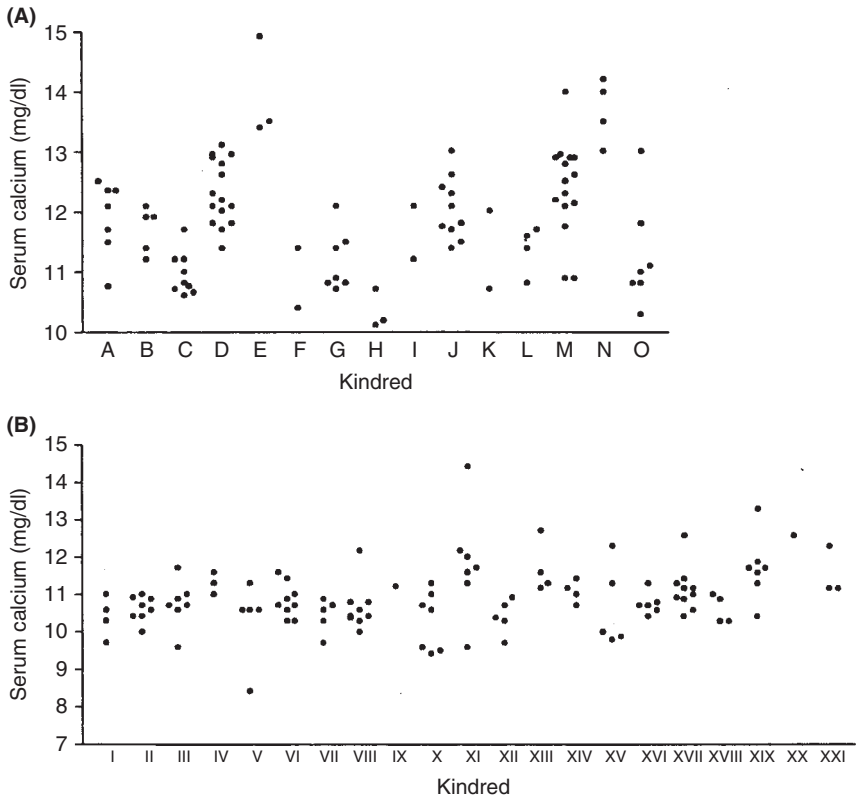

FIGURE 4 Scatter of serum calcium levels in FBHH kindreds. (A) Data from 15 kindreds reported by the National Institutes of Health group (adapted from Marx *et al.* (1981) *Medicine* **60,** 397, with permission). (B) Data from 21 kindreds reported by the Mayo Clinic group (adapted from Rajala and Heath (1987) *J. Clin. Endocrinol. Metab.* **65,** 1039, with permission). The mean ± SD calcium level in A is 12.1 ± 1.6 mg/dl and in B 10.9 ± 0.8, the mean serum calcium level from both studies is 11.4 ± 1.4 mg/dl.

et al., (1993), and the same group quickly demonstrated three distinct missense mutations in the calcium receptor genes in three separate families with $FBHH_{3q}$ (Pollak *et al.,* 1993). Numerous groups have since found various kinds of mutations in this gene that cosegregate with the $FBHH_{3q}$ trait (Aida *et al.,* 1995; Chou *et al.,* 1995; Heath *et al.,* 1996; Hendy *et al.,* 2000; Janicic *et al.,* 1995; Pearce *et al.,* 1995b; see later). For an up-to-date summary of the mutations identified to date, (see http://www.casrdb.mcgill.ca).

The CaSR exhibits a modest degree of homology with the metabotropic glutamate receptors (mGluRs) and other members of the structurally related members of the family C, G protein-coupled receptors (GPCRs), e.g., the gamma-aminobutyric acid ($GABA_B$), pheromone, taste, and odorant receptors (Brauner-Osborne, *et al.,* 2007). The CaSR has three domains: a large extracellular domain (ECD) (612 aa), a seven-transmembrane-spanning segment characteristic of the GPCR superfamily (~250 aa), and an intracytoplasmic tail (222 aa). The extracellular domain contains important Ca^{2+}-binding determinants, likely within the so-called venus fly-trap (VFT) domain in this portion of the receptor, based on homology modeling of the CaSR ECD with the known three-dimensional structure of the extracellular domain of mGluR1 (Hu and Spiegel. 2003). The transmembrane and cytoplasmic domains of the CaSR, including the C-tail, are thought to transduce structural changes in the receptor resulting from binding of Ca^{2+} into alterations in intracellular signaling systems that modulate tissue function.

The CaSR is expressed in many tissues but is found at the highest levels in the parathyroid gland, the thyroid C-cells, and various regions of the kidney, especially the cortical thick ascending limb, a segment that plays a critical role in calcium handling (Brown *et al.,* 1995b). Activation of the normal CaSR suppresses parathyroid hormone secretion, stimulates calcitonin secretion, and enhances renal calcium excretion. Therefore, reduction or loss of the normal function of one allele of the calcium receptor, in FBHH, impairs calcium-sensing, with a resultant shift in the calcium-PTH curve to the right and reduced excretion of renal calcium at any given level of serum calcium concentration.

Most of the inactivating mutations of the human CaSR gene found so far represent single amino acid substitutions, but insertion, deletion, truncation, frame shift, and splice site mutations have also been described (see summary at http://www.casrdb.mcgill.ca). To date, more than 100 different FBHH mutations of the CaSR gene are known (http://www.casrdb.mcgill.ca). Most have been described

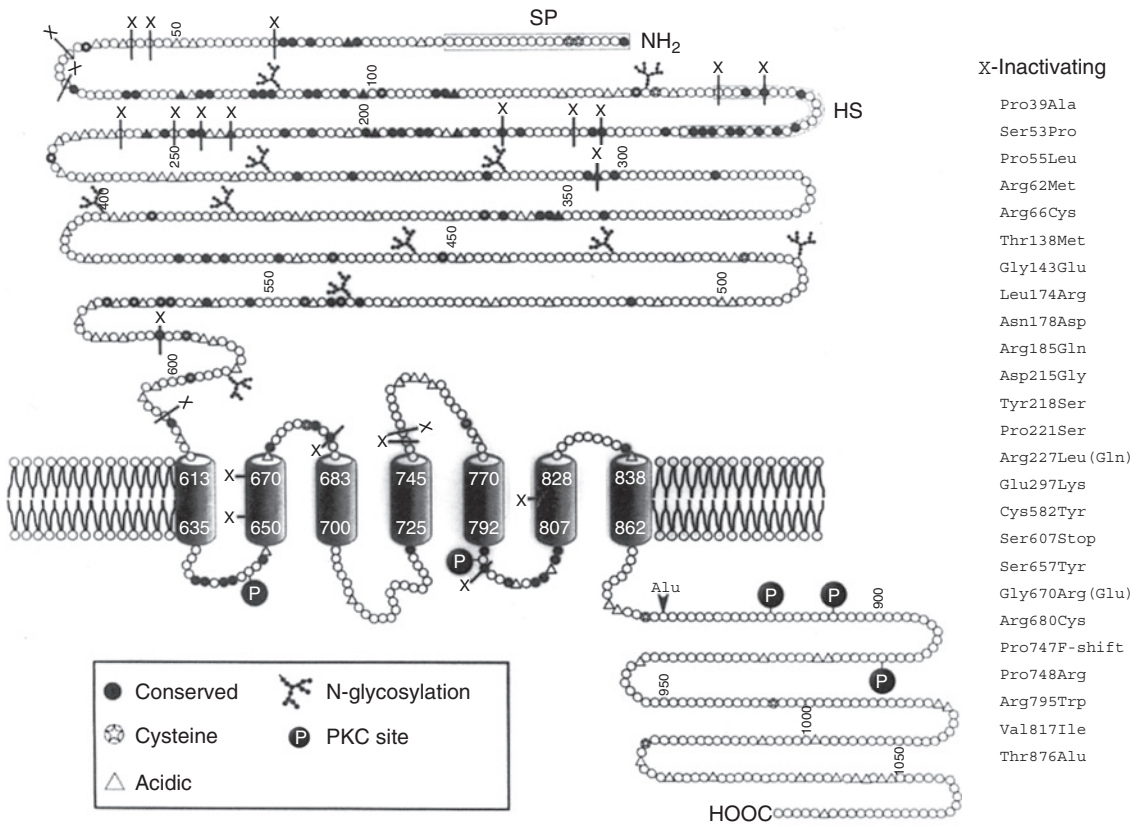

FIGURE 5 Schematic representation of the proposed structure of the extracellular Ca^{2+} calcium receptor cloned from human parathyroid gland. SP, signal peptide; HS hydrophobic substance. Also shown are 25 inactivating (missense and nonsense) mutations causing familial benign hypocalciuric hypercalcemia (FBHH). Mutations are indicated using the three-letter amino acid code, with the normal amino-acid indicated before and the FBHH mutation shown after the number of the relevant codon. Adapted from Bai *et al.* (1996), with permission. For updated information regarding mutations and polymorphisms in the CaSR please refer to *(http://www.casrdb.mcgill.ca)*

only in a single family, although three mutations (R185Q, P55L, and T138M) have been identified in two or more apparently unrelated families. These $FBHH_{3q}$ mutations have been mostly in the extracellular or transmembrane portions of the receptor (Fig. 5). Essentially all impair the capacity of Ca^{2+} to activate the mutant receptors when they are expressed heterologously, e.g., in human embryonic kidney (HEK) 293 cells. The functional abnormalities range from mild (~2-fold) reductions in the apparent affinity of Ca^{2+} for activating the receptor to complete loss of activity. Mutations in the ECD may alter the receptor's capacity to bind extracellular calcium ions by disrupting specific Ca^{2+}-binding sites (Silve *et al.,* 2005) or may cause a more generalized change of the receptor's structure and/or its ability to reach the cell surface. For example, two mutations in the signal peptide of the CaSR, which normally directs translocation of the nascent receptor polypeptide into the lumen of the endoplasmic reticulum, severely reduced receptor biogenesis and cell surface CaSR expression (Pidasheva *et al.,* 2005). Mutations in the transmembrane regions of the CaSR, in addition to producing generalized disturbances of receptor structure and/or function, may more specifically impair receptor-mediated intracellular signaling, namely, by interfering with G protein binding (Bai *et al.*, 1996). Recently kindreds have been described with mutations in the cytoplasmic tail of the receptor, one of which presented with symptoms that combine those of FBHH and hyperparathyroidism, a feature reported in some kindreds previously (Toss *et al.,* 1989; Carling *et al.,* 2000; Marx *et al.,* 1981a; Menko *et al.,* 1983). It has been postulated that this mutation may produce more severe "resistance" to Ca^{2+} in parathyroid than in kidney, therefore, resulting, in a greater hypercalciuric response to hypercalcemia than observed in most FBHH families.

The CaSR normally resides on the cell surface as a disulfide-linked dimer, involving cysteines 129 and 131 within the receptor's ECD. The variability in the severity of the hypercalcemia in FBHH may result, in part, from the capacity of mutant CaSRs to impair the function of their wild type partner within wild type-mutant heterodimers (the expected ratio of wild type homodimers, wild type-mutant heterodimers and mutant homodimers would be 1:2:1). This effect of the mutant on the wild type receptor is the so-called dominant negative effect. It has been demonstrated *in vitro* by cotransfecting wild type and

mutant receptor cDNAs and comparing their function to those of the mutant and wild type receptors when transfected individually. Some mutations (e.g., Bai, *et al.,* 1997) right-shift the relationship between the extracellular calcium concentration and receptor activation for the cotransfected wild type receptor. Therefore, not only is the function of the mutant homodimer impaired (i.e., ~25% of the cell surface receptor) but also that of the heterodimer (~50%). In the families harboring such mutations, the serum calcium concentration can be unusually high, presumably reflecting the dominant negative action of the mutant receptors *in vivo* (Bai *et al.,* 1996). In contrast, a simple truncation mutation that totally abrogates production of cell surface receptor would still leave intact the ~50% of the wild type receptor arising from the normal CaSR allele. Indeed, some families with truncation mutations of the CaSR exhibit minimal or no hypercalcemia (Kobayashi *et al.,* 1997), presumably owing to the presence of a greater complement of normally functioning receptors than in cases where a dominant negative effect is operative.

In addition to the variability in serum calcium concentration in FBHH families, some kindreds may be at increased risk for pancreatitis, and in three such kindreds Pearce found three heterozygous missense mutations in the extracellular domain of the calcium receptor (Pearce *et al.,* 1996). This observation, in conjunction with that of an expression of the calcium receptor in the pancreatic duct (Bruce *et al.,* 1999; Racz *et al.,* 2002), suggests the intriguing possibility that specific mutations may indeed carry a higher risk of pancreatitis. Alternatively, mutations of the CaSR receptor may interact with mutations of the gene encoding the pancreatic secretory trypsin inhibitor (SPINK1) to aggravate the risk for pancreatitis (Felderbauer *et al*., 2006).

The role of the CaSR gene in controlling parathyroid function and the role of CaSR inactivation in causing FBHH have been elegantly supported by the mouse gene inactivation studies of Ho *et al.* (1995). Mice heterozygous for a disrupted CaSR gene have mild hypercalcemia [10.4 ± 0.55 mg/dl (mean $\pm$ SD)], nonsuppressed PTH levels, and reduced urinary calcium excretion compared to normal mice. The affected mice had normal radiographic skeletal morphology and parathyroid gland histology. Their levels of CaSR protein in parathyroid and kidney are about 50% of normal, supporting the argument made above that total loss of one CaSR allele in FBHH (i.e., by truncation) results in mild hypercalcemia that contrasts with the more severe hypercalcemia observed when a dominant negative mechanism is at play.

Thus, several mechanisms have been suggested to account for the reduced activity of the CaSR and impaired Ca^{2+}-sensing in FBHH, acting alone or in combination:

1. Inability to produce a normal complement of cell surface receptors owing to impaired biogenesis and/or accelerated degradation.
2. Decreased affinity of the receptor for extracellular calcium, despite adequate cell surface expression, owing to generalized changes in structure or specific loss of Ca^{2+}-binding motifs.
3. Failure of the cell surface CaSR to couple normally to its respective signal-transduction pathway(s), e.g., activation of appropriate G proteins.
4. A dominant-negative effect wherein the mutated receptor interferes with the function of the normal receptor.

Initially, three relatively common, apparently "benign" polymorphisms were identified in the intracellular C-tail of the CaSR encoded by exon 7 (present in up to one third of unaffected subjects) (Heath *et al.,* 1996). Subsequently, with the wealth of data available from the human genome project, more than 400 SNPs (single nucleotide polymorphisms) have been identified in the CaSR gene within coding as well as noncoding regions (Yun, *et al.,* 2007); see also *http://www.ncbi.nlm.nih.gov/SNP/_and_snp.ims.u-tokyo.ac.jp*). Those present within the coding region, however, other than the three noted above (A986S, R990G, and Q1011E), are very uncommon. The alanine (A) to serine (S) polymorphism of amino acid 986 (A986S) has been described in apparently healthy asymptomatic individuals, and associated in some studies with mild increments in serum calcium and low bone mineral density (Heath *et al.,* 1996., Cole *et al.,* 1999; Lorentzon *et al.,* 2001; Scillitani *et al.,* 2004). However, such observations have not been reproducible (Bollerslev *et al*., 2004; Harding *et al*., 2006). One study demonstrated no effect of these benign CaSR polymorphisms on receptor function when tested in vitro in kidney HEK cells (Harding *et al.,* 2006). Interestingly, a large study from Germany of over 2500 individuals with coronary artery disease revealed an association of the S allele with higher serum calcium levels both in patients and controls (Marz *et al*., 2007). Subjects with the S allele were also noted to have a 30% increased risk of coronary disease and myocardial infarction, and a 25−48% increased risk of cardiovascular and total mortality, independent of risk factors, and serum calcium (Marz *et al*., 2007).

The Molecular Bases of $FBHH_{19p}$ and $FBHH_{OK}$

Two hypercalcemic syndromes similar to $FBHH_{3q}$ have been linked to loci on chromosomes 19*p* (Heath *et al.,* 1993) and 19*q,* the latter originally known as $FBHH_{OK}$ (Trump *et al.,* 1995; Lloyd *et al.,* 1999). The $FBHH_{OK}$ syndrome has been associated with osteomalacia in one family (Trump *et al.,* 1995). At this writing, the molecular bases of the non-3*q* forms of FBHH are still unknown. However, the region mapped for $FBHH_{19p}$ (chromosome 19*p*) contains an interesting candidate gene, GNA11, which encodes a Gq protein that is expressed in human parathyroid tissue (Varrault *et al.,* 1995). It is possible that GNA11 is the

$FBHH_{19p}$ gene. The GNA11 gene product may be the Galpha11 protein acting in concert with the CaSR protein to control PTH secretion (Brown *et al.,* 1995b; Nemeth and Heath, 1995). Thus, inactivation either of one copy of the CaSR gene or of the GNA11 gene might confer the FBHH syndrome.

Autoimmune FBHH

Four cases in two families of autoimmune FBHH with biochemical features similar to those of genetic forms of FBHH have been described (Kifor *et al.,* 2003; Pallais *et al.,* 2004). All four of the patients had mild, PTH-dependent hypercalcemia, with PTH levels in the mid-normal range. Three of the four had relative hypocalciuria. All four subjects had other autoimmune disorders, three with thyroiditis and one with sprue. In those subjects, FBHH was due to the presence of anti-CaSR antibodies that interfered with calcium-mediated suppression of PTH and CaSR-mediated stimultation of mitogen-activated protein kinase (MAPK) and phospholipase C (PLC) activities. More recently, Makita *et al.* (2007) described another patient with the clinical presentation of FBHH and a blocking antibody to the receptor. Interestingly, this antibody, while inhibiting CaSR-induced activation of MAPK, potentiated the activation of PLC, suggesting a potentially important role for MAPK in CaSR-mediated inhibition of PTH secretion.

A CLINICAL STRATEGY FOR FBHH

The differential diagnosis of hypercalcemia is not the dilemma it once was; in patients with established hypercalcemia, a single measurement of serum intact PTH by an immunometric assay will allow a correct diagnosis of 1° HPT at least 80% of the time. However, many patients with 1° HPT are asymptomatic or oligosymptomatic, many have serum intact PTH concentrations within population normal ranges, and some have surprisingly low urinary calcium excretion (Marx *et al.,* 1977). A given patient, then, may present with asymptomatic mild to moderate hypercalcemia, minimal or no hypophosphatemia, urinary calcium excretion below 100 mg/day (Law and Heath, 1985), low Ca:Cr clearance ratio, and mild elevation of serum intact PTH, with no family history of hypercalcemia. The physician has no simple or inexpensive way of determining if this patient has a small parathyroid tumor or one of the variants of FBHH. What is the clinician to do? Genetic linkage studies are not practical, because of family sampling problems, cost, the large number of possible mutations, and the genetic heterogeneity of the syndrome, including the existence of FBHH variants whose molecular etiologies are not yet understood. Direct DNA screening studies of the CaSR gene are informative, if abnormal, but even $FBHH_{3q}$ families do not have known mutations of the CaSR gene coding region in a substantial minority (about a third) of cases. In any case, most clinical laboratories cannot provide appropriate molecular testing for CaSR mutations. Rapid advances in DNA testing technology may change this situation soon, however. For now, the strategy for most clinicians to follow must be based on inference and clinical judgment.

For hypercalcemic patients over the age of 40, with no familial history of hypercalcemia, a clinical and biochemical picture consistent with 1° HPT is overwhelmingly likely to represent just that. The data of Marx *et al.* suggest odds of >1000:1 in favor of 1° HPT in this situation (Marx *et al.,* 1980). Obtaining a measurement of 24-hr urinary calcium could be helpful, as hypercalciuria virtually excludes the diagnosis of FBHH, but normocalciuria or even low urinary calcium excretion does not exclude 1° HPT, particularly in elderly women. Furthermore, some families with FBHH and hypercalciuria have been described (Carling *et al.,* 2000; Simonds *et al.,* 2002). A conservative approach, if the urinary calcium were very low, the serum PTH normal, and the patient clinically well, would be to sample available first-degree relatives for occult hypercalcemia. One's suspicion for FBHH would be heightened if the patient were young (under age 40, especially if under 30), if there were a family history of hypercalcemia, if anyone in the family had undergone unsuccessful neck exploration for hypercalcemia, if neonatal hyperparathyroidism had occurred in the family, and if the urinary excretion of calcium were particularly low (say, less than 50 mg/day) in the patient and other hypercalcemic relatives. In such case, one should defer surgical therapy and observe. The key point is that FBHH does not require treatment in the vast majority of cases. The goal in the clinic must be to identify FBHH before any family member has surgery, but this is regrettably not always going to be possible with our current state of knowledge. Fortunately, in most cases, watchful waiting is a reasonable course, at least for a few years, whether the underlying condition is uncomplicated 1° HPT or FBHH (Silverberg *et al.,* 1999). One recent report documented the efficacy of the calcimimetic cinacalcet in normalizing the serum calcium concentration in a patient with hypercalcemia and a heterozygous mutation in the CaSR (Timmers *et al.,* 2006). Although this therapy is not approved for therapeutic use in patients with FBHH, it may nevertheless be useful in elucidating the etiology of nonspecific symptoms in such patients or, alternatively, as a therapy in atypical cases with unusually severe hypercalcemia.

NEONATAL PRIMARY HYPERPARATHYROIDISM

Clinical Characteristics

Neonatal primary hyperparathyroidism can be a mild syndrome representing the neonatal expression of FBHH, or

it can present as a much more dramatic disease with high morbidity and even mortality if untreated, a syndrome known as neonatal severe primary hyperparathyroidism (NSHPT). Owing to the severity of its symptoms, signs, and biochemical abnormalities, NSHPT was described several decades before FBHH. It manifests at birth, with severe hypercalcemia, hypotonia, osteitis fibrosa cystica, respiratory difficulty, failure to thrive, parathyroid hyperplasia, and, in general, markedly elevated serum levels of PTH (Fujita *et al.,* 1983; Marx *et al.,* 1982; Page and Haddow, 1987; Sereni *et al.,* 1982; Steinmann *et al.,* 1984). Additional clinical features include chest wall deformities, sometimes resulting in a flail chest syndrome secondary to multiple rib fractures, dysmorphic facies, and anovaginal and rectovaginal fistulas (Marx *et al.,* 1982; Spiegel *et al.,* 1977; Steinmann *et al.,* 1984). The hypercalcemia is usually severe, ranging from 14 to 20 mg/dl [one patient had a serum calcium concentration of 30.8 mg/dl (Corbeel *et al.,* 1968)], PTH levels are elevated by 5- to 10-fold (Fujimoto *et al.,* 1990), and examination of the parathyroid glands reveals four gland hyperplasia (Cole, 1997; Cooper *et al.,* 1986; Fujimoto *et al.,* 1990; Lutz *et al.,* 1986; Marx *et al.,* 1982; Matsuo *et al.,* 1982). Some affected infants have died from NSHPT, others have survived after total or subtotal parathyroidectomy, and, in more recent series, a substantial percentage of cases survived without parathyroid surgery. Indeed, some neonates with neonatal hyperparathyroidism who originally presented with respiratory compromise and demineralization have been reported to improve (Harris and D'Ercole, 1989; Orwoll *et al.,* 1982; Page and Haddow, 1987; Wilkinson and James, 1993). Rarely, individuals with homozygous inactivating mutations of the CaSR, known to cause NSHPT, have been identified serendipitously for the first time in childhood or even adulthood with moderate to severe hypercalcemia (with serum calcium levels of 14−20 mg/dl), albeit compatible with a relatively asymptomatic state, suggesting residual activity of the two inherited mutated receptors (Aida *et al.,* 1995; Chikatsu *et al.,* 1999; Miyashiro *et al*., 2004). The surprising lack of apparent symptoms and complications of hypercalcemia such as impaired renal function or a urinary concentrating defect in these individuals support the notion that the CaR mediates at least some of the symptoms of hypercalcemia as well as associated effects on the kidney. Marked phenotypic variation was noted in four affected individuals from one kindred carrying the same homozygous point mutation encoding an early stop codon (Waller *et al.*, 2004). Whereas two patients underwent parathyroidectomy in early childhood, the other two survived into adolescence without parathyroidectomy (Waller *et al.,* 2004). The explanation for such phenotypic variation remains elusive.

In neonatal hyperparathyroidism, the serum calcium level is usually less elevated than in NSHPT and patients have no evidence of bone disease, the latter being a prominent feature of NSHPT. This probably reflects the fact that these neonates carry only one abnormal copy of the FBHH gene, whereas the severity of hypercalcemia and bone disease in NSHPT results from the inheritance of a double dose of the abnormal gene.

Genetic Basis of NSHPT

NSHPT may occur as a sporadic disorder, but has also been described in kindreds having FBHH (Fujita *et al.,* 1983; Marx *et al.,* 1982; Page and Haddow, 1987; Sereni *et al.,* 1982; Steinmann *et al.,* 1984). When NSHPT has occurred in FBHH families, in some cases both parents have been hypercalcemic, suggesting the possibility that NSHPT is the clinical manifestation of homozygosity for an FBHH mutation (Chou *et al.,* 1995; Janicic *et al.,* 1995; Pollak *et al.,* 1993); although in occasional cases, as stated above, patients presented for the first time in childhood or even adulthood (Aida *et al.,* 1995; Chikatsu *et al.,* 1999; Miyashiro *et al.,* 2004).

Thus, NSHPT can result from any of the following genetic alterations in the CaSR:

1. Homozygous form of FBHH: the neonate from a consanguineous marriage inherits a double dose of FBHH mutation, one from each heterozygous parent (Marx *et al.,* 1981, 1982, 1985; Pollak *et al.,* 1994).
2. Compound heterozygous form of FBHH: the neonate is the offspring of two individuals with two different mutations in the CaSR (Kobayashi *et al.,* 1997).
3. Heterozygous form of NHPT: when the neonate occurs sporadically or comes from an FBHH family with only one parent affected (Harris and D'Ercole, 1989; Orwoll *et al.,* 1982; Page and Haddow, 1987; Powel *et al.,* 1993; Spiegel *et al.,* 1977; Wilkinson and James, 1993). Several potential explanations may be offered for that observation. The parents are both carriers of a CaSR mutation but only one is recognized, the offspring may experience a negative dominant effect of the abnormal gene on the normal one (Bai *et al.,* 1997), or the off-spring carries *de novo* heterozygous mutations (Bai *et al.,* 1997; Pearce *et al*., 1995b).

It is also possible that in some cases the gestation of an FBHH fetus in an unaffected mother induces secondary hyperparathyroidism in the former because of exposure of the fetal parathyroid gland to the relative hypocalcemia of the maternal-fetal circulation.

Mice Models of NSHPT

Mice homozygous for a disrupted CaSR gene have more substantial hypercalcemia (14.8 ± 1.0 mg/dl), higher PTH levels, and increased parathyroid size compared to mice heterozygous for the mutated gene (Ho *et al.,* 1995). The homozygotes grow poorly, have multiple bony abnormalities and usually die within 4 weeks (Ho *et al.,* 1995).

Homozygous null mutation mice also have reduced skeletal radiodensity, kyphoscoliosis, and bowing of long bones, reminiscent of the skeletal anomalies in human NSHPT (Fujita *et al.,* 1983; Marx *et al.,* 1982; Page and Haddow, 1987; Sereni *et al.,* 1982; Steinmann *et al.,* 1984). These important data fulfill "Koch's postulates" for $FBHH_{3q}$ and make it almost certain that inactivating mutation of the human CaSR gene is the cause of FBHH and NSHPT in many, if not most, kindreds.

Management of Neonatal Hyperparathyroidism

In older reports, cases that were managed medically had a much worse prognosis than did those who underwent total parathyroidectomy (Cooper *et al.,* 1986; Fujimoto *et al.,* 1990; Hillman *et al.,* 1964; Marx *et al.,* 1982; Matsuo *et al.,* 1982; Spiegel *et al.,* 1977). Since 1980, milder forms of neonatal hyperparathyroidism have been noted that may improve with medical therapy alone. At this point it would be wise to aggressively support any neonate presenting with NSHPT or neonatal hyperparathyroidism with hydration, mechanical ventilation (if needed due to chest wall abnormalities), and rely on surgery only in those who fail to improve with supportive measures. In some cases, a bisphosphonate may be useful as a temporizing measure, presumably because of the severe hyperparathyroid bone disease (Waller, *et al.* 2004). It is also possible that the calcimimetic CaR activators, such as cinacalcet, may be of use, as this drug has recently been shown to be effective in ameliorating the hypercalcemia in a case of FBHH that was more severe than the norm (Timmers, *et al.,* 2006). For this drug to be active in this setting, however, there would have to be some residual activity of the mutant CaR(s), which would enable them to be sensitized to extracellular calcium by the calcimimetic. The surgical intervention of choice would be total parathyroidectomy with immediate or delayed autotransplantation. Bony remineralization generally occurs within a matter of months(s) after successful parathyroid surgery (Cooper *et al.,* 1986; Fujimoto *et al.,* 1990; Lutz *et al.,* 1986). Any person known to have FBHH should ask his/her spouse to have a measurement of serum calcium performed; if the other spouse is hypercalcemic and both appear to have FBHH, then a pediatrician knowledgeable about NSHPT should be in attendance at the birth of any children they might have. Consanguinity of the couple obviously would heighten concern about NSHPT, because there would be a 25% chance of their child having the disorder.

CaSR-based therapeutics are well into clinical trials (Silverberg *et al.,* 1997; Wada *et al.,* 1999). They may be useful tools not only in our understanding of the role of the CaSR in several organs, but also in the medical management of disorders of abnormal calcium-sensing. In NSHPT, as long as there is some residual function of the CaSR, calcium receptor agonists would presumably be helpful. They could also be used in the more severe variants of FBHH in the neonatal period as well as in adulthood—for instance in the most recent FBHH syndrome described (Carling *et al.,* 2000), as well as in autoimmune FBHH.

CONCLUSIONS

Study of the FBHH syndrome has led to fascinating, important advances in our understanding of the regulation of systemic calcium metabolism (Brown *et al.,* 1995a; Pearce *et al.,* 1995a). What appeared at first to be a single, homogeneous hypercalcemic syndrome represents at least three genetically distinct disorders: $FBHH_{3q}$ (probably always a disorder of the parathyroid CaSR), $FBHH_{19p}$ (which may result from mutation of a gene encoding another component of the calcium receptor activation pathway, a G_{sa} protein gene), and $FBHH_{3q}$ (which accounts for the overwhelming majority of cases to date). It is possible that FBHH may also map to as-yet-unidentified genes that encode for additional CaSR or for proteins that alter the function of these sensors. $FBHH_{3q}$ is the clinical manifestation of heterozygous reduction or loss of CaSR function in the parathyroid glands and renal tubules, whereas NSHPT is usually the phenotype of homozygous loss or reduction of CaSR function. On the other end of the spectrum, activating mutation in the CaSR causes undersecretion of PTH, otherwise known as autosomal dominant hypocalcemia or hypercalciuric hypocalcemia (**see Chapter 65 Genetic Regulation of the Parathyroid Gland Development**). Further insights into the structure−function relationship of the CaSR will undoubtedly enhance our understanding of the wide spectrum of the phenotypic expressions of FBHH and NSHPT. Furthermore, as-yet-unexplained phenotypic features of NSHPT may be providing subtle hints in this "experiment of nature" of currently unknown roles for the CaSR in nonclassical calcium-targeted organs. When the physician suspects FBHH in an individual patient, current knowledge permits only presumptive nongenetic diagnosis of the syndrome, but continuing research may soon lead to DNA-based screening studies not only for diagnosis of the FBHH syndrome, but also for determining the specific molecular basis, in individual patients. The goal of avoiding needless surgery in FBHH would then be achievable.

INTRODUCTION

Multiple endocrine neoplasia type 1 (MEN1) syndrome is a rare disorder presenting with varying combinations among its three main endocrine tumors (parathyroid entero-pancreatic, and pituitary), but it includes a varying combination of more than 20 endocrine and nonendocrine tumors (Gagel and Marx, 2007). In fact, other endocrine and nonendocrine neoplasms such as foregut carcinoids, lipomas, and skin tumors are also common in MEN1. Furthermore, other endocrine and nonendocrine tissues can be affected but with a lower frequency (Table I). Current definition of MEN1 operationally consists of a case with two of these three principal MEN1-related endocrine tumors. Many tumors in MEN1 are benign, even if some enteropancreatic neuroendocrine tumors (mainly gastrinomas) and foregut carcinoids are often malignant. Though often regarded as a treatable endocrinopathy, MEN1 can also be regarded as a cancer syndrome lacking effective prevention or cure for associated malignancies. About one third of MEN1 carriers die eventually from an MEN1-related cancer (Wilkinson *et al.,* 1993; Doherty *et al.,* 1998). This is a lethality similar to that of untreated MEN2. MEN1 exhibits an autosomal dominant pattern of inheritance. Familial MEN1 syndrome is defined as MEN1 syndrome in an individual who has at least one first-degree relative with at least one of the three main endocrine tumors. Sporadic cases associated with mutation of the *MEN1* gene represent about 10% of cases. MEN1 has received attention out of proportion to its rarity because it is judged a promising model for insights into common tumors. The tumor develops after inactivation of both *MEN1* gene copies at chromosome 11q12–q13, with acquisition of a homozygous recessive state at the tissue level, a process of subchromosomal rearrangement that led to initial localization of the *MEN1* gene and also that assisted later in *MEN1* gene discovery by positional cloning (Larsson *et al.,* 1988; Bystrom *et al.*, 1990; Chandrasekarappa *et al.,* 1997).

The syndrome was originally described as an autopsy finding in a patient with acromegaly and four enlarged parathyroid glands (Erdheim, 1903). More than 20 years later, two groups reported a patient with the triad of parathyroid, pancreatic, and pituitary adenomas (Cushing and Davidoff, 1927). In 1953, Underdahl *et al.,* published an early review of related syndromes with a total of 14 cases (Underdahl *et al.,* 1953). However, it remained for Wermer to recognize transmission in a large family and to suggest that an autosomal dominant gene caused the trait with high penetrance (Wermer, 1954). This insight is commemorated by referring to MEN1 also as Wermer syndrome.

The clinical features of the disorder were then clarified greatly after 1960, when radioimmunoassays for the various

Principles of Bone Biology, 3rd Edition

TABLE I MEN1-Associated Tumors

Typical (or More Frequent) Tumors	Less Prominent Tumors	Rare Tumors
Endocrine		
Parathyroid adenoma (~90%)	Foregut-derived carcinoid (5%)	Adrenal medulla
Anterior pituitary (~25%) (prevalently PRLoma) (20%)	Adrenal cortical (~25%) (mainly nonfunctioning)	
Neuroendocrine cells of GI tract (gastrinoma, insulinoma, VIPoma, glucagonoma, PPoma) (~50%)		Ductal adenocarcinoma of the pancreas
Nonendocrine		
Nonsecreting of GI tract (20%) and of pituitary (10%)	Lipoma (visceral and cutaneous) (~30%)	Ependymoma
	Skin tumor [facial angiofibroma (85%), truncal collagenoma (70%)]	Leiomyoma of esophagus or uterus
		Meningioma

GI, *gastrointestinal*; P*ancreatic* P*olypeptide*tumor, PP*oma*; PRL*oma*; V*asoactive* I*ntestinal* P*eptide* VIP*oma*.

products of the affected endocrine tumors were developed (Yalow, 1978; Malarkey, 1979; Nussbaum and Potts, 1991). Progress in the management of MEN1 paralleled knowledge of the pathogenesis of common-variety endocrine tumors and included improving surgical and pharmacological interventions (Albright and Ellsworth, 1990; Bevan *et al.,* 1992; Schmid *et al.,* 1961).

CLINICAL ASPECTS

MEN1 Variants

Because of the constantly growing clinical and genetic knowledge about this syndrome, the MEN1-associated endocrinopathies, and their sporadic counterparts, it has become possible to recognize peculiar MEN1 variants (differing clinical expressions from one gene) and phenocopies (similar phenotype but not from the same gene; Marx, 2001).

Because primary hyperparathyroidism (PHPT) is the earliest and most frequent expression of MEN1, familial isolated hyperparathyroidism (FIHP; Kassem *et al.,* 1994) in one-fifth of families with isolated hyperparathyroidism can be a prelude to typical MEN1 or an atypical expression of MEN1 (Marx *et al.,* 1982). However, in a much larger and more "elderly" family, isolated hyperparathyroidism (FIHP) could be a distinctive variant from *MEN1* mutation or an expression from a different gene (Kassem *et al.,* 2000; Miedlich *et al.*, 2001). FIHP is characterized by parathyroid adenoma or hyperplasia without other associated endocrinopathies in two or more individuals in one family. Germline mutations in *MEN1* gene have been reported in 0% (Simonds *et al.,* 2002) to 57% of families with FIHP (Pannett *et al.,* 2003; Warner *et al*., 2004).

A variant (or subtype), caused by *MEN1* mutation, termed the prolactinoma or "Burin" MEN1 variant shows high penetrance of hyperparathyroidism and of prolactinoma (Petty *et al.*, 1994); the prevalence of gastrinoma is lower than in typical MEN1 (Hao *et al.,* 2004). The prolactinoma MEN1 variant has been associated with *MEN1* mutation or 11q13 linkage in each of three tested families (Agarwal *et al.,* 1997). The *MEN1* mutations in FIHP and "Burin" MEN1 variants have not shown any informative pattern; the causes of these variants are not known. Thus, a family with an MEN1-variant and proven or likely *MEN1* mutation should remain under surveillance for other expressions of MEN1. Recently, Ozawa *et al.* (2007) reviewed an MEN1 variant defined by sporadic tumors of both the parathyroids and pituitary and with a lower prevalence of *MEN1* mutations than in familial MEN1 (7% versus 90%), suggesting different causes.

MEN1 Phenocopies

An MEN1 phenocopy is a trait that strongly resembles MEN1 in a patient or a family without identified *MEN1* mutation. It could be a case of FIHP in which *MEN1* mutation analysis failed to detect mutation; thus, it could be caused by mutation in another gene, such as the calcium-sensing receptor gene (*CASR*), accounting for familial hypocalciuric hypercalcemia (FHH) syndrome (Pollak *et al.,* 1993), and the *HRPT2* gene responsible for the hyperparathyroidism-jaw tumor syndrome (HPT-JT; Szabo *et al.,* 1994; Teh *et al.,* 1998a; Carpten *et al.,* 2002). Currently, about 15% (Simonds *et al.,* 2002; Warner *et al*., 2004) of families with FIHP have identifiable *CASR* mutations, whereas *HRPT2* mutation is less frequent (Simonds *et al.,* 2003; Warner *et al.,* 2004).

Familial isolated pituitary tumor, generally somatotropinoma, has so far yielded no *MEN1* mutation with a collective experience of more than 100 tested families (Tanaka *et al.,* 1998; Teh *et al.,* 1998b; Tsukada *et al.,* 2001; Daly *et al.*, 2007). Although positive linkage to 11q13 has been reported in each of about four large kindreds with isolated familial somatotrophinoma (Gadelha *et al.,* 2000; Luccio-Camelo *et al.,* 2004), mutation in the *MEN1* gene has not been detected. Consequently, the involvement of a nearby gene at 11q13 was sought.

The pituitary tumor gene at 11q13 was identified by a Finnish group (Vierimaa *et al.,* 2006); it was a previously characterized gene termed aryl hydrocarbon receptor interacting protein (*AIP*). Daly *et al.* (2007) confirmed this in a large series with germline *AIP* mutations in 11 of 73 (15%) kindreds with Familial Isolated Pituitary Adenoma (FIPA).

Recently one small family meeting the criteria of MEN1 was reported (Pellegata *et al.,* 2006). It showed no *MEN1* mutation, but affected members had a *p27* mutation linked to their MEN1 trait. The tumors observed were somatotropinoma (2), parathyroid (1), and renal angiomyolipoma (1). This seems to be a rare and important phenocopy of classic MEN1, and more families will need to be studied to understand the complete phenotype.

Differences between MEN1 Tumors and Common Tumors

The endocrine tumors of MEN1 are generally seen as a model of common-variety endocrine tumors. This is supported by the fact that the *MEN1* gene initiates a large proportion of common-variety endocrine tumors (see later discussion). However, there are also two important differences between the categories of MEN1 and common tumor.

First, any MEN1 tumor by itself can show a signature of the *MEN1* gene (i.e., gene expression) that is different from another gene that might initiate a common-variety tumor in the same tissue. This may account for the unusual location of MEN1 carcinoids (foregut as opposed to more distally). It also likely accounts for the larger size of pituitary tumor in MEN1 (Verges *et al.,* 2002); common-variety tumor of the pituitary is almost always initiated by genes other than *MEN1*. And in the parathyroid, it helps account for why parathyroid cancer is rare in MEN1. This unusual parathyroid pathology is usually promoted by mutation on both copies of the *HRPT2* gene (Shattuck *et al.,* 2003).

Second, the tumors of MEN1 are often multiple within a tissue affected at high penetrance. This is a general property of all hereditary tumors, and it reflects the fact that each cell (because of having inherited the gene mutation in all cells) in a target tissue is at high risk for tumor initiation from a second mutation of the other copy of the same gene. This accounts for parathyroid adenoma in three to four glands underlying the hyperparathyroidism of MEN1. It is also a feature in the Zollinger-Ellison syndrome of MEN1; there are numerous submucosal microgastrinomas. The multiplicity of endocrine tumors in these two tissues makes these tumors unusually resistant to standard surgical methods optimized to ablate one tumor. And many modifications to management have been developed (see later discussion). The most extreme is frequent avoidance of surgery for gastrinoma of MEN1 and treatment only with stomach acid-blocking drugs.

Primary Hyperparathyroidism in MEN1

Primary hyperparathyroidism is the most common endocrinopathy in MEN1, reaching nearly 100% by age 50 (Skarulis, 1998), and it is usually the first endocrine manifestation of MEN1 syndrome in 90% of individuals, recognized as early as age 8 in several cases (Trump *et al.,* 1996).

The clinical features of the parathyroid hyperfunction in MEN1 show similarities to those of sporadic or common-variety primary hyperparathyroidism (Bilezikian *et al.,* 1995; Kleerekoper, 1995) with a long period of asymptomatic hypercalcemia and a low morbidity. The complications of the disorder are prevented by early intervention from an experienced surgeon.

In contrast to sporadic hyperparathyroidism, hyperparathyroidism (often asymptomatic) in patients with MEN1 develops at a younger age (Betts *et al.,* 1980; Skogseid *et al.,* 1991). Its average onset age is 20 to 25 years (Trump *et al.,* 1996; Skarulis 1998), three decades earlier than typical for sporadic parathyroid adenoma. Moreover, different from sporadic primary hyperparathyroidism (Heath *et al.,* 1980), primary hyperparathyroidism in MEN1 has a similar prevalence in females and males. Finally, unlike single adenoma of sporadic primary hyperparathyroidism, primary hyperparathyroidism in MEN1 is associated with multiple and asymmetric parathyroid gland enlargement (Hellman *et al.,* 1992; Marx *et al.,* 1991). MEN1-associated hyperparathyroidism increases gastrin secretion from gastrinoma(s), precipitating and/or exacerbating symptoms of Zollinger-Ellison syndrome (ZES; Marx, 2001), and consequently a successful parathyroidectomy could decrease the severity of the ZES in MEN1 (Jensen, 1997). Still, because of excellent pharmacotherapy for ZES, ZES does not represent a sufficient indication for parathyroidectomy in MEN1.

After successful subtotal parathyroidectomy, hyperparathyroidism in MEN1 recurs progressively, reaching 50% by 8–12 years after surgery (Rizzoli *et al.,* 1985; Burgess *et al.,* 1998a). In theory, it could be due to the further growth of a neoplastic parathyroid tissue or to a new somatic mutation at 11q13 in the seemingly normal parathyroid remnant.

Burgess *et al.* (1999) reported a reduction of bone mass in MEN1-affected women with hyperparathyroidism by 35 years of age (44%), with an increased likelihood of skeletal fractures. If surgery is delayed or withheld, the use of bone antiresorptive agents should be considered in order to reduce hypercalcemia and limit PTH-dependent bone resorption, reducing future risk of osteoporosis. Parathyroidectomy and maintenance of a normocalcemic state resulted in improvement of both lumbar and femoral BMD.

Well-Differentiated Endocrine Tumors of the Gastro-Entero-Pancreatic Tract

The prevalence of gastro-entero-pancreatic (GEP) involvement (including tumors of the stomach, duodenum, and pancreas; Klöppel *et al.,* 2004) in MEN1-affected individuals varies in different clinical series at 30% to 75% (Marx, 2001; Skogseid *et al.,* 1991; Vasen *et al.,* 1989) and approaches 80% in surgery or autopsy series. A GEP tumor is often recognized because of clinically overt features during the fifth decade but may be detected by chemistries or by imaging much earlier (third decade) in asymptomatic *MEN1* carriers. Unlike nonfamilial endocrine tumor of the upper gastrointestinal tract, tumors in patients with MEN1 are usually multiple and develop at a younger age; MEN1-associated gastrinoma and insulinoma exhibit an average onset age 1 decade earlier than their sporadic counterparts (Skarulis, 1998), and, in particular, ZES usually occurs before age 40 years (Gibril *et al*., 2004). Moreover, the gastrointestinal manifestations are influenced by other endocrinopathies (mainly primary hyperparathyroidism; Bone, 1990; Norton *et al.,* 1993).

Initial presentation of MEN1 as ZES occurs only in a small proportion of patients (Benya *et al.,* 1993a). The early presentation of these tumors is frequently associated with the lack of detection of the tumor by routine abdominal imaging techniques (Galiber *et al.,* 1988; Norton *et al.,* 1993).

The majority of tumors with MEN1 ZES are in the duodenum and are usually small (diameter <0.5 cm). The most frequent GEP functional endocrine tumors in MEN1 are gastrinomas (54%) and benign insulinomas (15%; Eberle and Grun, 1981; Jensen and Gardner, 1993; Metz and Jensen, 1993; Norton *et al.,* 1993). About 40% of MEN1 cases exhibit gastrinoma, and about one-fourth of all gastrinoma cases have MEN1. Moreover, 25% of individuals with MEN1 syndrome/ZES deny awareness of any family history of MEN1 syndrome (Gibril *et al*., 2004). Most MEN1 gastrinomas are malignant; half have metastasized before diagnosis (Townsend and Thompson, 1990; Brandi *et al*., 2001). One-third of patients with sporadic and MEN1-associated ZES eventually die from the malignant aspects of their tumor(s). Poor prognosis is associated with pancreatic (not duodenal) primary (more aggressive than duodenal gastrinomas, as suggested by their larger size and greater risk for hepatic metastasis), liver metastases (there is not a clear evidence that lymph node metastases negatively influence prognosis), ectopic Cushing syndrome, or very high gastrin level (Yu *et al.,* 1999).

The diagnosis of gastrinoma is made by elevated serum gastrin and high gastric acid output, with or without symptoms. Confirmatory tests can include secretin-stimulated gastrin levels (Wiedenmann *et al.,* 1998). A 72-hr fast protocol may be helpful in the diagnosis of insulinoma that is characterized by fasting hypoglycemia with high plasma or serum concentration of insulin and high plasma or serum concentration of C-peptide or proinsulin (Brandi *et al*., 2001; Marx, 2001).

Pancreatic glucagonomas, vasoactive intestinal peptide tumors (VIPomas), growth hormone releasing factor tumors (GRFomas), and somatostatinomas have also been described in MEN1 (Eberle and Grun, 1981; Norton *et al.,* 1993) and usually exhibit a large diameter (>3 cm; Mignon *et al*., 1993). However, nonfunctional[1] (NF) endocrine tumors, difficult to diagnose by both biochemical and imaging tests, are the most prevalent GEP endocrine neoplasms in MEN1, more than half being pancreatic polypeptide tumors (PPomas; Eberle and Grun, 1981; Metz and Jensen, 1993; Norton *et al.,* 1993; Jensen, 1999). These tumors may occur in nonoperated individuals as well as in the remnants that remain after resection for a GEP tract tumor. Type II tumors of gastric histamine-secreting enterochromaffin-like cells (ECLomas or gastric carcinoids) frequently accompany Zollinger-Ellison-associated hypergastrinemia (Jensen and Gardner, 1991; Maton and Dayal, 1991). It is generally believed that prolonged hypergastrinemia worsens ECLomas (Frucht *et al.,* 1991; Maton and Dayal, 1991; Bordi *et al.,* 1998). This is particularly true for patients with MEN1 (Frucht *et al.,* 1991; Jensen and Gardner, 1991; Maton and Dayal, 1991). The mean age at diagnosis of gastric carcinoids is 50 years. Currently, ECLomas are included in the well-differentiated endocrine tumors of the GEP tract. They are common in MEN1 and are usually recognized incidentally during gastric endoscopy for ZES (Benya *et al.,* 1993b; Bordi *et al.,* 1998; Gibril *et al*., 2000).

Though sporadic carcinoid tumors are mainly in the midgut or hindgut, MEN1 carcinoids are all in the foregut (Duh *et al.*, 1987; Godwin, 1975). Foregut carcinoids in MEN1 rarely oversecrete amine or peptide hormones. MEN1 thymic carcinoid exhibits a male predominance, and cigarette smoking appears to be associated with a higher risk for thymic carcinoid (Teh *et al.,* 1997). MEN1 bronchial carcinoid is mainly in females. Bronchial carcinoids,

[1]Nonfunctional tumors are those that do not make a known hormone, make a hormone but do not secrete enough to cause a syndrome, or make and secrete a hormone (such as pancreatic polypeptide or calcitonin) that does not cause a syndrome.

often multicentric, may exhibit both synchronous and metasynchronous occurrence. In contrast to thymic carcinoids, most bronchial carcinoids usually behave indolently, albeit with the potential for local mass effect, metastasis, and recurrence after resection (Sachithanandan *et al*., 2005).

Tumors of the Anterior Pituitary or the Adrenal in MEN1

An anterior pituitary tumor is the first clinical manifestation of MEN1 in 25% of simplex cases (i.e., a single occurrence of MEN1 syndrome in a family) and in 10% of familial cases (Carty *et al.,* 1998; Falchetti *et al*., 2005). Verges *et al.* (2002) reported pituitary adenomas as the initial manifestation of MEN1 syndrome in 17% of individuals and significantly more frequent in women than in men (50% versus 31%, $P < 0.001$). The occurrence of anterior pituitary tumors in MEN1 syndrome ranges between 10% and 60% depending on the study and methods utilized in the various studies (Metz *et al.,* 1994; Brandi *et al*., 2001). Between 65% (Brandi *et al*., 2001) and 85% of pituitary tumors in MEN1 syndrome are macroadenomas, compared to only 42% in common-variety tumor (Verges *et al.,* 2002).

