Principles of Bone Biology

THIRD EDITION

Volume 1

EDITED BY

John P. Bilezikian

Lawrence G. Raisz

T. John Martin

Dedication

Gideon A. Rodan

We pay special tribute in this Third Edition of *Principles of Bone Biology* to one of the original three editors, Gideon Rodan, who passed away after a long illness on January 1, 2006. Gideon was a wonderful scientist who made outstanding contributions to our understanding of bone cell biology and to the treatment of metabolic bone diseases. His quiet but highly effective leadership style, superb intellect and major scientific achievements brought together bone and mineral investigators from all over the world. He was a beloved friend whose insight, empathy and sense of humor enriched our lives. Gideon's wisdom and breadth of knowledge were invaluable in selecting and evaluating the contributions to the first two editions of this book.

Gideon's education in mathematics and basic sciences in Israel, and his PhD at the Weitzman Institute on physicochemical aspects of mineral metabolism, provided the fuel for a career of sustained achievement and scholarship. He began his academic career at the University of Connecticut Dental School, rapidly became Chairman of the Department of Oral Biology, and built a program of research that brought that School to great prominence. He was a mentor supreme, with a large number of students, post-doctoral trainees and close colleagues who went on to have successful careers. They remained intensely loyal to him. A former President of the American Society of Bone and Mineral Research (ASBMR), Gideon was also the first recipient of the ASBMR Excellence in Mentorship award, an Award that has been named for him in perpetuity. After moving to the pharmaceutical industry in 1984 to lead research and development in bone biology and osteoporosis at Merck, Gideon fulfilled one of his obligations to that position many times over by selecting and then developing alendronate as a treatment for osteoporosis. This achievement set the bar for all future drug development programs in osteoporosis. Most remarkably at Merck, however, Gideon retained and developed even further the rigorous academic approach to bone biology that had always characterized him, wherever he was. In his never-ending quest to teach, to train, and to learn, Gideon was helped enormously by his wife, Sevgi, also his lifelong co-worker.

We all owe much to the innovative thought that Gideon brought to all levels of bone and mineral research. His great contributions directed our thinking and our concepts for an entire generation that has followed him. Gideon would have contributed as much to this third Edition as he did to the first two Editions. It is with the greatest admiration and respect that we dedicate this Third Edition of *Principles of Bone Biology* to his memory.

T. J. Martin, L. G. Raisz and J. P. Bilezikian.

Preface to the Third Edition

The two previous editions of *Principles of Bone Biology* have been well received. They have not only provided a resource for investigators already working in the field, but have helped new investigators rapidly "get up to speed" in developing their projects and grant proposals. The rapid progress in our field in the last 6 years mandates that we update this text, so that it can continue to serve as a basic resource.

In this third edition, most of the chapters have been prepared by authors of the previous edition but the chapters have been extensively revised and updated. In addition a number of new authors have gracefully consented to join us. This has involved consolidation, reconfiguration, and reorganizing the information being presented. The two-volume format has been retained along with approximately the same text length. The loss of Gideon Rodan has been deeply felt by all of us and these volumes are dedicated to him. In the spirit that Gideon would have applauded, we are delighted that his close colleague and friend Jack Martin has joined us as Editors to continue this work to which Gideon contributed so much. Finally we would like to acknowledge the help of the staff at Elsevier-Academic Press who have worked valiantly to maintain schedules and have enabled us to complete this third edition. We trust that the book will be successful in providing a complete repository of the most current and accurate information in the field of bone biology.

John P. Bilezikian

T. John Martin

Preface to the First Edition

The world of modern science is undergoing a number of spectacular events that are redefining our understanding of ourselves. As with any revolution, we should take stock of where we have been, where we are, and where we are going. Our special world of bone biology is participating in and taking advantage of the larger global revolution in modern science. Often with shocking but delightful suddenness, we are gaining new insights into difficult issues, discovering new concepts to explain old observations, developing new approaches to perennial mysteries, and applying novel technological advances from other fields to our own. The pace with which the bone world is advancing is impressive not only to the most ardent optimists, who did not expect so much so soon, but also to the more sober minded who, only several years ago, would have brushed off the notion that progress could come with such lightening speed.

The rationale for this book is rooted in the recognition of the revolution in bone biology. We need a new repository of knowledge, bringing us both to the core and to the edge of our universe. Our goal is to provide complete, truly up-to-date, and detailed coverage of this exciting and rapidly developing field. To achieve this, we assembled experts from all over the world and asked them to focus on the current state of knowledge and the prospects for new knowledge in their area of expertise. To this end, *Principles of Bone Biology* was conceived. It is designed to be useful to students who are becoming interested in the field and to young investigators at the graduate or postgraduate level who are beginning their research careers. It is also designed for more established scientists who want to keep up with the changing nature of our field, who want to mine this lode to enrich their own research programs, or who are changing their career direction. Finally, this book is written for anyone who simply strives for greater understanding of bone biology.

This book is intended to be comprehensive but readable. Each chapter is relatively brief. The charge to each author has been to limit size while giving the reader information so complete that it can be appreciated on its own, without necessary recourse to the entire volume. Nevertheless, the book is also designed with a logic that might compel someone to read on, and on, and on!

The framework of organization is fourfold. The first 53 chapters, in a section titled "Basic Principles," cover the cells themselves: the osteoblast, the osteoclast, and the osteocyte; how they are generated; how they act and interact; what turns them on; what turns them off; and how they die. In this section, also, the biochemistry of collagenous and noncollagenous bone proteins is covered. Newer understandings of calcium, phosphorus, and magnesium metabolism and the hormones that help to control them, namely, parathyroid hormone, vitamin D metabolites, calcitonin, and related molecules, are presented. A discussion of other systemic and local regulators of bone metabolism completes this section.

The second section of this book, "Molecular Mechanisms of Metabolic Bone Diseases," is specifically devoted to basic mechanisms of a variety of important bone diseases. The intention of these 17 chapters is not to describe the diseases in clinical, diagnostic, or therapeutic terms but rather to illustrate our current understanding of underlying mechanisms. The application of the new knowledge summarized in Part I to pathophysiological, pathogenetic, and molecular mechanisms of disease has relevance to the major metabolic bone disorders such as osteoporosis, primary hyperparathyroidism, and hypercalcemia of malignancy as well as to the more uncommon disorders such as familial benign hypocalciuric hypercalcemia, pseudohypoparathyroidism, and osteopetrosis.

The third section of this book, "Pharmacological Mechanisms of Therapeutics," addresses the great advances that have been made in elucidating how old and new drugs act to improve abnormalities in bone metabolism. Some of these drugs are indeed endogenous hormones that under specified circumstances are useful therapies: estrogens, vitamin D, calcitonin, and parathyroid hormone are representative examples. Others agents such as the bisphosphonates, fluoride, and calcium are reviewed. Finally, agents with therapeutic potential but still in development such as calcimimetics, insulin-like growth factors, transforming growth factor, bone morphogenetic protein, and fibroblast growth factor are presented with a view to the future. The intent of this 12-chapter section is not to provide step-by-step "how-to" instructions for the clinical uses of these agents. Such prescribing information for established

therapies is readily found in other texts. Rather, the underlying mechanisms by which these agents are currently believed to work is the central point of this section.

The fourth and final section of this book, "Methods in Bone Research," recognizes the revolution in investigative methodologies in our field. Those who want to know about the latest methods to clone genes, to knock genes out, to target genes, and to modify gene function by transfection and by transcriptional control will find relevant information in this section In addition, the selection and characteristics of growth conditions for osteoblastic, osteoclastic, and stem cells; animal models of bone diseases; assay methodologies for bone formation and bone resorption and surrogate bone markers; and signal transduction pathways are all covered. Finally, the basic principles of bone densitometry and bone biopsies have both investigative and clinical relevance. This 15-chapter section is intended to be a useful reference for those who need access to basic information about these new research technologies.

The task of assembling a large number of international experts who would agree to work together to complete this ambitious project was formidable. Even more daunting was the notion that we would successfully coax, cajole, and otherwise persuade authors of 97 chapters to complete their tasks within a six-month period. For a book to be timely and still fresh, such a short time leash was necessary. We are indebted to all the authors for delivering their chapters on time.

Finally, such a monumental undertaking succeeds only with the aid of others who helped conceive the idea and to implement it. In particular, we are grateful to Jasna Markovac of Academic Press, who worked tirelessly with us to bring this exciting volume to you. We also want to thank Tari Paschall of Academic Press, who, with Jasna, helped to keep us on time and on the right course. We trust our work will be useful to you whoever you are and for whatever reason you have become attracted to this book and our field. Enjoy the book. We enjoyed editing it for you.

Part I

Basic Principles

Chapter 1

Modeling and Remodeling

The Cellular Machinery Responsible for the Gain and Loss of Bone's Material and Structural Strength

Ego Seeman

Department of Endocrinology and Medicine, Austin Health, University of Melbourne, Melbourne, Australia

INTRODUCTION

Propulsion against gravity requires levers. Bones are levers and must be stiff, that is, they must resist deformation. Impact loading imparts energy to bone. Because energy cannot be destroyed, it must be stored or dissipated. Thus, bone must also be flexible in order to absorb energy by changing shape; it must be able to shorten and widen in compression and lengthen and narrow in tension without cracking (Currey, 2002). Bone must also be light to allow mobility.

The elastic properties of bone allow it to absorb energy by deforming reversibly when loaded (Lanyon *et al.,* 1976; Turner *et al.,* 2006). If the load imposed exceeds bones' ability to deform elastically, plastic deformation occurs but this is irreversible; it is accompanied by a permanent change shape with accumulation of microcracks that allow energy release (Currey, 2002). The ability to develop microdamage is a defense against the alternative, namely, a complete fracture, but microcracks compromise strength as they accumulate (Burr *et al.,* 1998). If both the elastic and plastic zones of deformation are exceeded, structural failure – fracture – occurs.

Bone achieves the paradoxical properties of stiffness yet flexibility, strength yet lightness through its material composition and its structural design – the way this material is fashioned in three-dimensional space containing "nothing" – void space. Excavation of a marrow cavity during growth confers strength in tubular bones like the femur or tibia, which function mainly as levers, by shifting the mineralized cortical bone radially increasing resistance to bending (Ruff and Hayes, 1988). It also confers lightness by minimizing the mass needed to achieve this resistance to bending.

For structures like the vertebral body that must have greater flexibility than long bones, nature again takes advantage of void to achieve a different type of strength – the ability to deform (tolerate strain or change in length) without cracking. Lightness is achieved by fashioning the mineralized bone material with many voids; as a porous sponge-like structure of trabecular plates and sheets. Stiffness and the ability to tolerate large loads is sacrificed in favor of greater ability to deform – peak loads achievable are less than in tubular bones but the ability to absorb energy by changing length without cracking is greater.

Material Strength

Type 1 collagen is tough: It is distensible in tension but lacks resistance to bending so it needs to be stiffened. This is achieved by creating a composite of collagen plus mineral but more mineral is not necessarily better. Greater the mineral content produces greater the material stiffness, but the ability to deform and so absorb and store energy decreases as a result. For a given increase in the percentage mineral ash, stiffness increase fivefold but work to fracture decreases fourteen-fold (Currey, 2002) (Fig. 1, upper panel).

Nature selects the mineral concentration most suited to the particular function a given bone *usually* performs. Ossicles in the ear are over 80% mineral, a feature selected for so that they can vibrate like tuning forks without storing energy in deformation (Fig. 1, lower panel). These bones sacrifice the ability to deform in favor of stiffness to transmit sound with high fidelity. The slightest deformation and they crack but deformation is unlikely because they are protected safely in the skull. On the other hand, deer antlers are less densely mineralized to facilitate deformation so energy can be absorbed like springs during head butting in mating season. Greater energy-absorbing ability of antlers is favored over stiffness but they do not need stiffness; they are not load-bearing (Currey, 1969).

The organization of the composite of mineral and collagen is incompletely understood. Although the mineral is the material that stiffens bone, it is also the most brittle component and must be protected. Collagen fibers contain

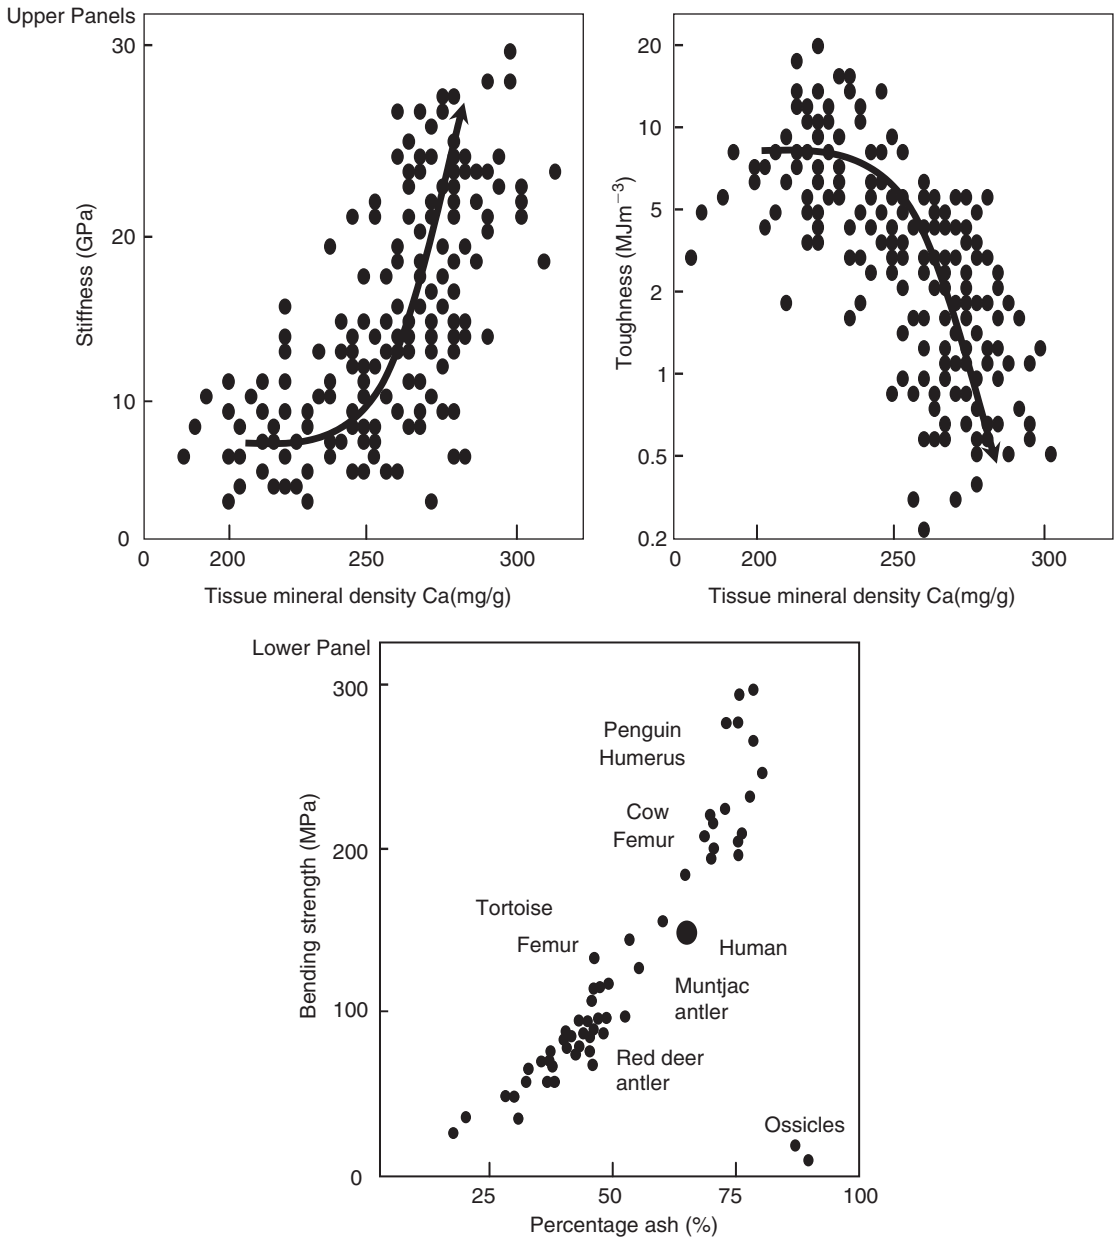

FIGURE 1 Upper panels: As tissue mineral content increases stiffness increases but toughness decreases. Adapted from Currey (2002). Lower panel: Ossicles of the ear are 90% mineral. They function as sound transducers and have little resistance to bending; they are brittle and will crack when slightly deformed. Antlers are about 40% mineral allowing them to deform without cracking. Adapted from Currey (1969).

mineral, interfibrillary matrix, and mineralized fibrils. The mineralized fibrils are composed of platelets of mineral and an intrafibrillary matrix phase of noncollagenous proteins. The brittle mineral confers stiffness and is protected during loading by energy absorption by collagen deformation and by noncollagenous proteins that dissipate energy by reversibly breaking intrahelical bonds that are "sacrificed" to provide "hidden" length (Fantner *et al.,* 2005; Gupta *et al.,* 2006) (Fig. 2). Stresses at the tissue, fiber, and mineral levels decrease in proportions of 12:5:2.

Structural Strength

During growth, the bone with its appropriate material composition is fashioned into three-dimensional masterpieces of biomechanical engineering. Although there is variability in the material composition of bone, this composition is similar in land-dwelling mammals (Keaveney *et al.,* 1998), so that most of the diversity in bone strength is the result of structural diversity that is obvious at the macroscopic level from bone to bone but the diversity in cross-sectional size,

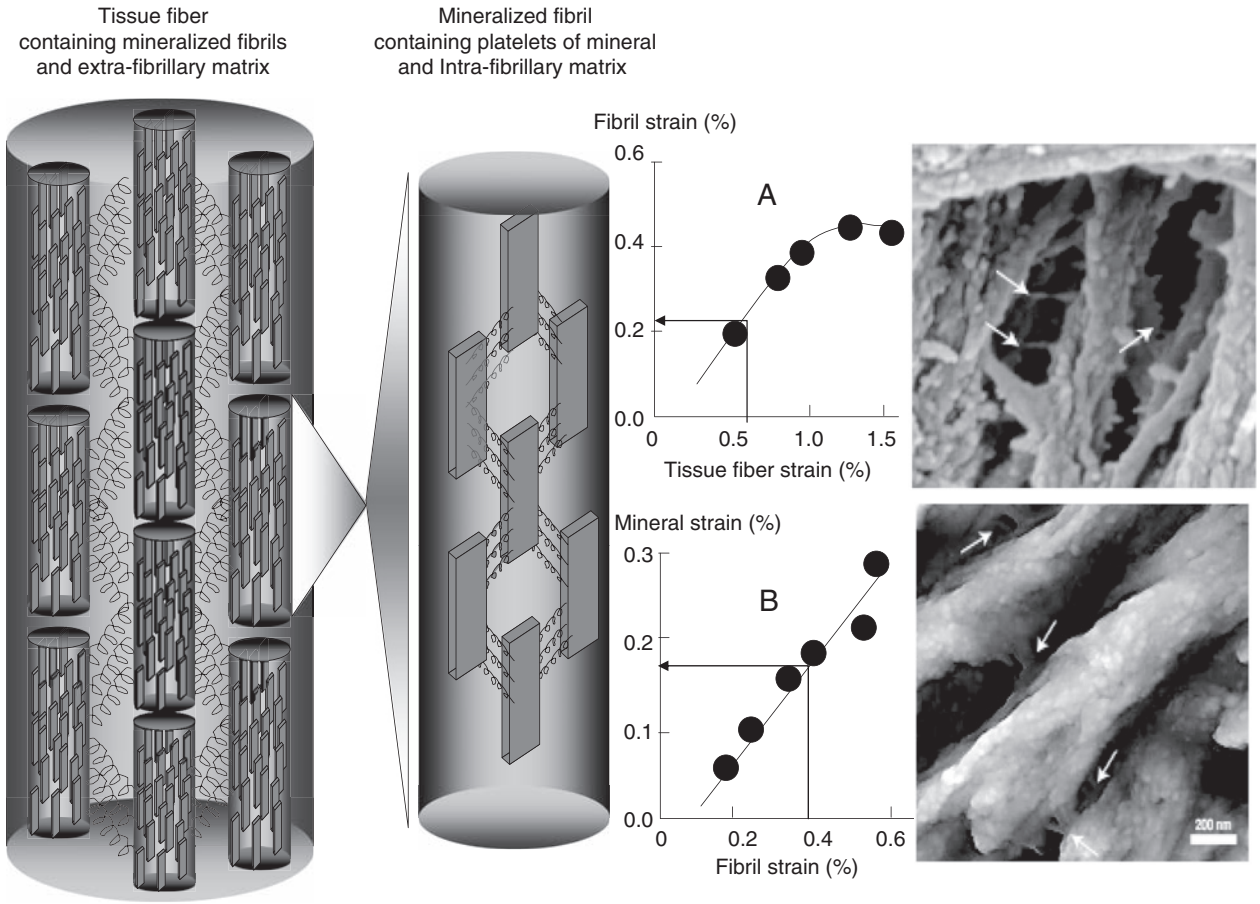

FIGURE 2 A collagen tissue fiber contains mineralized fibrils. The fibrils contain mineral platelets bound by noncollagenous proteins, helical structures that can absorb and dissipate energy during tensile strain by the breakage of sacrificial intra-helical bonds allowing uncoiling to provide "hidden length." This avoids overloading the mineral platelets. Graph A: Tissue fiber strain distributed to fibrils. Graph B: Fibrils absorb strain minimizing mineral strain. Adapted from Gupta *et al.* (2006). Images of noncollagenous glue like proteins. From Fantner *et al.* (2005).

shape, and the way its architecture is distributed in three-dimensional space from cross-section to cross-section as cortical and trabecular bone along a bone has only recently been given attention (Zebaze *et al.,* 2005; Zebaze *et al.,* 2007).

Structural diversity is largely due to individual differences in genetic makeup rather than individual differences in life style (Pocock *et al.,* 1987; Christian *et al.,* 1989). Fetal limb buds removed *in utero* and grown *in vitro* develop the shape of the proximal femur implying that bone shape is "imprinted" in the genetic material (Murray and Huxley, 1925). Studies in families and twins support this view (Seeman *et al.,* 1989; Seeman *et al.,* 1996). Although the many genes responsible for the diversity in bone's structural strength, and the contribution of environmental factors to this diversity, are largely undefined, the final pathway mediating genetic and environmental influences on structural diversity is the cellular machinery of bone modeling and remodeling (Parfitt, 1989).

BONE MODELING AND REMODELING DURING GROWTH AND THE ATTAINMENT OF PEAK STRENGTH

Bone *modeling* (construction) is the process by which bone is formed by osteoblasts without prior bone resorption. This process is vigorous during growth and produces changes in bone size and shape. Bone *remodeling* (reconstruction) occurs throughout life. Bone is first resorbed by osteoclasts and then formed in the same location by osteoblasts. These cells form the basic metabolic unit (BMU) that reconstructs bone in distinct locations on the three (endocortical, intracortical, and trabecular) components of its inner (endosteal) envelope and to a much lesser extent on the outer (periosteal) envelope (Orwoll *et al.,* 2003; Blizoites *et al.,* 2006).

Bone modeling and remodeling achieve strength for loading and lightness for mobility in two ways: by strategically depositing bone in locations where it is needed

to modify bone size and shape, and by removing bone from where it is not needed to avoid bulk. The enormous capacity of this cellular machinery to modify structure during growth is seen in the morphological differences between the playing and nonplaying arm of tennis players. Modeling and remodeling modifies bone size, shape, and mass distribution of the humerus of the playing arm without changing its mass (Haapasalo *et al.,* 2000; Bass *et al.*, 2002; Seeman, 2002). However, this ability to adapt structure to its loading circumstances after the completion of longitudinal growth is limited because periosteal apposition decreases precipitously and the age-related changes in remodeling occur that produce structural decay (see Section III).

The Purpose of Modeling and Remodeling During Growth – Optimizing Strength and Minimizing Mass

If bone had only to be strong it could achieve this with bulk – more mass, but mass takes time to grow, is costly to maintain and limits mobility. Bone also must serve a second need – lightness to facilitate mobility. Longer tubular bones need more mass to construct their length than shorter bones do, but wider and narrower cross-sections do not necessarily differ in the absolute amount of material needed to construct them (Zebaze *et al.,* 2007).

Although it seems obvious that the total cross-sectional area (cortical area plus marrow area) of a wider femoral neck or femoral shaft must be assembled with more mass, this is not the case. The total cross-sectional area of a tubular bone and its bone mass are independent; wider and narrower bone cross-sections are assembled using a similar amount of material (Fig. 3). Thus, larger cross-sections are assembled with less material relative to their size producing a lower apparent volumetric bone mineral density (vBMD) and so avoiding bulk. Smaller cross-sections are assembled with more material relative to their size, producing a higher vBMD while avoiding the fragility of slenderness.

Bulk is avoided in larger cross-sections by greater endocortical resorption, which excavates a correspondingly larger marrow cavity so that the endocortical envelope approximates the periosteal envelope; wider tubular bones are assembled with a relatively thinner cortex (producing the same cortical bone area because the thinner "ribbon" of cortex is distributed around a larger perimeter). By analogy, constancy of mass achieves a wider or narrower cylinder by rolling a sheet of paper with fewer or more rolls of the sheet.

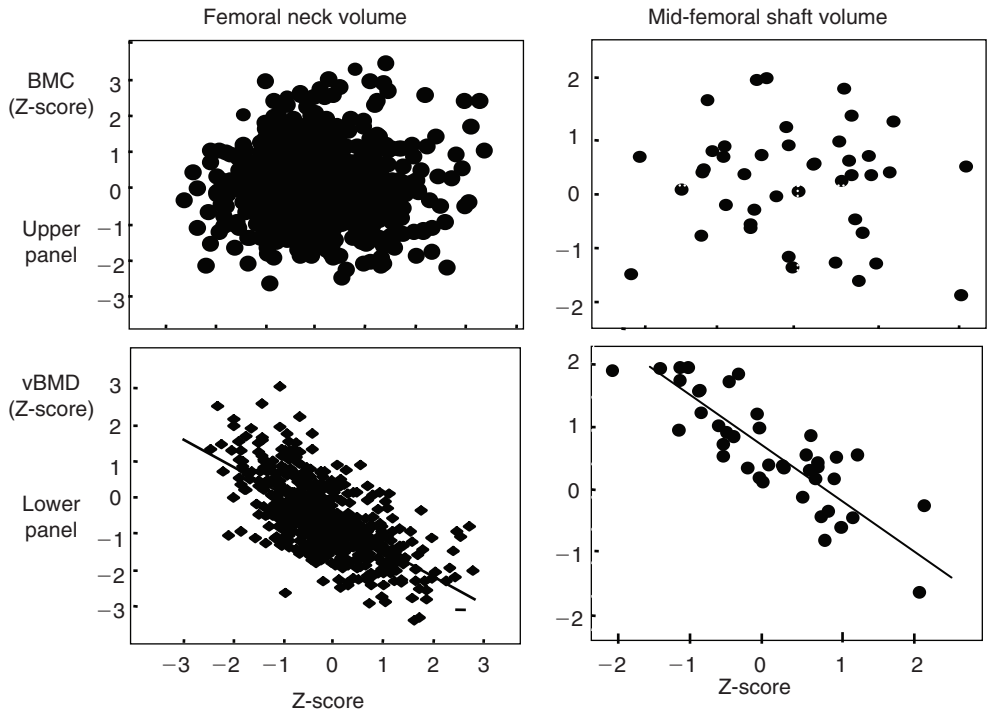

FIGURE 3 Upper panels: There is no association between the bone mineral content (BMC) Z-score and the volume of a femoral neck (FN) or femoral midfemoral shaft (FS) cross-sectional slice (including marrow volume). Lower panels: Larger cross-sections are assembled with relatively less mass and so have a lower volumetric apparent bone mineral density (vBMD). ("Apparent" refers to the vBMD of the whole cross-section, bone plus marrow areas.) Adapted from Zebaze *et al.* (2007).

Diversity in Bone Size, Shape, and the Spatial Distribution of its Mass

Long bones are not drinking straws with the same dimensions throughout their length; long bones do not have a single cross-sectional diameter, the same cortical thickness or marrow cavity diameter. Group means obscure variance – the diversity in structure and mass distribution so critical to determining diversity in bone strength. Bone strength and lightness are also achieved by altering bone shape. Diameters of a cross-section differ at each degree around the periosteal perimeter creating differences in the external shape of the cross-section. Differences in the medullary diameters at corresponding points around the endocortical perimeter determine the shape of the marrow cavity and the proximity of these two envelopes, which in turn then determine cortical thicknesses around the perimeter of the cross-section and the distance the cortical mass is placed from the neutral axis (Zebaze *et al.*, 2007).

This diversity in bone size, shape, and mass distribution is the result of differing degrees of focal bone formation at each point around the periosteal perimeter and resorption at the corresponding point on the endocortical surface during growth. Bone strength is optimized, not by using a greater net amount of mass, but by strategically modifying bone size, shape, and the distribution of mass using the minimum net amount of bone needed to do so.

For example, total cross-sectional area of the femoral neck is greatest adjacent to the shaft of the femur and smaller nearer the femoral head but the amount of bone in each cross-section is no different (Fig. 4). What differs is the way this bone is distributed in space as cortical and trabecular bone. Adjacent to the femoral shaft, the femoral neck cross-section is elliptical with long axis in the superoinferior direction. The marrow cavity shape follows the external shape, but not identically; the greater periosteal apposition superiorly and inferiorly relative to mediolaterally produces the elliptical shape. Differences in periosteal

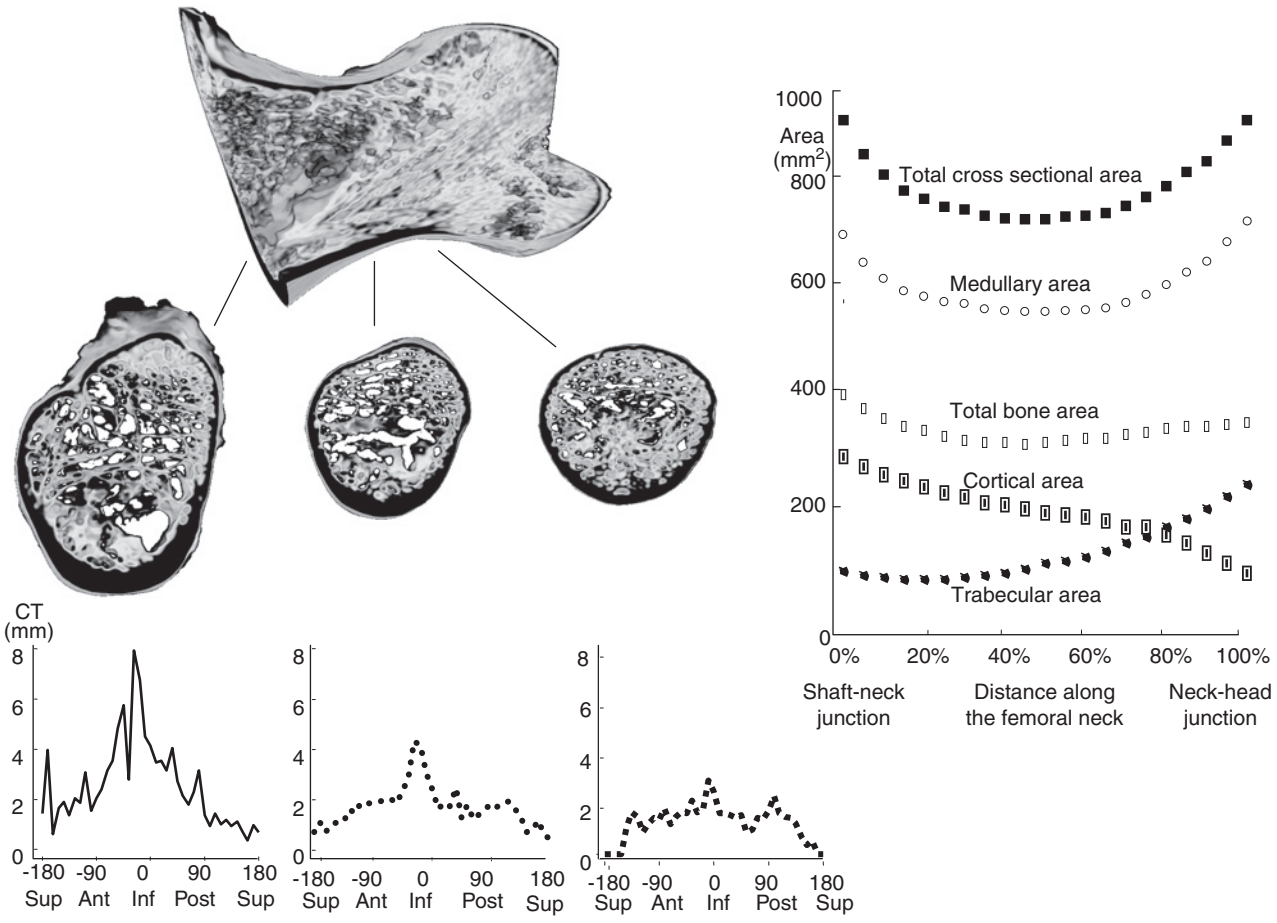

FIGURE 4 Femoral neck (FN) size and shape varies along its length. A similar amount of bone material is used to assemble each cross-section despite each cross-section varying in total cross-sectional area (CSA), shape, and proportions of cortical and trabecular bone. Adjacent to the femoral shaft the FN shape is elliptical and the bone is mainly cortical with varying cortical thickness (CT) at each point around the perimeter. At the mid-FN and adjacent to the femoral head the shape is more circular, there is more trabecular bone, reciprocally less cortical bone, which is similar in thickness around the perimeters. Adapted from Zebaze *et al.* (2007).

apposition and endocortical resorption produce a thicker cortex inferiorly and a thinner cortex superiorly (Zebaze *et al.,* 2007).

The bone in the cross-section at the junction of the femoral neck with the femoral shaft is largely cortical. Moving proximally, femoral neck shape becomes more circular reflecting similar degrees of periosteal apposition around the perimeter and the bone mass is distributed progressively more as trabecular and less cortical bone while cortical thickness is similar around the perimeter (as can be seen by the similar distribution profile in the lower part of Fig. 4).

The relative contributions of genetic factors and loading circumstances to this diverse structural organization is uncertain but modeling, by deposition bone, and remodeling by removing bone, assemble very different structures along the length of the femoral neck to accommodate differing loading patterns using similar net amounts of material.

This principle of optimizing strength and minimizing mass is illustrated in a prospective study of growth of a tibial cross-section assessed using quantitative computed tomography (Wang *et al.,* 2005; Wang *et al.,* 2007). In prepubertal girls, tibial cross-sectional shape was already elliptical at age 10. During two years, focal periosteal apposition increased the ellipticity by adding twice the amount of bone anteriorly and posteriorly than added medially and laterally. Consequently, estimates of bending strength increased more in the anteroposterior (Imax) than mediolateral direction (Imin) (Fig. 5). Marrow area changed little so more mass was distributed as a thicker cortex anteroposteriorly due to periosteal apposition without concurrent endocortical resorption. Resistance to bending increased by 44% along the principal axis (Imax) with a 22% increase in mass. If cortical thickness increased by the same amount of periosteal apposition at each point around the tibial perimeter, the amount of bone producing the same increase in bending resistance would be 205 mg, fourfold more than observed.

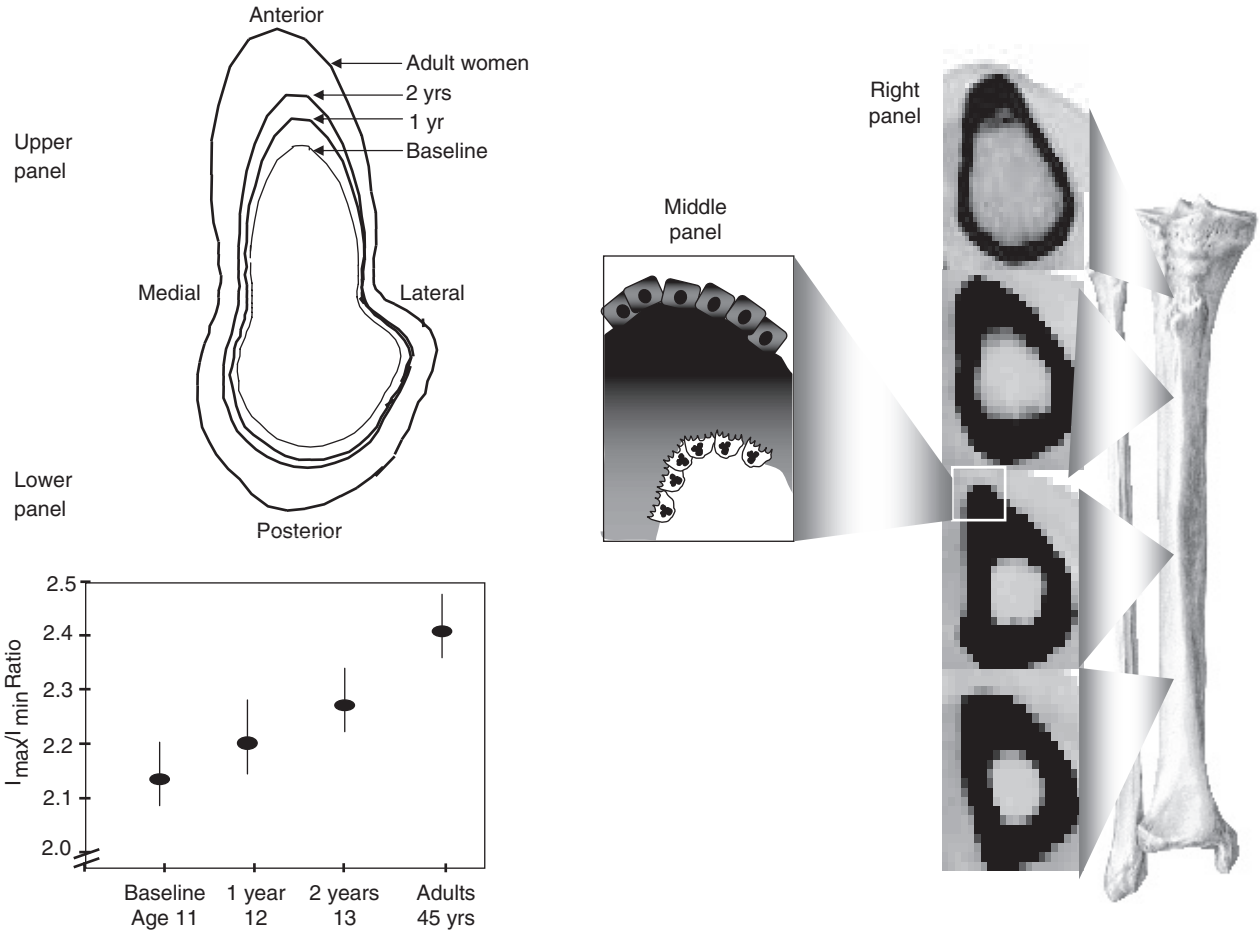

FIGURE 5 Left upper and lower panel: Bone mass distribution around the center of the tibial cross-section. More bone is deposited anteriorly and posteriorly than medially and laterally during two years of growth, increasing the ellipticity of the cross-section. Bending resistance increases more along the anteroposterior axis (Imax) than mediolateral axis (Imin) as reflected in the increasing ratio. Middle and right panel: Diagram depicting periosteal apposition and endocortical resorption modifying cortical thickness. Shape of the tibial cross-sections varies along the length of the tibial shaft. Adapted from Wang *et al.* (2007).

It is also intuitive that a bone with a larger cross-sectional area must be constructed with more periosteal bone than a smaller cross-section. The contrary was observed. During two years, the absolute amount of bone deposited on the periosteal surface of the tibial cross-section was similar in children with baseline tibial total cross-sectional area in the upper, middle, and lower tertile at age 10. Thus, larger cross-sections were assembled with less mass *relative* to their starting cross-sectional size avoiding bulk, and smaller cross-sections were assembled with more mass *relative* to their starting total cross-sectional size offsetting the fragility associated with slenderness.

Deposition of similar amounts of bone on the periosteal surface of larger and smaller cross-sections (and so less in relative terms on the former and more on the latter) was possible because the differences in bone size were established early, probably in utero (see later discussion). Consequently, the deposition of the same amount of bone on the periosteal surface of an already larger cross-section confers more bending resistance than deposition of the same amount of bone on a smaller cross-section because resistance to bending is proportional to the fourth power of the distance from the neutral axis (Ruff and Hayes, 1988).

This ability of bone to increase its strength in response to loading by adapting its design rather than increasing its mass is convincingly documented in racket sports. During growth, greater loading of the playing arm achieves greater bone strength by modifying its external size, shape, and the spatial distribution of its internal architecture. Focal periosteal apposition and endocortical resorption at some locations but endocortical bone formation at others changes the distribution of bone in space without a net change in its mass to accommodate loading patterns so that vBMD does not change; bending strength increases without increasing bulk, the latter hardly conducive to a good forehand volley (Haapsalo *et al.,* 2000; Bass *et al.,* 2002).

Trait Variances in Adulthood Originate Before Puberty

Although adults have larger skeletons than children, differences in bone size and mass in adult life probably have their origins established early in life. In a 3-year prospective study of growth in 40 boys and girls, Loro *et al.* report that the variance at Tanner stage 2 (prepuberty) in vertebral cross-sectional area and volumetric trabecular BMD, femoral shaft cross-sectional area (CSA) and cortical area was no less than at Tanner stage 5 (maturity); 60–90% of the variance at maturity was accounted for by the variance present before puberty. Thus, the magnitude of trait variances (dispersion around the age-specific mean) is largely established before puberty (Loro *et al.,* 2000).

The ranking of individual values at Tanner stage 2 was unchanged during 3 years in girls (Fig. 6). These traits tracked so that an individual with a large vertebral or femoral shaft cross-section, or higher vertebral vBMD or femoral cortical area before puberty retained this position at maturity. The regression lines for each of the quartiles did not cross during three years. Similar observations were made in boys (not shown).

Similar observations have been reported using peripheral computed tomography of the tibia in 258 girls. The magnitude of variance at ages 10–13 did not differ from that two years later, and did not differ from that of their premenopausal mothers (Wang *et al.,* 2007). Likewise, Garn *et al.* monitored 744 women and men during 25 years. About 90% of the variance in cortical thickness in adulthood was accounted for by variance at completion of growth 25 years earlier (Garn *et al.,* 1992). Emaus *et al.* reported distal and ultra distal radius size and mass tracked during 6.5 years follow-up of 5,366 women and men ages 45–84 (Emaus *et al.,* 2005; Emaus *et al.,* 2006).

Finding that the magnitude of the trait variances at maturity is no different from the magnitude of their variances before puberty suggests that growth in larger and smaller bones occurs at the same rate (Wang *et al.,* 2007). (If larger bones deposit more bone during growth than smaller bones, variance will increase.) In addition, the constant variance and tracking also suggests that environmental factors are likely to contribute little to total variance of a trait in the population.

If variance is established before puberty, when is growth more rapid in some individuals than others to give rise to these large variances in bone size and mass (1 SD = ~10% of the mean)? Do bones from individual to individual begin by being the same size then some grow more rapidly (deposit more bone per unit time than others) to form the upper tertile of a trait while others grow more slowly forming the middle and lower tertile?

The answer to this question is unknown. In infants and children between ages 1 and 10, the variance in diaphyseal diameter and muscle diameter was established at 1–2 years of age (Maresh, 1961). In a cross-sectional study of 146 stillborn fetuses ages 20–41 weeks' gestation, the percentage of a femur, tibia, and humerus diaphyseal cross-section that was cortical area was about 80–90% at 20 weeks' gestation and remained so across the 20 weeks of intrauterine life, suggesting that as bone size increased during advancing intrauterine life, the proportion of bone within the cross-section remained constant and was established prior 20 weeks' gestation (Rodriguez *et al.,* 1992). By contrast, one cross-sectional study using three-dimensional ultrasound suggested variance in femoral volume doubled during intrauterine growth (Chang *et al.,* 2007).

The divergence of data points of graphic analyses of growth creating the impression of increasing variance may be more apparent than real because larger numbers differ by larger absolute amounts. Further studies are needed to define the magnitude to trait variances by sex and race and to define the genetic and environmental components of that variance.

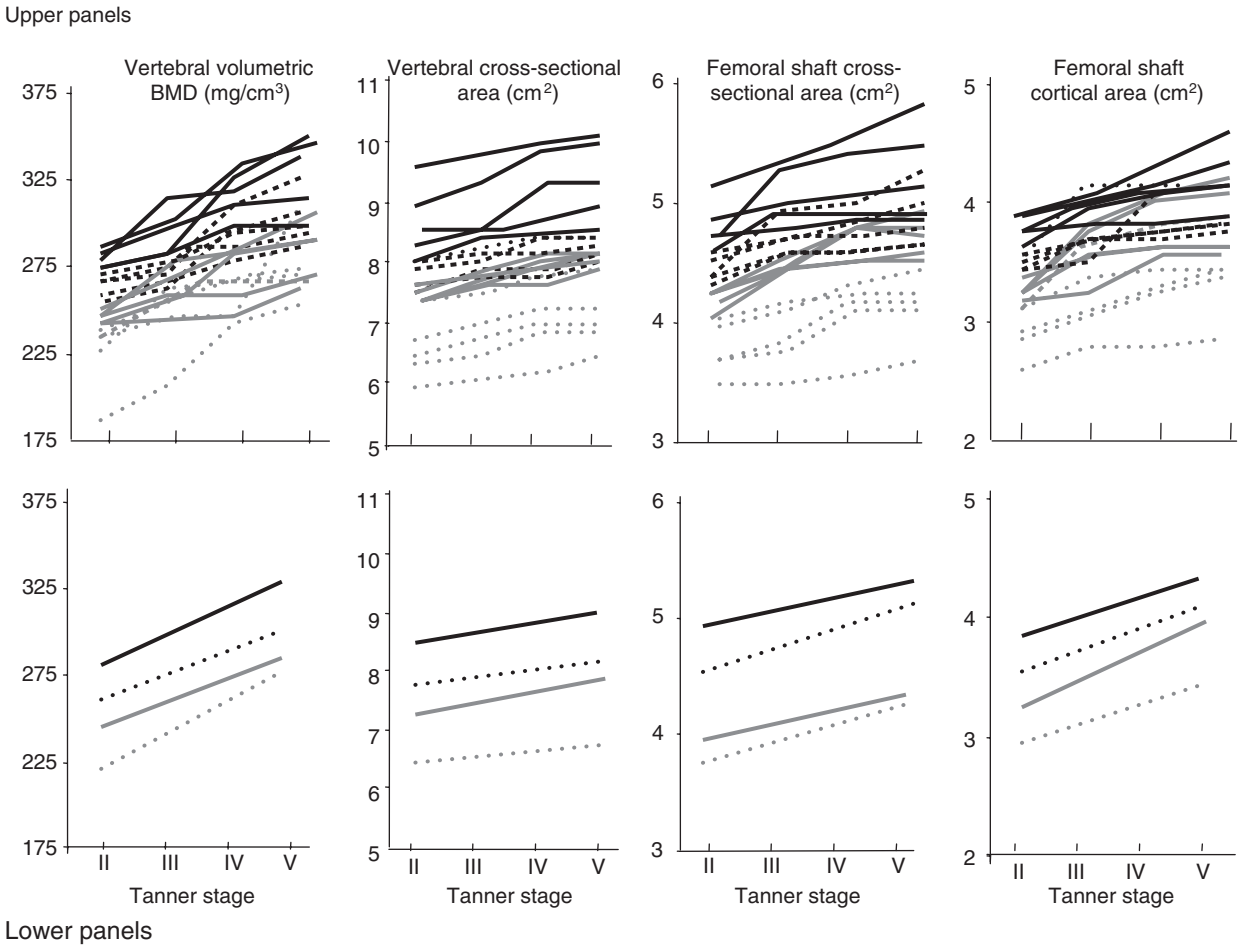

FIGURE 6 Upper panels: Variances in vertebral volumetric bone mineral density (vBMD) and cross-sectional area, femoral shaft total cross-sectional area and cortical area are established before puberty in girls. Individual values track retaining their percentile of origin during 3 years. Lower panels: The regression lines for each quartile do not overlap during 3 years. Adapted from Loro *et al.* (2000).

The obvious inference from the early establishment and constancy of trait variances is that genetic rather than environmental factors account for this variance. Studies in family members, twins, birth cohorts followed for many decades, and studies of fetal limb buds grown *in vitro* support this view (Murray and Huxley, 1925; Pocock *et al.,* 1987; Seeman *et al.,* 1996). However, this does not mean that traits *in an individual* are immutably fixed.

This flawed notion confuses variance in a population and the effect of environmental or disease on a trait in an individual. Muscle paralysis in utero, exercise during growth, or effects of disease in adulthood all have profound effects on bone structure in individuals (Bass *et al.,* 2002; Pitsillides, 2006). Lifestyle change can influence the population mean of a trait as documented many times by secular increases in height, a highly heritable trait (Bakwin, 1964; Meredith, 1978; Cameron *et al.,* 1982; Tanner *et al.,* 1982; Malina and Brown, 1987). However, under stable conditions, lifestyle differences within a population make only a small contribution to trait variances compared with genetic differences in that population.

Sex and Racial Differences in Axial and Appendicular Structure

For the vertebrae, increasing bone size by periosteal apposition builds a wider vertebral body in males than in females and in some races than in others (Seeman, 1998). Trabecular number per unit area is constant during growth. Therefore, individuals with a low trabecular number in young adulthood are likely to have had lower trabecular numbers in childhood (Parfitt *et al.,* 2000). The age-related increase in trabecular density is the result of increased thickness of existing trabeculae. Before puberty there is no difference in trabecular density in boys and girls of either Caucasian or African American origin (Gilsanz *et al.,* 1988; Gilsanz *et al.,* 1991). This suggests that both vertebral body size and the mass within its periosteal envelope increase in proportion until Tanner stage 3 (Fig. 7).