It was formerly reported that every type of anterior pituitary adenoma, except "true" gonadotropinoma, has been reported in MEN1 (Teh *et al.,* 1998b; Corbetta *et al.,* 1997), but Benito *et al.* (2005) reported the presence of a metastatic gonadotrophic pituitary carcinoma in a female individual with MEN1. The frequency of plurihormonal tumors is greater in MEN1 tumors, with fewer null-cell tumors when compared to sporadic isolated pituitary tumors (Scheithauer *et al.,* 1987).

The mean age at the time of diagnosis of MEN1 pituitary tumors is about 40 years (Oberg *et al.,* 1989; Vasen *et al.,* 1989; Skarulis, 1998), similar to that for sporadic isolated pituitary tumors (Scheithauer *et al.,* 1987). Prolactinoma (with or without simultaneous growth hormone [GH] oversecretion) is the most frequent pituitary tumor in MEN1, followed by GHoma (Scheithauer *et al.,* 1987). A universal consensus regarding the cancer risk of MEN1-associated pituitary tumors does not exist, and although Verges *et al.* (2002) reported that 32% of pituitary macroadenomas were invasive, dissemination of MEN1-associated pituitary tumors is rare.

Primary adrenocortical neoplasms are common in MEN1 (20–40%) and they are usually bilateral, hyperplastic, and nonfunctional (Skarulis, 1998; Skogseid *et al.,* 1992, 1995; Burgess *et al.,* 1996). The adrenal cortex tumors are occasionally associated with primary hypercortisolism, this resulting mainly from pituitary oversecretion of adrenocorticotrophic hormone (ACTH) (Maton *et al.,* 1986); hyperaldosteronism has been much more rare (Skogseid *et al.,* 1992; Beckers *et al.,* 1992; Honda *et al*., 2004). Most of the adrenal enlargements exhibit an indolent clinical course (Metz *et al.,* 1994; Burgess *et al.,* 1996).

Pheochromocytoma is in less than 1% of cases and always unilateral in MEN1 (Brandi *et al.,* 2001). A low-penetrance tumor is almost never bilateral. Because $11q13$ loss of heterozygosity (LOH) is associated with pheochromocytoma in MEN1, pheochromocytoma should be considered a direct result of *MEN1* gene inactivation (Cote *et al.,* 1998a). Thus, it is appropriate to measure urinary catecholamines prior to surgery to diagnose and treat a pheochromocytoma to avoid dangerous and potentially lethal blood pressure peaks during surgery.

Nonendocrine Tumors

Lipomas are frequently associated with MEN1 (20–30%; Ballard *et al*., 1964; Marx *et al.,* 1982; Metz *et al.,* 1994; Darling *et al.,* 1997). They are often multiple and can also occur viscerally. Lesions, often multicentric, may be small or large and cosmetically disturbing. They typically do not recur after removal. Multiple facial angiofibromas were observed in 40% to 90% of MEN1 patients, with half of the cases having five or more (Hoang-Xuan and Steger, 1999; Sakurai *et al.,* 2000); truncal collagenomas were almost as common (Darling *et al.,* 1997).

Leiomyoma of the esophagus, uterus, or rectum has occurred; the frequency of leiomyoma in MEN1 has not been analyzed (Vortmeyer *et al.,* 1999; Dackiw *et al.,* 1999). They are benign neoplasms derived from smooth (nonstriated) muscle (McKeeby *et al.,* 2001; Ikota *et al.,* 2004).

TREATMENTS

Primary Hyperparathyroidism

Surgery for hyperparathyroidism in MEN1, more so than for the sporadic form, is still the preferred treatment. No general consensus has been reached on which technique could be the optimal surgical approach in MEN1-associated HPT. The decision about timing for parathyroid surgery usually takes into account the following criteria: (1) severity of symptoms or signs of HPT; (2) concentration of circulating PTH and calcium; (3) presence of MEN1-associated endocrinopathies, especially ZES; (4) patient age. Successful treatment of HPT is often followed by a decrease of the elevated circulating levels of gastrin. Persistence, late recurrence, and hypoparathyroidism are all more frequent after surgery for MEN1 than for sporadic adenoma. Several approaches address these problems.

In particular, the rapid intraoperative assay of PTH makes it possible for the operating surgeon to monitor the correction of hyperparathyroidism, to be sure when the important tumors have been removed, and to perform,

when necessary, an immediate parathyroid autograft (Tonelli *et al.,* 1994, 2000).

Calcium-sensing receptor agonists, a new and novel class of drugs, have been demonstrated to act directly on the parathyroid gland, decreasing PTH release (Brown *et al.*, 1995; Peacock *et al.,* 2005) and perhaps even decreasing parathyroid tumor growth. They might acquire an important role in treatment of hyperparathyroidism, including that from MEN1.

Subtotal Parathyroidectomy

Subtotal parathyroidectomy is the surgical ablation of three parathyroid glands and part of the fourth gland, leaving no more than 50 mg of tissue from the least abnormal gland (Carling and Udelsman, 2005). Some authors suggest that the whole fourth parathyroid gland be left without biopsy when it appears to be of normal size. This kind of procedure has been proposed in order to avoid permanent hypoparathyroidism and to reduce the period of temporary postsurgical hypocalcemia. Rates of chronic hypocalcemia with these surgical approaches range from 0% to 30% (Goretzki *et al.,* 1991; Grant and Weaver, 1994; Kraimps *et al.,* 1992; O'Riordain *et al.,* 1993; Thompson and Sandelin, 1994). Frequent late recurrence of hyperparathyroidism follows successful subtotal parathyroidectomy in MEN1. The prevalence of recurrence increases proportionately with time after surgery (Hellman *et al.,* 1992; Kraimps *et al.,* 1992; Prinz *et al.,* 1981; Rizzoli *et al.,* 1985; Burgess *et al.,* 1998a). Elaraj *et al.* (2003) showed that subtotal and total parathyroidectomy resulted in longer recurrence-free intervals compared with lesser resection. Cumulative recurrence rates for procedures with a less than subtotal parathyroid resection were 8%, 31%, and 63% at 1, 5, and 10 years, respectively, whereas for more extensive parathyroid resection, subtotal or total, the cumulative recurrence rates were 0%, 20%, and 39% at 1, 5, and 10 years, respectively (Elaraj *et al*., 2003).

Total parathyroidectomy with simultaneous autologous parathyroid graft (Wells *et al.,* 1980) is a more radical approach for MEN1-associated hyperparathyroidism. The whole parathyroid and thymic tissues are removed for the purpose of avoiding subsequent exploration for hyperparathyroidism or for thymic carcinoid. The parathyroid graft is performed by one of two main procedures. The first is the use of fresh autologous tissue kept in refrigerated saline solution and grafted immediately at the end of surgery. The advantage of this approach is that the graft is more likely to succeed. The disadvantage is not being able to verify the absence of functioning tissue remnant, normal remaining ectopic gland, or supernumerary gland. In the second procedure, implantation is performed some days or months after surgery using cryopreserved autologous tissue. With this approach the lack of circulating PTH can be evaluated after parathyroidectomy. However, the viability of parathyroid tissue may be lower after cryopreservation. In both techniques, the parathyroid gland to be transplanted is the one that macroscopically exhibits the features closest to a normal gland, preferably lacking any nodular histopathology. The tissue that is transplanted varies from 5 to 20 1-mm^3-sized fragments. The graft is generally placed within the brachioradialis muscle so that it is sometimes possible to verify its function by simple blood sampling from the ipsilateral antecubital vein.

Because normal parathyroid glands can also be found in MEN1 patients, some authors believe that four-glands surgery is not always necessary. In this way the risk of permanent hypocalcemia is avoided. If partial parathyroidectomy is performed, an acceptable approach includes removal of the pathological and the normal homolateral gland, including thymectomy, and biopsy of the contralateral apparently normal parathyroids (Dralle and Scheumann, 1994). Consequently, the risk of persistent hyperparathyroidism is reduced and the lack or presence of multiglandular parathyroid involvement is determined. Whatever the approach to parathyroidectomy, an initial neck operation in MEN1 should include transcervical thymectomy. Most of the thymus can thereby be removed along with possibly included parathyroid tissue and carcinoid tissue.

Neuroendocrine Tumors

Gastrinoma(s)

Gastric acid hypersecretion in virtually all patients with hypergastrinemia can be effectively controlled using histamine H_2-receptor antagonists or H^+, K^+-ATPase inhibitors (Brunner *et al.,* 1989a, 1989b; Jensen, 1997, 1999).

The surgical approach, if any, to be taken for gastrinoma(s) in MEN1 is controversial (Norton *et al.,* 1999) because successful outcome of surgery is rare. Some authors recommend surgery only in case of precise localization of gastrinoma, or in presence of particularly aggressive familial gastrinomas (Melvin *et al.,* 1993; Sheppard *et al.,* 1989), whereas other authors would perform surgery in all cases (Thompson *et al.,* 1993). Because MEN1 syndrome gastrinomas occur most commonly in the first and second portions of the duodenum, and less commonly the third and fourth duodenal portions and the first jejunal loop (Pipeleers-Marichal *et al.,* 1990), it is important that all these sites be examined during preoperative imaging, intraoperative exploration, and pathological examination of surgical specimens (Tonelli *et al.,* 2005).

Consequently, surgery has to follow the necessary procedures of tumor localization, such as SRS and selective infusion of secretin or calcium in selective pancreatic arteries followed by hepatic vein sampling for gastrin measurement (Imamura and Takahashi, 1993). Even though none of these procedures is completely precise for identifying sites of hypersecretion, transarterial challenge can indicate if excessive hormonal release is in the head or in the

corpocaudal segment. Small duodenal gastrinomas are not easily appreciated by external palpation, by intraoperative ultrasound, or by duodenal transillumination. The best approach appears to be intraluminal digital examination of tumors after large longitudinal exposure of the duodenum. The possibility that removal of duodenal gastrinomas and peripancreatic periduodenal lymph nodes might cure hypergastrinemia has been proposed. Duodenal gastrinomas can be approached by a wide longitudinal duodenectomy and treated either by enucleation from the submucosa, if less than 5 mm in diameter, or by full-thickness excision of the duodenal wall if more than 5 mm in diameter. However, this conservative therapy is accompanied by a low percentage of cure (negativity of secretin stimulation test; Thomson *et al.,* 1993) and by neoplastic recurrence (Bartsch *et al.,* 2005). A more aggressive surgical approach is pancreatoduodenectomy. This procedure may be used in those cases where gastrin production is clearly localized in the duodenum or the head of the pancreas. The procedure results in removal of the duodenum, a frequent site of one or more gastrinomas, and removal of metastatic peripancreatic lymph nodes and of tumoral nodules from the pancreatic head. The main shortcoming of this approach is principally represented by the surgical risk for pancreatic fistula or pancreatitis. These complications can be higher than observed in surgery for ductal pancreatic neoplasia due to the increase softness of MEN1 pancreatic tissue. Mortality, following pancreatoduodenectomy in MEN1 patients, is not observed if performed in highly skilled surgical Centers (Bartsch *et al.,* 2005; Tonelli *et al*., 2005). In other functioning neuroendocrine tumors (glucagonoma, VIPoma, PPoma, and somatostatinoma) and nonfunctioning tumors, the indications for surgery and the usual localization of the tumors is easier, because the latter are generally represented by large neoplasms. However, the need of pancreatic surgery for asymptomatic individuals with MEN1 syndrome can be decided when the patient is carefully monitored by endoscopic ultrasound and when the size of the lesion approaches 2 cm.This size criterion is recommended here. Other groups have used smaller or larger size cutoffs. This controversy will not be covered further here.

Endoscopic ultrasound can detect islet tumors in larger numbers and smaller sizes than other methods (Kann *et al.,* 2006). It is not effective in imaging duodenal microgastrinomas because of duodenal motion. It is not clear that detection of the many small, inevitable, and asymptomatic islet tumors in MEN1 is important. The roles for this technically demanding method will be explored further in the coming years.

Patients with systemic metastasis are usually excluded from surgery. Total pancreatectomy is generally not justified because of associated complications. A long-acting somatostatin analogue is now considered to be the drug of choice for controlling hormone secretion under conditions such as glucagonoma and VIPoma (Lamberts *et al.,* 1998; Maton *et al.,* 1989).

Insulinoma

Although one-third of MEN1 pancreatic islet microadenomas exhibit insulin immunoreactivity, only selected lesions larger than 5 mm are symptomatic (Klöppel *et al.,* 1986). Only rarely does insulinoma in MEN1 exhibit malignant degeneration, characterized by extrapancreatic infiltration and/or metastasis. Surgery is usually indicated for insulinoma for the following reasons: (a) Generally hypoglycemia is not easily controlled by drugs; (b) hypoglycemic syndrome is cured by resection of pancreatic macroscopic lesions (O'Riordain *et al.,* 1994); and (c) malignant degeneration is prevented. Surgery can be aided by pre- or intra-operative localization of a pancreatic nodule. According to Tonelli *et al.* (2005), the best surgical approach for an MEN1 insulinoma is intraoperative localization of nodules greater than 0.5 cm diameter by palpation or intraoperative ultrasound followed either by enucleation (removal) of these nodules or by pancreatic resection if multiple large, deep tumors are present. It has been reported that a limited resection or simple enucleation of nodules is more frequently followed by persistence or recurrence of the disease (Demeure *et al.,* 1991; Lo *et al.,* 1998; Simon *et al.,* 1998; Jordan, 1999). A reliable evaluation between different surgical techniques is still not possible because of the rarity of cases. Certainly, it is important to eliminate all the nodules macroscopically evident or greater than 5 mm (by ultrasound). Thus, the treatment of choice is removal of the main pancreatic nodules by pancreatic resection with removal of residual small tumors by enucleation. In case of corporocaudal pancreatic localization, splenic preservation is recommended. Removal of nodules in the pancreatic head is needed in about 50% of patients. This surgical procedure can cause both pancreatic fistulas and pancreatitis and, although a general consensus does not exist, intraoperative monitoring of glucose and insulin may be helpful to verify removal of the tumor (Carneiro *et al*., 2002).

Carcinoids

Surgery remains the first choice for treatment of bronchial and thymic carcinoid tumors. Thymic carcinoid recurred in all individuals with MEN1 syndrome who were followed for more than 1 year after resection of the tumor (Gibril *et al.,* 2003). Prophylactic thymectomy should be considered at the time of neck surgery for primary hyperparathyroidism in males with MEN1 syndrome, particularly those who are smokers or have relatives with thymic carcinoid (Ferolla *et al.,* 2005).

Bronchial carcinoid in MEN1 has a low grade of malignancy. Our method is to remove a small solitary nodule with as conservative a pulmonary procedure as possible. Known metastatic disease is usually not treated surgically, but the course is usually indolent.

In contrast to the surgical approach suggested for the tumors previously mentioned, the approach to ECLomas

in the setting of MEN1 is controversial, because of the multiplicity of gastric primary lesions and because of the uncertainties regarding the prospects of long-term cure as a result of partial or total gastrectomy. The treatment protocol for MEN1 ECLomas should, therefore, be lowering of gastrin levels, intensified endoscopic surveillance and therapy, and gastrectomy on appearance of macrolesions.

Somatostatin analogues have been successfully employed in the treatment of type II gastric carcinoids in three patients with MEN1 syndrome (Tomassetti *et al.,* 2000). During the treatment serum gastrin levels dramatically decreased and tumors regressed in all patients; one of the patients exhibited more than 30 foci widespread throughout the corpus and the fundus of the stomach that disappeared after 1 year of treatment. The regression of tumors was attributed to the decreasing of serum gastrin levels known to be an important factor in the pathogenesis of gastric carcinoid tumors in patients with MEN1 and ZES (Rindi *et al.,* 1996; Bordi *et al.,* 1998). Although long-acting somatostatin analogues can control the secretory hyperfunction associated with carcinoid syndrome, the risk for malignant progression of the tumor remains unchanged (Schnirer *et al.,* 2003).

Pituitary Tumors

In general, the therapy (medical, radiation, surgical) of pituitary tumors is the same as for sporadic pituitary tumors. Dopamine agonists such as cabergoline, bromocriptine, and quinagolide are the preferred treatment of prolactin (PRL)-secreting microadenomas (Bevan *et al.,* 1992). Optimal ways to prevent or monitor for dopaminergic drug-induced cardiac fibrosis have not been established (Schade *et al.,* 2007).

In particular, cabergoline can be considered the current treatment of choice because of its reduced side effects and greater potency, whereas somatostatin analogues are the medical therapy of choice for the treatment of growth hormone-secreting tumors (Beckers *et al.,* 2003).

In contrast, in nonsecreting pituitary adenomas surgical treatment is the treatment of choice, even if in 5% to 15% of cases, medical treatment with potent dopaminergic agonists or sometimes with somatostatin analogues may shrink the adenoma before surgery (Colao *et al.,* 1998). Although general agreement on this topic does not exist, Beckers *et al.* (2003) suggested that aggressive therapy is more frequently needed in MEN1-associated pituitary tumors than in sporadic tumors.

PATHOPHYSIOLOGY

MEN1 is an autosomal dominant disorder with penetrance that approaches 100% with increasing age and with a variable expression (different clinical phenotypes in affected members within an MEN1 kindred, in terms of tumor tissue type, onset age, and clinical aggressiveness) (Marx and Simonds, 2003). More precisely, the age-related penetrance for all clinical features rises above 50% by 20 years of age and above 95% by 40 years of age (Trump *et al.,* 1996; Bassett *et al.,* 1998; Skarulis, 1998). Anticipation has not been described. A prevalence of about 1 in 30,000 has been reported (Marx, 2001).

Pathogenic and pathophysiological issues include recent identification of the *MEN1*-encoded protein, named *menin*, and its still-unknown pathways in normal or tumor tissues.

Pathology/General Considerations

Pathological changes (i.e., a neoplasm or its precursors) in the target organs of the MEN1 syndrome are more extended than suggested by clinical and biochemical features of the patients. Several lesions, including most pancreatic or gastric endocrine proliferations, can be clinically silent, and others may present overt symptomatology only at advanced stages. A review of 32 autopsy case reports (Majewski and Wilson, 1979) revealed that, by the age of 30, pathological lesions are consistently found in each of the three main involved glands (parathyroids, endocrine pancreas, pituitary), initiating the concept that the MEN1 syndrome is an "all-or-none" phenomenon. Whether this concept may apply to other organs whose involvement has become apparent since that review has not been clarified. These include the tissues of the embryonic foregut (duodenum, stomach, lung, thymus), in which carcinoid tumors with potential malignant outcome may develop, as well as tissues that only rarely exhibit clinical morbidity in MEN1, such as adrenal cortex, adipose tissue, and skin (Friedman *et al.,* 1994; Padberg *et al.,* 1995; Darling *et al.,* 1997).

The sequence of events leading to neoplasia appears to be a subtle, diffuse one that follows a similar pattern in all MEN1 target organs. On a histopathological basis, the initial lesion appears to be a diffuse proliferation of the affected endocrine tissue with bilateral involvement of many paired organs and multifocal growth. Whether this change reflects polyclonal hyperplasia or *de novo* arising multiple clonal lesions, however, has not been clarified yet. A clear-cut stage of polyclonal hyperplasia has been identified only in the mouse model of MEN1 (Crabtree *et al.,* 2001, 2003); however, it suggests that a far more subtle polyclonal stage might precede all tumors in hereditary MEN1. One study has identified a stage of multifocal and hyperplastic precursors in gastrinoma from MEN1 but not from sporadic cases (Anlauf *et al.,* 2005). In that study, mono- versus polyclonality of the precursor stages was not proven.

The next step is development of multiple micro- and, eventually, macronodular lesions (Fig. 1). The transition between these lesions and true neoplasms is virtually unrecognizable on histopathological grounds. In fact, evidence from clonality studies in MEN1 parathyroids and pancreatic lesions revealed monoclonality of the same tissues that were

FIGURE 1 Numerous, scattered islet cell adenomas (numbered 1–6) of various size and architecture in a transverse section of the pancreas of a patient with MEN1 syndrome and ZES (H&E, 4). Reprinted with permission from Pilato *et al.* (1988).

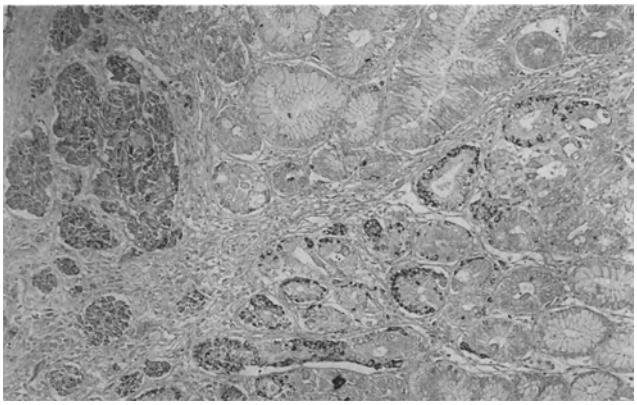

FIGURE 2 Immunostaining for basic FGF in the gastric endocrine cells of a patient with MEN1 syndrome and ZES. The peptide is expressed by both intraglandular cells showing hyperplastic pretumoral lesions (on the right) and carcinoid tumor (on the left) (immunoperoxidase, 100).

classifiable as hyperplastic according to the established histopathological criteria (Larsson *et al.,* 1988; Friedman *et al.,* 1989). LOH analysis of multiple tumors of the same organ, including parathyroids, pancreas, duodenum, and stomach (Morelli *et al.,* 1996; Lubensky *et al.,* 1996; Debelenko *et al.,* 1997a, 1997b), consistently showed different patterns and sizes of chromosomal or subchromosomal deletions, indicating that each of multiple mono- or oligoclonal tumors is the result of an independent mutational event.

Malignancy in MEN1 syndrome is mostly confined to pancreatic, duodenal, thymic, and bronchial neuroendocrine neoplasms. Notably, malignancy in the parathyroid is very rare in MEN1 (Sato *et al.,* 2000). Gastric carcinoid tumors may also pursue a very aggressive course (Bordi *et al.,* 1997; Norton *et al.*, 2004). Gastric carcinoid tumors in multiple endocrine neoplasia-1 patients with Zollinger-Ellison syndrome can be symptomatic, demonstrate aggressive growth, and require surgical treatment (Schnirer *et al*., 2003).

In a study of a large Tasmanian kindred, enteropancreatic malignancies were found in 14 of 69 patients (20%; Burgess *et al.,* 1998b). All but one of these patients also presented hypergastrinemia. Liver metastases are common in these cases, but their origin may be difficult to ascertain. They may derive from either pancreatic (more commonly) or duodenal gastrinoma(s). However, ECL cell carcinoids of the stomach, which are dependent on the trophic stimulus of hypergastrinemia, may also contribute (Bordi *et al.,* 1998). Immunostaining for gastrin or for the isoform 2 of the vesicular monoamino transporter (VMAT-2), the latter of which is specific for ECL cells (Rindi *et al.,* 2000), may help to establish the tissue origin of the primary tumor. As typical of endocrine tumors, histopathological definition of malignancy based on traditional criteria is often flawed. The use of immunohistochemical markers of cell proliferation, however, is useful in this regard (Bordi and Viale, 1995).

Immunohistochemistry using markers of neuroendocrine cells, such as chromogranin A, synaptophysin, and neuronspecific enolase, as well as specific hormonal products of the individual endocrine glands is useful in tumor characterization and in the assessment of preneoplastic lesions. Because of the identification in serum of an MEN1 mitogenic factor (Brandi *et al.,* 1986), structurally similar to basic fibroblast growth factor (FGF; Zimering *et al.,* 1993), immunohistochemistry, alone or in combination with molecular biology, has also been used to localize basic FGF in MEN1-related endocrine tissues. Ezzat *et al.* (1995) found high levels of basic FGF mRNA in adenomatous but not in normal pituitary glands, a finding consistent with the evidence of a pituitary origin of circulating basic FGF in MEN1 and sporadic pituitary tumor (Zimering *et al.,* 1993). Basic FGF mRNA levels correlated with *in vivo* and *in vitro* release of basic FGF but were consistently associated with lack of basic FGF immunoreactivity in tumor cells, suggesting a constitutive secretion of this peptide. However, basic FGF is elevated in serum of many patients with MEN1 and may play a pathogenetic role (Hoang-Xuan and Steger, 1999). In contrast, immunohistochemical expression of basic FGF was well documented in the gastric proliferating ECL cells (Fig. 2; Bordi *et al.,* 1994) and in pancreatic endocrine tumors (Chaudhry *et al.,* 1993) in both MEN1 and sporadic patients.

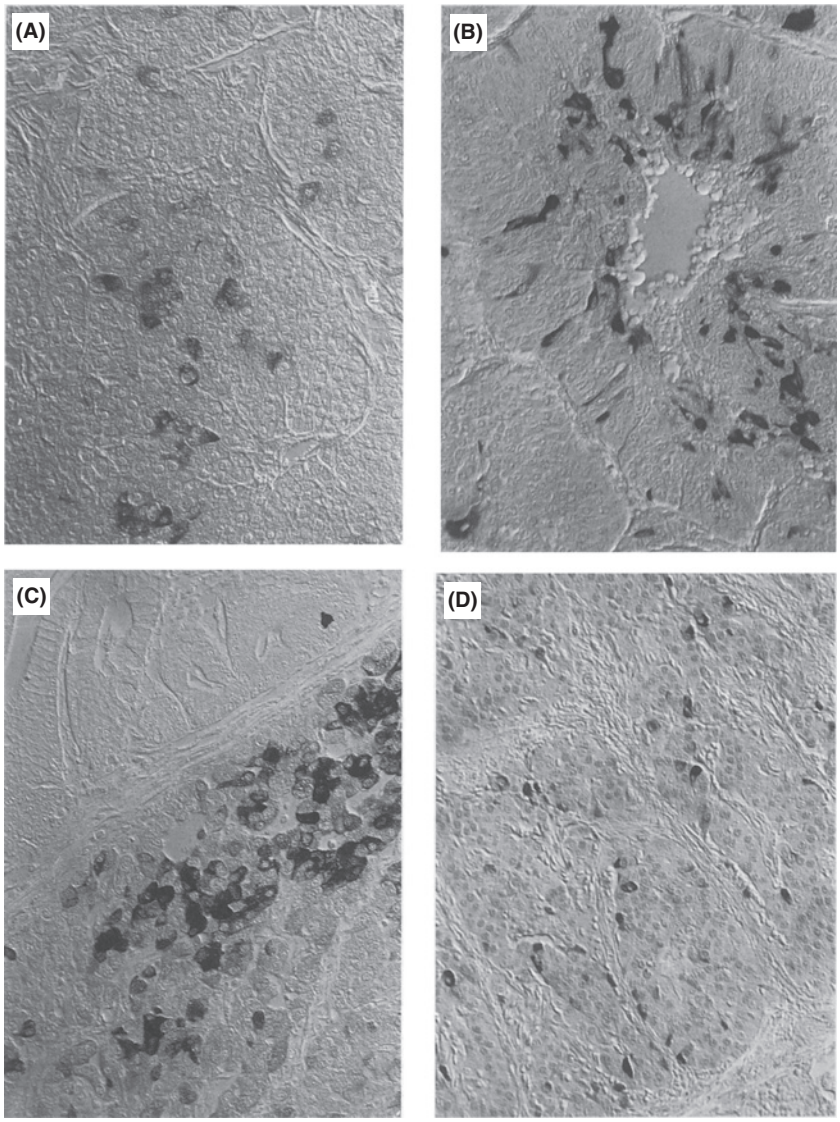

FIGURE 3 Immunohistochemical expression of α-subunit of glycoprotein hormones in different types of tumors in MEN1 patients: parathyroid (**A**), lung carcinoid (**B**), gastric carcinoid (**C**), duodenal gastrinoma (**D**) (immunoperoxidase, 170).

The expression of glycoprotein hormone α-subunit has been revealed by immunohistochemistry in all types of endocrine tumors involved in the MEN1 syndrome, including those of pituitary, pancreas, foregut, and parathyroids (Carlinfante *et al.,* 1998; Fig. 3). Such expression has been regarded as a marker of malignancy in pancreatic (Heitz *et al.,* 1983) but not in gastric (Bordi *et al.,* 1995a) or pulmonary (Bonato *et al.,* 1992) endocrine tumors. Burgess *et al.* (1998b) reported that serum levels of this protein were elevated in 71% of MEN1 patients with metastatic tumors but only in 7% of those without metastatic neoplasms ($P < 0.05$).

Pathology of the Parathyroids

It is generally assumed that in primary hyperparathyroidism of the MEN1 syndrome all parathyroid glands are pathologically involved. Size heterogeneity of parathyroid glands is, however, a consistent finding in MEN1 (Friedman *et al.,* 1994; Padberg *et al.,* 1995) with an average ratio of 9.5 between volumes of the largest and the smallest glands (Marx *et al.,* 1991). Small glands may show no detectable differences from normal glands, also when observed at the microscopic level (Harach and Jasani, 1992). When associated with asymmetric growth of one gland these findings rarely simulate adenoma (DeLellis, 1995). Parathyroid tumor within the thymus, in the thyroid gland, at the carotid bifurcation, or in the mediastinum may be responsible for surgical failures (Mallette, 1994). With four parathyroid tumors in MEN1, the odds of one being abnormally located should be about fourfold that for a solitary adenoma.

By histology, the parathyroid changes are very similar to those of non-MEN1 hyperplasia or of secondary

hyperparathyroidism, although size variability is a more striking feature in MEN1 (Harach and Jasani, 1992). Both nodular and diffuse patterns of hyperplasia occur, the former being more frequently seen (DeLellis, 1995). In either pattern, chief cells are the predominant cell type and are variously associated with oxyphil or transitional oxyphil cells. Neighboring intraglandular nodules may strongly differ in their cytological and architectural features (Friedman *et al.,* 1994).

Morphological distinction between these hyperplastic nodules and true adenomas is difficult if not impossible (Friedman *et al.,* 1994; Padberg *et al.,* 1995). To date, the issue has not been clarified even by clonality studies. As a rule the size of monoclonal lesions is significantly larger than that of polyclonal lesions (Friedman *et al.,* 1989; Falchetti *et al.,* 1993). Arnold *et al.* (1995), using X-chromosome inactivation analysis in patients with either primary MEN1 and non-MEN1 parathyroid hyperplasia or uremic hyperparathyroidism, demonstrated definite monoclonal status in 67% of glands with nodular hyperplasia and in 62% of glands with diffuse hyperplasia. These results cast doubts on the long-standing assumption that multiglandular parathyroid disease is a morphologic feature specific for polyclonal parathyroid hyperplasia.

The intensity and topographic distribution of parathyroid hormone immunoreactivity show pronounced variations in MEN1 parathyroid glands (Friedman *et al.,* 1994; Harach and Jasani, 1992). As a rule, hyperplastic areas reveal less immunoreactive hormone content than contiguous normal areas (Harach and Jasani, 1992), a finding consistent with defective mechanism(s) for hormone storage.

The endothelial cells of parathyroid glands, a target of the mitogenic activity of MEN1 growth factor (Brandi, 1991; Friedman *et al.,* 1994), have been investigated by ultrastructural morphometry in a series of MEN1 patients (D'Adda *et al.,* 1993). The parathyroid endothelial component was found to be significantly more expanded in MEN1 than in uremic hyperparathyroidism, indicating its potential role in the proliferation of parathyroid tissues in MEN1.

Pathology of the Endocrine Pancreas

Pathological changes of the pancreas in MEN1 patients have been often inconsistently defined, making evaluation of the actual incidence of specific lesions and of their relationships difficult and unreliable. Two basic changes showing specific functional and clinical characteristics, multiple islet cell microadenomas (microadenomatosis) and grossly single endocrine tumors, may be found (Friedman *et al.,* 1994; Klöppel *et al.,* 1986; Padberg *et al.,* 1995; Thompson *et al.,* 1984). Terms such as *nesidioblastosis* or *islet cell hyperplasia* should be avoided owing to their difficult histological identification and uncertain clinical significance.

Microadenomatosis is the most common pancreatic islet lesion in MEN1 cases. The multiple adenomas, scattered throughout the whole pancreatic gland (see Fig. 1), may be very numerous (up to 100 in some cases) and range in size from microadenomas slightly larger than unaffected islets to occasional macroadenomas with a diameter larger than 0.5 cm. Like the multiple nodules of parathyroid hyperplasia, even contiguous pancreatic lesions may exhibit striking variations in their histological arrangement, stromal content, and cytological characteristics. The microadenomas are functionally silent and are consistently benign both histologically and clinically. They are composed exclusively of cell types normally present in the pancreas, often coexisting in single tumors but lacking the typical topographic distribution seen in normal islets. The dominant hormonal peptide in these microadenomas is not random (Pilato *et al.,* 1988), a definite predominance of glucagon-, insulin-, and PP-producing cells being most often observed (Klöppel *et al.,* 1986; Pilato *et al.,* 1988; Padberg *et al.,* 1995; Le Bodic *et al.,* 1996). In small lesions such a predominance may be the only distinctive feature with respect to unaffected islets. In spite of their most frequent association with ZES, gastrin immunoreactivity is uncommonly found in these islet multiple microadenomas, with duodenal microgastrinomas and/or their metastases being responsible for hypergastrinemia in these patients.

Perren *et al.* (2006) recently described, in addition to enteropancreatic microadenomas, small aggregates of endocrine neoplastic cells with a similar monohormonal staining pattern defined as MECCs (monohormonal endocrine cell clusters) near to neither sclerosis nor duct cells. By LOH analysis these MECCs lesions clearly revealed their monoclonal and thus neoplastic nature. Findings from this study raised the possibility that MEN1-associated endocrine tumors may originate from at least two different pancreatic compartments but mainly from islets rather than ductal cells (Perren *et al.,* 2006).

Large, macroscopically single endocrine tumors, indistinguishable from those found without MEN1, are less frequently found in MEN1 syndrome. Usually they develop on the background of islet cell microadenomatosis. Like their sporadic counterparts, these neoplasms are frequently malignant and may metastasize to the liver. A large tumor size ($\geq$3 cm) is weakly predictive of this metastatic evolution (Cadiot *et al.,* 1999). Macroscopically single pancreatic tumors are composed of cells producing either endogenous (insulin, glucagon, PP) or ectopic (gastrin, VIP, GHRF, calcitonin, PTH-related peptide) hormones, and they often show functional activity covering the wide spectrum of clinical syndromes associated with pancreatic endocrine tumors. It has been assumed that functioning insulinomas in MEN1 are more frequently single tumors curable with surgical resection (Klöppel *et al.,* 1986; Thompson *et al.,* 1984; Tonelli *et al.,* 2005). However, others reported a frequent multicentricity of MEN1 insulinomas

(DeLellis, 1995). When the one dominant insulinoma in MEN1 is removed with confirmation of its overproduction of insulin (preoperative insulin localization, intraoperative serum glucose and insulin), the nonfunctional feature of coexistent pancreatic nodules is usually confirmed during surgery.

Pathology of the Pituitary

Pituitary tumors are found in more than 60% of MEN1 patients (Scheithauer *et al.,* 1987; Capella *et al.,* 1995) and are often appreciated only when the gland is examined microscopically (Majewski and Wilson, 1979). Despite their high penetrance in MEN1, the pituitary tumors are rarely multiple. They are usually represented by macroadenomas associated with diffuse or nodular hyperplasia of extratumoral pituitary cells (Capella *et al.,* 1995). The MEN1 tumors, like sporadic tumors, are grossly invasive in 10% to 15% of cases. By immunohistochemistry, they are most often found to produce PRL or GH, to be endocrinologically functioning, and to be plurihormonal more often than their sporadic counterparts. Between 65% (Brandi *et al.,* 2001) and 85% (Verges *et al.,* 2002) of pituitary tumors in MEN1 syndrome are macroadenomas versus a lower proportion in common tumors.

Pathology of the Foregut Carcinoid Tissues

Duodenal gastrinomas are common MEN1 tumors, being the cause of the ZES in more than 90% of MEN1 cases (Padberg *et al.,* 1995). They are multiple tumors, often so small (<1 cm diameter) that they escape detection even at intraoperative inspection and so diffusely distributed that they might require removal of the whole duodenum for adequate correction of hypergastrinemia. Immunostaining for gastrin is usually strong. Metastases are frequent and mostly restricted to regional lymph nodes (Pipeleers-Marichal *et al.,* 1990).

MEN1-associated duodenal gastrin-producing tumors may derive from hyperplastic gastrin cell proliferation as a precursor lesion. Anlauf *et al.* (2005) classified three pathological features: (a) macrotumors (>2 mm); (b) microtumors (0.25–2 mm); and (c) hyperplastic lesions.

Gastric, ECL-cell carcinoids may develop in MEN1 patients affected by ZES through a sequence of hyperplasia—dysplasia—neoplasia (Solcia *et al.,* 1988; Bordi *et al.,* 1998). In these cases hypergastrinemia acts as a potent promoter for ECL cell proliferation (Bordi *et al.,* 1995a). However, the lack of ECL-cell carcinoids in cases of sporadic ZES indicates that biallelic inactivation of the *MEN1* gene (Cadiot *et al.,* 1993; Debelenko *et al.,* 1997a) is also essential for the evolution of ECL cell hyperplasia into neoplasia (Solcia *et al.,* 1990; Bordi *et al.,* 1998). Malignant behavior is rare in these carcinoids (Rindi *et al.,* 1996). However, several cases of gastric endocrine tumors having aggressive behavior and very poor outcome have been observed (Bordi *et al.,* 1997; Schnirer *et al*., 2003; Norton *et al.,* 2004). In one of these, multiple benign gastric carcinoids coexisted with a malignant poorly differentiated endocrine carcinoma causing the patient's death (Bordi *et al.,* 1997). 11*q*13 LOH was documented in these undifferentiated neoplasms.

Thymic and bronchial carcinoid tumors can also be regarded as an integral part of the MEN1 syndrome (Padberg *et al.,* 1995). The thymic carcinoids of MEN1 syndrome tend to be aggressive (Gibril *et al.,* 2003; Ferolla *et al.,* 2005), whereas three fourths of the latter are benign (Duh *et al.,* 1987; Teh *et al.,* 1997), although with the potential for local mass effect, metastasis, and recurrence after resection (Sachithanandan *et al.,* 2005). Surprisingly, thymic carcinoids of MEN1, including the majority that are malignant, do not exhibit 11q13 LOH (Teh *et al.,* 1997). Inactivation of the wild-type copy of the *MEN1* gene by other mechanisms needs to be explored.

Pathology of Other Organs

Various tumors of thyroid follicular cells, adrenal cortex, cutaneous and visceral adipose tissue, and skin have been described in MEN1 patients (Brandi *et al.,* 1987; Friedman *et al.,* 1994; Padberg *et al.,* 1995). These are mostly benign neoplasms. Multiple facial angiofibromas, similar to those in tuberous sclerosis, and discrete papular collagenomas of the trunk are commonly found in MEN1 patients (Darling *et al.,* 1997). Angiofibromas are benign tumors composed of blood vessels and connective tissue. These consist of acneiform papules that do not regress and that may extend across the vermilion border of the lips. Collagenomas consist of multiple, skin-colored, sometimes hypopigmented, cutaneous nodules, symmetrically arranged on the trunk, neck, and upper limbs. They are typically asymptomatic, roundish, and firm-elastic, from a few millimeters to several centimeters in diameter.

Enlargement of the adrenal glands is found in about 40% of MEN1 patients (Burgess *et al.,* 1996; Komminoth, 1997). Silent adrenal gland enlargement is likely a polyclonal or hyperplastic process (because LOH at 11q13 is not found therein), which rarely results in monoclonal neoplasm (Skogseid *et al*., 1992). Langer *et al.* (2002) showed that the median tumor diameter at diagnosis was 3.0 cm (range 1.2–15.0 cm), with most tumors being 3 cm or smaller. The underlying pathologic lesions affect the adrenal cortex and are usually represented by diffuse or (macro)nodular hyperplasia or by adenoma, although exceptional cases of carcinomas have been reported (Komminoth, 1997). Although general agreement does not exist, some suggest surgical removal of adrenocortical tumors that exceed 3 cm in diameter because of their malignant potential (Langer *et al*., 2002).

Because of their common occurrence and lack of *MEN1* inactivation, thyroid tumors lesions do not seem to be causally related to the *MEN1* gene. In contrast, allelic loss at the *MEN1* locus has been reported in most *MEN1* tumors: dermal angiofibroma, truncal collagenoma, intracranial meningioma, esophageal leiomyoma, and lipoma (Morelli *et al.,* 1995; Pack *et al.,* 1998; Vortmeyer *et al.,* 1999). Moreover, 11*q*13 LOH was found in rare adrenal medullary tumors of MEN1 (Cote *et al.,* 1998b) but surprisingly not found in the common adrenocortical tumors of MEN1 patients (Skogseid *et al.,* 1992).

Miscellaneous Nonendocrine Malignancies in Patients with MEN1 Syndrome

A number of malignant tumors of various, nonendocrine origin, including exocrine pancreas, kidney, bladder, endometrium, and skin, have been reported in MEN1 patients (Bordi *et al.,* 1995b; Thompson *et al.,* 1984: Doherty *et al.,* 1998; Nord *et al.,* 2000). At least five cases of ductal pancreatic adenocarcinoma have been reported, suggesting an increased risk for this tumor in MEN1 (Bordi and Brandi, 1998). 11*q*13 LOH was not found in the single tumor investigated (Bordi *et al.,* 1995b). Malignant melanomas have been reported in seven typical MEN1 patients from seven MEN-1 kindreds (Nord *et al.,* 2000). However, no role of the *MEN1* gene in the development of sporadic or familial melanomas is proven (Boni *et al.,* 1999; Nord *et al.,* 2000).

BIOCHEMICAL AND RADIOLOGICAL TESTS FOR TUMORS IN LIKELY *MEN1* MUTATION CARRIERS

Periodic surveillance for tumor emergence is recommended for asymptomatic individuals with an *MEN1* disease-causing mutation and others at risk for MEN1 syndrome-associated tumors (i.e., those known to have MEN1 syndrome. About 25% of MEN1 families do not have an identifiable *MEN1* mutation. In such families, a screening program in unaffected members at 50% risk should be less comprehensive. Affected individuals may present with any of the MEN1-associated lesions in early teenage years or escape clinical symptoms for several decades (Skogseid *et al.,* 1991). A periodic investigation should be performed to look for the frequent endocrine and nonendocrine tumors associated with this syndrome in potentially affected individuals (Table II). MEN1-associated lesions may develop slowly in unaffected mutation carriers, despite earlier extensive biochemical testing. Such screening may detect the onset of a tumor about 10 years before symptoms develop, thereby providing an opportunity for earlier treatment (Bassett *et al.,* 1998). Early screening for MEN1 tumors in asymptomatic *MEN1* mutation carriers may help to reduce morbidity, but this is not proven. The overall age-related penetrance of all MEN1-related tumors is near zero below age 5 years (Stratakis *et al.,* 2000), rising quickly to more than 50% by 20 years, and more than 95% by 40 years (Metz *et al.,* 1994; Trump *et al.,* 1996; Bassett *et al.,* 1998; Skarulis, 1998). Individuals at highest risk of developing MEN1 tumors (mutant *MEN1* carriers have near 100% lifetime risk) should be screened yearly for tumors. Screening should commence in early childhood, and it should continue for life (Trump *et al.,* 1996). Because such screening for MEN1 tumors can be difficult and expensive with large numbers of available and of recommended tests, a protocol should be designed to make best use of available resources (see Table II).

Primary hyperparathyroidism is often the first clinical manifestation and the most common pathology associated with the MEN1 syndrome (Lamers and Froeling, 1979; Marx

TABLE II Survey for Tumors in an MEN1 Carrier

Tumor	Age to Begin (Years)	Biochemical Tests (Annually)	Imaging Tests (Every 3 Years)
Parathyroid adenoma	8	Calcium, PTH	None
Gastrinoma	20	Gastrin	None
Insulinoma	5	Fasting glucose	None
Other enteropancreatic	20	Chromogranin-A??[a]	|^{111}In|DTPA octreotide; CT/MRI
Anterior pituitary	5	Prolactin; IGF-1	MRI
Foregut carcinoid	20	Chromogranin-A??[a]	CT, endoscopy[b]

CT, *computed tomography*; DTPA, *diethylenetriamine pentaacetic acid*; IGF-1, *insulin-like growth factor* 1; MRI, *magnetic resonance imaging.*

et al., 1986; Oberg *et al.,* 1982), being asymptomatic in 50% of hyperparathyroid cases. Accurate clinical and laboratory screening for parathyroid function promotes early biochemical diagnosis. This can help to (1) diagnose a cancer or (2) diagnose parathyroid tumor in a known carrier. A bone mineral density evaluation by dual-energy x-ray absorptiometry (DEXA), quantitative computed tomography (QCT), or ultrasound (US), both at cortical and trabecular sites can define the fracture risk in cases with hyperparathyroidism. Preoperative parathyroid tumor imaging has little role in the unoperated case. Tc-99m Sesta-MIBI scan is the most useful among many methods prior to parathyroid reoperation. However, a well-experienced neck surgeon remains the most important "clinical device" for successful initial surgery of hyperparathyroidism. Intraoperative measurement of PTH "online" is promising to test whether deleterious amounts of parathyroid tumor remain during initial or repeat surgery (Tonelli *et al.,* 2000).

Gastrinoma constitutes the second commonest manifestation but potentially the most morbid feature of MEN1 (Croisier *et al.,* 1971; Eberle and Grun, 1981). As for hyperparathyroidism, clinical and biochemical screening could promote early detection of gastrinoma and other GEP disease. Tests to consider would include basal evaluation of gastrin, insulin, C-peptide, blood glucose, proinsulin, glucagon, PP, and chromogranin-A (Skogseid *et al.,* 1987; Brandi *et al.,* 2001; see Table II). More complex or invasive tests (basal output of gastric acid, secretin or calcium stimulation for gastrin, supervised fasting for insulin) have been developed to increase sensitivity; they may be used after a screening test indicates the need for more information. Tests with abnormal levels should be repeated. False-positives include high proinsulin/insulin levels in patients developing insulin resistance or hypergastrinemia in patients with hypochlorhydria (such as from parietal cell autoimmunity or from gastric acid-blocking drugs). Somatostatin receptor scintigraphy ([^{111}In]diethylenetriamine pentaacetic acid [DTPA]-octreotide scan) is a proven method for imaging of pancreatic islet tumor; computed tomography (CT) or magnetic resonance imaging (MRI) are interchangeable here. Unfortunately, because of the small size and multiplicity of duodenal gastrinomas, the methods most sensitive for the pancreas have low sensitivity for MEN1 gastrinomas (Bansal *et al.,* 1999; Cadiot *et al.,* 1996). Endoscopic ultrasound (EUS) will image many micro-adenomas in the pancreas of MEN1. This information does not lead to intervention, and the role for EUS in MEN1 remains uncertain.

Insulinoma that had been negative to preoperative imaging is usually readily identified by intraoperative ultrasonography (Bansal *et al.,* 1999). However, since radiology of the enteropancreatic lesion is neither sensitive nor specific, surgery should be done if the biochemical diagnosis is unequivocal, even rarely without symptoms (Skogseid *et al.,* 1996; Granberg *et al.,* 1999).

Symptoms of pituitary neoplasms associated with the MEN1 syndrome depend on both the tumor volume and the hormonal secretion from the gland. Prolactin is the most frequent product of hypersecretion from the anterior pituitary in MEN1 (Croisier *et al.,* 1971; Eberle and Grun, 1981; Majewski and Wilson, 1979). Circulating prolactin measurement should be performed under basal conditions at 0 and 60 minutes in order to avoid an influence of stress on hormonal secretion. MRI is the preferred pituitary imaging method. False positives are from pregnancy or psychotropic drugs. Finally, even in cured patients, pituitary tumor screening should continue because the remaining pituitary cells may cause recurrence or the development of new adenoma.

Computed tomographic or magnetic resonance imaging of the chest are recommended for early diagnosis of thymic or bronchial carcinoids. Type II gastric ECL cell carcinoids are recognized mainly at gastric endoscopy incidental to evaluation for ZES.

DNA-BASED TESTS

MEN1 Gene Discovery

In 1997 the *MEN1* gene was identified by positional cloning (Chandrasekharappa *et al.,* 1997; Lemmens *et al.,* 1997). Combined subchromosomal mapping studies with both linkage in MEN1 kindreds (Larsson *et al.,* 1988) and microdeletion analysis in tumors (Larsson *et al.,* 1988; Friedman *et al.,* 1989; Emmert-Buck *et al.,* 1997) demonstrated that the MEN1 trait was in close linkage to *PYGM,* the gene for muscle phosphorylase, at chromosome 11q13. All candidates to be the *MEN1* gene were near this gene. Each candidate gene in the minimized interval was sequenced in a panel of DNAs from MEN1 probands. One candidate gene showed mutation in most of the probands, proving that it was the sought-after *MEN1* gene.

The proposed model for tumorigenesis in familial MEN1 was according to Knudson's "two hit" hypothesis (Knudson, 1993; Larsson *et al.,* 1988). An affected *MEN1* copy is inherited in the germline from the affected parent (first hit) while the wild type copy, from the healthy parent, is eliminated from one somatic cell (second hit). The second hit was deduced indirectly from loss of heterozygosity or allelic loss at the *MEN1* locus, when tumoral DNA was compared to germline DNA. These findings strongly suggested biallelic gene inactivation as the mechanism of tumorigenesis from *MEN1*.

MEN1 Sequencing in Germline DNA

Genetic diagnosis of monogenic disorders is made possible only if either cloned material from a specific gene is sequenced to allow mutation testing or the chromosomal

localization of the specific gene is known, and tightly linked genetic markers have been characterized (haplotype testing). Testing the *MEN1* mutation carrier state is possible by either approach.

Most laboratories find an *MEN1* mutation in 70% to 90% of index cases in typical MEN1 families (Agarwal *et al.,* 1997; Teh *et al.,* 1998b; Marx, 2001; Ellard *et al.,* 2005; Klein *et al.,* 2005). Rare *MEN1* families have a mutation in the p27 gene (Pellegata *et al.,* 2006). The positive rate is lower (20–80%) in index cases with sporadic MEN1. The positive rate is even lower (10%) in familial isolated hyperparathyroidism (Kassem *et al.,* 2000), and the rate is nearly zero in familial pituitary tumor (Tanaka *et al.,* 1998; Gadelha *et al.,* 2000; Daly *et al.,* 2007). The likelihood of finding a mutation is correlated with the number of MEN1-related tumors and increased in the presence of a family history (Ellard *et al.,* 2005). Sporadic cases with both parathyroid and pituitary tumors have a particularly low prevalence (10%) of *MEN1* mutation (Ozawa *et al.,* 2007).