At puberty, trabecular density increases by race and sex, but within a race there is no sex difference in trabecular density. This increase is probably the result of cessation of external growth in bone size but continued bone formation

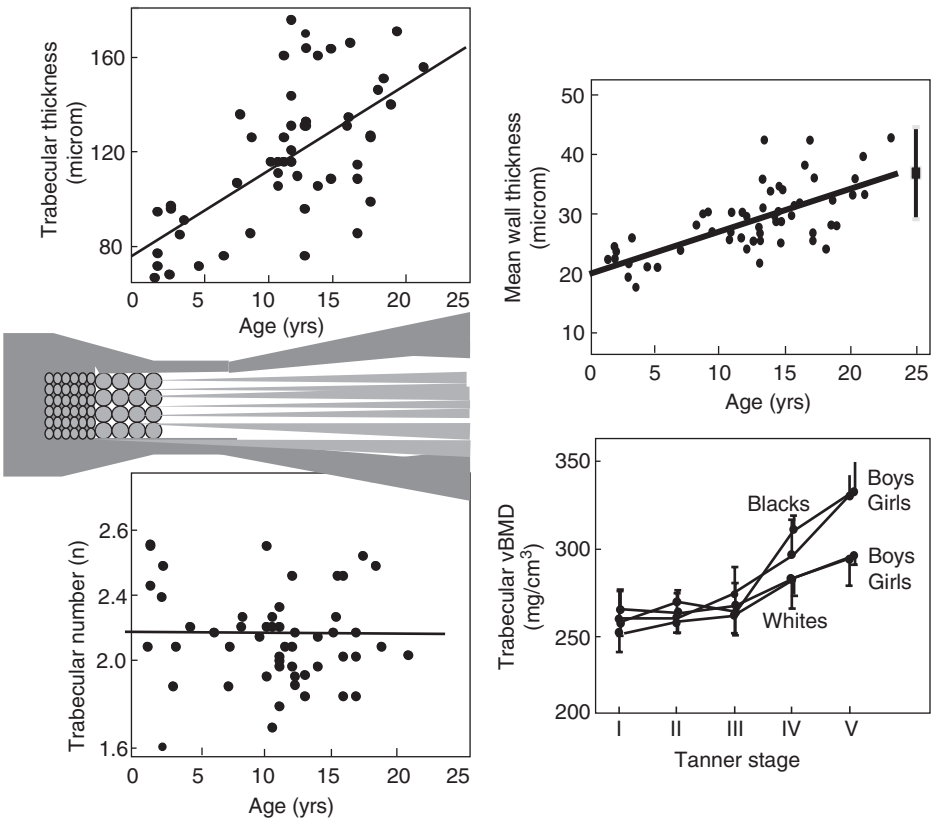

FIGURE 7 Trabecular volumetric bone mineral density (vBMD) increases with advancing age due an increase in trabecular thickness not numbers. This occurs by an increase in bone formation reflected in the increase in mean wall thickness. Adapted from Parfitt *et al.* (2000). Before puberty, trabecular vBMD is no different by sex or race, increases at Tanner stage 3 similarly by sex within a race but more greatly in African Americans than Caucasians. Adapted from Gilsanz *et al.* (1991).

on trabecular and endocortical envelopes resulting in more bone within the periosteal envelope of the bone – higher vBMD. Thus, growth does not build a "denser" vertebral body in males than females; it builds a bigger vertebral body in males. Strength of the vertebral body is greater in young males than females because of size differences. Within a sex, African Americans have a higher trabecular density than whites due to a greater increase in trabecular thickness (Han *et al.,* 1996). The mechanisms responsible for the racial dimorphism in trabecular density but resemblance in males and females within a race are yet to be defined. The greater trabecular thickness in African Americans accounts for the lower remodeling rate in adulthood because there is less surface available for remodeling (Han *et al.,* 1996).

Sex differences in appendicular growth are partly the result of differences in timing of puberty (Fig. 8). Before puberty there are already sex differences in diaphyseal diameter (Iuliano *et al.,* 2008). As long bones increase in length by endochondral apposition, periosteal apposition widens the lengthening long bone. Concurrent endocortical resorption excavates the marrow cavity but as periosteal apposition is greater than endocortical resorption, the cortex thickens. In females, earlier completion of longitudinal growth with epiphyseal fusion and earlier inhibition of periosteal apposition produces a smaller bone.

Bone length continues to increase in males and periosteal apposition increases cortical thickness. However, cortical thickness is similar in males and females because endocortical apposition in females contributes to final cortical thickness (Garn, 1970; Bass *et al.,* 1999). Cortical thickness is similar by race and sex. What differs is the position of the cortex in relationship to the long axis of the long bone (Wang *et al.,* 2005; Duan *et al.,* 2005). It is not clear whether the wider diaphysis in males than females is the result of accelerated periosteal apposition in males as commonly believed, or is the result of continued longitudinal growth in males as they enter puberty one to two years after females (Garn, 1970).

In summary, the cellular machinery of bone modeling and remodeling adapt bone size, shape, and mass distribution to its loading circumstances throughout the whole of growth ensuring that strength is optimized by depositing bone where it is needed and mass is minimized by removing bone from where it is not. The magnitude of the trait variances in adulthood are largely expressed in childhood. Traits track in their percentile of origin established at some time before puberty, if not in utero. Thus, differences in bone size and mass from individual to individual

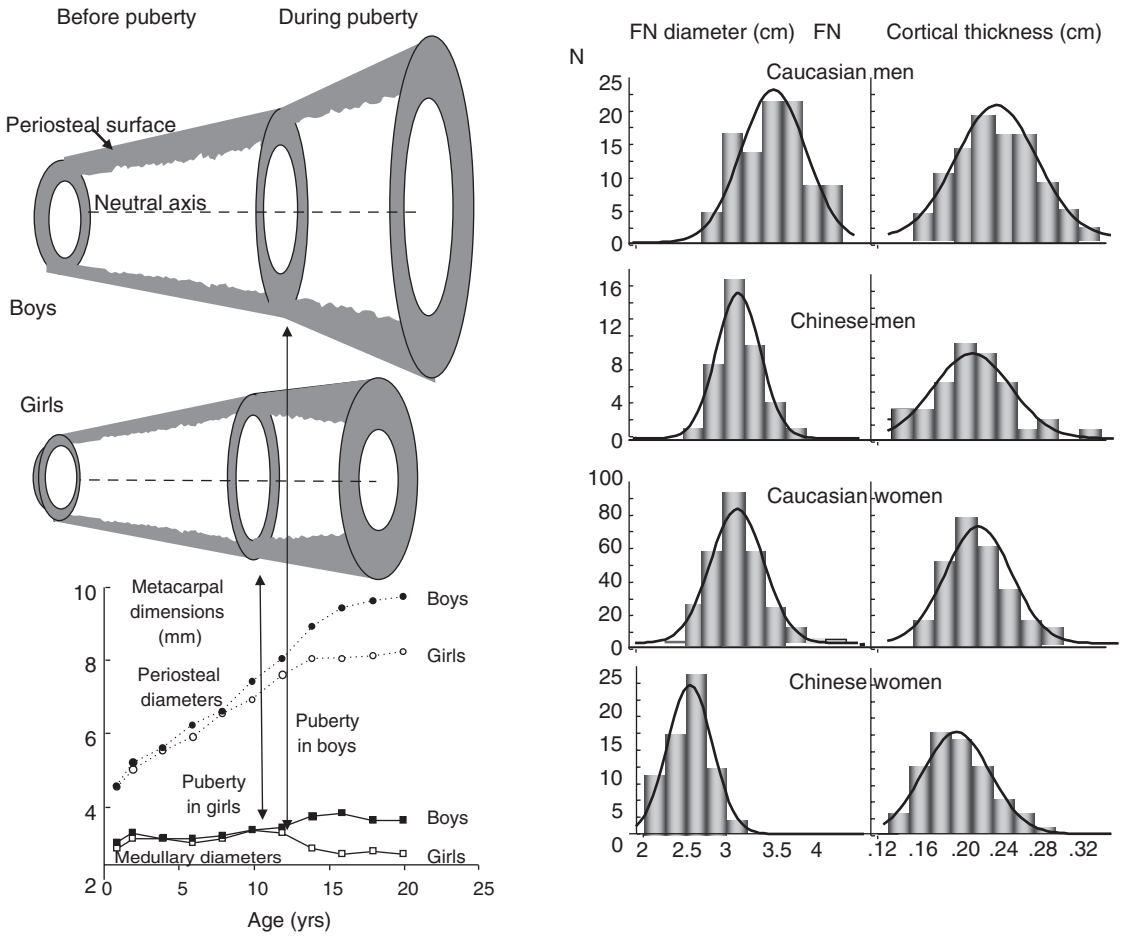

FIGURE 8 Long bone diameter is already greater in males than females before puberty. Growth in length and width continues longer in males because puberty occurs later. Endocortical apposition in females contributes to cortical thickness so that final cortical thickness is similar in males and females but displaced further radially in males. Adapted from Garn (1970). Distribution of femoral neck (FN) diameter differs by sex and race but femoral neck cortical thickness is similar by sex and race. E. Seeman with permission.

in adulthood are likely to be already evident early in life. This is obvious for cross-sectional size because periosteal apposition is minimal after completion of longitudinal growth. It is less obvious that the amount of bone within the periosteal envelope in adulthood is also largely established during growth (Zebaze *et al.,* 2007).

Variance in bone mass at completion of growth is an order of magnitude greater than variance in rates of bone loss during aging (1 SD = 10% versus 1%, respectively) (Parfitt, 1996). Thus, bone size, architecture, and mass attained during growth is likely to play an important role in determining the relevance of bone loss during advancing age (Hui *et al.,* 1999; Seeman *et al.,* 2001). For example, in children with larger tibial cross-sections, the advantage of assembling the larger bone with a relatively thinner cortex (to avoid bulk) may be a disadvantage when age-related bone loss occurs. Women with hip fractures and their daughters have larger femoral neck diameters and reduced vBMD (Filardi *et al.,* 2004). In smaller bones, the fragility of slenderness is offset by constructing them with more mass relative to their size as less endocortical resorption excavates a smaller marrow cavity, leaving a relatively thicker cortex. This balance may be compromised as bone loss produces cortical thinning and intracortical porosity which reduce compressive strength and resistance to bending.

BONE MODELING AND REMODELING IN ADULTHOOD AND THE EMERGENCE OF BONE FRAGILITY

The Purpose of Modeling and Remodeling in Adulthood – Maintenance of Bone Strength

The purpose of modeling and remodeling during growth is to achieve the skeleton's peak strength. The purpose of bone remodeling during adulthood is to maintain bone strength by removing damaged bone. *Bone, like roads, buildings, and bridges, develops fatigue damage during repeated loading but

only bone has a mechanism enabling it to detect the location and magnitude of the damage, to remove it, replace it with new bone, and thus to restore bone's material composition, micro- and macroarchitecture (Parfitt, 1996; Parfitt, 2002).

Bone resorption is not bad for bone unless it becomes excessive and untargeted. On the contrary, the resorptive phase of the remodeling cycle removes damaged bone and is essential to bone health. Indeed, prolonged suppression of remodeling using potent anti-resorptive therapy may result in microdamage accumulation, fractures, and reduced bone healing (Mashiba *et al.,* 2000; Odvina *et al.,* 2005). The formation phase of the remodeling cycle restores bone's structure provided that the volume of damaged bone removed is replaced by the same volume of normal bone. This process depends on the normal production, work, and life span of osteoclasts and osteoblasts, but the BMU is a *multicellular* unit and many cell types participate in the remodeling cascade.

The Pivotal Role of Osteocyte Death in Bone Remodeling

The osteocyte is one of these cells and is likely to play a pivotal role in bone modeling and remodeling. Osteocytes are the most numerous, longest-lived, and least studied cells of bone. There are about 10,000 cells per cubic millimeter and 50 processes per cell (Marotti *et al.,* 1990). These processes connect osteocytes with each other and with flattened lining cells on the endosteal surface. Thus, bone with its haversian and Volkmann canals and its lacunar-canalicular system is no less intricate in design than the hepatobiliary, bronchoalveolar, or glomerulotubular communication systems (Fig. 9, Panel 1). The dense lace-like network of osteocytes with their processes ensures that no part of bone is more than several microns from a lacuna containing its osteocyte suggesting that these cells are part of the machinery guarding the integrity of the composition and structure of bone (Parfitt, 2002).

Microcracks sever osteocyte processes in their canaliculi, producing osteocyte apoptosis (Hazenberg *et al.,* 2006) (Fig. 9, Panel 2). Apoptotic osteocytes may also be a form of damage, perhaps reducing the energy absorbing/dissipating capacity of bone when lacunae mineralize. Estrogen deficiency and corticosteroid therapy result in apoptosis (Manolagas, 2006). The increased remodeling rate in midlife in women may be partly the result of osteocyte death. Alternatively, or in addition, osteocyte apoptosis can produce damage to surrounding mineralized matrix producing bone fragility (independent of bone loss). Corticosteroid-treated mice have large osteocyte lacunae surrounded by matrix with a 40% reduction in mineral and reduced elastic modulus (Lane *et al.,* 2006). Genetic ablation of osteocytes produces bone fragility and failed mechanotransduction (Tatsumi *et al.,* 2007). Prevention of osteocyte death may be an attractive therapeutic target if they are damage or produce damage (Keller and Kneissel, 2005; Manolagas, 2006). Fragility can be prevented using anti-apoptotic agents (O'Brien *et al.,* 2004; Manolagas, 2006).

Whether apoptotic osteocytes are a consequence of damage, are the damage itself, or produce matrix damage, the number of dead osteocytes provides the topographical information needed to identify the location and size of damage (Verborgt *et al.,* 2000; Taylor 1997; Schaffler and Majeska, 2005) (Fig. 9, Panel 3). Osteocyte apoptosis is likely to be one of the first events signaling the need for remodeling. It precedes osteoclastogenesis (Clark *et al.,* 2005). *In vivo*, osteocyte apoptosis occurs within three days of immobilization and is followed within two weeks by osteoclastogenesis (Aguirre *et al.,* 2006). *In vitro*, death of the osteocyte-like MLO-Y4 cells induced by scratching results in the formation of TRACP positive (osteoclast-like) cells along the scratching path (Kurata *et al.*, 2006).

Thus, just as the spider knows the location and size of its wriggling prey by signals sent along its vibrating web, the need for reparative remodeling is likely to be signaled by osteocyte death via their processes connected by gap junctions to flattened osteoblast lining the inner or endosteal surface of bone where remodeling takes place. The nature of the signal from the osteocyte remains unknown.

The Pivotal Role of the Bone Remodeling Canopy in Bone Remodeling

It is not yet feasible to study the life of a BMU *in vivo*, documenting its birth, daily work in resorption, and formation to its end as an ossified osteon or hemi-osteon; the "fossilized" record of that remodeling cycle. Inferences regarding the sequence of events and their molecular regulation must be made with trepidation because observations are based on histomorphometric "snapshots" and *in vitro* studies of cell systems.

Bone remodeling occurs on the endocortical, trabecular, and intracortical components of the endosteal envelope. The endocortical and trabecular surfaces are adjacent to marrow. The intracortical surface forms the wall of haversian canals. While remodeling occurs on these endosteal surfaces, damage occurs deep to them, within the matrix of osteons or the interstitial bone between osteons in the case of cortical bone or within hemi-osteons in the case of trabecular bone. So, information concerning the location and size of damage must reach these surfaces and cells involved in remodeling must reach the site of damage beneath the endosteal surface. This anatomical arrangement makes the flattened lining cells conduits transmitting the health status of the bone matrix to the bone marrow environment, which in turn is a source of the cells of the BMU, but not the only source.

Apoptotic osteocytes signal the location and size of the damage burden to the flattened lining cells of the endosteal

Central regulation of bone remodeling and the role of remodeling in energy metabolism will not be discussed (Ducy *et al.,* 2000; Lee *et al.,* 2007).

surface leading to the formation of a bone remodeling compartment (BRC), which confines and targets remodeling to the damage minimizing removal of normal bone (Hauge *et al.,* 2001) (Fig. 9, cartoon and especially Panel 5). The regulatory steps between osteocyte apoptotic death and creation of the BRC are not known. Bone lining cells express collagenase mRNA (Fuller and Chambers, 1995). An early event creating the BRC may be collagenase digestion of unmineralized osteoid to expose mineralized bone, a requirement for osteoclastic bone resorption to proceed.

The flattened bone lining cells are probably osteoblasts. They express markers of the osteoblast lineage, particularly those forming the canopy over the BRC (Hauge *et al.,* 2001; Parfitt, 2001). These canopy cells also express markers for a range of growth factors and regulators of osteoclastogenesis such as RANKL suggesting that the canopy has a central role in the differentiation of precursor cells of marrow stromal origin, monocyte-macrophage origin, and vascular origins toward their respective osteoblast, osteoclast, or vascular phenotypes.

The Multidirectional Steps of the Remodeling Cycle

Although the two classical events of remodeling – resorption of a volume of bone by osteoclasts and formation of a similar volume of bone by osteoblasts occur sequentially (Hattner *et al.,* 1965), the cellular and molecular regulatory events leading to these two fully differentiated functions may not be sequential. Some may be contemporaneous and multidirectional; osteoblastogenesis and its regulators determine osteoclastogenesis and the volume of bone resorbed whereas osteoclastogenesis and the products of the resorbed matrix regulate osteoblastogenesis, while both may be regulated to some extent by osteocytes and its products (e.g., sclerostin). How this cellular and molecular traffic is orchestrated from beginning to end is far from clear.

Signaling from apoptotic osteocytes to cells in the canopy expressing the osteoblast phenotype may influence further differentiation toward osteoblast precursors expressing RANKL and fully differentiated osteoid-producing

osteoblasts. So even at this stage, regulation of osteoclastogenesis and osteoblastogenesis is occurring simultaneously through osteoblast precursors. In the MLO-Y4 cell line, damaged osteocyte-like cells have been reported to secrete M-CSF and RANKL (Kurata *et al.,* 2006). Whether this occurs in human subjects *in vivo* is not known but raises the possibility that osteocytes participate in the differentiation of monocyte-macrophage precursor cells toward the osteoclast lineage. Both osteoblast and osteoclast precursors circulate and so may arrive at the BRC via the circulation and via capillaries penetrating the canopy (Eghbai-Fatourechi *et al.,* 2005; Eghbai-Fatourechi *et al.,* 2007; Fujikawa *et al.,* 1996). The contribution of precursors from the canopy, the marrow via sinusoids or capillaries is not well-defined.

Angiogenesis is essential to bone remodeling. Osteoprogenitor cells are associated with vascular structures in the marrow and several studies suggest there may be common progenitors giving rise to cells forming the blood vessel and the perivascular cells that can differentiate toward cells of multiple lineages (Doherty *et al.,* 1998; Howson *et al.,* 2005; Sacchetti *et al.,* 2007; Matsumoto *et al.,* 2006; Kholsa, 2007; Otsura *et al.,* 2007; Khosla *et al.,* 2008).

Once differentiated, teams of osteoclasts resorb a volume of damaged bone but little is known of the factors determining the volume of bone resorbed, particularly how resorption stops after the damaged region has been resorbed. Osteoclasts phagocytose osteocytes and this may be one way the signal for resorption is removed (Fig. 9, Panel 4).

Products from the osteoclasts independent of their resorption activity, and products from the resorbed matrix partly regulate osteoblastogenesis and bone formation (Suda *et al.,* 1999; Martin and Sims, 2005; Lorenzo, 2000). In addition, products from the osteocyte may contribute to regulation of bone formation. For example, sclerostin is secreted by osteocytes and perhaps other cells as well. It is a product of the ScleroSteosis (SOST) gene and inhibits bone formation. Its inhibition is permissive to bone formation. Whether osteoblast precursors are generated before resorption has occurred, either from the canopy, or by products of the osteoclast before it started matrix resorption is not known. If so, these cells form preemptive teams of cells ready to deposit bone, die, become lining cells or osteocytes depending on later signals from osteoclasts, the resorbed matrix or products of the osteocyte such as sclerostin or cell–cell contact (Zhao *et al.,* 2006).

After the reversal phase, osteoblasts deposit osteoid partly or completely filling the trench cross-section (establishing the size of the negative BMU balance in that cross-section) and forming the lamellae that then undergo primary and secondary mineralization. In a given cross-section, how the osteoblasts change polarity to produce the differently orientated collagen fibers from lamella to lamella is not known. Most osteoblasts die, others become lining cells whereas others become entombed in the osteoid they formed to become osteocytes which communicate with each other to "rewire" the osteocytic canalicular communicating system for later mechanotransduction, damage detection, and repair (Han *et al.,* 2004).

In summary, bone remodeling may not be exclusively damage-driven but if it is, the osteocyte appears to play a pivotal role in initiating this remodeling cycle and perhaps participating in the regulation of the volumes of bone ultimately resorbed and formed by the BMU. Many of the advances that have taken place raise more questions than they answer. Some very fundamental questions concern the role of remodeling in intermediary metabolism, the link between central control of remodeling and regulation of remodeling for regional structural adaptation to loading and focal damage removal.

Even the question of what is "damage" betrays many areas in need of exploration. Damage at the nano- or microstructural level has not been comprehensively categorized in morphological terms so that the causes of damage, biomechanical effects, biochemical and structural means of detecting, signaling, and repairing different types of damage remain unstudied (Akkus *et al.,* 2004; Burr *et al.,* 1998; Danova *et al.,* 2003; Diab *et al.,* 2006; Diab and Vashisha, 2005; Garnero *et al.,* 2006; Landis, 2002; Ruppel *et al.,* 2006; Silva *et al.,* 2006; Taylor, 1997).

Age-Related Changes in Modeling and Remodeling Adulthood

Although bone can accommodate loading circumstance by adaptive modeling and remodeling during growth, this capacity diminishes because four age-related changes in the cellular machinery of bone modeling and remodeling compromise bone's material properties and structural design. Bone's ability to adapt to loading is impaired because each time a remodeling event occurs there is loss of bone and some structural decay (Seeman and Delmas, 2006).

Remodeling rate is rapid during growth because each remodeling event deposits only a small moiety of bone (Parfitt, 2002). As growth nears its "programmed" completion, rapid remodeling is no longer needed and remodeling rate slows. With the completion of longitudinal growth, the only requirement for bone formation is the repair of micro- and macrodamage so there is a decline in bone formation, a mechanism proposed to be responsible for bone fragility over 65 years ago (Albright *et al.,* 1941).

Thus, the first age-related change in this machinery is a reduction in bone formation at the cellular level by each BMU (Lips *et al.,* 1978; Vedi *et al.,* 1984) (Fig. 10). The second abnormality is also a reduction in bone formation but at the tissue level – bone modeling on the periosteal envelope slows precipitously after completion of

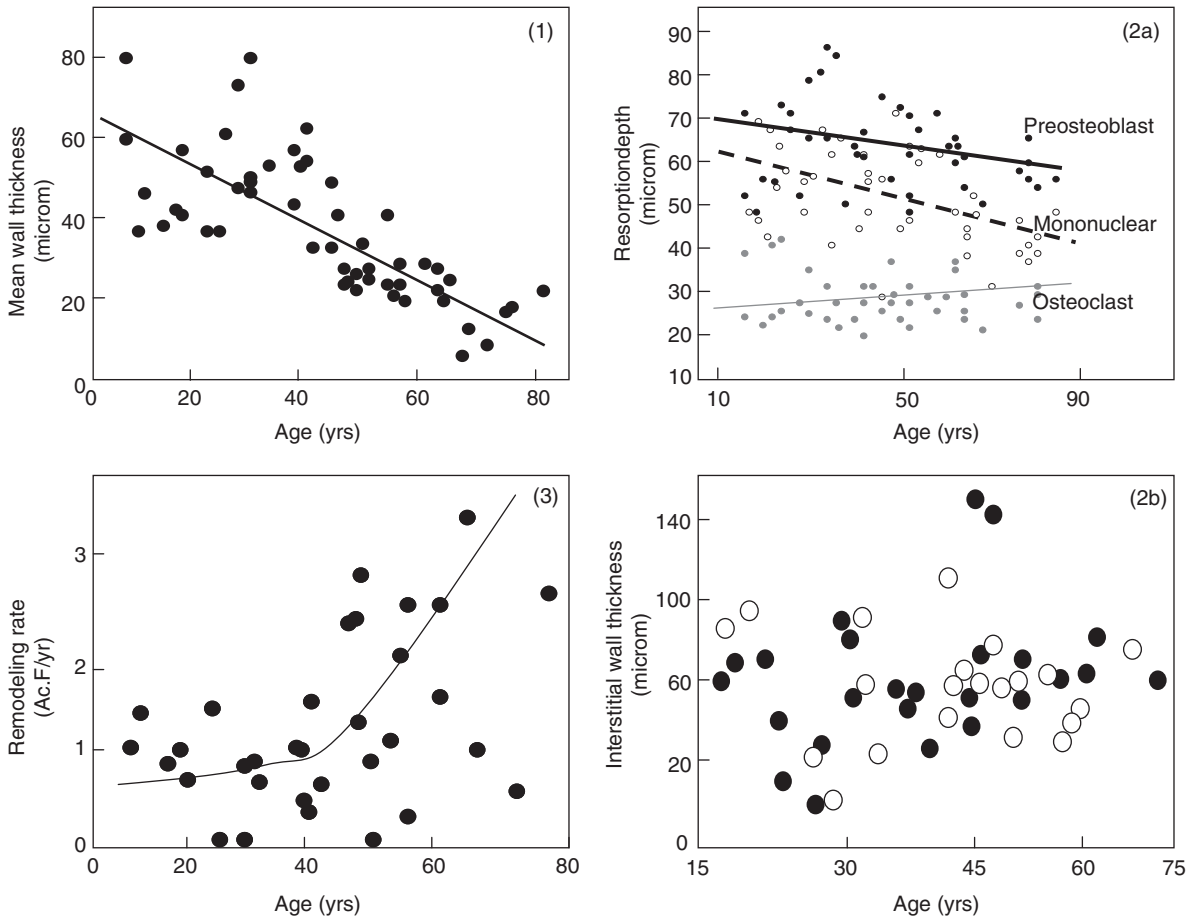

FIGURE 10 Endosteal bone loss is the result of: (1) a reduction in the volume of bone formed in each basic metabolic unit (BMU) reflected in a reduction in mean wall thickness with age. Adapted from Lips *et al.* (1978); (2) A fall or little change in the volume of bone resorbed in each BMU. This is reflected in (2a) as little change in erosion depth defined by preosteoblasts, mononuclear cells, or osteoclast surfaces (Adapted from Ericksen *et al.,* 1985) and (2b) and no change in interstitial wall thickness (females black symbols) Adapted from Vedi *et al.* (1984); and (3) Increased remodeling rate (activation frequency). Courtesy J. Compston.

longitudinal growth but continues slowly so that bone diameters enlarge, but no more than a few millimeters during the next 60 years.

The mechanisms responsible for the reduction in the volume of bone formed in each BMU are not well-defined but may include a reduction in stem cell precursors of osteoblasts, a reduction in differentiation of stem cells to the osteoblast lineage, reduced osteoid production of individual cells, and a reduction in the life span of these cells (Bonyadi *et al.,* 2003; Nishida *et al.,* 1999; Stenderup *et al.,* 2001; Oreffo *et al.,* 1998).

The third abnormality in remodeling is believed to be an increase in the volume of bone resorbed by the BMU but this may be confined to a brief period following sex hormone deficiency (Ericksen, 1986; Ericksen *et al.,* 1999; Manolagas, 2000; Compston *et al.,* 1995). The opposite may occur across the whole of life – the volume of bone resorbed by each BMU appears to decrease as reflected in a lower resorption cavity depth and an age-related increase, rather than decrease, in interstitial thickness (Croucher *et al.,* 1991; Ericksen *et al.,* 1999). (If resorption depth increased with age, interstitial wall thickness, the distance between cement lines of opposing hemi-osteons in trabecular bone, should decrease.)

The fourth age-related abnormality in the cellular machinery contributing to structural decay is an increase in the rate of bone remodeling after menopause. This is accompanied by worsening of the negative bone balance in each BMU as the volume of bone resorbed increases and the volume of bone formed decreases in the many more BMUs now remodeling bone on the three (endocortical, intracortical, and trabecular) components of its endosteal envelope (Manolagas, 2000).

Bone Loss During Young Adulthood

If the volume of bone resorbed decreases to the same degree as the decrease in the volume of bone formed by the BMU there will be no net negative BMU balance at the

completion of a remodeling cycle so remodeling events will not produce any permanent bone loss or structural decay. However, at some stage in midlife or early, there is a net negative bone balance as the volume of bone resorbed exceeds that formed (irrespective of the absolute decrease in both) and this negative BMU balance is the necessary and sufficient requirement for loss of bone from the skeleton, structural decay, and bone fragility.

There is evidence using noninvasive methods such as densitometry or computed tomography for a decline in bone mass in young adulthood in women and in men (Riggs *et al.,* 1986; Gilsanz *et al.,* 1987; Riggs *et al.,* 2007). Assuming the decline is not an artifact produced by an increase in marrow fat with age (Bolotin and Sievänen, 2001), this decline is likely to be the result of bone loss driven by a decline in bone formation. More definitive statements cannot be made due to lack of histomorphometric data in premenopausal women and young adult men.

Riggs *et al.* report a decline in trabecular volumetric density prior menopause in a 3-year prospective study of 553 women and men (Riggs *et al.,* 2007). Before age 50, women lose 37% and men 42% of the total trabecular bone lost across life, and 6% and 15% of lifetime cortical bone loss. The structural and biomechanical consequences are likely to be less than bone loss later in life because (1) remodeling rate is slow, (2) trabecular bone loss probably proceeds by reduced bone formation rather than increased bone resorption in the BMU, (3) bone loss proceeds by trabecular thinning rather than loss of connectivity so a given decrement in trabecular BMD produces less loss of strength than produced by loss of connectivity (van der Linden *et al.,* 2001), and (4) continued periosteal apposition partly offsets endocortical bone loss shifting the cortices radially maintaining cortical area and resistance to bending (Szulc *et al.,* 2006).

Bone Loss During Menopause and Advancing Age

Variance in the positive BMU balance on trabecular surfaces during growth is small compared with the variance in the rate of remodeling so that the rate of gain in bone mass is driven more by the remodeling rate. Similarly, the variance in the negative BMU balance during aging is small compared with the variance in the rate of remodeling so the rate of bone loss during menopause and aging is driven more by the remodeling rate.

Thus, the higher rate of bone remodeling is a most important determinant of bone loss and the increase in remodeling rate in midlife associated with estrogen deficiency is responsible for accelerated bone loss. Perimenopausal women with remodeling rates in the lowest quartile lose little bone (Szulc *et al.,* 2006). Estrogen deficiency also increases the volume of bone resorbed by each BMU by prolonging the life span of osteoclasts, and reduces the volume of bone formed by each BMU by reducing the life span of osteoblasts, thereby aggravating the negative BMU balance (Manolagas, 2000). Whether the changes in the life span of the cells is permanent or temporary is not known but the combination of a rapid remodeling and a more negative BMU balance than observed before menopause accelerates bone loss and structural decay after menopause.

Before menopause, remodeling is slow. The birth rate of new BMUs creating resorption cavities is matched by slow completion of previously created BMUs in their formation phase. At menopause, this steady state is perturbed by an increase in the birth rate of new BMUs on bone's endosteal envelope. The now many BMUs remove bone while the fewer BMUs created before menopause complete remodeling by depositing bone. This perturbation produces a net acceleration in bone loss and a rapid decline in BMD (Fig. 11).

This is the remodeling transient, a reversible loss of bone mass and bone mineral that is a consequence of the normal delay in onset and slower progression of the formation phase of the remodeling cycle in the many remodeling foci created after menopause (Parfitt, 1980). The temporary deficit in bone mass and mineral has three components: the excavation site that lacks osteoid and mineral, the osteoid that lacks mineral, and bone that has undergone primary but not secondary mineralization. Primary mineralization occurs rapidly, secondary mineralization, the slow enlargement of crystals of calcium hydroxy-apatite-like mineral takes many months to years to go to completion (Akkus *et al.,* 2003). At any time, there are osteons created in the immediate postmenopausal period and fewer, earlier created, osteons at various stages of completing secondary mineralization.

Bone loss slows in the three to five years following menopause, not because remodeling rate slows. It doesn't. The rate of bone loss slows because steady state is restored at the new higher remodeling rate. Now the large numbers of BMUs excavating resorption cavities are matched by completion of remodeling by bone formation the large numbers of BMUs created in early menopause. Bone loss continues at a faster rate than before menopause but at a slower rate than immediately after menopause because BMU balance is negative, perhaps more negative than before menopause producing a permanent deficit in bone mass and mineral mass. The higher the remodeling rate and the more negative the BMU balance, the greater the bone loss and structural decay. If the worsening BMU balance produced by changes in the life span of osteoclasts and osteoblasts is temporary, and the negative BMU balance lessens but persists, the rate of loss will also lessen, but it will persist because bone loss is driven by the high remodeling rate.

Remodeling occurs on bone surfaces (envelopes), much more on the endosteal envelope than the periosteal envelope (Balena *et al.,* 1992; Orwoll, 2003), and more on the

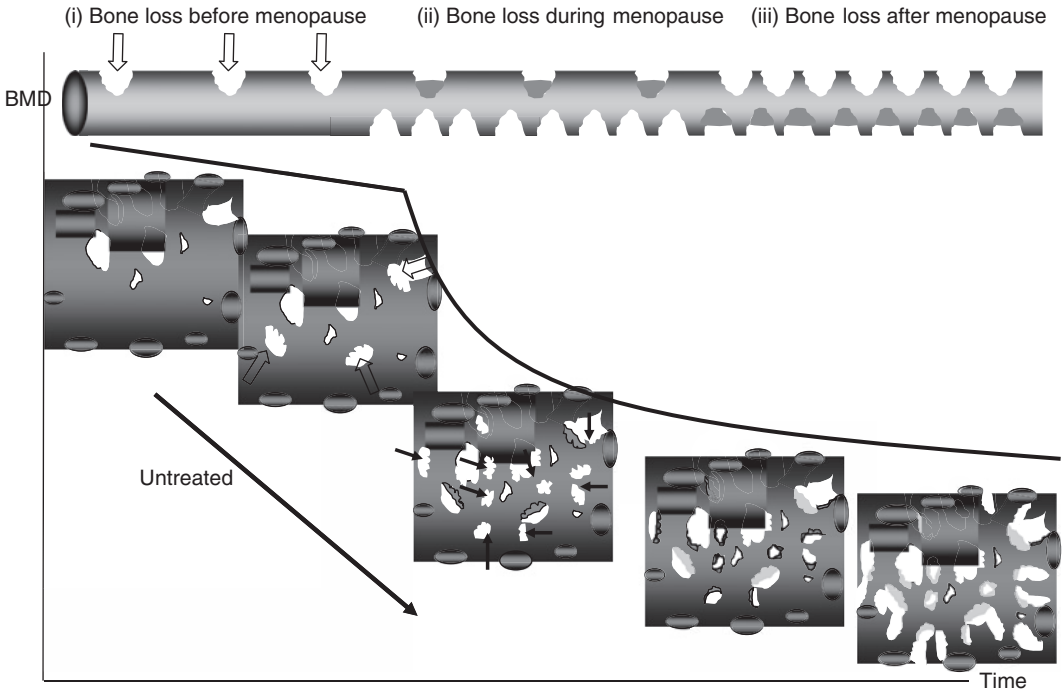

FIGURE 11 (i) Bone loss is slow before menopause because remodeling is slow; only a few sites on the trabecular surface remove bone (open arrows). (ii) Bone loss accelerates at menopause as remodeling rate increases. Now many basic multicellular units (BMUs) remove bone (black arrows) while the three BMUs initiated before menopause deposit bone. (iii) Bone loss after menopause slows because steady state is restored. The many BMUs removing bone at menopause are now in their formation phase but as many new BMUs are created and resorb bone. Bone is lost because each remodeling event removes bone from bone. E. Seeman with permission.

trabecular than endocortical and intracortical surfaces of the endosteal envelope. Trabecular bone has more surface per unit bone volume than cortical bone so that trabecular bone is more likely to be remodeled than cortical bone. Excavated resorption sites create stress "concentrators," that focus stresses to a single point (as a small cut in a test tube makes it easy to snap) (Hernandez *et al.,* 2006) (Fig. 12, upper panels). The high remodeling rate and negative BMU balance produces trabecular thinning and complete loss of trabeculae. Increased resorption depth is more likely to produce perforation and complete loss of trabeculae than either greater numbers of resorption cavities or reduced formation in the BMU in women (Parfitt, 1996). A 10% loss of trabecular density by perforation reduces strength more greatly than the same loss by trabecular thinning (Fig. 12, lower panel).

As remodeling continues, trabeculae are lost so the trabecular surface available for resorption decreases but remodeling on endocortical surface continues increasing the endocortical surface (like the folds of a curtain) (Parfitt, 1984; Brown *et al.,* 1987; Arlot *et al.,* 1990; Foldes *et al.,* 1991). Remodeling on the intracortical surface (haversian canals) increases intracortical porosity (Martin, 1984; Brockstedt *et al.,* 1993; Yeni *et al.,* 1997) (Fig. 13). Increased porosity due to increased numbers of pores and/or increased size of pores by coalescence of adjacent remodeling cavities increases the surface available for remodeling "trabecularizing" the cortex. Either total bone surface does not change (increasing in cortical bone, decreasing in trabecular bone) or increases (in regions of cortical bone only) so that late in life, bone loss is more cortical than trabecular in origin.

As age advances and remodeling continues at the same intensity due to estrogen deficiency and perhaps secondary hyperparathyroidism, the extent of coalescence of pores increases so the number of pores in cortical bone decreases but the total area of porosity increases, and perhaps more so in patients with hip fractures than controls (Bell *et al.,* 1999). Cortices porosity reduces the ability of bone to limit crack propagation so that bone cannot absorb the energy imparted by a fall and so it is released in the most undesirable way by fracturing (Martin, 1984; Yeni *et al.,* 1997). The continued remodeling at a similar intensity with its negative BMU balance, on the same amount or more surface, removes the same amount of bone from an ever-decreasing amount of bone accelerating the loss of bone and structural decay.

Rapid remodeling also modifies the material properties of bone increasing fracture risk. More densely mineralized bone is removed and replaced with younger, less densely mineralized bone, reducing stiffness (Boivin and Meunier, 2002; Boivin *et al.,* 2003). Increased remodeling impairs isomerization of collagen reducing bone strength (Viguet-Carrin *et al.,* 2006; Garnero *et al.*, 1996). Interstitial bone deep to surface remodeling becomes more densely mineralized and more highly cross linked with advanced glycation

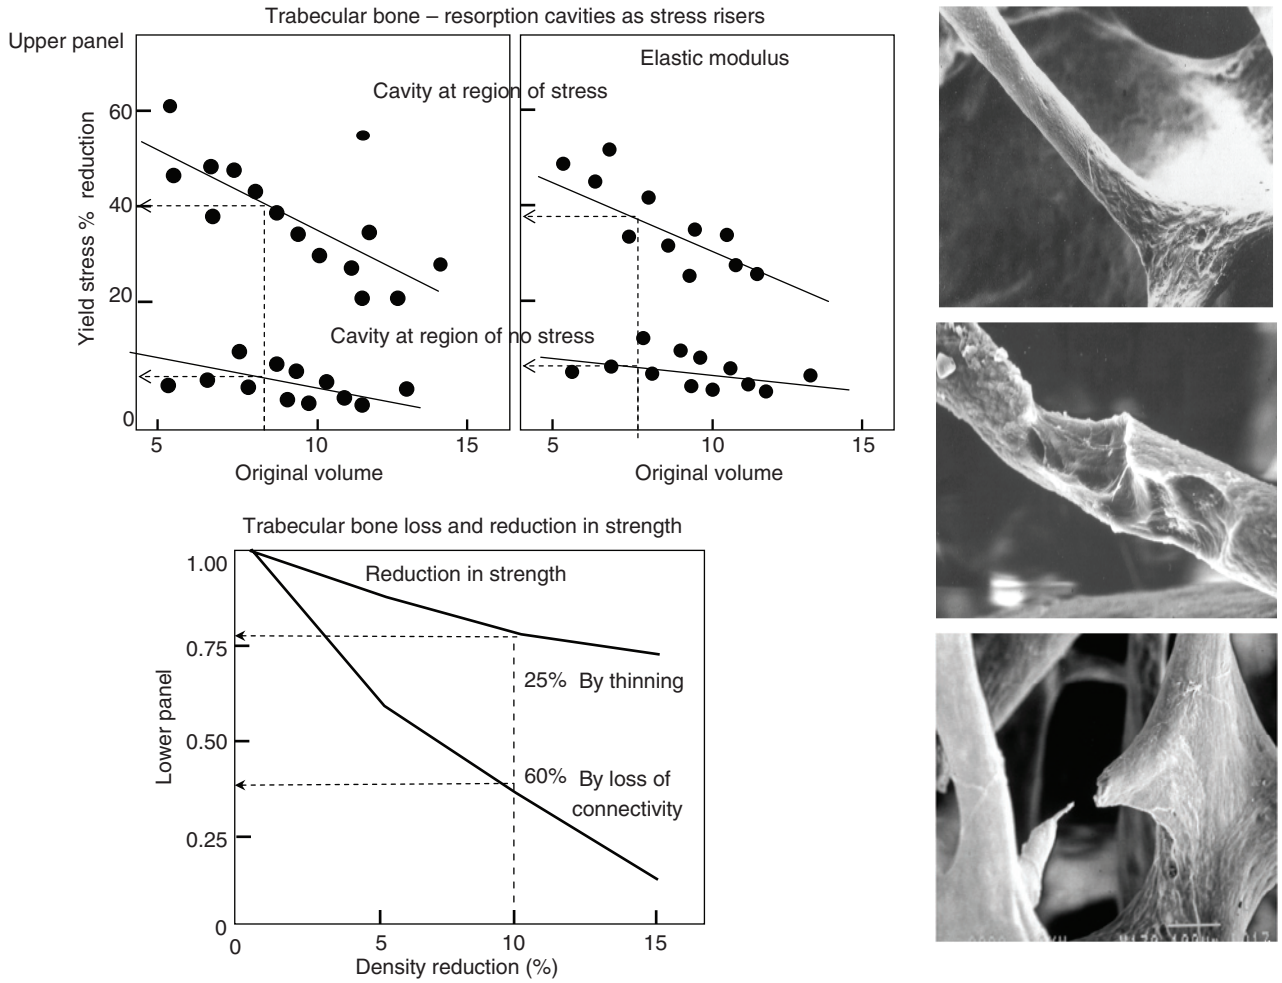

FIGURE 12 Upper panels: When resorption cavities occur in regions of stress on trabecular bone the decline in yield stress and elastic modulus is greater than produced by cavities in unstressed regions. Adapted from Hernandez *et al.* (2006). Lower panel: Reduction in strength produced by 10% deficit in trabecular density is greater when this deficit is produced by loss of trabecular connectivity than by thinning. Adapted from Van der Linden *et al.* (2001). Images show an intact trabecula, a resorption cavity, and loss of connectivity. Mosekilde and Mosekilde, 1990 With permission from the publisher.

products (AGEs) like pentosidine, both processes reducing bone toughness; it is easier for microcracks to travel through homogeneously mineralized bone and lengthen. Interstitial bone (between osteons) has reduced osteocyte numbers, accumulating microdamage (Bailey *et al.,* 1999; Banse *et al.,* 2002; Nalla *et al.,* 2004; Qui *et al.,* 2005; Yeni *et al.,* 1997).

Net Effects of Reduced Periosteal Bone Formation and Endosteal Bone Loss

The challenges regarding identifying the existence of periosteal apposition during adulthood, its site specificity, magnitude, and sex differences are considerable. In cross-sectional studies, secular changes in bone size may obscure or exaggerate periosteal apposition. These problems are not necessarily resolved by adjusting for height. Secular increases in stature occur in one or both sexes, in some races but not others and may occur in the skelton of the upper or lower body (Bakwin, 1964; Meredith, 1978; Cameron *et al.,* 1982; Tanner *et al.,* 1982; Malina and Brown, 1987). These secular trends can produce misleading inferences when increments or lack of increments in bone diameters are used as surrogates of periosteal apposition.

For example, in cross-sectional studies, absence of an increment in periosteal diameter across age may not mean periosteal apposition was absent. Earlier born individuals (the elderly in a cross-sectional sample) may have been shorter and had more slender bones than later born individuals (young normals in a cross-sectional sample). When periosteal apposition occurs, earlier born with more slender bones have an increase in bone diameter that comes to equal that in later born group (who have not yet had age-related periosteal apposition) leading to the flawed inference that there was no periosteal apposition in the cross-sectional sample.

When comparisons are made between sexes (or races) in cross-sectional studies, if the truth is that periosteal

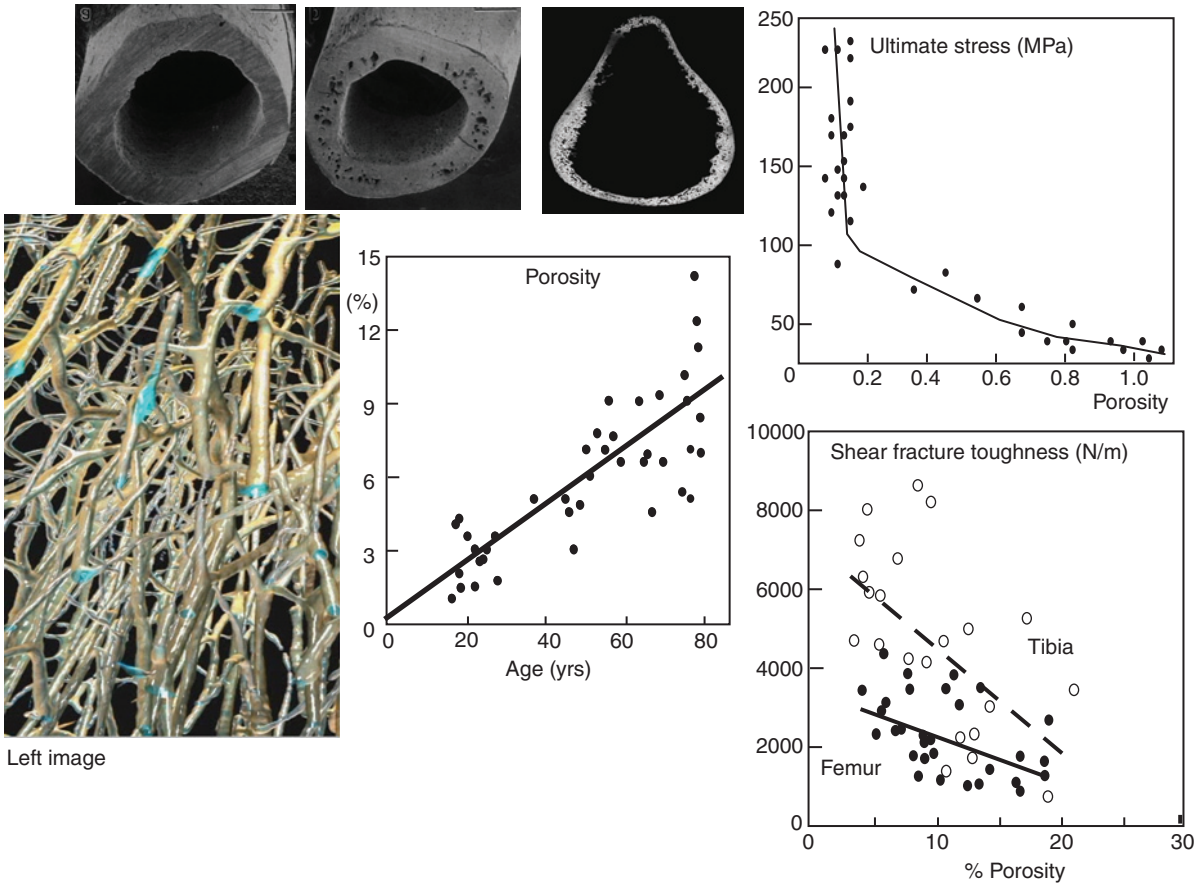

FIGURE 13 Cortical porosity increases as age advances (Brockstedt *et al.* 1993). This is associated with a decline in ultimate stress (adapted from Martin, 1984) and reduction in toughness (adapted from Yeni *et al.,* 1997). Upper images illustrate increasing porosity and thinning. Left image shows haversian canals in longitudinal section responsible for porosity in cross-section. Courtesy M. Knackstedt, Australian National University, Canberra. (See plate section)

apposition is greater in men than women but men have a secular increase in bone size and women do not, then the secular increase in men will blunt the increment in bone width across age in men and make it appear that the age-related increase in vertebral and femoral neck diameters (and so periosteal apposition) is similar in women and men. Longitudinal studies are also problematic because changes in periosteal apposition during aging are small (Balena *et al.,* 1992). The precision of methods to determine bone diameter, usually bone densitometry, and problems with edge detection when bone mineral density is changing limit the credibility of these measurements.

Periosteal apposition is believed to increase as an adaptive response to compensate for the loss of strength produced by endocortical bone loss, so there will be no *net* loss of bone, no cortical thinning, and no loss of bone strength (Alhborg *et al.*, 2003). In a 7-prospective study of over 600 women, Szulc *et al.* report that endocortical bone loss occurred in premenopausal women with concurrent periosteal apposition (Szulc *et al.,* 2006) (Fig. 14). As periosteal apposition was less than endocortical resorption, the cortices thinned but there was no *net* bone loss because the thinner cortex was now distributed around a larger perimeter conserving total bone mass. Moreover, resistance to bending increased despite bone loss and cortical thinning because this same amount of bone was now distributed further from the neutral axis. So bone mass alone is a poor predictor of strength because resistance to bending is determined by the spatial distribution of the bone.