There has been no genotype-phenotype relationship, including unrevealing *MEN1* mutations in index cases for families with the prolactinoma variant of MEN1 (Agarwal *et al.,* 1997; Hao *et al.,* 2004).

MEN1-like states with unusually low prevalences of *MEN1* mutation have helped point to other genes as causes. For example, the *HRPT2* gene was shown to be one cause of familial isolated hyperparathyroidism (FIHP; Carpten *et al.,* 2002), and another unidentified gene for FIHP has been tentatively located by linkage analysis to the short arm of chromosome 2 (Warner *et al.,* 2006).

Advantages of DNA-Based Analysis

The advantages of *MEN1* mutation analysis are first that a negative test does not need to be repeated serially, unlike the biochemical screening test for ascertainment of MEN1 through tumor discovery. Second, most results of an *MEN1* mutation test influence long-range planning. Thus, a test identifying an *MEN1* mutant gene carrier may lead to earlier and more frequent biochemical screening for tumors. Screening for MEN1 tumors in asymptomatic mutation carriers may help to reduce morbidity. Lairmore *et al.* (2004), in a prospective clinical study on *MEN1* gene mutant carriers, revealed that a biochemical evidence for a neoplasm can be identified on average 10 years earlier than clinical evidence of the disease itself, providing the opportunity for earlier treatment. Moreover, in a family with a known *MEN1* mutation, the finding of a family member at no risk for tumors because of no mutation should lead to a decision for no further screening of that member.

Limitations of DNA-Based Analysis

Unfortunately, the obtained information does not usually influence an immediate intervention or longevity. This reflects the lack of a therapy or prevention of proven value for MEN1-associated malignancy, in total contrast to the situation in MEN2. Second, mutation analysis may provide a false negative for an entire family; in fact, *MEN1* mutations are not detectable in 5% to 30% of MEN1 families. Simplex MEN1 cases (i.e., a single occurrence of MEN1 syndrome not in an MEN1 family) are less likely to test positive than familial cases, in part because some of these simplex cases are caused by somatic mosaicism (Klein *et al.,* 2005). In the event that sequence analysis fails to identify a germline mutation in an individual with typical MEN1 syndrome, deletions or other gross rearrangements can be tested for by Southern blot analysis. It is estimated that between 1% and 3% of *MEN1* germline mutations are large deletions that could be detected on a Southern blot analysis or by other gene dosage procedures (i.e., PCR-based; Kishi *et al.* 1998; Bergman *et al.,* 2000; Cavaco *et al.,* 2002; Ellard *et al.,* 2005; Klein *et al.,* 2005).

In the event that a disease-causing mutation is not identified using sequence analysis or targeted mutation analysis, haplotype analysis may be utilized in certain families. In fact, if large enough for haplotype analysis, virtually any MEN1 family is likely to be positive for an 11q13 haplotype shared in all affected cases (Olufemi *et al.,* 1998; Larsson *et al.,* 1995; Courseaux *et al.,* 1996).

DNA-Based Analysis of Tumors

Tumor DNA has been evaluated extensively for 11q13 LOH and for *MEN1* mutation. These analyses have contributed importantly to research. In particular, analysis of 11q13 LOH contributed to narrowing the *MEN1* gene candidate interval for gene discovery (Emmert-Buck *et al.,* 1997; Chandrasekharappa *et al.,* 1997) and to understanding the clonality of certain lesions, such as parathyroid tumors and skin lesions in MEN1 (Friedman *et al.,* 1989; Pack *et al.,* 1998). *MEN1* mutation analysis confirmed a role of *MEN1* inactivation in oncogenesis of many sporadic endocrine tumors (about 30% of parathyroid adenoma, insulinoma, gastrinoma, or bronchial carcinoid; Heppner *et al.,* 1997; Boni *et al.,* 1998). On the other hand, analysis of tumor DNA for *MEN1* involvement has little application in current clinical settings. It does not give a useful predictor of tumor aggressiveness, and it does not substitute for *MEN1* mutation analyses of germline DNA.

Mutation Types in the *MEN1* Gene

About 700 different mutations, both somatic and germline, of the *MEN1* gene have been identified (Thakker, 2001; Gagel and Marx, in press). The mutations are varied and scattered throughout the coding region with no clear evidence for clustering (Fig. 4). Approximately half of mutations are unique. The other half are repeating mutations; the repeats reflect either a common founder or a mutational

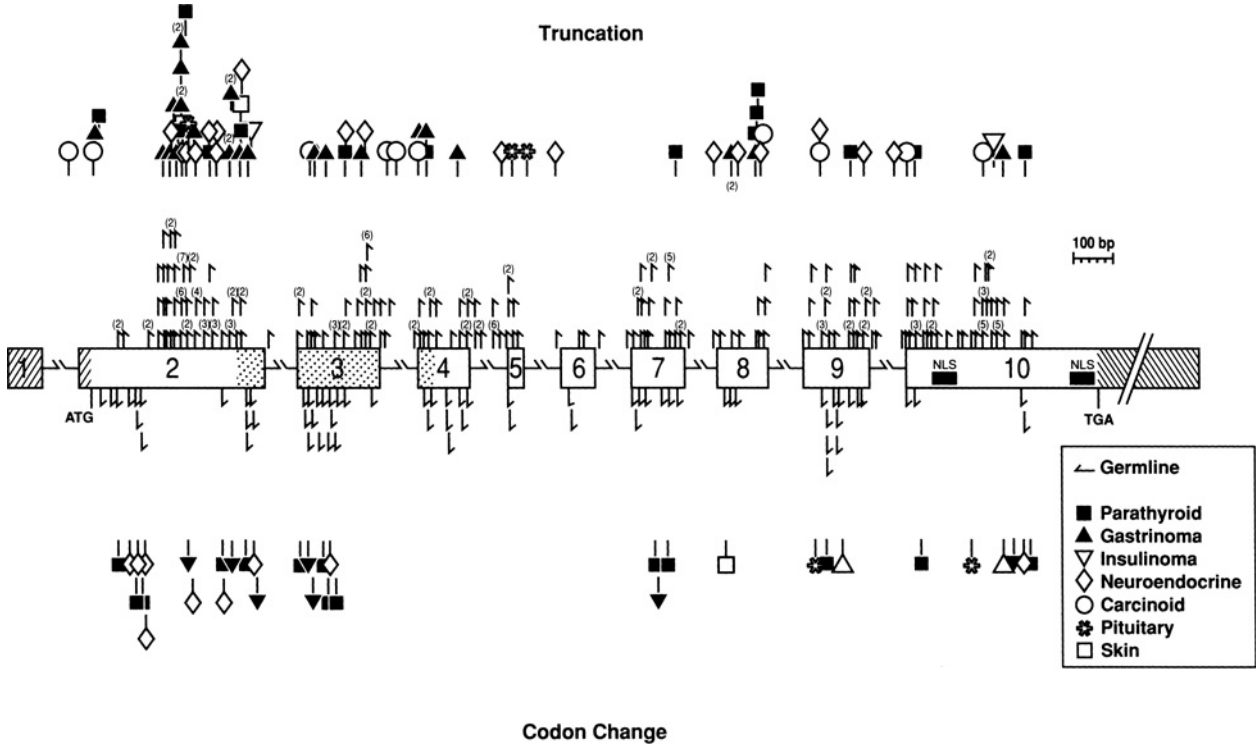

FIGURE 4 Genomic organization of the *MEN1* gene and of *MEN1* germline and somatic mutations, published as of April 2006. The gene contains 10 exons (with the first exon untranslated) and extends across 9 kb.Mutations shown above the exons cause menin truncation, and those shown below the exons cause a codon change. All unique mutations are represented; numbers in parenthesis designate multiple reports of the same mutation in presumed unrelated persons. The hatched areas indicate the untranslated regions. The location of the two nuclear localization signals (NLS), at codons 479–497 and 588–608, are indicated. Missense mutations in a region of menin (aa 139–242) (identified by stippling) prevented interaction with the API transcription factor JunD.

hotspot (Agarwal *et al.,* 1998). These potential mutational hot spots could be due to the presence in the vicinity of repeated long tracts of either single nucleotides or shorter elements. These repeated sequences may undergo misalignment during replication; a slipped strand mispairing model is the most likely mechanism to be associated with this sort of mutational hot spot (Agarwal *et al.,* 1999; Calender, 2000). All or most pathologic *MEN1* mutations are likely inactivating, as expected for a tumor suppressor gene: Approximately 60% of mutations are frameshift and 25% are nonsense. In total, some 80% of *MEN1* mutations predict protein truncation and thus an inactive or absent menin protein product. None of them have been associated to specific clinical manifestations of the disorder. Thus genotype/phenotype correlations appear to be absent in MEN1 (Teh *et al.,* 1998b; Agarwal *et al.,* 1997; Bassett *et al.,* 1998; see Fig. 4). The remaining 15% to 20% of *MEN1* gene mutations consist of missense mutations (inframe with change of one or two amino acids) potentially altering the interaction with one or more menin partners. In particular, a missense mutant of menin could favor a rapid degradation of menin that could account for a common mechanism for inactivation.

Germline mutational analysis of the *MEN1* gene in many centers failed to detect mutations in 5% to 30% of MEN1 patients. This failure could be explained if the mutation was a large deletion, causing the loss of the whole gene or a whole exon (Teh *et al.,* 1998b; Agarwal *et al.,* 1997; Bassett *et al.,* 1998). Consequently, the PCR amplification and mutational analysis shows only the normal allele. However, large deletions or other gross rearrangements can be tested for by Southern blot analysis. It is estimated that between 1% and 3% of MEN1 germline mutations are large deletions that could be detected on a Southern blot analysis or by other gene dosage procedures (i.e., PCR-based; Kishi *et al.,* 1998; Bergman *et al.,* 2000; Cavaco *et al.,* 2002; Ellard *et al.,* 2005; Klein *et al.,* 2005). Alternatively, undiscovered mutations may be within the untested parts of the gene, such as introns or the regulatory regions. Thus, even though no *MEN1* gene mutation is found in some MEN1 index cases, this does not exclude its involvement. In fact, when MEN1 families have been large enough for linkage analysis, the trait has been linked to 11*q*13 in most (Larsson *et al.,* 1992; Corseaux *et al.,* 1996; Olufemi *et al.,* 1998), suggesting cause by the *MEN1* gene in the majority.

MEN1 Gene Mutation in Endocrine Tumors

Endocrine tumors may occur either as part of MEN1 or, more commonly, as sporadic, nonfamilial tumors.

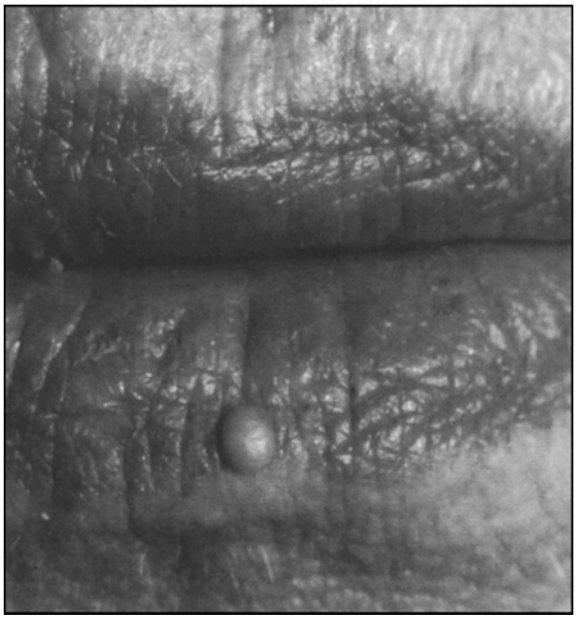

FIGURE 5 MEN1-associated angiofibroma of the lip.

Mutational analysis of MEN1-associated and sporadic endocrine tumors revealed that most tumors from MEN1 patients harbor the germline mutation together with a somatic LOH involving chromosome 11q13 (Marx *et al.,* 1998), as expected from Knudson's two-hit model and the proposed role of the *MEN1* gene as a tumor suppressor. However, LOH involving chromosome 11q13, which is the location of the *MEN1* gene, has also been observed in 5% to 50% of sporadic endocrine tumors, suggesting inactivation of the *MEN1* gene in the etiology of these tumors. Of those with 11q13 LOH, about half have shown somatic *MEN1* mutation; this includes sporadic parathyroid adenomas, sporadic gastrinomas, sporadic insulinomas, sporadic bronchial carcinoids, and sporadic anterior pituitary adenomas (Heppner *et al.,* 1997; Debelenko *et al.,* 1997c; Zhuang *et al.,* 1997). All together, these observations establish that *MEN1* is the known gene most frequently mutated in common-variety endocrine tumors.

MEN1 Gene Mutation in Nonendocrine Tumors

At least five different mesenchymal tumors in MEN1 can be caused by mutational inactivation of the *MEN1* gene. These include skin/dermal lipoma, angiofibroma (Fig. 5), and collagenoma. In each case loss of the normal allele has been proven with material from MEN1 patients (Pack *et al.,* 1998). Furthermore, sporadic lipoma and sporadic angiofibroma is occasionally associated with somatic *MEN1* mutation (Vortmeyer *et al.,* 1998; Boni *et al.,* 1998). Esophageal and uterine leiomyoma and intracranial meningioma also were associated with 11q13 LOH in most tested tumors of MEN1 (McKeebey *et al.,* 2001). This establishes that, like other multiple neoplasia syndromes, the tissue pattern of tumors in MEN1 does not follow a simple developmental distribution or any other recognizable distribution.

FUNCTIONS OF THE *MEN1* GENE AND ITS ENCODED MENIN IN NORMAL AND TUMOR TISSUES

The Normal *MEN1* Gene

The gene spans 9 kb and consists of 10 exons with a 1830-bp coding region (see Fig. 4) that encodes a novel 610-amino-acid protein, referred to as menin. The first exon and last part of exon 10 are not translated. A major transcript of 2.8 kb has been described in a large variety of human tissues (pancreas, thymus, adrenal glands, thyroid, testis, leukocytes, heart, brain, lung, muscle, small intestine, liver, and kidney; Lemmens *et al.* 1997). Moreover, an additional transcript of approximately 4 kb has been detected in pancreas and thymus, suggesting a tissue-specific alternative splicing (Lemmens *et al.,* 1997).

Menin: The *MEN1* Gene-Encoded Protein Product

Initial analysis of the predicted amino acid sequence encoded by the *MEN1* transcript did not reveal homologies to any other proteins, sequence motifs, signal peptides, or consensus nuclear localization signals, and thus the putative function of the protein menin could not be predicted (Guru *et al.,* 1998). Menin is widely expressed from an early developmental stage and is found in both endocrine and nonendocrine tissues.

Intracellular Localization

Studies, based on immunofluorescence, revealed that menin was located primarily in the nucleus. Furthermore, at least two independent nuclear localization signals (NLSs) were identified and located in the C-terminal quarter of the protein (Guru *et al.,* 1998). All of the truncated *MEN1* proteins that would result from the nonsense and frameshift mutations, if expressed, would lack at least one of these NLSs.

It is possible that menin-DNA interaction may play a crucial role in regulating cell proliferation by modulating the G2-M and/or G1-S phases progression (Yaguchi *et al.,* 2002; La *et al.,* 2004b). The nuclear localization of menin suggested that it may act either in the regulation of transcription, DNA replication, or in the cell cycle.

Menin Molecular Partners

Menin partners have been identified in the nuclear and cytoplasmic compartments (Poisson *et al.*, 2003); these have included a variety of transcriptional regulatory, cytoskeletal, and DNA processing and repair proteins (Agarwal *et al.*, 2005). None of the menin partners or menin pathways has yet been proven to be critical in MEN1 tumorigenesis or in menin normal physiology.

Menin-Nm23: Through interaction with a putative tumor metastasis suppressor, nm23H1/nucleoside diphosphate kinase (nm23), menin may regulate a GTPase activity (Yaguchi *et al.*, 2002).

Menin-ASK: The activator of S-phase kinase (ASK) is a component of the cell division cycle (CDC) kinase complex, crucial for cell proliferation, and it interacts with menin. Menin may inhibit the ASK-induced cell proliferation *in vivo* (Schnepp *et al.*, 2004).

Menin- Glial Fibrillary Acidic Protein (GFAP): Menin interacts with intermediate filament proteins, such as GFAP and vimentin. Menin and GFAP colocalize at the S–G_2 phase of the cell cycle in glioma cells. Such an interaction might serve as a cytoplasmic sequestering network for menin at the S and early G_2 phase of the cell cycle (Huang *et al.*, 1999). Menin could have an inhibitory role before the S phase starts, and it must be transferred to the cytoplasm to enable the S phase to proceed (Suphapeetiporn *et al.*, 2002; Lin *et al.*, 2003). Thus, the intermediate filament network could sequester menin away from the nucleus and its target genes (Lopez-Egido *et al.*, 2002).

Menin-Jun D: Menin interacts in several different test systems directly with JunD, a member of the AP1 family of transcription factors- repressing junD's transcriptional activity (Agarwal *et al.*, 1999). Studies have demonstrated that menin binds directly to the full-length form of JunD (FL-JunD) in normal conditions converting JunD to a growth suppressor, whereas junD acts as a growth promoter when it is unable to bind menin (Yazgan *et al.*, 2001; Agarwal *et al.*, 2003). JunD's conversion to an oncogene might be a component of MEN1-associated tumorigenesis.

Menin-MLL: Immunoprecipitation of menin showed that menin could be associated with several proteins in a large complex. The components of the human complex are highly homologous to the components of a yeast transcriptional complex, termed COMPASS (Hughes *et al.*, 2004). Interestingly, menin has no homologue in yeast. Menin's direct interaction in the human complex seems to be with MLL1 or MLL2. MLL1 has been studied in detail as the Mixed Lineage Leukemia protein that undergoes rearrangement as the cause in many leukemias. Menin's interaction with MLL1 in hematopoiesis or leukemogenesis seems to be as a growth promoter; in this mode, it does not account for growth suppression in the MEN1 process (Yokoyama *et al.*, 2005). However, the MLL1 complex can also act on the promoter of the *p18* and *p27* genes, where its expression of those genes results in growth suppression (Milne *et al.*, 2005).

Menin-Transforming Growth Factor β (TGFβ): The role of TGFβ in tumorigenesis is complex. It can stimulate tumorigenesis, causing tumor cell invasion and metastasis, whereas it generally causes growth inhibition in normal cells, including epithelial, endothelial, and fibroblastic cells. Activation of the TGFβ receptor stimulates transcription factors of the Smad family, which transfer its effects to the nucleus. TGFβ increases the expression of menin in a dose-dependent fashion; conversely, a reduced menin interferes with TGFβ-mediated inhibition of cell proliferation in endocrine cells (Kaji *et al.*, 2001). TGFβ exerts growth inhibitory and transcriptional responses through Smad2 and Smad3, which associate with the common mediator Smad4 after receptor-mediated phosphorylation of several substrates. Translocation of this complex into the nucleus leads to the increased expression of specific target genes. Menin has been found to physically interact with Smad3, and impaired menin function blocks the Smad3-mediated transcriptional effects of TGFβ (Kaji *et al.*, 2001). Impaired TGFβ signaling might disrupt the balanced cellular steady state, pushing the cells toward inappropriate growth and tumor formation.

Menin-Insulin-like Growth Factor Binding Protein 2 (IGFBP-2): Menin can also control proliferation through the suppression of endogenous IGFBP-2, which inhibits cell proliferation induced by IGFs and by TGFβ (La *et al.*, 2004b). Menin-mediated suppression of IGFBP-2 is, at least in part, executed through alteration of the chromatin structure of the IGFBP-2 gene promoter (La *et al.*, 2004b). La *et al.* (2006) recently showed that subtle mutations in menin NLSs compromise the ability of menin to repress expression of the IGFBP-2 gene.

Menin-Fanconi Anemia Complementation Group D2 (FANCD2) Protein: Menin interacts with *FANCD2*, one of the seven mutated genes in Fanconi anemia. FANCD2 is involved in a BRCA1-mediated DNA repair pathway. The interaction between menin and FANCD2 is enhanced by γ-irradiation and may be regulated by phosphorylation, which further enhances the function of these proteins in DNA repair (Jin *et al.*, 2003). Interestingly, past studies revealed that lymphocytes from patient with heterozygous *MEN1* mutation exhibit a premature centromere division, thus suggesting a possible role of menin in controlling DNA integrity (Sakurai *et al.*, 1999). Moreover, hypersensitivity to alkylating agents occurred in lymphocytes from patients with MEN1 (Itakura *et al.*, 2000) indicating a possible role of menin as a negative regulator of cell

proliferation after one type of DNA damage (Ikeo *et al.,* 2000).

Menin-Replication Protein A (RPA): Menin interacts with the second subunit of the RPA complex, which is required for DNA replication, recombination, and repair and is involved in the regulation of apoptosis and gene expression (Sukhodolets *et al.,* 2003).

Menin-Nuclear Factor κB (NFκB): Menin interacts specifically with three members of the NFκB family (Heppner *et al.,* 2001). These transcription factors are major regulators of the cellular response to stress. Menin acts as an inhibitor of NFκB-mediated transcriptional activation in a large mediator complex to repress or recruit other repressors, such as histone deacetylases.

Menin Interactions with Chromatin and Genes

Most menin-interacting proteins may imply a role for menin in the regulation of gene expression, and menin may have downstream effects on critical genes regulating normal and tumor processes. Genes regulated by menin overexpression have been identified by DNA microarray analysis in a human endocrine pancreatic cell line (BON1) transfected with vector pcDNA3 alone or with the *MEN1* gene (Stalberg *et al.,* 2004). Menin upregulates procaspase 8 and downregulates IGFBP-2. DNA microarray comparison between independently derived strains of *Men1*+/+ and *Men1*–/– mouse embryos showed the expected decreased expression of *Men1* gene itself in the menin-null cells and a decreased expression of Hoxc6, Hoxc8, and Cyt19 (Yokoyama *et al.*, 2004). The decreased expression of the Hox genes observed in the *Men1* knockout is similar to that in the *MLL* knockout (Milne *et al.*, 2002). Indeed, menin could be a positive regulator of MLL-associated H3K4 methyltransferase activity, required for the expression of the Hox genes. By chromatin immunoprecipitation experiments, menin and MLL were found to occupy the homeobox gene locus at Hoxc8, and menin overexpression was found to upregulate Hox gene expression (Hughes *et al.,* 2004). On the other hand, menin knockdown produced downregulation of Hoxa9 protein expression (Yokoyama *et al.,* 2004).

Through a general genetic screen for negative regulators of hTERT, menin was identified as a direct repressor of hTERT (Lin and Elledge, 2003).

Chromatin immunoprecipitation (ChIP) studies revealed that menin interacts with thousands of sites in chromatin. Most were in promoters, but significant numbers were elsewhere (Scacheri *et al.,* 2006). A separate ChIP study analyzed chromatin with an independent method, termed SACO. Again hundreds of interaction sites were found, and many were in the 3′ end of genes and in introns (Agarwal *et al.,* 2006). A specific menin binding sequence in DNA was not found in either study, suggesting that the many menin interactions with chromatin were indirect.

Menin Functions in Endocrine Tumor Tissues

Parathyroid Tumors

In the parathyroid cell from sporadic primary and secondary HPT, menin mRNA levels have been reported to be increased or not modified, whereas in MEN1-associated PHPT they are reduced (Bhuiyan *et al.*, 2000). As mentioned earlier, TGFβ is an interacting partner of menin and it is a crucial negative regulator of both parathyroid cells proliferation and PTH secretion. Consequently, the loss of TGFβ-dependent signaling secondary to menin inactivation may substantially contribute to parathyroid tumorigenesis in MEN1, favoring proliferation and PTH secretion and production of parathyroid affected cells (Sowa *et al.,* 2004b).

Pancreatic Tumors

Overexpression of menin in rat insulinoma cells inhibits their function and proliferation, via inhibition of promoter activity of the genes for insulin and others and increase of cell apoptosis. Menin expression significantly enables the inhibition of either the insulin promoter activity or glucose-dependent insulin secretion (Sayo *et al.,* 2002).

More recently, it has been hypothesized that menin mediates its tumor suppressor action by regulating histone methylation, particularly of H3K4, in promoters of HOX genes and/or *p18*, *p27*, and possibly other CDK inhibitors (Milne *et al.,* 2005; Karnik *et al.,* 2005). Consistent with this hypothesis, H3 K4 methylation and expression of p18 and p27 were shown to be dependent on menin in pancreatic islets (Karnik *et al.,* 2005).

Scacheri *et al.* (2006) identified the developmentally programmed transcription factor HLXB9, overexpressed in islets in the absence of menin, as a molecular partner normally bound by menin only in islets, and not in HeLa or HepG2 cells. These data raise the possibility for a specific bias for endocrine tumor formation in MEN1 resulting from changes in expression in distinct genes, such as *HLXB9*, specifically targeted by menin in endocrine tissues.

Pituitary Tumors

Although *MEN1* mutation has a limited role in the development and progression of sporadic pituitary tumors, its role in pituitary tumorigenesis is supported by the presence of pituitary tumors in MEN1 syndrome (Farrell and Clayton, 2000; Satta *et al.,* 1999). Recent studies have elucidated several interactions between pituitary-specific pathways

and menin. Activin, a member of the TGFβ superfamily, is a negative regulator of pituitary cell growth and of PRL, of ACTH, and of GH secretion (Hendy *et al.,* 2005). In addition, activin suppresses the transcription and expression of Pit-1, a pituitary transcription factor that has an essential role in the development and maintenance of lactotrope cells and in the regulation of PRL and GH expression (Lacerte *et al.*, 2004). The Smad pathway and menin are key regulators of activin effects, and menin is required for activin-mediated inhibition of PRL and GH expression, and this effect is mediated by Pit-1 gene expression and stability (Namihira *et al.,* 2002; Lacerte *et al.,* 2004).

Nonendocrine Functions of Menin

Roles have been suggested for menin other than in endocrine tumorigenesis. In particular, menin regulates physiological aspects in both bone development and hematopoiesis.

Bone Development

A newly recognized function of menin is the regulation of the differentiation of multipotential mesenchymal stem cells into osteoblastic cells (Sowa *et al.*, 2004). Bone morphogenetic proteins (BMPs) and TGFβ, members of the TGF superfamily, are crucial regulators of bone formation; the interactions of menin with the BMP-2 signaling pathway and Runx2 may differ depending on the osteoblast differentiation stage. Menin promotes the commitment of multipotential mesenchymal stem cells into the osteoblastic lineage through interactions with Smad1 to Smad5 and Runx2, whereas after the commitment to the osteoblast lineage the interaction of menin and Smad3 inhibits osteoblast differentiation by negatively regulating the BMP-2–Runx2 cascade (Sowa *et al.,* 2004a). Furthermore, JunD enhances both the expression of osteoblastic differentiation markers (i.e., Runx2, type 1 collagen, osteocalcin, and bone alkaline phosphatase) and bone mineralization, and menin could influence osteoblastic differentiation through JunD interactions (Naito *et al.,* 2005).

Hematopoiesis

Menin, as part of an MLL-containing complex, has been shown to interact with H3K4 methyltransferase activity of MLL, to regulate Hox gene expression *in vitro*. Menin activates Hoxa9 expression, at least in part, by binding to the Hoxa9 locus. Excision of the *MEN1* gene gradually decreased the total white blood cell count but did not significantly reduce red blood cell numbers (Chen *et al.,* 2006). Thus, menin may have a role in the maintenance of the steady-state peripheral white blood cell count (Chen *et al.,* 2006), but it remains to be delineated what determines the tissue-specific activities of menin and whether the menin–MLL–Hox pathway has a role in suppressing tumorigenesis in endocrine organs.

ANIMAL MODELS

In the mouse, it has been reported that the *Men1* gene is generally transcribed early (7 days postcoital), whereas at a later gestational stage, its expression is more readily found in tissues such as brain, thymus, and liver (Stewart *et al.,* 1998). Homozygous deletion of *Men1* is lethal *in utero*, and such embryos exhibit delayed development with defects of multiple organs, including the neural tube, heart, liver, and cranial and facial development (Crabtree *et al.,* 2001; Bertolino *et al.,* 2003). These findings strongly suggest that *Men1* gene plays a critical role in the development of multiple organs, in addition to its proposed role in the tumorigenesis of endocrine tissues in MEN1 patients. Recently, generation of homozygously deleted *Men1* gene in liver tissue of the mouse, considered not normally predisposed to developing tumors in both humans or mice with heterozygous *MEN1* mutation, revealed that menin-null livers appeared entirely normal, remaining tumor-free until late adulthood. These results indicate the need for more understanding of tissue specificity in MEN1 tumors (Scacheri *et al.,* 2004).

Inactivation of certain other tumor suppressor genes alone or in combination can cause specific endocrine tumors in mice. In particular, mice with simultaneous homozygous knockout of two genes, $p18^{INK4c}$ and $p27^{KIP1}$, develop tumors of parathyroid, pituitary, pancreas islet, and duodenum (like MEN1). They also develop C-cell cancers and pheochromocytoma (like MEN2; Franklin *et al.,* 2000). A spontaneous strain of rat shows a similar spectrum of tumors caused by homozygous mutation of *p27* (Pellegata *et al.,* 2006). And a human family was shown to express MEN1 caused by a heterozygous p27 mutation (Pellegata *et al.,* 2006). The knocked-out *p18* and *p27* genes encode members of the two cyclin-dependent kinase inhibitor families that participate in the G1 phase of the cell cycle, a phase that also includes retinoblastoma and cyclin D1.

This syndromic resemblance raises the possibility that the pathways of MEN1 and/or MEN2 interact with the cell cycling pathway and perhaps with each other.

The mouse *Menl* gene is highly homologous to *MEN1* (Guru *et al.,* 1999). Heterozygous knockout of *Men1* in the mouse results in a promising model of MEN1 (Crabtree *et al.,* 2000). Those mice develop tumors of the parathyroids, pancreatic islets, and pituitary. Unlike the ACTH-secreting pituitary intermediate lobe tumors with G1 phase tumor suppressor gene knockouts, these pituitary tumors are prolactinomas. The mouse tumors are associated with LOH at the mouse *Menl* locus. Crosses of these mice with mice showing other gene knockouts have indicated that

Men1–/+ does not synergize with Rb1– or p27=, but there is synergy in tumorigenesis with p18= (Bai *et al.,* 2006; Loffler *et al.,* 2006). This suggests that *MEN1* is in a pathway, which is linear with *p27* and *Rb1* but not with *p18*.

CONCLUSION

The discovery of the *MEN1* gene has led to changes in clinical management and to new insights about normal and abnormal functions. More studies are necessary to clearly elucidate the molecular mechanisms underlying MEN1-associated tumorigenesis.

New tools are in place to answer many questions shortly. Similarly, there are prospects for novel treatments based upon DNA, RNA, or even other small molecules.

ACKNOWLEDGMENTS

Studies of MEN1 pathophysiology on the NIH campus were done with a dedicated group of collaborators and were supported mainly by NIDDK and by NHGRI.

Chapter 58

Prostaglandins and Bone Metabolism

Carol C. Pilbeam*, Shilpa Choudhary, Katherine Blackwell and Lawrence G. Raisz
New England Musculoskeletal Institute, University of Connecticut Health Center, Farmington, Connecticut 06030

INTRODUCTION

In the 37 years since prostaglandin E_2 (PGE_2) was first shown to stimulate cyclic AMP production and resorption in bone organ cultures (Klein and Raisz, 1970), ample evidence has accumulated to demonstrate that prostaglandins (PGs) and other eicosanoids have important physiologic and pathologic roles in skeletal metabolism. PGs are autocrine-paracrine (or local) factors. They are not stored but are synthesized and released as needed and rapidly metabolized in their passage through the lung. PG production is regulated by many systemic hormones and other local factors involved in bone metabolism, and PGs may function to integrate or amplify responses to these agents at the cellular level. Understanding the role of PGs in skeletal metabolism has been complicated because they act locally and transiently, they are regulated at multiple levels, and they have multiple receptors. Moreover, dual effects can be demonstrated for PGs in most test systems *in vitro*. This chapter will summarize current knowledge on the regulation of PG production in bone and the effects of PGs and other eicosanoids on bone resorption and formation.

PG PRODUCTION

Metabolic Pathways

Eicosanoids are derived from 20-carbon polyunsaturated fatty acids (PUFAs). PUFAs result from metabolism of the dietary omega (ω)6 (or n-6) and ω3 (or n-3) essential fatty acids, linoleic acid (C18:2ω6) and linolenic acid (C20:3ω3) (Min and Crawford, 2004). The shorthand for fatty acids, X:YωZ, refers to X carbon atoms and Y double bonds, whereas Z is the position of the first double bond counting from the terminal methyl (CH_3) group. There are three major families of eicosanoids (Fig. 1): (1) prostanoids (PGs and thromboxane), synthesized via the cyclooxygenase pathway; (2) leukotrienes, lipoxins, and hydroxy-fatty acids, synthesized via various lipoxygenase pathways (5-, 12-, and 15-lipoxygenase); and (3) epoxy and omega derivatives, synthesized via the cytochrome P-450-dependent epoxygenase pathway (Capdevila *et al.*, 2000; Murphy *et al.*, 2004; Smith, 1989). Although important functions are being proposed for a rapidly growing number of metabolites generated by these pathways, the prostanoids and leukotrienes are still considered the most important biologically active eicosanoids, and they are the ones most studied in bone.

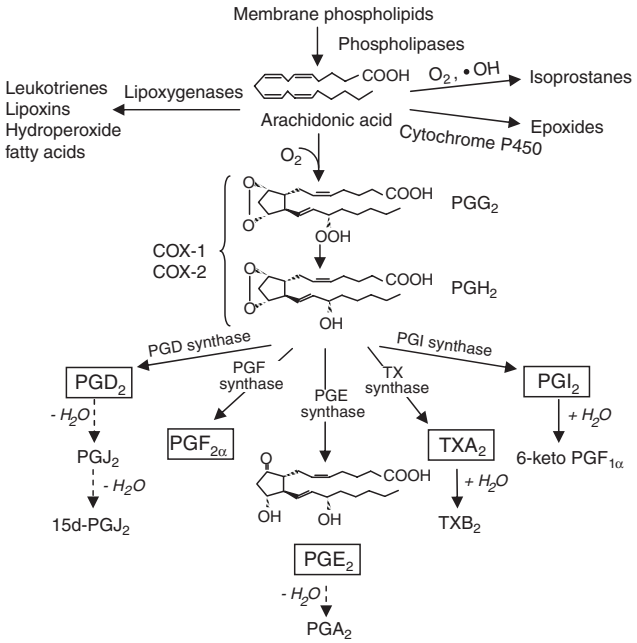

FIGURE 1 Major families of eicosanoids derived from arachidonic acid. The family of prostanoids (prostaglandins and thromboxane) is generated via the bifunctional cyclooxygenase (COX) enzyme, previously called prostaglandin G/H synthase (PGHS), which converts arachidonic acid to PGG_2 and PGG_2 to PGH_2. Specific synthases subsequently convert PGG_2 to various prostanoids. Other major families are (1) leukotrienes, lipoxins, and hydroxy fatty acids, (2) isoprostanes, and (3) products of the cytochrome P450–dependent epoxygenase pathway.

The lipid-soluble acid that was originally identified in seminal fluid as an activity causing muscle contraction or relaxation was named "prostaglandin" because it was thought to originate from the prostate gland (von Euler, 1936). PGs have now been shown to be produced in most tissues and cells except red blood cells. PGs derived from different substrates differ by the number of double bonds and by the substituents on the cyclopentane ring. The predominant PUFA substrates for cyclooxygenase in humans are dihomo-γ-linolenic acid (C20:3ω6), which gives rise to the 1 (1 double bond)-series of PGs; arachidonic acid (AA; C20:4ω6), which gives rise to the 2-series of PGs; and eicosapentaenoic acid (EPA; C20:5ω3), which gives rise to the 3-series of PGs (Wilson, 2004).

PGs of the 1-series, such as PGE_1, have not yet been shown to play an important role in normal physiology, but PGE_1 and synthetic analogues have been used to maintain patency of the ductus arteriosus in neonates with ductus dependent congenital heart defects (Talosi *et al.*, 2004) and to treat arterial occlusive disease and erectile dysfunction (Creutzig *et al.*, 2004; Ivey and Srivastava, 2006; Urciuoli *et al.*, 2004). Some reports have suggested that the PGE_1 analogue, misoprostol, originally developed as therapy for prevention of gastric ulceration, may prevent bone loss of estrogen depletion (Sonmez *et al.*, 1999; Yasar *et al.*, 2006). EPA, a constituent of fish oil, gives rise to the 3-series PGs, such as PGE_3. The ratio of EPA/AA in tissue phospholipids reflects the dietary ratio and in Western diets is less than 0.1, but can be increased by ingestion of fish oil (Wada *et al.*, 2007). AA is the major precursor in most mammalian systems. AA gives rise to PGs of the 2-series, the most important of the physiologically active PGs and the PGs most studied in bone, because they are highly produced by osteoblastic cells and can have marked effects on both bone resorption and formation.

The production of PGs involves three major steps, which are similar for the 1, 2, and 3 series of PGs. Steps for the 2-series of PGs, shown in Figure 1, are (1) hormone- or stress-activated mobilization of AA; (2) conversion of AA to the unstable endoperoxide intermediates, prostaglandin G_2 (PGG_2) and prostaglandin H_2 (PGH_2); and (3) conversion of PGH_2 by terminal synthases, which have some tissue specificity, to PGE_2, PGD_2, $PGF_{2\alpha}$, prostacyclin (PGI_2), and thromboxane (TXA_2). The committed step in the conversion of AA to PGs, and the step inhibited by nonsteroidal anti-inflammatory drugs (NSAIDs), is catalyzed by a bifunctional enzyme that converts free AA to PGG_2 in a cyclooxygenase reaction followed by reduction of PGG_2 to PGH_2 in a peroxidase reaction (Smith and Song, 2002). This enzyme, formally named prostaglandin endoperoxide H synthase or prostaglandin G/H synthase (PGHS), is popularly called cyclooxygenase (COX) in reference to its first function. The gene name is *ptgs*. All three steps are subject to transient activation, and it is not possible to make a simple conclusion as to which of these steps is "rate-limiting" for prostanoid production under all conditions because all three steps can be limiting.

PGI_2 and TXA_2 are spontaneously inactivated by hydrolytic conversion to 6-keto $PGF_{1\alpha}$ and TXB_2, respectively (see Fig. 1). In fluids containing albumin, PGE_2 and PGD_2 are slowly dehydrated within the cyclopentane ring to the cyclopentenone prostaglandins PGA_2 and PGJ_2, respectively. PGJ_2 is metabolized further to yield 15-deoxy-Δ^{12-14} PGJ_2 (15d-PGJ_2). The cyclopentenone PGs, which are not thought to act via the classical PG receptors, are active when given exogenously and can have opposite effects from some of the primary PGs (Negishi and Katoh, 2002; Straus and Glass, 2001). However, their physiological importance is unclear.

Phospholipase A_2 Enzymes

Phospholipase A_2 (PLA_2) enzymes catalyze the hydrolysis of membrane phospholipids from membrane glycerophospholipids, releasing free fatty acids, such as AA and lysophospholipids. There are multiple members of the PLA_2 superfamily, which is currently divided into 15 groups and many subgroups (Schaloske and Dennis, 2006). There are five distinct types of enzymes, and two of these, cytosolic PLA_2 ($cPLA_2$) and secreted PLA_2 ($sPLA_2$), are important for PG production (Murakami and Kudo, 2004). The $cPLA_2$s are large proteins ranging in size from 61 to 114 kDa. The most important $cPLA_2$ for PG production is thought to be $cPLA_{2\alpha}$ (85 kDa), which is selective for AA at the *sn-2* position. $cPLA_{2\alpha}$ is constitutively expressed in most cells, but its expression can be regulated to some degree. For example, PGs themselves can enhance both COX-2 and $cPLA_2$ expression (Murakami *et al.*, 1997), and IL-4 can inhibit both COX-2 and $cPLA_2$ expression (Kawaguchi *et al.*, 1996). However, the activation of $cPLA_{2\alpha}$ is essential for initiation of stimulus-coupled AA release (Murakami and Kudo, 2004). The initial step in activation is the Ca^{2+} (submicromolar concentrations)-dependent translocation of $cPLA_{2\alpha}$ from the cytosol to the nuclear/endoplasmic reticulum membrane where the COX enzymes reside. Maximal activation of $cPLA_{2\alpha}$ requires phosphorylation of two serine residues in the catalytic domain by the mitogen-activated protein kinase (MAPK) pathway. Because $cPLA_{2\alpha}$ is thought to be the major enzyme for releasing AA, it is not surprising that phenotypes of $cPLA_{2\alpha}$ knockout mice overlap the phenotypes of mice with targeted disruption of COXs in a number of respects (Murakami and Kudo, 2004). The skeletal phenotypes of these knockouts have not been reported.

Secretory PLA_2s ($sPLA_2$s) are small secreted proteins (14–18 kDa) that require millimolar Ca^{2+} concentrations for activation and do not have a distinct fatty acid selectivity. Expression of $sPLA_2$ enzymes is induced by pro-inflammatory agents, and they appear to play a role in

inflammatory diseases and innate immunity (Schaloske and Dennis, 2006). $sPLA_2$s can act in an autocrine or paracrine manner (Murakami and Kudo, 2004). $sPLA_2$s can hydrolyze phospholipids in the outer plasma membrane of the cell of origin or neighboring cells, releasing AA that can be incorporated into cells, or $sPLA_2$s can be internalized, perhaps via caveolae/raft dependent vesicular pathways, and release AA from endoplasmic reticulum/perinuclear membranes (Murakami and Kudo, 2004). There are at least 10 mammalian $sPLA_2$s. The group IIA (GIIA) and V (GV) enzymes are thought to be major $sPLA_2$ contributors to PG production (Bingham *et al.*, 1999; Kuwata *et al.*, 1999). GV PLA_2 has been reported to be the primary $sPLA_2$ in the mouse (Sawada *et al.*, 1999). Some mouse strains, such as 129Sv and C57Bl/6, naturally lack type GIIA PLA_2 but develop normally (Kennedy *et al.*, 1995). However, they do have increased resistance to colorectal tumorigenesis (MacPhee *et al.*, 1995). It is interesting to note that many knockouts of PLA_2s or other enzymes in the PG pathway are in a C57Bl/6 or 129Sv background and, hence, they are really double knockouts (Schaloske and Dennis, 2006). It should also be noted that the MC3T3-E1 osteoblastic cell line, commonly used to study osteoblastic function and differentiation *in vitro*, was derived from C57Bl/6 mice and should therefore lack GIIA PLA_2.

Two Isoforms for COX

The two enzymes for COX, COX-1 and COX-2, are encoded by separate genes. The human COX-1 gene is located on chromosome 9 and the human COX-2 gene is located on chromosome 1. COX-1 is expressed at relatively stable levels in most tissues and is considered to be constitutive, whereas COX-2 is generally expressed at very low basal levels in most tissues but can be induced to high levels by multiple factors (Herschman, 1994; Smith *et al.*, 2000; Tanabe and Tohnai, 2002). COX-2 was initially identified as a phorbol ester-inducible primary response or immediate-early gene (TIS10) in murine 3T3 cells (Kujubu *et al.*, 1991) and a v-*src*-inducible gene product in chicken fibroblasts (Xie *et al.*, 1991). The human COX-2 gene is about 80% homologous with the chicken and murine genes (Hla and Neilson, 1992). The COX-1 gene is approximately 22 kb with 11 exons and 10 introns, and it encodes 2.8 kb mRNA (Yokoyama and Tanabe, 1989). The COX-2 gene is approximately 8 kb with 10 exons and 9 introns and encodes 4.0 to 4.6 kb mRNA (Fletcher *et al.*, 1992; Kraemer *et al.*, 1992). A major difference between COX-1 and COX-2 mRNAs is the 2 kb 3′-untranslated region (UTR) of COX-2 that contains multiple copies of AUUUA sequences, which have been associated with rapid degradation of mRNA. COX-1 and COX-2 are about 80% identical at both amino acid and nucleic acid levels, differing mainly at the N- and C-terminal ends (Herschman, 2004; Kang *et al.*, 2007; Tanabe and Tohnai, 2002). COX-2 lacks the first exon in the COX-1 gene and consequently has a shorter signal peptide region in the N-terminus. On the other hand, COX-2 contains an extra sequence in the C-terminal region encoding a 19-amino-acid insert involved in protein degradation (Mbonye *et al.*, 2006).

Both COX-1 and COX-2 proteins are homodimeric (approximately 68–72 kDa/subunit) heme-containing glycoproteins (Kang *et al.*, 2007; Kulmacz *et al.*, 2003; Mbonye *et al.*, 2006; Smith and Song, 2002). Although some early studies suggested differences in cellular locations of the two enzymes, later studies confirmed that both enzymes are located similarly in the luminal surfaces of the endoplasmic reticulum and the contiguous inner membrane of the nuclear envelope (MirAfzali *et al.*, 2006; Spencer *et al.*,1998, 1999). Unlike many membrane proteins, COX-1 and COX-2 do not have a transmembrane domain and are anchored only to one leaflet of the lipid bilayer (monotopic) through the hydrophobic surfaces of amphipathic helices (Kulmacz *et al.*, 2003; Spencer *et al.*, 1999). Recent studies have indicated that a heterodimer containing an inactive COX-2 monomer associated with a native COX-2 monomer retains full PG synthesis capability (Yuan *et al.*, 2006). Other studies have suggested that COX-1 and COX-2 monomers may heterodimerize and produce PGs (Yu *et al.*, 2006).

COX-1 and COX-2 have essentially the same catalytic mechanisms (Kulmacz *et al.*, 2003; Rouzer and Marnett, 2005; Smith and Song, 2002; van der Donk *et al.*, 2002). The cyclooxygenase (COX) and peroxidase (POX) active sites are in distinct and physically separated regions of the proteins. The initiation of COX activity is dependent on heme oxidation in the POX site by peroxidase. Heme oxidation leads to oxidation of a critical tyrosine in the COX active site. The tyrosyl radical in the COX site converts AA to an arachidonyl radical, the arachidonyl radical reacts with two molecules of oxygen to produce PGG_2, and then PGG_2 diffuses to the POX site where it is reduced to PGH_2. Studies of mice developed with a targeted knock-in of a mutation of the critical tyrosine site in the COX active site, leaving the POX activity intact, suggest that the predominant features of the COX-2 knockout mice are due to the absence of COX activity (Yu *et al.*, 2007). NSAIDs bind at the COX site, competing with AA and leaving the POX activity intact. The COX active site is about 20% larger in COX-2 compared to COX-1 and has a slightly different shape due to several differences in amino acids, making it possible to develop NSAIDs selective for one or the other COX isoforms (Kulmacz *et al.*, 2003; Rainsford, 2004; Smith *et al.*, 2000). The "classical" NSAIDs can inhibit both COX-1 and COX-2 but generally bind more tightly to COX-1 (Smith *et al.*, 2000). Currently available selective COX-2 inhibitors are tight-binding, time-dependent inhibitors of COX-2 but only rapid, competitive, and reversible inhibitors of COX-1 (Smith *et al.*, 2000).

Splice variants of both COX-1 and COX-2 genes have been identified (Diaz *et al.*, 1992; Roos and Simmons, 2005; Shaftel *et al.*, 2003). A splicing variant of COX-1, arising via the retention of intron 1, was identified in canine tissues and called COX-3 (Chandrasekharan *et al.*, 2002). COX-3 was reported to be differentially sensitive to inhibition by acetaminophen. However, later studies concluded that this variant is unlikely to be a therapeutic target of acetaminophen and probably has little or no COX activity in humans (Davies *et al.*, 2004; Kis *et al.*, 2005, 2006; Qin *et al.*, 2005; Snipes *et al.*, 2005). Interestingly, recent studies suggest that acetaminophen is a COX-2 selective inhibitor. Acetaminophen is reported to inhibit COX-2 to a degree comparable to selective COX-2 inhibitors in a study of human volunteers (Hinz *et al.*, 2007). Acetaminophen may inhibit COX-2 at the level of the POX catalytic site, with inhibitory effects being inversely proportional to the ambient peroxide levels (Aronoff *et al.*, 2006).

Why Are There Two COX Enzymes?

Despite having similar catalytic mechanisms, COX-1 and COX-2 appear to be independently functioning biosynthetic pathways (Simmons *et al.*, 2004; Smith and Langenbach, 2001). This is due in part to the differential regulation of their expression. The COX-1 promoter has relatively few identified functional regulatory elements, and COX-1 mRNA is constitutively expressed in most tissues. The COX-2 promoter, on the other hand, has multiple potential transcriptional regulatory elements typical of early response genes, and COX-2 mRNA is rapidly and transiently inducible in many tissues (Kang *et al.*, 2007). Differences in the response of COX-1 and COX-2 gene expression are exemplified by their differential responses to serum in MC3T3-E1 cells (Pilbeam *et al.*, 1993). Differential protein stability also contributes to the difference in expression. COX-1 protein has a long half life of 12 to 24 hours or more, whereas COX-2 protein has a half life of 2 to 7 hours (Kang *et al.*, 2007; Mbonye *et al.*, 2006).

Differential regulation of expression cannot account for all differences. When COX-1 is inserted under the regulatory sequences that drive COX-2 expression, COX-1 can substitute for only some, not all, of the deficits seen with COX-2 disruption (Yu *et al.*, 2007). There are clearly differences in PG production by COX-1 and COX-2. Osteoblasts from COX-2 KO mice make little PGE_2 in culture despite the constitutive expression of COX-1, unless AA is added to cultures (Chikazu *et al.*, 2005; Choudhary *et al.*, 2003; Okada *et al.*, 2000a; Xu *et al.*, 2007b). One explanation is that COX-2 is much more efficient at using low endogenous AA concentrations (below 5 μM) than is COX-1 (Swinney *et al.*, 1997). A greater cellular peroxide level may be required for COX-1 activation compared to COX-2 (Kulmacz *et al.*, 2003). Cellular glutathione peroxidase capacities and glutathione levels are high enough in many tissues to keep COX-1 in the latent state, and cells generally have unused capacity for prostanoid production. It has been suggested that having an inducible COX isoform might provide the means to increase PG production without the cellular damage that might ensue if peroxide levels were increased enough to activate COX-1 (Kulmacz *et al.*, 2003).