Endocortical resorption increased during the perimenopausal period, yet periosteal apposition decreased – it did not increase as predicted if the notion that periosteal apposition is a compensatory mechanism is correct. The cortices thinned as periosteal apposition declined further. Nevertheless, bending strength remained unchanged – despite bone loss and cortical thinning because periosteal apposition was still sufficient to shift the thinning cortex outwards.

Bone fragility emerged only after menopause when accelerated in endocortical bone resorption and deceleration in periosteal apposition produce further cortical thinning. As periosteal apposition was now minimal, there was little outward displacement of the thinning cortex so cortical area now declined as did resistance to bending. Endocortical

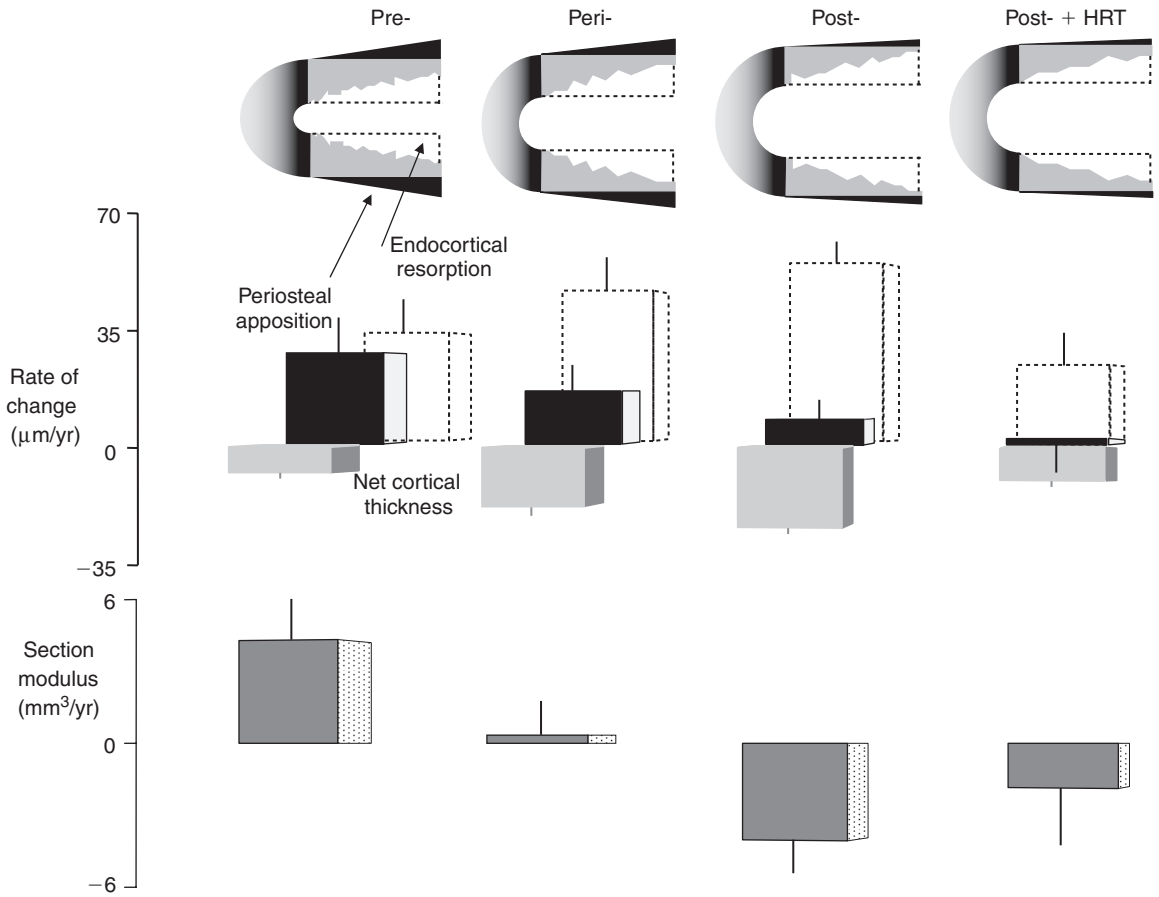

FIGURE 14 The amount of bone resorbed by endocortical resorption (open bar) increases with age. The amount deposited by periosteal apposition (black bar) decreases. The net effect is a decline in cortical thickness (grey bar). In premenopausal women, the thinner cortex is displaced radially increasing section modulus (Z). In perimenopausal women Z does not decrease despite cortical thinning because periosteal apposition still produces radial displacement. In postmenopausal women, Z decreases because endocortical resorption continues, periosteal apposition declines and little radial displacement occurs. In women treated with hormone replacement therapy (HRT), resorption is decreased with no effect on periosteal apposition. Z is less reduced than in untreated women. Adapted from Szulc *et al.,* 2006.

resorption was reduced but not abolished in women receiving hormone replacement therapy while periosteal apposition was no different to untreated women; cortical thinning was reduced and the resistance to bending occurred but less than in untreated women.

Periosteal envelope is regarded exclusively as a bone-forming surface. This is incorrect (Balena *et al.,* 1992). During growth, bone resorption is critical for the in-wasting that produces the fan-shaped metaphyses (Rauch *et al.,* 2001). Blizoites and colleagues report that bone resorption occurs in adult nonhuman primates (Blizoites *et al.,* 2006). Femur specimens from 16 intact adult male and female nonhuman primates showed that periosteal remodeling of the femoral neck in intact animals was slower than in cancellous bone but more rapid than at the femoral shaft. Gonadectomized females showed an increase in osteoclast number on the periosteal surface compared with intact controls. If these data are correct, adult skeletal dimensions may decrease in size as age advances.

Thus, even though the genius of bone biology Fuller Albright suggested over 65 years ago that osteoporosis was a disorder of reduced bone formation (Albright *et al.,* 1941), research into the pathogenesis of bone fragility during the last 40 years has focused on the role of increased bone resorption. During aging, both increasing endocortical bone resorption and reduced periosteal apposition cause *net* bone loss, alterations in the distribution of the remaining bone, and the emergence of the bone fragility. The cellular basis of the vigor of bone formation during growth and progressive decline in vigor during aging on the periosteal surface and within each BMU is yet to be defined.

Sex and Racial Differences in Trabecular and Cortical Bone Loss

A greater proportion of women than men sustain fragility fractures during their lifetime. The reasons for this sexual

dimorphism are not clear. Men have a larger skeleton than women do so that resistance to bending is greater in men than women. Bone loss in most, but not all, men is the result of a negative BMU balance produced by reduced formation rather than increased resorption by the BMUs, so trabecular bone loss occurs by thinning rather than loss of connectivity (Aaron *et al.,* 1987). Men do not have a midlife decline in sex hormones and increase in remodeling rate that drives structural decay produced by the negative BMU balance. Better preservation of trabecular bone in elderly men leaves more trabecular surfaces for remodeling to occur upon so trabecular bone loss continues longer in men (Aaron *et al.,* 1987). Net trabecular bone loss across age is only slightly greater in women than men (Riggs *et al.,* 2004), or is similar (Aaron *et al.,* 1987; Meunier *et al.,* 1990; Kalender *et al.,* 1989; Mosekilde and Mosekilde, 1990; Seeman, 1997; Seeman *et al.,* 2001). However, the same deficit in trabecular density produced by thinning (as occurs in men) produces less reduction in strength than produced by loss of connectivity (as occurs in women) (Van der Linden *et al.*, 2001).

Marrow cavity expansion occurs in both sexes but whether it is greater in women than men is uncertain (Riggs *et al.,* 2004). Cortical porosity increases less in men than in women because remodeling rate is lower in men and so crack propagation in cortical bone is probably better resisted in men than in women. Periosteal apposition is reported to be greater in men than in women in some (Duan *et al.,* 2001, Duan *et al.,* 2003, Duan *et al.,* 2005, Wang *et al.,* 2005, Seeman *et al.,* 2001) but not all studies (Riggs *et al.,* 2004).

Thus, methodological issues must temper the inferences that can be made regarding the basis of sexual dimorphism in bone strength (Seeman *et al.,* 2004). The absolute risk for fracture in women and men of the same age and BMD is similar (Kanis *et al.,* 2001; Kanis *et al.,* 2005). The lower fracture incidence in men than in women is likely to be the result of lower proportion of elderly men than elderly women having material and structural properties (cortical thinning, porosity, trabecular thinning, loss of connectivity, microdamage) below the critical level at which the loads on the bone are greater than the bone's net ability to tolerate them. Structural failure occurs less in men because the relationship between load and bone strength is better maintained in men than in women (Riggs *et al.,* 2006, Bouxsein *et al.,* 2006).

The Heterogeneous Material and Structural Basis of Bone Fragility in Patients with Fractures

Patients with fractures are grouped by having "one or more minimal trauma vertebral fractures," or sustaining a fall from "no greater than the standing position." However, the pathogenesis and structural basis of the bone fragility underlying the fractures is heterogeneous. Patients with vertebral fractures may have high, normal, or low remodeling rates (Brown *et al.,* 1984; Arlot *et al.,* 1990; Delmas, 2000). Some have a negative BMU balance due to reduced formation, increased resorption, or both, or no negative BMU balance at all (Ericksen *et al.,* 1990). Some patients with vertebral fractures have increased, whereas others have reduced, tissue mineral density (Ciarelli *et al.,* 2003) (Fig. 15). Some patients have reduced osteocyte density; others do not (Qui *et al.,* 2003; Qui *et al.,* 2005). Contemporary therapeutics gives no consideration to the underlying pathogenesis or structural abnormalities present in an individual. Whether anti-fracture efficacy can be improved from its current values of 50% for vertebral and hip fractures and 20% for nonvertebral fractures (Delmas, 2002) by defining the pathogenesis and structural basis in an individual remains uncertain, but it is worthy of exploration.

SUMMARY AND CONCLUSION

The purpose of modeling and remodeling during growth is to optimize bone strength by depositing bone where it is needed and to minimize mass by removing it from where it is not needed. Bone must be stiff – resistant to deformation, yet flexible – able to store energy in elastic deformation or to dissipate it. Otherwise, energy will be released by structural failure – fracture.

These paradoxical properties are achieved by bone's material composition and structural design. Material composition is similar among mammals so differences in bone strength in adulthood are largely the result of structural diversity. This diversity is already expressed before puberty. The magnitude of the variance in bone size and mass in prepubertal children is similar to that in their parents. Individuals with traits in the 5th, 50th, or 95th percentile in adulthood occupied these positions in early life because traits track along their percentile of origin. Long bones with a larger cross-section have a biomechanical advantage so the same periosteal apposition on a larger cross-section (i.e., less relative to size) confers greater stiffness than on a smaller cross-section. Endocortical resorption excavates a larger marrow cavity shifting the cortex radially, increasing stiffness and minimizing mass; larger bone cross-sections have a lower volumetric bone mineral density (vBMD). In slender bones, higher vBMD is the result of similar amounts of periosteal apposition (more relative to size) and less endocortical resorption, which excavates a smaller marrow leaving a relatively thicker cortex to offset the fragility of slenderness. Varying cellular activity around the periosteal and endocortical envelopes fashions the diverse shapes of adjacent cross-sections. Vertebral bodies are fashioned as a honeycomb of trabecular plates and void spaces conferring flexibility and lightness.

Modeling and remodeling are successful during growth, not adulthood. The purpose of modeling and remodeling during adulthood is to maintain bone strength by damage

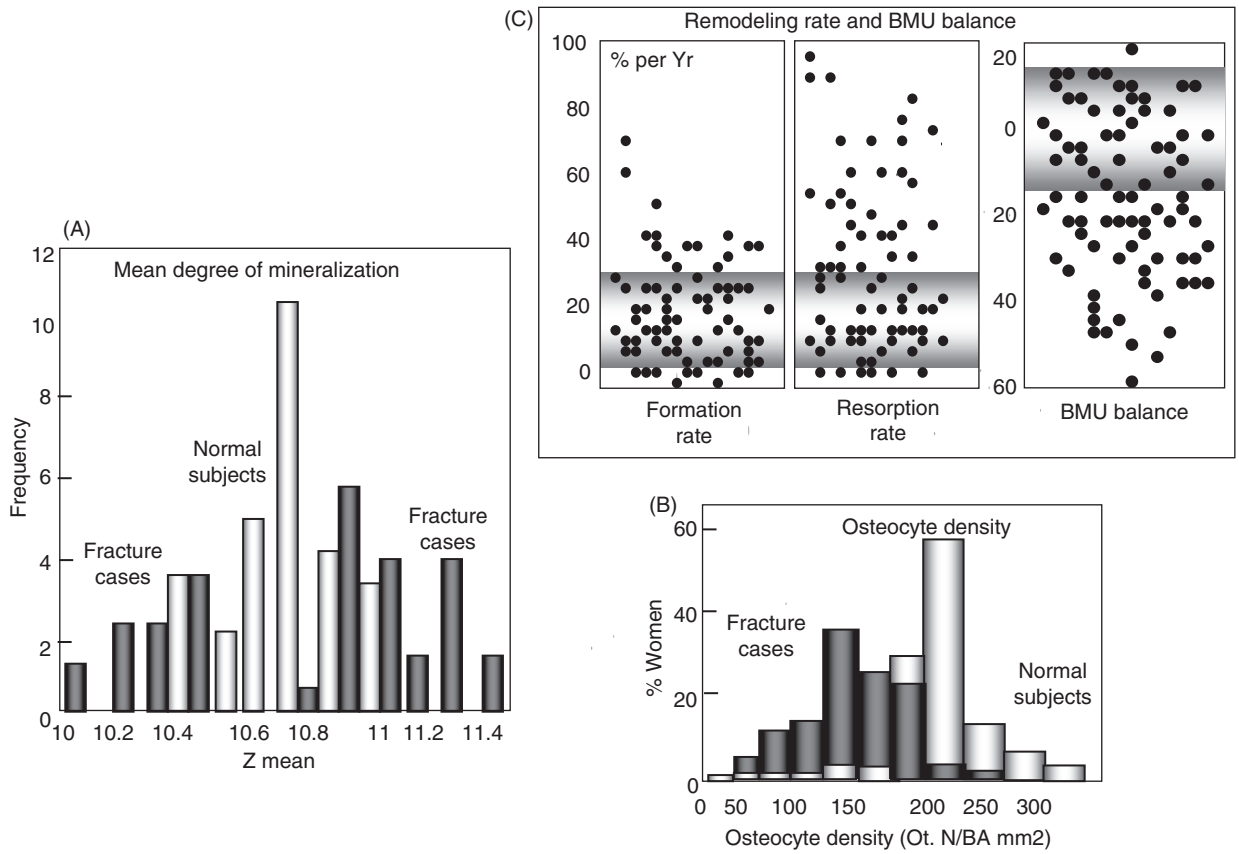

FIGURE 15 Bone fragility in patients with fractures has a heterogenous pathogenesis and structural basis. Patients have tissue mineral density in the upper or lower part of the normal distribution (adapted from Ciarelli *et al.,* 2003). Some have reduced or normal osteocyte density (adapted from Qui *et al.,* 2003). Formation and resorption rates may be lower normal or high bone balance in the basic multicellular level (BMU) may be normal or negative (adapted from Ericksen *et al.,* 1990).

repair but four age-related changes compromise bone's material composition and structure; a decline in periosteal bone formation, a decline in the volume of bone formed by each basic multicellular unit (BMU), continued resorption by each BMU, and high remodeling. Bone loss occurs in early adulthood but the structural and biomechanical consequences are modest because the negative BMU balance is driven by reduced bone formation not increased resorption, remodeling is slow and modest periosteal apposition offsets endocortical bone loss shifting the thinner cortex radially. After menopause, increased remodeling, worsening negative BMU balance, and a decline in periosteal apposition accelerate cortical thinning and porosity, trabecular thinning, and loss of connectivity. Interstitial bone, deep to surface remodeling, becomes more densely mineralized, has few osteocytes, greater collagen cross-linking, and accumulating microdamage. Late in life secondary hyperparathyroidism sustains high remodeling producing further cortical thinning and porosity. These age-related changes produce the material and structural abnormalities responsible for bone fragility.

Recent advances raise many questions concerning the uni-, bi- and multidirectional regulation and steps in remodeling, how resorption and formation phases are regulated and co-regulated, how osteocytogenesis occurs and the lacunar-canalicular system is reestablished for mechanotransduction and damage detection. Damage removal may not be the only reason bone remodels but is likely to be one of its main purposes in adulthood. However, the nature of "damage" has not been systematically defined and so questions remain concerning the determinants of damage production, its biomechanical consequences, and how different types of damage are signaled for repair. Thus, our understanding of why or how bones fail at the material and structural level remains incomplete. This is an essential direction of enquiry if we are to provide targeted approaches to drug therapy.

Chapter 2

Biomechanics of Bone and Age-Related Fractures

Elise F. Morgan
Orthopaedic and Developmental Biomechanics Laboratory, Department of Aerospace and Mechanical Engineering, Boston University, Boston, Massachusetts

Mary L. Bouxsein*
Orthopedic Biomechanics Laboratory, Department of Orthopaedic Surgery, Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, Massachusetts

INTRODUCTION

The bones that make up the skeleton function in many important capacities. Bones are the primary structural elements in the body, protecting vital organs and providing a rigid framework for locomotion. In addition, the skeleton participates in mineral homeostasis and is a primary site of hemopoiesis. Through remodeling, our bones are capable of self-repair and of adapting their structure in response to changes in mechanical, biological, and biochemical demands. Many of these demands differ across anatomic sites, and thus is it not surprising that the microstructure of bone is remarkably varied, ranging from the dense, composite fiber-reinforced structure of the diaphyseal cortex to the honeycomb-like, open-cell architecture of the trabecular bone in metaphyseal regions.

One primary reason for studying the mechanics of bone is to improve our understanding of how and why bones fracture. From an engineering viewpoint, fractures represent a structural failure of the bone whereby the forces and/or moments applied to the bone exceed its load-bearing capacity. Therefore, when investigating the biomechanics of age-related fractures, one must consider the mechanical properties of bone as well as the applied loads and how these two factors change with age.

In this chapter we define and explain some of the basic terms and concepts used in bone mechanics with particular emphasis on the concepts most relevant to the study of age-related fractures. The next portion of the chapter presents a review of the current understanding of the mechanical behavior of cortical and trabecular bone and of whole bones. This information provides a foundation for the final portion of the chapter that focuses on the biomechanics of age-related fractures. In this final section, we consider the roles of both skeletal loading and bone fragility as they relate to hip and spine fractures and identify important directions of future research in these areas.

BASIC CONCEPTS AND DEFINITIONS

Material versus Structural Behavior

In studying the mechanical behavior of bone, it is important to distinguish between the mechanical behavior of a whole bone as a structure (structural behavior) and the mechanical behavior of the bony tissue itself (material behavior). The material behavior of a specimen is independent of its geometry (size and shape), and it reflects the intrinsic properties of the material itself. Typically, the material behavior of a specimen is determined by conducting mechanical tests on standardized specimens under simple loading conditions. In contrast, the structural behavior of a specimen, determined by conducting mechanical tests on whole-bone specimens subjected to physiological or traumatic loading conditions, reflects both the morphology and the material properties of the specimen. Bone fractures observed clinically are likely the result of material failure of the bone tissue that leads to catastrophic failure of the bone structure.

In a hierarchical composite material such as bone, the definition of material properties requires additional clarification. In describing the properties of bone as a tissue, one could consider the mechanical properties of single trabeculae, the calcified bone matrix, single osteons, or small specimens of cortical or trabecular bone. For purposes of

*Corresponding author: Mary L. Bouxsein, Ph.D., Orthopedic Biomechanics Laboratory, Beth Israel Deaconess Medical Center, RN115, 330 Brookline Ave., Boston, MA 02215. Phone: (617) 667-2940, Fax: (617) 667-7175, E-mail: mbouxsei@bidmc.harvard.edu

this chapter, we consider bone "material" to include the calcified bone matrix, the marrow spaces in trabecular bone, and Haversian and Volkmann's canals in cortical bone. Thus, we take a continuum mechanics approach, in that the specimen is small enough to be homogeneous (uniform), but large enough to include a sufficient number of trabeculae (for trabecular bone) or osteons (for cortical bone) to characterize the material behavior of trabecular bone and cortical bone. We note that this scope necessarily excludes the rapidly growing body of research in which techniques such as microtensile and bending tests (Ascenzi and Bonucci, 1967, 1968; Ascenzi *et al.*, 1985, 1994; Choi and Goldstein, 1992; Hernandez *et al.*, 2005; Rho *et al.*, 1993; Townsend *et al.*, 1975), pushout tests (Ascenzi and Bonucci, 1972; Dong and Guo, 2004), nanoindentation (Fan *et al.*, 2002; Hengsberger *et al.*, 2002; Hoc *et al.*, 2006; Hofmann *et al.*, 2006; Rho *et al.*, 1999; Turner *et al.*, 1999; Zysset *et al.*, 1998), and acoustic microscopy (Katz and Meunier, 1993; Litniewski, 2005) have been used to characterize the micro- and nanoscale mechanical properties of bone.

Biomechanical Properties

The primary biomechanical properties describe the relationship between forces, or loads, applied to the bone or bone specimen and the deformations that result from these applied forces. It is interesting to note that, *in vivo*, the forces applied to bones have several possible origins, including external forces acting on the body (such as a ground reaction force during walking or an impact force owing to a fall), internal forces created by ligament tension or muscle contraction, and internal bone-on-bone contact forces. The resistance within the bone that develops in response to these applied forces is known as stress, and it represents local force intensity with dimensions of force per unit area. The local deformation that results from the applied forces is referred to as strain, which is defined as a relative change in size or shape and therefore is often expressed in terms of percent. When forces are applied to a bone, a complex and varied distribution of stresses and strains arise throughout the bone structure. These stresses and strains can be categorized as normal stresses and strains or shear stresses and strains (Fig. 1). For a given plane within the bone structure, normal stresses act perpendicular to that plane (i.e., tension and compression) and shear stresses act parallel to that plane. Normal strains represent elongation or shortening, whereas shear strains represent distortion.

Bone mechanical properties can be defined with the aid of a load–deformation curve or stress–strain curve. The load–deformation curve (Fig. 2) describes the amount of load needed to produce a unit of deformation and reflects the structural behavior of the bone. Thus, the shape of

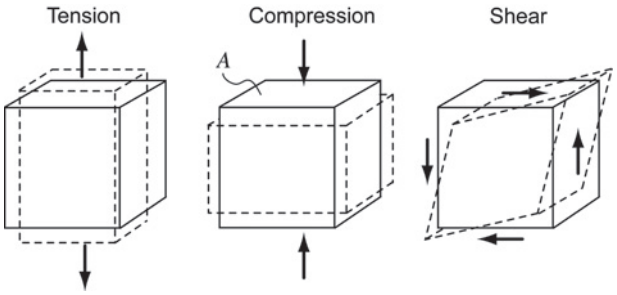

FIGURE 1 Normal and shear stresses acting on a specimen produce normal and shear strains. The dotted lines represent the specimen that is deformed under the action of the applied forces. (From Morgan *et al.*, 2008, with permission).

this curve depends on both the size and shape of the bone, as well as the properties of the tissue that comprise it. In general, load and deformation are linearly related until the yield point is reached, at which time the slope of the load–deformation curve is reduced. Before the yield point, the bone is considered to be in the elastic region, and if unloaded, would return to its original shape with no residual deformation. The slope of the load–deformation curve in this elastic region defines the structural stiffness of the bone. In contrast to a bone's behavior in the elastic region, in the postyield region, the bone undergoes permanent deformation and will not return to its original shape even when the load is removed completely. If the load continues to increase, the ultimate or failure load is reached, after which the structure often fails catastrophically. The energy required to cause failure of the structure is computed as the area under the load–displacement curve, and is termed the work to failure.

The stress–strain curve (Fig. 3) is analogous to the load–deformation curve but reflects the material behavior of the bone tissue. Typically, a stress–strain curve is generated by conducting a mechanical test on a specimen of standardized geometry, such that one can easily compute stress from force and strain from displacement. The slope of the stress–strain curve in the elastic region is the elastic (or Young's) modulus. The values of stress and strain at the yield point are the yield stress and yield strain, respectively. Similarly, the values of stress and strain at the ultimate point are the ultimate stress and ultimate strain. The ultimate stress and strain may or may not be equal to the fracture stress and fracture strain, where the latter is a measure of the ductility of the specimen. Materials that sustain little deformation before fracture are brittle materials, whereas those that undergo significant deformation before fracture are considered to be ductile materials. The area under the stress–strain curve is the amount of work per unit volume of material required to fracture the specimen

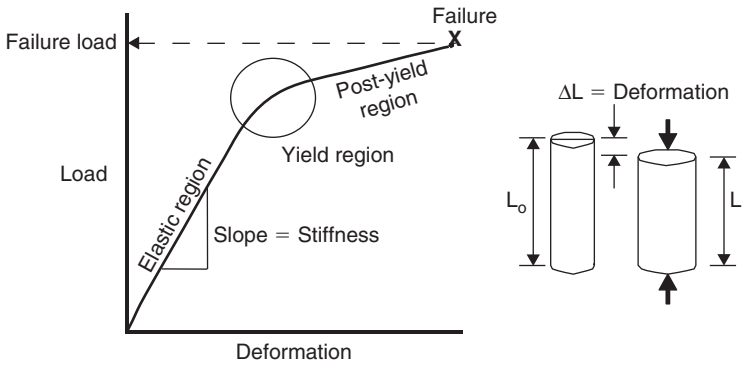

FIGURE 2 The load versus deformation plot is used to describe the structural behavior of a specimen. The elastic region is distinguished from the plastic region by the yield region. In the elastic region, when the load is removed there will be no residual deformation and the bone will return to its original shape. In contrast, in the postyield region, the bone will undergo permanent deformations that will remain even if the load is removed.

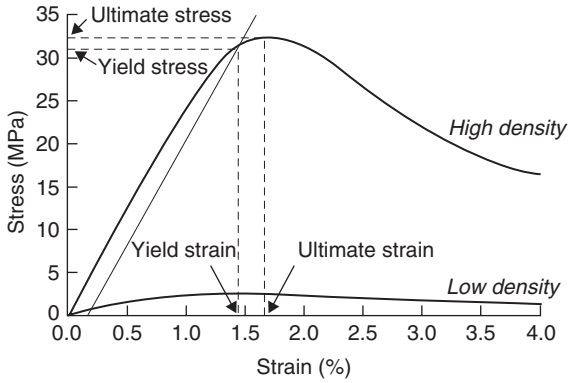

FIGURE 3 Representative stress–strain curves for high- and low-density trabecular bone specimens in compression. The elastic modulus, yield stress, yield strain, ultimate stress, and ultimate strain are indicated for the high-density specimen. Owing to the smoothness of the stress–strain curve, the yield point is typically defined via the 0.2% offset method: the intersection of the curve and a line with slope equal to the elastic modulus but with an *x*-intercept of 0.2% strain marks the yield point. Trabecular bone does not exhibit a well-defined fracture point in compression but rather continues to compact in on itself. For tensile loading, the fracture point is defined as the point just before the stress drops to zero as a consequence of the specimen pulling apart.

and is a measure of the toughness of the specimen. Tough bone will be more resistant to fracture, but it may yield at a lower stress and, according to that measure, be considered weaker. Indeed, a loose inverse relationship between toughness and strength exists for most engineering materials. A second measure of the toughness of a material is the fracture toughness, which is the resistance of the material to the initiation and propagation of cracks.

Additional material properties that are relevant in the study of bone include fatigue properties and viscoelastic properties. These properties characterize the response of the tissue to repeated loading and the time-dependent material behavior, respectively. A primary outcome of fatigue testing is the speed at which properties such as the elastic modulus and yield or ultimate stress decrease with increasing numbers of loading cycles, as this quantifies the rate of material degradation. The intrinsic properties of viscoelastic materials, such as bone, depend on loading rate and can differ substantially under quasi-static loading compared with the higher loading rates that occur during trauma.

MECHANICS OF BONE TISSUE

Role of Bone Composition and Microstructure

The mechanical properties of cortical bone are heavily dependent on porosity and the degree of matrix mineralization (Currey, 1988, 1990; Martin and Ishida, 1989; Schaffler and Burr, 1988). More than 80% of the variation in the elastic modulus of cortical bone can be explained by a power-law relationship with matrix mineralization and porosity as explanatory variables (Currey, 1988, 1990). Some studies show that, with increasing age, the mineralization of the matrix increases, leading to stiffer, but more brittle material behavior (Currey, 1969; Grynpas, 1993), although other studies indicate no age-related changes in the degree of mineralization (Roschger *et al.*, 2003, 2008).

The elastic modulus and strength of trabecular bone are also determined to a great extent by bone density (Keaveny *et al.*, 2001). Power-law relationships with bone density as the explanatory variable explain 60% to 90% of the variation the modulus and strength of trabecular bone (Carter and Hayes, 1976, 1977b; Gibson and Ashby, 1988; Hernandez *et al.*, 2001; Keaveny and Hayes, 1993; Morgan and Keaveny, 2001; Mosekilde *et al.*, 1987; Rice *et al.*, 1988) (Fig. 4). These power-law relationships indicate that small changes in apparent density can lead to dramatic changes in mechanical behavior. For instance, a 25% decrease in apparent density, approximately equivalent to 15 to 20 years of age-related bone loss (Riggs *et al.*, 2004), would be predicted to lead to a 44% decrease in the

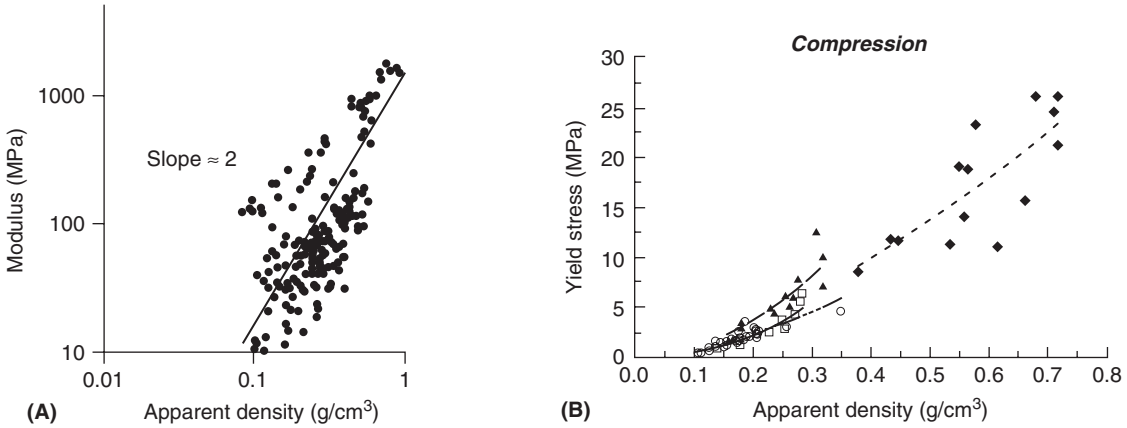

FIGURE 4 **(A)** Elastic modulus as a function of apparent density for trabecular bone specimens from a wide variety of species and anatomic sites. In general, the modulus varies as a power-law function of density, with an exponent of approximately two. (From Keaveny and Hayes, 1993, with permission.) **(B)** Compressive yield stress as a function of apparent density for human trabecular bone specimens from multiple anatomic sites. In general, the dependence of yield stress on density is different for different anatomic sites, although the exponents of the power-law relationships are approximately two. (From Morgan and Keaveny, 2001, with permission).

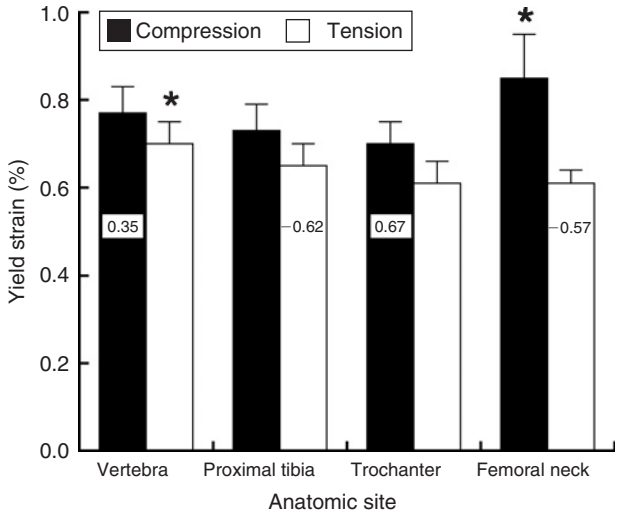

FIGURE 5 Mean compressive and tensile yield strains of human trabecular bone from multiple anatomic sites. Error bars indicate 1 SD. Significant relationships with apparent density are indicated by the Pearson correlation coefficient, *r*, within the column. An asterisk (*) denotes a significant difference in the mean with respect to all other sites in the same loading mode. (From Morgan and Keaveny, 2001, with permission).

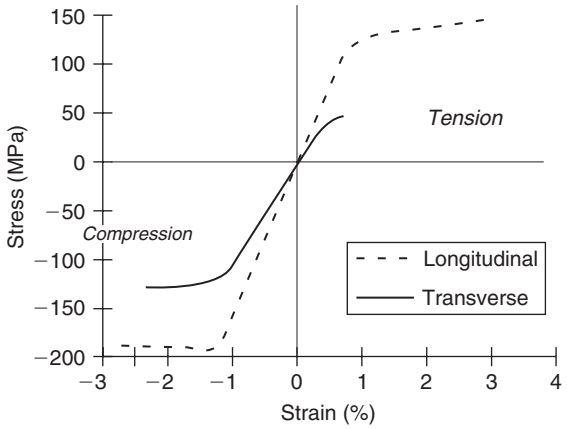

FIGURE 6 Typical stress versus strain diagram for longitudinally (L) and transversely (T) oriented specimens of cortical bone from the diaphysis. For specimens tested in compression, load and displacement are converted to stress and strain by dividing by the cross-sectional area and original length of the specimen, respectively. The figure shows the inherent anisotropy in bone, as specimens testing in the longitudinal direction are significantly stronger than those tested in the transverse direction.

strength of trabecular bone. Notably, however, the yield and ultimate strains of trabecular bone are only weakly, if at all, dependent on density (Kopperdahl and Keaveny, 1998; Morgan and Keaveny, 2001; Turner, 1989) and are relatively constant for a given anatomic site (Morgan and Keaveny, 2001) (Fig. 5).

Both cortical and trabecular bone are anisotropic materials, meaning that their mechanical properties depend on the loading direction. The anisotropic nature of bone reflects its function as a load-bearing structure, because it is generally stiffest and strongest in the primary loading direction. For example, cortical bone from the femoral diaphysis has a higher elastic modulus and strength when loaded in the longitudinal direction than when loaded in the transverse direction (Reilly and Burstein, 1975; Reilly *et al.*, 1974) (Fig. 6). Trabecular bone from the vertebral body is much stiffer and stronger in the vertical direction than in the transverse direction (Arnold *et al.*, 1966; Mosekilde and Mosekilde, 1986; Mosekilde *et al.*, 1985). Yet, trabecular bone properties from the iliac crest and central femoral head are nearly isotropic (Ciarelli *et al.*, 1991; Mosekilde and Mosekilde, 1988), indicating that the degree of anisotropy varies with anatomical site and functional loading (Amling *et al.*, 1996; Ulrich *et al.*, 1999). Although the anisotropy of bone tissue affords greater resistance to loads applied in the primary loading direction for a given amount of tissue, it necessarily

results in a lesser load-bearing capacity in directions "off-axis," or oblique, to the principal loading direction. The off-axis mechanical behavior of trabecular bone may be particularly relevant during impact after a fall, which results in applied loads of different magnitudes and directions than those arising from habitual activities. Moreover, the anisotropy of bone complicates efforts to determine the mechanical behavior of bone tissue under multiaxial stress states (a combination of normal and/or shear stresses acting along multiple directions). Multiaxial stresses can arise during trauma (Lotz *et al.*, 1991) and in regions surrounding bone implants (Cheal *et al.*, 1985). Multiaxial yield criteria for trabecular (Bayraktar *et al.*, 2004a; Keaveny *et al.*, 1999; Zysset *et al.*, 1999) and cortical bone (Cezayirlioglu *et al.*, 1985) have been developed; however, little is known about the multiaxial, postyield behavior of either type of bone tissue.

Given the anisotropic nature of trabecular bone and the variation in predicted modulus for a given density (Britton and Davie, 1990; Keaveny *et al.*, 2001), it is clear that density alone cannot explain all of the variability in the mechanical behavior of trabecular bone. Empirical observations and theoretical analyses indicate that trabecular architecture plays an important role in determining the mechanical properties of trabecular bone. Trabecular architecture can be characterized by the thickness, number, and separation of the individual trabecular elements, as well as the extent to which these elements are interconnected. Advances in nondestructive, high-resolution imaging techniques have provided new insights into the relative influence of architecture and density on age-related changes in the mechanical behavior of trabecular bone (Goulet *et al.*, 1994; Ulrich *et al.*, 1999).

However, defining the precise role of microarchitecture in prediction of the mechanical behavior of bone and its influence on fracture risk is complicated by the fact that microarchitecture characteristics are strongly correlated to each other and to bone density. Trabecular number, trabecular thickness, and connectivity all decline with decreasing density, whereas trabecular separation and anisotropy increase (Compston, 1994; Goulet *et al.*, 1994; Mosekilde, 1988, 1989; Snyder *et al.*, 1993; Ulrich *et al.*, 1998). Previous studies using architectural features derived from a model that assumes that trabecular bone architecture is "plate-like" suggested that architectural features provided only modest improvements in the prediction of mechanical properties over those provided by bone density alone (Goulet *et al.*, 1994; Snyder and Hayes, 1990). However, these previous findings should be interpreted with caution, because more recent data indicate significant differences in structural indices derived from the traditional plate-model compared with those computed directly from high-resolution three-dimensional images (Hildebrand *et al.*, 1999), and indices of trabecular structure determined directly from three-dimensional microcomputed architecture have been shown to significantly improve the prediction of the mechanical behavior of trabecular bone specimens from several skeletal sites (Majumdar *et al.*, 1998; Matsuura *et al.*, 2008; Newitt *et al.*, 2002; Ulrich *et al.*, 1999) and prediction of the strength of whole vertebrae (Hulme *et al.*, 2007).

Several studies have indicated that trabecular architecture differs in fracture subjects compared with those who have not suffered a fracture (Aaron *et al.*, 2000; Legrand *et al.*, 2000; Link *et al.*, 1999). However, few of these studies have controlled for the confounding influence of differences in bone density between the two groups, and few have investigated microarchitecture at the sites of fracture. Ciarelli and colleagues (2000) measured microarchitecture of trabecular bone specimens from the femoral neck in subjects with hip fracture compared with unfractured autopsy subjects. Whereas there were no differences in trabecular thickness, number, separatio, or connectivity among samples that were matched for equal bone density, the degree of anisotropy differed between the two groups even after controlling for density differences. These data suggest a role for trabecular architecture in the etiology of fractures that may be independent of changes in bone density. Recent *in vivo* studies also suggest that independent of bone mineral density (BMD) status, trabecular architecture is deteriorated in those with fragility fractures (Boutroy *et al.*, 2005; Link *et al.*, 2002; Sornay-Rendu *et al.*, 2007). Clearly, this is an area of great interest, and additional studies are required to define the role of *in vivo* assessments of trabecular architecture in the prediction of fracture risk.

As mentioned previously, because changes in trabecular architecture are strongly intercorrelated, it is difficult to discern the relative effect on bone strength of reductions in trabecular number versus trabecular thickness for both vertically and horizontally oriented trabecular struts. To address this issue Silva and Gibson (1997) developed a two-dimensional model of vertebral trabecular bone to simulate the effects of age-related changes in trabecular microstructure. They found that reductions in the number of trabeculae decreased vertebral bone strength two to five times more than reductions in trabecular thickness that resulted in an identical decrease in bone density (Fig. 7). For instance, removing longitudinally oriented trabecular elements to create a 10% reduction in density resulted in a 70% reduction in bone strength. In contrast, reducing trabecular thickness to achieve a 10% reduction in density resulted in only a 20% reduction in strength. This study implies that it is important to maintain trabecular number in order to preserve bone strength with aging. Consequently, therapies designed to counter age-related declines in bone strength should strive to maintain or restore the number of trabeculae, rather than just increasing the thickness of existing trabecular struts. A final aspect of trabecular architecture that may have been underappreciated initially is the potential detrimental effect of increased variability in trabecular thickness and number within a

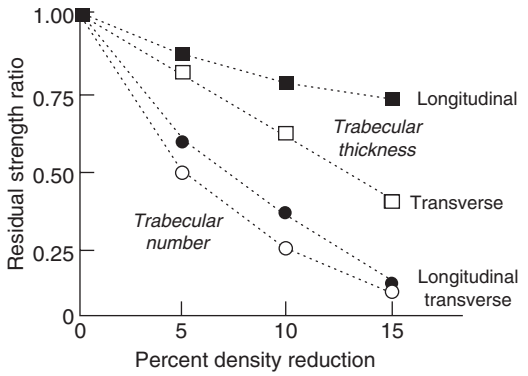

FIGURE 7 A plot of the predicted effect of bone density reductions, either by a reduction in trabecular thickness or loss of trabecular elements, on the strength of vertebral trabecular bone. (From Silva and Gibson, 1997). Strength reductions were at least twice as sensitive to changes in the number of trabeculae as to changes in the thickness of trabeculae. Findings were similar for loading in the transverse direction.

given trabecular bone specimen (Kothari *et al.*, 1999; Yeh and Keaveny, 1999).

Other microstructural and compositional features that influence the mechanical behavior of bone include the histological structure (primary versus osteonal bone), the collagen content and orientation of collagen fibers, the number and composition of cement lines, and the presence of fatigue microdamage. In reviewing the potential role of skeletal microdamage in age-related fractures, Burr and colleagues (1997) suggest that microdamage caused by repetitive loading of bone likely initiates at the level of the collagen fiber or below, and may include collagen fiber-matrix debonding, disruption of the mineral-collagen aggregate, and failure of the collagen fiber itself. They hypothesize that the accumulation and coalescence of these small defects eventually leads to microcracks that are visible under light microscopy. Laboratory studies have shown that damage accumulation in devitalized bone leads to a decrease in bone strength (Burr *et al.*, 1998; Carter and Hayes, 1977a; Hoshaw *et al.*, 1997; Wachtel and Keaveny, 1997). Thus, it has been hypothesized that the accumulation of microdamage *in vivo* may contribute to the increased fragility of the aging skeleton (Burr, 2003).

Microcracks occur naturally in human specimens from several anatomic locations, including trabecular bone from the femoral head, iliac crest, and vertebral body, as well as cortical bone from the femoral and tibial diaphyses (Chapurlat *et al.*, 2007; Courtney *et al.*, 1996; Fazzalari *et al.*, 1998; Mori *et al.*, 1997; Norman and Wang, 1997; Schaffler *et al.*, 1994, 1995; Stepan *et al.*, 2007; Wenzel *et al.*, 1996). It appears that the incidence of microcracks increases with age, probably in an exponential fashion, and that after age 40, microdamage may accumulate faster in women than in men (Norman and Wang, 1997; Schaffler *et al.*, 1995). Studies have also shown that the density of microcracks in the femoral head of older women is more than double that seen in younger women (Mori *et al.*, 1997), and that microdamage morphology differs between bone tissue from young versus old donors, with "diffuse damage" more prevalent in the young tissue and linear microcracks more prevalent in old tissue (Diab *et al.*, 2006; Diab and Vashishth, 2007). In addition, results of several studies indicate that microcracks accumulate more rapidly as bone mass decreases (Mori *et al.*, 1997; Stepan *et al.*, 2007; Wenzel *et al.*, 1996).

The effects of *in vivo* microdamage on bone mechanical properties have proved difficult to establish. In a series of studies investigating the consequences of suppressed bone remodeling by bisphosphonate treatment in dogs, Burr and colleagues have determined that one year of treatment leads to increased microdamage accumulation and reduced bone toughness in the rib (Mashiba *et al.*, 2000). In this study, a significant linear relationship between increased microdamage and decreased toughness was found. However, whereas bisphosphonate treatment was also found to reduce the toughness of vertebral trabecular bone, the treatment had no effect on work-to-failure and led to an increase in ultimate load for the vertebra (Mashiba *et al.*, 2001). Moreover, a longer-term follow-up study demonstrated that microdamage did not continue to accumulate between one and three years of treatment, yet toughness declined further over this period of time (Allen and Burr, 2007). These data indicate that the observed decrease in toughness may result from factors other than microdamage. In the context of evaluating the safety of long-term bisphosphonate treatment, it is important to note that these studies have used normal (i.e., gonadally sufficient) dogs and employed bisphosphonate doses equivalent to five to six times those used for treatment postmenopausal osteoporosis. Indeed, an investigation using doses comparable to those used clinically has indicated that, despite increases in microdamage accumulation with treatment, no adverse effect on bone mechanical properties results (Allen *et al.*, 2006).

Age-Related Changes in the Material Properties of Bone

The elastic modulus and ultimate strength of cortical (Burstein *et al.*, 1976; Currey, 1969; Lindahl and Lindgren, 1967; McCalden *et al.*, 1993; Smith and Smith, 1976; Zioupos and Currey, 1998) and trabecular (Bell *et al.*, 1967; Ding *et al.*, 1997; Mosekilde and Mosekilde, 1986, 1990; Mosekilde *et al.*, 1985, 1987) bone decrease with increasing age in both men and women. In human cortical bone from the femoral mid-diaphysis, the tensile and compressive strengths and elastic modulus decrease approximately 2% per decade after age 20 (Burstein *et al.*, 1976). In addition, the deformation incurred and energy absorbed before fracture decrease approximately 5% to 12% per decade,

TABLE I Age-Related Changes in Vertically Oriented Trabecular Bone Specimens that were Compressed in Either the Vertical or Horizontal Direction

	Vertical loading		Horizontal loading	
	% per decade	Correlation with age (*r*)	% per decade	Correlation with age (*r*)
Ash density	−8.7	−0.85 *	−8.7	not reported
Ultimate stress	−12.8	−0.79 **	−15.5	−0.87**
Elastic modulus	−13.5	−0.83 **	−15.9	−0.83**
Energy to failure	−14	−0.75 **	−15.2	−0.88**
Ultimate strain	+4	0.45 *	+3.1	0.30***

The mean percent change per decade and the linear correlation with age are presented. Specimens were taken from 42 persons, aged 15 to 87. (Data from Mosekilde *et al.*, 1987.) *$P < 0.01$; **$P < 0.001$; ***$0.05 < P < 0.06$

indicating that cortical bone becomes more brittle and less tough with increasing age (Burstein *et al.*, 1976; McCalden *et al.*, 1993; Zioupos and Currey, 1998). Indeed, the fracture toughness decreases by approximately 4% per decade (Zioupos and Currey, 1998), and the energy required to fracture a cortical bone specimen under impact loading decreases threefold between the ages of 3 and 90 (Currey, 1979). These changes in the elastic and ultimate properties of cortical bone are caused, in large part, by the increase in porosity with age (McCalden *et al.*, 1993). However, additional possible causes of the age-related decline in cortical bone properties include increased matrix mineralization and/or altered collagen cross-linking (Vashishth *et al.*, 2001).

Human trabecular bone exhibits a similar age-related decline in material properties (Ding *et al.*, 1997; Mosekilde and Mosekilde, 1986, 1990; Mosekilde *et al.*, 1985, 1987), primarily as a consequence of the decline in apparent density with age. For example, the density of vertebral trabecular bone declines approximately 50% from ages 20 to 80, and the material properties (compressive elastic modulus, ultimate stress, and energy to failure) decrease approximately 75% to 90% (Mosekilde *et al.*, 1987) (Table I). In trabecular bone of the proximal tibia, an age-related decline in apparent density of 25% is accompanied by a 30% to 40% reduction in compressive strength and energy absorption properties (Ding *et al.*, 1997). In addition, the strength anisotropy of trabecular bone from human lumbar vertebrae increases with age, as the ratio of compressive strengths of vertically and horizontally loaded specimens increases from about 2 at age 20 to 3.5 at age 80 (Arnold *et al.*, 1966; Mosekilde *et al.*, 1985). This observation may reflect age-related changes in the trabecular architecture of vertebral bodies, whereby horizontally oriented trabeculae thin and disappear to a greater extent than vertically oriented trabeculae (Mosekilde, 1988; Mosekilde *et al.*, 1987; Parfitt, 1984; Twomey *et al.*, 1983).

It is important to note that changes in density do not fully describe the age-related decline in trabecular bone mechanical properties. In trabecular bone specimens from the iliac crest that were matched pairwise for density, yield stress was approximately 40% lower in specimens from older donors (older than 60 years) compared with younger donors (younger than 40 years) (Britton and Davie, 1990). This difference between young and old bone may reflect differences in trabecular architecture and in the mechanical properties of trabecular tissue (the material comprising individual trabeculae). Although few data are available on the effects of age on trabecular tissue, results of a recent study indicate that the elastic modulus, yield stress, and yield strain of trabecular tissue are higher in osteoporotic versus normal trabecular bone (McNamara *et al.*, 2006). Overall, in general, it is believed that the elastic modulus and yield strain of trabecular tissue are slightly lower than those of cortical bone (Bayraktar *et al.*, 2004b; Guo and Goldstein, 1997).