In many cell types, there is an early burst of PG synthesis secondary to activation of PLA_2 that releases substrate for preexisting COX-1, followed by a later or "delayed" phase of PG production secondary to induction of COX-2 (Herschman, 2004). The delayed phase can also be autoamplified by the early production of PGs, which can stimulate COX-2 expression (Murakami *et al.*, 1997). An example of the early and late phases is seen in the PG production by osteoblasts subjected to fluid shear stress (Klein-Nulend *et al.*, 1997) or to IL-1 (Harrison *et al.*, 1994). It has been proposed that some differences in PG production arise because COX-1 and COX-2 are functionally coupled to different PLA_2s (Balsinde *et al.*, 1998; Reddy and Herschman, 1997). That relationship appears complex—dependent on cell type, ligand, and relative enzyme concentration—and it is probably prudent to say that both $cPLA_2\alpha$ and some $sPLA_2$s can supply AA for both COX-1 and COX-2 (Herschman, 2004).

Because of the differential responses of COX-1 and COX-2, it was initially hypothesized that COX-2 is predominantly responsible for acute pathological PG responses, such as those associated with inflammation and pain, whereas COX-1 produces prostanoids needed for ongoing "housekeeping" functions, including maintenance of renal blood flow, platelet aggregation, and gastric cytoprotection. This hypothesis led to the development of highly selective inhibitors of COX-2 activity, such as rofecoxib and celecoxib, for treatment of pain and inflammation associated with diseases such as arthritis and periodontitis. Studies using these inhibitors have led to the realization that the initial hypothesis was too simple and that COX-2 has physiologic as well as pathologic functions in multiple tissues.

Prostaglandin E Synthases

The terminal PG synthases may be differentially distributed in tissues and were originally thought to influence PG production largely by determining the predominant type of prostanoid synthesized in a particular tissue. However, it is now known that expression of some of them can be regulated by many factors. PGE_2 is the best studied PG in bone. Prostaglandin E synthase (PGES), which converts COX-derived PGH_2 to PGE_2 occurs in multiple forms. For recent reviews see Murakami and Kudo (2006) and Park

et al. (2006). The membrane-bound glutathione-dependent PGES called mPGES-1, cloned by Jakobsson (Jakobsson *et al.*, 1999) and later by Murakami (Murakami *et al.*, 2000), is inducible, located in the endoplasmic reticulum and perinuclear membranes, and is the predominant PGES metabolizing the PGH_2 produced by COX-2 (Forsberg *et al.*, 2000; Murakami and Kudo, 2006; Pettersson *et al.*, 2005). For these reasons, and because mPGES-1 is coordinately regulated by factors that regulate COX-2, mPGES-1 is said to be coupled to COX-2. A cytosolic form of PGES, cPGES, is preferentially coupled to COX-1 and thought to maintain PGE_2 production for cellular homeostasis (Tanioka *et al.*, 2000). cPGES may be regulated by being stimulated to translocate from the cytosol to the nuclear membrane to form a complex with COX-1 (Park *et al.*, 2006). A third PGES, called mPGES-2, is constitutively expressed and may be functionally coupled to both COX-1 and COX-2 (Watanabe *et al.*, 1997).

Mice deficient for mPGES-1 develop normally but have reduced inflammatory and pain responses (Kamei *et al.*, 2004; Trebino *et al.*, 2003). Lipopolysaccharide (LPS)-induced bone resorption and bone loss are reduced in mice deficient for mPGES-1 (Inada *et al.*, 2006). Hence, this enzyme may be a target for drug therapy to prevent inflammatory bone loss that would leave the production of other prostanoids intact. One interesting aspect of targeting mPGES-1 instead of COX-2 is that inhibition of mPGES-1 may augment prostacyclin (PGI_2) production and therefore be associated with less cardiovascular side effects than COX-2 selective inhibitors (Wang *et al.*, 2006a).

Isoprostanes

Although synthesis of eicosanoids is predominantly dependent on enzymatic metabolism of AA by COX-1 and COX-2, nonenzymatic free radical induced peroxidation of free or membrane-bound AA can give rise to natural products that are isomers of enzymatically derived PGs, called isoprostanes (IsoPs; Montuschi *et al.*, 2004, 2007; Morrow, 2006; Pratico *et al.*, 2004). In contrast to PGs generated enzymatically, the side chains of IsoPs are predominantly orientated *cis* relative to the cyclopentane ring. Some PG receptors may also be receptors for IsoPs. The most studied Iso-P group is F_2-IsoPs, a group of 64 compounds isomeric in structure to COX-derived $PGF_{2\alpha}$. Studies suggest that formation of F_2-IsoPs is altered in inflammation and other clinical settings associated with oxidative stress, and measurement of F_2-IsoPs may provide a tool for studying the role of oxidative stress in human disease (Milne *et al.*, 2007). There has been one report of negative association of urinary 8-Iso-$PGF_{2\alpha}$ levels with bone mineral density (BMD) in humans (Basu *et al.*, 2001), but it seems likely that urinary IsoP levels will reflect general, rather than specific, pathology. $PGF_{2\alpha}$ is known to be present in human urine in significant concentrations and was presumed to be derived from COX activity. Recently, however, it was reported that levels of putative $PGF_{2\alpha}$ in urine cannot be suppressed by NSAIDs and that $PGF_{2\alpha}$ in urine is likely to be derived via the IsoP pathway (Yin *et al.*, 2007). IsoPs themselves may also be pathophysiological mediators of disease (Montuschi *et al.*, 2004), although some of them, the cyclopentenone IsoPs, which are structural isomers of the bioactive cyclopentenone PGs, PGA_2 and PGJ_2, may be anti-inflammatory (Musiek *et al.*, 2005). Free radicals have been reported to be involved in bone resorption, but little is known about the importance of IsoPs in bone. 8-Iso-PGE_2 has been reported to stimulate osteoclastogenesis (Tintut *et al.*, 2002), but this may be due to nonenzymatic conversion of 8-Iso-PGE_2 to PGE_2 (Raisz, unpublished observations).

PG RECEPTORS

G-Protein Linked Receptors

There are at least nine G-protein linked PG receptors mediating prostanoid actions; (Fig. 2). There is a G-protein-coupled receptor (GPCR) for the F and I types of PGs and for thromboxane, called FP, IP, and TP, respectively. PGD_2 has two GPCRs, DP1 and the recently identified DP2, which belongs to the chemoattractant receptor family (Kostenis and Ulven, 2006). PGE_2 effects are associated with four classes of GPCRs, called EP1, EP2, EP3, and EP4.

Much of the complexity of PGE_2 effects on skeletal tissues may be attributable to the multiple transmembrane GPCRs for PGE_2 and their ability to activate different signaling pathways (Coleman *et al.*, 1994; Kobayashi and Narumiya, 2002). Even more complex actions are possible if these receptors can undergo nuclear compartmentalization (Gobeil *et al.*, 2003) or heterodimerize with other GPCRs (Barnes, 2006). The EP1 receptor acts largely by increasing calcium flux. Although often said to be coupled to $G\alpha_q$, the absence of a phosphatidylinositide response has led to speculation that it is coupled to an as yet unidentified G protein (Sugimoto and Narumiya, 2007). Both the EP2 and EP4 receptors are coupled to $G\alpha_s$ and can stimulate cyclic 3,5-adenosine monophosphate (cAMP) formation, but there may be a greater cAMP response to EP2

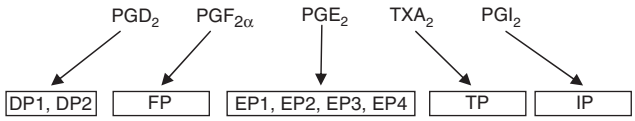

FIGURE 2 Prostaglandin and thromboxane receptors. There are at least nine G-protein-coupled receptors (GPCRs) mediating prostanoid actions. PGD_2 has two receptors, DP1 and the recently identified DP2, which belongs to the chemoattractant receptor family and is also called $CRTH_2$. PGE_2 effects are associated with four classes of GPCRs, called EP1, EP2, EP3, and EP4.

than to EP4 (Fujino *et al.*, 2005; Sakuma *et al.*, 2004). The EP_3 receptor is coupled to $G\alpha_i$ and acts largely by inhibiting cAMP production. However, there are multiple alternative transcripts of the EP_3 receptor that can act through other signal transduction pathways (An *et al.*, 1994). Mice deficient in each EP receptor subtype have been generated, and highly selective agonists for these receptors have been developed (Sugimoto and Narumiya, 2007).

EP2 and EP4 are the receptors most extensively studied in bone. Despite their importance in bone, much of what is known about EP2 and EP4 receptor signaling pathways comes from studies in non-bone tissues, designed to elucidate the role of PGE_2 in promoting tumorigenesis. These studies are summarized in several recent reviews (Castellone *et al.*, 2006; Cha and DuBois, 2007; Dorsam and Gutkind, 2007; Eisinger *et al.*, 2007; Wang and DuBois, 2006). Other data have come from studies of Chinese hamster ovary (CHO) cells or human embryonic kidney (HEK)-293 cells transfected with EP receptors (Fujino *et al.*, 2002; Nishigaki *et al.*, 1996). Potential signaling pathways by which PGE_2 may promote tumorigenesis are shown in Figure 3. EP2 and EP4 receptors stimulate $G\alpha_s$ and activate adenylyl cyclase (AC), producing cAMP and activating protein kinase A (PKA). The cAMP pathway is able to crosstalk with several other pathways that regulate cell growth, motility, migration and apoptosis. Interaction with the Wnt/β-catenin signaling pathway, resulting in increased expression of Wnt target genes, is one example (Castellone *et al.*, 2005; Shao *et al.*, 2005). Under basal conditions, β-catenin is targeted to a molecular "destruction" complex in the cytoplasm, which includes axin and glycogen synthase kinase-3β (GSK-3β). GSK-3β phosphorylates β-catenin, and phosphorylated β-catenin undergoes ubiquitin-dependent degradation. On stimulation of the EP2 or EP4 receptor, PKA may inhibit ubiquitination of β-catenin, leading to the stabilization and nuclear translocation of β-catenin (Hino *et al.*, 2005). In addition, $G\alpha_s$ subunits may bind the regulator of G-protein signaling (RGS) domain of axin, which releases GSK-3β from its complex with axin. Free $G\beta\gamma$ subunits can stimulate Akt through activation of phosphatidylinositol 3-kinase (PI3K), and then Akt can phosphorylate and inactivate GSK-3β, leading to the stabilization and accumulation of β-catenin. Studies in HEK-293 cells stably transfected with EP receptors suggest that the activation of T-cell factor (Tcf)/β-catenin signaling may occur primarily through a PKA-dependent pathway for EP2 and through a PI3K-dependent pathway for EP4 (Fujino *et al.*, 2002).

PGE_2 has also been shown to activate the MAPK extracellular signal-regulated kinase (ERK) pathway in various non-bone cells via the EP4 receptor (Fujino *et al.*, 2003; Pozzi *et al.*, 2004; Rao *et al.*, 2007; Qian *et al.*, 2006; Wang *et al.*, 2005). Several potential pathways leading to ERK activation have been proposed (see Fig. 3). PGE_2 can

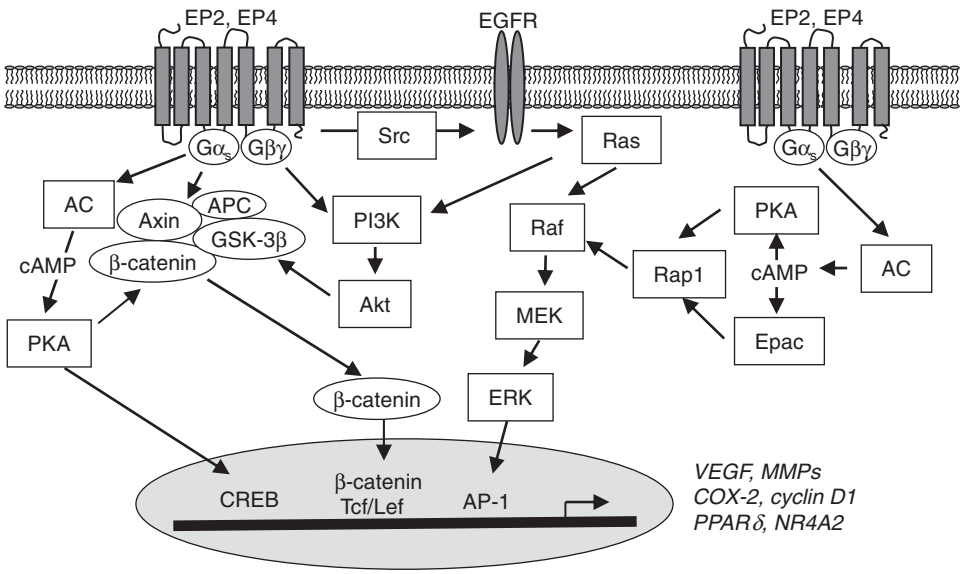

FIGURE 3 EP2 and EP4 receptor signaling pathways postulated to be involved in the promotion of tumorigenesis by PGE_2 (Cha and Dubois, 2007; Dorsam and Gutkind, 2007). EP2 and EP4 are $G\alpha_s$-coupled receptors that can activate adenylyl cyclase (AC), elevate cyclic AMP (cAMP), activate protein kinase A (PKA), and phosphorylate the cAMP response element binding (CREB) transcription factor. PGE_2 may also stimulate stabilization, nuclear translocation, and transcriptional activation of β-catenin through several pathways, including activation of the phosphatidylinositol 3-kinase (PI3K)–Akt pathway. Activation of extracellular signal-regulated kinase (ERK) leading to activation of activating protein-1 (AP-1) transcription factors, such as c-Fos and c-Jun, may occur via transactivation of epidermal growth factor receptor (EGFR) or via PKA-dependent or independent pathways. Downstream targets regulated by these pathways may include vascular endothelial growth factor (VEGF), matrix metalloproteinases (MMPs), peroxisome proliferator-activated receptor-δ (PPARδ), and NR4A2, a member of the Nurr1 orphan nuclear receptor family.

transactivate the epidermal growth factor receptor (EGFR) signaling pathway by a number of mechanisms, including proteolytic release of EGFR ligands, such as amphiregulin or transforming growth factor-α (TGF-α) (Buchanan *et al.*, 2003; Pai *et al.*, 2002; Shao *et al.*, 2003). Although little studied in response to PGE_2, cAMP is also capable of activating Rap1, a small guanosine triphosphatase (Gesty-Palmer *et al.*, 2006; Stork and Dillon, 2005). This activation can occur through a PKA-dependent pathway or a PKA-independent pathway mediated by the guanine exchange factor called EPAC (exchange protein directly activated by cAMP) (Fujita *et al.*, 2002; Gerdin and Eiden, 2007; Li *et al.*, 2006c). cAMP can stimulate proliferation in some cells and inhibit in others, associated with stimulation and inhibition, respectively, of ERK (Faure and Bourne, 1995; Stork and Schmitt, 2002). The ability to stimulate ERK depends on the expression of B-Raf, a MAPK kinase target of Rap1 (Fujita *et al.*, 2002; Stork and Dillon, 2005; Wang *et al.*, 2006b). In cells that do not express B-Raf, Rap1 antagonizes Ras-dependent ERK activation.

It is possible that EP2 or EP4 receptors can change signaling specificity (G-protein "switching"), similar to β-adrenergic GPCRs (Martin *et al.*, 2004). In HEK-293 cells stably transfected with EP2 or EP4 receptors, EP4 but not EP2 can couple to a pertussis toxin sensitive G-protein ($G\alpha_i$) that can activate ERK signaling and inhibit cAMP-dependent signaling (Fujino and Regan, 2006). Alternatively, GPCRs coupled to $G\alpha_s$, including the PTH/PTH-related peptide receptor, have been shown to activate ERK via G-protein independent pathways involving β-arrestin (Gesty-Palmer *et al.*, 2006; Shenoy and Lefkowitz, 2005) and c-Src (Sun *et al.*, 2007). Such G-protein independent pathways have not yet been associated with EP receptors but might explain some of the biphasic effects of PGE_2.

Some of the downstream targets identified as being upregulated by PGE_2 in studies examining the PGE_2 promotion of carcinogenesis may also be important for both normal bone metabolism and metastatic bone disease (Castellone *et al.*, 2006; Cha and DuBois, 2007). Among these targets are angiogenic factors, such as vascular endothelial growth factor (VEGF), matrix metalloproteinases (MMPs), COX-2 itself, and NR4A2 (a member of the Nurr1 orphan nuclear receptor family). NR4A2 has been shown to be expressed in osteoblasts and to stimulate osteoblastic differentiation (Holla *et al.*, 2006; Lee *et al.*, 2006; Pirih *et al.*, 2005).

EP receptors are expressed in both osteoblastic and osteoclastic cells. EP3 and EP4 were demonstrated in human fetal and adult osteoblasts by immunolocalization (Fortier *et al.*, 2004). Studies using Northern blot analysis and reverse transcription polymerase chain reaction (RT-PCR) showed EP1, 2, and 3 receptors in rat calvarial osteoblasts (Kasugai *et al.*, 1995) and EP 1, 2, and 4 receptors in murine osteoblastic MC3T3-E1 cells (Kasugai *et al.*, 1995; Suda *et al.*, 1996). A study in human osteosarcoma cells using real-time RT-PCR reported expression of all four EP receptors (Shoji *et al.*, 2006). EP3 and EP4 receptors have been reported in mature human osteoclasts (Fortier *et al.*, 2004; Sarrazin *et al.*, 2004). Both EP2 and EP4 receptors appear to be involved in regulation of osteoblast function, including the ability of these cells to support osteoclast formation, based on experiments with KO animals and selective agonists, which are described later. EP receptors may also be important in chondrocytes. All four EP receptors have been shown to be expressed in growth plate chondrocytes, but the EP1 receptor pathway appears to be the major EP pathway involved in regulating proliferation and differentiation of these cells (Brochhausen *et al.*, 2006; Sylvia *et al.*, 2001).

Although less studied, receptors for other prostanoids are also expressed in osteoblasts. Studies have shown IP receptor expression in MC3T3-E1 cells (Wang *et al.*, 1999) and cultured primary human osteoblastic cells (Sarrazin *et al.*, 2001). IP receptors have also been demonstrated by immunolocalization in human bone (Fortier *et al.*, 2001). Cultured human osteoblasts have been shown to produce PGD_2 and to have DP1 and DP2 receptors (Gallant *et al.*, 2005; Samadfam *et al.*, 2006). In MC3T3-E1 osteoblastic cells, PGD_2 and PGI_2 can induce COX-2 expression (Pilbeam *et al.*, 1994). Agonists for IP, DP, and TP receptors have also been shown to induce COX-2 expression in primary murine calvarial osteoblasts (Sakuma *et al.*, 2004). A functional TP receptor was demonstrated in primary human osteoblasts (Sarrazin *et al.*, 2001). The FP receptor is reported to be expressed in primary human osteoblastic cells (Sarrazin *et al.*, 2001). There is also evidence for an FP pathway in rodent clonal osteoblastic cells, which may act through a protein kinase C (PKC) pathway to induce COX-2 (Pilbeam *et al.*, 1994), inhibit collagen synthesis (Fall *et al.*, 1994), and activate the MAPK pathway (Hakeda *et al.*, 1997).

Expression of EP receptors is likely to vary with stage of differentiation and with treatment regime. In bone marrow macrophage osteoclast precursors, which express all four EP receptors, EP2 and EP4 receptor expression is downregulated with maturation (Kobayashi *et al.*, 2005b). Studies in CHO cells stably overexpressing EP2 and EP4 receptors suggest that the EP4 receptor undergoes short term agonist-induced desensitization, whereas the EP2 receptor is desensitized in response to prolonged agonist exposure (Nishigaki *et al.*, 1996).

Peroxisome Proliferator-Activated Receptors (PPARs)

PPARs are members of the nuclear receptor family of transcription factors that are important in lipid metabolism and may have a variety of effects on cellular function.

Three major subtypes, α, γ, and δ (also called β), have been described (Bishop-Bailey and Wray, 2003; Hihi *et al.*, 2002). Upon ligand binding, PPARs form heterodimeric complexes with retinoid X receptors and bind to PPAR response elements, attracting coactivators and other proteins, to mediate gene transcription.

PGs have been suggested to be endogenous ligands for PPARs. PPARγ and PPARδ are expressed in human osteoblastic cells (Maurin *et al.*, 2005), and PPARδ may be expressed by mature osteoclasts (Mano *et al.*, 2000a). PGI_2 is proposed to be an endogenous ligand for PPARδ, and PPARδ may be the receptor mediating effects of PGI_2 on embryo implantation in the mouse (Lim and Dey, 2002). However, PPARδ knockout mice do not show an implantation defect (Ide *et al.*, 2003). Studies suggest that PPARδmay be a downstream mediator of effects of PGE_2 on promoting colorectal tumor growth (Cha and DuBois, 2007; Wang *et al.*, 2004a; Wang and DuBois, 2007). This effect is postulated to occur not by binding of PGE_2 to PPARδ but via an indirect transactivation of PPARδ signaling by PGE_2. PPARδ may be a direct transcriptional target of the β-catenin/TCF pathway, which may be stimulated by PGE_2 (see Fig. 3).

PPARγ has been widely studied because it mediates the insulin-sensitizing effects of thiazolidinediones on glucose and lipid metabolism. Administration of rosiglitazone or other PPARγ agonists to rodents can result in bone loss (Li *et al.*, 2006b; Rzonca *et al.*, 2004), while deficiency of PPARγ results in increased bone mass (Cock *et al.*, 2004). PPARγ is expressed in adipocytes and is important for adipogenesis. It is also expressed in bone marrow precursors and may play a role in determining adipocyte versus osteoblastic differentiation from a common stem cell (Lecka-Czernik and Suva, 2006). Activation of PPARγ may also have anti-inflammatory actions (Zingarelli and Cook, 2005). PPARγ has a wide array of potential ligands, including AA, NSAIDs at high concentrations, and some lipoxygenase metabolites. It has been proposed that a spontaneous dehydration product of PGD_2, the cyclopentenone 15-deoxy-Δ^{12-14} PGJ_2 (15d-PGJ_2) (see Fig. 1), is the endogenous ligand mediating anti-inflammatory effects of PPARγ (Scher and Pillinger, 2005). Pharmacological doses of 15d-PGJ_2 can activate PPARγ, as well as inhibit several other signaling transduction pathways. However15d-PGJ_2 levels *in vivo* are reported to be several orders of magnitude too low to be the endogenous mediator of PPARγ activation (Bell-Parikh *et al.*, 2003; Powell, 2003).

Although PGE_2 itself is unlikely to be a ligand for PPARs, metabolites of PGE_2 may be ligands. PGE_2 can be metabolized in cells by 15-hydroxyprostaglandin dehydrogenase (PGDH) to 15-keto-PGE_2 (Tai *et al.*, 2002). PGDH is expressed in many tissues (Tai *et al.*, 2006; Yan *et al.*, 2004), including calvarial osteoblasts (Pilbeam, unpublished observations). Although 15-keto-PGE_2 is orders of magnitude less potent at the EP2 and EP4 receptors than PGE_2 itself (Nishigaki *et al.*, 1996), 15-keto-PGE_2 may function as a PPAR ligand and stimulate the differentiation of murine fibroblasts into adipocytes (Chou *et al.*, 2007). It remains to be seen if this effect occurs at levels of 15-keto-PGE_2 that occur *in vivo.*

REGULATION OF PG PRODUCTION IN OSTEOBLASTS

Stimulation of PG Production

Early studies using complement-sufficient antisera, which contain antibodies to rodent cell surface antigens, showed that this serum could increase resorption of fetal rat long bones by stimulating endogenous PG production (Raisz *et al.*, 1974). Subsequently, many agonists were found to increase bone PG production, including many of the regulators of bone metabolism. Prostanoids produced by bone include PGE_2, $PGF_{2\alpha}$, and 6-keto-$PGF_{1\alpha}$, the metabolite of PGI_2, as well as some PGD_2 and thromboxane (Feyen *et al.*, 1984; Gallant *et al.*, 2005; Klein-Nulend *et al.*, 1991a, 1997; Pilbeam *et al.*, 1989; Raisz *et al.*, 1979; Raisz and Martin, 1983; Voelkel *et al.*, 1980). In some studies of cultured calvarial bone and primary calvarial cells, more 6-keto-$PGF_{1\alpha}$ than PGE_2 was measured in the media (Pilbeam *et al.*, 1989). On the other hand, there was no detectable accumulation of 6-keto-$PGF_{1\alpha}$ seen in media from clonal MC3T3-E1 osteoblastic cells (Harrison *et al.*, 1994), and it is possible that endothelial cells are the main source of PGI_2 in bone organ cultures.

Among the factors that stimulate PG production in bone are proinflammatory mediators, such as interleukin-1 (IL-1; Sato *et al.*, 1986) and TNF-α (Tashjian *et al.*, 1987); multifunctional regulators of cell growth and differentiation, such as transforming growth factor (TGF)-α and -β (Hurley *et al.*, 1989; Sumitani *et al.*, 1989; Tashjian *et al.*, 1985); systemic calcium-regulating hormones, such as parathyroid hormone (PTH; Pilbeam *et al.*, 1989) and $1,25(OH)_2D_3$ (Klein-Nulend *et al.*, 1991b); and mechanical loading of bone (Lanyon, 1992; Rawlinson *et al.*, 1991; Reich and Frangos, 1993). Thyroid hormone (Klaushofer *et al.*, 1995), platelet-derived growth factor (PDGF; Tashjian *et al.*, 1982), bradykinin (Ljunggren *et al.*, 1991b), and thrombin (Ljunggren *et al.*, 1991a) can also stimulate PG production in osteoblasts.

Most commonly used osteoblastic cell models constitutively express COX-1. Prior to the identification of the inducible COX-2, many of us tried to explain marked increases in PG production by small increases in COX-1 expression coupled with ligand-stimulated AA release, despite the rather large mismatch in size of effects (Klein-Nulend *et al.*, 1991a). Following identification of COX-2 in the early 1990s (O'Banion *et al.*, 1991; Kujubu *et al.*, 1991; Xie *et al.*, 1991), it became clear that induction of COX-2

in osteoblastic cells was responsible for most acutely stimulated PG production. Multiple agonists have been shown to induce COX-2 in osteoblastic cells. Some examples are cytokines—IL-1 (Harrison *et al.*, 1994; Kawaguchi *et al.*, 1994; Min *et al.*, 1998), TNF-α (Kawaguchi *et al.*, 1996) and IL-6 (Tai *et al.*, 1997); growth factors—TGFα (Harrison *et al.*, 1994), TGF-β (Pilbeam *et al.*, 1997a), basic fibroblast growth factor (FGF-2; Kawaguchi *et al.*, 1995b), and bone morphogenetic protein (BMP-2; Chikazu *et al.*, 2005); systemic hormones—PTH (Kawaguchi *et al.*, 1994; Tetradis *et al.*, 1996, 1997) and 1,25$(OH)_2$ vitamin D_3 (Okada *et al.*, 2000a); calcium (Choudhary *et al.*, 2003) and strontium (Choudhary *et al.*, 2007); and fluid shear stress or mechanical loading (Klein-Nulend *et al.*, 1997; Mehrotra *et al.*, 2006a; Pavalko *et al.*, 1998; Wadhwa *et al.*, 2002a).

When COX-2 was initially identified, it was mistakenly thought to have very limited cell and tissue expression, in part because the tissue preparations used to screen for expression were obtained under conditions that did not induce COX-2. Although the expression of COX-2 in bone has not received much attention outside the bone research field, bone may be one of the highest COX-2 expressing tissues in the body. We injected mice transgenic for the COX-2 promoter (−371/+70 bp) fused to a luciferase reporter with LPS and measured COX-2 mRNA and luciferase activity in multiple tissues 4 hours later (Fig. 4; Freeman *et al.*, 1999). LPS-stimulated COX-2 mRNA expression was highest in calvarial bone and brain, and the induction of COX-2 promoter activity was greatest in calvarial bone. Hence, although PGs produced by COX-2 expression in other cell types interfacing with bone, such as macrophages and vascular endothelial cells, may influence bone cell differentiation and function, the converse may also be true—osteoblasts may be an important source of PGs that influence neighboring cells in the bone marrow and in the vascular network.

Fresh serum is a potent stimulator of COX-2 expression and PGE_2 production in cultured osteoblastic MC3T3-E1

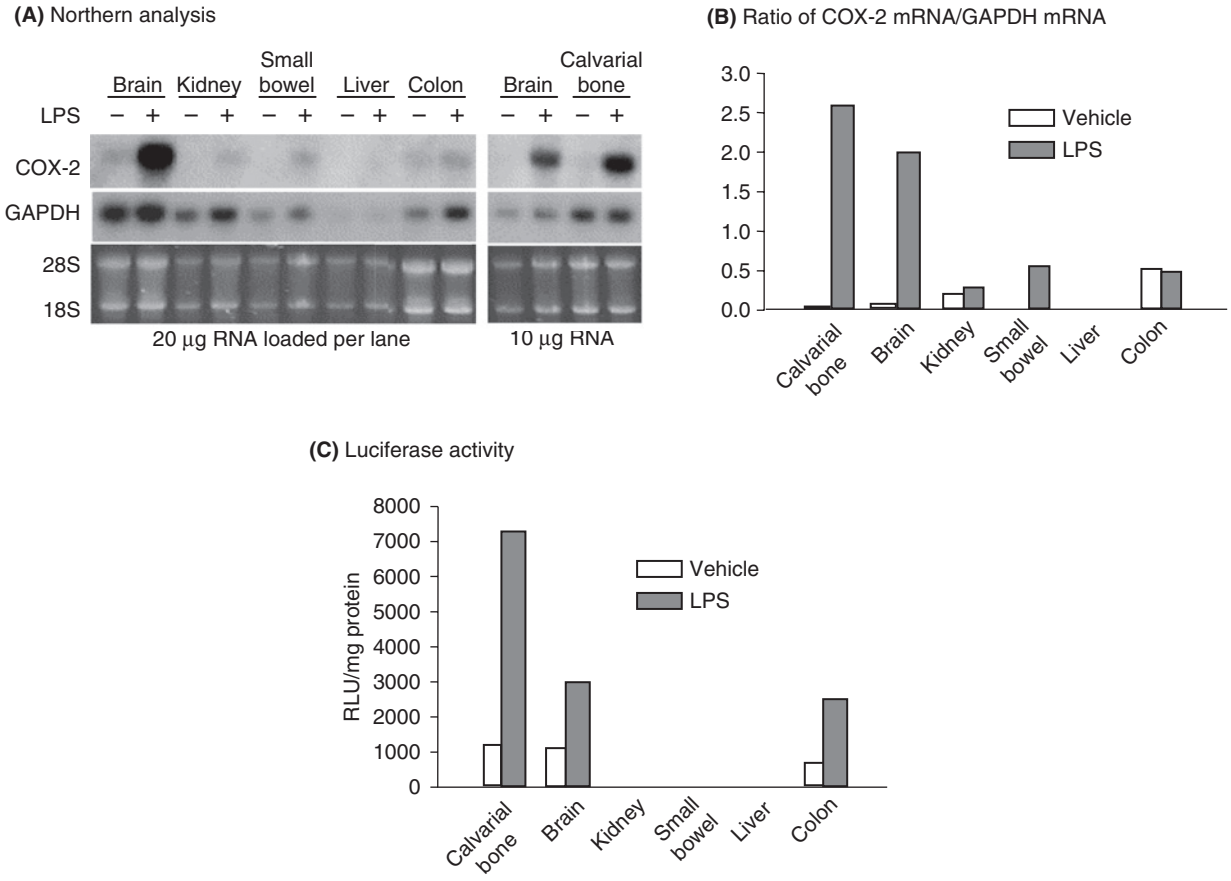

FIGURE 4 Comparison of lipopolysaccharide (LPS) induced COX-2 mRNA and promoter activity *in vivo* (Freeman *et al.*, 1999). Mice transgenic for 371 bp of the COX-2 promoter fused to a luciferase reporter were injected with LPS (IP, 4 mg/mouse) or vehicle and killed 4 hours later. RNA and luciferase measurements were made on the same tissue from a single mouse. (**A**) Northern blot analysis. (**B**) Quantification of Northern analysis. Compared to other tissues, it is more difficult to extract RNA or luciferase from mineralized calvariae. On the other hand, COX-2 mRNA is poorly expressed in some of the other tissues relative to calvariae. Hence, we ran two Northern gels and compared bone to brain, at 10 μg total RNA, and other tissues to brain, at 20 μg total RNA, on separate gels. The housekeeping gene glyceraldehyde 3–phosphate dehydrogenase (GAPDH) and ethidium bromide stained 28S and 18S ribosomal RNA on gels are shown to assess loading. (**C**) Luciferase activity. Each sample was analyzed in triplicate.

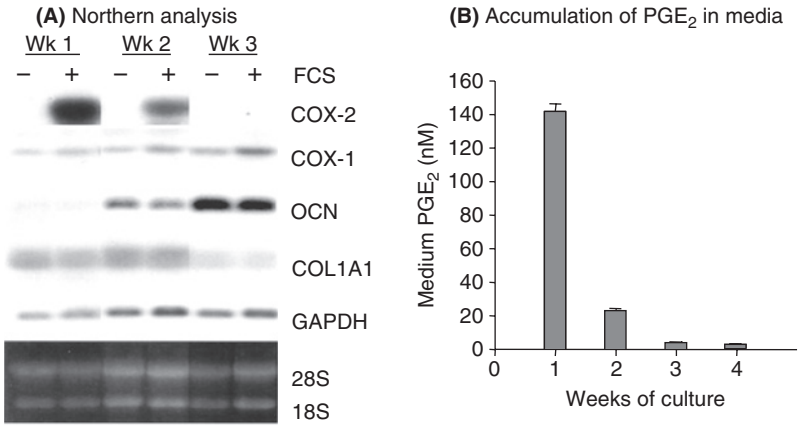

FIGURE 5 Serum-stimulated COX-2 mRNA expression and PGE_2 production in MC3T3–E1 cells (Pilbeam, unpublished data). Cells were cultured for 3 to 4 weeks with replacement of medium containing 10% heat-inactivated fetal calf serum (FCS) every 3 to 4 days. At the beginning of week 2, 50 μg/mL phosphoascorbate was added. At the end of each week of culture, cells were serum deprived for 24 hours and then treated with fresh 10% FCS for 2 hours. (**A**) Northern blot analysis. Levels of mRNA were analyzed for COX-1, COX-2, osteocalcin (OCN), and type 1 collagen (COL1A1) as markers of osteoblastic differentiation. The housekeeping gene GAPDH and ethidium bromide stained 28S and 18S ribosomal RNA on gels are shown to assess loading. (**B**) Medium PGE_2 accumulation after serum stimulation was measured by radioimmunoassay (Xu *et al.*, 2007b). PGE_2 levels in the serum-deprived cultures prior to treatment with FCS were below the detection limit of the assay (<0.1 n*M*).

cells (Pilbeam *et al.*, 1993; Fig. 5). At the end of each week in culture, cells were serum deprived for 24 hours and then treated with fresh fetal calf serum (FCS, 10%) for 2 hours. As cells became more differentiated, the serum induction of COX-2 and PGE_2 production diminished, suggesting that early osteoblastic precursors are more sensitive to this effect of serum. Compared to effects at the end of the first week, serum-stimulated PGE_2 production was reduced 85% after 2 weeks of culture and 97% after 3 weeks. The serum induction of COX-2 can occur when culture media are replaced with media containing fresh serum under routine culture conditions, and the associated PGE_2 production is likely to stimulate the osteoblastic differentiation that occurs under these conditions (see following discussion and Fig. 8).

In some osteoblastic cell cultures (Pilbeam *et al.*, 1994), in contrast to bone organ cultures (Kawaguchi *et al.*, 1994, 1996), little PGE_2 may be produced despite induction of COX-2 expression, unless serum is present or AA is added, suggesting that substrate availability is limiting. Some agonists, such as TGF-β (Pilbeam *et al.*, 1997a), extracellular calcium (Choudhary *et al.*, 2003), and PDGF (Chen *et al.*, 1997), stimulate substantial PGE_2 production in serum-free cultures of osteoblasts, probably secondary to effects on both COX-2 expression and phospholipase activation.

PGE_2 can stimulate its own production by stimulating COX-2 and $cPLA_2$ expression (Kawaguchi *et al.*, 1994; Murakami *et al.*, 1997; Pilbeam *et al.*, 1993, 1994). This autoamplification can also amplify the effects of PGE_2 agonists. For example, $PGF_{2\alpha}$, a poor stimulator of resorption, increases PGE_2 production in organ culture, and PGE_2 then enhances the effects of $PGF_{2\alpha}$ on resorption (Raisz *et al.*, 1990). Other PGs can also induce COX-2. Effects of selective agonists for the EP1-4, IP, TP, FP, and DP receptors were examined in cultured murine calvarial osteoblasts (Sakuma *et al.*, 2004). PGE_2 and the selective agonists for EP2 were the most effective stimulators of COX-2 expression, but agonists for EP4, IP, TP, and DP were also able to increase COX-2 expression or promoter activity. The PG induction of COX-2 in this system generally paralleled the PG stimulation of cAMP production and was mediated predominantly via the PKA pathway. However, in MC3T3-E1 cells, induction of COX-2 expression was greater with $PGF_{2\alpha}$ and PGD_2 than with PGE_2, indicating involvement of a phopholipase C signaling pathway (Pilbeam *et al.*, 1994; Takahashi *et al.*, 1994).

The autoamplification effect may be particularly important in cell and organ cultures, where PGs are not rapidly degraded, and may account for the biphasic or recurrent induction of COX-2 seen in some long-duration cultures. For example, in cultured neonatal calvariae treated with FGF-2, COX-2 mRNA expression peaked at 2 to 4 hours of treatment, decreased to undetectable at 24 hours, but was elevated again at 48 hours (Kawaguchi *et al.*, 1995b). The recurrent elevation of COX-2 could be blocked by inhibiting COX activity with NSAID. The induction of COX-2 secondary to PG production may involve different signaling pathways than the initial induction by the COX-2 agonist and may complicate interpretation if unrecognized. *In vivo*, this autoamplifying mechanism could contribute to prolonging the effects of short periods of impact loading or mechanical strain in skeletal tissue and to prolonging effects of cytokines in inflammatory diseases. The autoamplification effect might be self-limited by homologous desensitization. EP2 and EP4 receptors can be desensitized by PGE_2 (Nishigaki *et al.*, 1996), and PGE_2 pretreatment

can downregulate the PGE_2 induction of COX-2 (Pilbeam *et al.*, 1994).

Inhibition of PG Production

Glucocorticoids (GCs) have been shown in many studies to be potent inhibitors of stimulated PG production, and their anti-inflammatory actions are thought to be due in part to this inhibition. Prior to the identification of COX-2, GCs were thought to work predominantly through interference with release of AA release. Although GCs can inhibit agonist-stimulated release of AA (Sampey *et al.*, 2000), it is now clear that the majority of GC effects on PG production in bone and other tissues are the result of inhibiting COX-2 expression (Kawaguchi *et al.*, 1994; Pilbeam *et al.*, 1993). GCs can also inhibit mPGES-1 (Korotkova *et al.*, 2005). The inhibition of COX-2 occurs by both transcriptional and post-transcriptional mechanisms (DeWitt and Meade, 1993; Lasa *et al.*, 2001; Newton *et al.*, 1998). A number of factors can induce COX-2 via MAPK signaling pathways (Choudhary *et al.*, 2003; Tsatsanis *et al.*, 2006; Wadhwa *et al.*, 2002b), and some of the effects of GCs on COX-2 expression may be mediated via the GC induction of MAPK phosphatase-1 (MKP-1), also called dual specificity phosphatase-1 (DUSP-1), which dephosphorylates and inactivates MAPKs (Abraham *et al.*, 2006). Retinoic acid is also a potent transcriptional inhibitor of COX-2 gene expression and PG production in osteoblasts, inhibiting induction of COX-2 by multiple factors (Pilbeam *et al.*, 1995). The ability of retinoic acid to inhibit COX-2 expression may explain some of its anticancer actions (Eisinger *et al.*, 2006; Kong *et al.*, 2005; Li *et al.*, 2002). It is also interesting to note that retinoic acid, similar to GCs, can induce MKP-1 (Xu *et al.*, 2002). The cytokines IL-4 and IL-13 have also been shown to inhibit COX-2 expression and PG production in bone organ and cell cultures (Kawaguchi *et al.*, 1996; Onoe *et al.*, 1996). Other agents reported to inhibit PG production in bone cells are vitamin K_2 (Hara *et al.*, 1993) and interferon-γ (Peterlik *et al.*, 1985).

Estradiol has been shown to reduce PG production in some culture models. Estradiol decreased PTH-stimulated PG production in cultured murine calvaria (Pilbeam *et al.*, 1989). This effect was not associated with decreased COX-2 mRNA expression (Pilbeam, unpublished data). Medium PGE_2 levels in cultured calvaria dissected from ovariectomized rats were increased relative to levels in calvaria from estrogen replete rats, and this increase was reversed by estradiol administration *in vivo* (Feyen and Raisz, 1987). When marrow supernatants from ovariectomized or sham-operated mice were added to murine calvarial cultures, marrow supernatants from ovariectomized mice stimulated more bone resorption than supernatants from estrogen-replete mice, and this increase was mediated by increased PG production secondary to increased COX-2 expression (Kawaguchi *et al.*, 1995a; Miyaura *et al.*, 1995). The increased COX-2 expression in these cultures was secondary to increased IL-1α activity in the supernatants and was reversed by *in vivo* treatment of the ovariectomized mice with estradiol (Kawaguchi *et al.*, 1995a). Some studies have suggested that endogenous PGs might mediate some of the bone loss due to estrogen deficiency (Gregory *et al.*, 2006). Partial reversal of bone loss in ovariectomized rats by an NSAID has been reported, although the effect was not sustained (Kimmel *et al.*, 1992; Lane *et al.*, 1990). However, it may not have been possible to produce a sustained inhibition of COX-2 activity with the nonselective NSAID at tolerated concentrations. We examined the effects of ovariectomy on COX-2 wild-type (WT) and KO mice in an outbred CD-1 background. Mice underwent ovariectomy or sham operation at 4 months of age and were killed 9 weeks later (Xu *et al.*, 2006a). Following ovariectomy, COX-2 KO mice had a significantly greater decrease (−8.2%) in total body BMD than COX-2 WT mice (−4.5%). Hence, COX-2 deficiency did not prevent the bone loss associated with ovariectomy.

As discussed earlier, NSAIDs inhibit PG production by blocking the cyclooxygenase catalytic site. Because PGs themselves can induce COX-2 expression, NSAIDs can also decrease COX-2 expression by reducing PG-mediated autoamplification. NSAIDs have been widely used to study the role of endogenous PGs. NS-398 was the first selective NSAID to become commercially available for *in vitro* and animal studies and is still widely used. The fact that NS-398 loses its selectivity at high doses is often overlooked. In rodent osteoblastic cells, NS-398 at a concentration of 0.01 μM was selective for inhibition of COX-2 activity; however, at concentrations of 0.1 and 1 μM, NS-398 also inhibited COX-1 activity by 60% and 85%, respectively (Pilbeam *et al.*, 1997b). Hence, there was little selectivity of NS-398 at 1 μM, a commonly used dose. NSAIDs may also have effects independent of inhibiting PG production. As the result of many studies employing COX-2 selective NSAIDs to study effects of PGs on promotion of tumorigenesis, it has become apparent that high doses of these inhibitors can have multiple effects on cell growth and survival in addition to inhibiting COX-2 activity (Grosch *et al.*, 2006; Paik *et al.*, 2000).

Transcriptional Regulation of COX-2

Acute changes in PG production in osteoblasts are primarily the result of regulation of COX-2 expression. Although COX-2 expression is regulated by post-transcriptional mechanisms (Cok and Morrison, 2001), it is the transcriptional regulation that has been most studied. In osteoblasts, COX-2 frequently behaves like an immediate early gene in response to agonists, with the induction of mRNA expression being rapid, transient, and independent of new protein

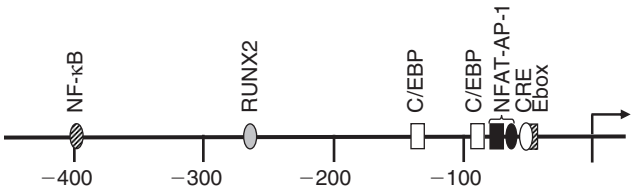

FIGURE 6 *Cis*-acting sites in the murine COX-2 promoter. Only sites thought to be important for regulating COX-2 transcription in osteoblastic cells and in osteoclast precursors (RAW264.7 murine macrophages) are shown. See text for discussion.

production. Multiple *cis*-acting promoter elements and *trans*-acting factors have been demonstrated to be involved in COX-2 induction, depending on cell type (Kang *et al.*, 2007). In murine MC3T3-E1 osteoblastic cells, 371 bp of the 5′-flanking COX-2 gene proximal to the transcription start site is adequate to mediate transcriptional induction by many agonists (Harrison *et al.*, 2000; Kawaguchi *et al.*, 1995b; Okada *et al.*, 2000c; Pilbeam *et al.*, 1997a; Tetradis *et al.*, 1997; Wadleigh and Herschman, 1999). This length of promoter does not include known NF-κB binding sites. *Cis*-acting sequences in this region shown to mediate effects on COX-2 expression in osteoblastic cells include a cAMP response element (CRE) at −57/−52 bp (ACGTCA) and an activator protein-1 (AP-1) binding site at −69/−63 bp (AGAGTCA) (Fig. 6). Both of these sites are involved in the phorbol ester (PMA) and serum induction of COX-2 promoter activity (Okada *et al.*, 2000c). The AP-1 site can inducibly bind Fos/Jun, while the CRE site constitutively binds CREB and ATF proteins. One study reported mutation of the CRE site abolished COX-2 promoter responses to serum, growth factors and cytokines in MC3T3-E1 cells (Wadleigh and Herschman, 1999). We have also seen involvement of the CRE site in COX-2 promoter responses to FGF-2, TNFα and PTH in MC3T3-E1 cells (Chikazu *et al.*, 2001; Okada *et al.*, 1998, 2000c; Tomita *et al.*, 1998) but have not found mutation of the CRE alone to abolish induction of the COX-2 promoter response by any agonist.

One or more CCAAT enhancer binding protein (C/EBP) sites located between −150 and −40 bp have been shown to mediate the IL-1 induction of COX-2 promoter activity in MC3T3-E1 cells (Harrison *et al.*, 2000; Wadleigh and Herschman, 1999; Yamamoto *et al.*, 1995). Putative C/EBP sites have been identified at −93/−85 bp (TGGGAAAG) and at −138/−130 bp (TTGCGCAAC). Joint mutation of these two sites has been reported to reduce COX-2 promoter activity in response to multiple factors, including FGF-2, PDGF, and a combination of IL-1 and TNFα (Wadleigh and Herschman, 1999). However, nuclear extracts from control and IL-1 treated MC3T3-E1 cells bound specifically only to an oligonucleotide spanning the −138/−130 bp C/EBP site (Harrison *et al.*, 2000). Another study found both the C/EBP site at −138/−130 bp and an NF-κB binding site at −401/−393 bp were required for maximal response to TNFα in MC3T3-E1 cells (Yamamoto *et al.*, 1995). However, mutation of this NF-κB site was found to have no affect on COX-2 responses to multiple agents in another study (Wadleigh and Herschman, 1999). Mutations in the C/EBP (−138/−130 bp) site, AP-1 site, and CRE also reduced the fluid shear stress stimulation of COX-2 promoter activity in MC3T3-E1 cells (Ogasawara *et al.*, 2001).

After publication of our initial study on the AP-1 site, we noticed that this AP-1 site was actually part of a nuclear factor of activated T-cells (NFAT)/AP-1 composite binding site, GGA(N)9TCA, at −77/−63 bp. We found that this composite site mediated in large part the PTH induction of COX-2 promoter activity in MC3T3-E1 cells (Chikazu *et al.*, 2001). Transcription factors of the NFAT family, originally identified as important regulators of gene expression in T cells, have now been shown to be expressed in multiple tissues (Macian, 2005). NFAT transcription factors are known to be critical for osteoclastogenesis (Hirotani *et al.*, 2004; Ikeda *et al.*, 2004; Matsuo *et al.*, 2004), and a role for them in bone formation has also been demonstrated (Koga *et al.*, 2005; Stern, 2006; Winslow *et al.*, 2006). NFAT proteins and the AP-1 heterodimer, Fos/Jun, can cooperatively bind the composite DNA site and activate or repress gene expression (Macian *et al.*, 2001). Whether or not signaling pathways lead to cooperative interactions of AP-1 and NFAT may determine distinct biological programs of gene expression (Macian *et al.*, 2000). More distantly separated GGA and TCA motifs have also been shown to support independent binding of NFAT and AP-1. In addition to the composite site at −77/−63 bp, there are GGA motifs at −111/−109 bp and at −90/−88 bp in the murine COX-2 promoter, but we have not found mutations of these more distant sites to affect COX-2 promoter activity (Pilbeam, unpublished data).

Runx2 (Cbfa1) is an essential transcription factor for osteoblast differentiation and can regulate the expression of many genes associated with osteoblastic differentiation. We identified a Runx2 consensus sequence (AACCACA) at −267/−261 bp in the murine COX-2 promoter and showed this site to mediate the BMP-2 induction of COX-2 (Chikazu *et al.*, 2005). The Runx2 site is the only *cis*-acting site lying between −371 and −150 bp, other than a regulatory sequence for TGFβ (Pilbeam *et al.*, 1997a), that we have found to mediate COX-2 promoter activity in MC3T3-E1 cells. Transcriptional activity of Runx2 is also necessary for maximal fluid shear stress induction of COX-2 promoter activity in MC3T3-E1 cells (Mehrotra *et al.*, 2006a). Multiple signaling pathways have been shown to regulate the activity of Runx2, and Runx2 can interact with many other transcription factors (Barakat and Lieu, 2003; Franceschi *et al.*, 2003; Gutierrez *et al.*, 2002; Porte *et al.*, 1999; Xiao *et al.*, 2000). Thus, transcriptional

activity of Runx2 may be important for enhancing or integrating the actions of multiple other transacting factors on COX-2 induction.

Because RAW264.7 murine macrophages can be induced with receptor activator of NF-κB ligand (RANKL) to differentiate into osteoclasts, the regulation of COX-2 in these cells may reflect COX-2 regulation in osteoclast precursors. LPS induction of COX-2 in RAW264.7 cells is frequently studied as a model of inflammation. Mutation of the CRE or combined mutation of the C/EBP sites at −93/−85 bp and −138/−130 bp significantly reduced the LPS induction of COX-2 promoter activity, whereas mutation of the NF-κB binding sites had no effect on induction (Wadleigh *et al.*, 2000). A recent study identified a second CRE (CRE-2) upstream of the NF-κB site as important in the LPS induction of COX-2 promoter activity in these cells, along with the original CRE, the AP-1 site, and the C/EBP site (−138/−130 bp; Kang *et al.*, 2006). In that study, the E-box, which overlaps the CRE site (see Fig. 6), was found to be a transcriptional repressor. Several studies have suggested that the Ets family of transcription factors, including PU.1 (Joo *et al.*, 2004) and ESE-1 (Grall *et al.*, 2005), play a role in the regulation of COX-2 in RAW264.7 cells in response to LPS. RANKL has also been shown to induce COX-2 promoter activity in RAW264.7 cells (Han *et al.*, 2005). Although this induction was said to be abolished by deleting an NF-κB binding site, the NF-κB binding site was included in a large region from −518 to −362 bp that was deleted. Specific mutation of the NF-κB binding site will be necessary to confirm its involvement.

Transcriptional regulation of COX-2 by most factors appears to involve multiple signaling pathways and multiple cis-acting sites (Kang *et al.*, 2007; Tsatsanis *et al.*, 2006). Recent studies suggest that p300 may integrate these different pathways (Deng *et al.*, 2004; Kang *et al.*, 2006). p300 is a coactivator of transcription for multiple nuclear proteins and a histone acetyl transferase (HAT) that can generate a more accessible chromatin structure for transcription factors (Wolffe and Pruss, 1996). p300 is also capable of acetylating nonhistone proteins, such as Runx2 (Jeon *et al.*, 2006).

PGs AND BONE RESORPTION

Early work on the effects of PGs on bone resorption in organ culture showed that PGs of the E series are the most potent activators, with an effective concentration range of 1 n*M* to 10 μ*M* (Klein and Raisz, 1970; Raisz and Martin, 1983). $PGF_{2\alpha}$ is less effective than PGE_2, stimulating resorption at concentrations of 0.1 μ*M* and above, and the ability of $PGF_{2\alpha}$ to stimulate resorption is partly dependent upon its induction of PGE_2 (Raisz *et al.*, 1990). PGI_2 can also stimulate resorption, while PGD_2 is ineffective. Many factors that stimulate PG production also stimulate resorption in organ culture, and the resorption stimulated by such factors can be mediated in part by PG production (Akatsu *et al.*, 1991; Tashjian *et al.*, 1982, 1987). However, the dependence of resorption in organ culture on stimulated PG production is quite variable, and some potent stimulators of PGE_2, such as PTH, do not exhibit PG-dependent resorption in these systems (Igarashi *et al.*, 2002; Pilbeam *et al.*, 1989; Stern *et al.*, 1985).

PGE_1 and PGE_2, but not $PGF_{2\alpha}$, stimulate osteoclast formation in marrow cultures (Collins and Chambers, 1991). In contrast to organ culture resorption studies, studies in marrow culture consistently demonstrate a dependence of osteoclast formation on agonist-stimulated PG production. Multiple agonists can stimulate PG-dependent osteoclast formation in marrow cultures, including IL-1 (Akatsu *et al.*, 1991; Lader and Flanagan, 1998; Sato *et al.*, 1996); TNF-α (Lader and Flanagan, 1998); PTH (Inoue *et al.*, 1995; Sato *et al.*, 1997); $1,25(OH)_2D_3$ (Collins and Chambers, 1992); IL-11 (Girasole *et al.*, 1994; Morinaga *et al.*, 1998); IL-6 (Tai *et al.*, 1997); IL-17 (Kotake *et al.*, 1999); phorbol ester (Amano *et al.*, 1994); and FGF-2 (Hurley *et al.*, 1998). TGF-β can enhance osteoclastogenesis at low concentrations by a PG-dependent mechanism but inhibit osteoclastogenesis at higher concentrations (Shinar and Rodan, 1990).

Induction of COX-2 is likely to be responsible for the PG enhancement of stimulated osteoclastogenesis. In marrow cultures from COX-2 KO mice stimulated by $1,25(OH)_2D_3$ (Fig. 7) or PTH, PGE_2 production is markedly decreased and osteoclast formation is reduced by 60% to 70% or more compared to WT cultures (Okada *et al.*, 2000a). Marrow cultures from mice with disruption of only one COX-2 allele had levels of osteoclast formation and PGE_2 production intermediate to those in COX-2 WT and KO cultures. Treatment of WT cultures with a COX-2 inhibitor mimicked the results observed in cultures from COX-2 KO mice. There was no effect of disruption of both COX-1 alleles on stimulated PGE_2 production or osteoclastogenesis in these cultures. We found similar results for osteoclastogenesis stimulated by IL-1 (Pilbeam, unpublished data) and FGF-2 (see Fig. 7), suggesting that PGs produced by COX-2 are necessary for maximal *in vitro* osteoclastogenesis in response to multiple agents.

PGE_2 may stimulate osteoclastogenesis in several ways. PGE_2 can act on osteoclast supporting cells (osteoblasts or their precursors in the mesenchymal lineage) to increase expression of RANKL, which is essential for osteoclast differentiation (Li *et al.*, 2000; Suzawa *et al.*, 2000; Tsukii *et al.*, 1998). PGE_2 may also decrease expression of osteoprotegerin (OPG), the decoy receptor for RANKL, in osteoblasts (Suda *et al.*, 2004). PGE_2 may also act on cells of the hematopoietic lineage to increase differentiation of osteoclastic precursors. In cultured spleen cells, PGE_2 enhanced the effects of RANKL and M-CSF on osteoclast

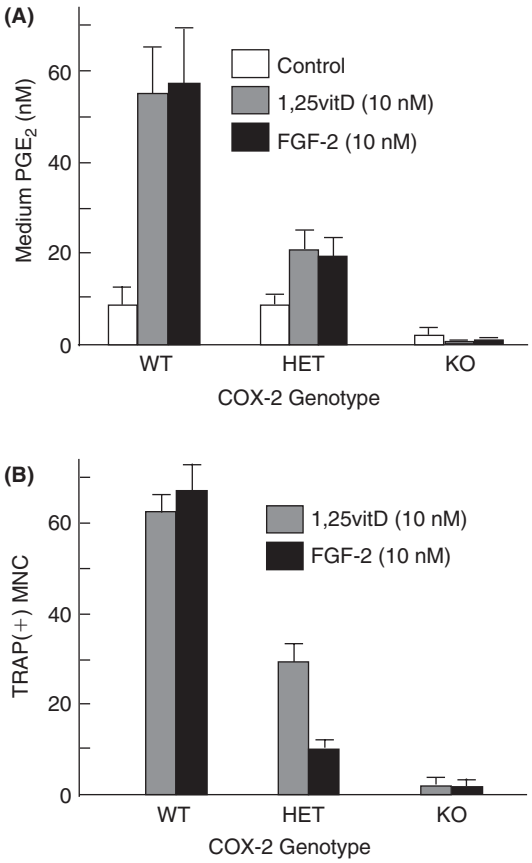

FIGURE 7 PGE_2 production and osteoclast formation in marrow cultures: comparison of COX-2 wild type (WT), heterozygous (HET), and knockout (KO) mice (Okada, Y., Tomita, M., Hurley, M., Raisz, L., and Pilbeam, C., unpublished data). Marrow was flushed from tibiae and femurs and cultured in α-MEM with 10% FCS. Cultures were treated for 7 days with vehicle (control), 1,25 $(OH)_2$ vitamin D_3 (1,25vitD), or FGF-2. (**A**) Medium PGE_2 accumulation measured by radioimmunoassay (Xu *et al.*, 2007b). (**B**) Osteoclasts per well. Cultures were stained for tartrate resistant acid phosphatase (TRAP) and TRAP positive cells with more than three nuclei were counted as osteoclasts. No osteoclasts were formed in control cultures. Bars are means ± SEM for three wells.

formation (Li *et al.*, 2000; Okada *et al.*, 2000a; Wani *et al.*, 1999). Osteoclast formation was reduced 50% in spleen cells from COX-2 KO mice compared to spleen cells from COX-2 WT mice (Okada *et al.*, 2000a). This reduction was associated with increased expression of granulocyte-macrophage colony-stimulating factor (GM-CSF), an inhibitor of osteoclast formation in these cultures, and could be reversed by addition to the cultures of blocking antibody to GM-CSF. GM-CSF may act by diverting progenitor cells into the macrophage rather than osteoclast pathway. PGE_2 also enhanced osteoclastogenesis in the presence of RANKL in RAW264.7 cells (Kaneko *et al.*, 2007; Kobayashi *et al.*, 2005a). This effect was attributed to cAMP-dependent PKA phosphorylation of a serine residue in TGFβ-activated kinase 1 (TAK1), a MAPK kinase that can enhance downstream signaling in response to RANKL and other cytokines (Kobayashi *et al.*, 2005a).

Studies using cells and tissues from EP receptor KO animals and selective EP receptor agonists have tried to define the specific receptors involved in the PGE_2 stimulation of resorption. Neonatal murine calvarial cultures express all PGE receptor subtypes, but PGE_2-stimulated resorption appears to be largely mediated via the EP4 receptor, with only a minor contribution from EP2 (Suzawa *et al.*, 2000). A marked decrease in resorptive response to PGE_2 was found in cultured calvariae from EP4 KO animals, and there was impaired response to PGE_2 even in calvariae from mice with only one EP4 allele disrupted (Miyaura *et al.*, 2000; Zhan *et al.*, 2005). In fetal rat long-bone cultures treated with agonists selective for EP2 and EP4, only the EP4 agonist was effective in stimulating resorption (Raisz and Woodiel, 2003). However, aged EP4 KO mice are reported to have significantly increased osteoclast numbers on trabecular surfaces and increased eroded endocortical surface compared to WT mice (Li *et al.*, 2005), and administration of an EP4 selective agonist to rats subjected to protocols causing bone loss, such as immobilization, suggested that the EP4 agonist increased bone formation but not resorption (Yoshida *et al.* 2002).

Both EP4 and EP2 receptors are involved in the PGE_2 effects on the osteoclastic support cells. A selective antagonist for EP4 partially inhibited osteoclastogenesis in murine marrow cultures, not only in response to PGE_2, but also in response to $1,25(OH)_2D_3$ and PTH (Tomita *et al.*, 2002). In bone marrow cultures and cocultures of osteoblasts and spleen cells, osteoclast formation was impaired when cells from either EP2 or EP4 receptor KO animals were used (Li *et al.*, 2000; Sakuma *et al.*, 2000). These studies confirmed earlier results using selective EP agonists and antagonists (Ono *et al.*, 1998). The EP2 receptor may also be involved in the effects of PGE_2 on hematopoietic precursors (Ono *et al.*, 2005). Spleen cells from EP2 KO animals showed an impaired osteoclastogenic response when treated with M-CSF, RANKL, and PGE_2 (Li *et al.*, 2000).

Some studies have found PGE_2 to have inhibitory effects on osteoclast formation from hematopoietic precursors. In murine spleen cell cultures, studied over an extensive time course, effects of PGE_2 were biphasic. PGE_2 had an initial inhibitory effect on osteoclast formation, possibly mediated by both EP2 and EP3 receptors, and a later stimulatory effect, mediated by the EP2 receptor, possibly acting on T-cells (Ono *et al.*, 2005). Although PGE_2 stimulated osteoclast formation in human marrow cultures (Lader and Flanagan, 1998), PGE_2 inhibited osteoclast formation in human CD14+ cells from peripheral blood mononuclear cells (PBMCs) in the presence of RANKL and M-CSF (Take *et al.*, 2005).

PGE_2 added to isolated osteoclasts actively resorbing bone *in vitro* transiently inhibits their activity (Fuller and Chambers, 1989). A similar transient inhibition of bone

resorption and lysosomal enzyme release in mouse calvarial bone cultures by PGE_2 has also been observed (Lerner *et al.* 1987). Moreover, the transient decrease in serum calcium that occurs after systemic injection of IL-1 in mice was blocked by indomethacin and, thus, appears to be PG mediated (Boyce *et al.* 1989b). The inhibitory effect of PGE_2 on osteoclast activity or motility may involve both the EP4 and EP2 receptors (Mano *et al.*, 2000b; Okamoto *et al.*, 2004). EP2 and EP4 receptor expression is downregulated during differentiation in bone marrow macrophage cultures, and this may be one way osteoclasts escape the inhibitory effects of PGE_2 (Kobayashi *et al.*, 2005b). This inhibitory effect may be due to a direct activation of adenylate cyclase in osteoclasts, thereby mimicking the effect of calcitonin to inhibit osteoclast function. The physiologic relevance of this transient inhibition is unknown.

Little is known about the role of endogenous PGs in bone resorption *in vivo*. If PGs are stimulators of new osteoclast differentiation rather than osteoclast activity, a role for PGs in bone resorption might be most evident when the ability to generate new osteoclasts from osteoclastic precursors becomes rate limiting.

PGs AND BONE FORMATION

Studies in cell and organ culture indicate that PGs can have both stimulatory and inhibitory effects on bone formation. Anabolic effects can be seen in fetal rat calvarial organ cultures, in which PGE_2 stimulates both cell replication and differentiation (Woodiel *et al.*, 1996). At high concentrations, however, PGs can inhibit collagen synthesis in cell and organ culture (Fall *et al.*, 1994). This inhibitory effect appears to occur largely via transcriptional inhibition of collagen and to be mediated by the FP receptor rather than an EP receptor.

Systemic injection of PGE_2 in rats can increase both periosteal and endosteal bone formation in the rat and produce substantial increases in bone mass, similar to the effects of PTH (Jee and Ma, 1997; Lin *et al.*, 1994; Suponitzky and Weinreb, 1998). Systemic administration of PGE_2 or PGE_1 in humans (Faye-Petersen *et al.*, 1996; Ueda *et al.*, 1980) and dogs (Norrdin and Shih, 1988) has also been shown to increase cortical and cancellous bone mass. Although local injection of PGE_2 has been shown to have local anabolic effects in mice (Yoshida *et al.*, 2002), systemic injection of PGE_2 in mice, following the protocols established for rats, has generally been associated with a greater increase in resorption than formation, resulting in bone loss (Raisz, unpublished data). However, we recently found 3 mg/kg of PGE_2 injected twice a week for 4 weeks in mice increased bone formation rate and did not cause bone loss (Gao *et al.*, 2007b).

The most consistent anabolic effects of PGE_2 are seen in cultures designed to study osteoblastic differentiation. PGE_2 stimulates osteoblastic differentiation in marrow stromal cell and primary calvarial cell cultures (Flanagan and Chambers, 1992; Kaneki *et al.*, 1999; Nagata *et al.*, 1994; Scutt and Bertram, 1995; Xu *et al.*, 2007b). In addition, PGE_2 given to rats *in vivo* stimulates osteoblastic differentiation in *ex vivo* cultured bone marrow (Keila *et al.*, 1994; Weinreb *et al.*, 1997). In agreement with these studies, osteoblastic differentiation is decreased in marrow stromal cell cultures from mice deficient in COX-2 (Choudhary *et al.*, 2007; Okada *et al.*, 2000b; Zhang *et al.*, 2002b). An example of marrow stromal cells cultured from COX-2 WT and KO mice is shown in Figure 8. Medium PGE_2 production peaked between days 3 and 7 of culture in WT cultures and was generally undetectable in KO cultures despite constitutive expression of COX-1. Osteocalcin mRNA expression and Von Kossa staining for mineralization (see Fig. 8), as well as the area of staining for alkaline phosphatase and the area covered by all cells (Xu *et al.*, 2007b), were decreased in COX-2 KO cultures compared to WT cultures. Although decreased osteoblastic differentiation was also seen in primary calvarial cells from COX-2 KO mice, osteoblastic cell proliferation was increased relative to WT cultures (Xu *et al.*, 2007b).

Both EP2 and EP4 receptors have been implicated in the anabolic effects of PGE_2 *in vitro* (Alander and Raisz, 2006; Li *et al.*, 2007; Raisz and Woodiel, 2003; Woodiel *et al.*, 1996). *In vivo* studies of the skeletal phenotype of EP4 KO mice have been limited by the high rate of neonatal death (>95%) occurring within 72 hours of birth as a result of failure of the ductus arteriosus to close (Segi *et al.*, 1998). In an attempt to improve their survival, EP4 receptor deficient mice have been bred as mixtures of multiple genetic backgrounds. Aged EP4 receptor KO mice, studied in a highly mixed background, were shown to have reduced bone mass and impaired fracture healing compared to WT mice (Li *et al.*, 2005). Bone mechanical properties were reduced in both EP2 and EP4 KO mice (Akhter *et al.*, 2001, 2006).

PGE_2 can stimulate both the bone remodeling and angiogenesis needed for fracture healing. Early studies showed that exogenously applied PGE_2 stimulated callus formation in rabbits (Keller *et al.*, 1993). In addition, nonselective NSAIDs inhibited repair of spinal fusions (Dimar *et al.*, 1996) in rats and the fixation of implants in femora of rabbits (Jacobsson *et al.*, 1994). Following the development of selective COX-2 NSAIDs, multiple studies in animals showed that NSAIDs impaired fracture healing (Altman *et al.*, 1995; Bergenstock *et al.*, 2005; Brown *et al.*, 2004; Einhorn, 2003; Endo *et al.*, 2005; Murnaghan *et al.*, 2006; Simon *et al.*, 2002; Simon and O'Connor, 2007). The impairment of healing may be greater with selective COX-2 inhibitors, compared to nonselective NSAIDs, and is probably reversible after discontinuation of brief NSAID treatment (Gerstenfeld *et al.*, 2007). Fracture healing was impaired in COX-2 KO mice (Zhang *et al.*, 2002b), and a selective COX-2 inhibitor delayed

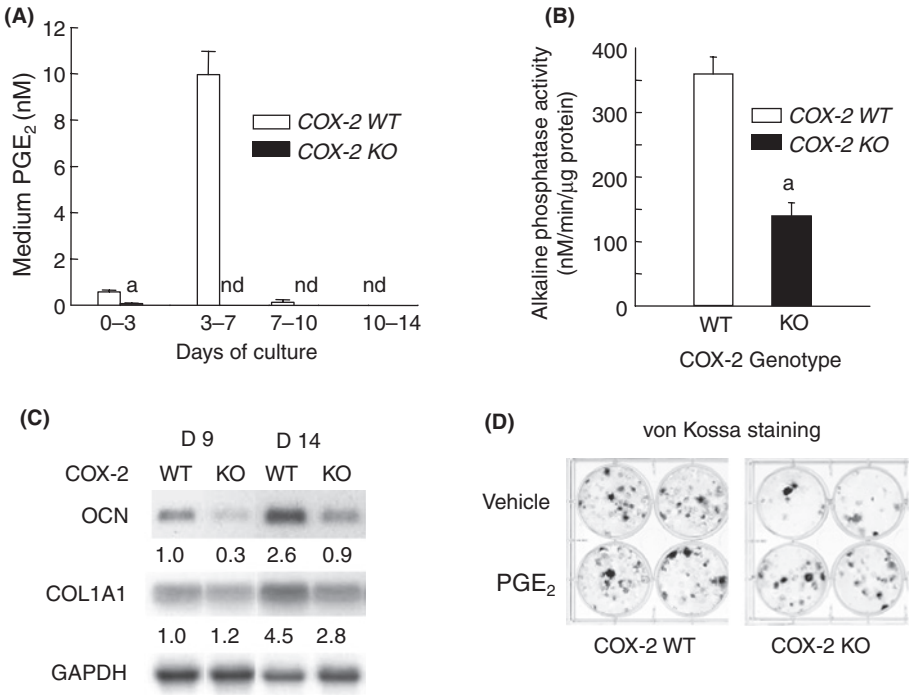

FIGURE 8 PGE_2 production and osteoblastic differentiation in marrow stromal cell (MSC) cultures from mice deficient in COX-2 (Okada, Y., Tomita, M., and Pilbeam, C., unpublished data). Marrow was flushed from tibiae and femurs, cultured in α-MEM with 10% FCS and 50 μg/mL phosphoascorbate. Ten millimolar β-glycerophosphate was added for the last 2 weeks of culture. (**A**) Medium PGE_2 accumulation measured by radioimmunoassay (Xu *et al.*, 2007b). nd, not detectable (<0.1 n*M*). (**B**) Measurement of alkaline phosphatase (ALP) activity normalized to total protein in cells cultured for 14 days. Bars are the means ± SEM of three wells of cells. [a]Significant difference compared to WT, $P < 0.01$. (**C**) Northern analysis for type I collagen (COL1A1) and osteocalcin (OCN) mRNA. Ratios of mRNA levels to the housekeeping gene GAPDH are shown below the bands. (**D**) Von Kossa staining of mineralized nodules in cells cultured for 21 days with vehicle or PGE_2 (1 μ*M*). Means and SEM for stained areas were calculated from three wells. The mineralized areas in KO MSC were significantly less than in WT MSC ($P < 0.01$). There was also a significant effect of PGE_2 ($P < 0.01$) in the KO cultures.

allograft healing in a mouse model, whereas local delivery of PGE_2 enhanced bone formation at the cortical bone graft junction (O'Keefe *et al.*, 2006). On the positive side, perioperative treatment with aspirin or other NSAIDs may prevent the excessive bone formation response resulting in heterotropic ossification, a complication of hip arthroplasty that can adversely affect the outcome (Kienapfel *et al.*, 1999; Neal *et al.*, 2000; Nilsson and Persson, 1999).

Systemic PGE_2 is an unacceptable therapeutic option for enhancing fracture healing because of its side effects, such as diarrhea and hypotension. It is possible that selective EP receptor agonists could have the required anabolic effects without these side effects. Local injection of a nonprostanoid EP2 receptor agonist into the bone marrow or incorporated into a polymer matrix and then injected into the periosteum of rats increased bone formation, bone mass, bone strength, and fracture healing in rats (Li *et al.*, 2003). Bone healing was also shown to be improved by this EP2 agonist when applied locally to canine long-bone segmental and fracture model defects (Paralkar *et al.*, 2003). Systemic infusion or subcutaneous injection of an EP4 receptor agonist was able to restore bone mass in immobilized and ovariectomized rats (Yoshida *et al.*, 2002). These authors also showed that local infusion of PGE_2 onto the periosteal surfaces of rat femurs caused new bone formation in WT mice but not in EP4 receptor KO mice. Subcutaneous injection of a nonprostanoid EP4 receptor agonist restored bone mass and strength in aged ovariectomized rats (Ke *et al.*, 2006), and subcutaneous injection of an EP4 receptor agonist was shown to increase cortical bone healing in a rat drill hole model (Tanaka *et al.*, 2004). Thus, local application of an EP2 receptor agonist and local and systemic application of EP4 agonists have been shown to have anabolic effects *in vivo* and to enhance fracture healing. It is not yet clear if these selective agonists will have limiting side effects. Receptor pathways for the anabolic effects have not been fully elucidated, and the multiple signaling pathways identified for effects of PGs in tumor progression, discussed earlier, are likely to play a role in the anabolic effects in bone.

COX-2 KNOCKOUT MICE

Studies of mice in which either the gene for COX-1 or COX-2 is disrupted have shown that COX-1 and COX-2

have some overlapping functions, but that deficiency of COX-2 has more profound effects than deficiency of COX-1 (Dinchuk *et al.*, 1995; Langenbach *et al.*, 1995, 1999a; Morham *et al.*, 1995). Because few COX-2 KO mice could be generated when mice were backcrossed into the C57Bl/6 background (Scott Morham, personal communication), most early studies were done in a mixed C57Bl/6, 129 background. In this background, COX-1-deficient mice survive normally, whereas COX-2-deficient mice have increased mortality. One study reported that 35% of COX-2 KO mice died with a patent ductus arteriosus within 48 hours of birth (Loftin *et al.*, 2001). Other studies did not find a high incidence of neonatal death among COX-2 KO mice but found shortened life span secondary to renal dysplasia (Morham *et al.*, 1995). Renal development in COX-2 KO mice in the C57Bl/6, 129 background appeared normal until postnatal day 10, after which there was progressive renal architectural disruption and functional deterioration, with about 20% of COX-2 KO mice dying between 7 and 23 weeks of age from renal failure (Norwood *et al.*, 2000). Also, in this background, COX-2-deficient females are infertile, with multiple failures in female reproductive processes, including ovulation, fertilization, and implantation (Lim *et al.*, 1997).

We also found that COX-2 KO mice in the C57Bl/6, 129 background died 4 times faster after weaning than WT mice, with 40% dying between 2 and 10 months of age, whereas mice heterozygous for COX-2 gene disruption had normal mortality (Xu *et al.*, 2005b). Several 4-month-old KO mice with renal dysfunction had low serum calcium, high serum phosphate, and PTH levels greater than 2000 ng/dL, consistent with secondary hyperparathyroidism (HPTH). In COX-2 KO mice surviving to 10 months of age without evident renal dysfunction, PTH was still significantly increased compared to WT mice (114% in females, 150% in males). In addition, both male and female KO mice had increased $1,25(OH)_2D_3$ levels (180%), along with slightly elevated serum calcium, compared to WT mice, suggesting that older, apparently healthy, COX-2 KO mice might have primary HPTH. Skeletal analyses showed decreased lumbar BMD by DXA in 4-month-old KO females and decreased femur BMD in 10-month-old KO males, as well as decreased cortical width by μCT in 4-month-old KO males and 10-month-old KO females. Histomorphometric analyses of the distal femur showed increased mineral apposition rate and bone formation rate in 10-month-old KO males, whereas there was increased percent osteoclast surface in 10-month-old KO females. Interestingly, there was little difference in trabecular bone between KO and WT mice, by either μCT or histology, except for increased trabecular bone volume per total volume (BV/TV) in 10-month-old KO males. The overall picture for the 10-month-old KO male mice—increased PTH and $1,25(OH)_2D_3$ levels, decreased cortical but not trabecular bone, and increased bone formation rate—was consistent with effects expected for HPTH. We concluded that direct effects of COX-2 deficiency on bone might be obscured by effects of secondary HPTH in KO mice with renal dysfunction or effects of primary HPTH in healthy KO mice.

Another study of 4.5-month-old female COX-2 KO mice in a C57Bl/6, 129 background also reported reduced femoral BMD by DXA, reduced cortical thickness, but increased distal femoral BV/TV in KO compared to WT mice (Alam *et al.*, 2005). In this study, only 60% of KO mice survived to weaning and 28% died after weaning before they could be studied. In contrast, another study of 4-month-old mice in a 129 background found that only COX-2 KO males, and not KO females, had decreased bone volume fraction in the distal femur and decreased femoral BMD, both measured by μCT, compared to WT mice (Robertson *et al.*, 2006). The COX-2 KO mice in this study were said to have a lower survival rate than the KO mice in our study.

It is possible that the absence of type GIIA secretory PLA_2 in mice with C57Bl/6 or 129 genetic backgrounds might result in a more severe phenotype in the absence of COX-2 (Kennedy *et al.*, 1995). For example, COX-2 KO females in an outbred CD-1 background are fertile (Wang *et al.*, 2004b), and COX-2 KO mice in a C57Bl/6, DBA background have less severe renal pathology (Laulederkind *et al.*, 2002). A study of 3-month-old females in a C57Bl/6, DBA background showed KO mice to have thinner and more porous cortical bones than WT mice (Chen *et al.*, 2003). We studied a large group (30–40 per genotype) of 5-month-old male COX-2 KO and WT mice in an outbred CD-1 background and found that KO mice had no increased mortality after weaning compared to WT mice and no significant renal dysfunction (Xu *et al.*, 2005a). However, COX-2 KO mice still had increased serum PTH compared to WT mice (mean ± SEM of 66 ± 13 versus 27 ± 3 ng/dL, $p < 0.01$), but no difference in serum calcium, phosphorus, or $1,25(OH)_2D_3$. KO mice had small but significant decreases in femoral BMD (−5%) by DXA and in cortical area (−9%) by μCT, with increased cortical porosity (15%), compared to WT mice. In contrast to our earlier study, COX-2 KO mice had decreased distal femoral BV/TV (−20%) by histology compared to WT. A study of 3-month-old female mice in a mostly DBA background also reported no difference in survival or serum creatinine of COX-2 KO mice compared to WT mice but found increased PTH and serum calcium levels in KO mice compared to WT (Myers *et al.*, 2006). KO mice also had lower femoral BMD than WT mice.

Hence, apparently healthy COX-2 KO mice appear to have HPTH in several genetic backgrounds, although it is not clear whether the HPTH is primary or secondary. Most studies have also found COX-2 KO mice to have reduced BMD compared to WT mice, although there may be some protective effect of female gender in this regard. In addition, studies have consistently found bones from COX-2

KO mice to have inferior mechanical properties compared to WT mice (Alam *et al.*, 2005; Chen *et al.*, 2003; Myers *et al.*, 2006). *In vitro* studies would suggest that absence of COX-2 should reduce both bone resorption and formation. However, studies have not found decreased bone turnover in the COX-2 KO mice (Xu *et al.*, 2005b). Because PGE_2 and PTH can both stimulate osteoblast and osteoclast differentiation, the systemic effects of HPTH may compensate for the effects of COX-2 deficiency. Thus, it is not yet possible to make conclusive statements about the direct effects of COX-2 deficiency on bone *in vivo*.

Given that PTH induces COX-2 and that PGE_2 can have anabolic effects, we expected that COX-2 deficiency might impair the anabolic response to PTH. However, we found that the anabolic effect of intermittent PTH was greater in COX-2 KO mice than in WT mice (Xu *et al.*, 2007a). In addition, whereas PTH treatment of marrow stromal or primary osteoblast cultures *in vitro* is generally not anabolic, and often catabolic, PTH treatment of cultures from COX-2 KO mice is anabolic (Huang *et al.*, 2007). Because both PGE_2 and PTH stimulate cAMP signaling, it is possible that endogenous PGs might result in cross-desensitization of PTH-stimulated responses, or perhaps PGs can inhibit some anabolic responses to PTH.

The role of COX-1 in bone is still unclear. We have not seen effects of COX-1 deficiency on osteoblasts or osteoclasts in culture (Okada *et al.*, 2000a; Xu *et al.*, 2007b). One study reported a beneficial effect of COX-1 deficiency on bone parameters *in vivo* (Myers *et al.*, 2006). Several studies, which compared relative COX-1 mRNA expression in COX-2 WT and KO mice, have suggested that COX-1 may compensate for COX-2 deficiency in C57Bl/6, 129 mice (Alam *et al.*, 2005; Zhang *et al.*, 2002a) and that COX-1 compensation explains the rescue of female infertility in CD-1 mice (Wang *et al.*, 2004b). However, we have never found increased COX-1 mRNA expression in freshly isolated bone or cultured osteoblastic cells from COX-2 KO mice (C56Bl/6,129 or CD-1) under basal or stimulated conditions (Pilbeam, unpublished observations). It is possible that other aspects of the PG production pathway, such as phospholipases or terminal enzymes, may be upregulated in COX-2 KO mice. Clearly there must be compensation by COX-1 in some tissues because double COX-1, COX-2 deficient mice die from failure of ductus arteriosus closure shortly after birth (Loftin *et al.*, 2001).

PGs AND MECHANICAL LOADING OF BONE

Bone is a dynamic tissue that can adapt to mechanical loading with changes in structure to achieve a better balance between stresses and load-bearing capacity. Mechanical loading of bone is an important regulator of bone turnover. Loading of bone can lead to new bone formation, whereas unloading of bone can lead to bone loss. Multiple studies have shown that PGs mediate some of the anabolic effects of mechanical loading on bone (Li *et al.*, 2006a). New bone formation resulting from loading of an isolated avian ulna preparation *in vitro* or from loading of rat tail vertebrae *in vivo* was blocked by inhibiting PG production (Chow and Chambers, 1994; Pead and Lanyon, 1989). Several studies showed PG-dependent new bone formation in bone explants subjected to cyclic mechanical loading *in vitro* and suggested that the PG mediating these effects was PGI_2 (Cheng *et al.*, 1997; Lanyon, 1992; Rawlinson *et al.*, 1991). PGs produced in response to loading are thought to be largely the result of loading-induced COX-2 expression, and a selective COX-2 inhibitor (NS-398) prevented endosteal bone formation in a rat tibial bending model (Forwood, 1996). In humans, loading increased release of PGE_2 in the tibial metaphysis, measured by *in situ* microdialysis (Thorsen *et al.*, 1997), which was blocked by selective inhibition of COX-2 activity (Langberg *et al.*, 2003). However, selective COX-2 inhibitors can inhibit both COX isoforms at high doses, and immunohistochemical localization of COX-1 and COX-2 after tibial bending in rats suggested involvement of both isoforms in loading responses (Forwood *et al.*, 1998). In addition, another study reported no difference between COX-2 WT and KO mice in their periosteal anabolic responses to ulnar loading and suggested that COX-1 compensated for absent COX-2 (Alam *et al.*, 2005). It is possible that HPTH (either secondary or primary) might have compensated to some extent for COX-2 deficiency in this latter study. PGs may also be involved in other effects of loading. Orthodontic tooth movement stimulates PG production, and PGs enhance orthodontic movement of teeth, presumably as a result of PG-stimulated bone resorption (Giunta *et al.*, 1995; Kehoe *et al.*, 1996; Sandy *et al.*, 1993).

External forces applied to bone result in small deformations, or strains, in the bone matrix, which are converted into intracellular signals that frequently lead to new gene transcription (Pavalko *et al.*, 2003; Turner and Pavalko, 1998). Although the specifics of how mechanical loading is coupled to cellular responses in bone are still being debated, as well as which cells are involved, interstitial fluid flow in the lacunar-canalicular network in bone, where large stresses on cells can be generated by fluid flow in narrow channels, is likely to play an important role (Burger and Klein-Nulend, 1999; Han *et al.*, 2004; Hillsley and Frangos, 1994; Knothe *et al.*, 1998; Srinivasan and Gross, 2000; Turner *et al.*, 1994; Weinbaum *et al.*, 1994). *In vivo,* osteocytes may be the targets because of their location in the lacunar-canalicular network, but *in vitro* many cell types are mechanosensitive, and fluid shear stress (FSS) is often modeled *in vitro* by subjecting osteoblasts as well as osteocytes, plated on fixed surfaces, to cyclic laminar fluid flow.

When osteoblasts are subjected to FSS, there is an early release of PGE_2, probably due to FSS-stimulated release of AA that is converted to PGs by constitutively expressed

COX-1, followed by a more sustained production of PG (Klein-Nulend *et al.*, 1997; Reich and Frangos, 1993). FSS induces COX-2 mRNA expression and PG production in primary mouse osteoblastic cells with little effect on COX-1 mRNA levels, and the induction of COX-2 correlates with the sustained production of PG (Klein-Nulend *et al.*, 1997). In MC3T3-E1 cells, 5 minutes of FSS is sufficient to induce COX-2 mRNA (Saegusa *et al.*, 2004). Other studies on MC3T3-E1 cells have shown that the induction of COX-2 involves cytoskeletal-integrin interactions (Pavalko *et al.*, 1998) but does not require intact microfilaments or microtubules (Norvell *et al.*, 2004). FSS induced PGE_2 may also mediate intracellular communication via gap junctions through the prostaglandin EP2 receptor (Cherian *et al.*, 2003). Using MC3T3-E1 cells stably transfected with a COX-2 promoter-luciferase reporter construct and calvarial cells from mice transgenic for this construct, we showed pulsatile FSS as low as 0.1 dyn/cm^2 induced new COX-2 gene transcription via the ERK signaling pathway (Wadhwa *et al.*, 2002b). There are multiple signaling pathways upstream of ERK that may be involved in the effects of FSS on osteoblasts (Hughes-Fulford, 2004). We found the induction of COX-2 in osteoblasts by 4 hours of pulsatile FSS to be dependent on a PKA pathway (Wadhwa *et al.*, 2002a), whereas the early induction by 1 hour of FSS, followed by return to static culture, was dependent on a protein kinase D (PKD) pathway (Mehrotra *et al.*, 2004).

COX-2: INFLAMMATION AND CANCER

PG production is frequently found to be increased in inflammatory processes, such as rheumatoid arthritis. Because many cytokines involved in inflammation are potent inducers of COX-2 expression and PGE_2 production and because PGE_2 is a potent stimulator of bone resorption, it is often assumed that COX-2 derived PGE_2 contributes to the bone loss and cartilage destruction associated with inflammatory diseases. There are some studies to support this conclusion, showing that NSAIDs decrease alveolar bone loss in periodontitis (Howell *et al.*, 1991; Jeffcoat *et al.*, 1993). In addition, inflammatory responses are reduced in mice null for mPGES-1 (Kamei *et al.*, 2004) and in COX-1 and COX-2 KO mice (Langenbach *et al.*, 1999b). However, cytokines themselves are potent inducers of bone resorption, independent of PG production. In a study in which IL-1 was injected *in vivo* above the calvaria of mice for 3 days, IL-1 stimulated resorption was initially PG-independent (Boyce *et al.*, 1989a). However, after the IL-1 injections were stopped, increased resorption continued for 3 to 4 weeks, and this resorption was PG-dependent. Hence, PGs produced by proinflammatory cytokines may be important in prolonging resorption responses to cytokines.

Inflammatory bone loss may reflect not only increased bone resorption but also decreased bone formation. Cytokines can inhibit production of bone matrix proteins independently of cytokine-induced PG production (Rosenquist *et al.*, 1996). It is possible that cytokine-induced PG production might stimulate osteoblastic differentiation and have a compensatory effect for the catabolic actions of cytokines. In IL-1α transgenic mice, treatment *in vivo* with an inhibitor of COX-2 reduced joint inflammation but increased osteopenia by suppressing bone formation (Niki *et al.*, 2007). PGs themselves may also have anti-inflammatory properties (Gomez *et al.*, 2005; Hata and Breyer, 2004). Some studies have suggested that COX-2 metabolites are proinflammatory only during the early stages of an inflammatory response; and, at later times, COX-2 generates a different set of PGs, the cyclopentenone PGs derived from PGD_2, which have anti-inflammatory effects (Rajakariar *et al.*, 2006).

Inflammation has been associated with the progression of many cancers (Harris, 2007; Sarkar *et al.*, 2007). A role for PGs in tumorigenesis was initially suggested by epidemiological studies showing a reduction in the incidence of colorectal cancer in individuals taking NSAIDs and by studies showing constitutive upregulation of COX-2 in tumor cells. Hundreds of studies have now implicated COX-2 and PGE_2 in tumorigenesis in multiple tissues, including colon, breast, prostate, and lung, and COX-2 produced PGE_2 has been shown to enhance tumor cell growth and survival, promote angiogenesis, and facilitate metastasis (Cha and DuBois, 2007; Trifan and Hla, 2003; Wang and DuBois, 2006). One caveat is that many studies used NSAIDs at much higher concentrations than required to inhibit PGE_2 synthesis, and selective COX-2 inhibitors at high doses can have effects independent of PGE_2 inhibition to reduce cell growth and survival (Grosch *et al.*, 2006; Jang *et al.*, 2004). Studies have also suggested that genetic variants in the COX-2 gene or promoter, or chromosomal gain at the COX-2 locus associated with COX-2 overexpression, may correlate with the risk for various cancers or with survival of cancer patients (Ali *et al.*, 2005; Cox *et al.*, 2004; Gallicchio *et al.*, 2006; Gao *et al.*, 2007a; Knosel *et al.*, 2004; Shahedi *et al.*, 2006; Tan *et al.*, 2007; Zhang *et al.*, 2005). Use of selective COX-2 inhibitors to treat or prevent cancer is currently contraindicated because these inhibitors may increase the risk for cardiovascular problems, including myocardial infarction and stroke (Fitzgerald, 2004; Grosser *et al.*, 2006). Hence, there is interest in developing therapies against downstream targets, such as mPGES-1 (Mehrotra *et al.*, 2006b), to inhibit PGE_2 and not PGI_2, which may have beneficial cardiovascular effects, or against specific PGE_2 receptors involved in the tumor-promoting effects (Fulton *et al.*, 2006; Ma *et al.*, 2006).

The role of COX-2 in osteosarcomas has not yet been determined. Several studies have shown COX-2 to be expressed in osteosarcomas (Dickens *et al.*, 2003; Mullins *et al.*, 2004) and in cell lines derived from osteosarcomas (Wong *et al.*, 1997; Min *et al.*, 1998). Although one study

reported that high COX-2 expression positively correlated with osteosarcoma grade (Masi *et al.*, 2007), another study reported that expression of COX-2 was characteristic of more benign osteoblastomas and not high-grade osteoblastic osteosarcomas (Hosono *et al.*, 2007). Our own research would argue that COX-2 overexpression may not enhance growth and survival of osteosarcoma cells. We observed that COX-2 mRNA expression was not detectable by Northern analysis in rat osteosarcoma ROS 17/2.8 cells (Pilbeam *et al.*, 1997b). We found expression and regulation of COX-2 to be quite variable among Saos-2, U2OS, and TE85 human osteosarcoma cell lines (Xu *et al.*, 2006b). Expression, measured by RT-PCR or Northern analysis, ranged from easily measurable constitutive or inducible expression to no detectable constitutive or inducible expression. Similar variability was seen in three "strains" of Saos-2 cells, all derived originally from the same tumor. (We used "strain" to denote cells carried for several years by different laboratories.) Although COX-1 was constitutively expressed in all three Saos-2 strains, PGE_2 production was not measurable ($<1\,pg/10^5$ cells) in the media of cells with little COX-2 mRNA expression. We overexpressed COX-2 in osteosarcoma cells, by both stable transfection and retroviral infection, and found that overexpression of COX-2 decreased cell growth and increased apoptosis, and these effects were not reversed by NSAIDs (Xu *et al.*, 2006b). Increased apoptosis was secondary to increased production of reactive oxygen species (ROS), probably from the COX-2 peroxidase site, and inhibition of ROS production by antioxidants blocked the COX-2 effect on apoptosis. In contrast, COX-2 overexpression decreased apoptosis and ROS in a colon cancer cell line, consistent with other studies in colon carcinoma cells, suggesting that the promotion of tumorigenesis by COX-2 overexpression is tissue/cell dependent. On the other hand, a recent study of U2OS cells reported that overexpression of COX-2 was associated with increased cell number, which could be decreased by treatment with high-dose NS-398 or celecoxib (Lee *et al.*, 2007). However, treatment of osteosarcoma cells with high-dose NS-398 has also been shown to have effects independent of COX-2 inhibition (Moalic *et al.*, 2001).

OMEGA-3 FATTY ACIDS AND BONE

Omega-3 (ω-3 or n-3) fatty acids have been proposed as dietary supplements to treat cardiovascular disease and inflammatory conditions (Calder, 2006; Fritsche, 2006; Mozaffarian and Rimm, 2006; Mozaffarian, 2007). Omega-3 and ω-6 essential fatty acids are derived from the dietary precursors, linoleic acid and α-linolenic acid, respectively. Linoleic acid and α-linolenic acid are converted via an alternating series of desaturations and elongations into AA and EPA, respectively (Vaddadi, 2004). EPA can be further converted into docosahexaenoic acid (DHA). In addition to being derived endogenously from α-linolenic acid, EPA and DHA can be obtained directly from the diet, primarily from fish oils. Both AA and DHA are abundant at the *sn*-2 site in structural phospholipids. AA and EPA, but not DHA, are substrates for COX.

The beneficial effects of ω-3 fatty acids are likely to be multifactorial (Calder, 2006; Wada *et al.*, 2007). Direct effects might be due to incorporation of ω-3 fatty acids into membranes and replacement of AA. This might change the physical properties of the membrane and reduce production of the 2-series of prostanoids by both the COX-1 and COX-2 pathways (Wada *et al.*, 2007). In rat bone organ cultures, PGE_3 and PGE_2 were equipotent in stimulating bone resorption, but there was less PGE_3 produced from EPA compared to PGE_2 produced from AA (Raisz *et al.*, 1989). Indirect effects of ω-3 fatty acids include alteration of the expression of inflammatory genes through effects on transcription factor activation (Calder, 2006; Wada *et al.*, 2007). In addition, EPA and DHA can give rise, via the lipoxygenase pathway, to a recently identified family of anti-inflammatory mediators called resolvins that may be important in the resolution phase of inflammation (Schwab *et al.*, 2007; Serhan, 2007).

Some animal studies suggest that ω-3 fatty acids may reduce bone loss due to ovariectomy (Sun *et al.*, 2003; Watkins *et al.*, 2006), inflammatory diseases (Bhattacharya *et al.*, 2005; Kesavalu *et al.*, 2006), and aging (Bhattacharya *et al.*, 2007). However, one study reported that high-dose EPA supplementation exacerbated the effects of ovariectomy on BMD (Poulsen and Kruger, 2006). Whether these animal studies are applicable to humans is unclear (Fritsche, 2007), and there are few human observational studies. One recent study, which correlated levels of serum fatty acid with BMD in young men, suggested that ω-3 fatty acids, especially DHA, are positively associated with bone mineral accrual and peak BMD (Hogstrom *et al.*, 2007). Another study, which relied on self-reported increased dietary intake, found that a higher ratio of ω-6 to ω-3 fatty acids was associated with lower BMD at the hip in both sexes (Weiss *et al.*, 2005). Frequent consumption of fish has also been associated with significantly greater BMD in Japanese postmenopausal women (Ishikawa *et al.*, 2000). Given their proposed effects on inflammation, perhaps the greatest effect of ω-3 fatty acids might be expected to be seen in inflammatory bone loss. However, a high-dose trial of fish-oil supplementation to patients with Crohn's disease did not show any effect on markers of bone turnover (Trebble *et al.*, 2005). More interventional trials are needed to determine if ω-3 fatty acid supplementation is beneficial for bone.

NSAIDs AND BONE LOSS IN HUMANS

Several studies have examined the effects of nonselective NSAIDs on BMD in humans. In a study of

postmenopausal women 65 years of age or older, there was no significant difference found in N-telopeptide cross-link excretion, a marker of bone resorption, between self-reported users of NSAID or aspirin compared to nonusers (Lane *et al.*, 1997). In a similar cohort, the use of aspirin or NSAIDs was found to be associated with a small (1–3%), but significant, increase in BMD of the hip and spine, but there was no clinically significant protective effect on risk for fracture (Bauer *et al.*, 1996). In a study of older women from Rancho Bernardo, California, the regular use of propionic acid NSAIDs (ibuprofen, naproxen, ketoprofen), but not acetic acid NSAIDs (indomethacin, diclofenac, sulindac, tolmetin), was associated with higher BMD at multiple skeletal sites (Morton *et al.*, 1998). Those who concurrently used estrogen and propionic acid NSAIDs had the highest BMD at all sites. Another study stratified relative COX-1 and COX-2 selectivity of traditional NSAIDs and compared effects on men and women, mean age 74 years (Carbone *et al.*, 2003). Their data suggested that the combination of relatively COX-2 selective traditional NSAIDs and aspirin was associated with higher BMD at multiple skeletal sites in men and women. On the other hand, a cross-sectional study of men, average age 74 years, found no association between markers of bone turnover and NSAID use (Cauley *et al.*, 2005). A recent study examined effects of selective COX-2 inhibitors on BMD in men and women, age 65 and older (Richards *et al.*, 2006). In men, daily COX-2 inhibitor use was associated with a 2.4% to 5.3% *lower* hip and spine BMD compared to nonusers. In contrast, in postmenopausal women not on estrogen replacement therapy, daily COX-2 inhibitor use was associated with a 0.9% to 5.7% *higher* BMD at hip and spine sites. The authors postulated that beneficial effects of mechanical loading might be reduced by COX-2 inhibition in men, whereas the proinflammatory state associated with estrogen withdrawal might be suppressed by COX-2 inhibition in postmenopausal women.

One factor that may complicate the interpretation of clinical studies with NSAIDs is the variability between individuals in their response to NSAIDs. A study of celecoxib and rofecoxib in healthy humans found considerable variability at an individual level in the degree of COX-2 inhibition and selectivity attained by both drugs (Fries *et al.*, 2006). Approximately one third of the variability was attributable to differences between individuals, suggesting the contribution of genetic sources of variance. Another potentially complicating factor is that some drugs thought to be devoid of significant PG inhibition, and therefore not taken into account in the studies, may also be COX inhibitors. An example is acetaminophen (paracetamol), which has recently been shown to have substantial COX-2 inhibition (Hinz *et al.*, 2007).

The highly selective inhibitors of COX-2, such as rofecoxib and celecoxib, were developed to minimize gastrointestinal complications of traditional NSAIDs, thought to be secondary to suppression of COX-1-derived PGs. Subsequently, clinical studies showed the COX-2 selective inhibitors to elevate the risk of myocardial infarction and stroke (Grosser *et al.*, 2006). Hence, it is unlikely that large clinical studies with highly selective COX-2 inhibitors will be undertaken to examine effects on bone in healthy humans, at least not until the cardiovascular risks are better understood. Given the potential importance of inhibiting the COX-2 pathway in treating or preventing cancer, it is likely that new drugs will be developed to target the involved tissues or to decrease specific downstream prostanoids.

LIPOXYGENASE AND BONE

An alternate pathway for AA metabolism is the lipoxygenase (LOX) pathway (Fig. 9). The three major forms of LOXs in mammalian species, 5-LOX, 12-LOX, and 15-LOX, initially oxidize AA to 5-, 12- and 15-hydroperoxyeicosatetraenoic acid (HPETE), respectively (Brash, 1999). Each HPETE can then be reduced by glutathione peroxidase to the corresponding 5-, 12-, and 15-hydroxyeicosatetraenoic acid (HETE). 5-LOX is a bifunctional enzyme that also metabolizes 5-HPETE to leukotriene (LT) A_4. The leukotrienes LTC_4, LTD_4, and LTE_4 are called peptidoleukotrienes (peptido-LT). Similar to PGs, LTs are generally considered to be proinflammatory agents. More recently identified eicosanoid products of the LOX pathway, lipoxins and resolvins, are proposed to be anti-inflammatory and to mediate processes required for resolution of acute inflammation (Serhan, 2007). Lipoxins are generated from AA via various LOX pathways or as the products of aspirin-acetylated COX-2 and may reduce bone loss associated with inflammation (Serhan *et al.*, 2003). Resolvins are derived via the LOX pathway from ω-3 PUFAs.