MECHANICS OF WHOLE BONES

Diaphyseal fracture patterns

An important goal of producing fractures in the laboratory is to simulate the mechanisms of accidents that typically result in fractures and to produce types of fractures that are similar to those observed clinically. Numerous classifications of fractures exist and the classification strongly depends on the anatomical localization of the bone involved. For long bones, which are frequently involved in biomechanical testing, fractures can be classified based

on morphological criteria related to the mechanism of the injury into transverse, oblique, spiral, or butterfly fractures (Fig. 8). Transverse fractures, which can be produced by tensile loading or pure bending, are characterized by a cortex that is broken once and a fracture line that is normal or slightly oblique with the longitudinal axis of the bone. During bending the transverse fracture line presents on the opposite site of the fulcrum, the bone fails in tension. In oblique fractures the fracture line ascends at an angle of approximately 30° or greater. Oblique fractures are most likely produced by pure compressive forces, but may occur under bending loads if bending is applied unevenly or with an additional compressive component. Spiral fractures have two distinct types of fracture lines visible on a projectional x-ray: a line spiraling around the entire bone and a longitudinal line linking the proximal and distal portions of the spiral. The angle of ascent may vary between 20° and 90° but is never transverse. Spiral fractures are produced by torsional loads or by a combination of torsional and axial loads. Butterfly fractures are characterized by at least one fragment in which one cortex is broken once and the other cortices are broken several times. They are typically produced by bending or axial compression with bending. Heavily comminuted fractures with undefined direction of the fracture line result from crush fractures in which the bone is compressed until failure perpendicular to its longitudinal axis.

The types of loading associated with clinically observed fractures at anatomic sites such as the distal radius, spine, and proximal femur are not as clear. For example, wedge fractures in the vertebra likely result from combined axial compression and anterior bending, whereas biconcave fractures may be caused by the relatively high compressive forces transferred from the nucleus pulposis to the center of the endplates. To some extent, these hypotheses are supported by results of *in vitro* experiments that determine what applied loading conditions produce gross fracture patterns comparable to those occurring *in vivo*. Similarly, laboratory tests on the proximal femur simulate gait or fall-loading conditions and are able to reproduce clinically observed fracture patterns.

Age-Related Changes in Bone Geometry

Age-related changes in the material properties of bone tissue are frequently accompanied by a redistribution of the cortical and trabecular bone material. It is likely that the structural rearrangement of bone tissue is driven both by "preprogrammed" behavior of the endosteal and periosteal bone cells as well as the local mechanical loading environment and biochemical signals. Hence, the adaptation pattern depends on age, gender, skeletal site, physical activity patterns, and expression (local and systemic) of cytokines and growth factors.

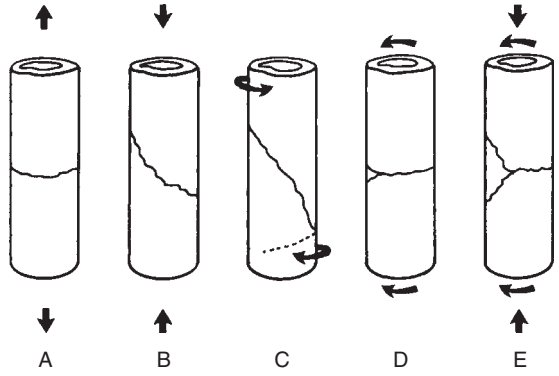

FIGURE 8 Fracture patterns in the diaphysis and associated loading conditions (Morgan *et al.*, 2008).

The general pattern of adaptation in the appendicular skeleton includes endosteal resorption and periosteal apposition of bone tissue (Fig. 9). Thus, the diameter of the bone increases, but the thickness of the cortex decreases. This redistribution of bone tissue away from the center of the bone allows the bone to better resist bending and torsional loads. Resistance to bending and torsional loading is particularly important, because the highest stresses in the appendicular skeleton are because of these loading modes (Martin, 1993). The most efficient design for resisting bending and torsional loads involves distributing the material far from the neutral axis of bending or torsion (generally the center of the bone). The distribution of mass about the center of a structural element is quantitatively described by the area moment of inertia. For example, consider three circular bars, each of the same length and composed of the same material (Fig. 10). The resistance of each bar to tensile and compressive loads is directly proportional to the cross-sectional area. However, the resistance to bending and torsional loads is influenced not only by how much bone (i.e., the cross-sectional area), but also by how it is distributed. Therefore, the bending and torsional rigidities of Bar C are twice that of Bar A owing to its greater moment of inertia.

Some studies indicate that both men and women exhibit endosteal resorption accompanied by periosteal expansion (Bouxsein *et al.*, 1994; Garn *et al.*, 1967; Ruff and Hayes, 1982, 1983; Smith and Walker, 1964), whereas others report that, in comparison with men, women exhibit lesser (Beck *et al.*, 1993; Martin and Atkinson, 1977; Meema, 1963; Seeman, 2001, 2002, 2003). Smith and Walker (1964) studied femoral radiographs of 2030 women aged 45 to 90 and reported that periosteal diameter and cortical cross-sectional area (assuming a circular cross-section) both increased approximately 11% in 35 years. Furthermore, the section modulus (an indicator of the resistance to bending loads) increased 32% in the same period. In contrast, direct assessment of cadaveric femurs and tibiae from 75 Caucasian adults showed that although

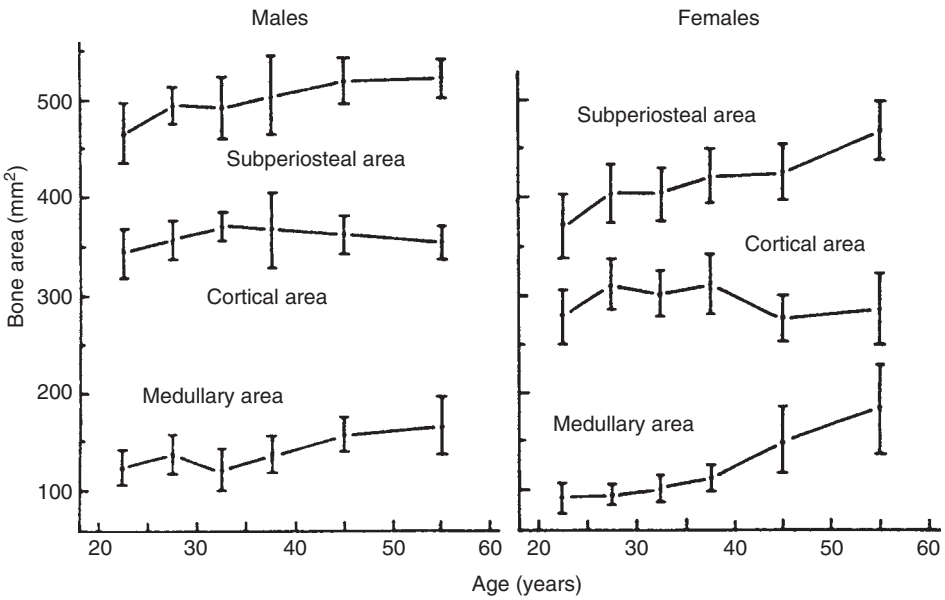

FIGURE 9 Age-related changes in the femoral midshaft demonstrating periosteal expansion and endosteal resorption. The data represent the mean ±2 standard errors. (From Ruff and Hayes, 1982, with permission).

	A	B	C
Area	1	1	0.87
Resistance to tensile and compressive loads	100%	100%	87%
Resistance to bending and torsional loads	100%	164%	208%

FIGURE 10 Illustration of the influence of cross-sectional geometry on the structural strength of circular structures.

both men and women undergo endosteal resorption and medullary expansion with age, only men show subperiosteal expansion and bone apposition at the femoral diaphysis (Ruff and Hayes, 1988). In men, cortical area is nearly constant and moments of inertia increase slightly with age. In women, however, both cortical area and moments of inertia decrease with age. The authors conclude, therefore, that in this sample from modern humans, only men exhibit bone-remodeling patterns that would compensate for the age-related decline in bone material properties in long bones (Ruff and Hayes, 1988).

In general, it is thought that men undergo the pattern of favorable geometric adaptation mentioned earlier to a greater extent than women, and that this may contribute to lower fracture rates in elderly men than women (Beck *et al.*, 1993; Duan *et al.*, 2001b; Kaptoge *et al.*, 2003; Ruff and Hayes, 1982, 1988; Seeman, 1997; Smith and Walker, 1964); however, recent data employing three-dimensional quantitative computed tomography challenge this paradigm (Riggs *et al.*, 2004; Sigurdsson *et al.*, 2006). Riggs *et al.* examined 373 women and 323 men aged 20 to 97 years and showed that, whereas women have greater declines in volumetric bone density, both men and women show similar age-related increases in bone area and moments of inertia at the femoral neck and vertebral body, demonstrating that the extent to which bone geometry exhibits favorable geometric changes with aging is similar in men and women (Riggs *et al.*, 2004). It is clear that carefully conducted longitudinal studies are needed to sort out this issue. However, because age-related expansion of bone size is subtle in the adult skeleton, a definitive study will require highly accurate measurements over several years duration. Indeed, a recent longitudinal study with measurements over approximately seven years showed that in postmenopausal women periosteal expansion does not compensate fully for endosteal resorption at the one-third radius site, and furthermore that women with the highest bone remodeling exhibited the greatest declines in cortical geometry (Szulc *et al.*, 2006).

As seen from the results of the previous studies, the sex-specific nature of age-related changes in skeletal structure remains controversial. The discrepancies in findings related to sex-specific bone adaptation patterns may be attributed to several factors. Most importantly, most of these studies use a cross-sectional design, thereby possibly introducing secular changes that confound the data and eliminating the possibility of a causal relationship with age. In addition, differences in methodology (direct versus *in vivo* measurements), subject populations (archaeological versus modern human specimens), and measurement site (metacarpal

versus femoral shaft versus femoral neck) likely contribute to the conflicting findings. However, the extent to which age-related changes in bone geometry contribute to the increased fracture risk with increasing age is unknown.

Contributions of Cortical and Trabecular Bone

One of the foremost goals of research on the material properties of cortical and trabecular bone is to apply knowledge gained about these properties to the study of the biomechanics of whole bones. In this respect, it is of interest to determine the respective contributions of cortical and trabecular bone to whole-bone strength and stiffness. For the vertebra and proximal femur, the strength of the whole bone is predicted well simply by the density of the trabecular bone and measures of bone cross-sectional area (Brinckmann *et al.*, 1989; Cody *et al.*, 1991; Lotz *et al.*, 1990; McBroom *et al.*, 1985). However, research to date also suggests that the role of the cortical shell in the vertebra is complex and varies with age. No strong consensus exists as to how much the cortical shell contributes to the stiffness and strength of the vertebra (Eswaran *et al.*, 2006; McBroom *et al.*, 1985; Rockoff *et al.*, 1969; Yodanandan *et al.*, 1988). A recent micro-finite-element study estimated that the fraction of the applied compressive load borne by the shell varies from 0.38 to 0.54 across vertebrae (Eswaran *et al.*, 2006). Several studies have also indicated that the shell load fraction is maximal at the narrowest transverse cross-section of the vertebra (Cao *et al.*, 2001; Eswaran *et al.*, 2006; Homminga *et al.*, 2001; Silva *et al.*, 1997) and increases as the density and modulus of the trabecular bone decrease (Cao *et al.*, 2001; Faulkner *et al.*, 1991). This latter finding implies that the load-bearing capacity of the shell becomes increasingly important with age.

The respective contributions of trabecular and cortical bone in the proximal femur are similarly multifaceted. Finite-element analyses have indicated that for both gait and sideways fall-loading conditions, the cortical bone bears approximately 30% of the load in the subcapital region, 50% at the midpoint of the femoral neck, 96% at the base of the femoral neck, and 80% in the intertrochanteric region (Lotz *et al.*, 1995). Comparisons of stress and strain distributions in healthy versus osteoporotic femora indicate that although the distributions are similar, peak stresses and strains are elevated in the osteoporotic bones (Lotz *et al.*, 1995; Van Rietbergen *et al.*, 2003). Although the locations of the peak stresses and strains are not exclusively in the trabecular compartment, results of other finite-element studies indicate that, for a variety of loading conditions that simulate various types of falls, failure of the trabecular bone begins prior to or simultaneously with failure of the cortical shell (Ford *et al.*, 1996; Keyak *et al.*, 1998; Lotz *et al.*, 1991).

BIOMECHANICS OF AGE-RELATED FRACTURES

Applied Load versus Bone Strength: The Factor of Risk Concept

Strategies designed to prevent fractures must be based on a sound understanding of their etiology. From an engineering viewpoint, fractures of any type are caused by a structural failure of the bone. This failure occurs when the forces and/or moments applied to the bone exceed its load-bearing capacity. The load-bearing capacity of a bone depends primarily on the material that comprises the bone (and its corresponding mechanical behavior), the geometry of the bone (its size, shape, and distribution of bone mass), and the specific loading conditions. Thus, it is clear that factors related both to the forces applied to the bone, as well as to its load-bearing capacity are important determinants of fracture risk (Fig. 11). In support of this concept, clinical studies have repeatedly shown that factors related both to skeletal fragility as well as to the loads applied to the skeleton are important determinants of fracture risk (Bouxsein *et al.*, 2006b; Cumming and Klineberg, 1994; Greenspan *et al.*, 1994, 1998; Grisso *et al.*, 1991; Hayes *et al.*, 1993; Melton *et al.*, 2007; Nevitt and Cummings, 1993; Riggs *et al.*, 2006).

Insight into the relative contributions of skeletal fragility versus skeletal loading may be gained by using a standard engineering approach for evaluating the risk of structural failure, whereby the loads applied to the structure during its normal usage are compared with the loads known to cause failure. This comparison of applied load versus failure load gives an estimate of how "safely" the structure is designed. To apply these concepts in the study of the etiology of fractures, one can compute a "factor of risk," Φ, which is defined as the ratio of the load delivered to a bone (applied load) to the load-bearing capacity of that bone (failure load) (Bouxsein, 2007; Hayes, 1991):

$$\Phi = \text{applied load/failure load}$$

Theoretically, when the factor of risk is less than one, the forces applied to the bone are lower than those required to fracture it, and the bone is not at risk for fracture. However, when the factor of risk exceeds one (i.e., applied loads exceed bone failure load), fracture is predicted to occur. A high factor of risk can occur either when the bone is very weak and its load-bearing capacity is compromised, or when very high loads, such as those resulting from trauma, are applied to the bone. In elderly individuals, it is likely that the coupling of a weak bone with an increased incidence of traumatic loading leads to the dramatic rise in fracture incidence with age (Bouxsein *et al.*, 2006b; Riggs *et al.*, 2006).

To apply the factor-of-risk concept in studies of hip and vertebral fracture, the loads applied to the bone of interest and the corresponding load required to fracture the bone must

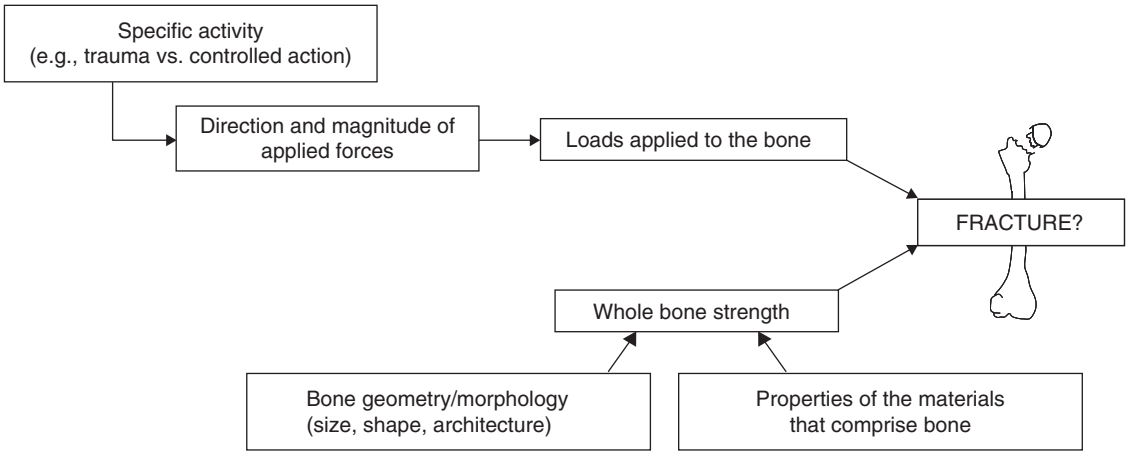

FIGURE 11 Etiology of fractures from biomechanical perspective. Fractures occur when the loads (or forces) applied to the bone exceed its strength (or structural capacity).

be identified. For example, the majority of hip fractures are associated with a fall. Therefore, to compute the factor of risk for hip fracture owing to a fall, information about the loads applied to the femur during a fall and about the load-bearing capacity of the femur in a fall configuration is required. Although this approach is relatively easy to conceive, in practice it is difficult to apply. There are surprisingly few data describing the magnitude and direction of loads applied to the skeleton during activities of daily living and even fewer data describing the loads engendered during traumatic events, such as a trip, slip, or fall. Moreover, because of the complex morphology of the skeleton and associated muscle and tendon attachments, it is difficult to design a laboratory study that mimics the loading environment encountered by the bone *in vivo*. Therefore, it is challenging to determine the load-bearing capacity of skeletal elements under realistic loading conditions. Moreover, because these are "biological structures," both the applied loads and structural capacity can change with aging, pharmacological intervention, and disease. Nevertheless, despite these uncertainties and limitations, rough estimates of the factor of risk for hip and vertebral fracture can be derived to provide insights into the complex roles of loading severity and skeletal fragility in the etiology of age-related fractures (Bouxsein *et al.*, 2006a, 2006b; Duan *et al.*, 2001a; Melton *et al.*, 2007; Riggs *et al.*, 2006).

Biomechanics of Hip Fractures

Recall that the "biomechanics" view of fractures states that a fracture occurs when the loads applied to the bone exceed its load-bearing capacity. Therefore, to study the etiology of hip fractures it is important first to identify what event(s) are associated with hip fractures, and then to determine the loads that are applied to the bone during that event, and what the load-bearing capacity of the femur is during that loading situation. It is estimated that more than 90% of hip fractures in the elderly are associated with a fall (Cummings *et al.*, 1990; Grisso *et al.*, 1991). Yet, fewer than 2% of falls in the elderly result in a hip fracture (Michelson *et al.*, 1995; Nevitt *et al.*, 1991; Tinetti, 1987), leading to the question of what is a "high-risk" fall with regard to hip fracture?

Several surveillance studies have been conducted to more fully characterize falls as they relate to hip fracture (Cumming and Klineberg, 1994; Greenspan *et al.*, 1994, 1998 ; Hayes *et al.*, 1993; Nevitt and Cummings, 1993; Nevitt *et al.*, 1991). For example, among nursing home residents, falling to the side and impacting the hip or side of the leg increased the risk of hip fracture approximately 20-fold relative to falling in any other direction (Hayes *et al.*, 1993). An increase in the potential energy content of the fall, computed from fall height and body mass, was also associated with an increased risk for fracture. Several studies have confirmed that falling to the side, versus falling in any other direction, is a risk factor for hip fracture (Greenspan *et al.*, 1994, 1998; Kannus *et al.*, 2006; Nevitt and Cummings, 1993).

Factors that Influence the Load Applied to the Femur in a Sideways Fall

Laboratory investigations have been conducted to explore the characteristics of sideways falls. In a study of the descent phase of sideways falls, young, healthy adults (age 19 to 30) were asked to fall sideways, as naturally as possible, onto a thick gymnastics mattress and impact velocities and energies that occur during falls from standing height were studied (van den Kroonenberg *et al.*, 1996). The impact velocity was 7% lower in "relaxed" than in "muscle-active" falls, and despite instructions to break the fall with an outstretched arm, only two of six subjects were able to do so (Fig. 12). In the remaining subjects hip impact occurred first, followed by impact of the arm or hand. Finally, in these young adults, approximately 70% of the total energy available was dissipated during the descent

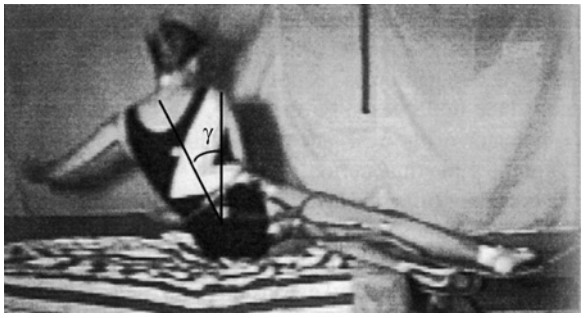

FIGURE 12 Example of a sideways fall onto a thick gymnastics mattress. Despite instructions to break the fall with the hand, only two of six subjects were able to do so. In the other subjects, hip impact occurred first, thus providing insight into the high-risk nature of sideways falls. (From van den Kroonenberg *et al.*, 1996, with permission).

phase of a sideways fall owing to muscle activity and the stiffness and damping characteristics of the hip and knee joints. It is likely that with age, the ability to dissipate energy during a fall and/or to activate protective responses will decrease, thus explaining why elderly individuals suffer more severe falls than young adults.

The forces applied to the proximal femur during a sideways fall depend not only on the dynamics of the descent phase of the fall, but also on characteristics of the impact phase of the fall. Using a system that allows impact forces from falls to be predicted with reasonable accuracy from the body's response to safe, simulated collisions, Robinovitch and colleagues (1991, 1995, 1997a, 1997b) found that during a sideways fall with impact to the greater trochanter, only about 15% of the total impact force is distributed to structures peripheral to the hip, whereas the remainder of the force is delivered along a load path directly in line with the hip (Robinovitch *et al.*, 1997a). The forces applied to the hip are reduced by increasing thickness of trochanteric soft tissues, but the force attenuation owing to trochanteric soft tissues alone is likely insufficient to prevent hip fracture in a fall where an elderly person lands directly on the hip (Robinovitch *et al.*, 1995). Biomechanical models developed to estimate peak impact forces delivered to the proximal femur during a sideways fall from standing height indicate that peak impact forces applied to the greater trochanter ranged from 2900 to 4260 N (≈650 to 960 lbs) for the 5th to 95th percentile woman, based on weight and height (van den Kroonenberg *et al.*, 1995).

Factors that Influence the Strength of the Proximal Femur

As mentioned previously, several factors contribute to the load-bearing capacity of the proximal femur, including its intrinsic material properties as well as the total amount (size) and spatial distribution (shape) of the bone tissue. Because the mechanical properties of both cortical and trabecular bone are strongly related to bone density, age-related bone loss has been argued to be a primary contributor to the steep increase in hip fracture incidence with age. Indeed, there is strong evidence from prospective clinical studies that low BMD is a risk factor for hip fracture (Cummings *et al.*, 2002; Marshall *et al.*, 1996).

Several laboratory studies have evaluated the load-bearing capacity of the proximal femur by using a configuration designed to simulate the single-leg stance phase of gait (Alho *et al.*, 1988; Bousson *et al.*, 2006; Cody *et al.*, 1999; Dalén *et al.*, 1976; Keyak *et al.*, 1998; Leichter *et al.*, 1982). The loads required to fracture the femur in this configuration range from approximately 1000 N to 13,000 N (225 to 3000 lbs). These studies demonstrated a strong relationship between the load required to fracture the femur in this stance configuration and noninvasive measurements of bone geometry and bone mineral density or content.

Other studies have evaluated the load-bearing capacity of the proximal femur in a configuration designed to simulate a sideways fall with impact to the greater trochanter (Bauer *et al.*, 2006; Bouxsein *et al.*, 1995a, 1995b; Cheng *et al.*, 1997a; Courtney *et al.*, 1994, 1995; Keyak *et al.*, 1998; Lochmuller *et al.*, 2002; Pinilla *et al.*, 1996). Tested at impact-loading rates, femurs from young individuals (age 17 to 51) are approximately 80% stronger than those from the older individuals (age 59 to 83) (Courtney *et al.*, 1995). Loading direction dramatically influences femoral failure loads. For instance, 1.5- to 2-fold greater loads are required to fracture femurs testing in a single-leg stance configuration than in a sideways fall configuration, further supporting the high risk of sideways fall in terms of hip fracture risk (Keyak *et al.*, 1998). Moreover, subtle differences in the direction of a sideways fall can influence femoral strength as much as 25 years of age-related bone loss (Pinilla *et al.*, 1996).

In addition to age, loading rate, and loading direction, femoral geometry also influences the load-bearing capacity of the proximal femur. The relationship between femoral geometry and load-bearing capacity is not unexpected. Because the load-bearing capacity is a structural property, it is influenced by the size of the specimen, and thus larger femurs have a greater load-bearing capacity. Femoral neck area, neck width, and neck axis length are all positively correlated with femoral failure loads (Bouxsein *et al.*, 1995b; Cheng *et al.*, 1997a; Courtney *et al.*, 1995; Pinilla *et al.*, 1996). However, additional laboratory studies are required to understand the complex relationship between hip geometry and femoral failure load.

Although it is important to understand what factors influence femoral strength in the laboratory environment, it is also critical to develop techniques that can be used clinically to predict femoral strength. Several studies have confirmed that noninvasive assessments of bone mineral

density and geometry using dual-energy x-ray absorptiometry (DXA) or quantitative computed tomography (QCT) are strongly correlated to the strength of human cadaveric femurs. In particular, femoral bone mineral content and density explain between 40% and 80% of the variation in load-bearing capacity of the proximal femur (Bauer *et al.*, 2006; Bouxsein *et al.*, 1995b, 1999; Cheng *et al.*, 1997a; Cody *et al.*, 1999; Lochmuller *et al.*, 1998b). Application of QCT-based finite-element analysis may improve these predictions.

Interactions between Fall Severity and Femoral Strength: The Factor of Risk for Hip Fracture

Case-control studies have demonstrated the importance of both fall severity and bone mineral density as risk factors for hip fracture (Greenspan *et al.*, 1994, 1998; Nevitt and Cummings, 1993). Further insight may be achieved by considering a factor of risk for hip fracture. The previous two sections have described how laboratory techniques can be used to develop and validate methods for estimating the loads applied to the femur and the load-bearing capacity of the femur from data that can be acquired in a clinical setting. Thus, these findings can be used to estimate the factor of risk for hip fracture owing to a sideways fall from standing height.

A few studies have applied the factor-of-risk concept in a case-control study of individuals with hip fracture compared with those that are fracture free. The numerator of the factor of risk, the applied load, was estimated from previous studies of the descent and impact phases of a sideways fall with impact to the lateral aspect of the hip. Each individual's body height and weight was used as input parameters for the model to estimate the impact force delivered to the proximal femur during a sideways fall from standing height. The denominator of the factor of risk, or load-bearing capacity of the proximal femur, was determined from linear regressions between noninvasive bone densitometry and femoral failure loads in a fall configuration (Bouxsein *et al.*, 1999). Myers and coworkers (1994b) reported a strong association between the factor of risk and hip fracture in elderly fallers, with the odds of hip fracture increasing by 5.1 for a 1 SD increase in the factor of risk (95% confidence interval: 2.9, 9.2), whereas the odds ratio for a 1 SD decrease in femoral BMD was 2.0 (95% confidence interval: 1.4, 2.6). In another study, trochanteric soft tissue thickness, femoral BMD, and the ratio of fall force to femoral strength was compared in 21 postmenopausal women with incident hip fracture versus 42 age-matched controls (Bouxsein *et al.*, 2006a). Reduced trochanteric soft tissue thickness and low femoral BMD were associated with increased risk of hip fracture. The factor of risk for hip fracture was significantly higher (i.e., worse) in cases than controls (0.92 ± 0.44 vs. $0.6\,5 \pm 0.50$, respectively, $P = 0.04$).

Biomechanics of Vertebral Fractures

Investigations of the etiology and biomechanics of vertebral fractures are particularly difficult, because the precise definition of a vertebral fracture remains controversial (Ferrar *et al.*, 2005). Second, a minority of radiographically evident vertebral deformities come to clinical attention (Cooper *et al.*, 1992; Delmas *et al.*, 2005; Nevitt *et al.*, 1998), although they are associated with significant morbidity and are strong predictors of future fracture risk (Delmas *et al.*, 2003; Klotzbuecher *et al.*, 2000; Nevitt *et al.*, 1998). Furthermore, few vertebral deformities are of acute onset; rather, they are believed to develop slowly over time, and therefore the activities associated with vertebral fracture are poorly understood.

In contrast to the growing recognition of the importance of bone fragility and fall severity in the etiology of hip fractures, the role of spinal loading in the etiology of age-related vertebral fractures has received relatively little attention. Because loads are applied to the spine during nearly every activity of daily living, it is crucial to distinguish which activities (and the resulting loads on the spine) are associated with vertebral fractures to try to understand the loading environment that leads to structural failure of the vertebrae.

Factors that Influence the Loads Applied to the Spine

Although no clinical study has yet examined the relative roles of bone fragility and load severity as risk factors for vertebral fracture, several investigators have reviewed medical records or interviewed patients to assess the "degree of trauma" associated with vertebral fractures (Bengnér *et al.*, 1988; Cooper *et al.*, 1992; Patel *et al.*, 1991; Santavirta *et al.*, 1992). Cooper *et al.* (1992) reviewed medical records from a 5-year period to determine the circumstances associated with "clinically diagnosed" vertebral fractures in a population-based sample of 341 Rochester, Minnesota, residents. In their study, a specific loading event was reported for approximately 50% of the total fractures (Table II). In contrast to the commonly held belief that lifting plays a major role in the development of vertebral fractures, relatively few of the fractures were associated with lifting. Excluding fractures that were diagnosed incidentally, only 10% of fractures were associated with "lifting a heavy object," whereas nearly 40% were associated with falling. In a hospital-based study, nearly 50% of acute, symptomatic vertebral fractures in individuals over age 60 were associated with a fall, whereas 20% were associated with "controlled" activities, such as bending, lifting, and reaching (Myers *et al.*, 1996). Therefore, determining the forces on the spine during controlled activities and falls may improve our understanding of the biomechanics of vertebral fractures.

Although it is impossible to measure the loads on the vertebral bodies *in vivo*, investigators have used kinematic

TABLE II Circumstances Associated with Clinically Diagnosed Vertebral Fractures

Reported activity/ circumstance	No. of persons	% of symptomatic fractures	% of total fractures
Pathological fracture	12	4	3.5
Traffic accident	20	7	6
Fall from greater than standing height	27	9	8
Fall from standing height or less	86	30	25
Lifting a heavy object	29	10	8.5
"Spontaneous"	113	39	33
Diagnosed incidentally (asymptomatic)	54	NA	16

Data from Cooper et al. (1992).

analysis, electromyographic measurements, and biomechanical modeling to estimate the loads on the lumbar spine during various activities (Adams and Dolan, 2005). These models were originally developed to study the potential origins and mechanisms of low-back pain and injury in working adults. Therefore, they are generally based on anthropometric data from young, healthy adults and are limited to estimating the vertebral forces in the lumbar region. However, Wilson (1994) extended these models to include the mid- and lower thoracic spine and incorporated geometric properties of the trunk by using QCT scans of older individuals. Using this model, the compressive forces applied to the T8, T11, and L2 vertebrae during various activities for a woman who weighed 65 kg and was 1.6 m tall (mean values from a cohort of 120 women aged 65 years or older) were computed (Table III). The estimated forces applied to the spine ranged from approximately 400 to 2100 N for typical activities. For example, rising from a chair without the use of one's hands results in compressive forces equal to 60% and 173% of body weight on the T11 and L2 vertebrae, respectively. Standing straight and holding an 8-kg weight with the arms slightly extended creates a compressive load on L2 equal to 230% of body weight, whereas flexing the trunk forward 30° and holding the same weight generates a compressive force on L2 of 320% of body weight. From these estimates, it is clear that everyday activities, such as rising from a chair or bending over and picking up a full grocery bag, can generate high forces on the spine. Although it may be highly relevant, there are no estimates of the load applied to the spine during falls.

Factors that Influence Vertebral Strength

The use of noninvasive assessments of skeletal status to predict vertebral strength *in vivo* is based on the assumption that much of the variability in the strength of whole vertebrae can be explained by variations in bone mineral density and/or geometry. As in other skeletal structures, the load-bearing capacity of a whole vertebra is determined by its intrinsic material properties, as well as its overall geometry and shape. In the spine, compressive loads are transferred from the intervertebral discs to adjacent vertebral bodies. Therefore, age-related changes in the properties of the intervertebral disc, the vertebral centrum, and the vertebral shell can each influence the load-bearing capacity of the vertebrae. For instance, the thickness of the shell decreases from approximately 400–500 μm at age 20 to 40, to 200–300 μm at age 70 to 80, and to 120–150 μm in osteoporotic individuals; whereas bone density of the vertebral centrum declines from 15% to 20% at age 20 to 40 to 4% to 8% in osteoporotic individuals (Mosekilde, 1998).

A number of laboratory studies have investigated the relationships among the strength of human lumbar and thoracic vertebrae and age, bone density, and vertebral geometry (Bell *et al.*, 1967; Biggemann *et al.*, 1988, 1991; Cheng *et al.*, 1997b; Cody *et al.*, 1991; Crawford *et al.*, 2004; Lochmuller *et al.*, 1998a; McBroom *et al.*, 1985; Moro *et al.*, 1995; Mosekilde *et al.*, 1985; Myers *et al.*, 1994a; Vesterby *et al.*, 1991). These studies indicate that the strength of thoracolumbar vertebrae is reduced from a value of 8000–10,000 N at age 20 to 30 to 1000–2000 N by age 70 to 80 (Biggeman and Brinckman, 1995; Mosekilde, 1998), and in severely osteoporotic individuals, the load-bearing capacity may be even less (Moro *et al.*, 1995).

The strength of human vertebrae is strongly correlated with noninvasive estimates of vertebral bone density and geometry, with approximately 50% to 80% of the variance in load-bearing capacity explained by parameters measured noninvasively. For example, strong correlations have been

TABLE III Predicted Compressive Loads on the L2 and T11 Vertebrae during Various Activities

Activity	Predicted load on T11		Predicted load on L2	
	N	% of body weight	N	% of body weight
Relaxed standing	240	41	290	51
Rising from a chair, without use of hands	340	60	980	173
Standing, holding 8-kg weight close to body	320	57	420	74
Standing, holding 8-kg weight with arms extended	660	117	1302	230
Standing, trunk flexed 30°, arms extended	370	65	830	146
Standing, trunk flexed 30°, holding 8-kg weight with arms extended	760	135	1830	323
Lift 15-kg weight from floor, knees bent, arms straight down	593	104	1810	319

The loads were computed from the model developed by Wilson (1994) *for a woman who weighs* 58 *kg and is* 162 *cm tall.*

reported between vertebral failure loads and (1) bone density and vertebral cross-sectional area assessed by QCT (Brinckmann *et al.*, 1989; Buckley *et al.*, 2007; Cody *et al.*, 1991), (2) bone mineral density assessed by DXA (Cheng *et al.*, 1997b; Lochmuller *et al.*, 1998a; Moro *et al.*, 1995; Myers *et al.*, 1994a; Tabensky *et al.*, 1996), and (3) estimated vertebral strength by QCT-based finite-element analysis (Buckley *et al.*, 2007; Crawford *et al.*, 2004). Thus, it appears that noninvasive assessments of bone mass and bone mineral density provide a reasonable estimate of the failure loads of cadaveric vertebrae subjected to controlled compression tests in the laboratory. It remains to be seen whether BMD or other bone density parameters can predict the strength of vertebrae subjected to loading conditions that more closely resemble those occurring *in vivo*, such as falling or compression combined with forward flexion or compression combined with lateral bending.

Interactions between Spinal Loading and Vertebral Strength: The Factor of Risk for Vertebral Fracture

Although it has not been clearly demonstrated by clinical surveillance studies, it seems reasonable to suggest that, similar to hip fractures, both bone fragility and skeletal loading are important factors in the etiology of vertebral fractures. To explore this, Myers and Wilson (1997b) examined relationships between spinal loading and vertebral fragility by computing the factor of risk for vertebral fractures, Φ, defined as the ratio of applied forces to failure load, for a various activities of daily living. Their analyses predicted that for very low BMD values, a woman would be at high risk for vertebral fracture during many routine activities of daily living (Fig. 13). Individuals with extremely low bone mineral density may be at risk for vertebral fracture during simple activities such as tying one's shoes or opening a window. Individuals with low bone mineral density (but still in the osteopenic range) may be at risk for vertebral fracture when lifting groceries out of the car or picking up a toddler. These examples illustrate the need for strategies to prevent vertebral fractures, such as reducing spinal loading by avoiding certain "high-risk" activities.

Application of the factor of risk for vertebral fracture in a population-based sample of 697 women and men aged 20 to 97 years (Bouxsein *et al.*, 2006b) showed that men had a higher predicted vertebral strength at all ages, largely owing to their greater vertebral cross-sectional area. Whereas both sexes exhibited a marked decline in lumbar vertebral compressive strength with age ($P < 0.001$), the decline was greater in women than men (-49% versus -31%, $P < 0.001$). The factor of risk for vertebral fracture increased with age in both sexes, but significantly more so in women than in men, such that for bending forward and lifting, the factor of risk exceeded the fracture "threshold" of one in 31% of women and 12% of men who were 50 years and older, values that are similar to the reported prevalence of vertebral fracture (Fig. 14). Moreover, the estimated factor of risk for vertebral fracture

BMD (g/cm^2)	0.3	0.4	0.5	0.6	0.7	0.8	0.9
Get up from sitting	1.5	0.6	0.4	0.3	0.2	0.2	0.2
Lift 15 kg knees straight	2.6	1.1	0.7	0.5	0.4	0.3	0.3
Lift 15 kg w/ deep knee bend	2.1	0.9	0.6	0.4	0.3	0.3	0.2
Lift 30 kg knees straight	3.7	1.5	1.0	0.7	0.6	0.5	0.4

Tie shoes sitting down	1.4	0.6	0.4	0.3	0.2	0.2	0.2

FIGURE 13 Factor of risk for vertebral fracture for eight common activities as a function of lumbar bone mineral density. The numerator of the factor of risk was determined from models of spine loading at L2 for an elderly woman of average height and weight. The denominator was determined on the basis of regression analysis between lateral lumbar BMD and the load-bearing capacity of the L2 vertebrae. The values for lateral BMD cover a wide range, including very low values. The *t*-score (number of standard deviations from the mean value for BMD in young women) is approximately +1 for a BMD = 0.9 g/cm^2 and is −5 for BMD = 0.4 g/cm^2. The factor of risk is predicted to be greater than or close to 1 for low BMD values (i.e., fracture predicted to occur, shaded area). (From Myers and Wilson, 1997a, with permission).

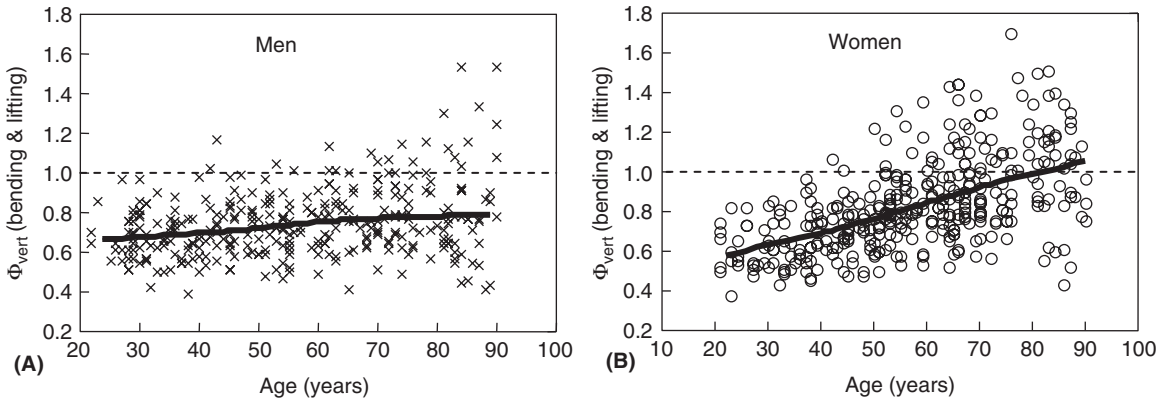

FIGURE 14 Factor of risk for vertebral fracture in men **(A)** and women **(B)** aged 20 to 97 for the activity of bending forward and lifting 10 kg. Note the marked age-related increase in the factor of risk in women. (Data from Bouxsein *et al.*, 2006b, with permission).

was significantly higher in subjects with prevalent vertebral fractures than in those with no fractures (Melton *et al.*, 2007).

SUMMARY AND CLINICAL IMPLICATIONS

When studying the mechanical behavior of whole bones, one must consider the material properties of bone tissue in addition to whole-bone geometry. Both of these factors contribute to the structural behavior of the whole bone, and both can change with age. Basic descriptions of bone material properties include measures of the elastic, yield, and postyield behavior. Both cortical and trabecular bone are anisotropic, and although these tissues are frequently tested in the primary loading direction, the material properties in other directions can be highly relevant in scenarios such as falls, when the applied loads are oblique to the primary loading direction. In addition, stresses and strains that occur in bone tissue *in vivo* can be multiaxial, and comparatively little is known about bone material behavior under general multiaxial stress and strain states once the elastic region has been exceeded.

Many aspects of the composition and microstructure profoundly affect bone material properties. Variations among bone specimens in characteristics such as porosity, mineralization, and trabecular architecture can explain much of the heterogeneity in bone material properties and also much of the age-related decline in these properties. However, the effects of composition and microstructure on the postyield behavior of cortical bone and trabecular tissue are less well understood. In addition, the mechanical consequences of microdamage accumulation *in vivo* are still unclear.

Age-related changes in bone material properties are accompanied by subtle but significant changes in how cortical and trabecular bone are distributed throughout the whole bone. This redistribution can alter the way in which the applied loads are shared between the cortical shell and trabecular compartment in bones such as the vertebra and proximal femur. Evidence to date suggests that this redistribution also results in changes in bone geometry that compensate for, or at least mitigate, the decline in the mechanical competence of bone tissue with age. The sex-specific nature of this compensatory mechanism remains controversial, and noninvasive methods for accurate quantification of changes in bone geometry would tremendously benefit longitudinal studies of this type of bone adaptation.

In this chapter, we have emphasized the concept that age-related fractures represent a structural failure whereby the forces applied to the bone exceed its load-bearing capacity. Viewing fractures in this manner, it is clear that studies of their etiology must include both factors that influence skeletal fragility, as well as those that influence the forces that are applied to the skeleton. Biomechanically based estimates of fracture risk that incorporate both skeletal loading and bone strength may improve identification of those at greatest risk, and also enhance interpretation of therapeutic interventions.

To date investigators have focused primarily on methods to prevent bone loss and to restore bone to the osteopenic skeleton. However, alternative approaches for fracture prevention that are directed at reducing the loads applied to the skeleton may prove to be both effective and cost-efficient. Ultimately, fracture prevention may be best achieved by an educational program designed to limit high-risk activities in conjunction with interventions targeted at increasing bone mass and reducing loads applied to the skeleton during traumatic events.

Chapter 3

Embryonic Development of Bone and Regulation of Intramembranous and Endochondral Bone Formation

Andrew C. Karaplis*

Division of Endocrinology, Department of Medicine and Lady Davis Institute for Medical Research, Sir Mortimer B. Davis-Jewish General Hospital, McGill University, Montréal, Canada

INTRODUCTION

The skeletal system is multifunctional in that it provides the rigid framework and support that gives shape to the body, serves to protect delicate internal organs, endows the body with the capability of movement, acts as the primary storage site for mineral salts, and functions in hematopoiesis. The vertebrate skeleton comprises two main subdivisions, the axial and appendicular components. The axial skeleton encompasses the skull, spine, sternum, and ribs, whereas the appendicular skeleton defines the bones of the extremities. The skull, in turn, is best regarded as consisting of two units: the chondrocranium, whose elements first develop in cartilage and include the cranial base and capsules surrounding the inner ears and nasal organs, and the cranial vault and most of the upper facial skeleton, which arise from the direct conversion of undifferentiated mesenchymal cells into bone.

Skeletal cells are derived from three distinct embryonic cell lineages: neural crest cells contribute to the craniofacial skeleton; sclerotome cells from somites give rise to the axial skeleton; and lateral plate mesoderm cells form the appendicular component. Bone formation arising from a cartilaginous template is referred to as endochondral ossification. This is a complex, multistep process requiring the sequential formation and degradation of cartilaginous structures that serve as templates for the developing bones. Formation of calcified bone on a cartilage scaffold, however, occurs not only during skeletogenesis but is also an integral part of postnatal growth, bone remodeling, and fracture repair. Intramembranous bone differs from the endochondral component in that it is formed in the absence of cartilaginous anlagen. Rather, it arises directly from mesenchymal cells condensing at ossification centers and being transformed directly into osteoblasts.

The organization and morphology of the developing skeleton are established through a series of inductive interactions. The functional elements in these inductive and morphogenetic processes are not individual cells but rather interacting populations that elaborate an extensive extracellular matrix that, in turn, feeds back onto these matrix-producing cells and controls their differentiation potential. Over the past 15 years, considerable insight has been gained into the molecular mechanisms that control these developmental programs. Genetic and biochemical analyses of human heritable skeletal disorders in concert with the generation of transgenic and knockout mice have provided useful tools for identifying key molecular players in mammalian skeletogenesis. It is the nature and interplay of these signaling cascades controlling skeletal patterning and cellular differentiation that will be the focus of this chapter.

THE AXIAL SKELETON

Somitogenesis

A defining feature of the vertebrate body plan is metameric segmentation of the musculoskeletal and neuromuscular systems. The origin of this basic anatomic plan during embryogenesis is segmentation of the paraxial mesoderm (for reviews, see Burke, 2000; Christ *et al.*, 1998). Upon gastrulation, paraxial mesoderm cells segregate from axial and lateral mesoderm to form two identical strips of unsegmented tissue (referred to as presomitic mesoderm in the mouse embryo or segmental plate in the avian embryo) on

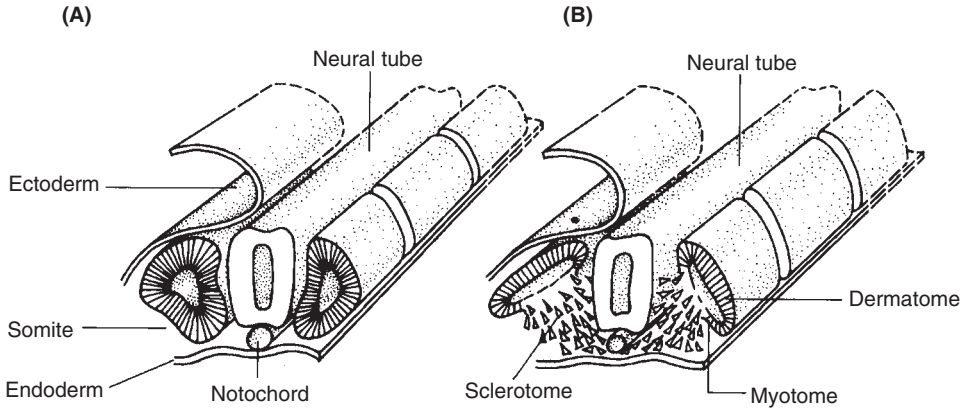

FIGURE 1 Diagrammatic representation of sclerotome formation. (**A**) Organization and differentiation of somites in the trunk region of the mouse embryo. (**B**) Ventral medial somite cells (those further away from the back and closer to the neural tube) undergo mitosis, migrate ventrally, lose their epithelial characteristics, and become mesenchymal cells that give rise to the sclerotome. They ultimately become the vertebral chondrocytes that are responsible for constructing the axial skeleton (vertebrae and ribs). The notochord provides the inductive signal by secreting SHH. After formation of the vertebral bodies, the notochordal cells die, except in between the vertebrae where they form the intervertebral discs. Adapted from Hogan *et al.* (1994), Fig. 26, p. 77).

either side of the neural tube. Paraxial mesoderm in vertebrates gives rise to the axial skeleton as well as all trunk and limb skeletal muscles and portions of the trunk dermis and vasculature. Through a series of molecular and morphogenetic changes this unsegmented tissue is converted into a string of paired tissue blocks on either side of the axial organs, called somites (Fig. 1A). The process, referred to as somitogenesis, occurs sequentially by the addition of new somites in a strict craniocaudal (head-to-tail) direction along the body axis with a periodicity that reflects the segmental organization of the embryo (see later). The recruitment of new presometic tissue from the primitive streak into the posterior end of the presometic mesoderm, as well as cell division within it, permits the presomite mesoderm to maintain its longitudinal dimension as somite budding is taking place anteriorly. Somite formation is preceded by epithelialization of the presometic mesoderm so that a new pair of somites is formed when cells are organized into an epithelial sphere of columnar cells enveloping mesenchymal cells within the central cavity, the somitocoel. This epithelial structure, however, is not maintained because somite maturation is accompanied by a commitment of its cells to different lineages in response to signals that arise from adjacent tissues. Cells on the ventral margin undergo an epitheliomesenchymal transition as they disperse and move toward the notochord, giving rise to the sclerotome, which serves as the precursor of the vertebrae and ribs (see Fig. 1B). The dorsal epithelial structure of the somite is maintained in the dermomyotome which eventually gives rise to the epaxial muscles of the vertebrae and back (medial myotome), the hypaxial muscles of the body wall and limbs (lateral myotome), and the dermis of the skin of the trunk (dermatome).

Somitogenesis has long been known to be driven by mechanisms intrinsic to the presomitic mesoderm. Although many of the elements of the network have been identified, their interaction and their influence on segmentation remain poorly understood. Although mathematical models have been proposed to explain the dynamics of subsets of the network (Baker *et al.*, 2008; Cinquin, 2007), the mechanistic bases remain controversial. In general, two distinct molecular pathways have been implicated in vertebrate segmentation. The first is referred to as the oscillator or "segmentation clock" (McGrew *et al.*, 1998; Palmeirim *et al.*, 1997; Pourquie, 1999). This clock corresponds to a molecular oscillator identified on the basis of rhythmic production of mRNAs for the basic helix-loop-helix (bHLH) Notch target genes *mHes1*, *mHes7*, the glycosyltransferase Notch modifier *Lunatic fringe* (*mLfng*), the Notch ligand *Delta-like 1* (*Dll1*), as well as genes in the Wnt signaling pathways (Aulehla *et al.*, 2008), and also the fibroblast growth factor (FGF) pathway (Dequeant *et al.*, 2006). It is the coordinated regulation of these three pathways that underlies the clock oscillator although it is not known, in any species, which set of genes "drives" the oscillations. Nevertheless, the expression of these genes appears as a wave that arises caudally and progressively sweeps anteriorly across the presomitic mesoderm (Fig. 2(A). Although a new wave is initiated once during the formation of each somite, the duration of the progression of each wave equals the time to form two somites. This wave does not result from cell displacement or from signal propagation in the presomitic mesoderm but rather reflects intrinsically coordinated pulses of *Lunatic fringe* expression.