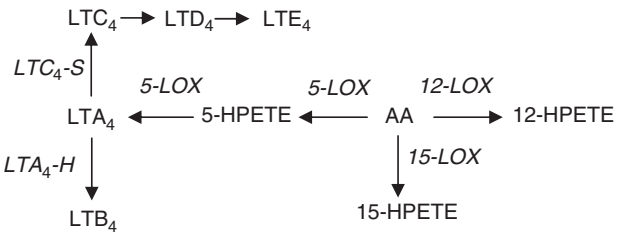

FIGURE 9 Lipoxygenase (LOX) pathways. 5-, 12-, and 15-LOX catalyze the insertion of molecular oxygen into arachidonic acid (AA) producing 5-, 12-, and 15-hydroperoxy-eicosatetraenoic acid (HPETE), respectively. Each HPETE can then be reduced by glutathione peroxidase to the corresponding 5-, 12-, and 15-hydroxyeicosatetraenoic acid (HETE). 5-LOX is a bifunctional enzyme that can also metabolize 5-HPETE to leukotriene A_4 (LTA_4). LTA_4 is converted to LTC_4 by LTC_4-synthase (LTA_4-S) and to LTB_4 by LTA_4-hydrolase (LTA_4-H). LTC_4 is unstable and converted rapidly to LTD_4 and LTE_4 by transpeptidases. Lipoxins can be generated by pathways initiated by both 5- or 15-LOX.

Although less studied than products of the COX pathway, products of the LOX pathway have been shown to play active roles in bone metabolism. A number of studies have shown LTs to directly stimulate resorption. In neonatal mouse organ cultures, LTs and HETEs had biphasic effects on bone resorption, with low doses stimulating and high doses inhibiting resorption (Meghji *et al.*, 1988). Effects of some LTs were partially inhibited by indomethacin, suggesting mediation by PGs. A cell line established from giant-cell tumors of bone produced an activity in the medium that stimulated bone resorption in neonatal mouse calvariae and pit formation by isolated rat osteoclasts on dentine (Gallwitz *et al.*, 1993). This activity was identified as 5-HETE and peptido-LT. Peptido-LTs were also shown to stimulate isolated avian osteoclasts to form resorption lacunae (Garcia *et al.*, 1996b). Isolated avian osteoclasts were shown to express both high and low affinity LTB_4 receptors, and LTB_4 increased both TRAP activity and pit formation by these osteoclasts (Flynn *et al.*, 1999). LTB_4 increased osteoclastic bone resorption and osteoclast numbers and eroded surfaces *in vivo* following local administration over the calvariae of normal mice and *in vitro* in organ cultures of neonatal mouse calvariae (Garcia *et al.*, 1996a). LTB_4 also increased the formation of resorption lacunae by isolated neonatal rat osteoclasts. Recently, LTB_4 was reported to induce osteoclastogenesis in cultured human PBMCs by a RANKL-independent mechanism (Jiang *et al.*, 2005).

Several studies have shown products of the LOX pathway to have negative effects on bone formation. LTB_4, LTD_4, and 5-HETE inhibited BMP-2 induced bone formation in mouse calvarial organ culture and blocked the formation of mineralized nodules in response to BMP-2 and dexamethasone in fetal rat calvarial cell culture (Traianedes *et al.*, 1998). 5-LOX KO mice were reported to have increased bone biomechanical properties and cortical thickness (Bonewald *et al.*, 1997). Recently, the mouse 15-LOX gene was identified as a negative regulator of peak BMD (Klein *et al.*, 2004). 15-LOX KO mice had higher femoral BMD and biomechanical properties than WT mice. Transient overexpression of 15-LOX in murine bone marrow stromal cell cultures reduced alkaline phosphatase activity and osteocalcin secretion. Pharmacological inhibitors of 15-LOX improved BMD and bone strength in two rodent models of osteoporosis. In contrast, overexpression of human 15-LOX in transgenic rabbits was shown to protect against bone loss associated with periodontal disease (Serhan *et al.*, 2003). This effect was attributed to the enhanced production of anti-inflammatory metabolite lipoxins in the rabbits.

The identification of 15-LOX as a susceptibility gene for peak BMD in mice may have relevance for human osteoporosis. An autosomal genome screen of 17 large pedigrees in humans detected linkage for hip, spine, and wrist BMD to the 17p13.1 chromosomal region, where 12- and 15-LOX genes are located (Deng *et al.*, 2002; Devoto *et al.*, 1998; Funk *et al.*, 2002). Another study reported association between a single polynucleotide polymorphism (SNP) located in the 5 -flanking region of the 15-LOX gene and total BMD in postmenopausal Japanese women (Urano *et al.*, 2005). Although the human 15-LOX gene shares significant sequence homology with the murine 15-LOX gene, the 12-LOX gene of humans is functionally more related to the 15-LOX gene of mice (Chen *et al.*, 1994). Considering this, two independent studies recently looked at the contributions of multiple SNPs in the 15- and 12-LOX genes of Caucasian men and women and found that polymorphisms in the 12-LOX gene, but not the 15-LOX gene, were associated with variations in hip and spine BMD (Ichikawa *et al.*, 2006; Mullin *et al.*, 2007).

It is possible that some effects of the LOX pathway may occur via PPARγ-dependent mechanisms. Products of the LOX pathway may be ligands for PPARγ (Bishop-Bailey and Wray, 2003). PPARγ haploinsufficient mice have increased BMD (Akune *et al.*, 2004), and an association between a SNP of the PPARγ gene and total body BMD was reported in postmenopausal women (Ogawa *et al.*, 1999).

SUMMARY

PGs are abundantly expressed in bone, and their production is highly regulated by multiple local and systemic factors that induce COX-2 expression. *In vitro,* PGE_2 generally stimulates the differentiation of both osteoblasts and osteoclasts, but inhibitory effects on bone formation and resorption are also seen. *In vivo,* the predominant effects of exogenous PGE_2 are to stimulate both bone formation and bone resorption, but the relative magnitude of these can vary so that in some models there is net bone loss whereas in others there is a gain in bone mass. Some of the complexity of PGE_2 actions may be explained by the multiplicity of receptors for PGE_2. Many studies have now implicated COX-2 and PGE_2 in the promotion of tumorigenesis, suggesting that PGE_2 functions as a general regulator of cell growth and apoptosis. Studies of the role of COX-2 and PGE_2 in cancer have highlighted new and complex signaling pathways for the EP2 and EP4 receptors that may also be important for PGE_2 effects in bone cells. The development of selective inhibitors for COX-2 and selective agonists and inhibitors for EP receptors, as well as transgenic mice deficient in PG synthetic enzymes and receptors, has led to a better understanding of the role of PGs in fracture healing and to the development of potential therapeutic agents to increase bone mass and accelerate fracture healing. Despite the availability of mice deficient in COX-2, the effects of endogenously produced PGs on bone remodeling under physiologic and pathologic conditions remain elusive. Reasons for this may be

the redundancy of the PG pathways, as well as potential compensatory mechanisms involving other hormones, such as PTH. Although this complexity makes it more difficult to understand fully the role of PGs in bone, further studies that clarify the mechanisms of PG action could lead to a better understanding of the physiology and pathophysiology of bone and the discovery of new therapeutic applications of altering PGs in skeletal disorders.

Chapter 63

Parathyroid Hormone-Related Peptide and Other Systemic Factors in Skeletal Manifestations of Malignancy

David Goltzman

Calcium Research Laboratory and Department of Medicine , McGill University and Royal Victoria Hospital of the McGill University Health Centre, Montreal, Quebec, Canada H3A 1A1

INTRODUCTION

Hypercalcemia is one of the most frequent paraneoplastic syndromes and often occurs in advanced stages of the disease. The median survival rate often varies from 6 to 10 weeks following the onset of hypercalcemia (Body *et al.*, 2000); however, breast cancer patients experience a somewhat longer median survival of 3 to 4.5 months (De Wit and Cleton, 1994).

The association between elevated blood calcium and neoplastic disease was first noted in the 1920s (Zondek *et al.*, 1923), when it was postulated that release of calcium from bone by the direct osteolytic action of malignant cells was responsible for hypercalcemia associated with malignancy. However, hypercalcemia was often accompanied by hypophosphatemia, the hallmark of hyperparathyroidism (HPT), and also occurred in the absence of skeletal metastases. In 1941 it was hypothesized that a malignant tumor might release a systemically active factor resulting in hypercalcemia (Albright, 1941). This hypothesis was raised when a patient with a renal carcinoma, metastatic to bone, presented with hypercalcemia and hypophosphatemia in the absence of any obvious parathyroid dysfunction. The patient's biochemical abnormalities were temporarily normalized following tumor reduction but became apparent again as the tumor resumed its growth. It was reasoned that since hyperphosphatemia did not accompany hypercalcemia, despite evidence of osteolysis, perhaps the tumor was secreting a phosphaturic substance such as parathyroid hormone (PTH). Although no bioassayable hormone was detected in the tumor, the important observation had been made that hypercalcemia associated with malignancy (MAH) could have a humoral basis and that the factor might be related to PTH. Despite the striking similarities between the biochemical manifestations of HPT and MAH that precipitated Albright's hypothesis, it subsequently became apparent that there were also a number of important differences between these syndromes. Early attempts at the differential diagnosis of these hypercalcemic disorders identified not only subnormal concentrations of immunoreactive PTH (Powell *et al.*, 1973) and no detectable PTH mRNA in the tumors (Simpson *et al.*, 1983), but also a mild hypokalemic alkalosis in patients with malignancy-associated hypercalcemia (MAH). In contrast, elevated PTH and mild metabolic acidosis were associated with HPT (Lafferty, 1966). The search for a novel protein with PTH-like bioactivity intensified using several bioassays that had been developed for PTH (Goltzman *et al.*, 1981; Nissenson *et al.*, 1981; Rodan *et al.*, 1983). Using both *in vivo* and *in vitro* approaches, PTH-like bioactivity was identified in the blood and in tumor extracts from patients with MAH. These same bioassays were used in various combinations during the purification of a novel protein, named parathyroid-hormone-like peptide (PLP), from tumor tissue (Burtis *et al.*, 1987; Moseley *et al.*, 1987; Strewler *et al.*, 1987). When the gene was cloned and demonstrated to be structurally homologous to PTH, the protein was renamed parathyroid-hormone-related protein, or PTHrP (Mangin *et al.*, 1989; Suva *et al.*, 1987).

The term *humoral hypercalcemia of malignancy* (HHM) was later coined to distinguish the syndrome caused by a circulating factor, now known to be PTHrP, from hypercalcemia caused by the direct lytic action of tumor cells in bone. The demonstration that neutralizing antibodies to PTHrP could reduce or eliminate the hypercalcemia in animal models of HHM (Kukreja *et al.*, 1988; Henderson *et al.*, 1990) provided strong evidence that this was indeed the causal factor of this syndrome. HHM was associated primarily with renal cell carcinomas and squamous cell cancers originating in a variety of primary sites,

Principles of Bone Biology, 3rd Edition

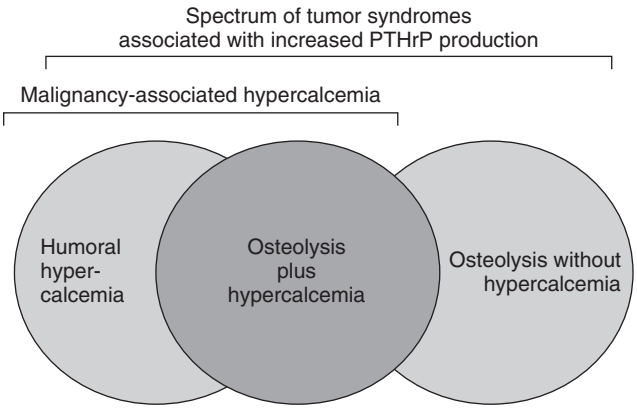

FIGURE 1 Spectrum of tumor syndromes associated with increased PTHrP production. PTHrP may be produced and released by tumors that have not metastasized to bone. Circulating PTHrP can then produce hypercalcemia via an endocrine mechanism ("Humoral Hypercalcemia of Malignancy"). Other tumors that have metastasized to bone may also produce and release PTHrP. Hypercalcemia associated with these tumors may result from osteolysis but also from circulating PTHrP acting in an endocrine mode ("Osteolysis plus Hypercalcemia"). Some tumors that have metastasized to bone may produce PTHrP, but although osteolysis may occur, circulating concentrations are not increased and hypercalcemia does not occur ("Osteolysis without Hypercalcemia").

whereas hypercalcemia due to local osteolysis was commonly associated with metastatic breast disease and with hematologic malignancies. Nevertheless, it is now clear that the "direct" lytic action of tumor cells is also mediated in part by PTHrP, and that PTHrP released by these tumors may also act on a systemic basis (Fig. 1).

MOLECULAR AND CELLULAR BIOLOGY OF PTHrP

Characteristics of the PTHrP Gene

The genes encoding PTH and PTHrP have been localized to the short arms of human chromosomes 11 and 12, respectively, placing them among syntenic groups of functionally related genes and suggesting a common ancestral origin (Goltzman *et al*., 1989). Similarities in their structural organization and in the functional properties of their amino termini provide further support for the hypothesis that *PTH* and *PTHrP* are members of a single gene family. The human *PTHrP* gene is a complex unit that spans more than 15 kb of DNA. Its mRNA is transcribed from at least three promoters and undergoes differential splicing, giving rise to heterogenous mRNA species. The cDNA encodes a prototypical secretory protein with predicted mature isoforms of 139, 141, and 173 amino acids. The rat *PTHrP* gene is driven by a single promoter, and encodes a protein of 141 amino acids with marked sequence homology to human PTHrP up to residue 111, which suggests conserved functionality (Yasuda *et al*., 1989). Indeed species conservation of PTHrP is evident with high homology across a variety of mammalian species (Burtis *et al*., 1992).

PTHrP Overproduction in Malignancy

PTHrP is widely distributed in embryonic and adult tissues and has essential functions in development and growth. These include roles in the normal development of the cartilaginous growth plate (Amizuka *et al*., 1994), in bone anabolism (Miao *et al*., 2005), in mammary gland development including the development of mammary ducts and nipple formation (Foley *et al*., 2001), in calcium transport across the placenta (Kovacs *et al*., 1996), in smooth muscle relaxation, in vasodilatation (Schordan *et al*., 2004), and in tooth eruption (Philbrick *et al*., 1998). In view of its broad distribution pattern in many cell types, overproduction of PTHrP by malignant cells most likely results from deregulated expression of an endogenous protein during the process of malignant transformation, that is, "eutopic" rather than "ectopic" production.

A number of potential mechanisms have been invoked to explain overexpression of PTHrP in malignant cells, including gene amplification (Sidler *et al*., 1996) and alterations in the methylation status of critical regulatory regions of the gene during neoplastic transformation (Broadus and Stewart, 1994; Ganderton and Briggs, 1997). Furthermore, the complex organization of the human PTHrP gene suggests that changes in tissue-specific promoter usage or splice variants might also contribute to overproduction of PTHrP during the process of malignant transformation. One extensive clinical study examined a variety of tumors, including 13 breast malignancies, with exon-specific probes to identify transcripts arising from all three promoters and from the different 3′ splice variants (Southby *et al*., 1995). Although the authors failed to identify tissue-specific or tumor-specific transcripts, they did show that PTHrP was transcribed from multiple promoters in tumor samples, compared with a single promoter in normal tissue harvested from the same individual. The resulting overall increase in transcription could then lead to cumulative overexpression of the protein in neoplastic tissue. Others, however, have reported the presence of specific transcripts related to the stage of cancer progression. Thus Bouizar *et al.* (1999) investigated the differential expression of PTHrP isoforms in different stages of breast cancer progression as a result of differential use of a downstream TATA promoter. The amount of mRNA encoding the 1−139 isoform was much higher in the tumors of patients who later developed metastases than in those of patients who developed no metastases. The mRNA encoding this isoform was also more abundant in breast tumors from patients who developed bone metastases than in those of patients who developed metastases in soft tissues. In contrast the amounts of mRNA encoding the 1−141 isoform were similar in these different groups.

Regulation of PTHrP Production

Growth Factors and Cytokines

A variety of growth factors have been found to be potent stimulators of *PTHrP* gene transcription (Kremer *et al*., 1991; Sebag *et al*., 1994). Thus, basal levels of mRNA and unstimulated release of PTHrP into conditioned medium were both significantly higher in Ras-transformed keratinocytes, a model of epithelial carcinogenesis, compared with their nontransformed counterpart (Henderson *et al*., 1991; Kremer *et al*., 1991; Sebag *et al*., 1992), and PTHrP gene expression could be stimulated by EGF. In contrast, insulin-like growth factor I (IGF-I) was a more effective stimulator of gene transcription in breast epithelial cells (Sebag *et al*., 1994). Signaling by growth factors through receptor tyrosine kinases (RTKs) therefore appears to be an important mechanism for regulating PTHrP gene expression, and oncogenic transformation by the Ras component of the RTK signal transduction pathway in many malignant cells. Transfection of a constitutively active derivative of the hepatocyte growth factor receptor known as Tpr-Met into PTHrP-producing cells resulted in a substantial increase in the expression and release of PTHrP (Aklilu *et al*., 1996), whereas introduction of a point mutation into Tpr-Met, which prevented its association with the Ras signaling pathway, led to a significant reduction in PTHrP expression and release. Similar reductions were observed in cells treated with agents that inhibit Ras function by preventing it from anchoring to the cell membrane and transducing a signal (Ras farnesylation inhibitors; Aklilu *et al*., 1997, 2000). These studies demonstrated an important role for Ras in enhancing PTHrP production in transformed cells.

Other growth factors and cytokines have also been found to play a critical role in PTHrP overproduction, including, notably, transforming growth factor β (TGFβ). PTHrP mRNA is typically unstable with a short half-life, but cytokines such as TGFβ increase PTHrP mRNA stability (Sellers *et al*., 2004).

Steroid Hormones

Several steroid hormones have been reported to influence the production of PTHrP. Thus estradiol has been reported to inhibit PTHrP gene promoter activity in breast cancer cell models *in vitro* and to diminish PTHrP production *in vivo* (Rabbani *et al*., 2005). Similarly, androgens (dihydrotestosterone) have also been shown to inhibit PTHrP production in models of prostate cancer both *in vitro* and *in vivo* at least in part via a transcriptional mechanism (Pizzi *et al*., 2003). Glucocorticoids have also been shown to inhibit PTHrP production (Sebag *et al*., 1994; Tenta *et al*., 2005; Glatz *et al*., 1994).

The secosteroid 1,25 dihydroxyvitamin D ($1,25(OH)_2D$) has been shown to inhibit PTHrP gene transcription (Kremer *et al*., 1991; Sebag *et al*., 1992). A $1,25(OH)_2D$ responsive repressor sequence was identified between bases -1121 to -1075 upstream of the single promoter in the rat *PTHrP* gene (Kremer *et al*., 1996a). Using nuclear extracts prepared from normal human keratinocytes in mobility shift analyses, it was determined that the PTHrP repressor site bound a vitamin D receptor (VDR)-retinoid X receptor (RXR) heterodimer. The VDR-RXR complex was also identified in extracts of nuclei from immortalized keratinocytes but not from the Ras transformed cells that had previously shown resistance to $1,25(OH)_2D_3$-induced inhibition of PTHrP expression (Solomon *et al*., 1998). Expression of wild-type RXRα in the transformed cells resulted in reconstitution of the VDR-RXR heterodimer. Subsequent work by the same group determined that disruption of the VDR-RXR complex in Ras transformed keratinocytes resulted from mitogen-activated protein kinase (MAPK)-stimulated phosphorylation of RXRα by the activated Ras/Raf/MAPK pathway (Solomon *et al*., 1999). Analogues of vitamin D (EB1089) were also found to inhibit PTHrP production and prevents the development of malignancy-associated hypercalcemia in an animal model *in vivo* (Haq *et al*., 1993).

Viral Proteins

Viral proteins, notably Tax, have been implicated in transcriptional stimulation of PTHrP production in malignant states. TAX is a 40-kDa nuclear phosphoprotein that transactivates its own promoter as well as those of a number of host genes. It interacts with a variety of transcription complexes that bind to DNA consensus elements in the *PTHrP* promoter including the cAMP response element, Ets-1, serum response element, and the AP-1 binding site (Dittmer *et al*., 1993; Ejima *et al*., 1993). PTHrP mRNA has been identified in samples harvested from asymptomatic HTLV-I carriers as well as from leukemic cells of ATL patients (Motokura *et al*., 1989), and elevated circulating levels of PTHrP were detected in most hypercalcemic individuals in the acute phase of the disease (Ikeda *et al*., 1994). In view of the documented role of human T-cell leukemia virus type I (HTLV-I) infection in the pathogenesis of adult T-cell leukemia-lymphoma (ATL) and the high incidence of PTHrP overexpression in these patients, it was proposed that the TAX might stimulate PTHrP gene transcription. The MT-2 cell line, in which TAX is overexpressed, was used to determine that PTHrP gene transcription was indeed enhanced and that maximal stimulation of *PTHrP* involved activation of PKA and PKC (Ikeda *et al*., 1995).

Calcium

Various well-established cancer cell lines have been found to express both CaR mRNA and protein (Cattopadhyay, 2006.). These include cell lines derived from breast cancer (MCF-7, MDA-MB-231; Sanders *et al*., 2000), and prostate cancer (PC-3, LnCaP; Sanders *et al*., 2001).Both pharmacological and molecular evidence indicates that elevated Ca^{2+} upregulates PTHrP synthesis and release via

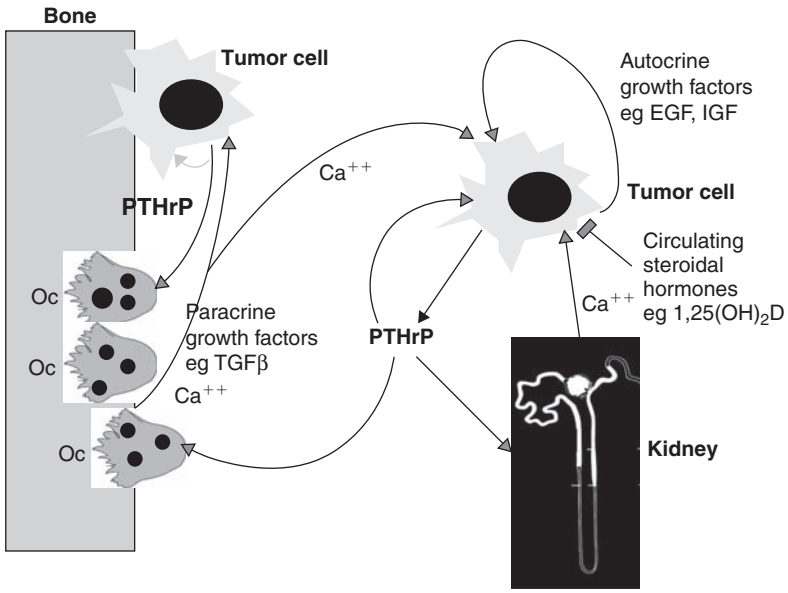

FIGURE 2 Regulation of PTHrP production by tumors that have and have not metastasized to bone. The production and release of PTHrP may be increased (→) by growth factors acting in an autocrine/paracrine mode such as EGF or IGF. PTHrP released from such tumors may enhance calcium (Ca^{++}) reabsorption by its action on the kidney nephron and by stimulating osteoclastic (Oc) osteolysis and calcium release from bone. The hypercalcemia itself then may augment PTHrP release from such tumors. Other circulating factors such as steroidal molecules may also modulate PTHrP production, generally by producing inhibitory effects (—|). Once tumors have metastasized to bone, they can also release PTHrP, which may cause osteoclastic osteolysis in a paracrine mode, resulting in the release of growth factors (such as TGFβ) and calcium from resorbed bone. Such growth factors, acting in a paracrine mode, and released local calcium may then further stimulate PTHrP release from metastases. PTHrP produced by tumors may also influence the course of progression of such tumors.

CaR activation in these cell lines. Stimulation of PTHrP release due to CaR activation involves *de novo* synthesis of PTHrP mRNA, in view of the fact that the pan-RNA polymerase inhibitor actinomycin D inhibits the effect of Ca^{2+} on the expression of PTHrP mRNA and protein release. Consequently elevated calcium induced by circulating PTHrP may have a stimulatory effect on further PTHrP release by the tumor. Furthermore the majority of calcium in the body is stored in bone, and bone-derived calcium is released during bone resorption resulting in an increase in extracellular calcium (Ca^{2+}) in the bony microenvironment to levels, in the vicinity of resorbing osteoclasts, that are manyfold higher (ranging from 8 to 40 m*M*) than the level of systemic Ca^{2+} (Silver *et al*., 1988). Evidence is accumulating that these large local changes in Ca^{2+} may be "sensed" by cancer cells metastatic to bone and could enhance further PTHrP release from tumor cells metastatic to bone.

Overall therefore, these studies indicate that increased PTHrP production can result from alterations in the interaction between stimulatory and inhibitory signaling pathways in malignant cells (Fig. 2).

Processing and Degradation of PTHrP

PTHrP appears to undergo endoproteolytic cleavage in the secretory pathway, resulting in the release of multiple fragments. The Fischer rat implanted with the Rice-H500 Leydig cell tumor is a well characterized model of HHM and has been used to investigate the regulation of PTHrP metabolism (Rabbani *et al*., 1993). Biosynthetic labeling of nascent PTHrP revealed rapid processing into three distinct amino-terminal species of 1−36, 1−86, and 1−141 amino acids, which were constitutively released into the extracellular environment. These observations were in agreement with similar studies that had been performed in malignant human cells (Soifer *et al*., 1992).

Like PTH, PTHrP is synthesized as a prohormone with an amino-terminal extension. The biological potency of pro-PTHrP is considerably less than that of PTHrP-(1-34) (Liu *et al*., 1995). A furin recognition sequence is found between the propeptide and the mature protein, and studies (Liu *et al*., 1995) have shown that pro-PTHrP was indeed a substrate for the prohormone convertase furin.

MECHANISMS OF ACTION OF PTHrP

Interaction of Amino-Terminal PTHrP with Cell Surface Receptors

Sequence homology between PTH and PTHrP is restricted to only eight of the first 13 residues; however, this domain is known to be required for activation of signal transduction cascades. Additional conformational similarities in the 14−34 region, a domain that appears critical for peptide

binding to the receptor, permit amino-terminal fragments of the proteins to act as equivalent agonists for their common receptor, the type 1 PTH/PTHrP receptor (PTH1R). The PTH1R is a seven-transmembrane G-protein linked receptor that has the "signature" G protein-coupled receptor (GPCR) topology, a seven-membrane-spanning, "serpentine" domain, as well as a large extracellular ligand-binding domain and an intracellular COOH-terminal domain. The receptor couples to Gs and Gq leading to activation of the protein kinase A (PKA) and protein kinase C (PKC) pathways (Mannstadt *et al*., 1999) and, like other GPCRs, undergoes cyclical receptor activation, desensitization, and internalization (Weinman *et al*., 2006). After ligand binding and endocytosis, the PTH1R is either recycled to the cell membrane or targeted for degradation. Arrestins contribute to the desensitization of both Gs and Gq mediated PTH1R signaling. PTH1R activation and internalization can be selectively dissociated (Sneddon *et al*., 2004). PTH1R signaling can be modified by scaffolding proteins such as the Na^+/H^+ exchanger regulatory factor (NHERF) 1 and 2 through PDZ1 and PDZ2 domains (Mahon *et al*., 2002; Sneddon *et al*., 2003).

PTH1R signaling via the cAMP pathway, leading to PKA activation and phosphorylation of the cyclic AMP response element binding protein (CREB), has been extensively documented. CREB binds to the cyclic AMP response element (CRE) in the promoter region of many genes and transcriptionally modulates their expression.

PTH1R, as with PTHrP, is expressed in a wide variety of embryonic and adult tissues, including cartilage and bone, and therefore mediates the autocrine/paracrine actions of locally produced and secreted PTHrP.

Actions of Carboxy-Terminal PTHrP

In the past, several investigators have reported a variety of functions for fragments of PTHrP that share no homology with PTH. These include the pentapeptide PTHrP-(107−111), which was named osteostatin for its potential to inhibit osteoclastic bone resorption in culture (Fenton *et al*., 1991). Other studies using carboxy-terminal fragments of PTHrP have shown that such fragments inhibit production of the early osteoblast marker osteopontin (Seitz *et al*., 1995) in isolated osteoblasts and are almost as effective as PTHrP-(1–34) in stimulating functional osteoclast formation from progenitor cells (Kaji *et al*., 1995). These studies support *in vivo* observations demonstrating decreased osteoblastic and increased osteoclastic activity in association with elevated circulating levels of carboxy-terminal fragments of PTHrP in patients with HHM (Burtis *et al*., 1994). Several reports have reported the presence of cell surface binding proteins for carboxy-terminal fragments of PTHrP on skeletal cells (Orloff *et al*., 1995); however, to date, the molecular nature of these binding proteins remain unclear.

Intracellular Mechanism of PTHrP Action

Although most of the cellular actions of PTHrP have been attributed to the interaction of its amino terminus with the cell surface PTH1R, there are also reports that PTHrP may have a direct, intracellular mode of action. There is evidence in the literature for three potential mechanisms for the translocation of PTHrP, a prototypical secretory protein, into the cytoplasmic compartment of target cells. One involves the alternative initiation of PTHrP translation to exclude the "pre" or leader sequence, which is necessary for entry of the molecule into the endoplasmic reticulum and secretory pathway (Nguyen *et al*., 2001). A second involves retrograde transport of nascent PTHrP from the endoplasmic reticulum (Meerovitch *et al*., 1997, 1998) into the cytoplasm. Finally, a third involves internalization of secreted PTHrP via a PTH1R-independent cell-surface binding protein for PTHrP (Aarts *et al*., 1999).

The intracrine action of PTHrP appears to be mediated at least in part, through residues 87−107 in the mid-region of the protein. This region shares sequence homology with a lysine-rich bipartite nuclear localization sequence (NLS) in nucleolin (Schmidt-Zachmann and Nigg, 1993) and with an arginine-rich NLS in the retroviral regulatory protein TAT (Dang and Lee, 1989). The PTHrP NLS is both necessary and sufficient to direct the passage of PTHrP to the nuclear compartment of transfected cells and to localize endogenously expressed PTHrP to nucleoli in chondrocytes and osteoblasts *in vitro* and *in vivo* (Henderson *et al*., 1995). Endogenous PTHrP has been identified in the coarse fibrillar component of nucleoli by immunoelectron microscopy. This compartment is occupied by complexes of newly transcribed 45s ribosomal RNA and protein that are destined for assembly into ribosomes, and PTHrP has been shown to bind to GC-rich homopolymeric RNA and total cellular RNA with specificity and high affinity (Aarts *et al*., 1999), compatible with a role in ribosomal biogenesis. The biological impact of nucleolar PTHrP on cell function was demonstrated *in vitro* when chondrocytes expressing wild-type PTHrP were protected from apoptosis induced by serum deprivation, whereas cells expressing the protein without the NLS were not. Subsequently the nuclear localization of PTHrP was also found to be protective, in studies *in vitro*, for prostate cancer cell apoptosis (Dougherty *et al*., 1999) and breast cancer (Sepulveda *et al*., 2002).

Nuclear localization of PTHrP occurs in a cell cycle-dependent manner with higher expression in the G2 and M phases of the cycle (Okano *et al*., 1995; Lam *et al*., 1997). The cell cycle-dependent localization of PTHrP is regulated by the activity of the cyclin-dependent kinases (cdk) cdc2 and cdk2, which phosphorylate PTHrP at threonine^{85} within a consensus cdc2/cdk2 site (Lam *et al*., 2000). Phosphorylation increases as cells progress from G_1 to G_2 and M of the cell cycle and leads to decreased nuclear

entry, perhaps by enhancing binding to a cytoplasmic retention factor. PTHrP appears to bind with high affinity to importin β1 and the GDP-bound protein, Ran (Lam *et al*., 1999). PTHrP nuclear import seems dependent on microtubular integrity, implying a role for the cytoskeleton in transport to the nucleus (Lam *et al*., 2002). After translocation across the nuclear envelope, GTP-bound Ran may release PTHrP into the nucleus, where it apparently can act in the nucleolus to bind RNA, thereby regulating mRNA processing or mRNA transport. Functionally, intranuclear PTHrP seems to delay apoptosis (Henderson *et al*., 1995) and to increase cell proliferation.

Despite this evidence in favor of an intracrine action of PTHrP, ultimately, *in vivo* studies will be required to determine the role of nuclear PTHrP in physiology and in the pathophysiology of cancer.

PTHrP ACTIONS TO PRODUCE THE MANIFESTATIONS OF HHM

Actions in Kidney

An elevation in the circulating level of PTHrP in patients with HHM initially results in phosphate wasting and calcium retention by the kidney, in association with an increase in the nephrogenous component of excreted cAMP. This is analogous to the effects of excess circulating PTH in HPT and results from the interaction of PTHrP with the PTH1R. Thus in the proximal tubule, stimulation of adenylate cyclase causes internalization of the type II Na^+/Pi^- (inorganic phosphate) cotransporter leading to reduced apical Na^+/Pi^- cotransport, decreased phosphate reabsorption, and phosphaturia (Keusch *et al*., 1998). About 20% of filtered calcium is reabsorbed in the cortical thick ascending limb of the loop of Henle (CTAL) and 15% in the distal convoluted tubule (DCT), and it is here that PTHrP also binds to the PTH1R and, again by a cyclic AMP-mediated mechanism, enhances calcium reabsorption. In the CTAL, at least, this appears to occur by increasing the activity of the Na/K/2Cl cotransporter that drives NaCl reabsorption and also stimulates paracellular calcium and magnesium reabsorption. PTHrP can also influence transcellular calcium transport in the DCT. This is a multistep process involving transfer of luminal Ca^{2+} into the renal tubule cell via the transient receptor potential channel (TRPV5), translocation of Ca^{2+} across the cell from apical to basolateral surface (a process involving proteins such as calbindin-D28K), and finally active extrusion of Ca^{2+} from the cell into the blood via a Na^+/Ca^{2+} exchanger, designated NCX1. PTHrP most likely stimulates Ca^{2+} reabsorption in the DCT primarily by augmenting NCX1 activity via a cyclic AMP-mediated mechanism. In the proximal tubule, PTH can, after binding to the PTH1R, also stimulate the 25-hydroxyvitamin D 1α hydroxylase [1a(OH)ase], leading to increased synthesis of $1,25(OH)_2D$. Consequently increased circulating levels of $1,25(OH)_2D$ are often observed in HPT. In contrast, circulating $1,25(OH)_2D$ levels are often low in patients with HHM (Stewart *et al*., 1980). These apparent discrepancies were not resolved by early animal models of HHM in which circulating $1,25(OH)_2D_3$ levels were high (Sica *et al*., 1983; Strewler *et al*., 1986). Neither was the problem solved by *in vivo* and *in vitro* studies performed with synthetic amino-terminal fragments of PTHrP, which suggested that the peptides had identical bioactivity (Chorev and Rosenblatt, 1994; Fraher *et al*., 1992; Rabbani *et al*., 1988). More recently, continuous infusion of PTH(1–34) and of PTHrP(1–36) into healthy young adults for 2 to 4 days demonstrated that renal $1,25(OH)_2D$ synthesis was stimulated effectively by PTH but poorly by PTHrP (Horwitz *et al*., 2005), supporting the apparent discrepancies between the circulating concentrations of $1,25(OH)_2D$ in HPT and HHM .

Actions in Bone

In bone, the PTH1R is localized on cells of the osteoblast phenotype that are of mesenchymal origin (Rouleau *et al*., 1990). Nevertheless, both PTH and PTHrP enhance osteoclastic bone resorption. This effect of PTH on increasing osteoclast stimulation is indirect, with PTH binding to the PTH1R on preosteoblastic stromal cells (Rouleau *et al*., 1990) and enhancing the production of the cytokine RANKL [receptor activator of nuclear factor (NF) kappaB ligand], a member of the tumor necrosis factor (TNF) family (Blair *et al*., 2007). Simultaneously, levels of a soluble decoy receptor for RANKL, termed osteoprotegerin, are diminished facilitating the capacity for increased stromal cell-bound RANKL to interact with its cognate receptor, RANK, on cells of the osteoclast series. Under the influence of RANKL stimulation, multinucleated osteoclasts, derived from hematogenous precursors committed to the monocyte/macrophage lineage, then proliferate and differentiate as mononuclear precursors, eventually fusing to form multinucleated osteoclasts. These can then be activated to form bone-resorbing osteoclasts. RANKL can drive all of these proliferation/differentiation/fusion/ activation steps although other cytokines, notably monocyte-colony stimulating factor (M-CSF), may also participate in this process.

In comparing HPT and HHM, histomorphometric evaluation of bone biopsies also revealed that whereas catabolic activity was significantly increased in both disorders, discrepancies in bone formation were noted, with decreases in HHM but increases in those with parathyroid disease (Stewart *et al*., 1982). Nevertheless, in animal models of HHM, bone turnover appeared to be coupled (Sica *et al*., 1983; Yamamoto *et al*., 1995). In recent infusion studies in humans however, both PTH and PTHrP appeared to produce inhibition of formation and stimulation of resorption (Horwitz *et al*., 2005).

Actions in Tumor Cells

PTH1R and PTHrP are frequently coexpressed in tumors (Downey *et al*., 1997), and PTHrP has been reported to stimulate cell proliferation in a variety of cancer cell models including MCF-7 breast cancer cells (Hoey *et al*., 2003), SV-40 immortalized breast epithelial cells (Cataisson *et al*., 2000), renal carcinoma cells (Massfelder *et al*., 2004), and colon cancer cells (Shen and Falzon, 2005). The amino-terminal domain of PTHrP via PTH1R has also been reported to inhibit apoptosis (Hastings *et al*., 2003) and to enhance cancer cell adhesion to bone matrix components (Shen and Falzon, 2003). PTHrP has also been shown, by tumors that secrete it, to promote growth and survival by the nuclear localizing domain via an intracrine mechanism (Sepulveda and Falzon, 2002). PTHrP could therefore offer a selective advantage to tumor cells that produce it by contributing to tumor cell survival and growth.

DETECTION OF PTHrP PRODUCED BY TUMORS

Circulating Levels of PTHrP

Shortly after the discovery and characterization of PTHrP, assays were developed to detect this factor in the circulation. Assays that have been employed to measure PTHrP include those recognizing epitopes in the amino-terminal region, the mid-region (Wu *et al*., 1996), and the carboxyl region of PTHrP and those employing two-site assays to measure longer domains. Discrepancies in results among these assays may depend at least in part on the variable molecular nature of PTHrP forms that circulate, either due to variable tumor production or clearance, especially in the presence of altered hepatic and/or renal function in cancer patients. To date the production, circulating nature, and clearance of heterogeneous PTHrP forms has not been nearly as well characterized as has the production, circulating nature, and clearance of heterogeneous PTH forms. Such heterogeneous PTHrP moieties may be differently detected by individual assays and therefore yield different results. Nevertheless certain consistent themes have emerged from the use of PTHrP assays.

The first generalized finding is that circulating PTHrP levels are increased in virtually all patients with HHM (Stewart *et al*., 1980). Second is that although renal cell carcinomas and squamous cell carcinomas have most frequently been associated with HHM, assays capable of directly measuring PTHrP demonstrated a much broader spectrum of tumors associated with excess PTHrP production than was previously considered, including breast, colon, and hematologic cancers (Henderson *et al*., 1990). Furthermore, cases of prostate cancer (Kao *et al*., 1990) and melanoma (Kageshita *et al*., 1999), not typically believed to be part of the HHM spectrum, have been reported in association with high circulating PTHrP levels. Thus, circulating PTHrP levels have been reported as elevated in 50% to 90% of hypercalcemic cancer patients with solid tumors (Budayr *et al*., 1989; Ratcliffe *et al*., 1992; Ralston *et al*., 1990; Burtis *et al*., 1990; Kao *et al*., 1990; Henderson *et al*., 1990; Rankin *et al*., 1997) and in 25% to 60% of such patients with hematologic malignancies (Kremer *et al*., 1996b; Firkin *et al*., 1996). Third, circulating PTHrP concentrations have frequently been reported to be elevated in hypercalcemic patients that have metastasized to the skeleton. Thus, hypercalcemia with breast cancer has as well been classically associated with osteolytic lesions, but assays have generally detected elevated PTHrP in breast cancer, whether or not skeletal metastases were present (Grill *et al*., 1991). These studies therefore suggested that PTHrP as a systemic factor may contribute to the hypercalcemia of tumors that have spread to bone as well as to the hypercalcemia of those that have not.

To date, measurement of serum PTHrP has not however been a useful method for early tumor detection, possibly because of assay limitations related to measurement of PTHrP fragments but more likely because of the advanced stage of tumors that release PTHrP into the circulation (Kremer *et al*., 1996b; Rankin *et al*., 1997). Furthermore, the finding of hypercalcemia in association with suppressed PTH using highly sensitive and specific assays to measure intact PTH has often been taken as presumptive evidence of elevated circulating PTHrP as the cause of the hypercalcemia, in lieu of direct measurement of PTHrP.

In some studies sequential PTHrP measurement has correlated with response to therapy (Henderson *et al*., 1990; Oda *et al*., 1998), but to date, PTHrP has not been widely utilized to monitor disease status.

PTHrP may have value in prognostic evaluation. Thus, PTHrP assays have generally shown that there is a positive correlation between circulating PTHrP levels and more advanced stages of cancer (Rankin *et al*., 1997; Kremer *et al*., 1996b; Firkin *et al*., 1996), and several studies have reported that elevation of serum PTHrP levels was associated with a worse prognosis (Truong *et al*., 2003; Pecherstorfer *et al*., 1994; Hiraki *et al*., 2002). One study, which did not find that serum concentration of PTHrP was associated with a poor prognostic factor, did not correct for confounding factors (Lee *et al*., 1997).

Overall, the clinical significance of PTHrP assays in diagnosis and prognosis requires more extensive evaluation.

PTHrP in Tumor Tissue

PTHrP has also been studied in tumor tissue and is frequently expressed in many tumors including breast cancer (Southby *et al*., 1990; Kohno *et al*., 1994), lung cancer (Brandt *et al*., 1991), and renal cell cancer (Iwamura *et al*.,

1999). The prognostic value of PTHrP expression in breast cancer tissue is uncertain, because PTHrP immunostaining is reported to be either positively or negatively associated with prognosis. Thus, the presence of PTHrP in tissue samples obtained from breast cancer patients has been associated with a more favorable outcome by one group (Henderson *et al*., 2001, 2006), but not by two others (Liapis *et al*., 1993; Yoshida *et al*., 2000). The discrepancies in these findings may perhaps be due to the use of different PTHrP antibodies for immunohistochemical analysis.

PTHrP expression in tumor samples appears to be correlated in some reports with poor prognosis in lung cancer (Hidaka *et al*., 1998), renal carcinoma (Iwamura *et al*., 1999), and colorectal tumors (Nishihara *et al*., 1999).

RELATIONSHIP OF PTHrP-PRODUCING TUMORS WITH THE BONE MICROENVIRONMENT

Up to two-thirds of patients with MAH have bone metastases, and as indicated earlier, elevated circulating levels of PTHrP have been detected in association with hypercalcemic tumors that have spread to bone (Henderson *et al*., 1990). Thus, certain malignancies—notably breast, lung, renal, and thyroid carcinomas, which are frequently associated with hypercalcemia—have as well a strong propensity to spread to bone. PTHrP is thus expressed not only by tissues of tumors associated with hypercalcemia that have not metastasized to bone but also by tumors which have colonized the skeleton (Powell *et al*., 1991; Southby *et al*., 1990; Vargas *et al*., 1992). It seems unlikely that local osteolysis per se will produce sustained hypercalcemia in the absence of a reduction of the renal clearance of calcium caused either by kidney damage or by the calcium-reabsorptive action of a humoral agent such as PTHrP. Therefore PTHrP as an endocrine factor is an important contributor to the pathophysiology of the hypercalcemia, not only of those tumors that have not metastasized to bone but also to those which have already colonized bone.

Furthermore, increasing evidence suggests that it may also be a mediator of focal osteolysis induced by skeletal metastases while acting in a paracrine mode. Evidence for this has been presented in models of MDA-MB-231 breast cancer (El Abdaimi *et al*., 2000; Guise *et al*., 1996) and prostate cancer (Rabbani *et al*., 1999). Tumor cells can thus release PTHrP which acts at both the systemic (primary tumor) and local (skeletal metastases) levels to stimulate osteoclastic bone resorption, at least in part, through the RANKL/RANK/OPG system.

Bone provides a fertile environment for growth of tumors that are metastatic to the skeleton with a well-developed blood supply (in hematopoietic marrow) as a source of nutrients and numerous growth factors that can provide a growth advantage. Thus, bone matrix is a unique storage site of immobilized growth factors such as transforming growth factor (TGF)-β, insulin-like growth factor (IGF) I and II, fibroblast growth factor (FGF)-1 and -2, and platelet-derived growth factors (PDGF). Tumor-derived PTHrP that produces osteolysis results in the release of such active growth factors from the matrix, which facilitates growth of the tumor cells. In turn, growth factors such as TGF-β (Kakonen *et al*., 2002; Yin *et al*., 1999), as well as calcium per se, following their local release during osteoclastic resorption, not only may enhance the growth of tumor cells but also may further stimulate PTHrP production (see Fig. 2). This enhancement of PTHrP production by tumors in the bone microenvironment may explain the observation that breast cancer tissue from skeletal metastases may be more frequently positive for PTHrP expression than from other sites (Powell *et al*., 1991) and that patients with PTHrP-negative primary breast cancers may have PTHrP-positive metastatic lesions (Henderson *et al*., 2006). Although there is no major evidence for an overall facilitatory effect of PTHrP in causing bone metastases, PTHrP may enhance skeletal invasion, once seeding to bone has occurred and micrometastases have been established. In addition to causing osteolysis and thereby facilitating tumor expansion, the enhanced release of PTHrP from such micrometastases may also augment direct effects of PTHrP on tumor growth, survival, and possibly adhesion to bone matrix (Shen and Falzon,, 2003). This process therefore can expand the bidirectional interaction between the tumor cells and bone cells.

OTHER SYSTEMIC MEDIATORS OF MAH

Cytokines

Cytokines such as interleukin IL-1, IL-6, and TNF have been identified as physiological regulators of skeletal metabolism. They are produced by cells in the bone microenvironment, where they regulate their own and each other's expression and activity, as well as that of their cell surface receptors and soluble binding proteins. The overall effect of this complex, interdependent activity is to stimulate bone resorption.

Circulating proinflammatory cytokines most probably contribute to a number of the systemic manifestations of malignancy such as anorexia, dehydration, and cachexia (Ogata, 2000). Mounting evidence also suggests that cytokines released into the systemic circulation by a variety of solid tumors, which often coexpress PTHrP, contribute to the bone destruction associated with MAH. In this respect it is interesting to note that circulating concentrations of IL-6 correlate in a positive manner with tumor burden in patients with squamous and renal cell carcinoma, which represent the two prototypical malignancies associated with hypercalcemia and elevated circulating levels of PTHrP (Costes *et al*., 1997; Nagai *et al*., 1998).

Many other factors, including vascular endothelial growth factor (VEGF) and cytokines such as interleukin-8 and -11, and soluble RANKL (Nagai *et al*., 2000) have been implicated in promoting hypercalcemia of malignancy (Horwitz and Stewart,, 2003). The relative contributions of systemically active PTHrP and cytokines to MAH have been examined in immune-compromised rodents carrying human tumors that overexpress both factors (Nagai *et al*., 1998). Nude rats transplanted with a human squamous carcinoma of the oral cavity (OCC), which was shown to overproduce both PTHrP and IL-6, rapidly developed severe hypercalcemia in association with high circulating levels of both PTHrP and IL-6. Hypercalcemic animals immunized with anti-IL-6 monoclonal antibody demonstrated a complete reversal in the biochemical abnormalities associated with elevated circulating IL-6, but only a small reduction in serum calcium. As measured by quantitative histomorphometry, there was a significant decrease in indices of bone resorption, as well as an increase in the mineral apposition rate in rats that received the neutralizing antibody. These results suggest that although IL-6 contributed to the skeletal abnormalities seen in OCC tumor-bearing rats, its contribution to the hypercalcemic syndrome was minor compared with that of PTHrP.

Using an alternate model, others demonstrated that mice carrying a human esophageal tumor (EC-GI), which coexpresses PTHrP and IL-1, develop a modest elevation in blood calcium (Sato *et al*., 1989). A comparable level of hypercalcemia was observed in normal mice receiving a continuous infusion of IL-1. However, a significant increase in blood calcium was noted in mice that received a minimal daily dose of PTHrP in addition to the IL-1 infusion, suggesting a synergistic effect of PTHrP and IL-1 on bone resorption in this model. This hypothesis was supported by experiments in which addition of a small amount of synthetic PTHrP to the culture medium greatly enhanced ^{45}Ca release from prelabeled mouse bones, in response to recombinant IL-1.

This work using animal models of human disease predicts that PTHrP is the principal mediator of MAH. The hypothesis is further supported by clinical studies in which elevated circulating levels of PTHrP correlate strongly with hypercalcemia in patients with tumors of widely diverse histological origin (Ogata, 2000). No such correlation has been demonstrated for hypercalcemia and elevated circulating levels of cytokines such as IL-6 or IL-1. However, it has been proposed that a systemic increase in PTHrP not only promotes hypercalcemia but also stimulates normal cells to produce factors such as TNF-α, IL-1, IL-5, IL-6, and IL-8 in patients presenting with end-stage malignancy. The observation that infusion of anti-PTHrP antibody into mice with high circulating levels of PTHrP and IL-6 resulted in a prolonged decrease in the concentration of both factors in the bloodstream lends some support to this hypothesis.

1,25-Dihydroxyvitamin D (1,25(OH)$_2$D)

The site of conversion of 25-hydroxyvitamin D [25(OH)D] to its active metabolite, 1,25(OH)$_2$D, by the 25(OH)D 1α-hydroxylase enzyme is known not to be restricted to the kidney. Although the kidney is still recognized as the primary site of circulating 1,25(OH)$_2$D production *in vivo,* several extrarenal sites of 1-α-hydroxylase activity have been identified. These include cells of the hematopoietic and immune systems, as well as cells in many other tissues that give may give rise to solid tumors associated with MAH. In contrast to the systemic role played by kidney-derived 1,25(OH)$_2$D$_3$ in calcium homeostasis, locally produced hormone is thought to regulate cell proliferation and differentiation in normal cells (Holick, 1999) and could modulate the development of neoplastic transformation within these cells.