The second pathway implicated in somitogenesis is *Notch/Delta-like 1* signaling, an essential regulator of paraxial mesoderm segmentation (see Fig. 2B). It centers on a large transmembrane receptor called Notch, which is able to recognize the transmembrane ligand, Delta-like 1. Upon ligand binding, Notch undergoes a proteolytic cleavage at

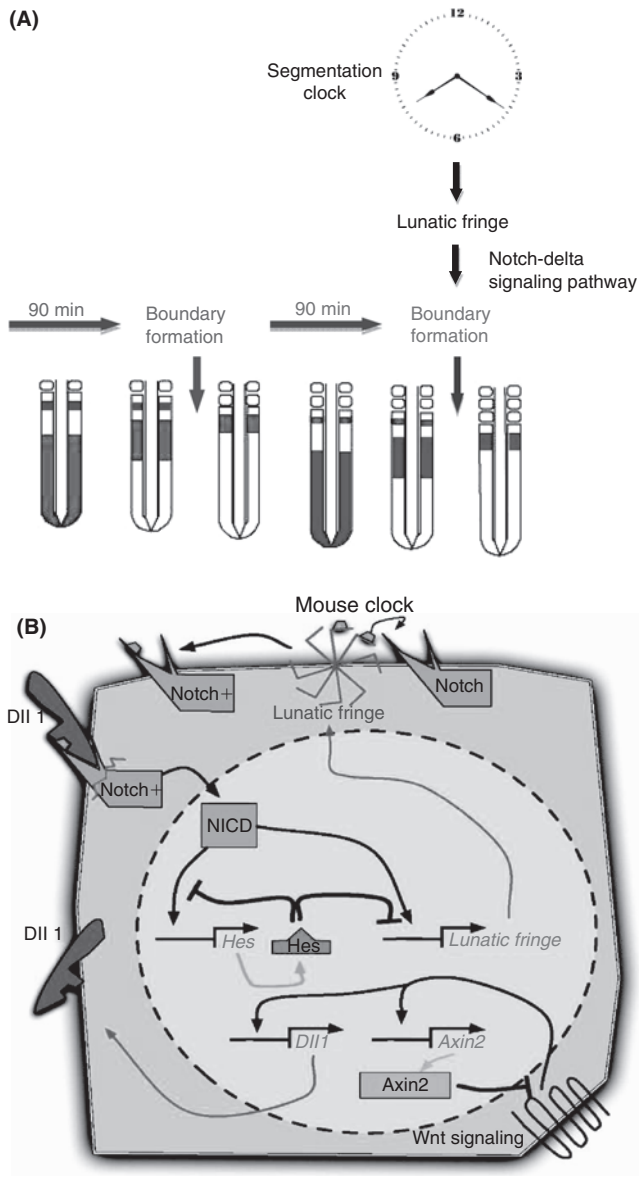

FIGURE 2 Proposed role of the segmentation clock in somite boundary formation. **(A)** Waves of *c-hairy* and Lunatic *Fringe* expression arise caudally and get narrower as they move anteriorly. A wave completes this movement in the time required to form two somites. Boundary formation occurs when the wave has reached its most rostral domain of expression where it is associated with rhythmic activation of the Notch signaling pathway that endows cells with setting-of-boundary properties. Adapted and modified from Pourquié (1999, Fig. 1, p. 560). **(B)** The mouse clock. The molecular mechanisms that have been proposed to drive the oscillation in mouse clocks. Mouse *hairy, hey*, and *hes* genes are summarized as Hes. NICD, Notch intracellular domain. See text for details. Adapted from Cinquin (2007) Fig. 2, p. 504.

the membrane level leading to the translocation of its intracytoplasmic domain into the nucleus. In the mouse, this leads to activate expression of downstream genes such as *Hes1/Hes7*, transcriptional repressors of the bHLH family downstream of Notch signaling. Many of the genes in this pathway are expressed strongly in the presomitic mesoderm and mutation studies in the mouse have established their role in the proper formation of rostral-caudal compartment boundaries within somites, pointing to a key role for a Notch signaling pathway in the initiation of patterning of vertebrate paraxial mesoderm (Barrantes *et al.*, 1999; Conlon *et al.*, 1995; Kusumi *et al.*, 1998; Yoon and Wold, 2000). It is now recognized that *Lunatic fringe* is the link between the *Notch* signaling pathway and the segmentation clock as its promoter is directly upregulated by Notch signaling and, in turn, Lunatic fringe modifies the Notch receptor post-translationally, making it more sensitive to activation by its ligand Delta-like 1.

Wnt/β-catenin signaling is cyclic in mouse presomitic mesoderm (Aulehla *et al.*, 2003), and induces cyclic transcription of the Wnt signaling inhibitors *Axin2*, *Nkd1*, *Dact1*, and *Dkk1*. *Axin2* is functionally equivalent to *Axin*, a critical component of the Wnt signaling pathway that acts as a scaffold for the β-catenin destruction complex. It has been proposed that *Axin2* and Wnt signaling form a negative feedback loop responsible for driving the mouse somitogenesis clock. Wnt signaling would drive transcription of *Axin2* mRNA, and Axin2 protein would inhibit Wnt signaling. However, *Axin2* mutants have no somitogenesis phenotype (Yu *et al.*, 2005), which suggests that *Axin2* may function in the clock redundantly with other genes. Recently it was shown that a Wnt signaling gradient is established through a nuclear β-catenin protein gradient in the posterior presomitic mesoderm. This gradient of nuclear β-catenin defines the size of the oscillatory field and controls key aspects of presometic mesoderm maturation and segment formation, emphasizing the central role of Wnt signaling in this process (Aulehla *et al.*, 2008).

As discussed previously, it is *Lunatic fringe* that delimits domains of Notch activity, thereby allowing for the formation of the intersomitic boundaries characterized morphologically by the epithelization event (for review, see Cinquin, 2007; Pourquie, 1999). Epithelization requires the expression of the gene *paraxis*. Paraxis is a bHLH transcription factor expressed in paraxial mesoderm and somites. In mice homozygous for a paraxis-null mutation, cells from the paraxial mesoderm are unable to form epithelia and so somite formation is disrupted (Burgess *et al.*, 1996). In the absence of normal somites, the axial skeleton and skeletal muscle form but are improperly patterned. Sosic *et al.* (1997) have shown that *Paraxis* is a target for inductive signals that arise from the surface ectoderm. The nature of this signal was recently reported to involve the β-catenin pathway. Wnt6 in the ectoderm overlaying the somites is responsible for the maintenance of the epithelial structure of the dorsal compartment of the somite: the dermomyotome (Linker *et al.*, 2005). The Wnt receptor molecule Frizzled7 transduces the Wnt6 signal. Intracellularly, this leads to the activation of the β-catenin/LEF1-dependent pathway. Hence, β-catenin activity,

initiated by Wnt6 and mediated by paraxis, is required for the maintenance of the epithelial structure of somites.

Specifying the Anterior-Posterior Axis

Initially, somites at different axial levels are almost indistinguishable morphologically and eventually give rise to the same cell types such as muscle, bone, and dermis. A great deal of research has therefore focused on identifying factors that dictate the ultimate differentiation fate of somitic cells as well as the overall patterning of the body plan. Burke (2000) has proposed that correct pattern requires two levels of information. At one level, short-range, local signals could dictate to a cell to differentiate into a chondroblast instead of a myoblast. These signals, however, would not contain all of the information required to also bestow regional identity to this chondrocyte and ensure that it would, for example, contribute to the development of the appropriate vertebral body, be that cervical, thoracic, or lumbar. In fact, additional information would be needed to provide global landmarks and ensure correct pattern formation.

Patterning of somites extends beyond the formation of distinct epithelial blocks. Early on they acquire cues that dictate anteroposterior as well as dorsoventral position. What signals are important for regional specification of segments along the anterior-posterior dimensions into occipital, cervical, thoracic, lumbar, and sacral domains? This regionalization is, in part, achieved by specific patterns of *Hox* gene expression (for reviews, see Mark *et al.*, 1997; McGinnis and Krumlauf, 1992; Veraksa *et al.*, 2000; Wellik, 2007). All bilateral animals, including humans, have multiple *Hox* genes, but in contrast to the single *Hox* cluster in *Drosophila* and other invertebrates, four clusters of *Hox* genes, *HOXA*, *HOXB*, *HOXC*, and *HOXD* have been identified in vertebrates. The mammalian *HOX* genes are numbered from 1 to 13, starting from the 3′ end of the complex. The equivalent genes in each complex (*HOXA-1*, *HOXB-1*, and *HOXD-1*) are referred to as a paralogous group. Comprising a total of 39 genes in humans, these clusters are arranged such that all the genes in each cluster are oriented in the same 5′ to 3′ direction. Moreover, genes located at the 3′ end of the cluster are expressed prior to and extend more anteriorly in the developing embryo than those at the 5′ end. The high degree of evolutionary conservation of homeotic gene organization and transcriptional expression pattern of these genes in flies and mammals argues strongly for a common scheme in anteroposterior axis formation.

How do *Hox* genes dictate pattern formation? It appears that there is a code of *Hox* gene expression that determines the type of vertebrae along the anterior-posterior axis. For example, in the mouse, the transition between cervical and thoracic vertebrae is between vertebrae 7 and 8, whereas in the chick, it is between vertebrae 13 and 14. In either case, the *Hox-5* paralogues are seen in the last cervical vertebra and the *Hox-6* paralogues extend up to the first thoracic vertebra, their anterior boundary. Changes in the *Hox* code lead to shifting in the regional borders and axial identities, otherwise known as homeotic transformations. Therefore, *Hox* loss of function results in the affected body structures resembling more anterior ones, whereas gain-of-function mutant phenotypes owing to ectopic expression of more posterior *Hox* genes cancel the function of more anterior ones and specify extra posterior structures. Persistent expression of *Hox* genes in discrete zones on the anteroposterior axis is required to remind cells of their position identity along the axis. Hox proteins are all transcription factors that contain a 60-amino-acid motif referred to as the homeodomain and exert their effect through activation and repression of numerous target genes. In mammals, little is known about the upstream mechanisms that initiate *Hox* gene expression (Manzanares *et al.*, 1997; Marshall *et al.*, 1996). More is known about factors involved in the maintenance of *Hox* expression in both flies and mice (see Veraksa *et al.*, 2000, and references therein). Studies with the Trithorax and Polycomb protein groups indicate that the former functions as transcriptional activators and the latter functions as transcriptional repressors of the *Hox* genes. In loss-of-function mutants for *Polycomb* genes *Bmi1* and *eed*, the domain of expression of the *Hox* gene is expanded causing homeotic transformation and, conversely, loss of the *Trithorax*-group gene *Mll* results in diminished levels of expression of the *Hox* gene with the phenotype resembling the mutants of the *Hox* gene themselves. Interestingly, the axial-skeletal transformations and altered *Hox* expression patterns of *Bmi1*-deficient and *Mll*-deficient mice are normalized when both *Bmi1* and *Mll* are deleted, demonstrating their antagonistic role in determining segmental identity (Hanson *et al.*, 1999). In summary, repeated identical units formed by the action of segmentation genes become different owing to *Hox* gene action.

Specifying the Dorsal-Ventral Axis

The newly formed somites comprise a sphere of columnar epithelial cells and a central cavity, the somatocoel, containing mesenchymal cells. Early somites are characterized by the expression of the *Pax3* gene. Following somite formation, however, expression of the gene is downregulated in the ventral half of the somite epithelium and in the somatocoel cells, whereas it persists in the dorsal half of the somite. The ventral medial cells of the somite subsequently undergo mitosis, lose their epithelial characteristics, and become mesenchymal cells again. This epitheliomesenchymal transition of the ventral part of the somite is preceded by the expression of *Pax1* in the somitic ventral wall and somatocoel cells as it signals the beginning of sclerotome formation. Mutations in *Pax1* affect sclerotome differentiation, as reported with different mutations in the *undulated* (*un*) locus (Balling *et al.*, 1988). Successful dorsoventral compartmentalization of somites ultimately leads to the

development of the sclerotome ventrally and the dorsally located dermomyotome.

In the fourth week of human development, cells from the somites migrate to the most ventral region of the somite in an area surrounding the notochord forming the ventral sclerotome (see Fig. 1B). These mesenchymal cells will differentiate to prechondrocytes and ultimately form the template of vertebral bodies and ribs. Initiation of sclerotome formation is under control of the notochord. Sonic hedgehog (Shh), a secreted signaling molecule known to play a role in the patterning of the central nervous system and the limb in vertebrates, is expressed in the notochord at that time and has been implicated as the key inductive signal in patterning the ventral neural tube and initiation of sclerotome formation (Fan and Tessier-Lavigne, 1994; Johnson *et al.*, 1994). Mutations in the gene encoding human SHH are associated with holoprosencephaly 3, an autosomal dominant disorder characterized by single brain ventricle, cyclopia, ocular hypotelorism, proboscis, and midface hypoplasia (Roessler *et al.*, 1996). In humans, loss of one *SHH* allele is insufficient to cause ventralization defects of sclerotomes. In the mouse, loss of both *Shh* alleles leads to brain abnormalities and a skeletal phenotype typified by complete absence of the vertebral column and posterior portion of the ribs (Chiang *et al.*, 1996). Formation of the sclerotome, however, does take place although the sclerotomes are smaller and *Pax1* expression is markedly decreased, suggesting that Shh does not initiate but rather maintains the sclerome program. McMahon and associates (1998) reported that *Noggin*, which encodes a bone morphogenetic protein (BMP) antagonist expressed in the node, notochord, and dorsal somite, is required for normal Shh-dependent ventral cell fate. In *Noggin*-null mice, somite differentiation is deficient in both muscle and sclerotomal precursors and *Pax1* expression is delayed, whereas addition of Noggin is sufficient to induce *Pax1*. These findings suggest that different pathways mediate induction and that *Noggin* and *Shh* induce *Pax1* synergistically. Inhibition of BMP signaling by axially secreted Noggin, therefore, is an important requirement for normal induction of the sclerotome.

In contrast to the sclerotome, it is dorsal signals that promote the development of the dermomyotome. These are members of the Wnt family of proteins emanating from the dorsal neural tube and the surface ectoderm necessary for the induction of myogenic precursor cells in the dermomyotome (Wagner *et al.*, 2000). Ectopic *Wnt* expression (*Wnt1*, *3a*-, and *4*) is able to override the influence of ventralizing signals arising from notochord and floor plate. This shift of the border between the two compartments is identified by an increase in the domain of *Pax3* expression and a complete loss of *Pax1* expression in somites close to the ectopic *Wnt* signal. Therefore, Wnts disturb the normal balance of signaling molecules within the somite, resulting in an enhanced recruitment of somitic cells into the myogenic lineage. In contrast, Shh reduces *Wnt* activity in the somitic mesoderm, at least in part, by upregulating *Secreted frizzled-related protein 2* (*Sfrp2*), which encodes a potential *Wnt* antagonist (Lee *et al.*, 2000).

In summary, dorsoventral polarity of the somitic mesoderm is established by competitive signals originating from adjacent tissues. Studies suggest that dorsoventral patterning of somites involves the coordinate action of multiple dorsalizing and ventralizing signals. The ventrally located notochord provides the ventralizing signals to specify the sclerotome, whereas the dorsally located surface ectoderm and dorsal neural tube provide the dorsalizing signals to specify the dermomyotome.

Sclerotome Differentiation

Pax1-expressing cells that arise from the ventromedial end of the sclerotome invade and colonize the perinotochordal space. These cells, expressing additional sclerotome markers such as twist and scleraxis, proliferate under the influence of *Shh* signaling from the notochord and form the perinotochordal tube from which vertebral bodies and intervertebral discs will develop. Segmentation begins by condensation of sclerotome cells that represent the intervertebral discs, thereby defining the boundaries of the future vertebral bodies. Notochordal cells die if surrounded by sclerotome cells that form a vertebral body, whereas those that become part of the intervertebral disc form the nucleus pulposus. The ribs, pedicle, and lamina of the neural arch arise from *Pax1*-expressing cells in the lateral sclerotome.

Not all of the sclerotome cells are under the influence of Shh and Noggin emanating from the notochord and consequently express *Pax1*. Cells located in the ventrolateral and dorsomedial angles of the sclerome escape the ventralizing signals. Whereas other sclerotomal cells migrate ventrally to surround the notochord where they form the vertebral body, these cells move dorsomedially to form the dorsal mesenchyme, which is the precursor of the dorsal part of the neural arch and the spinous process. These sclerotome cells express homeobox genes (*Msx1* and *Msx2*) as they are subjected to a different microenvironment, specifically to signals arising from the roof plate of the neural tube and surface ectoderm (Monsoro-Burq *et al.*, 1994). BMP4 is transiently expressed in these structures and likely exerts a positive effect on the induction of dorsalizing gene expression in sclerotome cells (Monsoro-Burq *et al.*, 1996).

The Cranial Vault and Upper Facial Skeleton

In contrast to the obvious segmentation of the axial skeleton, craniofacial development is a poorly understood process. The craniofacial skeleton forms primarily from neural

crest cells that migrate from hindbrain rhombomeres into the branchial arches. Neural crest cells are multipotential stem cells that contribute extensively to vertebrate development and give rise to various cell and tissue types, including mammalian craniofacial development. Migrating from the rhombomeric neuroectoderm to the pharyngeal arches, these cephalic neural crest cells proliferate as the ectomesenchyme within the arches, form mesenchymal condensations, and differentiate into cartilage and bone of endochondral and membranous skull, respectively. Little is known about the molecular basis underlying their migration but it appears that interactions with tissues encountered during migration strongly influence this segmental migratory pattern. Neural crest cells possess integrin receptors that are essential for interacting with extracellular matrix molecules in their surroundings. Aberrant migration of cephalic neural crest cells leads to craniofacial defects, as demonstrated in platelet-derived growth factor-α receptor- (Soriano, 1997) and Shh-deficient mice embryos (Ahlgren and Bronner-Fraser, 1999). Homozygotes die during embryonic development and exhibit incomplete cephalic development. Increased apoptosis is observed on pathways followed by migrating neural crest cells, indicating that these signaling molecules affect their survival.

Interactions between the neural crest-derived ectomesenchymal cells and surrounding cells are critical because defects in this process can also lead to craniofacial malformation. The development of the facial primordia is, in part, mediated by transcription factors that are programmed by an intricate array of intercellular signaling between the ectomysenchymal neural crest-derived cells and the epithelial and mesodermal cell populations within the arches (Francis-West *et al.*, 1998). *Hox* gene products, including *Hoxa1*, *Hoxa2*, and *Hoxa3*, play a role in the development of craniofacial structures derived from the second and third branchial arches, but they are not involved in the patterning of first arch derivatives. Other homeodomain proteins are expressed in cranial neural crest cells that migrate into the first branchial arch, including goosecoid (*Gsc*), *MHox*, and members of the *Dlx* and *Msx* families. A pivotal role in this process has been ascribed to components of the endothelin pathway. The G protein-coupled endothelin-A receptor (ET_A) is expressed in the ectomesenchyme, whereas the cognate ligand for ET_A, endothelin-1 (ET-1), is expressed in arch epithelium and the paraxial mesoderm-derived arch core. Absence of either ET-1 (Kurihara *et al.*, 1994) or ET_A (Clouthier *et al.*, 1998) results in numerous craniofacial defects. While neural crest cell migration in the head of ET_A-null embryos appears normal, expression of transcription factors (*Gsc*, *Dlx-2*, *Dlx-3*, *dHAND*, *eHAND*, and *Barx1*) important in the differentiation of cephalic crest cells in the arches during epithelial-mesenchymal interactions is either absent or significantly reduced in the ectomesenchymal cells (Clouthier *et al.*, 2000). Because *Dlx-1*, *Hoxa-2*, and *MHox* are normally expressed in these mutants it would argue that additional pathways work in conjunction with the ET_A pathway in patterning the facial primordia from buds of undifferentiated mesenchyme into the intricate series of bones and cartilage structures that, together with muscle and other tissues, form the adult face.

LIMB INITIATION AND DEVELOPMENT

Overview of Limb Development

Not all of the mesoderm is organized into somites. Adjacent to the somitic mesoderm is the intermediate mesodermal region, which gives rise to the kidney, and genital ducts and further laterally on either side is the lateral plate mesoderm. In the second month of human development, proliferation of mesenchymal cells from the lateral plate mesoderm give rise to the formation of limb buds (Fig. 3A). *Hox* genes expressed within the lateral plate mesoderm specify the positions at which forelimbs and hindlimbs will be developing (for review, see Ruvinsky and Gibson-Brown, 2000). T-box genes, which encode a family of transcription factors that share a conserved domain with the classical mouse *Brachyury* (*T*) gene, function as activators or repressors of transcription of downstream target genes involved in the regulation of vertebrate limb development. Specifically, transcripts of two of these genes, *Tbx5* and *Tbx4*, are activated as a result of a "read-out" of the *Hox* code for the pectoral and pelvic appendages, respectively (Takeuchi *et al.*, 2003; Zakany and Duboule, 2007). The positional information then leads to limb development within the perspective fields. This concept, however, is not supported by an elegant experiment leading to expression swapping between *Tbx5* and *Tbx4* in the forelimb (Minguillon *et al.*, 2005). Under these conditions, *Tbx4*, which is proposed to specify hindlimb identity, supports formation of a perfectly normal forelimb. In contrast, *Ptx1*, a gene normally expressed specifically in the hindlimb territory, can partially transform the forelimb into hindlimb when ectopically expressed (Lanctot *et al.*, 1999), and remains the best candidate for posterior limb identity specification.

The vertebrate limb is an extremely complex organ in that its patterning takes place in three distinct axes (for review, see Schwabe *et al.*, 1998). First is the proximal-distal axis (the line connecting the shoulder and the finger tip) which is defined by the apical ectodermal ridge (AER), a single layer of epidermal cells that caps the limb bud and promotes the proliferation of mesenchymal cells underneath. As the limb elongates, mesenchymal cells condense to form the cartilage anlagen of the limb bones. Second is the posterior-anterior axis (as in the line between the little finger and the thumb) which is specified by the zone of polarizing activity (ZPA), a block of mesodermal tissue near the posterior junction of the limb bud and the body wall. Third, is the dorsal-ventral axis (as in the line

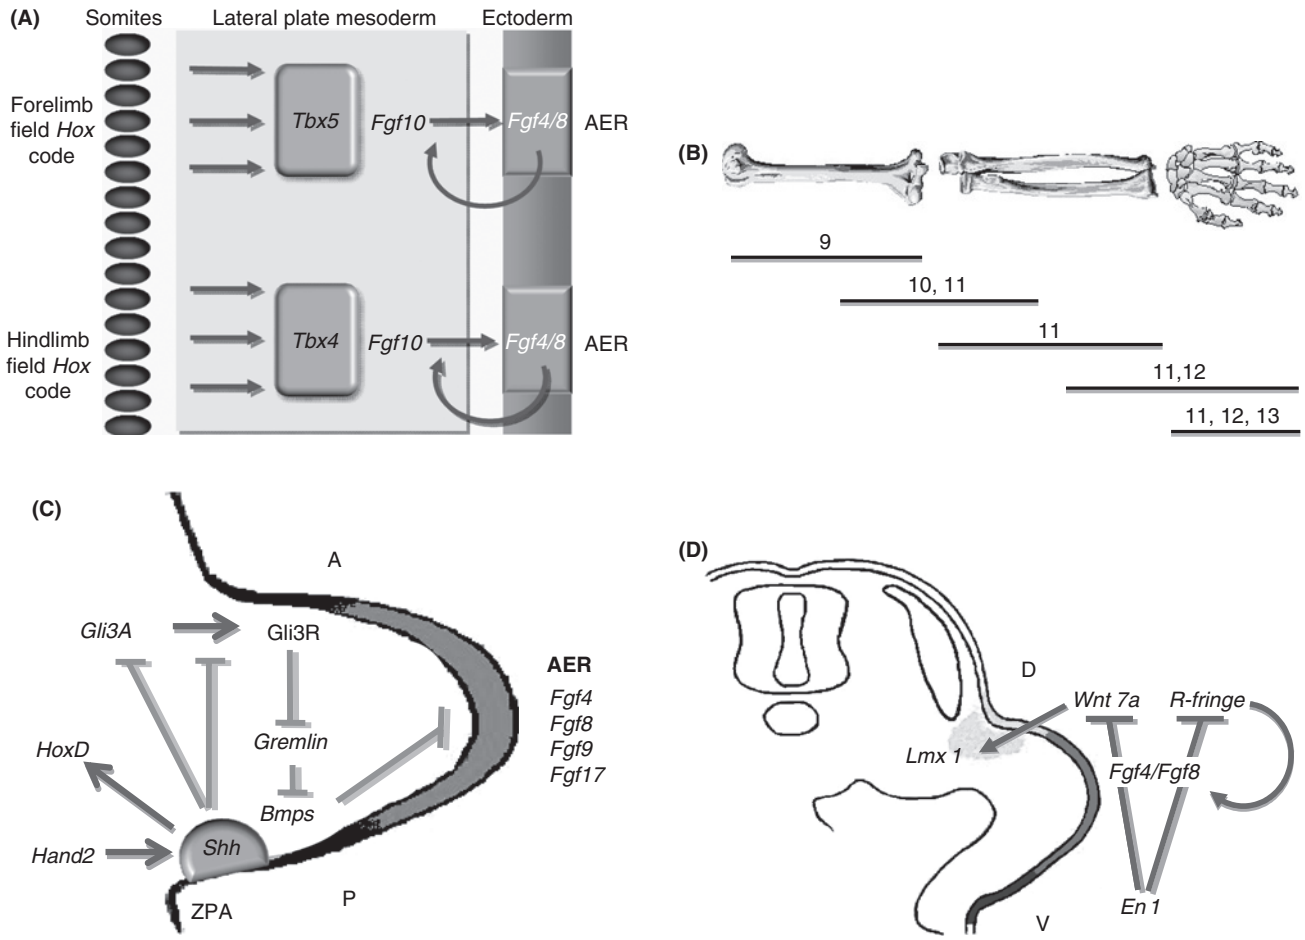

FIGURE 3 Molecular regulation of limb patterning. (**A**) Schematic model for specification of limb position. *Hox* genes expressed in the lateral plate mesoderm define the positions where limbs will develop. *Tbx4* and *Tbx5* expression activates the perspective fields and sets up the *Fgf10-Fgf4/8* positive-feedback loop implicated in induction of the AER in the overlying ectoderm and initiation of limb bud outgrowth. Adapted and modified from Ruvinsky and Gibson-Brown (2000), Fig. 3, p. 5237. (**B**) *HoxA* and *HoxD* genes involved in limb specification. Group 9 paralogous genes organize the proximal part of the limb, group 11 genes organize the distal part of the limb, and group 13 genes pattern the digits. Adapted and modified form Zakany and Duboule (1999), Fig. 1, p. 20. (**C**) Specification of the anterior-posterior axis. *Shh* expressed in the ZPA and *Fgfs* in AER participate in a positive feedback loop to provide the polarizing signal for anterior-posterior patterning of the limb. Adapted and modified from Robert and Lallemand (2006), Fig. 2, p. 2339. (**D**) Specification of the dorsal-ventral axis. *Wnt7a* and *Lmx1* expression correlate with dorsal fate whereas *En1* expression dictates ventral fate by repressing *Wnt7a* and *R-fhg*, a secreted molecule that directs the formation of the AER in the boundary between cells that express it in the dorsal ectoderm and cells that do not express it in the ventral ectoderm. D, dorsal; V, ventral. Adapted and modified from Niswander (1997), Fig. 1, p. 531.

between the upper and lower surfaces of the hand) which is defined by the dorsal epithelium.

The Proximal-Distal Axis

A variety of growth factors, patterning morphogens, transcription factors, and adhesion molecules participate in a highly orchestrated system that dictates the blueprint of the developing mammalian limb. The first step, initiation of the site where the presumptive limb will develop, is critically dependent on fibroblast growth factor (FGF) signaling mediated by high affinity FGF receptors (FGFRs). Expressed in the lateral plate mesoderm, *Fgf10* binds and activates the IIIb splice form of the FGF receptor 2 (FGFR2) in the AER in the overlying ectoderm. This signaling is absolutely crucial for limb bud initiation as evidenced by the complete absence of limb development in mice homozygous for a null *Fgf10* (Min *et al.*, 1998; Sekine *et al.*, 1999) or *Fgfr2* (Xu *et al.*, 1998) allele. In turn, *Fgf4* and *Fgf8* expressed in the AER act on the underlying mesoderm to maintain *Fgf10* expression, thereby promoting the elongation of the limb. As the limb grows, cells directly underneath the AER, in a region termed the progress zone (PZ), maintain their characteristics of undifferentiated mesenchyme while they continue to proliferate. In contrast, the more proximal mesenchymal cells begin to condense and differentiate into the cartilage anlage of the

limb. In this scheme, *Hox* gene expression pattern activates downstream target genes according to the position along the axis. These key signaling pathways control various aspects of limb development, including establishment of the early limb field, determination of limb identity, elongation of the limb bud, specification of digit pattern, and sculpting of the digits. Accumulating evidence indicates that *Hoxa* and *Hoxd* genes are involved in limb specification (for review, see Zakany and Duboule, 1999), as was demonstrated in mice lacking all Hoxa and Hoxd functions in their forelimbs (Kmita *et al.*, 2005). Such limbs were arrested early in their developmental patterning and displayed severe truncations of distal elements, partly owing to the absence of Shh expression. In contrast, *Hoxb* and *Hoxc* genes do not participate in limb patterning. Targeted mutations for each gene and compound mutants produced in mice have indicated that genes belonging to groups 9 and 10 determine the length of the upper arm, groups 10, 11, and 12 pattern the lower arm, and groups 11, 12, and mostly 13 organize the digits (see Fig. 3B).

The Anterior-Posterior Axis

It is now established that it is the mutual antagonism between Hand2 and Gli3, two transcriptional factors expressed in the posterior and anterior limb bud, respectively, that determines the anterior-posterior axis (reviewed in Robert and Lallemand, 2006) (see Fig. 3.3C). Hand2 induces in the ZPA expression of *Sonic hedgehog* (*Shh*), the major molecular determinant in the anterior-posterior patterning of the limb (Riddle *et al.*, 1993). Shh is a member of the vertebrate homologues of the *Drosophila* segment polarity gene, hedgehog (*hh*). Although only one *hh* gene has been identified in *Drosophila*, several *hh* genes are present in vertebrates. The mouse Hedgehog (Hh) gene family consists of *Sonic* (*Shh*), *Desert* (*Dhh*), and *Indian* (*Ihh*) hedgehog, all encoding secreted proteins implicated in cell–cell interactions. Signaling to target cells is mediated by a receptor that consists of two subunits, Patched (Ptc), a twelve-transmembrane protein that is the binding subunit (Marigo *et al.*, 1996; Stone *et al.*, 1996), and Smoothened (Smo), a seven-transmembrane protein that is the signaling subunit. In the absence of Hh, Ptc associates with Smo and inhibits its activities. In contrast, binding of Hh to Ptc relieves the Ptc-dependent inhibition of Smo (Nusse, 1996). Signaling then ensues and includes downstream components such as the Gli family of transcriptional factors. The three cloned *Gli* genes (*Gli1*, *Gli2*, and *Gli3*) encode a family of DNA-binding zinc finger proteins with diverse target specificities.

Expression of Shh in the polarizing region regulates the level of Gli3 by repressing the transcription of *Gli3* and preventing transformation of the protein (Gli3A) into its truncated form (Gli3R). *Shh* also acts to induce *HoxD* gene expression in the posterior limb bud. The unequivocal requirement for Shh signaling in limb development has been demonstrated by the *Shh* loss-of-function mutation resulting in the complete absence of distal limb structures (Chiang *et al.*, 1996). The profound truncation of the limbs indicates the existence of an interaction between the ZPA and the AER. The presence of *Gremlin* (*Gre*) in the initial mesenchymal response to *Shh* is required to relay this signal to the AER (Zeller *et al.*, 1999; Zuniga *et al.*, 1999). Gremlin expression is inhibited by the Gli3R and therefore concentrates in the posterior limb bud where it represses Bmp signaling. In turn, this prevents downregulation of *Fgf4* and *Fgf8* in the AER. This Shh/Fgf4 model is supported by genetic evidence showing that *Fgf4* expression is not maintained in *Shh*-null mouse limbs. Thus, Shh expression provides a molecular mechanism for coordinating the activities of these two signaling centers (Niswander *et al.*, 1994).

The Dorsal-Ventral Axis

Dorsoventral patterning is the least understood of the three axes of pattern formation in the limb (for review, see Niswander, 1997; Chen and Johnson, 2002). Molecular studies indicate that the signaling molecule *Wnt7a*, a secreted molecule encoded by *Radical fringe* (*R-fng*), and the transcription factor *Engrailed-1* (*En1*) are intimately involved in this process (see Fig. 3.3D). *Wnt7a* is expressed in the dorsal ectoderm and regulates the expression of a LIM homeodomain gene, *Lmx1*, in the dorsal mesenchyme, important for maintaining dorsal structure identity. *R-fng* expression is also localized in the dorsal ectoderm and dictates the location of AER as defined by the boundary between cells that do and cells that do not express *R-fng* (Laufer *et al.*, 1997). On the other hand, *En1* expression restricts *R-fng*, *Wnt7a*, and *Lmx1* to the dorsal ectoderm and mesenchyme and correlates with ventral fate.

The Skeletal Dysplasias

It is implicit from the foregoing discussion that mutations in the genes involved in limb patterning would tend to have profound effects on the final outcome of human limb design. For example, expansion of a polyalanine stretch in the amino-terminal end the protein product of *HOXD13* is the cause of synpolydactyly, type II, an autosomal dominant disorder characterized by variable syndactyly and insertion of an extra digit between digits III and IV (Muragaki *et al.*, 1996). In homozygous individuals, homeotic transformation of metacarpal and metatarsal bones occurs so that they resemble carpal and tarsal anlages rather than long bones.

Mutations in *GLI3*, the transcription factor involved in the transduction of hedgehog signaling, have been described in four human autosomal dominant disorders: Greig cephalopolysyndactyly syndrome, characterized by

peculiar skull shape, frontal bossing, high forehead, and the presence of (poly)syndactyly (Vortkamp *et al.*, 1991); Pallister–Hall syndrome, a neonatally lethal disorder characterized by hypopituitarism, renal agenesis, cardiac defects, cleft palate, short nose, flat nasal bridge, and short limbs (Kang *et al.*, 1997); postaxial polydactyly type A, a trait typified by the presence of a rather well formed extra digit that articulates with the fifth or an extra metacarpal (Radhakrishna *et al.*, 1997); and preaxial polydactyly IV, distinguished by mild thumb duplication, syndactyly of fingers III and IV, first or second toe duplication, and syndactyly of all toes (Radhakrishna *et al.*, 1999).

Heterozygous mutations in the *LMX1B* gene have been described in patients with the nail-patella syndrome, an autosomal dominant disorder encompassing nail dysplasia, hypoplastic patella, decreased pronation and supination, iliac horns, and proteinuria (Dreyer *et al.*, 1998). Functional studies indicate that these mutations either disrupt sequence-specific DNA binding or result in premature termination of translation. These are the first described mutations in a LIM-homeodomain protein that account for an inherited form of abnormal skeletal patterning.

MESENCHYMAL CONDENSATION AND SKELETAL PATTERNING

Mesenchymal Condensation

Mesenchymal condensations originate in areas where cartilage is to appear and where bone is to form by intramembranous ossification. These condensations define not only the position of the skeletal elements they represent but also their basic shape. Therefore, if a condensation were in the wrong place or of the wrong shape and size, it would be expected to produce a skeletal element that is similarly misplaced or misshapen.

Condensations can be easily visualized *in vivo* as they express cell surface molecules that bind peanut agglutinin lectin (Stringa and Tuan, 1996). Their formation takes place when previously dispersed mesenchymal cells form aggregations and, once again, it is *Shh*, *Bmp* (*Bmp2*-5, Bmp7), *Fgf*, and *Hox* genes that determine the fundamental attributes such as the timing, position, and shape that they will assume. Mesenchymal condensation can be envisioned as a multistep process involving initiation, setting of boundary, proliferation, adherence, growth, and finally, differentiation (for review, see Hall and Miyake, 2000) (Fig. 4A). Initiation arises as a result of epithelial–mesenchymal interaction upregulating the expression of a number of molecules associated with prechondrogenic and preosteogenic condensations, such as tenascin, fibronectin, N-CAM, and N-cadherin. Transforming growth factor-beta (TGFβ), and other members of the TGFβ superfamily that regulate many aspects of growth and differentiation, plays a pivotal

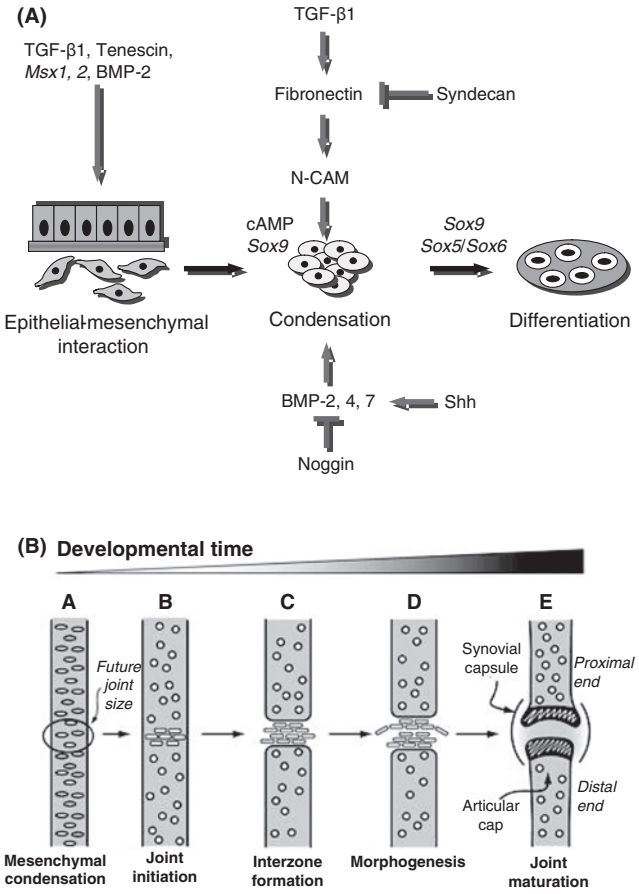

FIGURE 4 Regulation of mesenchymal condensation and joint formation. (**A**) Diagrammatic representation of the network of signaling factors involved in the formation of mesenchymal condensations and their subsequent transition to overtly differentiated cartilage. Adapted and modified from Hall and Miyake (2000), Fig. 3, p. 140). (**B**) Schematic representation of the major steps of synovial joint formation. Adapted from Pacifici *et al.* (2006), Fig. 1, p. 76). See text for details.

role in this process (reviewed in Moses and Serra, 1996). This family of signaling molecules, which includes several TGFβ isoforms, the activin and inhibins, growth and differentiation factors (GDFs), and the BMPs, potentiate condensation by promoting the establishment of cell–cell and cell–extracellular matrix interactions (Chimal-Monroy and Diaz de Leon, 1999; Hall and Miyake, 1995). Cell surface adhesion and extracellular matrix proteins contribute to the formation of condensations as they participate in cell attachment, growth, differentiation, and survival. The integrin family of cell surface receptors serves to mediate cell–matrix interactions thereby providing the link between the extracellular matrix and intracellular signaling that can affect gene expression. Integrins that act as receptors for fibronectin (α5β1), types II and VI collagen (α1β1, α2β1, α10β1), laminin (α6β1), and fitronectin and osteopontin (α5β3) are expressed early in the condensation process (Loeser, 2000). Further work is required, however,

to precisely define the role of these molecules in the developmental program of the process.

Mesenchymal cells within the condensations can differentiate either into chondrocytes or osteoblasts. Whereas the former takes place in areas of endochondral ossification, the latter takes place in areas of intramembranous ossification. The choice in cell fate is regulated by the canonical Wnt signaling which is itself induced in part by sonic hedgehog (Hu *et al.*, 2005). In the absence of Wnt signaling, the mesenchymal cells differentiate into chondrocytes. Levels of intracellular cAMP increase during prechondrogenic condensation and, along with the concomitant cell–cell interactions, are thought to mediate upregulation of chondrogenic genes. The transcription factor Sox9 [SRY (sex-determining region Y)-related HMG box gene 9] is a potent inducer of genes required for cartilage formation, such as collagen II (*Col2a1*) and aggrecan (*Agc*), and its phosphorylation by protein kinase A (PKA) increases its DNA binding and transcriptional activity (Huang *et al.*, 2000). Sox9 expression starts in mesenchymal chondroprogenitor cells and reaches a high level of expression in differentiated chondrocytes. Cells deficient in Sox9 are excluded from all cartilage but are present as a juxtaposed mesenchyme that does not express the chondrocyte-specific markers (Bi *et al.*, 1999). This exclusion occurs at the condensing mesenchyme stage of chondrogenesis, suggesting that Sox9 controls expression of cell surface proteins needed for mesenchymal condensation, thereby identifying Sox9 as the first transcription factor that is essential for chondrocyte differentiation and cartilage formation.

Sox5 and Sox6, which have a high degree of sequence identity with each other, belong to a different subgroup of Sox proteins and present no sequence homology with Sox9 except for the HMG box. Sox5 and Sox6 are coexpressed with Sox9 during chondrogenic differentiation. Physiological roles of Sox5 and Sox6 in chondrogenic differentiation were demonstrated by genetically manipulated mice. Whereas *Sox5* and *Sox6* single null mice are born with mild skeletal abnormalities, *Sox5*/*Sox6* double null fetuses die *in utero* with virtual absence of cartilage (Smits *et al.*, 2001). In these double mutants, mesenchymal condensations are formed, but there is no overt chondrocyte differentiation. Although levels of *Sox9* mRNA are comparable to those in wild-type cartilage, inactivation of the *Sox9* gene before chondrogenic mesenchymal condensations results in loss of *Sox5* and *Sox6* expression and severe generalized chondrodysplasia similar to that seen in $Sox5^{-/-}/Sox6^{-/-}$ mice. These data demonstrate important and redundant roles of Sox5 and Sox6 that lie downstream of Sox9 in chondrogenic differentiation after mesenchymal condensations (reviewed in Ikeda *et al.*, 2005). Once condensed mesenchymal cells differentiate into chondroblasts they begin to produce a matrix rich in collagen II, the molecule that best defines the chondroblast/chondrocyte phenotype, as well as collagens IX and XI and mucopolysaccharides.

Mesenchymal prechondrogenic condensations appearing in the early limb bud show no indication of future sites for synovial joint formation and are thus uninterrupted (reviewed in Pacifici *et al.*, 2006). Unknown upstream mechanisms possibly involving *Hox* genes determine the exact location for joint initiation (see Fig. 3.4B). The first overt morphological sign of joint formation is a further gathering and condensation of cells that are connected by gap junctions known as the interzone. It is readily recognizable as a thicker and quite compact structure oriented perpendicularly to the long axis of the long bone model and is composed of mesenchymal cells that never express matrilin-1 (Hyde *et al.*, 2007). Rather, these cells in the interzone express *Gdf5* and give rise to articular cartilage, synovial lining and other joint tissues, but contribute little if any to underlying growth plate cartilage and shaft (Koyama *et al.*, 2008). A number of genes, including *Noggin*, *Wnt14*, *Hif1a*, *Gdf5*, *Gdf6*, *Gli3*, and *Crux1*, have been implicated in a variety of cellular and developmental processes during joint formation and when mutated or misexpressed, can cause pathologies (Brunet *et al.*, 1998; Hartmann and Tabin, 2001; Hopyan *et al.*, 2005; Lizarraga *et al.*, 2002; Provot *et al.*, 2007; Settle *et al.*, 2003; Storm and Kingsley, 1996, 1999).

The Skeletal Dysplasias

A variety of human skeletal disorders arise as a consequence of gain-of-function and loss-of-function mutations in signaling pathways involved in mesenchymal condensation. GDF5 belongs to the TGFβ superfamily and is predominantly expressed throughout mesenchymal condensations in the developing skeleton. Mutations in *GDF5* are the cause of acromesomelic chondrodysplasia, Hunter–Thompson type (Thomas *et al.*, 1996), an autosomal recessive disorder characterized by short forearms, hands, and feet, and very short metacarpals, metatarsals, and phalanges. Mutations in *GDF5* have also been reported in patients with Grebe-type chondrodysplasia, an autosomal recessive disorder characterized by severe limb shortening and dysmorphogenesis with a proximal–distal gradient of severity (Thomas *et al.*, 1997). It is proposed that the mutant GDF5 protein is not secreted and is inactive *in vitro*. It produces a dominant negative effect by preventing the secretion of other, related BMPs, likely through the formation of heterodimers.

Defects in *SOX9* are the cause of campomelic dysplasia, a rare, dominantly inherited chondrodysplasia, characterized by craniofacial defects, bowing and angulation of long bones, hypoplastic scapulae, platyspondyly, kyphoscoliosis, eleven pairs of ribs, small thorax, and tracheobronchial hypoplasia (Foster *et al.*, 1994). It is often lethal, soon after birth, owing to respiratory distress attributed to the hypoplasia of the tracheobronchial cartilage and restrictive thoracic cage.

INTRAMEMBRANOUS BONE FORMATION

Overview

Intramembranous bone formation is achieved by direct transformation of mesenchymal cells into osteoblasts, the skeletal cells involved in bone formation. It is the process responsible for the development of the flat bones of the cranial vault, including the cranial suture lines, some facial bones, and parts of the mandible and clavicle. Although the addition of bone within the periosteum on the outer surface of long bones is also described as arising from intramembranous bone formation, current studies suggest that, in fact, it may be developmentally distinct (see "Endochondrial Ossification: Overview"). With respect to the molecular mechanisms leading to osteoblast differentiation, it can be said that they are rather sketchy. Like cartilage, bone cells are induced initially by specific epithelia (Hall and Miyake, 2000). Here, the cranial sutures will be discussed as intramembranous bone growth sites and this will be followed by a brief description of transcription factors, growth factors, and their receptors associated with normal and abnormal suture development. Intramembranous ossification in the periosteum will be described later on, in conjunction with endochondral bone formation.

Cessation of condensation growth in areas of membranous ossification leads to differentiation characterized by expression of the runt-related transcription factor 2, Runx2 (also known as Cbfa1 for core-binding factor, alpha subunit 1, or Osf2 for osteoblast-specific *cis*-acting element-2) in osteogenic cells, whereas it is downregulated in chondrogenic lineages (Ducy and Karsenty, 1998). Runx2 expression depends on Wnt signaling which results in high levels of β-catenin in mesenchymal cells. In turn, Runx2 induces the expression of another transcription factor called Osterix (Osx) (Nakashima *et al.*, 2002). These two factors are critical for differentiation of mesenchymal cells to osteoblasts. Ontogenetic cells begin to produce, most notably, collagen I in conjunction with a variety of noncollagenous, extracellular matrix proteins that are deposited along with an inorganic mineral phase. The mineral is in the form of hydroxyapatite, a crystalline lattice composed primarily of calcium and phosphate ions.

The Cranial Sutures

Cranial vault sutures identify the fibrous tissues uniting bones of the skull and are the major site of bone growth, especially during the rapid growth of the neurocranium. Sutures need to maintain patency while allowing rapid bone formation at the edges of the bone fronts in order to accommodate the rapid, expansile growth of the neurocranium (for review, see Morriss-Kay and Wilkie, 2005; Opperman, 2000). The closure of sutures is tightly regulated by growth factors and transcription factors (BMPs, FGFs and FGFR1-3, *EFNB1*, TWIST1, and MSXs) involved in epitheliomesenchymal signaling between the sutural mesenchyme, the underlying dura, and the approaching bone fronts. It is proposed that the approximating bone fronts set up gradients of growth factor signaling between them, which initiate suture formation. For example, a gradient of FGF ligand, from high levels in the differentiated region to low levels in the environment of the osteogenic stem cells, modulates differential expression of *FGFR1* and *FGFR2*. Signaling through FGFR2 regulates stem cell proliferation whereas signaling through FGFR1 promotes osteogenic differentiation (Iseki *et al.*, 1999). As sutures fuse, factors involved in pattern formation (*SHH*, *MSX1*) are all downregulated whereas at the same time *RUNX2* and collagen I (*COL1A1*) expression is seen at the bone fronts. In the end, the completely fused suture is indistinguishable from bone.

Recent research has advanced significantly our understanding of the molecular nature of interactions between FGF receptors, TWIST1, RUNX2 and downstream osteogenic differentiation genes in normal and abnormal skull growth (for review, see Opperman, 2000). Future work will undoubtedly provide additional insights into how these factors interact with MSX2 and other genes, thereby providing a more complete picture of the network of gene and protein interactions that control development and growth of the skull vault in health and disease.

The Craniofacial Disorders

As can be inferred from the preceding discussion, the composite structure of the mammalian skull requires precise pre- and postnatal growth regulation of individual calvarial elements. Disturbances of this process frequently cause severe clinical manifestations in humans. The homeobox genes *MSX1* and *MSX2* are of particular interest in that mutated forms are associated with human craniofacial disorders (for reviews, see Cohen, 2000, 2006). An autosomal dominant form of hypodontia is caused by a mutation in *MSX1* (Vastardis *et al.*, 1996) whereas heterozygous mutations in *MSX2* cause parietal foramina (oval-shaped defects on either side of the sagittal suture arising from deficient ossification around the parietal notch, normally obliterated during the fifth fetal month) (Wilkie *et al.*, 2000). These mutations, which lead to decreased parietal ossification by haploinsufficiency, are in marked contrast to the reported gain-of-function mutation (Pro148His) in *MSX2* associated with premature osseous obliteration of the cranial sutures or craniosynostosis Boston-type (Jabs *et al.*, 1993). It is likely that *MSX2* normally prevents differentiation and stimulates proliferation of preosteoblasic cells at the extreme ends of the osteogenic fronts of the calvariae, facilitating expansion of the skull and closure of the suture. Its haploinsufficiency decreases proliferation and accelerates differentiation of calvarial preosteoblast cells

resulting in delayed suture closure whereas its "overexpression" results in enhanced proliferation, favoring early suture closure (Dodig *et al.*, 1999).