Elevated serum concentrations of 1,25(OH)$_2$D$_3$ have been reported in some cases of non-Hodgkin's (Breslau *et al*., 1984) and Hodgkin's lymphoma (Jacobson *et al*., 1988), in contrast to the low circulating levels seen in the majority of hypercalcemic cancer patients. This increase in circulating 1,25(OH)$_2$D$_3$ was often seen in the presence of renal impairment, suggesting an extrarenal source of the hormone. Occasionally solid tumors, such as a human small cell lung cancer cell line, NCI H82, have been reported to synthesize a vitamin D metabolite with similar biochemical properties and bioactivity to authentic 1,25(OH)$_2$D$_3$ (Mawer *et al*., 1994). Whether or not the systemic increase in 1,25(OH)$_2$D$_3$ makes a significant contribution to hypercalcemia in these isolated cases remains a question of debate as the same malignancies often also release cytokines and PTHrP, which are known mediators of MAH.

PTH

Although PTH is normally only secreted by the parathyroid glands, authentic ectopic secretion of PTH (ectopic hyperparathyroidism) has been well documented in a variety of histological types of tumors including lung, ovary, thyroid, and thymus and has been associated with hypercalcemia (Nussbaum *et al*., 1990; Yoshimoto *et al*., 1989; Strewler *et al*., 1993; Rizzoli *et al*., 1994). Although this syndrome is well documented, it appears to represent an exceedingly rare event.

EXPERIMENTAL APPROACHES TO CONTROLLING OVERPRODUCTION OR OVERACTIVITY OF PTHrP IN MAH

Although effective antitumor treatment is still the best means to obtain long-term normalization of serum calcium in MAH, a marked reduction of tumor burden often is not

attainable because hypercalcemia generally complicates advanced and refractory cancer. Consequently, volume repletion and bisphosphonates, which inhibit osteoclastic bone resorption, have become the standard of therapy for MAH (Body *et al*., 1998), and newer antiresorptive agents are being developed (Capparelli *et al*., 2000). Bisphosphonates normalize serum Ca levels in more than 90% of patients with MAH, but they appear to be less efficient when hypercalcemia recurs in association with high circulating levels of PTHrP, possibly due to the renal calcium-reabsorbing effects of PTHrP (Rizzoli *et al*., 1999; Onuma *et al*., 2005). Glucocorticoid treatment can be beneficial for steroid-responsive tumors such as lymphoma. The central role of PTHrP in MAH has, however, stimulated the exploration of preventive and therapeutic measures by targeting PTHrP.

Immune Approaches to Reducing PTHrP

Anti-PTHrP neutralizing antibodies have been shown to be effective to reduce skeletal metastasis, bone lesions, and hypercalcemia (Iguchi *et al*., 1996; Guise *et al*., 2002), and humanized anti-PTHrP antibody has been engineered for therapeutic purposes (Sato *et al.*, 2003; Saito *et al.*, 2005).

Because of the high expression of PTHrP in a variety of tumors, PTHrP could also be a common target molecule in specific immunotherapy for patients with many tumor types, particularly those with bone metastases. PTHrP-specific and cancer-reactive cytotoxic T lymphocytes have thus been generated from patients with different tumor types and may play a role in targeting tumor metastases (Arima *et al*., 2005).

Vitamin D-Mediated Repression of PTHrP

$1,25(OH)_2D_3$ is a potent inhibitor of PTHrP in a variety of cellular systems. This inhibitory activity is mediated through the classic VDR, which also mediates the effects of $1,25(OH)_2D_3$ on calcium homeostasis. For this reason, administration of $1,25(OH)_2D_3$ in cases of MAH is counterproductive because of its intrinsic hypercalcemic effects. A concentrated effort has, therefore, been focused on the development of low-calcemic analogues of $1,25(OH)_2D_3$ that will effectively suppress PTHrP production but will not stimulate calcium absorption by the gut, calcium reabsorption by the kidney, and, most importantly, bone resorption. EB1089 and MC903 are two $1,25(OH)_2D_3$ analogues with conservative side-chain modifications that have been used to inhibit PTHrP production *in vitro*, and with variable degrees of success to prevent the hypercalcemic syndrome in models of MAH (Haq *et al*., 1993; Yu *et al*., 1995; El Abdaimi *et al*., 1999, 2000; Nakagawa *et al*., 2005). These studies suggested that low calcemic vitamin D analogues or nonsteroidal activators of the VDR that selectively fail to augment intestinal calcium absorption may prove useful in the management of MAH and in inhibiting skeletal metastases associated with excess PTHrP production.

Inhibition of Signaling to Reduce PTHrP Production or Action

Growth factors acting via receptor tyrosine kinases (RTKs) have been shown to be potent stimuli of PTHrP gene transcription. One of the best characterized signal transduction pathways downstream of RTKs is the Ras/Raf/Mek pathway. Activation of this pathway by growth factors or activated Ras was shown to increase PTHrP expression and release from a variety of cells in culture. Conversely, inhibition of the pathway through pharmacologic intervention, e.g., by a small molecule that acts as a competitive inhibitor of Ras farnesylation (one of the metabolic conversions that is required for Ras to be anchored to the inner aspect of the cell membrane and transmit a signal downstream; Aklilu *et al*., 1997) or by using dominant negative forms of Ras and Raf (Aklilu *et al*., 2000) successfully reduced PTHrP production. This suggested that specific inhibitors of components of the Ras signaling pathway could be used for therapeutic intervention to prevent the hypercalcemic syndrome associated with PTHrP overproduction *in vivo*.

Other small molecule inhibitors of PTHrP have been proposed as therapeutics including two small nucleotide analogues that were reported to inhibit production of PTHrP by tumor cells and reduce bone lesions with higher survival rates in animal models (Gallwitz *et al*., 2002).

Because PKA is the major signaling pathway that mediates PTHrP-induced production of RANKL by osteoblasts, antagonists against PKA could be another promising target.

Antisense Inhibition and RNA Interference of PTHrP Production

An alternative approach for diminishing PTHrP overproduction in malignancy employed antisense technology to inhibit endogenous PTHrP expression and diminish hypercalcemia. Thus the use of antisense PTHrP (Rabbani *et al*., 1995) or the use of antisense furin (Liu *et al*., 1995) to reduce bioactive PTHrP in MAH models *in vivo* led to diminished hypercalcemia, decreased tumor cell proliferation, and prolonged survival of the host animals. Newer techniques using small interfering RNA (siRNA) may prove useful in the future in furthering these initial approaches.

Overall these studies suggest that knowledge of the regulation of PTHrP production, processing and action may identify targets that may be useful for the development of agents to reduce circulating concentrations of bioactive PTHrP *in vivo* and to diminish hypercalcemia. Furthermore

such agents could prove beneficial in inhibiting the production of PTHrP by tumors that might diminish the establishment and growth of metastatic lesions and potentially of primary tumors.

INTRODUCTION

As primary tumors grow, they frequently metastasize to distant organs. Patients who succumb to cancer usually die because of metastases. In many cancer patients, these metastases cause more serious effects than the primary tumor itself. Tumors such as lung, prostate, breast, kidney, and thyroid frequently metastasize to bone. Complications of skeletal metastasis include fractures, bone pain, hypercalcemia, and cachexia. Bone metastases are especially prevalent in patients with prostate and breast cancer, in which a large proportion of the patients develop skeletal metastases at late stages in the disease course. Most commonly, the tumor cells metastasize to highly vascularized areas of the skeleton, such as the vertebral column, ribs, and long bones (Kakonen & Mundy, 2003). These metastases can either be osteolytic (bone destructive) or osteoblastic (bone forming). Prostate tumors tend to produce mixed lesions while breast tumors are frequently osteolytic (Keller & Brown, 2004).

The skeletal complications of malignancy have received considerable attention in recent years, in part due to the widespread use of bisphosphonates for the treatment of localized osteolysis associated with multiple myeloma and solid tumors. It is interesting to note that there has been considerable evolution in research focus over the past 30 years in the three major manifestations of cancer on bone, namely hypercalcemia, osteoporosis and metastatic bone disease (including the osteolysis associated with myeloma). In the 1970's and 1980's, the major focus was on hypercalcemia which was often difficult to manage and whose cause was unknown. In the 1990's and first decade of the 21st Century, attention shifted to metastatic bone disease, and its importance as the cause of many clinical manifestations of advanced malignancy. In the next decade, it may be that major attention will also be focused on osteoporosis associated with cancer, which is becoming increasingly more prevalent, in part due to patients living longer with advanced disease, and in part related to therapies aimed at slowing tumor growth which also have effects on the skeleton.

In this chapter, we will review osteolytic bone disease and osteoporosis, with major attention on osteolytic and osteoblastic bone disease. Our plan is to focus primarily on myeloma, breast cancer, prostate cancer, and myeloma as true malignancies which exemplify the spectrum of bone changes that occupy advanced cancer.

FREQUENCY OF METASTATIC BONE DISEASE

Metastatic bone disease occurs commonly in solid tumors of the breast, prostate and lungs. These are the three commonest solid tumors that affect humankind, and they are usually associated with bone metastasis at the stage that the patient has advanced disease. In most patients with breast and prostate cancer, essentially all patients will have bone metastases when the disease is advanced, if methods are used that detect micrometastases. Patients with metastatic bone disease due to these solid tumors have a marked impairment of their quality of life due to skeletal-related events such as intractable bone pain, bone fragility, and

*Corresponding author: Gregory R. Mundy, M.D., Vanderbilt Center for Bone Biology, 1235 MRB IV, Nashville, TN 37232-0575. Voice: 615-322-6110; fax: 615-343-2611. gregory.r.mundy@vanderbilt.edu

susceptibility to pathologic fracture. These patients can be expected to have a major skeletal-related event (episodes of intractable bone pain, hypercalcemia, pathologic fracture) every three to four months when untreated with specific bone-active agents.

Eighty percent of patients with bone metastases have breast or prostate cancer.

BREAST CANCER AND BONE METASTASIS

Spectrum of Metastases in Breast Cancer

Breast cancer metastasizes to bone frequently, as noted above, and usually causes extensive osteolysis. However, there is also usually a weak osteoblastic response demonstrated in patients by a small increase in serum alkaline phosphatase. In about 20 percent of all patients with metastatic bone disease due to breast cancer, this osteoblastic response is markedly enhanced and the patient has an osteoblastic metastasis easily recognized radiologically.

The osteoblastic metastasis of breast cancer is better studied than that of prostate cancer because the preclinical models to study the process are better developed.

In this section, we will discuss the osteolytic and osteoblastic process in breast cancer, and the important cell-cell interactions that occur in the bone microenvironment.

Tumor-Bone Interaction: The "Vicious Cycle"

The presence of many growth factors present in the bone matrix provides a fertile environment for tumor cells to metastasize to bone. Once tumors establish in bone, they secrete factors that stimulate bone resorption. As bone is destroyed by the tumor cells, these growth factors are released from the bone matrix and stimulate tumor growth. As these factors stimulate tumor cell proliferation, more osteolytic factors are produced by the tumor leading to more bone resorption. This in turn causes the release of growth factors and the process continues as a vicious cycle of bone destruction and tumor growth.

Some of the major factors, but likely not the only ones, contributing to this cycle of bone destruction are tumor-produced parathyroid hormone-related peptide (PTHrP) and bone-derived transforming growth factor β (TGF-β). TGF-β released from the bone matrix during osteolysis has been shown to stimulate tumor PTHrP production

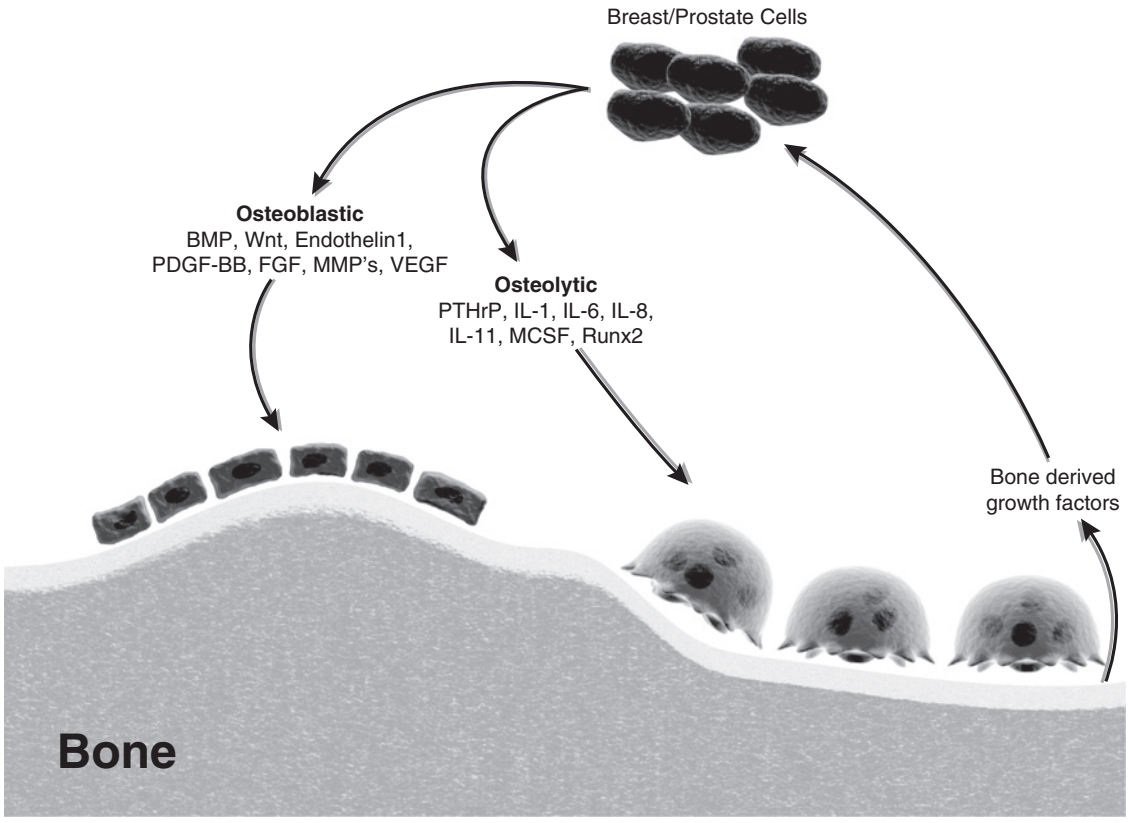

FIGURE 1 Factors implicated in the bone disease associated with breast and prostate cancer. When breast or prostate tumors metastasize to bone, factors secreted by the tumor cells disrupt normal bone remodeling. This alteration in bone remodeling can result in a spectrum of responses from osteolytic bone destruction to osteoblastic new bone formation depending on the factors produced by the tumor cells.

(Yin *et al.*, 1999). This relationship has been clearly shown using MDA-MB-231 cells transfected with a dominant-negative TGF-β receptor type II, which leaves the cells non-responsive to TGF-β (Yin *et al.*, 1999). In these cells the production of PTHrP was not enhanced in the bone microenvironment and there was a significant reduction in tumor-induced osteolysis (Yin *et al.*, 1999). The regulation of PTHrP by TGF-β was later demonstrated to be through both a smad-dependent and MAPK pathway (Kakonen *et al.*, 2002). In addition, recent experiments in several laboratories have indicated that inhibiting TGF-β inhibits osteolysis and tumor growth in bone (Bandyopadhyay *et al.*, 2006; Ehata *et al.*, 2007).

Many growth factors are stored in bone including bone morphogenetic proteins (BMPs), heparin-binding fibroblast growth factors, platelet derived growth factor, and Insulin like growth factor I and II (Hauschka, Mavrakos, Iafrati, Doleman, & Klagsbrun, 1986). These factors, like TGF-β, are released during bone resorption and likely contribute to tumor cell growth. While these and other factors likely play a role in the vicious cycle of bone destruction, the majority of studies have focused on the role of TGF-β.

Factors Responsible for Osteolysis

RANKL

Tumor cells that have established in the bone microenvironment secrete factors that stimulate osteoclastic bone resorption. One of the major factors responsible for this increased bone resorption is PTHrP, which can stimulate osteoblast expression of receptor activator of NF-κB ligand (RANKL) (Chikatsu *et al.*, 2000; Kitazawa & Kitazawa, 2002; Martin & Gillespie, 2001; Michigami, Ihara-Watanabe, Yamazaki, & Ozono, 2001; Thomas *et al.*, 1999). RANKL then binds to its receptor expressed on the osteoclasts, RANK. In addition, the presence of tumor cells frequently leads to a reduction in the expression of the decoy receptor for RANKL, osteoprotegerin (OPG) (Thomas *et al.*, 1999). Alteration of the expression of these proteins by the tumor cells results in an overall increase in RANKL/RANK binding and activation, often accompanied by a decrease in OPG, and a subsequent increase in osteoclast activation (Dougall & Chaisson, 2006; Wittrant *et al.*, 2004). Clinical trials using OPG or related molecules (RANK:Fc or RANKL antibodies) have successfully inhibited osteolysis caused by tumor cells that have metastasized to bone (Body *et al.*, 2003).

PTHrP

Parathyroid hormone-related peptide is expressed by tumor cells (Guise *et al.*, 2002; Powell *et al.*, 1991). Release of PTHrP by tumor cells stimulates RANKL-mediated osteoclastic bone resorption (Kitazawa & Kitazawa, 2002; Martin & Gillespie, 2001; Powell *et al.*, 1991; Thomas *et al.*, 1999). The production of PTHrP is regulated by TGF-β released from the resorbing bone (Kakonen *et al.*, 2002; Yin *et al.*, 1999) as described above. Factors which regulate PTHrP production are therefore important potential mediators of bone resorption. This was demonstrated by studies using PTHrP antibodies. Tumor-bearing mice which were treated with PTHrP displayed a reduction in tumor burden and osteolysis (Guise *et al.*, 1996). In addition, the chemotherapeutic agent, 6-thioguanine, which reduces PTHrP promoter activity, decreases tumor burden and osteolysis when used to treat tumor-bearing mice (Gallwitz, Guise, & Mundy, 2002).

Hedgehog Signaling

We have recently demonstrated that the hedgehog (Hh) signaling molecule Gli2 regulates PTHrP production and that overexpression of Gli2 leads to an increase in osteolysis (Sterling *et al.*, 2006). In addition, increasing evidence suggests that Hh signaling plays an important role in tumor invasion and metastasis (Mori, Okumura, Tsunoda, Sakai, & Shimada, 2006; Yanai *et al.*, 2007; Zhou & Hung, 2005). In tumor cell types such as prostate, in which Hh signaling is active at the primary site, inhibiting Hh signaling effectively inhibited tumor cell growth (Karhadkar *et al.*, 2004; Shaw & Bushman, 2007), indicating that this may be a potential method for inhibiting tumor cells that have metastasized to bone.

Interleukins

While tumor-produced PTHrP has been clearly shown to play a critical role in the activation of RANKL and subsequent osteolysis (Thomas *et al.*, 1999), tumor cells can secrete other factors that stimulate osteoclasts. One such family of cytokines is the Interleukins. IL-1, 6, 8, and 11 are each frequently produced by tumor cells and can lead to osteolysis (Bendre, Gaddy, Nicholas, & Suva, 2003; Bendre *et al.*, 2005; M. S. Bendre *et al.*, 2003). Of these, IL-8 expression has been best described to stimulate tumor-induced osteolysis. Studies have demonstrated a positive correlation in some human breast tumors between IL-8 expression and increased frequency of bone metastases in patients. Furthermore, they have demonstrated that IL-8 stimulates osteoclast differentiation and activity *in vitro* (M. S. Bendre *et al.*, 2003).

M-CSF

Another factor secreted by some tumor cells that can stimulate osteoclast formation is macrophage colony-stimulating factor (M-CSF). Breast cancer cells have been shown to secrete M-CSF, leading to an enhancement of RANKL expression (Mancino, Klimberg, Yamamoto, Manolagas, & Abe, 2001). Furthermore, expression of M-CSF in cancer patients has been correlated with poor prognosis. Analysis

of patient samples has indicated that M-CSF levels are dramatically higher in men with prostate cancer that has metastasized to bone and in women with advanced metastatic breast cancer than to normal patients or patients without metastases (McDermott *et al.*, 2002). These data indicate that production of M-CSF may play a key role in the stimulation of osteolysis in some tumor types.

Other Factors

Other factors that are associated with osteolysis include Runx2, a critical factor for normal bone development, and the matrix metalloproteinases. Runx2 is expressed in mammary epithelial cells and inhibition of Runx2 expression by tumor cells decreases the ability of tumors to induce osteolysis (Javed *et al.*, 2005; Pratap *et al.*, 2006; Shore, 2005). This is likely to be partially due to the ability of Runx2 to regulate the expression of MMP-9 (Pratap *et al.*, 2005). The matrix metalloproteinases are a family of extracellular matrix degrading proteins. MMP-9 produced by the tumor cells, and not the micro-environment, leads to tumor growth and osteolysis of prostate tumors residing in bone (Bonfil *et al.*, 2006; Nabha *et al.*, 2006). Alternatively, MMP-7 in the micro-environment contributes to osteolysis through activation of RANKL (Lynch, Crawford, Matrisian, & McDonnell, 2004; Lynch *et al.*, 2005). Despite the promising pre-clinical trials, MMP inhibitors have not been successful in patients, probably related to non-specificity of the inhibitors (Coussens, Fingleton, & Matrisian, 2002; Wagenaar-Miller, Gorden, & Matrisian, 2004).

In addition to the tumor-produced factors described above, several other factors are also be produced by tumor cells that are known to stimulate osteoclast activity. Through screening conditioned media of cells known to stimulate osteoclastic bone resorption, IL-1, IL-6, M-CSF, GF-CSF, TGF-β1, TGF-β2, and PTHrP (Pederson, Winding, Foged, Spelsberg, & Oursler, 1999) were identified as factors secreted by the tumor cells which stimulate osteoclast activity. While some of these have been well-described and are discussed in detail above, little is known about the relative roles of others of these factors. In addition, this screening experiment indicated that no single factor stimulated the osteoclasts as well as the complete media (Pederson *et al.*, 1999). This and other experiments have suggested that production of multiple factors by the tumor cells may be required for the total stimulation of osteoclast activity seen at the tumor site (Kang *et al.*, 2003).

Factors Responsible for Osteoblastic Metastases in Breast Cancer

At autopsy, approximately 90% of patients with prostate cancer have skeletal metastases, with osteoblastic metastases accounting for the majority of the lesions (Vessella & Corey, 2006). While predominantly osteoblastic, prostate tumors have an osteolytic component that in many cases is required for the establishment of the osteoblastic component (Keller & Brown, 2004; Zhang *et al.*, 2001). This has been in part demonstrated by the effectiveness of inhibiting prostate tumor growth in bone by using drugs that inhibit bone resorption such as bisphosphonates and OPG (Vessella & Corey, 2006; Zhang *et al.*, 2001). Once established in bone prostate tumor cells secrete osteoblastic factors which stimulate bone formation (Hall, Kang, MacDougald, & Keller, 2006; Koeneman, Yeung, & Chung, 1999). Some of the major mediators may include BMPs, Wnt, and Endothelin-1 (Feeley, Krenek *et al.*, 2006; Hall *et al.*, 2006; Yin *et al.*, 2003).

BMP

Bone morphogenetic proteins are major regulators of bone formation, and prostate tumor cells frequently express several of the BMPs (Bentley *et al.*, 1992; Koeneman *et al.*, 1999). Of the BMP family BMP 2, 7, and 6 have been associated with osteoblastic metastases (Bentley *et al.*, 1992; Feeley, Krenek *et al.*, 2006; Hauschka *et al.*, 1986; Masuda, Fukabori, Nakano, Shimizu, & Yamanaka, 2004). Additionally, inhibiting BMP using the BMP inhibitor Noggin decreases the osteoblastic component of mixed lesions (Feeley, Liu *et al.*, 2006).

Wnt Signaling

The Wnt pathway is essential for normal bone formation, and may also be involved in tumor invasion and metastasis (Vessella & Corey, 2006; Zhou & Hung, 2005). Tumors that induce osteoblastic metastases have been demonstrated to secrete Wnt proteins. Furthermore, mixed prostate lesions initially produce the Wnt inhibitor DKK-1, which is decreased as the tumors transition into an osteoblastic phase (Clines *et al.*, 2007; Hall *et al.*, 2006).

Endothelin-1

Endothelin-1 is a factor secreted by osteoblastic tumor cells and has also been shown to regulate the expression of DKK-1, indicating an important relationship between these two pathways (Clines *et al.*, 2007; Koeneman *et al.*, 1999; Mohammad & Guise, 2003). Osteoblastic breast and prostate tumor cells express ET-1, which stimulates bone formation and osteoblast proliferation (Mohammad & Guise, 2003).

Other Factors

While these are the major pathways demonstrated to play important roles in osteoblastic metastases, other pathways that may be involved include factors that activate osteoblast activity including PDGF-BB (Mehrotra, Krane, Walters, & Pilbeam, 2004; Yi, Williams, Niewolna, Wang, & Yoneda, 2002), VEGF (Guise *et al.*, 2005; Shimamura *et al.*, 2005), FGFs (Matuo *et al.*, 1992; Valta *et al.*, 2006), and urokinase (Achbarou *et al.*, 1994; Festuccia *et al.*, 1997;

Rabbani, Harakidas, Davidson, Henkin, & Mazar, 1995; Rabbani, Rajwans, Achbarou, Murthy, & Goltzman, 1994). Other molecules that may be important are Prostate Specific Antigen (Goya *et al.*, 2006) and OPG (Corey *et al.*, 2005; Kiefer *et al.*, 2004; Zhang *et al.*, 2001), which inhibits bone resorption.

Tumor micro-environment and the pre-metastatic niche

As time has progressed and this field advanced, it has become clear that the vicious cycle concept is exceedingly more complex than originally thought. In addition to the tumor cell interactions with the bone matrix, other cells such as the immune cells, osteoblasts, osteoclasts, and precursor cells all play important roles in bone metastasis and developing the appropriate micro-environment for the growth of tumor cells in bone.

Recent work has focused on the movement of bone marrow-derived precursor cells to sites of tumor cell metastases which help establish a niche environment for tumor cell growth prior to the tumor cells arriving at the metastatic site. One group refers to these cells as bone marrow-derived cells, and has demonstrated that these cells are important for malignant transformation, migration, and tumor vascularization (Kaplan, Psaila, & Lyden, 2006, 2007; Kaplan, Rafii, & Lyden, 2006; Kaplan *et al.*, 2005). These studies have shown that these hematopoietic bone marrow progenitors arrive at sites of metastasis before the tumor cells and secrete factors that allow tumor cells to grow at these sites at a later time (Kaplan *et al.*, 2005). Furthermore, they have demonstrated that VEGFR1 expression by these cells is critical for later metastasis progression, and that factors secreted by tumor cells help determine where these cells and later the tumor cells grow (Kaplan *et al.*, 2005). Other groups have reported similar finding that immune precursor cells similarly colonize in metastatic target organs, and secrete factors that are important for establishing metastasis (Yang *et al.*, 2004).

In addition to these bone marrow precursor cells, immune cells such as the B and T cells can influence bone metastases. For example, tumor-produced factors such as PTHrP, IL-7, and IL-8 may recruit T-cells to sites of tumor in bone (Fournier, Chirgwin, & Guise, 2006). Once recruited, factors secreted by the T-cells may then stimulate bone resorption (Fournier *et al.*, 2006). Other immune cells such as the Natural Killer cells and B cells are also likely to play a role in the vicious cycle of bone metastasis.

PROSTATE CANCER AND BONE METASTASIS

Prostate cancer frequently metastasizes to bone and studies have shown that approximately 90% of the men who die from prostate cancer will have evidence of bone metastases (Bubendorf *et al.*, 2000; Keller & Brown, 2004). These observations suggest that metastatic prostate cancer cells (seed) have a high affinity for the soil of the bone although the pattern of blood flow from the prostate to the spinal lumbar region via the Batson's plexus may also favorably contribute to prostate to bone metastasis. However, vascular flow does not explain why in more advanced cases of prostate cancer, the bone remains almost exclusively the target for metastatic prostate cancer cells. A typical hallmark of prostate metastases in the bone is the robust osteoblastic response induced by the tumors that are often easily discernable by x-ray. However, based on clinical observations, prostate cancers are not solely blastic but often have a lytic compartment to the lesion suggesting that osteolysis also plays a functional role in prostate cancer progression in the bone (Roudier *et al.*, 2004; Vinholes, Coleman, & Eastell, 1996). As a consequence, the humoral factors involved in breast tumor induced osteolysis can also have a role in prostate tumor progression in the bone.

The molecular mechanisms that govern prostate osteotropism are key to understanding why prostate tumor cells home to bone and how the prostate tumor cells interact with the myriad of cells present in the bone in order to support metastatic progression in the bone. The development of several animal models that reflect the human clinical scenario of prostate tumor induced osteolytic and osteoblastic response have been crucial in determining the contribution of humoral factors involved in prostate cancer progression in the bone. Many models have used the human prostate cancer cell lines PC-3 and LnCAP and studies have found that the intra-cardiac or intratibial injection of these cells into various immunocompromised mice result in the growth of prostate tumors in the bone (Singh & Figg, 2005). However, these tumor cell lines typically induce osteolytic lesions which do not reflect the pathology of human prostate to bone metastases but do allow for the study of how prostate tumor cells can induce the recruitment and activation of osteoclasts at the tumor bone interface. Interestingly, several investigators have derived cell lines from these parental cell lines which upon hematogenous or direct inoculation into the bone can generate mixed lesions (Singh & Figg, 2005). A number of transgenic murine models of primary prostate cancer progression also exist. Until recently, bone metastasis in these models had not been reported. However, using the probasin promoter, transgenic mice expressing the SV40 antigen and the serine proteinase hepsin in the prostate have been shown to develop prostate cancer and demonstrate metastasis to the bone, lung and liver and therefore may allow for the study of prostate tumor homing to the bone (Klezovitch *et al.*, 2004).

Several rat prostate cancer cell lines have been described that can induce osteoblastic and osteolytic type metastases. The use of rat prostate cancer cell lines allows for the study of prostate tumor-bone interaction in syngeneic rats thereby

ensuring that potential contributions of B and T cells to the process can be considered. Rat cell lines used include, the PA-III cell line which when deposited over the calvaria of Lobund-Wistar rats can induce osteolysis and a robust osteoblastic response (Pollard, 1996), and the MAT-Ly-Lu cell line which interestingly, when intravenously injected into Copenhagen rats induces systemic osteolytic lesions but when inoculated directly into the bone induces an osteoblastic response (Geldof & Rao, 1990). Other rat cell lines exist which mainly induce osteolytic lesions such as the Walker 256, 13762 and cSST2 cell lines (Blouin, Basle, & Chappard, 2005). Recently, Lynch *et al.*, have also have demonstrated that the transplantation of moderately differentiated primary prostate adenocarcinoma to the calvaria of F344 rats or immunocompromised mice induces an osteoblastic and osteolytic lesion that resembles the pathology of human prostate cancer progression in the bone.

Using these models, recent studies have begun to elucidate the humoral vocabulary that prostate cancer cells employ to communicate with bone stromal cells and vice versa. These factors include TGFβ, BMP, Wnts, ET-1, RANKL, vascular endothelial growth factor (VEGF), parathyroid hormone related peptide (PTHrP) and matrix metalloproteinases (MMPs) and the role of each in prostate cancer metastases is described herein:

TGF-β

The bone matrix represents that largest store of TGF-β in the body. During skeletal development, TGF-β is synthesized and incorporated into the bone matrix by osteoblasts. TGF-β is sequestered into the bone matrix in an inactive state via latency associated peptide (LAP) and latent TGF-β binding proteins (LTBPs) that are susceptible to cleavage by several MMPs (Saharinen, Hyytiainen, Taipale, & Keski-Oja, 1999). TGF-β effects are mediated by the TGF-β receptor (TβR) family which is comprised of three members, TβRI, -II and -III (Bierie & Moses, 2006). These receptors are expressed on both osteoblasts and osteoclasts (Janssens, Ten Dijke, Janssens, & Van Hul, 2005). While the role for TGF-β in regulating osteoblast function has been well described, TGF-β has also been shown to be important in mediating osteoclast differentiation and activation (Chambers, 2000; Fox, Haque, Lovibond, & Chambers, 2003; Quinn *et al.*, 2001). TGF-β is endogenously expressed at low levels in normal prostate tissue and in non-pathological scenarios, activation of the TGF-β signaling pathway promotes apoptosis (Bello-DeOcampo & Tindall, 2003). However, during prostate cancer progression, a number of studies have shown that TGF-β is often overexpressed in comparison to normal prostate (Zhu & Kyprianou, 2005). Furthermore, this increase in expression of the ligand has been correlated to decreased expression of the principle TβR, TβRII. This alteration in the TGF-β pathway is associated with more invasive hormone refractory prostate tumor phenotype (Guo, Jacobs, & Kyprianou, 1997). In the bone microenvironment, prostate tumor derived TGF-β can have several effects on the bone stromal cells including, inhibiting the proliferation and promoting the differentiation of bone marrow endothelial cells and in promoting the proliferation of osteoblast precursor cells and the expression of RANKL in the osteoblast cells in addition to the prostate cancer cells themselves (Barrett *et al.*, 2006; Zhang *et al.*, 2004). Therefore, the initial exposure of the bone stroma to tumor derived TGF-β can greatly alter normal bone matrix homeostasis and result in the proliferation and/or activation of several cell types such as the osteoblasts and osteoclasts. In addition, metastatic prostate tumor induced osteolysis can mediate TGF-β release from the bone matrix and further accelerate the 'vicious cycle'.

BMPs

Over 30 members of the BMP family exist but to date functions with respect to modulating osteoblast function and bone formation have been best described for BMP-2 and BMP-7. BMPs mediate their action via signaling through the BMP receptors (BMPR-IA, BMPR-IB and BMPR2). Several of the BMPs can be inhibited by Noggin and Gremlin which bind directly to the BMP and prevent the interaction of the ligand with the cognate receptor (Chen, Zhao, & Mundy, 2004). Prostate tumors have been shown to express BMPs (BMP-2, BMP-4 and BMP-7) (Yang, Zhong, Frenkel, Reddi, & Roy-Burman, 2005). Prostate tumor cells have also been shown to express BMPR-IB and BMPR-II (Yang *et al.*, 2005; Ye *et al.*, 2007) and in a similar manner to the TGF-β pathway, as the prostate tumors become more invasive, there is a decrease in BMP receptor expression. Subsequent studies have shown that the BMPs may regulate the migration and invasion of prostate tumor cell line (Feeley, Liu *et al.*, 2006). The expression of BMPs and the BMP receptors in primary prostate cancer is intriguing and may play an important role in the seeding of the tumor cells to the soil of the bone, where the BMP signaling pathway is essential for bone function. In this regard, the overexpression of noggin in the prostate tumor cell line, PC-3 significantly reduced the size of the osteolytic lesions induced by the tumor but whether the inhibition of BMP in the surrounding bone cells or tumor cells is responsible for the decrease in prostate tumor progression remains to be determined (Feeley, Liu *et al.*, 2006).

TGF-β and BMPs influence osteomimicry by prostate tumor cells

Perhaps one of the most novel recent advancements in understanding the progression of prostate cancer in the bone involves the concept of 'osteomimicry' whereby metastatic prostate tumor cells acquire an osteoblast-like phenotype in response to bone derived humoral factors

(Chung, Baseman, Assikis, & Zhau, 2005). Heightened TGFβ and BMP signaling in the bone can induce the expression of the Runx transcription factor family in tumor cells that regulate several bone related genes such as RANKL, OPG, OPN and BSP (Banerjee *et al.*, 2001; Barnes *et al.*, 2003; Enomoto *et al.*, 2003; Inman & Shore, 2003). The induction of a genetic program controlling the expression of bone related genes in the prostate tumor cells in turn can impact the behavior of the surrounding bone cells and assist in driving the 'vicious cycle'.

Wnts

Wnts are critical mediators of bone formation and therefore, alterations in Wnt signaling by metastatic prostate tumor cells in the bone can have profound effects on osteoblast function (Hall & Keller, 2006). Wnts act by binding to Frizzled and the co-receptor and Lrp5/6. The interaction of Wnt with its receptor complex ultimately results in the stabilization and nuclear translocation of the adherens junction protein, β-catenin. β-catenin has been shown to be an important regulator of genes such as Runx (Gaur *et al.*, 2005). Primary prostate tumors and cell lines have been shown to express Wnts and therefore, metastatic prostate tumor cells in the bone environment can induce osteoblast differentiation, hence bone formation (Hall, Bafico, Dai, Aaronson, & Keller, 2005). Interestingly, inhibitors of Wnt signaling such as dick kopf-1 (DKK-1) prevent ligand interaction with the Frizzled/Lrp5/6 pathway are also expressed at high levels by prostate tumor cells in the bone (Hall & Keller, 2006). These studies suggest that the expression of DKK-1 early during prostate tumor progression in the bone prevents Wnt signaling but increases RANKL expression in osteoblasts resulting in enhanced osteoclast maturation and bone degradation. Subsequently as the prostate cancer cells grow in the bone levels of DKK-1 decrease allowing for Wnt mediated osteoblastogenesis and bone formation. Other inhibitors of the Wnt signaling also exist in the bone environment such as sclerostin, an osteocyte derived factor. Although a weak antagonist of BMP signaling sclerostin has recently has been shown to bind to Lrp5 and prevent Wnt interaction with Frizzled (Li *et al.*, 2005; Winkler *et al.*, 2003). Therefore, the role of sclerostin in attenuating Wnt signaling may play an important role prostate tumor induced osteoblastic and osteolytic changes in the bone.

Endothelin-1 (ET-1)

ET-1, originally identified as a potent regulator vasoconstriction (Yanagisawa *et al.*, 1988), is a powerful stimulator of osteoblast function mediates this activity by signaling through the ET receptor ET_A (Takuwa, Ohue, Takuwa, & Yamashita, 1989; Van Sant *et al.*, 2007). Interestingly, prostate and breast cancer cell lines that induce an osteoblastic response in the bone have been shown to express high levels of ET-1 (Nelson *et al.*, 1995; Yin *et al.*, 2003). Using the ZR-75-1 breast cancer cell line which induces mixed bone lesions, Yin *et al.*, found that blocking tumor derived ET-1 action using a receptor neutralizing antibody or a small molecule inhibitor of ET_A prevented tumor induced osteoblastic and osteolytic changes in the bone (Yin *et al.*, 2003).

Receptor activator of nuclear κ B ligand (RANKL)

RANKL is a type II transmembrane protein that is a member of the tumor necrosis factor (TNF) family of cytokines that is an essential mediator of osteoclast activation (Kong *et al.*, 1999). RANKL mediates its effects by binding to the receptor activator of nuclear kappa B (RANK). Furthermore, osteoprotegerin (OPG), a soluble decoy molecule can prevent the RANKL/RANK interaction by binding to RANKL (Simonet *et al.*, 1997). In breast tumor induced osteolysis, studies have shown that tumor derived PTHrP can stimulate RANKL expression in osteoblasts and that the presence of RANKL on the osteoblast cell surface drives osteoclast maturation (Mundy, 2002). Interestingly, normal human prostate and primary prostate tumors have been shown to endogenously express RANKL although the function of RANKL in the prostate remains to be determined (Brown *et al.*, 2001). However, the expression of RANKL by prostate to bone metastases could have major implications for prostate tumor induced osteolysis. These studies suggest that the human prostate cancer cell line LnCAP and the LnCAP derivative C4-2B which causes mixed lesions in the bone expressed endogenous RANKL and that the osteolysis induced by the C4-2B cell line was prevented by treating mice with C4-2B induced bone lesions with OPG (Zhang *et al.*, 2001). Surprisingly, the decrease in osteolysis was concomitant with a decrease in the osteoblastic response which suggests that the prostate tumor induced osteoblastic response is dependent on osteolysis. Furthermore, the direct interaction of the prostate tumor cells with osteoclasts at the tumor bone interface was demonstrated (Zhang *et al.*, 2001). These studies raise the interesting question that in the context of the tumor: bone microenvironment, metastatic prostate tumor cells may be able to act as surrogate osteoblasts and circumvent the necessity for osteoblast derived RANKL by interacting directly with the immature osteoclast cells in order to mediate localized osteolysis.

Vascular Endothelial Growth Factor (VEGF)

The VEGF family encompasses a number of ligands (VEGF-A, -B, -C, -D and –E as well as placental growth factor) with VEGF-A being the most studied family member. VEGF activity is mediated by the VEGF receptors VEGFR-1/Flt-1, VEGFR-2/KDR, VEGFR-3/Flt-4, and

neuropilin-1 and 2 (Hicklin & Ellis, 2005). VEGF is a powerful stimulator angiogenesis and is an important requirement for tumor cell growth since in order for the tumor cell to grow beyond a certain size angiogenesis is required (Fidler, 2002). Several studies have shown that primary prostate cancers and prostate tumor cell lines express VEGF and the VEGF receptors and that in addition to contributing to angiogenesis, VEGF may also contribute to the migratory and metastatic phenotype of the cancer cells (Chen, De, Brainard, & Byzova, 2004; Muir, Chung, Carson, & Farach-Carson, 2006). Interestingly, the expression of VEGF by prostate cancer cells in the bone can also impact the behavior of the surrounding host cells. Rosenblum *et al.*, recently demonstrated using an inhibitor of the VEGF receptors that VEGF was important for osteoclast maturation both *in vitro* and *in vivo* (Mohamedali *et al.*, 2006). Keller *et al.*, have also demonstrated that in the bone environment, BMP-7 induced the expression of VEGF-A in the tumor cells and that VEGF-A subsequently contributed to osteoblast differentiation and mineralization (Dai *et al.*, 2004). Therefore, in addition to regulating angiogenesis, the presence of VEGF in the bone may also regulate prostate tumor cell migration, osteoclast and osteoblast function.

Parathyroid hormone-related peptide (PTHrP)

PTHrP is a potent mediator of metastatic breast tumor induced osteolysis (Mundy, 2002). Interestingly, PTHrP is expressed by primary prostate tumors where it is thought to have a role in cell survival and proliferation (Dougherty *et al.*, 1999; Guise, 2000; Ye, Falzon, Seitz, & Cooper, 2001). Studies have demonstrated PTHrP expression does not play a critical role in the homing of prostate tumor cells to the bone but in the bone environment, the contribution of tumor derived PTHrP to osteoclast activation cannot be ruled out (Blomme *et al.*, 1999).

Matrix Metalloproteinases

The MMPs are comprised of a family of at least 24 related proteinases that collectively are capable of degrading the entire extracellular matrix (ECM) and are often induced in stromal cells in response to the tumor (Lynch & Matrisian, 2002). While MMPs have been associated with primary prostate tumor development and metastasis, the role of MMP expression by prostate cancer tumor cells in the bone is less clear (Lokeshwar, 1999). In the bone, osteoclasts have been shown to be a rich source of MMPs which is not surprising given the role of these proteinases in ECM degradation (Delaisse *et al.*, 2003; Delaisse *et al.*, 2000). Osteoclast derived MMP-1, MMP-13 and cathepsin K are the principle mediators of fibrillar type I collagen degradation, the major constituent of the bone ECM. The resultant fragments of collagen generated by MMPs and cathepsin K have been identified as useful prognostic serum markers of prostate to bone metastasis (Fukumitsu *et al.*, 2002; Garnero *et al.*, 2003). The non-collagenous bone matrix proteins osteopontin (OPN) and bone sialoprotein (BSP) are also modulated by MMPs and the presence of OPN and BSP in the serum have been shown to be prognostic for patients with prostate to bone metastasis (Fedarko, Jain, Karadag, Van Eman, & Fisher, 2001; Ramankulov, Lein, Kristiansen, Loening, & Jung, 2007). MMP-3 and MMP-7 have been shown to mediate OPN cleavage and the resultant fragments can promote cell migration (Agnihotri *et al.*, 2001). OPN contains a functional RGD binding domain that interacts with the cell adhesion molecule alpha (v) beta 3 integrin. Alpha (v) beta3 is often overexpressed in metastatic prostate tumors and OPN has been shown to enhance the migration and invasion of several prostate cancer cell lines (Angelucci, Festuccia, D'Andrea, Teti, & Bologna, 2002). In a similar manner to OPN, BSP can form a complex with MMP-2 and alpha(v) beta 3 integrin and although BSP is not a direct substrate for MMP-2, the presence of this tri-molecular structure on the cell surface results in a more migratory and invasive cell phenotype (Karadag, Ogbureke, Fedarko, & Fisher, 2004). Therefore, MMP degradation and interaction with bone matrix proteins can potentially lead to a more migratory phenotype and given the prevalence of alpha (v) beta 3 expression by prostate cancer, collagen, OPN and BSP modulation by MMPs may influence prostate cancer homing to the bone (Cooper, Chay, & Pienta, 2002).

Surprisingly, mice deficient in MMPs, with the exception of MMP-13 and MMP-14, have subtle or no defects with respect to skeletal development (Holmbeck *et al.*, 1999; Inada *et al.*, 2004; Stickens *et al.*, 2004). This suggests that many of the MMPs expressed in the bone may have roles outside of direct bone matrix degradation. In this regard, it has become increasingly clear that the MMPs are potent mediators of cell-cell communication via the cleavage of growth factors and cytokines and therefore may play a role in facilitating prostate tumor bone interaction (Lynch & Matrisian, 2002).

MMP-2, MMP-3 and MMP-9 are important in mediating the release of TGF-β from either the LTBP molecule and/or the LAP molecule (Dallas, Miyazono, Skerry, Mundy, & Bonewald, 1995; Maeda, Dean, Gay, Schwartz, & Boyan, 2001; Maeda, Dean, Gomez, Schwartz, & Boyan, 2002; Yu & Stamenkovic, 2000). Therefore, prostate cancer induced osteoclast activation and MMP expression can control the release of TGF-β from the bone matrix and assist in driving the vicious cycle. Interestingly, TβRIII, also referred to as betaglycan, has been shown to enhance the binding of active TGF-β to TβRI but the solubilized form of TβRIII can act as a sink for free TGF-β and inhibit TGF-β signaling (Bierie & Moses, 2006). Recently, MMP-14 and MMP-16 have been found to mediate the shedding of TβRIII (Velasco-Loyden, Arribas, & Lopez-Casillas, 2004). Therefore, MMPs appear to key factors in regulating the bioavailabilty of TGF-β.

MMPs have been shown to mediate the shedding of the tumor necrosis factor (TNF) family members such as TNF and FasL (Haro *et al.*, 2000; Powell, Fingleton, Wilson, Boothby, & Matrisian, 1999) and roles for TNF in controlling bone matrix homeostasis have been defined (Gilbert, Rubin, & Nanes, 2005; Kitaura *et al.*, 2002). RANKL is also a member of the TNF family and has been shown to be cleaved by MMP-1, MMP-14 and the metalloproteinase TACE in several cell types (Lum *et al.*, 1999; Schlondorff, Lum, & Blobel, 2001). MMP-3 and MMP-7 were also found to cleave RANKL in the juxtamembrane stalk region which resulted in the release of a soluble bioactive form of RANKL (Lynch *et al.*, 2005). Recently, using a rat model of prostate tumor induced osteolytic and osteoblastic changes, MMP-7 was shown to contribute to the tumor-induced osteolysis via the cleavage of RANKL (Lynch *et al.*, 2005). These studies demonstrate the importance of MMPs in regulating the bioavailability of a soluble form of RANKL which may circumvent the necessity for premature osteoclasts to directly interact with RANKL presenting osteoblasts and as a consequence accelerate osteoclast recruitment and activation at the tumor bone interface.

MMP-1, -2 and -3 have previously been shown to process the major IGF-binding protein, IGF-BP3. IGF-BP3 directly binds to IGF-I and prevents the interaction of IGF-I with the IGF-I receptor (IGF-1R) (Denley, Cosgrove, Booker, Wallace, & Forbes, 2005; Fowlkes, Enghild, Suzuki, & Nagase, 1994; Thrailkill *et al.*, 1995). IGF-I is commonly found in the bone and as is an important regulator of osteoblast mediated bone formation and osteoclastogenesis (Canalis, Centrella, Burch, & McCarthy, 1989; Jiang *et al.*, 2006). IGF-I has also been shown to play an important role in the progression of primary prostate cancer (Gennigens, Menetrier-Caux, & Droz, 2006). Therefore, MMP processing of IGF-BP3 may enhance the levels of bioavailable IGF-I and subsequently assist in promoting prostate tumor progression in the bone microenvironment.

In addition to these described substrates, MMPs have been also shown to regulate the bio-availability of other humoral factors present in the bone such as stromal derived factor-1 (SDF-1)/ chemokine ligand 12 (CXCL12) and VEGF, factors that are important in hematopoietic stem cell mobilization from the bone marrow and in angiogenesis respectively (Bergers *et al.*, 2000; Heissig *et al.*, 2002; McQuibban *et al.*, 2001).

MYELOMA BONE DISEASE

Multiple myeloma is a hematological malignancy which is characterized by the development of a progressive and destructive osteolytic bone disease which differs from the osteolysis frequently seen with solid tumors. The bone destruction associated with multiple myeloma results in manifestations including lytic bone lesions, which primarily affect the axial skeleton, hypercalcaemia, severe bone pain, and pathological fractures which occur either spontaneously or following trivial injury. The majority of patients with multiple myeloma have discrete osteolytic lesions occurring in areas of myeloma cell infiltration. Myeloma cells are found in close association with sites of active bone resorption, and the interactions between myeloma cells, osteoclasts, stromal cells, myeloma-associated fibroblasts and osteoblasts are crucial both for the development of the osteolytic bone disease and for myeloma cell growth and survival in the bone marrow (Mundy, 1998; Mundy, Raisz, Cooper, Schechter, & Salmon, 1974). Although the precise molecular mechanisms responsible for the bone destruction in multiple myeloma are not completely understood, it is known that the bone destruction is primarily mediated by osteoclasts, and that this destruction is exacerbated by a reduction in osteoblastic bone formation. Patients with multiple myeloma have abnormal bone remodeling, where resorption and formation become uncoupled, with the end result being an increase in bone resorption and a decrease in bone formation. Histomorphometric studies have demonstrated that bone resorption is increased in patients with multiple myeloma, with an increase in both the number and activity of osteoclasts (Bataille *et al.*, 1991; Taube *et al.*, 1992; Valentin, Charhon, Meunier, Edouard, & Arlot, 1982). The increase in resorption is thought to be an early event in the development of myeloma bone disease (Bataille *et al.*, 1991). Although early stages of multiple myeloma have been associated with an increase in osteoblast recruitment, a very marked impairment of bone formation due to reduced osteoblast number and activity is a common feature in the later stages of the osteolytic bone disease (Bataille *et al.*, 1991; Bataille, Delmas, Chappard, & Sany, 1990; Evans, Galasko, & Ward, 1989). This has been confirmed in studies which demonstrate that markers of bone formation are decreased in patients with multiple myeloma (Abildgaard *et al.*, 1998; Woitge *et al.*, 2001).

Myeloma cells secrete a number of osteoclast activating factors which can promote osteoclast formation and activation, including lymphotoxin, TNF, IL-1, IL-3 and IL-6 (Garrett *et al.*, 1987; Kawano *et al.*, 1988; Lee *et al.*, 2004; Lichtenstein, Berenson, Norman, Chang, & Carlile, 1989). While *in vitro* studies have demonstrated a role for these factors in the development of myeloma bone disease, their role *in vivo* remains unclear. Cell-cell contact between myeloma cells and bone marrow stromal cells is critically important in the development of myeloma bone disease and plays a key role in the abnormal regulation of factors implicated in myeloma bone disease, including RANKL, OPG and Dkk1. Over recent years, our understanding of the osteoclastogenic and osteoblastic factors involved in the development of myeloma bone disease has improved. Factors which have been implicated include RANKL, OPG, MIP-1α, SDF-1, TGF-β, Dkk1 and sFRP-2. Many of these factors have been demonstrated to be dysregulated in patients with multiple myeloma, and all may play a role in either bone resorption or bone formation, either alone or in combination.

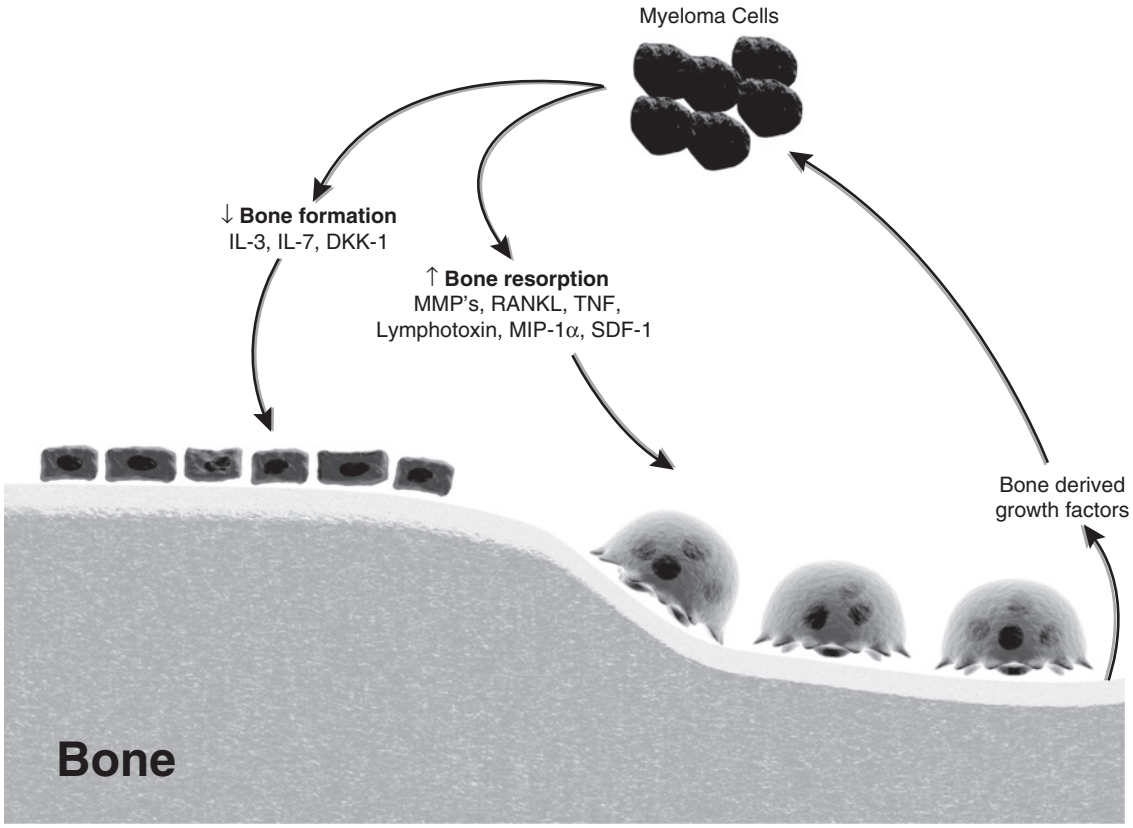

FIGURE 2 Factors implicated in myeloma bone disease. Myeloma bone disease is characterized by both an increase in bone resorption and a decrease in bone formation. These factors have been linked to the development of myeloma bone disease, by either increasing osteoclast activity or by inhibiting osteoblastic bone formation.

Pathophysiology of Osteoclast Stimulation

The mechanism of myeloma bone disease is an uncoupled bone remodeling with enhanced osteolytic resorption, which is mainly mediated by osteoclasts, and decreased bone formation. Both the number and activity of osteoclasts in myeloma patients are increased. Osteoclasts always occur adjacent to collections of myeloma cells, so the mechanism for the bone destruction in myeloma is locally mediated, presumably by cytokines released by the myeloma cells in the microenvironment of the osteoclasts (Mundy, Luben, Raisz, Oppenheim, & Buell, 1974; Mundy, Raisz *et al.*, 1974). Although it has been known for more than 30 years that osteoclasts are hyperstimulated by cytokines in myeloma, there are still unresolved questions as to the nature of the local mediators responsible for the increased osteoclast recruitment and activation.

The RANK/RANKL/OPG System

It is apparent that interactions between receptor activator of nuclear factor kappa B (RANK) expressed on the surface of the osteoclast lineage cells and RANK ligand (RANKL) expressed on stromal cells play a key role in the development and activation of osteoclasts in multiple myeloma. Bone marrow plasma cells derived from patients with multiple myeloma revealed high positive RANKL immunoreactivity as compared to healthy controls, and among patients with multiple myeloma RANKL immunoreactivity on plasma cells was positively correlated with the presence of osteolytic lesions (Heider *et al.*, 2004). RANKL induction by stromal cells was present in patients with multiple myeloma but not in patients with monoclonal gammopathy of undetermined significance (MGUS) (Pearse *et al.*, 2001; Roux *et al.*, 2002), indicating a specific threshold effect. There is some controversy as to whether myeloma cells directly express RANKL. A subset of myeloma cells have been described to express RANKL (Sezer, Heider, Jakob, Eucker, & Possinger, 2002). Several studies have unambiguously demonstrated that myeloma cells stimulate osteoclastogenesis by triggering an increase in RANKL expression by stromal cells through direct cell-to-cell contact (Giuliani, Bataille, Mancini, Lazzaretti, & Barille, 2001; Pearse *et al.*, 2001; Roux *et al.*, 2002; Sezer *et al.*, 2002), and this effect could be prevented by RANK-Fc, a specific inhibitor of RANKL (Pearse *et al.*, 2001). A decrease in osteoprotegerin (OPG), which is a decoy receptor for RANKL, may also be important. Myeloma patients

have OPG serum levels that are lower than those of controls and inversely correlated with the number of lytic lesions. Serum levels of sRANKL in patients with MM were elevated and correlated with bone disease. The sRANKL/OPG ratio was also increased and correlated with markers of bone resorption (Terpos *et al.*, 2003). Human myeloma cells do not express or release OPG but myeloma cells may interact with bone marrow stromal cells and osteoblasts to reduce the concentration of OPG released from these cells, which is consistent with the hypothesis that decreased OPG may play a role in the pathogenesis of myeloma bone disease (Giuliani *et al.*, 2001; Pearse *et al.*, 2001).

MIP-1α

Macrophage inflammatory protein-1 alpha (MIP-1α) is a member of the C-C chemokine family originally purified from lipopolysaccharide-treated monocyte cell lines (Wolpe *et al.*, 1988). MIP-1α is normally expressed by stromal and hematopoietic stem cells (Kukita *et al.*, 1997). Using competitive PCR, mRNA for MIP-1α was shown to be elevated in bone marrow plasma of myeloma patients compared to normal controls and MIP-1α can directly stimulate osteoclast formation and differentiation in a dose-dependent way (Choi *et al.*, 2000; Han *et al.*, 2001). Blockade of bone destruction in an animal model using an antisense strategy against MIP-1α suggested that MIP-1α is responsible for the enhanced bone resorption in myeloma (Choi *et al.*, 2001). Oyajobi et al (Oyajobi *et al.*, 2003) demonstrated that athymic mice bearing intra-muscular Chinese hamster ovarian (CHO)/MIP-1α tumors developed lytic lesions earlier and larger than those in mice with CHO/empty vector (EV) tumors, suggesting MIP-1α is sufficient to induce MM-like destructive lesions in bone *in vivo*.

MIP-1α binds to CCR1 and CCR5 receptors on the surface of osteoclast precursors to exert its effects on osteoclast formation. Neutralizing antibodies to CCR1 or CCR5 as well as the CCR1-specific antagonist markedly inhibit osteoclast formation stimulated by MIP-1α (Oba *et al.*, 2005). In addition, injection of recombinant MIP-1α produced a strong increase in osteoclast formation in normal mice, but not in RANK-/- animals in a murine model of myeloma (Oyajobi *et al.*, 2003), suggesting MIP-1α effects on osteoclasts are mediated through the RANKL pathway.

Other factors

VEGF

Vascular endothelial growth factor (VEGF) has an important role in the induction of neovascularization in solid tumors. However it was not until 1994 that the microvessel density (MVD) of bone marrow in myeloma patients was shown to correlate with disease progression and poor prognosis (Vacca *et al.*, 1994). Myeloma cells may secrete VEGF. VEGF may substitute for M-CSF in the induction of *in vitro* osteoclast differentiation (Niida *et al.*, 1999). A recent study demonstrated that blockade of both VEGF and osteopontin almost completely abrogated angiogenesis and bone resorption enhanced by coculture of myeloma cells and osteoclasts (Tanaka *et al.*, 2007), suggesting VEGF probably supports osteoclastic bone resorption.

SDF-1 alpha/CXCR-4

Stromal derived factor-1 alpha (SDF-1α; CXCL12) is a CXC chemokine. Its ligand is CXCR4 which is expressed on hematopoietic stem cells and lymphocytes, as well as malignant cells and osteoclast precursors (Juarez & Bendall, 2004; Smith *et al.*, 2004; Yu, Huang, Collin-Osdoby, & Osdoby, 2003). SDF-1 is expressed by bone marrow stromal cells and endothelial cells. SDF-1α/CXCR-4 plays an important role in hematopoietic stem cell homing and tumor migration and proliferation. Recent data showed SDF-1α may not only mediate the migration and homing of myeloma cells (Alsayed *et al.*, 2007), but increase osteoclast motility and bone resorbing activity (Zannettino *et al.*, 2005). This was associated with an overexpression of osteoclast activation-related genes, including RANKL, RANKL, TRAP, MMP-9, carbonic anhydrase-11 and cathepsin K. Osteoclast activation mediated by myeloma cells was reduced by a CXCR-4 specific inhibitor (Zannettino *et al.*, 2005). These findings suggest that SDF-1α may also be an important factor in the pathogenesis of myeloma bone disease.

Cell-cell direct interaction

The direct attachment of myeloma cells to bone marrow stromal cells (BMSCs) induces NF-κB activation and leads to up-regulation of IL-6, VEGF and RANKL in BMSCs (Abe *et al.*, 2004; Michigami *et al.*, 2000; Oyajobi, Traianedes, Yoneda, & Mundy, 1998). Data from many studies provide compelling evidence implicating these cellular interactions, not only in the growth of myeloma in bone, but also in initiating the sequence of events that lead to promotion of osteoclastogenesis and bone destruction. An example is a link between VCAM-1/VLA-4 and osteoclast formation via induction of RANKL following direct cell-cell contact between BMSCs and myeloma cells. 5TGM1 myeloma cells exhibit tight adherence to the mouse marrow stromal cell line ST2 in vitro and contact between the two cell types increased RANKL mRNA expression compared with either cell type alone (Michigami *et al.*, 2000; Oyajobi *et al.*, 1998). The effect of these cell-cell interactions was mimicked by treating the myeloma cells with recombinant soluble VCAM-1 (Oyajobi *et al.*, 1998) and, conversely, the production of the soluble activity was blocked by neutralizing antibodies to either α4 or to VCAM-1 (Michigami *et al.*, 2000).

In addition, MIP-1α utilizes CCR1 and CCR5 not only to induce communication between myeloma cells and precursors of osteoclasts resulting in osteoclast formation, but also to increase adhesion of myeloma cells to BMSCs (Obaa, Leea, & Ehrlicha, 2005). MIP-1α induced enhancement of IL-6 production by BMSCs can be significantly inhibited by either anti-MIP-1α, anti-CCR1, anti-CCR5 antibodies or CCR1-specific antagonist, BX471, compared to the control culture treated with isotype specific IgG (Obaa *et al.*, 2005).

Myeloma cells also adhere to osteoclasts directly. Cell-to-cell interaction with peripheral blood mononuclear cell derived osteoclasts enhanced growth and survival of primary MM cells as well as MM cell lines more potently than stromal cells (Abe *et al.*, 2004). Osteoclasts also protected MM cells from apoptosis induced by serum depletion or doxorubicin (Abe *et al.*, 2004). The effects were only be partially inhibited by anti-IL-6 and anti-osteopontin (OPN) antibodies. However, prevention of cellular contact between myeloma cells and osteoclasts abolished the effect of osteoclasts on myeloma cell growth. In addition, a cell-to-cell interaction between human myeloma cells and osteoclasts potently enhanced vascular tubule formation (Tanaka *et al.*, 2007). Blockade of both VEGF and OPN actions almost completely abrogated such vascular tubule formation as well as migration and survival of human umbilical vascular endothelial cells (HUVECs) enhanced by conditioned medium from coculture of myeloma cells and osteoclasts (Tanaka *et al.*, 2007). These observations suggest the presence of a close link between myeloma cells, osteoclasts, and vascular endothelial cells to form a vicious cycle, that osteoclasts activated by myeloma cells can lead to bone destruction, enhance the aggressive behavior and survival of myeloma cells and promote angiogenesis via cell-to-cell interaction with myeloma cells.

Pathophysiology of Osteoblast Inhibition in Myeloma

A key component of myeloma bone disease is the reduction in bone formation, resulting in both a generalized loss of bone and an inability to repair the osteolytic lesions which occur as a result of increased bone resorption. While there is an extensive knowledge of the factors which mediate osteoclastic bone destruction, the cellular and molecular mechanisms which regulate bone formation in multiple myeloma are poorly understood. Several studies have demonstrated that myeloma cells can suppress osteoblast formation and differentiation, and a number of factors have been identified which are dysregulated in multiple myeloma and may play a role in the inhibition of osteoblast formation or function, including Dkk1, sFRP-2, IL-3, Runx2, and TGF-β.

Inhibition of Wnt signaling

Wnts are secreted glycoproteins that activate receptor-mediated signaling pathways which play critical roles in cell development and differentiation both in embryogenesis and in adults (Moon, Kohn, DeFerrari, & Kaykas, 2004). Canonical Wnt signaling is transduced by two transmembrane protein receptor families; frizzled proteins and lipoprotein receptor-related proteins 5 and 6 (LRP5/6). Activation of the canonical Wnt signaling pathway results in the translocation of β-catenin to the nucleus and activation of downstream target genes. This pathway plays a key role in the regulation of bone mass, as demonstrated by mutations in the gene for LRP5, resulting in osteoporosis-pseudoglioma syndrome in humans and osteopenia in mice (Gong *et al.*, 2001). Over-expression of β-catenin in osteoblasts has been demonstrated to induce osteoblast proliferation and a high bone mass phenotype. (Kato *et al.*, 2002), furthermore, increasing Wnt signaling by inhibition of GSK-3β has been demonstrated to increase bone mass *in vivo* (Clement-Lacroix *et al.*, 2005). The key role of Wnt signaling in stimulating bone formation has raised the possibility that this signaling pathway may be important in diseases associated with abnormal bone formation, including multiple myeloma. In support of this, increasing Wnt signaling in the bone microenvironment in multiple myeloma, by inhibition of GSK-β with LiCl, resulted in the inhibition of myeloma bone disease, using a murine model of myeloma (Edwards *et al.*, 2006).

There are 2 classes of extracellular antagonists of the Wnt signaling pathway, with distinct inhibitory mechanisms, acting either by binding directly to Wnt (secreted FRPs, WIF-1) or by binding to part of the Wnt receptor complex (Dkk family). There is recent evidence to suggest a role for each of these classes of inhibitors in the development of myeloma bone disease.

The soluble, extracellular antagonist of the Wnt signaling pathway, Dkk1, has been identified as a potential mediator of osteoblast dysfunction in myeloma bone disease (Tian *et al.*, 2003). Dkk1 is expressed by osteoblasts and bone marrow stromal cells, and has been demonstrated to inhibit bone formation in osteoblasts *in vitro* (Rawadi, Vayssiere, Dunn, Baron, & Roman-Roman, 2003). Over-expression of Dkk1 in bone marrow aspirates from patients with multiple myeloma was initially identified by cDNA microarray. Dkk1 concentrations were increased in bone marrow plasma and peripheral blood of patients with multiple myeloma, as compared to healthy individuals or to patients with MGUS (Tian *et al.*, 2003). In addition, osteoblast differentiation was blocked by bone marrow serum from patients with myeloma, and the inhibitory effect was found to be the result of Dkk1 in the serum. The development of myeloma bone disease is dependent upon interactions within the local bone marrow microenvironment. Myeloma cells have been demonstrated to interact with osteoblasts and up-regulate expression of Dkk1 by osteoblasts (Oyajobi *et al.*, 2004). Furthermore, interactions between myeloma cells and mesenchymal stem cells have been demonstrated to promote the growth of myeloma cells, resulting in an

increase in Dkk1 and consequent inhibition of mesenchymal stem cell differentiation into osteoblasts (Gunn *et al.*, 2006). Preclinical studies have demonstrated the potential for targeting Dkk1 in myeloma bone disease. The treatment of myeloma-bearing SCID-rab mice with anti-Dkk1 antibody reduced osteolytic bone lesions, increased osteoblast number and significantly reduced tumor burden (Yaccoby *et al.*, 2007). Thus, Dkk1 may represent a novel therapeutic target for the treatment of myeloma bone disease.

Secreted Frizzled related protein-2 (sFRP-2) is a soluble antagonist of Wnt signaling which has been shown to be expressed by human myeloma cells(Oshima *et al.*, 2005). Furthermore, both exogenous sFRP-2 and myeloma-cell derived sFRP-2 have been shown to play a key role in bone formation *in vitro*, raising the possibility that sFRP-2 may play a role in the development of myeloma bone disease.

Transforming Growth Factor β

Transforming growth factor β is a ubiquitous, multifunctional growth factor that is released from the bone matrix during osteoclastic bone resorption and acts to inhibit osteoblast differentiation. In addition to inhibiting myeloma growth, inhibition of TGF-β has been demonstrated to block the ability of myeloma cells to inhibit osteoblast differentiation *in vitro*. These results suggest a role for TGF-β in mediating osteoblast dysfunction in myeloma, and the potential for targeting TGF-β in the treatment of myeloma bone disease (Takeuchi *et al.*, 2006).

Runx2

Runt-related transcription factor 2 (Runx2) is a transcription factor which acts to promote the formation and differentiation of osteoblasts from mesenchymal stem cells. The critical role for Runx2 in osteoblastogenesis is demonstrated by the complete lack of osteoblasts and bone formation in mice deficient in Runx2. Myeloma cells were found to inhibit Runx2 activity and reduce osteoblast differentiation in osteoprogenitor cells; an effect that was mediated by both cell-cell contact and interleukin 7(Giuliani *et al.*, 2005). In support of a role for Runx2 in the pathophysiology of myeloma bone disease, a significant reduction in the proportion of Runx2 positive osteoblasts was observed in patients with myeloma with evidence of osteolytic bone lesions, compared to those patients with no evidence of bone disease (Giuliani *et al.*, 2005).

IL-3

In addition to a role in osteoclastogenesis, recent evidence suggests that IL-3 may also play a role in regulation of bone formation in myeloma bone disease. (Ehrlich *et al.*, 2005; Lee *et al.*, 2004). While IL-3 had no effect on osteoblast cell lines, IL-3 inhibited basal and BMP-2 stimulated osteoblast formation from primary stromal cells *in vitro*. The inhibitory effects of IL-3 on osteoblast differentiation were found to be an indirect effect as a result of increasing the number of CD45 + hematopoietic cells in stromal cultures. Furthermore, bone marrow plasma from patients with myeloma was found to inhibit osteoblast differentiation, and this effect could be blocked with a neutralizing antibody to IL-3. These data identify IL-3 as a potential mediator of myeloma bone disease, with a dual effect to directly increase osteoclastic bone resorption, and indirectly inhibit osteoblast differentiation.

HGF

Hepatocyte growth factor (HGF) is produced by myeloma cells and is increased in the serum of patients with multiple myeloma (Seidel *et al.*, 1998). Levels of HGF are correlated with a poor prognosis and HGF acts as a growth and survival factor for myeloma cells (Andersen *et al.*, 2005). More recently, serum concentrations of HGF were negatively correlated with levels of bone specific alkaline phosphatase in patients with multiple myeloma, suggesting a role for HGF in myeloma bone disease(Standal *et al.*, 2007). HGF was found to inhibit BMP-induced osteoblastogenesis, including expression of the transcription factors Runx2 and Osterix, potentially by inhibiting nuclear translocation of receptor-activated SMADs (Standal *et al.*, 2007).

Proteasome Inhibitors

Proteasome inhibition is a new therapeutic strategy in the treatment of multiple myeloma, which is based on the exquisite sensitivity of myeloma cells to the activity of the proteasome. Bortezomib (Velcade™; PS-341) is a potent inhibitor of myeloma cell growth and survival *in vitro* and results from several completed or on-going clinical trials indicate striking therapeutic efficacy and acceptable toxicity profile of intravenous Bortezomib in myeloma patients when administered alone or in combination with dexamethasone and/or chemotherapeutic agents, after relapse or at first presentation (Jagannath, Barlogie *et al.*, 2005; Jagannath, Durie *et al.*, 2005; Richardson *et al.*, 2005a, 2005b; Richardson *et al.*, 2003; Yang, Vescio, Schenkein, & Berenson, 2003). Proteasome inhibitors are more effective in myeloma than in other cancers, which may reflect a dependence of myeloma cells on proteasome function and degradation of NF-κB. The tremendous impact of proteasome inhibition in the treatment of multiple myeloma is all the more exciting because we have recently shown that structurally-unrelated inhibitors of the ubiquitin-proteasome pathway (including Bortezomib) have beneficial anabolic effects on the skeleton *in vivo* (Garrett *et al.*, 2003; Oyajobi *et al.*, 2004). In addition to direct effects on osteoblasts, proteasome inhibitors have also recently been demonstrated to inhibit osteoclast formation and

bone resorption (Zavrski *et al.*, 2005). In support of these observations, Bortezomib has been demonstrated to reduce tumor burden and increase BMD in myeloma-bearing mice using the SCID-rab model of myeloma, an effect associated with an increase in osteoblasts and a reduction in osteoclasts (Pennisi *et al.*, 2006). Clinical studies have demonstrated significant increases in markers of bone formation, including alkaline phosphatase and osteocalcin in those patients who responded to Bortezomib treatment (Giuliani *et al.*, 2006; Shimazaki *et al.*, 2005; Zangari *et al.*, 2005; Zangari, Yaccoby, Cavallo, Esseltine, & Tricot, 2006). In addition to changes in markers of bone formation, Bortezomib treatment has also been shown to result in a reduction in serum Dkk1 and RANKL (Terpos *et al.*, 2006). These studies also suggest that the effect of Bortezomib on bone formation is specific to proteasome inhibition, and not a result of reducing tumor burden. Thus, Bortezomib may be effective both for the treatment of myeloma and of the associated bone disease.

Management of Patients with Metastatic Bone Disease

Management of patients with advanced cancer with cytotoxic agents or hormonal therapy will not be considered here. Rather, we will focus on the specific approaches aimed at treating the bone disease. This in essence means the use of agents which target the bone microenvironment rather than the tumor directly.

The most frequently used modalities are radiation therapy and bisphosphonates, drugs which specifically inhibit osteoclastic bone resorption. Radiation therapy is widely used for the treatment of severe bone pain when the disease is localized, and is often effective. The mechanism by which radiation therapy causes a palliative effect on bone pain remains unknown.

Bisphosphonates have been widely used for the past 30 years for patients with metastatic bone disease. They are now FDA-approved for all types of bone metastases, and have proven to be effective in reducing skeletal-related events by approximately 50% (Hortobagyi *et al.*, 1996; Lipton *et al.*, 2002; Theriault *et al.*, 1999). This is good but not optimal therapy for patients with metastatic bone disease. Bisphosphonates are associated with some complications, including propensity to precipitate renal failure, and osteonecrosis of the jaw (AAOMS, 2006; ADACSA, 2006; Marx & Stern, 2002; Ruggiero, Fantasia, & Carlson, 2006; Ruggiero, Mehrotra, Rosenberg, & Engroff, 2004; Surgeons, 2006) Impaired renal function has been seen most frequently in patients treated with zoledronic acid, but is unlikely to be an issue if the drug is given in appropriate doses to patients with normal renal function over the recommended periods of infusion time. Osteonecrosis of the jaw has been seen much more frequently in recent years, particularly in patients treated with intravenous bisphosphonates for cancer. This may be related to the cumulative dose and the fact that the bisphosphonates used are powerful and given intravenously. Patients with osteonecrosis of the jaw are frequently given relatively large doses and commonly have had either a recent dental procedure or have active dental disease. The pathophysiology of this condition is still not known, but may be related to bacterial infection in the oral cavity, and the high rate of bone turnover that is usually seen in the jaw.

Bisphosphonates are drugs which effectively reduce bone resorption, but do not restore bone that has been lost. Therefore, some patients with severe bone fragility caused by metastatic cancer will continue to have skeletal-related events despite optimal bisphosphonate therapy, and an underlying malignant disease which is in remission. This remains an ongoing problem for the treatment of patients with these advanced malignancies, particularly because many of these patients are living for prolonged periods of time.

Currently, the mostly widely used bisphosphonates for this indication are zoledronic acid, pamidronate and clodronate. There are differences in mode of administration (zoledronic acid 15–30 minute infusion, pamidronate 2–4 hours infusion, clondronate oral), and potency. There are less convincing differences in efficacy based on current evidence, although it is possible zoledronic acid is slightly more efficacious. Zoledronic acid has been associated with impaired renal function more frequently than the other agents, but it is also probably used more commonly for this indication.

Experimental approaches are now being developed for the treatment of patients with metastatic bone disease. These include approaches based on inhibition of TGF-β signaling in the stromal cells in the bone microenvironment, which may promote osteoblast differentiation and tends to inhibit PTHrP. Other approaches are focused on inhibiting PTHrP action or effects, and include anti-sera to PTHrP (Guise et al 1996) and small molecule inhibitors of PTHrP transcription (Gallwitz *et al.*, 2002).

OSTEOPOROSIS IN PATIENTS WITH CANCER

Osteoporosis is common in patients with advanced malignancy. Just how common is not known with any accuracy, but it is clear that it is not only frequent, but becoming more prevalent. Much of the emphasis in recent years has been on patients who have been treated with various therapies for the underlying malignancy, and osteoporosis is a side effect of a number of effective anti-cancer treatments (see below). This could be anticipated because attempts to kill tumor cells with cytotoxic agents are also likely to kill those normal cells with relatively high rates of cell turnover and proliferation, such as precursors of osteoblasts.

This has always been an issue in patients with malignancy treated with chemotherapy or corticosteroids, but has been emphasized much more in recent years in the hormone-dependent tumors, namely in carcinomas of the breast and prostate, which are frequently treated with therapies that influence hormones and control bone-cell activity. In the case of breast cancer, the widespread use of aromatase inhibitors and SERMs has led to generalized bone loss in patients with breast cancer, and in prostate cancer, the use of androgen deprivation therapy either by LHRH or by castration, or by the use of estrogen-related compounds has also caused widespread bone loss.

However, what is not emphasized so much is that osteoporosis is probably also common in patients with malignancy who are treatment-naïve and untreated with any of these drugs. This was first documented by Kanis and colleagues (1999) (Kanis *et al.*, 1999), who found a marked increase in the rate of vertebral fractures in untreated breast cancer patients. Kanis *et al.*, 1999 examined the prevalence and incidence of vertebral fractures in women with breast cancer at the time of diagnosis, during the next three years in women without skeletal metastases, and in women with advanced disease without skeletal metastases. They found that at the time of diagnosis, the prevalence of vertebral fractures was the same as in the control population but the annual incidence rate was five-fold greater per year over the first three years after diagnosis, and in women with advanced disease without skeletal metastases, was twenty-fold that of appropriate controls.

This has long been appreciated in myeloma. The pathophysiology of osteoporosis in this situation is unknown, but this type of low turnover osteoporosis is similar to that seen in men, in patients of advanced age, or patients treated with corticosteroid therapy. Treatment of this type of osteoporosis may be best accomplished with an anabolic agent.

Cancer-treatment-induced osteoporosis

It has been noted by the Institute of Medicine, National Research Council and NCI Office of Cancer Survivorship that systemic bone loss is an unfortunate feature of the majority of non-surgical cancer-treatments (Hewitt, 2006). The use of chemotherapy, radiation and hormonal therapy has undoubtedly improved the long-term prognosis for cancer sufferers, but the skeletal complications of such approaches often result in decreased bone mass and increased fracture risk for the patient. One mechanism for this effect in premenopausal women involves the decreased levels of circulating estrogen through primary ovarian failure as a result of chemotherapy and the onset of premature menopause (Hirbe, Morgan, Uluckan, & Weilbaecher, 2006; Shapiro, Manola, & Leboff, 2001). Aromatase inhibitors also have the potential to cause decreased BMD by disrupting normal estrogen levels (Ganz *et al.*, 2004; Mackey & Joy, 2005) and the resulting hypogonadism following androgen deprivation therapy is a primary cause of acquired osteoporosis (Hewitt, 2006; Krupski *et al.*, 2004). Interestingly, this effect is thought to be due to decreases in estrogen as well as testosterone levels (Smith, 2006).

Chapter 65

Genetic Regulation of Parathyroid Gland Development

R. V. Thakker
OCDEM, Nuffield Department of Clinical Medicine, University of Oxford, Headington, Oxford OX3 7LJ, United Kingdom

Congenital anomalies of parathyroid gland development, which lead to hypoparathyroidism, are common and occur in more than 1 in 4000 births. The four parathyroid glands, in man, develop from transient bilateral outpocketings of the pharyngeal endoderm, which are referred to as the pharyngeal pouches. There are four pairs of pharyngeal pouches, and the superior parathyroid glands develop from the fourth pharyngeal pouches, which are the most caudal, whereas the inferior parathyroid glands together with the thymus develop from the third pharyngeal pouches. The pharyngeal pouches together with the branchial arches and grooves form the branchial apparatus, which gives rise to a number of structures that include the face, jaws, oral cavity, neck, pharynx, larynx, ear, aortic arch, tonsils, thyroid, parathyroids, thymus, ultimobranchial body that results in calcitonin-producing cells, carotid glomus, and the epibranchial placodes that contribute to the facial, glossopharyngeal, and vagus nerves. Thus, developmental abnormalities of the branchial apparatus and pharyngeal pouches may lead to hypoparathyroidism that may be part of a complex congenital defect, as for example in the DiGeorge syndrome or a solitary endocrinopathy which is called *isolated* or *idiopathic* hypoparathyroidism. In addition, hypoparathyroidism may occur in association with other developmental anomalies involving dysmorphic features, sensorineural deafness, lymphedema, nephropathy, and cortical thickening of tubular bones. The molecular genetic basis for such forms of hypoparathyroidism has been investigated, and this has helped to elucidate further the mechanisms involved in the genetic regulation of parathyroid gland development. This chapter will focus on those forms of hypoparathyroidism that often present in early life, as these are likely to be associated with parathyroid gland agenesis or hypoplasia, or a congenital deficiency of parathyroid hormone (PTH), or an early destruction of the parathyroids (Table I). The hypoparathyroidism in these forms is characterized by hypocalcemia and hyperphosphatemia due to a deficiency in PTH secretion (Thakker, 1993; Bilezikian and Thakker, 1998).

COMPLEX SYNDROMES ASSOCIATED WITH HYPOPARATHYROIDISM

Hypoparathyroidism may occur as part of a complex syndrome that may be associated either with a congenital development anomaly or with an autoimmune syndrome. The congenital developmental anomalies associated with hypoparathyroidism include the DiGeorge, HDR (hypoparathyroidism, deafness, and renal anomalies), Kenney-Caffey, and Barakat syndromes, and also syndromes associated with either lymphedema or dysmorphic features and growth failure (see Table I).

DiGeorge Syndrome

Clinical Features and Genetic Abnormalities

Patients with DiGeorge syndrome (DGS) typically suffer from hypoparathyroidism, immunodeficiency, congenital heart defects, and deformities of the ear, nose, and mouth. The disorder arises from a congenital failure in the development of the derivatives of the third and fourth pharyngeal pouches with resulting absence or hypoplasia of the parathyroids and thymus. Most cases of DGS are sporadic, but an autosomal dominant inheritance of DGS has been observed, and an association between the syndrome and an unbalanced translocation and deletions involving 22q11.2 have also been reported (Scambler *et al.,* 1991); this is referred to as DGS type 1 (DGS1). In some patients, deletions of another locus on chromosome 10p have been observed in association with DGS (Monaco *et al.,* 1991), and this is referred to as DGS type 2 (DGS2). Mapping studies of the DGS1 deleted region on chromosome 22q11.2 defined a 250-kb to 3000-kb critical region (Gong *et al.,* 1996; Scambler et al., 2000), that contained approximately 30 genes. Studies of DGS1 patients reported deletions of several of the genes (e.g., rnex40, nex2.2–nex 3, UDFIL, and TBX1) from the critical region (Augusseau *et al.,* 1986; Budarf *et al.,* 1995; Yamagishi *et al.,* 1999;

Principles of Bone Biology, 3rd Edition

TABLE I Inherited Forms of Hypoparathyroidism and Their Chromosomal Locations

Disease	Inheritance	Gene Product	Chromosomal Location
Hypoparathyroidism associated with complex congenital syndromes	Autosomal dominant		22q11
DiGeorge type 1 (DGS1)	Autosomal dominant	Unknown	10p13–p14
DiGeorge type 2 (DGS2)	Autosomal dominant	GATA3	10p15
HDR			
Hypoparathyroidism associated with KSS, MELAS, and MTPDS	Maternal	Mitochondrial genome	21q22.3
APECED	Autosomal dominant	AIRE1	?
Kenney–Caffey	Autosomal dominant[a]	Unknown	?
Barakat	Autosomal recessive[a]	Unknown	?
Lymphedema	Autosomal recessive	Unknown	?
Nephropathy, nerve deafness	Autosomal dominant[a]	Unknown	?
Nerve deafness without renal dysplasia	Autosomal dominant	Unknown	1q42–q43
Dysmorphology, growth failure	Autosomal recessive	Unknown	11p15
Isolated hypoparathyroidism	Autosomal dominant	PTH[b]	11p15
	Autosomal recessive	PTH[b]	Xq27.1
	X-Linked recessive	SOX3	

APECED, *autoimmune polyendocrinopathy candidiasis-ectodermal dystrophy*; HDR, *hypoparathyroidism, deafness and renal anomalies*; KSS, *Kearns-Sayre syndrome*; MELAS, *mitochondrial encephalopathy, strokelike episodes, and lactic acidosis*; MTPDS, *mitochondrial trifunctional protein deficiency syndrome*.
[a]*Most likely inheritance shown.*
[b]*Mutations of* PTH *gene identified only in some families.*
[?]*Location not known.*

Scambler *et al.,* 1991), and studies of transgenic mice deleted for such genes (e.g., Udf1l, Hira, and Tbx1) revealed developmental abnormalities of the pharyngeal arches (Lindsay *et al.,* 1999; Magnaghi *et al.,* 1998; Jerome et al., 2001). However, point mutations in DGS1 patients have only been detected in the TBX1 gene (Yagi *et al.,* 2003), and TBX1 is now considered to be the gene causing DGS1 (Baldini *et al.*, 2003). TBX1 is a DNA binding transcriptional factor, of the T-Box family, that is known to have an important role in vertebrate and invertebrate organogenesis and pattern formation. The TBX1 gene is deleted in ~ 96% of all DGS1 patients. Moreover, DNA sequence analysis of unrelated DGS1 patients who did not have deletions of chromosome 22q11.2 has revealed the occurrence of three heterozygous point mutations (Yagi *et al.,* 2003). One of these mutations resulted in a frame shift with a premature truncation, whereas the other two were missense mutations (Phe148Tyr and Gly310Ser). All of these patients had the complete pharyngeal phenotype but did not have mental retardation or learning difficulties. Interestingly, transgenic mice with deletion of Tbx1 have a phenotype that is similar to that of DGS1 patients (Jerome *et al.,* 2001). Thus, Tbx1-null mutant-mice (−/−) had all the developmental anomalies of DGS1 (i.e., thymic and parathyroid hypoplasia; abnormal facial structures and cleft palate; skeletal defects; and cardiac outflow tract abnormalities), whereas Tbx1 haploinsufficiency in mutant mice (+/−) was associated only with defects of the fourth branchial pouch (i.e., cardiac outflow tract abnormalities). The basis of the phenotypic differences between DGS1 patients, who are heterozygous, and the transgenic +/− mice remain to be elucidated. It is plausible that Tbx1 dosage, together with the downstream genes that are regulated by Tbx1, could provide an explanation, but the roles of these putative genes in DGS1 remains to be elucidated.

Some patients may have a late-onset DGS1, and these develop symptomatic hypocalcemia in childhood or during adolescence with only subtle phenotypic abnormalities (Scire *et al.,* 1994; Sykes *et al.,* 1997). These late-onset DGS1 patients have similar microdeletions in the 22q11 region. It is of interest to note that the age of diagnosis in the families of the three DGS1 patients with inactivating Tbx1 mutations ranged from 7 to 46 years, which is in keeping with late-onset DGS1 (Yagi *et al.,* 2003).

Mouse Models Developing Features of DiGeorge Syndrome Reveal Roles of Hox and Pax Genes in Parathyroid and Thymus Development

In the mouse, the parathyroids develop with the thymus from common primordia that arise from the third pharyngeal pouch endoderm (Gordon *et al.,* 2001). The molecular mechanisms that regulate parathyroid/thymus organogenesis from the pharyngeal pouch endoderm have been investigated using knockout models, and the roles of transcription regulators e.g., Hoxa3, Pax1, Pax9, Eyal, Six1 and Six4 defined (Manley and Capecchi, 1998; Xu *et al.,* 2002; Zou *et al.,* 2006). The roles of Hoxa3 and Pax1 genes will be briefly reviewed because they form a genetic pathway with GCM2 (see later discussion) that regulates parathyroid organogenesis.

Homeobox (HOX) Genes

The HOX genes are a group of genes that specify the body plans of invertebrates, e.g., *Drosophila* and, in all likelihood, vertebrates (Deschamps, 2007). In *Drosophila* these homeobox genes specify the identity of cells within each parasegment. The function of the evolutionarily conserved genes in man and mouse is not known, but because the order of these genes on the chromosomes of *Drosophila*, man, and mouse is the same, and because this gene order reflects the order of the anterior boundaries of gene expression along the anteroposterior body axis of the early embryos of all three species, it would appear that these homeobox genes are equally important in mammalian development (Deschamps, 2007). The HOX genes all contain a 180-bp motif, which encodes a 60 amino acid DNA biding domain called the homeodomain. In man and mouse this set of 30 genes are known collectively as the HOX genes, and they are distributed in the genome in four separate clusters (HOXa, b, c and d), which may have arisen during chordate evolution as the result of two duplications of chromosomal segments (Kappen *et al.,* 1989; Manley and Capecchi, 1998). The homeobox genes of *Drosophila* encode transcription factors that share the DNA-binding motif, and these genes act as master switches directing the course of morphogenetic development of each segment. Because the human and mouse genes share similar homeobox sequences, the HOX proteins are thought to function also as transcriptional factors participating in the specification of regional information in the early mammalian embryo (Manley and Capecchi, 1998; Deschamps, 2007).

In order to determine the genetic function of some of the HOX genes, mouse knockout models have been generated. Disruption of HOXa3 resulted in an abnormal phenotype that had similarities to the DiGeorge syndrome (Chisaka and Capecchi, 1991; Manley and Capecchi, 1995, 1998). Null mutant mice (−/−) died in the neonatal period and were found to be lacking the thymus and parathyroids because of a failure to initiate the formation of the parathyroid/thymus primordial. These HOXa3 −/− mice also had defects of the heart and arteries, craniofacial abnormalities, and a reduction in the mass of the thyroid and submaxillary tissues. The HOXa3 +/− mice were phenotypically normal. Thus, although the HOXa3 −/− mice clearly indicated an important role for the HOXa3 gene in parathyroid and thymus organogenesis, there were nevertheless important differences between this mouse and the DiGeorge syndrome, which is an autosomal dominant trait, whereas the mouse syndrome is autosomal recessive.

Paired Box (PAX) Genes

The paired box (PAX) genes encode transcriptional factors that are expressed in a spatially and temporally restricted manner during embryonic development (Robson *et al.,* 2006). The PAX genes contain a highly conserved 128-amino-acid DNA-binding domain called the paired box. Man and mouse have nine PAX genes, and mice deficient (−/−) in either PAX1 or PAX9 have congenital parathyroid and thymic defects (Peters *et al.,* 1998; Su *et al.,* 2001). Studies of double knockout mice indicated that there is a genetic pathway that involves Hoxa3, PAX1, and glial cells missing 2 (Gcm2, see later discussion), in parathyroid development (Su *et al.,* 2001). Thus, gcm2 expression is absent in HOXa3 −/− mouse embryos that are 10.5 days post coitum (dpc), reduced in PAX1 −/− mouse embryos that are 11.5 dpc, and absent in Hoxa3 (+/−)/PAX1 (−/−) mice at 11.5 dpc (Su *et al.,* 2001). These studies have revealed that Hoxa3 is required for initiation of parathyroid organogenesis and for initial Gcm2 expression and that both HOXa3 and PAX1 are required for Gcm2 expression. Failure of Gcm2 expression results in a lack of parathyroids, and this is due to programmed cell death (apoptosis) of the parathyroid primordia at 12 dpc in mouse embryos (Su *et al.,* 2001; Liu *et al.,* 2007). Thus, there is an important transcription cascade involving HOXa3, PAX1 and Gcm2, in the embryonic development of parathyroids.

Hypoparathyroidism, Deafness, and Renal Anomalies Syndrome

Clinical Features and Role of GATA3 Mutations

The combined inheritance of hypoparathyroidism, deafness, and renal dysplasia as an autosomal dominant trait was reported in one family in 1992 (Bilous *et al.,* 1992). Patients had asymptomatic hypocalcemia with undetectable or inappropriately normal serum concentrations of PTH, and normal brisk increases in plasma cAMP in response to the infusion of PTH. The patients also had bilateral, symmetrical, sensorineural deafness involving all frequencies. The renal abnormalities consisted mainly of bilateral cysts that compressed the glomeruli and tubules and lead to renal impairment in some patients. Cytogenetic abnormalities were not detected, and abnormalities of the PTH gene were excluded (Bilous *et al.,* 1992). However, cytogenetic abnormalities involving chromosome 10p14–10pter were identified in two unrelated patients with features that were consistent with HDR. These two patients suffered from hypoparathyroidism, deafness, and growth and mental retardation; one patient also had a solitary dysplastic kidney with vesicoureteric reflux and a uterus bicornis unicollis (Fryns *et al.,* 1981), and the other patient, who had a complex reciprocal, insertional translocation of chromosomes 10p and 8q, had cartilaginous exostoses (Van Esch *et al.,* 1999). Neither of these patients had immunodeficiency or heart defects, which are key features of DGS2 (see earlier discussion), and further studies defined two nonoverlapping regions; thus, the DGS2 region was located on 10p13–p14 and HDR on 10p14–10pter. Deletion mapping studies in two other HDR patients further defined a critical 200-kb region that contained the GATA3 gene (Van Esch *et al.,* 2000).

GATA3 belongs to a family of dual zinc-finger transcription factors that are involved in vertebrate embryonic development. DNA sequence analysis in other HDR patients identified mutations that resulted in a haploinsufficiency and loss of GATA3 function (Van Esch *et al.,* 2000; Nesbit *et al.,* 2004a; Ali *et al.,* 2007). To date, 39 different heterozygous germline GATA3 abnormalities, which consist of 33 mutations and 6 whole gene deletions, have been reported (van Esch 2000; Muroya *et al.,* 2001; Nesbit *et al.,* 2004a; Zahirieh *et al.,* 2005; Mino *et al.,* 2005; Adachi *et al.,* 2006; Chiu *et al.,* 2006; Ali *et al.,* 2007). The GATA3 mutations are scattered throughout the coding region, and approximately 18% are nonsense mutations, 42% are frame-shift deletions or insertions, 15% are missense mutations, 8% are splice site mutations, 3% are in-frame deletions, and 15% are whole-gene deletions. Thus, the majority (>75%) of these HDR-associated mutations are predicted to result in truncated forms of the GATA3 protein. Each proband and family will generally have its own unique mutation, and there appears to be no correlation with the underlying genetic defect and the phenotypic variation, e.g., the presence or absence of renal dysplasia. More than 90% of patients with two or three of the major clinical features of the HDR syndrome, i.e., hypoparathyroidism, deafness, or renal abnormalities, have a GATA3 mutation (Ali *et al.,* 2007). The remaining 10% of HDR patients, who do not have a GATA3 mutation of the coding region, may harbor mutations in the regulatory sequences flanking the GATA3 gene, or else they may represent heterogeneity. The phenotypes of HDR patients with GATA3 mutations appear to be similar to those without GATA3 mutations (Ali *et al.,* 2007).

The HDR-associated GATA3 mutations are predicted to disrupt either one or both of the zinc-finger domains (Nesbit *et al.,* 2004a). The C-terminal finger (ZnF2) of GATA proteins binds DNA, whereas the N-terminal finger (ZnF1) stabilizes this DNA binding and interacts with other zinc-finger proteins, such as friends of GATA (FOGs; Tsang *et al.,* 1997; Tevosian *et al.,* 1999; Svensson *et al.,* 1999). The functional consequences of these HDR-associated GATA3 mutations have been assessed by electrophoretic mobility-shift assays to detect alterations in DNA binding, and by yeast two-hybrid assays to detect alterations in protein-protein interactions (Nesbit *et al.,* 2004a; Ali *et al.,* 2007). These studies have revealed that HDR-associated mutations involving the GATA3 ZnF2 or the adjacent basic amino acids result in a loss of DNA binding to the consensus motif, GATA, that would be associated with the promoter of the gene being regulated by GATA3 (van Esch *et al.,* 2000; Nesbit *et al.,* 2004a; Ali *et al.,* 2007). However, those HDR-associated mutations involving ZnF1 lead to either a loss of interaction with FOG2 ZnFs or altered DNA-binding affinity (Nesbit *et al.,* 2004a; Zahirieh *et al.,* 2005; Ali *et al.,* 2007). These findings are consistent with the proposed three-dimensional model of GATA3 ZnF1, which has separate DNA and protein-binding surfaces (Nesbit *et al.,* 2004a; Ali *et al.,* 2007). Thus, the HDR-associated GATA3 mutations can be subdivided into two broad classes that depend on whether they disrupt ZnF1 or ZnF2, and their subsequent effects on interactions with FOG2 and altered DNA binding, respectively.

Phenotype of GATA3 Knockout Mouse Model

The HDR phenotype is consistent with the expression pattern of GATA3 during human and mouse embryogenesis in the developing kidney, otic vesicle, and parathyroids (Labastie *et al.,* 1994, 1995; George *et al.,* 1994; Debacker *et al.,* 1999). However, GATA3 is also expressed in the developing central nervous system (CNS) and the hematopoietic organs in humans and mice, and this suggests that GATA3 may have a more complex role (George *et al.,* 1994; Debacker *et al.,* 1999; Pandolfi *et al.,* 1995). Indeed, studies of mice that are deleted for a Gata3 allele (+/−), or both Gata3 alleles (−/−) have revealed important roles for Gata3 in the development of the brain, spinal cord, peripheral auditory system, T-cells, fetal liver hematopoiesis and urogenital system (Pandolfi *et al.,* 1995).

Heterozygous (+/−) Gata3 Knockout Mice

Gata3 +/− mice are viable, appear to be normal with a normal life span, and are fertile (Pandolfi *et al.,* 1995). The lymphoid organs, peripheral blood, and bone marrow of the +/− mice have no abnormalities when compared to the +/+ mice. The +/− mice were not assessed for hypoparathyroidism, but renal abnormalities were absent. In contrast, analysis of auditory brainstem response (ABR) thresholds in alert Gata3 +/− mice, aged from 1 to 19 months of age, revealed a hearing loss when compared to their wild-type (+/+) littermates (van der Wees *et al.,* 2004). The hearing loss in these Gata3 +/− mice was associated with cochlear abnormalities that consisted of a significant progressive morphological degeneration which started with the outer hair cells at the apex and eventually involved all the inner hair cells, pillar cells, and nerve fibers (van der Wees *et al.,* 2004; van Looij *et al.,* 2005). These studies have shown that hearing loss in Gata3 haploinsufficiency commences in the early postnatal period and is progressive through adulthood, and that it is peripheral in origin and is predominantly due to malfunctioning of the outer hair cells of the cochlea (van der Wees *et al.,* 2004; van Looij *et al.,* 2005).

Homozygous (−/−) Gata3 Knockout Mice

Gata 3 −/− mice are embryonically lethal, and these null embryos die between 11 and 12 dpc (Pandolfi *et al.,* 1995). Examination of these Gata3 −/− embryos revealed a variety of abnormalities that included massive internal bleeding, resulting in anemia, marked growth retardation, severe deformities of the brain and spinal cord, a hypopigmented retina,