Osteogenic cell differentiation is influenced by the transcription factor, RUNX2. The function of RUNX2 during skeletal development has been elucidated by the generation of mice in which the *Runx2* locus was targeted (Otto *et al.*, 1997). Heterozygous loss of function leads to a phenotype very similar to human cleidocranial dysplasia, an autosomal dominant inherited disorder characterized by hypoplasia of the clavicles and patent fontanelles that arises from mutations in *RUNX2* (Mundlos *et al.*, 1997). Loss of both alleles leads to a complete absence of bone owing to a lack of osteoblast differentiation. *RUNX2*, therefore, controls differentiation of precursor cells into osteoblasts and is essential for membranous as well as endochondral bone.

Fibroblast growth factor receptors are major players in cranial skeletogenesis and, activating mutations of the human *FGFR1*, *FGFR2*, and *FGFR3* genes, cause craniosynostosis. Most mutations are found in *FGFR2*, although there are several in *FGFR3* and in *FGFR1*. A C→G transversion in exon 5 of *FGFR1*, resulting in proline to arginine substitution (P252R) in the extracellular domain of the receptor has been reported in affected members of five unrelated families with Pfeiffer syndrome, an autosomal dominant disorder, characterized by mild craniosynostosis, flat facies, shallow orbits, hypertelorism, acrocephaly, broad thumb, broad great toe, polysyndactyly and interphalangeal ankylosis (Muenke *et al.*, 1994).

Mutations in *FGFR2* (C342Y, C342R, C342S, and a C342W) have been described in patients with Crouzon syndrome (Reardon *et al.*, 1994; Steinberger *et al.*, 1995). This disorder, encompassing craniosynostosis, hypertelorism, hypoplastic maxilla, and mandibular prognathism, is easily distinguishable from Pfeiffer syndrome by the absence of hand abnormalities. Interestingly, the C342Y mutation is also reported in patients with Pfeiffer syndrome and in individuals with Jackson–Weiss syndrome (Tartaglia *et al.*, 1997), an autosomal dominant disorder characterized by midfacial hypoplasia, craniosynostosis, and cutaneous syndactyly, indicating that the same mutation can give rise to one of several phenotypes. Another conserved cysteine at position 278 is similarly predisposed to missense mutations leading to the same craniosynostotic conditions. On the other hand, mutations in S252 and P253 residues have been reported in most cases of Apert syndrome, a condition characterized by craniosynostosis and severe syndactyly (cutaneous and bony fusion of the digits). Although the mechanism whereby the same mutation can give rise to distinct phenotypes remains to be clarified, sequence polymorphisms in other parts of the mutant gene may affect its phenotypic expression (Rutland *et al.*, 1995). Finally, mutations within *FGFR2* have also been reported in other rare craniosynostotic conditions (for reviews, see Cohen 2006; Passos-Bueno *et al.*, 1999).

In contrast to the propensity of mutations in FGFR1 and FGFR2 affecting craniofacial development, only rarely do mutations in FGFR3 cause craniosynostoses (Muenke syndrome). For the most part, mutations in FGFR3 are associated with dwarfism, suggesting that the primary function of FGFR3 is in endochondral rather than intramembranous ossification. The vast majority of FGFR mutations identified to date are dominantly inherited and result in increased signaling by the mutant receptor (Naski and Ornitz, 1998). Altered cellular proliferation and/or differentiation are believed to underlie their pathogenetic effects.

As already discussed, other gene mutations for craniosynostosis are also known (outlined fully in Cohen, 2006, and references therein). *TWIST* mutations have been reported in Saethre–Chotzen syndrome. Most mutations truncate the *TWIST* protein, resulting in haploinsufficiency. Craniofrontonasal syndrome is caused by heterozygous loss-of-function mutations in *EFNB1* whereas *EFNA4* mutations are the cause of nonsyndromal coronal synostosis.

ENDOCHONDRAL OSSIFICATION

Overview

The axial and appendicular skeletons develop from cartilaginous model, the growth of which arises in a variety of ways (Johnson, 1986). Cartilage is unique among skeletal tissues in that it has the capacity to grow interstitially, i.e., by division of its chondrocytes. This property is what allows cartilage to grow very rapidly. Moreover, cartilage utilizes apposition of cells on its surface, matrix deposition, and enlargement of the cartilage cells as additional means of achieving maximal growth. Appositional growth is the principal function of the perichondrium, which envelops the epiphyses and the cartilaginous diaphysis, serving as the primary source of chondroblasts. With time, these cells differentiate to chondrocytes that secrete collagen II, aggrecan, and a variety of other matrix molecules that constitute the extracellular matrix of the hyaline cartilage (Fig. 5A). As development proceeds, a predetermined program of chondrocyte differentiation ensues in the central diaphysis, leading to chondrocyte hypertrophy. The hypertrophic chondrocytes express collagen X and direct the mineralization of the surrounding matrix, while signaling to adjacent perichondrial cells to direct their differentiation into osteoblasts, and also to stimulate the invasion of blood vessels. Capillaries invade the perichondrium surrounding the future diaphysis and transform it into the periosteum, whereas osteoblastic cells differentiate, mature, and secrete collagen I and other bone-specific molecules, including alkaline phosphatase. This will ultimately mineralize by intramembranous ossification and give rise to the bony collar, the cortical bone.

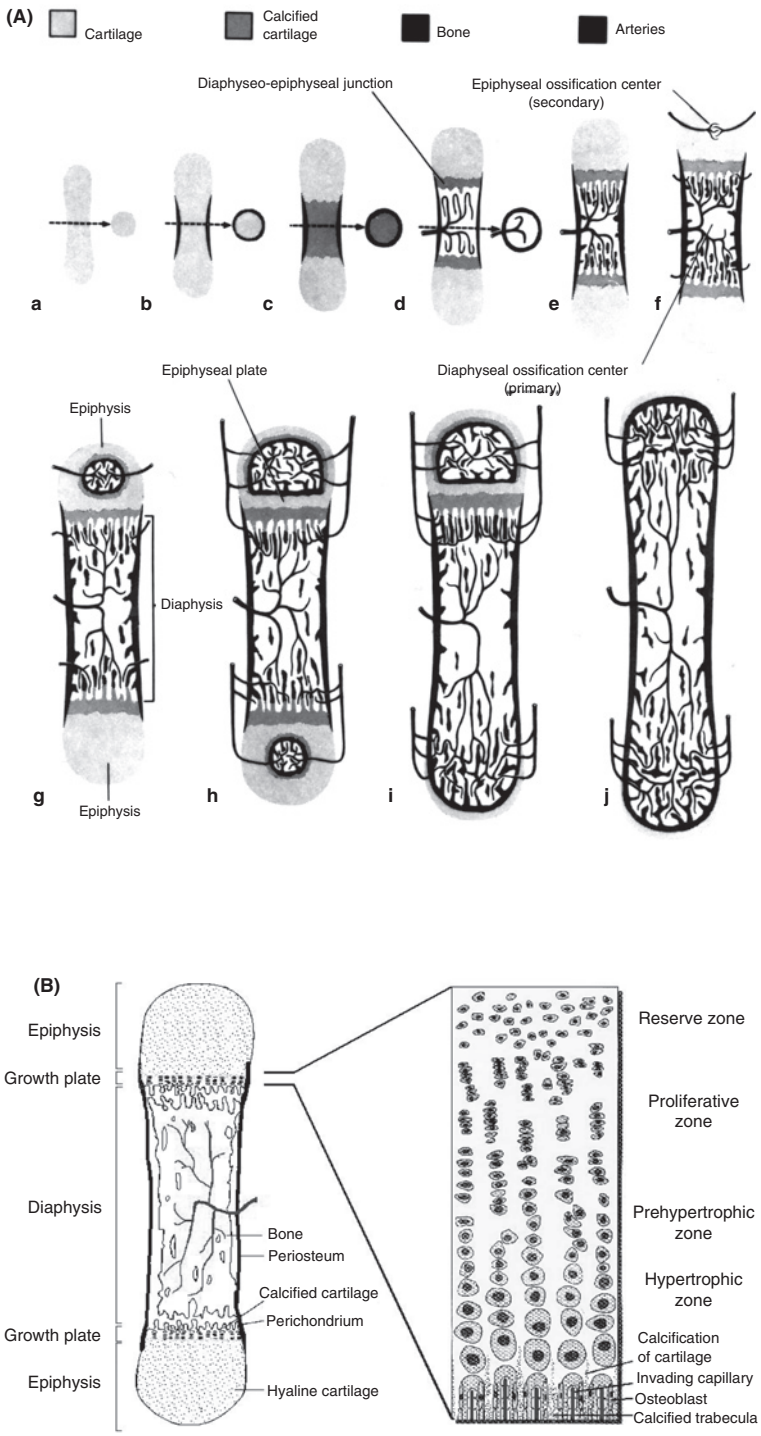

FIGURE 5 Formation and growth of long bones by endochondral ossification. (**A**) Mesenchymal condensation leads to the development of a cartilage model (a). Capillaries invade the perichondrium surrounding the future diaphysis and transform it into the periosteum (b). Chondrocyte differentiation ensues, just underneath the bone collar, leading to chondrocyte hypertrophy and apoptotic death associated with mineralization of the cartilage matrix (c). Vascular invasion from vessels allows for the migration of osteoblast precursor cells that deposit bone on the degraded matrix scaffold. Chondrogenesis at the ends of the long bone establishes the formation of growth plates (d, e). Secondary centers of ossification begin in late fetal life (f). Growth plates serve as a continuous source of cartilage conversion to bone thereby promoting linear growth (g, h). Long bones cease growing at the end of puberty, when the growth plates are replaced by bone but articular cartilage persists (i, j). Adapted from Recker (1992), Fig. 6, p. 223. (**B**) The mammalian growth plate. Schematic representation of the organization of the mammalian growth plate. Adapted from Wallis (1996), Fig. 1, p. 1578. See text for details.

Matrix mineralization, in turn, is followed by vascular invasion from vessels originating in the periosteal collar that allows for the migration of osteoblast precursor cells into the cartilaginous model (primary ossification center). These cells transform into mature osteoblasts and initiate new bone formation on the degraded matrix scaffolding. Osteoclasts, cells derived from the hematopoietic lineage, also enter the cartilage mold and digest the matrix that had been synthesized by the hypertrophic chondrocytes. The primary growth plates are then established and serve as a continual source of cartilage conversion to bone and linear growth of the long bone during development and postnatally. In late fetal life and early childhood, secondary centers of ossification appear within the cartilaginous epiphyses by a mechanism very similar to that used in the formation of the primary center. Cartilage is retained at the growth plate, extending the full width of the bone and separating epiphysis from diaphysis. Cessation of growth occurs at the end of puberty, when growth plates are replaced by bone.

The Growth Plate

The organization of the mammalian epiphyseal growth plate is represented diagrammatically in Fig. 3.5B. The growth plate conforms to a general basic plan that consists of four zones that, although distinct, encompass a merging continuum (for reviews, see Johnson, 1986; Stevens and Williams, 1999). In the reserve zone, chondrocytes are nearly spherical in cross section and appear to be randomly arranged, separated by large amounts of matrix consisting largely of collagen II and proteoglycans. Although parts of this zone are mitotically inert, others function as stem cell sources. The cells from this zone eventually become discoid and are arranged into rather regular columns forming the zone of proliferation. Column formation is in part owing to the characteristic division of chondrocytes in that their mitotic axis is perpendicular to the long axis of the bone. Two daughter cells become flattened and are separated by a thin septum of cartilage matrix. Elongation of the anlagen occurs mainly at its ends and arises primarily from the division of chondrocytes because it is here that cell proliferation is maximal. Eventually, the chondrocytes from this zone enlarge and lose their characteristic discoidal shape as they enter the zone of maturation (prehypertrophic chondrocytes). Growth here ceases to be caused by cell division and continues by increases in the size of the cells. In the midsection, the chondrocytes mature, enlarge in size (hypertrophy), and secrete a matrix rich in collagen X. These cells continue to enlarge to the point that their vertical height has increased nearly five times. Once glycogen stores have been depleted, they undergo programmed cell death or apoptosis (Farnum and Wilsman, 1987), leaving behind longitudinal lacunae separated by septae of cartilaginous matrix that become selectively calcified as well as largely uncalcified transverse septae. In response to these changes, vascular invasion ensues as new blood vessels enter the lower hypertrophic zone from the primary spongiosum and penetrate the transverse septae whereas calcified cartilage is removed by chondroclasts that accompany this erosive angiogenic process. The remaining longitudinal septae that now extend into the diaphysis are used by osteoblasts derived from bone marrow stromal cells to settle on and lay down extracellular matrix (osteoid) that calcifies into woven bone. With time, osteoclasts, cells derived from the hematopoietic lineage, resorb the woven bone and osteoblasts replace it with mature trabecular bone, thereby completing the process of endochondral ossification.

Mediators of Growth Plate Chondrocyte Proliferation and Differentiation

Proper skeletal formation, growth, and repair are critically dependent on the accurate orchestration of all the processes participating in the formation of endochondral bone at the growth plate. It is only recently, however, that fundamental insight has emerged into the molecular pathways regulating these processes. The major systemic and local influences on growth plate chondrocyte proliferation and differentiation and associated developmental abnormalities arising from their failure to function in the appropriate fashion will now be discussed. In specific situations, the distinction between systemic as opposed to local mediators may not be so apparent, and this will be pointed out.

Systemic Mediators

A variety of systemic hormones such as the growth hormone-insulin-like growth factor 1 (GH-IGF1) signaling system, thyroid hormone, estrogens, glucocorticoids, and vitamin D partake in the regulation of linear growth pre- and postnatally. The importance of these hormones in linear skeletal growth has been highlighted by both genetic studies in animals and by "experiments of nature" in humans.

Growth hormone and insulin-like growth factor 1

GH plays an important role in longitudinal bone growth. Children with elevated GH levels owing to pituitary adenomas exhibit gigantism. Alternatively, bone growth is impaired both in GH-deficient humans (Laron *et al.*, 1966; Rosenfeld *et al.*, 1994) and in the GH receptor-null mouse (Sjogren *et al.*, 2000; Zhou *et al.*, 1997). Homozygous-null mice display severe postnatal growth retardation, disproportionate dwarfism, and markedly decreased bone mineral content. Reduced bone length in GH receptor-negative mice is associated with premature growth-plate contraction and reduced chondrocyte proliferation that is not detectable until 3 weeks of age; before this, bone growth proceeded normally, indicating that GH is not required for normal murine prenatal development or early postnatal growth.

Although cortical and longitudinal bone growth and bone turnover are all reduced in GH receptor deficiency, many of these effects can be reversed by IGF1 treatment (Sims *et al.*, 2000), suggesting that the main defect relates to reduced IGF1 levels in the absence of GH receptor.

In the original "somatomedin hypothesis," it was proposed that GH's primary effect was to promote IGF1 production by the liver, with circulating IGF1 then stimulating the longitudinal expansion of growth plates in an endocrine fashion. Because longitudinal bone growth is not affected in the liver-specific *Igf1*-knockout mouse (Yakar *et al.*, 1999), locally produced IGF1 and/or direct effects of GH may substitute for deficient systemic IGF1. More recent work suggests that GH acts directly at the growth plate to amplify the production of chondrocytes from germinal zone precursors and then to induce local IGF1 synthesis (Nilsson *et al.*, 2005), proposed to stimulate the clonal expansion of chondrocyte columns in an autocrine/paracrine manner (Ohlsson *et al.*, 1998). Although the actions of GH on a range of cell types is mediated by Stat5 signaling, interestingly, the bone phenotypes in GH receptor- and *Stat5*-knockout animals (Teglund *et al.*, 1998) are different, suggesting that the effects of GH on bone, whether direct or through IGF1, are not mediated by the Stat5 transcription factors but by other cytokine or signaling cascades.

Recent data suggest that IGF-I protein in the growth plate is not produced primarily by the chondrocytes themselves. Instead, it derives from surrounding perichondrium and bone (Parker *et al.*, 2007). IGF1 plays a pivotal role in longitudinal bone growth, because *Igf1* gene deletion results in dwarfism in mice (Liu *et al.*, 1993; Powell-Braxton *et al.*, 1993) and extreme short stature in humans (Woods *et al.*, 1996). A study of longitudinal bone growth in the *Igf1*-null mouse indicates that growth plate chondrocyte proliferation and cell numbers are preserved despite a 35% reduction in the rate of long bone growth (Wang *et al.*, 1999). The growth defect owing to *Igf1* deletion has been traced to an attenuation of chondrocyte hypertrophy, which is associated with Glut4 glucose transporter expression, glycogen synthesis (GSK3β serine phosphorylation), and ribosomal RNA levels being significantly diminished in *Igf1*-null hypertrophic chondrocytes, resulting in reduced glycogen in these cells. Glycogen stores are normally accumulated by proliferative and early hypertrophic chondrocytes and depleted during maturation of the hypertrophic chondrocytes. Hypertrophic chondrocytes are highly active metabolically and are dependent on glycolysis to fuel their expansive biosynthetic activity. The decrease in ribosomal RNA in *Igf1*-null hypertrophic chondrocytes may reflect cellular "starvation" for fuel and building blocks for protein synthesis.

Thyroid hormones

Thyroid hormone deprivation has deleterious effects on bone growth (reviewed in Shao *et al.*, 2006). The observed delay in bone development is mediated by a direct effect of thyroid hormone on cartilage and an indirect effect of the hormone on GH and IGF1 action (O'Shea *et al.*, 2005; Weiss and Refetoff, 1996). Thyrotoxicosis, on the other hand, accelerates growth rate and advances bone age. In euthyroid human (Williams *et al.*, 1998) and rat cartilage (Stevens *et al.*, 2000), thyroid hormone receptor alpha1 (TRα1), TRα2, and TRβ1 proteins are localized to reserve zone progenitor cells and proliferating chondrocytes. When animals are rendered hypothyroid, growth plates become grossly disorganized, and hypertrophic chondrocyte differentiation fails to progress (Fraichard *et al.*, 1997; Stevens *et al.*, 2000). In thyrotoxic growth plates, histology is essentially normal but mRNA for parathyroid hormone-related protein (Pthrp) and its receptor is undetectable (Stevens *et al.*, 2000). PTHrP signaling exerts potent inhibitory effects on hypertrophic chondrocyte differentiation (see later) suggesting that dysregulation of local mediators of endochondral ossification may be a key mechanism that underlies growth disorders in childhood thyroid disease. Although thyroid hormone may also act directly on osteoblasts (Abu *et al.*, 2000), these effects have received much less attention.

Estrogens

The biosynthesis of estrogens from testosterone in the ovary, adipose tissue, skeletal muscle, skin, hair follicles, and bone is catalyzed by the enzyme aromatase, the product of the *CYP19* gene. In recent years a number of patients, two men and five women, have been described as suffering from aromatase deficiency owing to mutations in *CYP19*, resulting in the synthesis of a nonfunctional gene product and failure to synthesize estrogens (reviewed in Faustini-Fustini *et al.*, 1999). Males with this condition have sustained linear growth into adulthood as a consequence of failed epiphyseal closure. Reduced bone mineral density and bone age are also characteristic. The women show absence of a growth spurt and delayed bone age at puberty as well as unfused epiphyses later on, despite evidence of virilization.

Although not all effects of 17β-estradiol are due to direct control of gene expression (Pedram *et al.*, 2006), most its biological actions are mediated by two estrogen receptors (ER), ERα and ERβ, which regulate transcription through direct interaction with specific binding sites on DNA in promoter regions of target genes (for review, see Pettersson and Gustafsson, 2001). Smith and associates (1994) have described a man with a bi-allelic inactivating mutation of the ERα gene. This patient had normal genitalia but suffered from osteoporosis and was still growing at the age of 28 because the epiphyseal plates were unfused.

These two "experiments of nature" (aromatase and ERα deficiency), supported by the recent identification of ERα and ERβ expression in chondrocytes (Ushiyama *et al.*, 1999) and osteogenic cells of trabecular and cortical bone (Rickard *et al.*, 1999), have firmly established that estrogens

exert direct effects on the growth plate and are crucial for peripubertal growth and epiphyseal growth plate fusion at the end of puberty in both women and men. Moreover, they have revealed a greater appreciation for the importance of estrogens in bone mass maintenance in both sexes.

Glucocorticoids

Glucocorticoids have well-documented effects on the skeleton, as pharmocological doses cause stunted growth in children (Canalis, 1996). The skeletal actions of glucocorticoids are mediated via specific receptors, which are widely distributed at sites of endochondral bone formation. Studies now indicate that glucocorticoids are involved in chondrocyte proliferation, maturation, and differentiation earlier in life, whereas at puberty they are implicated primarily in chondrocyte differentiation and hypertrophy (reviewed in Nilsson *et al.*, 2005). Further investigation is required, however, to clarify the physiological actions of glucocorticoids on cartilage.

Glucocorticoid receptors are also highly expressed in rodent and human osteoblastic cells both on the bone-forming surface and at modeling sites (Abu *et al.*, 2000). Pharmacological doses of glucocorticoids in mice inhibit osteoblastogenesis and promote apoptosis in osteoblasts and osteocytes, thereby providing a mechanistic explanation for the profound osteoporotic changes arising from their chronic administration (Weinstein *et al.*, 1998).

Vitamin D

Vitamin D deficiency is the major cause of rickets in children and osteomalacia in adults. Inactivating mutations in the coding sequences of 25-hydroxyvitamin D_3 1α-hydroxylase (*CYP27B1*) (Fu *et al.*, 1997) and VDR genes are associated with rickets characterized by expansion of the hypertrophic zone of the growth plate coupled with impaired extracellular matrix calcification and angiogenesis (Donohue and Demay, 2002). However, a mineral-enriched diet can normalize the growth plates of vitamin D-resistant animals (Amling *et al.*, 1999) suggesting that the skeletal consequences of VDR ablation are a result of impaired intestinal mineral absorption. A direct role of vitamin D on bone is also suggested because VDR is expressed in osteoblasts and osteoclast precursors (Johnson *et al.*, 1996; Mee *et al.*, 1996).

The 25-hydroxyvitamin D-24-hydroxylase enzyme (24-OHase; *CYP24*) is responsible for the catabolic breakdown of 1,25$(OH)_2$ vitamin D_3. The enzyme can also act on the 25-(OH)vitamin D_3 substrate to generate 24,25-$(OH)_2$ vitaminD_3, a metabolite whose physiological importance remains unclear. Although earlier studies in *Cyp24*-knockout mice had suggested that the 24-hydroxylated metabolite of vitamin D, 24R,25$(OH)_2$ vitamin D_3 exerts distinct effects on intramembranous bone mineralization (St-Arnaud, 1999), more recent work has concluded that this metabolite is dispensable during bone development (St-Arnaud *et al.*, 2000).

Local Mediators

TGFβ

TGFβ1, *-2*, and *-3* mRNAs are synthesized in the mouse perichondrium and periosteum from 13.5 days post coitus until after birth (Millan *et al.*, 1991). As already discussed, TGFβ promotes chondrogenesis in early undifferentiated mesenchyme (Leonard *et al.*, 1991), but in high-density chondrocyte pellet cultures or organ cultures it inhibits terminal chondrocyte differentiation (Ballock *et al.*, 1993) and this effect appears to be partly mediated by induction of PTHrP expression (see later) (Serra *et al.*, 1999). TGFβs signal through heteromeric type I and type II receptor serine/threonine kinases. To delineate the role of TGFβs in the development and maintenance of the skeleton *in vivo*, Serra *et al.* (1997) generated transgenic mice that express a cytoplasmically truncated, functionally inactive TGF-type II receptor under the control of a metallothionein-like promoter, which can compete with the endogenous receptors for complex formation, thereby acting as a dominant-negative mutant. Loss of responsiveness to TGFβ promoted chondrocyte hypertrophy, suggesting an *in vivo* role for TGFβ in limiting terminal differentiation. In mouse embryonic metatarsal bone rudiments grown in organ culture, TGFβ inhibits several stages of endochondral bone formation, including chondrocyte proliferation, hypertrophic differentiation, and matrix mineralization (Serra *et al.*, 1999). Moreover, activation of Ihh signaling pathway fails to induce PTHrP or inhibit chondrocyte hypertrophy in embryonic metatarsal organ cultures from *TGFβ2*-null mice, indicating that TGFβ2 is at least one of the mediators of these responses to Ihh (see later) (Alvarez *et al.*, 2002).

Parathyroid hormone-related protein (PTHrP) and Indian hedgehog (Ihh)

PTHrP is a major determinant of chondrocyte biology and endochondral bone formation. It was discovered as the mediator of hypercalcemia associated with malignancy but is now known to be expressed by a large number of normal fetal and adult tissues (Philbrick *et al.*, 1996; Wysolmerski and Stewart, 1998). The amino-terminal region of PTHrP reveals limited but significant homology with parathyroid hormone (PTH), resulting in the interaction of the first 34 to 36 residues of either protein with a single seven-transmembrane spanning G protein-linked receptor termed the PTH/PTHrP receptor or the PTH receptor type 1 (PTHR1). Both PTH and PTHrP, through their interaction with this receptor, activate cAMP and calcium second messenger signaling pathways by stimulating adenylate cyclase and/or phospholipase C activity, respectively (Abou-Samra *et al.*, 1992; Juppner *et al.*, 1991). Targeted inactivation of *Pthrp* and *Pthr1* has established a

fundamental role for this signaling pathway in chondrocyte proliferation, differentiation, and apoptotic death (Amizuka *et al.*, 1994, 1996; Karaplis *et al.*, 1994; Lanske *et al.*, 1996; Lee *et al.*, 1996). Mice homozygous for the *Pthrp*- or *Pthr1*-null alleles display a chondrodysplastic phenotype characterized by reduced chondrocyte proliferation, and premature and inappropriate hypertrophic differentiation resulting in advanced endochondral ossification. Conversely, targeted expression of PTHrP (Weir *et al.*, 1996) or a constitutively active form of PTHR1 (Schipani *et al.*, 1997) to the growth plate leads to delayed mineralization, decelerated conversion of proliferative chondrocytes into hypertrophic cells, and prolonged presence of hypertrophic chondrocytes with delay of vascular invasion. Moreover, in chimeric mice with some chondrocytes missing the PTHR1, the mutant chondrocytes become hypertrophic much sooner than their wild-type counterparts.

Correlation of these findings to human chondrodysplasias arose initially from studies in patients with Jansen-type metaphyseal dysplasia. This autosomal dominant disorder is characterized by short stature, abnormal growth plate maturation, and laboratory findings indistinguishable from primary hyperparathyroidism despite low normal or undetectable levels of PTH and PTHrP. Schipani and associates (1995, 1996, 1999) reported heterozygous missense mutations in *PTHR1* that promote ligand-independent cAMP accumulation but with no detectable effect on basal inositol phosphate accumulation. These activating mutations have therefore provided an explanation for the observed biochemical abnormalities and the abnormal endochondral ossification characteristic of Jansen metaphyseal chondrodysplasia. In contrast to *PTHR1*-activating mutations in this disorder, Blomstrand chondrodysplasia arises from the absence of a functional PTHR1 (Jobert *et al.*, 1998; Karaplis *et al.*, 1998; Karperien *et al.*, 1999; Zhang *et al.*, 1998). This is a rare autosomal recessive chondrodysplasia characterized by skeletal abnormalities that bear a remarkable resemblance to the phenotypic alterations observed in the *Pthr1*-knockout mice. Mutations in *PTHR1* are also reported in patients with echondromatosis (Hopyan *et al.*, 2002) or with Eiken syndrome (Duchatelet *et al.*, 2005).

Binding of PTHrP to the PTHR1 stimulates multiple heterotrimeric G proteins, including G_s, G_q family, and $G_{12,13}$ (Singh *et al.*, 2005). Activation of each G protein triggers a series of downstream events that culminate in biological consequences whose physiological actions vary. Using genetic tools, the roles of activation of the G_s and G_q pathways by PTHrP in the fetal growth plate has been dissected. Signaling via G_q slows the proliferation and hastens the differentiation of chondrocytes, actions that oppose the effects of G_s signaling pathways which include delayed ossification and increased chondrocyte proliferation (Guo *et al.*, 2002). This seemingly counterproductive opposition may in fact help to smooth the functional gradient of PTHrP action across the growth plate (Kronenberg, 2006).

The pivotal role of PTHrP signaling in the growth plate has served as the impetus for subsequent studies aimed to identify and characterize upstream and downstream molecular components that regulate chondrocyte proliferation and differentiation.

Ihh is expressed in prehypertrophic chondrocytes of the mouse embryo. Earlier studies using overexpression and misexpression of Ihh in the developing cartilage demonstrated that Ihh delays the hypertrophic differentiation of growth plate chondrocytes (Vortkamp *et al.*, 1996). A number of *in vitro* as well as *in vivo* studies now indicate that the capacity of Ihh to slow chondrocyte differentiation is mediated by PTHrP. Ihh upregulates *Pthrp* expression in the growth plate. This expression, however, is abolished by targeted disruption of *Ihh* and leads to premature chondrocyte differentiation (St-Jacques *et al.*, 1999), thereby implicating PTHrP as the mediator of Ihh actions on chondrocyte hypertrophy. These observations, among others, have led to the proposal that an Ihh/PTHrP feedback loop regulates the pace of chondrocyte differentiation in the growth plate (Fig. 6) (Chung and Kronenberg, 2000; Kronenberg, 2006). PTHrP is synthesized by chondrocytes and perichondrial cells at the ends of the developing bones and acts on chondrocytes bearing PTHR1 to keep them proliferating and delaying their differentiation. Chondrocytes sufficiently far away from the source of PTHrP, however, stop proliferating and only then synthesize Ihh. Then, directly or indirectly, Ihh signals back

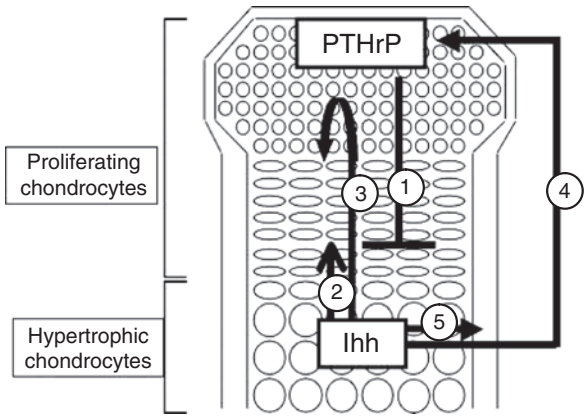

FIGURE 6 Ihh and PTHrP interaction in the growth plate. Ihh and PTHrP participate in a negative feedback loop to regulate the rate of chondrocyte proliferation and differentiation. PTHrP is expressed and secreted from perichondrial cells and chondrocytes at the ends of long bones and acts on proliferating chondrocytes to keep them proliferating and delay their differentiation into prehypertrophic and hypertrophic chondrocytes (1). When the source of PTHrP production is sufficiently distant, then chondrocytes stop proliferating and synthesize Ihh. In turn, Ihh increases the proliferation of adjacent chondrocytes (2), accelerates the differentiation of round proliferative chondrocytes into flat proliferating chondrocytes (3), stimulates the production of PTHrP at the ends of bones (4), and acts on perichondrial cells to convert them into osteoblasts of the bone collar (5). Adapted and modified from Kronenberg (2006, Fig. 2, p. 4).

to the end of the growth plate to stimulate the synthesis of more PTHrP. This feedback system thus determines the site at which chondrocytes stop proliferating and start making Ihh. In so doing, this negative feedback loop serves to regulate the rate of chondrocyte differentiation and hence the length of the zone of chondrocyte proliferation as well as to contribute to the striking uniformity of chondrocyte morphology across the growth plate. Ihh has a number of actions that are independent of PTHrP. Ihh stimulates the proliferation of adjacent chondrocytes, accelerates the differentiation of round proliferative chondrocytes into flat proliferating chondrocytes, and directs adjacent perichondrial cells to become osteoblasts (Long *et al.*, 2004; Long, 2001). PTHrP and Ihh together, therefore, determine both the entry and the exit of chondrocytes from the pool of flat proliferating chondrocytes. Further, by determining the site of Ihh production, PTHrP thus also determines the site at which perichondrial cells first become true osteoblasts in the bone collar adjacent to the growth plate.

What is the mechanism by which Ihh stimulates *Pthrp* expression? Although it is possible that Ihh interacts directly with *Pthrp*-expressing cells in the growth plate, it is more likely, given the number of restrictions imposed on Ihh diffusion (Chuang and McMahon, 1999), that the action is indirect. BMPs have been proposed to serve as secondary signals downstream of Ihh. For example, viral expression of a constitutively active form of the BMP receptor IA increased *Pthrp* mRNA expression in embryonic chicken limbs and blocked chondrocyte differentiation in a similar manner as misexpression of Ihh without inducing Ihh expression (Zou *et al.*, 1997). Further studies have indicated that BMP2 and BMP4 are the likely secondary signals, which act through the BMP receptor-IA to mediate the induction of Pthrp expression (Pathi *et al.*, 1999). It is of interest to note that TGFβ also stimulates *Pthrp* expression in mouse embryonic metatarsal bone rudiments grown in organ culture (Serra *et al.*, 1999). Furthermore, terminal differentiation is not inhibited by TGFβ in metatarsal rudiments from *Pthrp*-null embryos, supporting the model that TGFβ acts upstream of PTHrP to regulate the rate of hypertrophic differentiation. Whether, it is TGFβ or other members of the BMP family of proteins that serve as the intermediary relay that links the Ihh and PTHrP signaling pathways remains to be determined. Other studies, however, have failed to support a role for BMPs in this process (Haaijman *et al.*, 1999). Therefore, for now it would be prudent to conclude that the mechanism transmitting Ihh signaling to PTHrP-expressing chondrocytes remains, for the most part, uncertain. It is known, however, that when the gene encoding the transcription factor Gli3 is ablated along with *Ihh* in mice, then the double-null animals synthesize PTHrP in perichondrial cells but not in chondrocytes (Koziel *et al.*, 2005). The finding that ablation of Gli3 reverses some of the suppression of PTHrP synthesis in *Ihh*-null mice suggests that Ihh normally regulates perichondrial PTHrP expression, at least in part, by suppressing the expression of Gli3.

What are the downstream molecular mechanisms that convey PTHrP's inhibitory action on chondrocyte differentiation? Several transgenic studies have examined this question by assessing the significance of the cyclic AMP/PKA and phospholipase C/PKC signal transduction pathways on the cartilage differentiation program. In the first scenario, a PTHR1 with normal phospholipase C signaling, but deficient $G_s\alpha$ signaling was expressed in chimeric mice (Chung and Kronenberg, 2000). Cells with deficient $G_s\alpha$ signaling underwent premature maturation in the growth plate, whereas wild-type cells had a normal rate of differentiation. In the second scenario, mice expressing a mutant PTHR1 with normal $G_s\alpha$ signaling, but deficient phospholipase C signaling, exhibited abnormalities in embryonic endochondral bone development, including delayed ossification and increased chondrocyte proliferation (Guo *et al.*, 2002). These genetic experiments support the contention that PLC signaling via PTHR1 normally slows the proliferation and hastens the differentiation of chondrocytes, actions that oppose the dominant effects of PTHR1 and that involve cAMP-dependent signaling pathways. Thus, activation of G_s and G_q by activation of PTHR1 in chondrocytes leads to actions that oppose each other. The usefulness of this seemingly wasteful opposition of the two pathways is not certain. As in many other settings in which a stimulus activates opposing pathways, this complicated pattern may allow regulatory interactions with other pathways that are useful (Kronenberg, 2006).

Given that PKA-phosphorylated-SOX9 is present in the prehypertrophic zone of the growth plate, the same location where the gene for PTHR1 is expressed, then SOX9 is a likely target for PTHrP signaling (Fig. 7). What is the evidence to support this conclusion? SOX9 phosphorylated at serine 181 (S181), one of two consensus PKA phosphorylation sites, is detected almost exclusively in chondrocytes

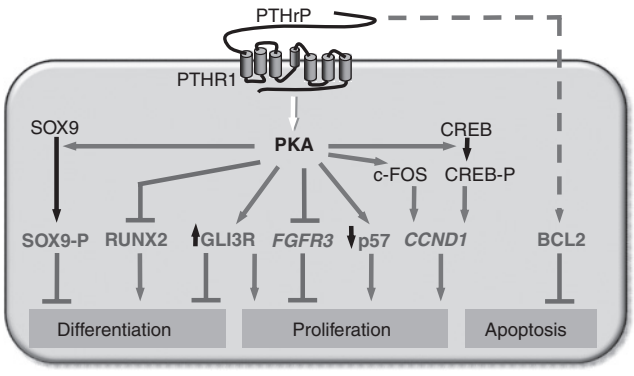

FIGURE 7 PTHrP and chondrocyte biology. Signaling pathways proposed to mediate the effects of PTHrP on differentiation, proliferation, and apoptotic death of chondrocytes (see text for details). The dashed line depicts putative PTHrP action that may not be mediated by PTHR1 (intracrine effect).

of the prehypertrophic zone in wild-type mouse embryos (Huang *et al.*, 2000). Moreover, no phosphorylation of SOX9 is observed in prehypertrophic chondrocytes of the growth plate or any chondrocytes of *Pthr1*-null mutants. Phosphorylation of SOX9 by PKA enhances its transcriptional and DNA-binding activity (Huang *et al.*, 2000). PTHrP greatly potentates the phosphorylation of SOX9 (S181), and increases the SOX9-dependent activity of chondrocyte-specific enhancers in *Col2a1*, the gene for collagen II. These findings indicate that SOX9 is a target of PTHrP signaling in prehypertrophic chondrocytes in the growth plate and that the PTHrP-dependent increased transcriptional activity of SOX9 helps maintain the chondrocyte phenotype of cells in the prehypertrophic zone, thereby delaying their maturation to the hypertrophic state. Recent experiments demonstrate that PTHrP also decreases the production of the transcription factor, Runx2, in chondrocytes (but not in osteoblasts) in explants of fetal long bones (Guo *et al.*, 2006). In such explants, PTH administration rapidly leads to a fall in Runx2 mRNA and protein in chondrocytes. Runx2 is required for the hypertrophic differentiation of chondrocytes and directly binds to the promoter region of the *Ihh* gene and strongly induces its expression (Yoshida *et al.*, 2004). This suggests that Runx2 is essential for chondrocyte maturation and regulates limb growth by organizing chondrocyte maturation and proliferation through the induction of *Ihh* expression. The action of PTHrP to suppress Runx2 production probably contributes in part to the delay in the differentiation of chondrocytes caused by PTHrP. The activity of Runx2 may also be repressed by Sox9 through a direct interaction between the two transcription factors (Zhou *et al.*, 2006).

Although the effects of PTHrP on chondrocyte differentiation are generally considered only in terms of its interaction with the cell surface receptor (PTHR1), studies *in vitro* as well as *in vivo*, now indicate that the capacity of PTHrP to influence this process, must also be assessed in relation to its intracrine actions at the level of the nucleus/nucleolus (Fiaschi-Taesch *et al.*, 2006; Henderson *et al.*, 1995). Nuclear localization of the protein has been associated with inhibition of differentiation, stimulation of proliferation, and delay in the apoptotic death of chondrocytes (Henderson *et al.*, 1996), likely by increasing *Bcl2* gene expression in these cells (Amling *et al.*, 1997). However, the events that determine the timing and degree of PTHrP nucleolar translocation, or the role that it may serve in the *in vivo* biology of chondrocytes, remain for the most part undefined.

Mechanisms underlying the molecular regulation of chondrocyte proliferation have been investigated, notably using transgenic mice that carry either gain- or loss-of-function mutations. From these studies, it has become evident that one of the most potent inducers of chondrocyte proliferation is Ihh. In support of this contention is the observation that the most striking feature of the *Ihh*-null endochondral skeleton is a profound decrease in limb length arising as a consequence of severe reduction in growth plate chondrocyte proliferation (St-Jacques *et al.*, 1999). Although this effect, unlike that on differentiation, is for the most part independent of PTHrP (Karp *et al.*, 2000), it is evident that PTHrP exerts its own unique influence on proliferation (Amizuka *et al.*, 1994; Karp *et al.*, 2000), even in the absence of Ihh (Koziel *et al.*, 2005).

Several signaling pathways have been implicated in mediating PTHrP's action on chondrocyte proliferation. G_s activation leads to production of cyclic AMP and activation of protein kinase A (PKA). It appears that it is the actions of cyclic AMP and PKA that not only delay differentiation but also lead chondrocytes to continue proliferating. Many of the transcriptional effects of cAMP are mediated by the cAMP response element (CRE) binding protein CREB, which binds to the CRE element in the upstream region of a variety of genes. CREB is a member of the CREB/activating transcription factor (ATF) family of transcription factors and is phosphorylated by PKA following increases in intracellular cAMP levels. Phosphorylation permits its interaction with p300/CBP and other nuclear coactivators, leading to gene transcription (Montminy, 1997). A role for CREB in skeletal development was not suggested initially by the phenotype of the *Creb*-knockout mice perhaps in part because of functional compensation by other CREB family members (Rudolph *et al.*, 1998). In keeping with this supposition is the observation that targeted overexpression of a potent dominant negative inhibitor for all CREB family members to the murine growth plate causes a profound decrease in chondrocyte proliferation resulting in short-limbed dwarfism and perinatal lethality owing to respiratory compromise (Long *et al.*, 2001). Similarly, disruption of the gene encoding the transcription factor ATF2, another member of the CREB/ATF family, also profoundly inhibits proliferation of chondrocytes (Reimold *et al.*, 1996).

The cyclin D1 gene (*Ccnd1*) is a key regulator of progression through the G_1 phase of the cycle (see later) and has been identified as a target for the transcription factor ATF2 (Beier *et al.*, 1999). ATF2 is present in nuclear extracts from chondrogenic cell lines and binds, as a complex with a CRE-binding protein (CREB)/CRE modulator protein, to the cAMP response element (CRE) in the cyclin D1 promoter. Moreover, site-directed mutagenesis of the cyclin D1 CRE causes a reduction in the activity of the promoter in chondrocytes, whereas overexpression of ATF2 in chondrocytes enhances activity of the cyclin D1 promoter. Inhibition of endogenous ATF2 or CREB by expression of dominant-negative inhibitors of CREB and ATF2 significantly reduce the activity of the promoter in chondrocytes through the CRE. Finally, levels of cyclin D1 protein are drastically reduced in chondrocytes of ATF2-negative mice. These data identify the cyclin D1 gene as a direct target of ATF2 in chondrocytes and suggest that reduced expression of cyclin D1 contributes to the defective cartilage development of these mice. Homozygous deletion

of *Ccnd1* in mice results primarily in reduced postnatal growth (Sicinski *et al.*, 1995). It is likely that alterations in the proliferation of chondrocytes may have contributed to this phenotype. However, the skeletal defects of these mice are clearly less severe than those of the ATF2-null mice, possibly because of the presence of intact cyclins D2 and D3. This advocates that additional target genes of ATF2 are involved in the reduction of chondrocyte proliferation in ATF2-deficient mice. In particular, it will be of interest to determine whether other D-type cyclin genes (cyclin D2 and D3) are regulated by ATF2 in chondrocytes. Finally, it remains to be seen whether PTHrP induces cyclin D1 expression through activation of CREB and how this impacts on chondrocyte proliferation. Alternatively, such a response may be mediated by the transcription factor AP-1, which is also central to PTHrP's action in chondrocytes (Ionescu *et al.*, 2001). Signaling by PTHR1 activates AP-1, a complex formed through interactions between c-Fos and c-Jun family members, by inducing the expression of c-Fos in chondrocytes. The protein complex binds to the phorbol 12-myristate 13 acetate (PMA) response element (TRE), a specific *cis*-acting DNA consensus sequence in the promoter region of target genes, like cyclin D1.

Because the genes of the cell cycle machinery execute the intracellular control of proliferation, it is likely that these genes play a pivotal role during endochondral ossification. A large body of experimental evidence now indicates that the major regulatory decisions controlling cell cycle progression, and hence proliferation of mammalian cells, takes place during the G_1/S phase checkpoint (reviewed in Sherr, 1993; Sherr and Roberts, 1995). Because cell cycle genes play an important role in proliferation, it is reasonable to speculate that they might be involved in the biological responses of chondrocytes to PTHrP. This view is supported by targeted disruption in mice of the pRb-related p107 and p130 genes (Cobrinik *et al.*, 1996) and the CDK inhibitor $p57^{Kip2}$ (p57) (Yan *et al.*, 1997). In both cases, bones from mutant mice show delayed ossification, elevated chondrocyte proliferation rate, and increased chondrocyte cell density, leading to severe skeletal defects. The absence of PTHrP or p57 has opposite effects on endochondral bone development, suggesting that PTHrP's proliferative actions in chondrocytes might be mediated by opposing p57. PTHrP was subsequently shown to decrease expression of *p57* in chondrocytes both in bone explants and *in vivo*, as deduced from measuring levels of *p57* mRNA and protein in mice missing PTHrP (MacLean *et al.*, 2004). Moreover, in double-knockout mice missing both *PTHrP* and *p57*, many growth plates exhibit patterns of proliferation much closer to normal than in the *PTHrP*-null growth plates. This outcome suggests that suppression of p57 synthesis is a major mechanism used by PTHrP to keep chondrocytes proliferating.

Last, it was shown recently that PTHrP promotes growth plate chondrocyte proliferation, in part, by potentiating the levels of the repressor form of Gli3 (Gli3R) in a PKA-dependent manner (Mau *et al.*, 2007).

Fibroblast growth factor receptor 3 (FGFR3)

Another major molecular player in growth plate chondrocyte biology is fibroblast growth factor receptor 3 (FGFR3) (reviewed in Ornitz, 2005). FGF1, FGF2, and FGF9 bind FGFR3 with relatively high affinity (Ornitz and Leder, 1992); however, the ligands of FGFR3 *in vivo* and their downstream effects in individual tissues have not been precisely defined. Gain-of-function mutations in FGFR3 have been linked to several dominant skeletal dysplasias in humans, including achondroplasia (Bellus *et al.*, 1995; Rousseau *et al.*, 1994; Shiang *et al.*, 1994), thanatophoric dysplasia (TD) types I (Rousseau *et al.*, 1996; Tavormina *et al.*, 1995) and II (Tavormina *et al.*, 1995), and hypochondroplasia (Bellus *et al.*, 1995). This group of disorders is characterized by a continuum of severity, from hypochondroplasia exhibiting a lesser degree of phenotypic severity, to achondroplasia, and to TDs, two lethal neonatal forms of dwarfism distinguished by subtle differences in skeletal radiographs. Achondroplasia is the most common genetic form of dwarfism in humans and results from a mutation in the transmembrane domain (G380R) of FGFR3, whereas thanatophoric dysplasia is the most common neonatal lethal skeletal dysplasia in humans and results from any of three independent point mutations in *FGFR3*. Nearly all reported missense mutations in families with TDI were found to cluster in two locations: codon 248 involving the substitution of an arginine for a cysteine residue (R248C) and the adjacent codon 249 causing a serine to a cysteine change (S249C). In all patients with TDII, a lysine to glutamic acid substitution at position 650 (K650E) was described in the tyrosine kinase domain of the FGFR3 receptor. Heterozygous *FGFR3* mutations have been reported also in patients with hypochondroplasia. In 8 of 14 alleles examined, a single C-to-A transversion causing an asparagine-to-lysine substitution at position 540 (N540K) of the protein was demonstrated.

Clinically, all of these mutations result in a characteristic disruption of growth plate architecture and disproportionate shortening of the proximal limbs. The mechanism by which *FGFR3* mutations disrupt skeletal development has been investigated extensively. Outside the developing central nervous system, the highest level of *FGFR3* mRNA is found in the cartilage rudiments of all bones, and during endochondral ossification, *FGFR3* is restricted to the resting and proliferating zones of cartilage in the growth plates (Peters *et al.*, 1993). Inactivation of FGFR3 signaling in mice leads to an increase in the size of the hypertrophic zone, as well as a coincident increase in bone length postnatally, suggesting that FGFR3 functions as a negative regulator of bone growth (Colvin *et al.*, 1996; Deng *et al.*, 1996). *In vitro* studies indicate that FGFR3-associated mutations confer gain-of-

function properties to the receptor by rendering it constitutively active (Naski *et al.*, 1996). Ligand-independent receptor tyrosine phosphorylation then leads to inhibition of cell growth and differentiation in cartilaginous growth plates (Naski *et al.*, 1998; Segev *et al.*, 2000).

The ligand that signals to FGFR3 during skeletal development is likely *Fgf18*, which is expressed in the perichondrium (Ohbayashi *et al.*, 2002). Growth plate histology of mice lacking *Fgf18* is similar to that of mice lacking *Fgfr3*. Both knockout mice show an upregulation of Ihh and Ptc expression and increased chondrocyte proliferation. These phenotypic similarities strongly suggest that FGF18 is a physiological ligand for FGFR3 in chondrocytes (Liu *et al.*, 2002; Ohbayashi *et al.*, 2002). While the molecular mechanisms that underlie the processes by which FGFR3 signaling inhibits bone growth remain sketchy at present, a model has been developed in which inhibition of chondrocyte differentiation occurs through the MAPK pathway while proliferation of chondrocytes is inhibited through a STAT1 pathway (Murakami *et al.*, 2004).

Transcription factors

Although the pivotal role of transcription factors in the development of the growth plate has been exemplified by the actions on Sox9, Runx2, and Gli3, recently, additional such factors have been implicated, rather unexpectedly at times, in this process. The fetal growth plate is a unique mesenchymal tissue, because it is virtually avascular and hence hypoxic. This prompted the question as to how chondrocytes could survive in this milieu. The transcription factor Hif-1α has emerged as the central regulator of the hypoxic response in mammals (reviewed in Provot and Schipani, 2007). Transcriptional activation by Hif-1α occurs on its binding to the hypoxia response element (HRE) within its target genes. One target of Hif-1α transcriptional activation is the angiogenic factor vascular endothelial growth factor (VEGF). Hif-1α accumulation is controlled by the von Hippel–Lindau (VHL) tumor suppressor, an E3-ubiquitin ligase that induces its degradation by the proteasome. To address the role of Hif-1α, in adaptive responses to hypoxia, a conditional knockout approach was used to remove specifically Hif-1α from chondrocytes (Schipani *et al.*, 2001). *Hif-1α-null* cells at the center of the growth plate, which is hypoxic, underwent massive cell death, a phenotype with striking similarity to the cell death observed after deletion of *Vegf* from chondrocytes (Zelzer *et al.*, 2004). This elegant work suggests that Hif-1α and VEGF are likely part of a common pathway that supports chondrocyte survival in endochondral bone development.

Histone acetylation, which is catalyzed by histone acetyltransferases (HATs) and promotes gene transcription by relaxing chromatin structure, is counterbalanced by histone deacetylation that favors chromatin condensation and transcriptional repression. The class II histone deacetylases (HDACs) HDAC 4, 5, 7, and 9 display cell type-restricted patterns with HDAC4 being highly expressed in prehypertrophic chondrocytes. Mice lacking HDAC4 display a remarkable phenotype characterized by inappropriate chondrocyte hypertrophy leading to ectopic bone formation (Vega *et al.*, 2004), abnormalities analogous to the phenotype observed in mice with constitutive expression of Runx2 in chondrocytes (Takeda *et al.*, 2001). Indeed, HDAC4 was shown to associate with and inhibit the activity of Runx2, thereby establishing HDAC4 as a key regulator of chondrocyte hypertrophy.

Another transcription factor, myocyte enhancer factor-2c (MEF2C), known to regulate muscle and cardiovascular development, was reported to be critical for normal chondrocyte hypertrophy and subsequent ossification. Chondrocytes in developing bones of Mef2c-null mice fail to express Runx2 and thereby fail to undergo hypertrophy indicating that MEF2C acts upstream of Runx2 in the induction of chondrocyte hypertrophy (Arnold *et al.*, 2007). Failure of endochondral ossification in heterozygous Mef2c-null mice can be reversed by deletion of Hdac4 alleles, and the premature ossification of Hdac4-null mice can be reversed by deletion of a Mef2c allele. These observations indicate that the balance between transcriptional activation by MEF2C and repression by HDAC4 dictates normal initiation and progression of chondrocyte hypertrophy. Since HDAC9 interacts with and suppresses the activity of MEF2 in the heart (Zhang *et al.*, 2002), it remains to be determined whether HDAC4 acts in a similar fashion in chondrocytes.

Interplay of Local Mediators

During the process of proliferation and differentiation, chondrocytes integrate a complex array of signals both from local and systemic factors. Understanding the specific role of one signaling pathway requires an appreciation of how it integrates with other signals participating in bone development. What is known about the interplay between FGFR3, PTHrP and Ihh signaling in the growth plate? The overlapping expression of FGFR3 and PTHR1 in the growth plate would suggest that these signaling pathways interact. In fact, the marked decrease in the size of the proliferative zone arising from inactivation of either PTHrP or PTHR1 in mice resembles the phenotype seen with constitutive activation of FGFR3 signaling. It is likely, therefore, that one pathway by which PTHrP can stimulate chondrocyte proliferation involves downregulation of *Fgfr3* expression. In fact, work by McEwen *et al.* (1999) supports a model whereby PKA signaling, by effectors such as the PTHR1, represses *Fgfr3* gene expression in proliferating chondrocytes of the epiphyseal growth plate and thus serves to regulate endochondral ossification (see Fig. 7). Moreover, *in vivo* studies indicate that FGFR3 signaling

can repress *Ihh* and *Pthr1* expression in the growth plate (Chen *et al.*, 2001; Naski *et al.*, 1998). This would, in turn, link the Ihh/PTHrP signaling to the FGFR3 pathway in the epiphyseal growth plate and hence complete a potential feedback loop that orchestrates endochondral bone growth.

The Articular Cartilage

Little is known about the factors that control the differentiation of joint mesenchymal interzone cells to form the opposing articular cartilage surfaces. In contrast to chondrocytes in the shaft, which tend to undergo maturation, hypertrophy, mineralization, and subsequent replacement by bone, these cells resist differentiation and produce abundant extracellular matrix to maintain normal joint function throughout life. The mechanisms that drive chondrocytes to this alternative fate are only now beginning to be unveiled. Endogenous TGFβs likely maintain cartilage homeostasis by preventing inappropriate chondrocyte differentiation because expression of a dominant-negative form of the transforming growth factor (TGF-) type II receptor in skeletal tissue results in increased hypertrophic differentiation in growth plate as well as articular chondrocytes (Serra *et al.*, 1997).

Studies by Iwamoto *et al.* (2000) have identified C-1-1, a novel variant of the ets transcription factor ch-ERG, which lacks a 27-amino-acid segment upstream of the ets DNA-binding domain. C-1-1 expression has been localized in the developing articular chondrocytes, whereas ch-ERG is particularly prominent in prehypertrophic chondrocytes in the growth plate. Virally driven overexpression of C-1-1 in developing chick leg chondrocytes blocks their maturation into hypertrophic cells and prevents the replacement of cartilage by bone. It also induces the synthesis of tenascin-C, an extracellular matrix protein that is unique to developing articular chondrocytes. In contrast, expression of ch-ERG stimulates chondrocyte maturation.

When the human C-1-1 counterpart (hERG3Delta81) is expressed throughout the cartilaginous skeleton of transgenic mice using Col2a1 gene promoter/enhancer sequences, the skeletal phenotype is severe and neonatal lethal (Iwamoto *et al.*, 2007). The transgenic mice are smaller than wild-type littermates and their skeletons are largely cartilaginous. Limb long bone anlagen are entirely composed of chondrocytes actively expressing collagen IX and aggrecan as well as articular markers such as tenascin-C. Typical growth plates are absent and there is very low expression of maturation and hypertrophy markers. This work identifies hERG3Delta81, the human counterpart of C-1-1, as a transcription factor instrumental in the genesis and maintenance of epiphyseal articular chondrocytes and provides a first glimpse into the mechanisms that dictate alternative chondrocyte developmental pathways.

COUPLING CHONDROGENESIS AND OSTEOGENESIS

The Formation of Bone Collar

As illustrated in Fig. 5A, the bone collar that forms in the perichondrium is the precursor of the cortical region of long bones. Hypertrophic chondrocytes have been proposed to play a critical role in coordinating growth plate chondrogenesis and perichondrial osteogenesis, although the molecular parameters that regulate these processes remain for the most part undefined. In earlier work, it was noted that *Ihh*-null mice have no bone collar (St-Jacques *et al.*, 1999) whereas overexpression of Ihh induces bone collar formation (Vortkamp *et al.*, 1996). Follow-up observations made in growth plates from genetically altered mice have identified *Ihh* expression by prehypertrophic chondrocytes as the critical determinant in the site of bone collar formation and in the induction of mature osteoblasts in the adjacent perichondrium (Chung Ui *et al.*, 2001). The presence of mature osteoblasts in membranous bones of Ihh mutants suggests that the bone collar, which is often referred to as being similar to intramembranous ossification, is in fact developmentally distinct.

In turn, a cascade of interacting factors in the perichondrium inhibits chondrocyte maturation. This was initially suggested from studies of chicken tibia organ cultures in which removal of the perichondrium resulted in increased chondrocyte proliferation and in a larger zone of chondrocyte hypertrophy (Long and Linsenmayer, 1998; Di Nino, *et al.* 2001). It was subsequently shown that the nuclear protein Twist-1, although it is never expressed in chondrocytes, regulates Runx2 activity in perichondrial cells where *Fgf18*, a negative regulator of chondrocyte maturation, is a target gene of Runx2 (Hinoi *et al.*, 2006). As a result, through its perichondrial expression, Runx2 exerts a negative influence on chondrocyte maturation.

Vascular Invasion of the Growth Plate

Ossification begins by the invasion of calcified hypertrophic cartilage. If ossification is to occur successfully, vascular invasion of the growth plate must take place. This process presents a challenge to the system because cartilage, a tissue highly resistant to vascularization, is replaced by bone, one of the most vascular tissues in the body. As such, this process would require the coordination of expression of factors that promote neovascularization and/or removal of factors that inhibit it, along with the proteolysis of the cartilage extracellular matrix that allows for vascular invasion to take place. In support of this concept is the observation that avascular cartilage expresses potent angiogenic inhibitors such as chondromodulin I (Hiraki *et al.*, 1997; Shukunami and Hiraki, 2007), whereas a number of

factors that promote neovascularization are being produced by hypertrophic chondrocytes.

Matrix metalloproteinases (MMPs), a family of extracellular matrix-degrading enzymes, have been implicated in this process (for review, see Vu and Werb, 2000). The MMPs are produced as latent proenzymes and can be inhibited by specific tissue inhibitors of metalloproteinases (TIMPs). Gene-targeting studies have implicated two particular MMPs in bone development: MMP9/gelatinase B (MMP9) and MT1-MMP (MMP14). MMP9 is highly expressed in multinucleated osteoclasts localized along the mineralized longitudinal septae and chondroclasts at the nonmineralized transverse septae of the cartilage–bone junction that lead the vascular invasion front. Endothelial cells, on the other hand, which are also abundant at the invasion front of the growth plate, do not express MMP9. Targeted disruption of *Mmp9* in mice leads to the development of abnormal growth plates in the long bones characterized by a nearly doubling in the length of the hypertrophic zone at birth with no changes noted in the reserve or proliferating zones (Vu *et al.*, 1998). By 3 weeks of age, the zone has enlarged to six to eight times the normal length. Because these cells appear normal and the matrix calcifies normally, alterations in the hypertrophic zone are attributed to a delay in the apoptosis of hypertrophic chondrocytes coupled with an impediment in vascular invasion. Because *Mmp9*-null hypertrophic cartilage exhibits a net decrease in angiogenic activity, the model for MMP9 action at the growth plate is attributed to the release of angiogenic factors sequestered in the extracellular matrix.

A variety of angiogenic factors are expressed in the growth plate, including members of the FGF family, IGF1, EGF, PDGF-A, members of the TGF- family, Cyr61 and transferrin. However, the importance of these factors in growth plate angiogenesis is still uncertain. Vascular endothelial growth factor (VEGF) is one angiogenic protein that is expressed in hypertrophic chondrocytes and binds to extracellular matrix. When made bioavailable, VEGF binds to its respective tyrosine kinase receptors Flt-1 (VEGFR1) and Flk-1/KDR (VEGFR2), both of which are expressed on endothelial cells (Ferrara and Davis-Smyth, 1997). Strong experimental evidence now links receptor activation to VEGF-induced mitogenesis, angiogenesis, and endothelial cell survival (Fong *et al.*, 1995; Gerber *et al.*, 1998; Shalaby *et al.*, 1995). Blockade of VEGF action through the systemic administration of a soluble receptor chimeric protein (Flt-(1-3)-IgG), recapitulates the phenotype of the *Mmp9*-null bones by impairing invasion of the growth plate (Gerber *et al.*, 1999). That VEGF plays a significant role in cartilage vascularization was substantiated by the observation that mice with conditional knockout of all three VEGF isoforms in chondrocytes showed delayed invasion of blood vessels into primary ossification centers and delayed removal of terminal hypertrophic chondrocytes (Zelzer *et al.*, 2004). It appears that MMP9 releases VEGF from the extracellular matrix (Bergers *et al.*, 2000), which in turn recruits endothelial cells and thus induces and maintains blood vessels. These blood vessels bring in not only nutrients, but also chondroclasts, osteoclasts, and osteoblasts as well as proapoptotic signal(s) (Engsig *et al.*, 2000). VEGF-mediated blood vessel invasion is therefore essential for coupling resorption of cartilage with bone formation. In the absence of blood vessel invasion, hypertrophic chondrocytes fail to undergo cell death, resulting in thickening of the growth plate. Therefore, the vasculature conveys the essential signals required for correct growth plate morphogenesis.

But what regulates the expression of VEGF? Recent work in mice null for *Fgf18* indicates an apparent delay in skeletal mineralization closely associated with delayed initiation of chondrocyte hypertrophy, skeletal vascularization, and osteoclast and osteoblast recruitment to the growth plate (Liu *et al.*, 2007). The concomitant observation that Ffg18 is necessary for *Vegf* expression in hypertrophic chondrocytes and the perichondrium supports a model in which Fgf18 coordinates neovascularization of the growth plate and subsequent recruitment of osteoblasts/osteoclasts, in part, through regulation of VEGF expression.

Vascular Invasion of the Epiphysis

In the epiphysis, hypertrophic cartilage is formed in the center, as chondrocyte maturation progresses inward. In order that osteogenic precursor cells come in for the ensuing ossification process, the formation of vascular canals must first take place. This involves degradation of uncalcified cartilage to clear a path for the invading blood vessels (see Fig. 3.5A). In the mouse, cartilage canals start off as invaginations of the perichondrium at day 5 after birth. At day 10, several small ossification nuclei arise around the canal-branched endings, which finally coalesce, and at day 18 a large secondary ossification center occupies the whole epiphysis. Interestingly, cartilage canal cells express collagen I and, during canal formation, several resting chondrocytes immediately around the canals are freed into the canal cavity and appear to remain viable, suggesting that cartilage canal cells belong to the bone lineage and may contribute to the formation of the bony epiphysis by differentiating into osteoblasts (Blumer *et al.*, 2007).

MT1-MMP (MMP14) is a membrane-bound matrix metalloproteinase capable of mediating pericellular proteolysis of extracellar matrix components. Its role in skeletal development was recognized following its targeted inactivation (Holmbeck *et al.*, 1999; Zhou *et al.*, 2000). In contrast to *Mmp9*-null mice, these animals display craniofacial dysmorphism and dwarfism, the former likely arising from impaired intramembranous bone formation whereas the latter reflects defects in endochondral ossification of the epiphyseal (secondary) centers of ossification. In the

Mmp14-null mice, invasion of the uncalcified epiphyseal hyaline cartilage by vascular canals, which represents a critical early step in the development of the secondary centers of ossification, fails to occur, leading to a delay in ossification. For reasons that are not exactly clear, this delay has profound consequences on the growth of the epiphyseal plate including thinning, disorganization, and lack of chondrocyte proliferation. It is speculated that the delay of epiphyseal vascularization results in a shortage of chondrocyte precursors and subsequent growth plate atrophy.

A role for CCN2/connective tissue growth factor (CCN2/CTGF) during secondary ossification center formation has also been suggested, although the evidence here remains circumstantial. CCN2/CTGF expression is reported in the central region of the epiphysis, where the chondrocytes become hypertrophic and the cartilage canals enter into the hypertrophic mass (Oka *et al.*, 2007). Nevertheless, the proposed role of CCN2/CTGF in supporting angiogenesis during the development of the secondary ossification center remains to be validated.

SUMMARY

In each phase of skeletal development, it is the appropriate interplay of a number of gene products that will determine the final phenotypic outcome. In this chapter, we have reviewed the developmental biology of the skeleton, the complex array of signals that influence each developmental stage, and finally, a number of inherited disorders of the skeleton arising from mutant gene products that influence primarily, although not exclusively, one of these specific phases. Knowledge of how specific gene defects contribute to bone pathophysiology will guide future efforts in the treatment of inherited and metabolic skeletal disorders.

ACKNOWLEDGMENTS

The author is grateful to M. Papageogiou for assistance with preparation of the manuscript. Research in the author's laboratory was supported in part by the Canadian Institutes for Health Research (CIHR) and the Canadian Space Agency. The author is the recipient of a National Researcher Award from the Fonds de la Recherche en Santé du Québec.

Chapter 4

Mesenchymal Stem Cells and Osteoblast Differentiation

Jane E. Aubin*
Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada

INTRODUCTION

Bone has the potential to repair itself throughout the life of an organism through the coordinated activities of osteoclasts, derived from hemopoietic stem cells (HSCs), and osteoblasts, derived from mulitpotential stem cells that have been variously termed stromal stem cells, mesenchymal stromal cells, skeletal stem cells, stromal fibroblastic stem cells, and most recently, mesenchymal stem cells (MSCs) among other monikers. Notwithstanding the limitations of the name in terms of developmental origin and ontogeny and the relative lack of evidence for the stemness of stromal-derived multipotent cells [sometimes also designated mesenchymal progenitor cells (MPCs)], as will be discussed further later, the term MSC has gained popularity and will be used in this chapter for convenience. I will review currently available paradigms governing development of osteoblasts and other mesenchymal cell types such as chondrocytes, adipocytes, and myoblasts among other mesenchymal cell types. I will also discuss evidence for MSC and osteoprogenitor deficiencies in disease and disease models, and the rapidly expanding literature on potential use of MSC in regenerative medicine applications, not only for bone, but also for other tissues and organs.

ONTOGENY OF OSTEOBLASTS AND CONTROL OF OSTEOBLAST DEVELOPMENT

CFU-F Assays and Osteogenic Cell Lineage Hierarchies

Friedenstein first showed that bone marrow stroma contains cells that have both significant proliferative capacity and the capacity to form bone when transplanted *in vivo* in diffusion chambers. Subsequently, he and others demonstrated that, in addition to bone, cartilage, marrow adipocytes, and fibrous tissue also formed *in vivo* and that all the tissues could arise from single colonies or colony-forming units-fibroblastic (CFU-F) [Friedenstein (1990); summarized in Bianco *et al.* (2001)]. *In vivo* analyses of stromal cells have been augmented by functional assays *in vitro* that show formation of a range of differentiated cell phenotypes and have led many to identify stromal populations as MSCs. However, the kinds of experiments needed to address whether marrow stroma contains a definitive stem cell—by the definition of self-renewal capacity and the ability to repopulate all the appropriate differentiated lineages or even by less stringent definitions—are only beginning to be done. For example, although expanded populations of stromal cells are routinely reported to express capacity to undergo differentiation along multiple mesenchymal lineages, CFU-F are heterogeneous in size, morphology, and potential for differentiation (Friedenstein, 1990; Kuznetsov *et al.*, 1997), consistent with the view that they are developmentally heterogeneous and belong to a lineage hierarchy in which only some of the cells are multipotential stem or primitive progenitors whereas others are more restricted. A growing body of data supports the view that only some single-cell-derived colonies of stromal cells express multilineage capacity whereas others express more restricted pontentiality, both by marker expression profiling (Zhang *et al.*, 2006a) and by functional/differentiation endpoints *in vitro* and *in vivo* (Gronthos *et al.*, 2003; Pittenger *et al.*, 1999; Rider *et al.*, 2007). There is also evidence that stromal cells are biochemically heterogeneous, i.e., that different stromal cell subpopulations express different regulatory proteins that function in angiogenesis, hematopoiesis, neural activities, and immunity and defense (Phinney, 2007). These data are consistent with limiting dilution and very-low-density plating studies that show that only a proportion of CFU-F are CFU-alkaline phosphatase (CFU-ALP) and, further, that only a proportion of these are CFU-osteogenic (CFU-O,

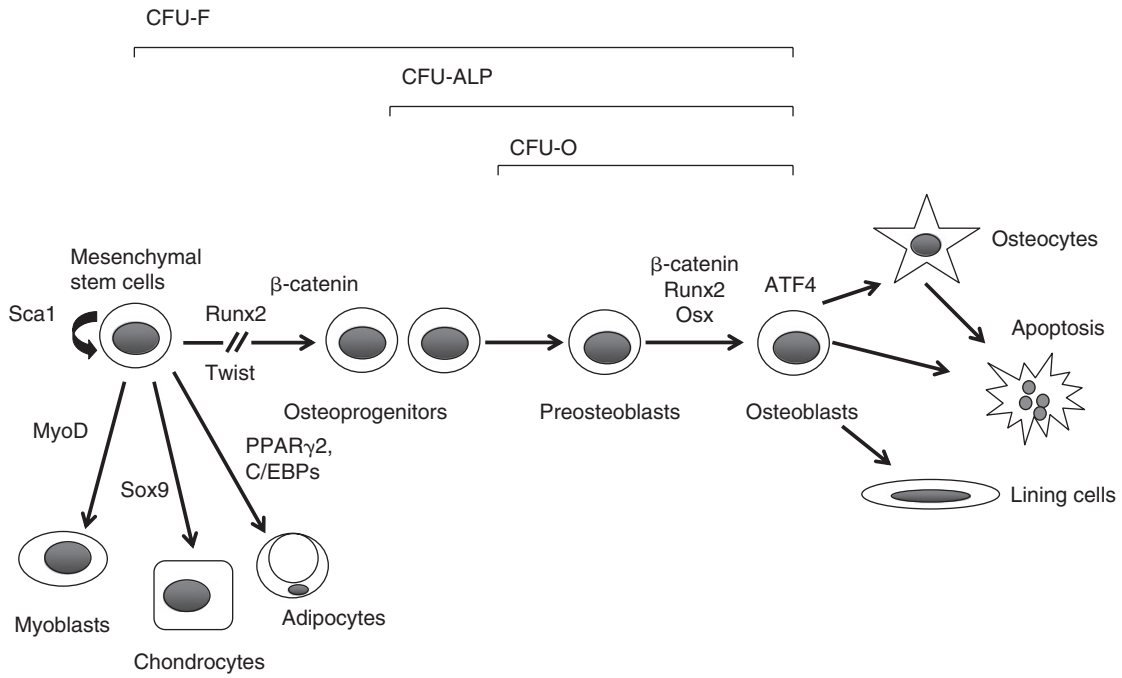

FIGURE 1 Schematic illustration of stem cell commitment to various end-stage mesenchymal cell types, including osteoblast lineage cells, with some of the known regulatory transcription factors indicated.

clonogenic bone colonies or bone nodules) with some variation reported between different species; CFU-adipocytic (CFU-A) also constitute a subset of CFU-Fs (Aubin, 1999; Wu *et al.*, 2000) (Fig. 1). What would help advance the field are assays comparable to those achievable for hemopoietic stem cells (HSCs), long-term culture-initiating cells (LTC-IC), and HSC/LTC-IC capable of long-term repopulating ability detected by their ability to serially repopulate lethally irradiated mice at limiting dilution (reviewed in Bryder *et al.*, 2006; Sauvageau *et al.*, 2004). Although such assays may be difficult to achieve for MSCs, especially *in vivo*, clear quantification and understanding of the clonality of mesenchymal cell progeny, the ratios of stem to other more restricted progenitors in various stromal populations, the identifiable commitment and restriction points in the stromal cell hierarchy, the self-renewal capacity, and the repopulation capacity of individual precursor cells should be goals. Attempts to combine retrospective assays for specific progenitor cell types with quantitative approaches *in vitro* and *in vivo* [e.g., gene marking, reviewed in Prockop (1997); limiting dilution, reviewed in Aubin (1999), and single cell transplantation experiments] are beginning to aid in the determination of the frequency and biological properties of various mesenchymal precursor cell populations and address where biology and concepts of HSCs versus MSCs may converge or diverge (Benveniste *et al.*, 2003; Ema *et al.*, 2006; Waller *et al.*, 1995b). A recent analysis of human stromal cells is particularly notable in showing that some single-cell-derived colonies with high expression of CD146 (melanoma-associated cell adhesion molecule, also known as Mel-CAM or MCAM) express at least some capacity for self-renewal and multipotentiality, including capacity to generate osteoblasts and the HSC niche, whereas CD146-negative/CD146^{low} can make osteoblasts but not the HSC niche [Sacchetti *et al.* (2007); see commentary (Aubin, 2008)]. Such observations will become increasingly important as work on stromal populations increases based on their proposed utility for tissue regeneration and as vehicles for gene therapy (see later).

Differentiation analyses of clonally derived immortalized (e.g., spontaneously or via large T antigen expression) cell lines derived from stroma, bone-derived cells, or other mesenchymal/mesodermal tissues, such as the mouse embryonic fibroblast line C3H10T1/2, the fetal rat calvaria-derived cell lines RCJ3.1 and ROB-C26, and the teratocarcinoma mesodermally derived C1 line, have also provided evidence for the existence of multipotential mesenchymal progenitor or stem cells capable of giving rise to multiple differentiated cell phenotypes, including osteoblasts, chondroblasts, myoblasts, and adipocytes (Aubin and Liu, 1996). Studies on these cell lines have led to suggestions of two different kinds of events underlying MSC commitment: a stochastic process with an expanding hierarchy of increasingly restricted progeny [e.g., RCJ3.1 (Aubin, 1998); see also that stromal cell clonal analysis as described earlier would fit this model] and a nonrandom, single-step process in which multipotential progenitors become exclusively

restricted to a single lineage by particular culture conditions [e.g., the C1 line in an environment of soluble inducers, substrate, and/or cell density (Poliard *et al.*, 1995)] have been proposed to underlie mesenchymal stem cell restriction (see discussion in Aubin, 1998). These models may be different endpoints on a single continuum, as particular culture restraints or environmental or local conditions *in vivo* may shift the frequency or probability of what might otherwise be random or stochastic commitment/restriction events to favor particular outcomes. This is consistent with the observation that at least certain hormones [e.g., 1,25-dihydroxyvitamin D_3 (Zhang *et al.*, 2006a); dexamethasone followed sequentially by triiodothyronine (Locker *et al.*, 2004)] and cytokines [e.g., leukemia inhibitory factor (Falconi *et al.*, 2007)] can regulate fate choices of multipotential cells *in vitro*.

Committed osteoprogenitors, i.e., progenitor cells restricted to osteoblast development and bone formation, at least under standard conditions, can also be identified by functional assays of their differentiation capacity *in vitro* (as so-called earlier, the CFU-O assay) in not only stromal cell populations, but also populations derived from calvariae, vertebrae, and other bones. However, as already indicated earlier, under some conditions and from some tissues, mixed colony types can also be seen. A number of studies on human bone-derived cells, both populations derived from human trabecular bone and clonally derived lines of human bone marrow stromal cells, have supported the observations on rodent marrow stromal populations that a bipotential adipocyte-osteoblast precursor cell exists [reviewed in Duque (2007); Gimble *et al.* (2006)]. It has also been suggested that the inverse relationship sometimes seen between expression of the osteoblast and adipocytic phenotypes in marrow stroma (e.g., in osteoporosis or in some culture manipulations) may reflect the ability of single or combinations of agents to alter the commitment or at least the differentiation pathway these bipotential cells will transit. In many cases, individual colonies are seen in which both osteoblast and adipocyte markers are present simultaneously. However, whether a clearly distinguishable bipotential adipo-osteoprogenitor can be identified or other developmental paradigms, such as transdifferentiation or plasticity, underlie expression in these two lineages needs to be analyzed further and is of significant clinical interest in osteoporosis and the aging or immobilized skeleton [summarized in Gimble *et al.* (2006)].

A variety of observations have suggested that a bipotential osteochondroprogenitor may also exist. However, as raised earlier for adipocyte-osteoblast phenotypes, the ability to transdifferentiate or change expression profiles may also characterize osteoblast-chondroblast lineages. The possible presence of undifferentiated/uncommitted stem cells and multi- and bipotential progenitors in cultures that may also contain monopotential but plastic progenitors at higher frequencies often complicates the ability to unambiguously discriminate the nature of the cells being affected. Difficulties in establishing unambiguous evidence for multipotentiality underscore the need for more markers and experiments to distinguish the molecular mechanisms underlying the ability of cells to express multipotentiality, the number and nature of commitment steps to a restricted phenotype(s), and both physiological and pathological mechanisms that may govern phenotypic conversions.

MSCs were originally isolated from the bone marrow but MSCs—or populations with similar developmental potential—have now been identified in many other tissues including adipose tissue (Gimble and Guilak, 2003; Tholpady *et al.*, 2003), umbilical cord blood (Karahuseyinoglu *et al.*, 2007; Kern *et al.*, 2006; Sarugaser *et al.*, 2005), muscle (Jiang *et al.*, 2002; Shefer and Yablonka-Reuveni, 2007), dental pulp (Shi and Gronthos, 2003), amniotic fluid (Roubelakis *et al.*, 2007), and skin (Toma *et al.*, 2005). Compact bone has also been suggested to be a source, perhaps even a richer source than bone marrow, of multipotential mesenchymal progenitors (Guo *et al.*, 2006; Short *et al.*, 2003). Interestingly, it has been suggested that the earliest embryonic appearance of MSCs is from neuroepithelium, not mesoderm, and that the neural source is replaced by nonneural sources as development continues (Takashima *et al.*, 2007). The isolation of MSCs from these various tissues usually involves adherence of the cells to tissue culture plastic, with or without subfractionation or enrichment strategies, and in most cases the adherent population is termed MSCs (or the CFU-F population). However, it is worth considering how adherent MSCs relate to nonadherent stem and progenitor cells for osteoblasts and other mesenchymal lineages described in the bone marrow and peripheral circulation.

Support for the existence of circulating mesenchymal precursor cells comes from several groups and models. For example, Zvaifler *et al.* (2000) reported human peripheral blood cells with a multipotentiality for mesenchymal lineages, including osteogenic cells, *in vitro*. This is consistent with data from Kuznetsov *et al.* (2001) who found that a small population of cells within the peripheral blood of humans, mice, rabbits, and guinea pigs adhered to tissue culture plates *in vitro*, a property of stromal elements. These cells also formed colonies with osteogenic capacity in ceramic-based implants placed subcutis in immunocompromised mice. Notably, the frequency of circulating osteogenic precursors measured by Kuznetsov and colleagues was extremely low, raising questions about their physiological significance. On the other hand, as many as 5% of circulating cells have been designated as potential osteoprogenitors in studies in which nonadherent cells were assayed directly from the peripheral blood, rather than the subpopulation of cells that are tissue culture plastic-adherent (Eghbali-Fatourechi *et al.*, 2005). These data support those of Long and colleagues (1995, 1999) who had reported cells with the capacity to form colonies in semisolid medium, express

osteoblastic markers and deposit mineralized matrix within a population of low-density, nonadherent marrow cells. Scutt and Bertram (1995) also found that some bone marrow cells that are initially nonadherent on plastic culture dishes with time adhere and form fibroblast colony-forming units *in vitro*. More recently, Horwitz and colleagues showed that plastic-nonadherent bone marrow cells have more than 10 times the bone-repopulating activity of plastic-adherent bone marrow cells in lethally irradiated mice (Dominici *et al.*, 2004). Even more striking in these latter studies was the finding that at least some of the cells in the plastic-nonadherent population, which were retrovirally marked to distinguish intrinsic development potential from fusion-related events, were able to generate both functional osteoblasts/osteocytes and hematopoietic cells supporting the idea that bone marrow may contain a primitive cell able to generate both the hematopoietic and osteoblastic lineages. Circulating stem and/or osteoprogenitor cells are unexpected based on earlier parabiosis experiments suggesting distinct precursors for hematopoietic versus stromal mesenchymal cells including osteoblasts (Walker, 1975). It is therefore worth considering whether the pool size of putative circulating osteoblastic cells changes under particular conditions that would make them easier or harder to detect. Eghbali-Fatourechi and colleagues (2005) hypothesized that the frequency of circulating osteoblasts changes with age and in states of high bone remodeling where they are regulated by particular bone-responsive hormones and growth factors, e.g., IGF-I and IGFBP3, as required for their active participation in bone formation. Much more work will be required to address whether and how the birth, life (differentiation/maturation), and/or death of putative circulating osteoblasts are regulated by a variety of factors. However, such studies suggest that marrow mesenchymal stem cells or their progeny, using as yet molecularly and biochemically uncharacterized transmigration and homing strategies, may have access to the blood stream directly from marrow, especially if mobilized by specific recruitment signal(s), much as hematopoietic stem cells do. This is consistent with the fact that the blood stream is a viable route of delivering at least some marrow-derived cells to the bone (Horwitz *et al.*, 1999, 2001). Their relationship to a putative vascular pericyte pool of osteogenic (Doherty *et al.*, 1998) or multipotential progenitor (Farrington-Rock *et al.*, 2004) cells also needs to be addressed [reviewed in Modder and Khosla (2008)].

Control of Osteoblast Development

Significant strides have been made in identifying the regulatory mechanisms underlying lineage restriction, commitment, and/or differentiation within some of the mesenchymal lineages (see Fig. 1). Master genes, exemplified by the MyoD, myogenin, and Myf-5 helix-loop-helix transcription factors in muscle lineages, are one paradigm in which one transcription factor is induced and starts a cascade that leads to the sequential expression of other transcription factors and of phenotype-specific genes (Berkes and Tapscott, 2005). A factor of a different transcription factor family, PPARγ2 mentioned earlier, together with other transcription factors, including the CCAAT/enhancer-binding (C/EBP) protein family, plays a key role in adipocyte differentiation (Rosen, 2005). Sox9, a member of yet another transcription factor family, is essential for chondrocyte differentiation, expression of various chondrocyte genes, and cartilage formation (Lefebvre and Smits, 2005).

With respect to osteoblasts, it is well-established that Runx2 (formerly called Cbfa1), a member of the runt homology domain transcription factor family, plays a crucial role in osteoblast development. Deletion of Runx2 in mice leads to animals in which the skeleton comprises only chondrocytes and cartilage without any evidence of bone (Komori, 2006; Komori *et al.*, 1997). Haploinsufficiency in mice (Komori *et al.*, 1997) and humans leads to the cleidocranial dysplasia phenotype [Mundlos *et al.*, 1997; Otto *et al.*, 1997; reviewed in Otto *et al.* (2002)]. Runx2 is the earliest of osteoblast differentiation markers currently known, its expression during development and after birth is high in osteoblasts, and it is upregulated in cultures treated with bone morphogenetic proteins (BMPs) and other factors that stimulate bone formation [reviewed in Komori (2006)]. Interestingly, studies have shown that Runx2 is also required alone or together with another Runx family member Runx3, depending on the skeletal element, for maturation of hypertrophic chondrocytes [Enomoto *et al.*, 2000; Yoshida, 2004; reviewed in Yoshida and Komori (2005)].

Many molecules that interact with and modify Runx2 activity have now been identified and it is beyond the scope of this chapter to review all of them; interested readers are referred to several other recent reviews (Franceschi *et al.*, 2007; Karsenty, 2007; Komori, 2006; Lian *et al.*, 2006) (see Fig. 1). However, some specific examples point toward a number of different mechanisms and pathways of importance. The basic helix-loop-helix (bHLH)-containing transcription factors Twist1 and Twist 2 are inhibitors of Runx2 in the craniofacial skeleton and in the appendicular skeleton, respectively (Bialek *et al.*, 2004). On the other hand, Schnurri 3, a zinc finger protein that controls Runx2 protein levels by promoting its degradation through the recruitment of the E3 ubiquitin ligase WWP1, also regulates osteoblast development (Jones *et al.*, 2006). Runx2 activity is also regulated via its interaction with signal transducers of transforming growth factor beta superfamily receptors, Smads. For example, Runx2 functions synergistically with Smad1 and Smad5 to regulate expression of bone-specific genes (Lee *et al.*, 2000; Zhang *et al.*, 2000) and to drive osteoblastogenesis *in vitro* (Phimphilai *et al.*, 2006) and *in vivo* (Ito and Zhang, 2001). The importance of the tightly regulated expression of not only Runx2 but also the factors that regulate it and that it regulates is underscored by the fact that

Runx2 can also inhibit chondrocyte and osteoblast differentiation. In cells of the bone collar and the perichondrium, Runx2 regulates expression of a secreted molecule, FGF18, which in turn inhibits osteoblast and chondrocyte differentiation (Hinoi *et al.*, 2006; Liu *et al.*, 2002).

Osterix (Osx), another zinc finger protein that belongs to the SP family of transcription factors, acts downstream of Runx2 and in its absence osteoblasts also do not form (Nakashima *et al.*, 2002). The regulation of Osx is still relatively poorly understood, but its transcription is positively regulated by Runx2 (Celil *et al.*, 2005) and negatively regulated by p53 (Wang *et al.*, 2006) with consequent reciprocal effects on osteoblast development and bone formation. In the absence of another zinc finger protein, Schnurri 2, Osx levels are also reduced leading to decreased bone formation (Saita *et al.*, 2007). Although it is clear that Osx acts to direct the commitment of preosteoblasts toward an immature osteoblast fate and away from a chondrogenic fate (Akiyama *et al.*, 2005; Nakashima *et al.*, 2002), there is as yet little information on exactly how Osx functions. It is known to form a complex with nuclear factor of activated T cells (NFAT) leading to cooperative regulation of bone formation, at least in part, via the transcriptional regulation of the Osx and of the COLIA1 promoters but not the Runx2-dependent activation of the osteocalcin promoter by the NFAT-Osx complex (Koga *et al.*, 2005).

Recently, the importance of Wnt signaling in osteoblast development and bone formation has emerged. Wnts are a family of 19 secreted proteins that bind to a membrane receptor complex composed of Frizzled (FZD) G protein-coupled receptors (GPCRs) and low-density lipoprotein (LDL) receptor-related proteins (LRPs) and activate intracellular signaling pathways. The best characterized is the canonical or Wnt/β-catenin pathway that signals through LRP-5 or LRP-6 and leads to inhibition of glycogen synthase kinase (GSK)-3β and subsequent stabilization of β-catenin, which translocates to the nucleus and activates lymphoid-enhancer-binding factor (LEF)/T-cell-specific transcription factors (TCFs); Wnts also activate noncanonical pathways [reviewed in Baron and Rawadi (2007); Krishnan (2006); Chan (2007)]. Wnts activate the canonical pathway by interacting with receptors of the Frizzled family and coreceptors of the LRP5/6 family. Loss-of-function mutations in Lrp5 result in low bone mass, whereas gain-of-function mutations in Lrp5 result in high bone mass [reviewed in Balemans and Van Hul (2007); Baron and Rawadi (2007); Krishnan *et al.* (2006)]. Conditional deletion of the β-catenin gene in neural crest cell precursors results in loss of cranial bones derived from neural crest cells (Brault *et al.*, 2001) and conditional deletion of β-catenin gene in mesenchymal progenitors revealed an essential role of β-catenin in osteoblast versus chondrocyte differentiation (Day *et al.*, 2005; Hill *et al.*, 2005, 2006) indicating that β-catenin plays a role in commitment of mesenchymal precursors to the osteoblast lineage. An additional mechanism by which Wnt may control osteoblast commitment is by blocking adipogenesis via the inhibition of the adipogenic transcription factors CCAAT/enhancer-binding protein α (C/EBPα) and peroxisome proliferator-activated receptor γ (PPARγ) as demonstrated *in vivo* in Wnt10b transgenic mice (Bennett *et al.*, 2005) or *in vitro* (Rawadi *et al.*, 2003). Other recent data support the view that commitment of mesenchymal precursors to an osteoblast rather than an adipocytic fate is via the ability of the noncanonical Wnt signaling pathway to suppress PPARγ function through chromatin inactivation triggered by recruitment of a repressing histone methyltransferase (Takada *et al.*, 2007).

The link between Wnts and other transcription factors has also been noted. Indian hedgehog (Ihh) null mice completely lack endochondral ossification owing to the lack of osteoblasts at those skeletal sites (St-Jacques *et al.*, 1999). In $Ihh^{-/-}$ mice, Runx2 is expressed in chondrocytes but not in perichondrial cells that differentiate into osteoblasts in wild-type mice, indicating that Ihh is required for Runx2 expression in perichondrial cells. Runx2 and Runx3 are essential for chondrocyte maturation and induce Ihh expression in prehypertrophic chondrocytes, which in turn induces Runx2 expression in perichondrial cells. Nuclear β-catenin is not detected in the perichondrial cells of $Ihh^{-/-}$ mice, indicating that Ihh is required for canonical Wnt signaling in perichondrial cells (Hu *et al.*, 2005). Very recently, it was shown that the noncanonical Wnt signaling pathway also regulates osteoblast development; Wnt-5a through the noncanonical Wnt signaling pathway suppressed PPARγ function through chromatin inactivation triggered by recruitment of a repressing histone methyltransferase promoting osteoblastogenesis versus adipogenesis in mesenchymal precursors *in vitro* and in mice (Takada *et al.*, 2007).

As already mentioned, other soluble factors beyond the Wnts appear also to alter commitment of MSCs and their more restricted progeny. Although review of all of them is beyond the scope of this chapter, it is worth noting that certain hormones [e.g., $1,25(OH)_2$ vitamin D_3 (Zhang *et al.*, 2006a)] and cytokines [e.g., leukemia inhibitory factor (LIF) (Falconi *et al.*, 2007)] (see also later) alter the frequency of specific mesenchymal colony types in bone-derived populations, an issue worthy of further investigation. Later I will address further a variety of other transcription factors and receptor signaling pathways that clearly also influence osteoblast activity, the rate of bone formation, and the amount of bone deposited.

IMMUNOPHENOTYPING AND ENRICHING MSC AND OSTEOPROGENITOR CELLS

In hematopoiesis, immune cell biology, and oncology, the availability of large panels of stem and progenitor cell antibodies has been invaluable for defining subpopulation makeup, purifying highly enriched stem cell populations

and analyzing cell commitment and developmental potential (Herzenberg and De Rosa, 2000). Fewer markers have been available for MSCs and their progeny, although the situation is beginning to change, especially for human and mouse cells, and combinations of antibodies and flow cytometry procedures are being used to subfractionate both marrow stromal cells and other osteogenic populations.

There is no one single antigen, cell surface or otherwise, that is able to unambiguously identify MSCs, and species specificity of some available reagents further complicates the analysis. However, many studies now suggest that both human and mouse multipotent populations, albeit heterogeneous by various functional criteria, express CD105 (transforming growth factor-B coreceptor), CD73 (membrane-bound ecto-5′-nucleotidase), and CD44 (hyaluronan receptor), but do not express CD45 (common leukocyte antigen), CD11b (Mac-1a; integrin α_M chain; highly expressed in a variety of hemopoietic cells including monocytes/macrophages, microglia, and others) or CD31 [platelet-endothelial cell adhesion molecule (PECAM)-1; highly expressed on endothelial cells; reviewed in Deans and Moseley (2000); Wagner (2005); Phinney (2007)]. There are conflicting data on whether MSCs do or do not express CD34 (a heavily glycosylated type I transmembrane protein/sialomucin), a marker routinely used to enrich for HSCs, and also expressed by hematopoietic progenitors of various sorts [see, e.g., Delorme and Charbord (2007); Simmons and Torok-Storb (1991a); Waller *et al.* (1995a)], but this may reflect, at least in part, changes with culture expansion and/or differences inherent in different strains of mice (Peister *et al.*, 2004). Sca-1 (stem cell antigen 1, Ly-6A/E; an 18-kDa phosphatidylinositol-anchored protein), another marker used in HSC enrichment especially in mice, has been used to enrich progenitor populations in other tissue types (Welm *et al.*, 2002). Some data suggest that Sca-1 is coexpressed with side population (SP) activity (ability to efficiently efflux Hoechst dye via the ATP-binding cassette transporter protein ABCG2), another phenotypic marker used to enrich for HSCs (Goodell *et al.*, 1996), and bone-derived multipotential mesenchymal cell populations (Zhang *et al.*, 2006b). Consistent with the view that Sca-1 may be a marker of MSCs, *in vivo* and *in vitro* analyses of Sca-1-deficient mice demonstrated that Sca-1 is required for the self-renewal of mesenchymal progenitors (Bonyadi *et al.*, 2003).

A few other monoclonal antibodies that react with surface antigens on MSCs *in vitro* have been generated and used frequently to fractionate marrow stromal cells and enrich for MSCs and/or osteoblastic cells, including the STRO-1 antibodies that react with human (but not other species) MSCs (Simmons and Torok-Storb, 1991b). The STRO-1+ fraction of adult human bone is still markedly heterogeneous, but when combined with an antibody directed against vascular cell adhesion molecule 1 (VCAM-1/CD106), yields a highly enriched population of human marrow stromal precursor cells (Gronthos *et al.*, 2003). Several analyses demonstrated that these cells have at least some stem cell characteristics, as defined by extensive proliferative capacity and retention of differentiation capacity for osteogenesis, chondrogenesis, and adipogenesis. Expression of STRO-1 has been used in a number of other combinations, including with antibodies recognizing the bone/liver/kidney isoform of alkaline phosphatase (ALP) in human marrow stromal cell populations in which an inverse association was found between the expression of STRO-1 and ALP (Gronthos *et al.*, 1999; Stewart *et al.*, 1999). Osteogenic cells were sorted from mouse bone marrow based on light scatter characteristics, Sca-1 expression, and their binding to wheat germ agglutinin (WGA) (Van Vlasselaer *et al.*, 1994). Osteopontin (OPN) expression combined with cell size and granularity was used to sort rat calvaria and bone marrow stromal cells to enrich for cells responsive to BMP-7; these were said to have stem-like properties (Zohar *et al.*, 1997, 1998). Fractionation based on ALP alone or in combination with parathyroid hormone/parathyroid hormone-related protein receptor (PTHR1) expression has also been used to significantly enrich osteoprogenitors from rat calvaria populations (Purpura *et al.*, 2003; Turksen and Aubin, 1991) and rat bone marrow stromal cell populations (Herbertson and Aubin, 1997).

Better understanding of the surface profiles and their temporal changes with commitment of MSCs and the development of osteogenic cells would advance the field. Further, although all the studies summarized have fractionated populations into subpopulations with different characteristics and differentiation potentials, few attempts have yet been made to quantify the most primitive progenitors or stem cells in these populations and their functional characteristics: self-renewal, proliferation, and differentiation potentialities at single-cell or colony levels so that clear lineage relationships and hierarchies can be established analogous to those that have been achieved in hematopoietic populations. Many studies have defined MSCs based mainly on their ability to differentiate into multiple mesenchymal lineage cells (adipocytic, osteogenic, chondrogenic, etc.) *in vitro*, but a growing number suggest at least some capacity of MSC populations to contribute to bone and cartilage formation *in vivo* (Meirelles Lda and Nardi, 2003; Peister *et al.*, 2004; Sun *et al.*, 2003). Particularly powerful are recent studies that have attempted to characterize *in situ* localization of marker expression within a tissue combined with functional assays to distinguish between tissue-specific resident stem/progenitor cells and multipotent hematopoietic, endothelial, or mesenchymal progenitors *in vitro* and *in vivo*. In this regard, in a series of *in vitro* analyses and *in vivo* transplantation experiments, Sacchetti *et al.* (2007) recently demonstrated that the CD146-positive subendothelial reticular cell subpopulation of human bone marrow stromal progenitors (BMSCs) form all assayable CFU-F and their clonal progeny *in vitro*, have at least some capacity for self-renewal, and regenerate bone, stroma, and the

hemopoietic microenvironment *in vivo*. Further analyses of human bone marrow-derived $CD146^+$ cells and analogous cells in mouse and other species will be crucial not only for understanding MSCs and osteoblasts, but also for understanding the bone niche for hematopoiesis (see also later).

OSTEOPROGENITOR CELLS AND REGULATION OF OSTEOBLAST DIFFERENTIATION AND ACTIVITY

Osteoprogenitor Cells

The morphological and histological criteria by which osteoblastic cells, including osteoprogenitors, preosteoblasts, osteoblasts, and lining cells or osteocytes, are identified have been reviewed extensively and will not be reiterated in detail here [see, e.g., Aubin and Heersche (2002)]. Morphological definitions are now routinely supplemented by the analysis of the expression of cell- and tissue-specific macromolecules, including the ecto-enzyme ALP, bone matrix proteins [type I collagen (COLL-I), osteocalcin (OCN), OPN, and bone sialoprotein (BSP), among others] and transcription factors that regulate them and commitment/differentiation events (e.g., Runx2, AP-1 family members, Msx-2, Dlx-5, etc.). Committed osteoprogenitors, i.e., progenitor cells restricted to osteoblast development and bone formation under default differentiation conditions, can be identified in bone marrow stromal cell populations and populations derived from calvaria and other bones by functional assays of their proliferation and differentiation capacity *in vitro* or, as often designated, the CFU-O assay. As mentioned earlier, CFU-Os appear to constitute a subset of CFU-F and CFU-ALP (Purpura *et al.*, 2003). Cells morphologically essentially identical to cells described *in vivo* and subject to many of the same regulatory activities can be identified, and the deposited matrix contains the major bone matrix proteins [see Bhargava *et al.* (1988); Malaval *et al.* (1994)].

Much has been learned from the *in vitro* bone nodule assay in which both the nature of the osteoprogenitors and their more differentiated progeny have been investigated by functional (the nature of the colonies they form, e.g., mineralized bone nodules), immunological (e.g., immunocytochemistry, Western blot analysis), and molecular (e.g., Northerns, PCR of various sorts, *in situ* hybridization, arrays and microarrays) assays. Bone nodules represent the *in vitro* end product of the proliferation and differentiation of CFU-O or osteoprogenitor cells present in the starting cell population. Estimates by limiting dilution and functional endpoints *in vitro* have indicated that osteoprogenitor cells are relatively rare in primary cell populations digested from fetal rat calvaria [i.e., $<1\%$ (Bellows and Aubin, 1989)] and rat (Aubin, 1999) and mouse (Falla *et al.*, 1993) bone marrow stroma (i.e., $0.5–1 \times 10^{-5}$ of the nucleated cells of unfractionated marrow) under standard isolation and differentiation culture conditions (ascorbic acid and a phosphate source, usually β-glycerophosphate). Estimates of osteoprogenitor frequency in adherent stromal cell layers, including those from humans, is significantly higher and ranges from $\sim 1\%$ up to $\sim 10\%$ of adherent cells by functional assays *in vitro* and *in vivo* (cells transplanted with ceramic particles) (Bianco *et al.*, 2006). Many authors have counted the number of nodules or colonies forming bone with or without limiting dilution for an estimate of osteoprogenitor numbers in other bone cell populations, e.g., from vertebrae (Bellows *et al.*, 2003; Ishida *et al.*; 1997; Lomri *et al.*, 1988), femoral trabecular bone fragments (Robey, 1995), primary spongiosa of femoral metaphysis (Onyia *et al.*, 1997), and compact bone (Short *et al.*, 2003), and in other tissues and organs, including peripheral blood where frequencies also range markedly [1 in 106 peripheral blood mononuclear cells in mice and guinea pigs, 1 in 107 in rabbits, and 1 in 108 (or less) in humans] depending on whether enrichment strategies were employed [for discussion, see, Modder and Khosla (2008)].

It is worth noting that many of the frequency estimates of progenitor numbers must be viewed with caution in the absence of unambiguous markers. Culture conditions significantly influence frequency estimates, and many base their estimates not on a Poisson analyses of limiting dilution (which quantifies absence or loss of progenitors over serial dilutions) or clonal analysis of single-cell plating in microtiter wells, but based on counting nodules in mass cultures at one or more plating densities, an approach subject to influences from "accessory" cells present in the population, some of which may be physiologically relevant to regulation of osteogenesis and others not (Aubin, 1999; Bord *et al.*, 2005; Eipers *et al.*, 2000; Kacena *et al.*, 2006). Second, based on data first reported in rat calvaria (Bellows and Aubin, 1989; Bellows *et al.*, 1987) and rat bone marrow stromal cell (Maniatopoulos *et al.*, 1988) cultures, additives expected to be stimulatory to osteogenesis such as dexamethasone are routinely added to osteogenic cultures *in vitro*, even though they may be without effect or even inhibitory in some species, at certain concentrations and in certain batches of serum [see, e.g., the inhibitory effect of dexamethasone in mouse stromal cultures (Falla *et al.*, 1993; Ishida and Heersche, 1998)]. On the other hand, the fact that many additives have been found to enhance osteogenesis supports the presence of "inducible" osteoprogenitor cells in bone marrow- and bone-derived populations (see later). Elucidation of species differences, the nature (i.e., multipotential or various committed progenitors) of progenitors present, at what proliferation and/or differentiation stages they are induced, and whether comparable activities can be discerned *in vivo* as well as *in vitro* warrants further attention, an issue that is advancing rapidly as various genetically modified mouse and other models become increasingly available.

Whether all progenitors from different sources that differentiate to osteoblasts and make bone belong to the same unidirectional lineage pathway (i.e., immature progenitors undergoing differentiation to mature osteoblasts), whether osteoprogenitor cells must transit all recognizable differentiation stages (or may skip steps under appropriate conditions) under all developmental situations, or whether recruitment from other parallel lineages and pathways can result in functional osteoblasts remains to be established. However, as discussed in more detail later, they do appear to reach similar endpoints with respect to the ability to make and mineralize a bone matrix, but they may not be identical. At least some precursor cell pools appear to undergo osteogenic differentiation as a default pathway *in vitro* whereas others require a stimulus beyond the presence of serum. Clearly, the presence of factors from accessory cells in bone-derived (Purpura *et al.*, 2003) and bone marrow-derived (Aubin, 1999; Eipers *et al.*, 2000; Miao *et al.*, 2004) cell populations points toward the intrinsic differentiation capacity of precursor cells being modulated by cell nonautonomous factors *in vitro* and *in vivo* (Kacena *et al.*, 2006). As already discussed, the relationship of inducible osteoprogenitors that apparently reside in the nonadherent fraction of bone marrow and are assayable under particular culture conditions, e.g., in the presence of PGE_2 [rat (Scutt and Bertram, 1995)] or as colonies in soft agar or methylcellulose [human (Long *et al.*, 1995)] to adherent osteoprogenitors and MSCs, also remains to be explicitly determined. Direct and unambiguous comparisons will require more markers for the most primitive progenitors, including stem cells.

Morphologically recognizable osteoblasts associated with three-dimensional nodules appear in long-term bone cell cultures at predictable and reproducible periods after plating. Time-lapse cinematography of individual progenitors forming colonies in low-density rat calvaria cultures indicated that primitive (glucocorticoid-requiring) osteoprogenitors divide ~8 times prior to overt differentiation, i.e., to achieving cuboidal morphology and matrix deposition (Malaval *et al.*, 1999). Interestingly, however, the measurement of large numbers of individual bone colonies in low-density cultures shows that the size distribution of fully formed bone colonies covers a large range but is unimodal, suggesting that the coupling between proliferation and differentiation of osteoprogenitor cells may be governed by a stochastic element, but distributed around an optimum, corresponding to the peak colony size/division potential (Malaval *et al.*, 1999). Osteoprogenitors measurable in functional bone nodule assays also appear to have a limited capacity for self-renewal in both calvaria (Bellows *et al.*, 1990a; Purpura *et al.*, 2004) and stromal (McCulloch *et al.*, 1991) populations *in vitro*, consistent with their being true committed progenitors with a finite life span [reviewed in Aubin and Heersche (2002)]. However, in comparison with certain other lineages, most notably hematopoietic cells, relatively little has been done to assess the regulation of self-renewal in different osteogenic populations beyond the effects of glucocorticoids. According to signaling threshold models, the differentiation of hematopoietic stem cells and embryonic stem cells is regulated by threshold levels of ligands and receptors (Davey *et al.*, 2007; Viswanathan *et al.*, 2005; Zandstra *et al.*, 2000). Very little has been done regarding osteoblast lineage to assess comparable pathways, yet the differential expression of a variety of receptors for cytokines, hormones, and growth factors during osteoblast development and in different cohorts of osteoblasts predicts that similar mechanisms may play a role in bone formation (see also later).

Differentiation of Osteoprogenitor Cells to Osteoblasts

A fundamental question in osteoblast development remains how progenitors progress from a stem or primitive state to a fully functional matrix-synthesizing osteoblast. Inherently based on observations *in vivo* and in bone nodule formation *in vitro*, the process has been conceived of as deterministic and subdivided into three stages: (i) proliferation, (ii) extracellular matrix development and maturation, and (iii) mineralization, with characteristic changes in gene expression at each stage; some apoptosis can also be seen in mature nodules. In many studies, it has been found that genes associated with proliferative stages, e.g., histones and proto-oncogenes such as c-fos and c-myc, characterize the first phase, whereas certain cyclins, e.g., cyclins B and E, are upregulated postproliferatively [Kalajzic *et al.*, 2005, Malaval *et al.*, 1994, Owen *et al.*, 1990; reviewed in Aubin (2001)]. Expression of the most frequently assayed osteoblast-associated genes COLLI, ALP, OPN, OCN, BSP, and PTH1R is upregulated asynchronously, acquired, and/or lost as the progenitor cells differentiate and the matrix matures and mineralizes. In general, ALP increases and then decreases when mineralization is well progressed; OPN peaks twice during proliferation and then again later but prior to certain other matrix proteins, including BSP and OCN; BSP is expressed transiently very early and is then upregulated again in differentiated osteoblasts forming bone; and OCN appears approximately concomitantly with mineralization [summarized in Aubin and Heersche (2002)] (Fig. 2). Notably, however, use of global amplification poly(A) PCR, combined with replica plating and immunolabeling, showed that all these osteoblast-associated markers are upregulated prior to the cessation of proliferation in osteoblast precursors except OCN, which is upregulated only in postproliferative osteoblasts; in other words, differentiation is well progressed before osteoblast precursors leave the proliferative cycle. Based on the simultaneous expression patterns of up to 12 markers, osteoblast differentiation can be categorized into a minimum of seven

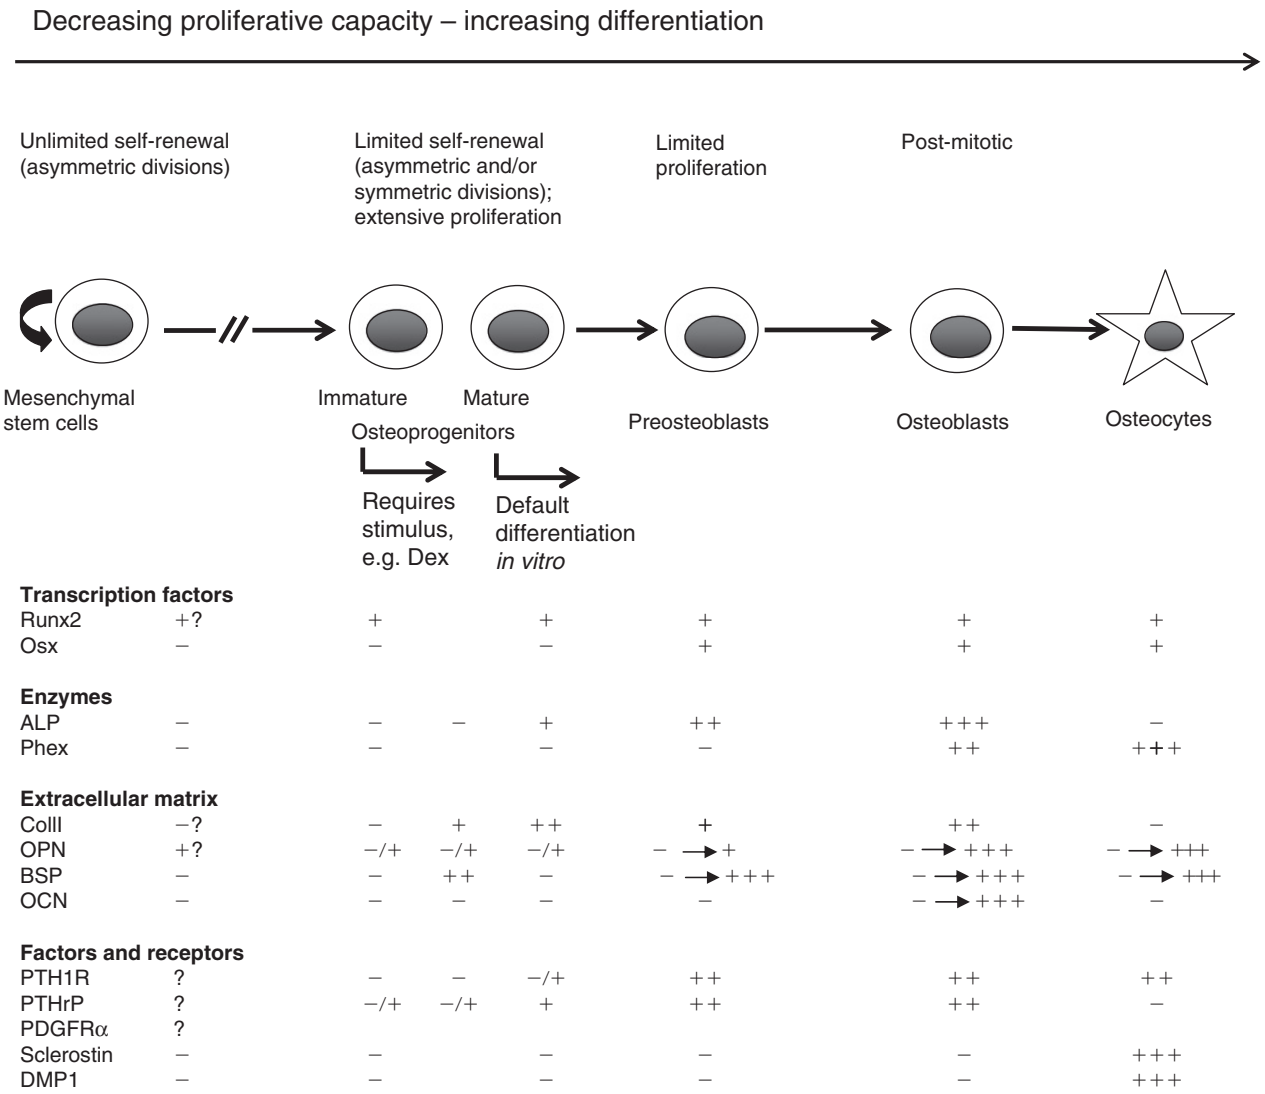

FIGURE 2 Sequential proliferation–differentiation steps in the osteoblast lineage as detectable from *in vitro* and *in vivo* experiments. Superimposed on this scheme are several well-established markers of osteoblastic cells with an indication of when during the differentiation sequence they are expressed, but also denoting heterogeneous expression of many of the markers. The list is not exhaustive, but does show some important categories of molecules in the lineage and their utility to help define transitions in osteoblast differentiation-maturation. −, no detectable expression; −/+ to + + + , expression ranging from detectable to very high; − ? + + + , intercellular heterogeneous expression.

transitional stages (Liu *et al.*, 2003), not just the three stages mentioned earlier. An interesting issue is whether osteoprogenitor cells in all normal circumstances must transit all stages or can "skip over" some steps under the action of particular environmental stimuli or regulatory agents.

Most or all of these molecules are downregulated as cells transition to ostecytic osteoblasts and to osteocytes. However, over the past several years, several markers have been found to be upregulated at these terminal differentiation stages. One of these is sclerostin, a Wnt antagonist that is mutated in human sclerosteosis and Van Buchem disease and that blocks BMP-induced bone formation; sclerostin is the subject of much current interest as a potential new therapeutic for bone disease (Chan *et al.*, 2007; van Bezooijen *et al.*, 2005). Among others are molecules regulating phosphate homeostasis and mineralization. For example, the mRNA for Phex, a phosphate-regulating gene with homology to endopeptidases on the X chromosome, which is mutated in X-linked hypophosphatemia (XLH), is expressed differentially as osteoblasts differentiate (Ecarot and Desbarats, 1999; Guo and Quarles, 1997; Ruchon *et al.*, 1998) and, depending on the species studied and the antibody used, the protein is reported to be expressed by osteoblasts and osteocytes (Ruchon *et al.*, 2000) or osteocytes alone (Westbroek *et al.*, 2002). Matrix extracellular phosphoglycoprotein (MEPE), a recently isolated RGD-containing matrix protein that acts as the tumor-derived phosphaturic factor in oncogenic hypophosphatemic osteomalacia,

is much more highly expressed in osteocytes than osteoblasts (Nampei *et al.*, 2004). Dentin matrix protein 1 (encoded by DMP1) is highly expressed in osteocytes (Toyosawa *et al.*, 2001) and, when deleted in mice and in humans with a newly identified disorder, autosomal recessive hypophosphatemic rickets, rickets, and osteomalacia result with renal phosphate-wasting associated with elevated fibroblast growth factor 23 (FGF23) levels (Feng *et al.*, 2006).

Although many osteoblast models have been reported to follow the general proliferation–differentiation outlined earlier, some differences have been reported. At least some of the variations may reflect inherent differences in the populations being analyzed, e.g., species differences or different mixtures of more-or-less primitive progenitors and more mature cells. However, as underscored by a couple of the preceding examples, there is also growing evidence from both *in vitro* and *in vivo* observations that different gene expression profiles may underlie developmental events in different osteoblasts. In another example, a study of ROS cells differentiating and producing mineralizing bone matrix in diffusion chambers *in vivo*, neither proliferation nor most differentiation markers followed the pattern described previously (Onyia *et al.*, 1999). One possible explanation is that different subpopulations of cells within the chambers were undergoing different parts of the proliferation—matrix synthesis—death cycle at different times, such that activities of some subpopulations may have been obscured among larger subpopulations engaged in other activities in the chamber at the same time. At least some data supported this view. Another possibility is that there are differences in proliferation–differentiation coupling and/or the nature of the matrix and process of mineralization in osteosarcoma cells versus normal diploid osteoblasts. In addition, however, it is growing clear that high levels of genes typical of some normal osteoblasts may not be required in others, i.e., that some pathways by which mineralized matrix can be formed *in vivo* or *in vitro* are different from others and that there is heterogeneity among osteoblast developmental pathways and/or the resulting osteoblasts.

The possibility that marked intercellular heterogeneity in expressed gene repertoires may characterize osteoblast development and differentiation is an important concept. It has been evident for some time that not all osteoblasts associated with bone nodules *in vitro* are identical (Liu *et al.*, 1994; Malaval *et al.*, 1994; Pockwinse *et al.*, 1995). Single-cell analysis of the most mature cells in mineralizing bone colonies *in vitro* showed that the heterogeneity of expression of markers by cells classed as mature osteoblasts is extensive and appears not to be related to cell cycle differences (Liu *et al.*, 1997). That this extensive diversity is not a consequence or an artifact of the *in vitro* environment was confirmed by the analysis of osteoblastic cells *in vivo*. When individual osteoblasts in 21-day fetal rat calvaria were analyzed, only two markers of nine sampled, ALP and PTH1R, appeared to be globally or ubiquitously expressed by all osteoblasts. All other markers analyzed (including OPN, BSP, OCN, PTHrP, c-fos, Msx-2, and E11) were expressed differentially at both mRNA and protein levels in only subsets of osteoblasts, depending on the maturational state of the bone, the age of the osteoblast, and the environment (endocranium, ectocranium) and the microenvironment (adjacent cells in particular zones) in which the osteoblasts reside (Candeliere *et al.*, 2001). The biological or physiological consequences of the observed differences are not known, but they support the notion raised earlier that not all mature osteoblasts develop via the same regulatory mechanisms nor are they identical molecularly or functionally. They predict that the makeup of different parts of bones may be significantly different, as suggested previously by the observations that the presence of and amounts of extractable noncollagenous bone proteins are different in trabecular versus cortical bone and in different parts of the human skeleton [for discussion, see Candeliere *et al.* (2001)]. They also suggest that the globally or ubiquitously expressed molecules serve common and nonredundant functions in all osteoblasts and that only small variations in the expression of these molecules may be tolerable; e.g., all bones display mineralization defects in ALP knockout mice (Fedde *et al.*, 1999; Wennberg *et al.*, 2000). Differentially expressed lineage markers, however, e.g., BSP, OCN, and OPN, vary much more, both between osteoblasts in different zones and between adjacent cells in the same zone and may have specific functions associated with only some positionally or maturationally defined osteoblasts. In this regard, it is striking that all of the noncollagenous bone matrix molecules are extremely heterogeneously expressed and that ablation of many of those studied to date, e.g., OCN (Ducy *et al.*, 1996) and OPN (Yoshitake *et al.*, 1999), does not result in a complete failure of osteoblast differentiation and maturation, although the amount, quality, and remodeling of the bone formed differs from normal.

The nature of the signals leading to the diversity of osteoblast gene expression profiles is not known, but the fact that the heterogeneity is apparently controlled both transcriptionally and post-transcriptionally implies that regulation is complex. The observations also suggest that it will be important to analyze the expression of regulatory molecules, including transcription factors, not only globally but at the individual osteoblast level. Another unanswered question remains as to whether the striking diversity of marker expression in different osteoblasts is nonreversible or reversible in a stochastic manner, governed by changes in a microenvironmental signal or receipt of hormonal or growth factor cues, or both. Because the heterogeneity observed extends to the expression of regulatory molecules, such as cytokines and their receptors, it also suggests that autocrine and paracrine effects may be elicited on or by

only a subset of cells at any one time and that the responses to such stimuli could themselves be varied.

The observed differences in mRNA and protein expression repertoires in different osteoblasts may also contribute to the heterogeneity in trabecular microarchitecture seen at different skeletal sites (Amling *et al.*, 1996), to site-specific differences in disease manifestation such as seen in osteoporosis (Riggs *et al.*, 1998), and to regional variations in the response to therapeutic agents (Compston, 2007). Further analysis of differential expression profiles for a variety of receptors in different skeletal sites, and at different maturational age of the cells and skeleton, should provide further insight into site-specific effects of various agents.

Many other molecules are now known to be made by osteoblast lineage cells, often with differentiation stage-specific changes in expression levels, but not all have been tested for a bone-related function. It is beyond the scope of this chapter to review all of them, but those markers that may comprise regulatory molecules within the HSC niche are increasingly of interest. The presence of HSCs close to endosteal bone surfaces and a role for osteoblasts in supporting hematopoietic progenitors *in vitro* are now well-accepted concepts [reviewed in Taichman (2005)]. However, the lack of markers for unambiguous identification of specific stromal cell subtypes and various osteoblastic cell subpopulations has led to some confusion about the exact nature of the HSC niche, and both a bone niche and a vascular niche have been proposed. For example, osteoblasts in the bone niche have been variously characterized as PTH-activatable Jag1+ (Notch ligand jagged 1-positive) osteoblastic cells (Calvi *et al.*, 2003), a spindle-shaped N-cadherin + CD45− subset of osteoblastic (SNO) cells at the bone surface (Lymperi *et al.*, 2007; Zhang *et al.*, 2003), and angiopoietin 1 (Ang1)+ osteoblasts regulating HSC number through the activation of the Tie-2/Ang1 signaling pathway (Arai *et al.*, 2004). As already mentioned, more recently, Sacchetti *et al.* (2007) demonstrated that human CD146+ osteoblast precursors, which also express Jag1, N-cadherin, Ang1, and CXCL12 [also known as stromal-cell-derived factor (SDF)-1], are cells that may comprise both the bone and the vascular niche [for discussion, see Aubin (2008)]. These and other studies underscore the interest in and necessity for additional markers by which to discriminate osteoblast maturational stage and osteoblast subpopulations.

An increasing number of studies using genomewide expression profiling of MSC and osteoblast transcriptomes, and a few protein profiles, are beginning to address the current paucity of markers and to add new insights into diverse aspects of osteoblast development and activity. These include analyses with cells under standard differentiation conditions (Jeong *et al.*, 2005; Qi *et al.*, 2003; Roman-Roman *et al.*, 2003), with specific gene mutations [those underlying craniosynostosis (Coussens *et al.*, 2007)] or treated with such agents as siRNA or DNA modifiers/regulators of DNA expression [histone deacetylase inhibitors (Schroeder *et al.*, 2007)], hormones and growth factor treatments [BMP, Nakashima *et al.* (2002); Wnt3a (Jackson *et al.*, 2005), mechanical loading and combinations of treatments (mechanical loading and estrogen effects in wild-type and $ER^{-/-}$ cells (Armstrong *et al.*, 2007)). Large databases of genes previously unrecognized as osteoblast-associated and falling into many functional clusters (e.g., transcription factors, transport molecules, cell cycle- and apoptosis-related molecules, cytokines-chemokines, extracellular matrix proteins, proteases, receptors, members of signal transduction pathways, molecules involved in lipid metabolism, cytoskeletal proteins, growth and differentiation factors, and others) are becoming available. Although the availability of such databases is increasing daily, in many, but not all, cases the data remain descriptive and issues remain not the least of which is the need for more highly purified populations of cells for analysis, more sophisticated bioinformatics approaches and more functional analysis of differentially expressed genes and gene families. Nevertheless, such interesting and important osteoblast-regulatory molecules as Osx (Nakashima *et al.*, 2002) were identified by such a strategy.

TRANSCRIPTION FACTOR, HORMONE, CYTOKINE, AND GROWTH FACTOR REGULATION OF CFU-F AND OSTEOPROGENITOR CELL PROLIFERATION AND DIFFERENTIATION

Transcription factors, hormones, cytokines, growth factors, and their receptors can serve both as markers and as stage-specific regulators of osteoblast development and differentiation (Fig. 1). It is beyond the scope of this chapter to review every factor known to influence osteoblast differentiation and bone formation at some level, because many will be covered in other chapters. However, a few examples are given that emphasize other issues discussed in this chapter, including heterogeneity of osteoblast response, proliferation–differentiation coupling, and differentiation stage-specific regulatory mechanisms.

Regulation by Transcription Factors

Transcription factors known to regulate osteoblast recruitment, osteoblast number, and the rate and duration of osteoblast activity are growing in number. For example, it is already evident from the preceding summary that Runx2 is necessary for osteoblast development, but Ducy *et al.* (1999) used a dominant-negative strategy in transgenic mice to show that Runx2 plays a role beyond osteoblast development, i.e., it also regulates the amount of matrix deposited by osteoblasts in postnatal animals. Several transcription

factors that belong to homeobox protein families [msh homeobox homologue 1 and 2 (Msx1 and Msx2) and Distal-less homeobox 5 and 6 (Dlx5 and Dlx6)] also play a role in osteoblast differentiation. For example, an activating mutation in Msx2 underlies Boston-type craniosynostosis (Ma *et al.*, 1996) whereas Msx2 inactivation in mice delays skull ossification, an outcome associated with decreased Runx2 expression (Satokata *et al.*, 2000). However, although it is clear that Msx2 is a positive regulator of bone formation *in vivo* (Ichida *et al.*, 2004; Ishii *et al.*, 2003), there are discrepant data on the underlying cellular mechanisms, i.e., effects of Msx2 on proliferation–differentiation. Differentiation stage-specific effects may provide at least a partial answer because endogenous Msx2 is expressed at higher levels in osteoprogenitors and is downregulated during differentiation (Hassan *et al.*, 2004). Thus, Msx2 stimulates proliferation and osteoblast differentiation in some mesenchymal cell lines (Cheng *et al.*, 2003) but inhibits Runx2 activity and osteoblast gene expression in more mature osteoblasts *in vitro* (Newberry *et al.*, 1998; Shirakabe, 2001; Lee, 2005). Other studies *in vitro* (Dodig *et al.*, 1999) and in mice (Liu *et al.*, 1999) suggest that enhanced expression of Msx2 keeps osteoblast precursors transiently in a proliferative state, delaying osteoblast differentiation, resulting in an increase in the osteoblast pool and ultimately in an increase in bone growth. It is worth noting that Msx2 promotes vascular calcification by activating paracrine Wnt signaling (Shao *et al.*, 2005).

Another example of skeletal site-specific effects is with Dlx5, which is expressed in osteoblasts in the entire skeleton, but whose deletion in mice results in abnormalities restricted to craniofacial bones. With a phenotype reminiscent of that seen in people with split-hand/split-foot malformation (SHFM), $Dlx5^{-/-}Dlx6^{-/-}$ mice have severe abnormalities in craniofacial bone formation, with complete absence of the calvaria, maxilla, and mandible, and anomalies in the axial and appendicular skeletons (Robledo *et al.*, 2002). It is not yet clear whether the defects in osteoblastogenesis are secondary to the retarded chondrocyte maturation that is also seen in $Dlx5^{-/-}Dlx6^{-/-}$ mice. However, Dlx5 is expressed in osteoprogenitors and expression levels increase in more mature osteoblasts (Hassan *et al.*, 2004; Newberry *et al.*, 1998; Ryoo *et al.*, 1997) where it activates expression of Runx2, BSP, and OCN (Holleville *et al.*, 2007).

Many members of the AP1 subfamily of leucine zipper-containing transcription factors regulate osteoblast differentiation and activity and two striking examples are summarized here [for review see Wagner and Eferl (2005)]. Osteosclerosis results when either Fra-1 (Jochum *et al.*, 2000), a Fos-related protein encoded by the c-Fos target gene *Fosl1* (referred to as *fra-1*), or ΔFosB, a naturally occurring splice variant of FosB (Sabatakos *et al.*, 2000), are overexpressed in transgenic mice. In both cases, the mice appear normal at birth, but with time, much increased bone formation is evident throughout the skeleton (endochondral and intramembranous bones). The osteosclerotic phenotype derives from a cell autonomous modulation of osteoblast lineage cells that is characterized by accelerated and more osteoblast differentiation and bone nodule formation *in vitro*. In a reciprocal experiment, when Fra-1 was deleted conditionally in embryonic tissues of mice, postnatal mice became progressively osteopenic; although osteoblasts were present in normal numbers, they appeared less mature and showed severely reduced bone-forming activity that included reduced expression of Col1a2, OCN, and matrix Gla protein (MGP) (Eferl *et al.*, 2004). It is still not clear mechanistically how ΔFosB expression leads to osteosclerosis. Initial suggestions that ΔFosB favored commitment of mesenchymal precursors cells toward an osteoblast fate rather than an adipogenic fate were consistent with the low fat mass of the osteosclerotic mice; it was subsequently shown that the changes in osteoblast and adipocyte differentiation in the ΔFosB mice resulted from independent cell autonomous mechanisms in adipocyte and osteoblast lineages (Kveiborg *et al.*, 2004). It is, therefore, worth noting that it is the further truncated Δ2ΔFosB isoform, rather than ΔFosB itself, that is responsible for the increased bone formation seen in ΔFosB transgenic mice. This suggests that further study of differentiation stage-specific aspects of the mechanism may shed light on the underlying osteoblast lineage perturbation, as differentiation stage-specific alternative splicing of fosB mRNA and selective initiation site use of ΔFosB appear to be involved (Sabatakos *et al.*, 2000).

Mice homozygous for mutations in the gene (AIM) encoding the nonreceptor tyrosine kinase c-Abl also have a bone phenotype, including osteoporotic (both thinner cortical and reduced trabecular) bones and reduced mineral apposition rates (Li *et al.*, 2000), apparently reflecting no change in osteoclast number or activity but an osteoblast defect manifested by delayed maturation *in vitro*. Whether a cell autonomous defect in osteoblasts is responsible for the osteopenia seen in the spontaneous mouse mutant staggerer (sg/sg) (Meyer *et al.*, 2000), which carries a deletion within the retinoic acid receptor-related orphan receptor a (RORα) gene, remains to be determined, but because RORα appears to regulate BSP and OCN transcriptionally, this is clearly one possibility, given the increased bone formation seen earlier in OCN null mice (Ducy *et al.*, 1996). The leucine-zipper containing protein ATF4, which is highly enriched in osteoblasts, regulates bone formation by regulating amino acid import (Yang *et al.*, 2004). This function requires the phosphorylation of ATF4 by the kinase Rsk2, which is inactivated in Coffin–Lowry syndrome and increased in osteoblasts in another disease, neurofibromatosis type 1 (Elefteriou *et al.*, 2006). Given the preceding summary of some of the AP1 factors, it is worth noting that Jun proteins can also interact with ATF family

members, raising the possibility that heterodimerization with ATF4 may be one mechanism by which these proteins can regulate osteoblast-specific gene expression (Chinenov and Kerppola, 2001).

Regulation by Hormones, Growth Factors, and Cytokines

Bone marrow injury associated with local bleeding, clotting, and neovascularization recapitulates a process similar to the normal developmental process and callus formation during fracture repair, with the induction of an environment rich in growth factors (e.g., PDGF, FGF, TGFβ, VEGF) followed by a process of very active bone formation [reviewed in Carano and Filvaroff (2003); Gerstenfeld *et al.* (2003); Harada and Rodan (2003)]. Similarly, in inflammatory bone disease (e.g., the subchondral bone loss seen in rheumatoid arthritis or the alveolar bone loss seen in periodontal disease), high levels of numerous cytokines (e.g., interferons, TNFα, IL1, IL6, and other gp130 family cytokines, etc.) are seen that often associated with stimulation of osteoclastogenesis but which may play direct roles in osteoblasts as well, either directly or as a consequence of release from the bone matrix [(reviewed in Findlay and Haynes (2005); Franchimont *et al.* (2005)]. Similar cytokines and growth factors are likely to contribute to the "vicious cycle" of osteolytic and osteoblastic bone disease seen in tumor metastases (reviewed in Chirgwin (2007)]. These and other cytokines may play roles in normal bone remodeling and osteoporosis (Eriksen *et al.*, 2007; Martin and Sims, 2005; Raisz, 2005). Thus, a growing list of systemic or local growth factors, cytokines, and hormones are being tested in animal models and cellular models *in vitro* and combinations of the two. Differing requirements and opposite results have sometimes been reported depending on the species studied and the model cell system under study (e.g., bone marrow stroma versus calvariae-derived populations), whether total CFU-F or specific subpopulations (e.g., CFU-ALP, CFU-O) are quantified, and the presence or absence of other factors. Nevertheless, because of increasingly detailed evaluation of bone parameters *in vivo* and careful documentation of proliferation and differentiation stages underlying the formation of CFU-F and bone nodules/CFU-O *in vitro*, the models are helping to clarify the nature of perturbations in a carefully orchestrated osteoprogenitor proliferation–osteoblast differentiation and activity sequence. As previously, it is not possible to summarize the effects of all hormones, cytokines, and growth factors that are being investigated in osteoblast lineage cells, but a few representative examples will highlight important concepts by which the target cells responding (stem cells, mesenchymal precursors, committed progenitors) and the precise nature of the responses in bone and nonbone cells in these complex environments are being elucidated.

There is substantial evidence that at least some of the actions of growth and differentiation factors depend on the relative stage of differentiation (either more or less mature) of the target cells, with the same factor sometimes having opposite effects on proliferative/progenitor stages and differentiation stages; the situation is even more complex when effects are differentiation stage-specific and mature osteoblast activity is also affected (Fig. 3). For example, the inflammatory cytokine IL-1 is stimulatory to CFU-O formation when calvaria-derived cultures are exposed transiently during proliferative culture stages, and inhibitory when cells are exposed to the same doses transiently during differentiation stages; the inhibitory effects dominate when cells are exposed chronically through proliferation and differentiation stages in culture (Ellies and Aubin, 1990). Many other factors of current interest similarly have

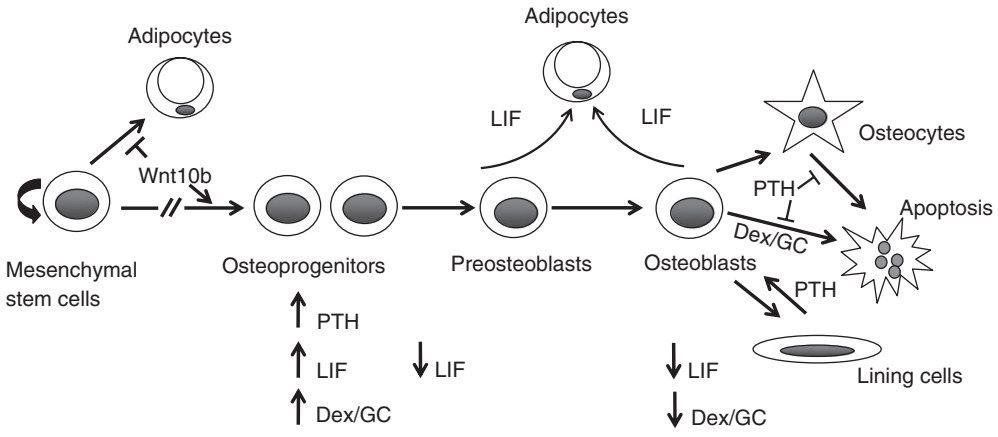

FIGURE 3 Regulation of osteoblast differentiation by hormones and cytokines. The list is not exhaustive, but examples are given to highlight some of the concepts discussed in the text.

biphasic or multiphasic effects *in vitro*, including EGF, TGFβ, and PDGF [for review see Aubin (2001)].

Members of the leukemia inhibitory factor (LIF)/IL6 family, including IL6, IL11, oncostatin M (OSM), and cardiotrophin-1 (CT-1) also fall into the category of factors with biphasic or multiphasic effects. These cytokines have long been studied as positive regulators of osteoclastogenesis and bone resorption. However, a wide variety of data indicate that at least some of the cytokines that signal through the gp130 receptor are also regulators of osteoblast lineage cells and bone formation. Metcalf and Gearing showed almost 20 years ago that mice engrafted with cells overexpressing LIF developed a fatal syndrome characterized by, among other features including cachexia, excessive new bone formation and ectopic calcifications in skeletal muscles and heart (Metcalf and Gearing, 1989). That LIF/IL-6 cytokine signaling is normally required in bone is exemplified by Stuve–Wiedemann syndrome, a severe autosomal recessive genetic disease whose prominent features include bowing of long bones, cortical thickening, and altered trabecular pattern, recently shown to result from null mutations of LIFR (Dagoneau *et al.*, 2004). Further, a series of mouse knockout and knockin studies showed that LIFR and gp130 are necessary for normal mouse bone development, because their absence leads to profound osteopenia accompanied by increased osteoclast number (Ware *et al.*, 1995; Yoshida *et al.*, 1996). With respect to bone formation, lack of gp130 signaling alters osteoblast phenotype and activity (Shin *et al.*, 2004), and loss of SHP2/ras/MAPK activation by gp130 induces high bone turnover with increased formation and resorption (Sims *et al.*, 2004). However, the nature of the target cells in bone and their response to changes in gp130 signaling are generally not yet clear. Further, a plethora of often contradictory data on effects of LIF/IL-6 family members on stromal and osteoblast lineage cells *in vitro* has been reported, with stimulatory, inhibitory, and biphasic effects on osteoprogenitor proliferation and differentiation. For example, LIF inhibits osteoprogenitor differentiation (i.e., bone nodule formation) in the rat calvaria (RC) cell culture model in a very differentiation stage-specific manner, i.e., at a late osteoprogenitor–early preosteoblast stage (Malaval *et al.*, 1995, 1998). In contrast, in rat bone marrow stromal cell cultures, LIF over the same concentration ranges stimulates nodule formation in early proliferation stages, but inhibits it at later times similarly to what is seen in RC cultures (Malaval and Aubin, 2001). Similarly, although IL-11 has also been described to inhibit osteogenesis in RC cultures (Hughes and Howells, 1993), it stimulates it in bone marrow stromal cell cultures (Suga *et al.*, 2001) and promotes osteoblast differentiation and bone apposition in transgenic mice and IL-11 overexpressing stromal cell cultures through STAT potentiation of the action of Smads (Takeuchi *et al.*, 2002). mOSM is the only member of the LIF/IL-6 family to increase osteoprogenitor recruitment (bone nodule formation) in RC cell cultures, and it does so during proliferation stages or at relatively early stages of differentiation (days 1–3/4 of culture) (Malaval *et al.*, 2005). Thus, LIFR and OSMR appear to display differential effects on differentiation and phenotypic expression of osteoblasts, apparently via different signals. The data suggest that IL-6, IL-11, which shares the gp130/gp130 receptor, and other family members act differently on the periosteum/suture and bone-tissue-derived RC cell population compared with stromal/endosteal cells. The observation that the inhibitory effect of LIF in RC cell cultures may occur at least in part through the ability of LIF to alter the fate of precursors away from the osteoblast lineage and toward the adipocytic lineage (Falconi *et al.*, 2007), together with the increased expression of LIF/IL-6 cytokines after menopause (Manolagas and Jilka, 1995) and PTH treatment (Greenfield *et al.*, 1996), and that the bone matrix synthesized by LIF-treated osteoblasts is abnormal (Cornish *et al.*, 1993; Falconi and Aubin, 2007) suggests that further detailed analyses of the gp130 family of cytokines are warranted.

An example of clinical significance is the effect of PTH on osteoblast lineage cells and its catabolic (chronic PTH treatment) versus anabolic (intermittent) action on bone. PTH receptor (PTH1R) is expressed throughout osteoblast differentiation, although the levels of expression and activity appear to increase as osteoblasts mature (Liu *et al.*, 2003). It is therefore not surprising that PTH elicits widespread but diverse effects on both early osteoprogenitor cells and mature osteoblastic cells (osteoblasts, osteocytes, lining cells) *in vivo* and *in vitro*, but analyses continue to reveal the basis of the bone effects seen. Analyses of bones from people and animals treated intermittently with PTH show that the increase in bone formation appears to be caused by an increase in the number of matrix-synthesizing osteoblasts; increased osteoblast development, attenuation of osteoblast apoptosis (Jilka *et al.*, 1999), and activation of quiescent lining cells (Dobnig and Turner, 1995) have all been proposed as explanations for this effect of PTH as either direct or indirect (from changes in expression of other growth factors) consequences [for reviews see Aubin and Heersche (2001); Jilka (2007); Rosen (2003)]. Chronic exposure to PTH inhibited osteoblast differentiation and bone nodule formation in an apparently reversible manner at a relatively late preosteoblast stage in rat calvarial cells *in vitro* (Bellows *et al.*, 1990b). However, when the cells were treated for 1-hour versus 6-hour pulses in 48-hour cycles during a 2- to 3-week culture period, either inhibition (1-hour pulse; apparently related to cAMP/PKA pathways) or stimulation (6-hour pulse; apparently related to cAMP/PKA, Ca^{2+}/PKC, and IGF-I) in osteoblast differentiation and bone nodule formation was seen (Ishizuya *et al.*, 1997). On the other hand, analysis of numbers of colony numbers in marrow stromal cell cultures from mice treated with intermittent PTH showed no increase in CFU-O (Jilka *et al.*, 1999). In mice deficient in PTH1R, not only is a well-studied

defect in chondrocyte differentiation seen (as also seen in PTHrP knockout mice), but also increased osteoblast number and increased bone mass (a phenotype not seen in PTHrP-deficient mice) (Lanske *et al.*, 1999), supporting the view that PTH plays an important role in the regulation of osteoblast number and bone volume. When Calvi *et al.* (2001) expressed constitutively active PTH1R in bone, osteoblastic function was increased in the trabecular and endosteal compartments, but decreased in the periosteum of both long bones and calvaria. Interestingly, a decrease in osteoblast apoptosis and an apparent increase in both osteoblast precursor proliferation and mature osteoblasts were seen in trabecular bone. The latter is also important in relation to the observation that bone comprises the HSC niche and that constitutively active PTH1R signaling with the expanded osteoblastic cell pool (Calvi *et al.*, 2003) and PTH treatment (Adams *et al.*, 2007) expands the HSC pool.

Review of all regulatory factors is beyond the scope of this chapter, and indeed, I have not touched on a growing number of reports on matrix and matrix–integrin effects on osteoblast development and/or activity *in vitro* and *in vivo* [see, e.g., Franceschi *et al.* (2003); Rubin *et al.* (2006)]. However, given their inclusion in the majority of CFU-F and CFU-O assays *in vitro* reported in this chapter, it is worth considering glucocorticoids (most often dexamethasone in *in vitro* assays) in more detail. Glucocorticoid effects *in vivo* and *in vitro* are complex and often opposite, i.e., stimulating osteoprogenitor self-renewal and differentiation *in vitro* in calvaria (and other bones)-derived and stromal cell models [Aubin, 1999; Purpura *et al.*, 2004; reviewed in Aubin (2001)] while stimulating osteoblast apoptosis (Gohel *et al.*, 1999; Weinstein *et al.*, 1998) and resulting in glucocorticoid-induced osteoporosis *in vivo* (Weinstein, 2001; Weinstein *et al.*, 1998). In an interesting recent report, Teitelbaum and colleagues found that whereas glucocorticoids delay osteoclast apoptosis, they retard the capacity of osteoclasts to resorb bone, *in vitro* and *in vivo*, by disrupting the cytoskeleton (Kim *et al.*, 2006). Notably, the arrested resorption induced by glucocorticoids translated to dampened osteoblast activity, in other words suppression of the resorptive phase of remodeling, contributes to the retarded bone formation central to glucocorticoid-induced osteoporosis (Kim *et al.*, 2007). The mechanisms by which osteoclasts signal to control osteoblast formation and activity deserve more attention (Kim *et al.*, 2007; Martin and Sims, 2005).

A mechanism by which glucocorticoids may act is through autocrine or paracrine regulatory feedback loops in which the production of other factors is modulated, including growth factors and cytokines that themselves regulate the osteoblast differentiation pathway. For example, in rat calvaria cultures, glucocorticoids downregulate the endogenous production of LIF, which, as summarized earlier, is inhibitory to bone nodule formation when cells are treated at a late progenitor/preosteoblast stage (Malaval *et al.*, 1998), and upregulate BMP-6, which is stimulatory possibly through LMP-1, a LIM domain protein (Boden *et al.*, 1998). These are but two of a growing list of examples of glucocorticoid regulation of endogenously produced factors with apparently autocrine or paracrine activities on osteoblast lineage cells (Liberman *et al.*, 2007).

Many factors of interest have effects on gene expression in mature osteoblasts that may correlate with effects on the differentiation process and may be opposite for different osteoblast genes, with glucocorticoids being a case in point. The molecular mechanisms mediating these complex effects are generally poorly understood; however, the ability to form particular transcription factor complexes, localization and levels of endogenous expression of cytokine/hormone/growth factor receptors, and expression of cognate or other regulatory ligands within specific subgroups of osteogenic cells as they progress from a less to a more differentiated state may all play roles. As mentioned earlier, growing evidence shows that the probability for self-renewal versus differentiation of hemopoietic stem cells is regulated, at least in part, by the maintenance of required/critical signaling ligands (soluble or matrix or cell-bound) above a threshold level. Although there are few explicit data or experiments examining these issues in MSCs or osteoprogenitor populations, it seems likely that similar threshold controls may apply.

STEM CELL/OSTEOPROGENITOR CELL CHANGES IN DISEASE AND AGING

The formation of colonies reflecting specific progenitor cell types (i.e., CFU-F, CFU-O, etc.) provides an estimate of the stem/progenitor cell status in normal or diseased states, as reflected in the numerous examples summarized earlier with genetically modified mice or animals treated with hormones and factors of interest. However, many discrepancies exist when such colony-counting methods have been used to assess changes in stem/progenitor frequency in aging people or animals and in certain disease models, probably reflecting such variables as age groups tested and culture parameters including whether cell enrichment/fractionation strategies were used. A decline in CFU-F, CFU-O, and CFU-ALP size and number with age has been reported in some studies done on stromal cell populations isolated from mice, rats, and humans, but in others no significant changes have been found [Bellows *et al.*, 2003; Bonyadi *et al.*, 2003; D'Ippolito *et al.*, 1999; Jilka *et al.*, 1996; Kajkenova *et al.*, 1997; Nishida *et al.*, 1999; Oreffo *et al.*, 1998; Stenderup *et al.*, 2001; for review, see Stolzing and Scutt (2006)]. Beyond a potential change in number, some data suggest an age-related loss of differentiation potential, loss of proliferation potential, loss of self-renewal capacity, impaired production and/or response to hormones and factors stimulating osteogenesis, and increases in senescence

[Gazit, 1998; Erdmann, 1999; Fujieda, 1999; Stenderup, 2003; Abdallah, 2006; for recent reviews, see Carrington (2005); Manolagas and Almeida (2007)].

Taken together, the known loss of bone with aging or menopause may be caused not only by a decrease in MSC or osteoprogenitor number, but also by a reduced responsiveness of osteoprogenitor cells to biological factors resulting in an alteration in their subsequent differentiation potentials or to local bone environment changes in these factors. This has fundamental and strategic implications regarding therapeutic intervention to prevent bone loss and to increase bone mass in postmenopausal women and in aging populations. It also opens up possibilities for experimental studies to test whether the necessary growth factors can be supplied to the deficient site by the transfer of marrow stroma from one bone tissue site to another or by genetically engineered autologous cell therapy. There has been an explosion of interest in the potential use of adult MSCs—among other cell sources including embryonic stem cells—for therapy in many degenerative disorders of metabolic, environmental, and genetic origins. The interest is documented by the rapid rise in research publications in this area, and MSCs have been noted to have potentials far beyond skeletal reconstruction and augmentation of skeletal mass [for recent reviews, see Delorme *et al.* (2006); Kassem (2004); Phinney and Prockop (2007); Shefer and Yablonka-Reuveni (2007)]. However, much remains to be done to define both MSC and osteoprogenitor number and differentiation capacity in normal aging and in various disease states including osteoporosis.

Transcriptional regulation of gene expression is a key mechanism controlling cellular differentiation and function in all cell types. Osteoblasts differentiate from mesenchymal precursor cells and then produce the bone-specific extracellular matrix. The identification of the key transcriptional events required for osteoblast differentiation and function was not as easy using *in vitro* or *ex vivo* approaches, which is best explained by the fact that osteoblast differentiation in the culture dish is not associated with obvious changes in cellular morphology. However, in the past decade these limitations have been overcome owing to a combination of molecular efforts and genetic studies in mice and humans. This chapter summarizes our current knowledge about the transcriptional control of osteoblast differentiation and function.

Runx2, A MASTER CONTROL GENE OF OSTEOBLAST DIFFERENTIATION AND FUNCTION

The power of a combined effort between molecular biologists and human geneticists in identifying key genes regulating cell differentiation, which has been so beneficial for our understanding of skeletal biology, is best illustrated by the discovery of Runx2 as the master gene of osteoblast differentiation. Runx2, previously termed Pebp2a1, Aml3, or Cbfa1, was originally cloned in 1993 as one of three mammalian homologues of the *Drosophila* transcription factor Runt (Kagoshima *et al.*, 1993; Ogawa *et al.*, 1993). Based on the finding that it is expressed in thymus and T-cell lines, but not in B-cell lines, Runx2 was thought to be involved in T-cell differentiation (Ogawa *et al.*, 1993; Satake *et al.*, 1995). However, 4 years after the cloning of Runx2, its crucial role as a transcriptional activator of osteoblast differentiation was demonstrated by several investigators at the same time using different experimental approaches (Ducy *et al.*, 1997; Komori *et al.*, 1997; Lee *et al.*, 1997; Mundlos *et al.*, 1997; Otto *et al.*, 1997).

One approach, purely molecular, aimed at the identification of osteoblast-specific transcription factors by using the *Osteocalcin* gene as a tool. The analysis of a proximal promoter fragment of one of the two mouse *Osteocalcin* genes, active only in osteoblasts, led to the identification of the only two known osteoblast-specific *cis*-acting elements, termed OSE1 and OSE2 (Ducy and Karsenty, 1997). Sequence inspection of OSE2 revealed homology to the DNA-binding site of Runt family transcription factors, and subsequent analysis demonstrated that the factor binding to OSE2 is related immunologically to transcription factors of the Runt family (Geoffroy *et al.*, 1995; Merriman *et al.*, 1995). Eventually, screening of a mouse primary osteoblast cDNA library revealed that only one of the three mammalian *Runx* genes, namely *Runx2*, is expressed predominantly in cells of the osteoblast lineage (Ducy *et al.*, 1997).

In situ hybridization further revealed that during mouse development, *Runx2* is first expressed in the lateral plate mesoderm at 10.5 days post-coitus (dpc), and later in cells of the mesenchymal condensations. Until 12.5 dpc these cells, which prefigure the future skeleton, represent common precursors of osteoblasts and chondrocytes. At 14.5 dpc osteoblasts first appear and maintain the expression of *Runx2*, whereas in chondrocytes *Runx2* expression is decreased significantly and restricted to prehypertrophic and hypertrophic chondrocytes. After birth, *Runx2* expression is strictly restricted to osteoblasts and cells of the perichondrium. Taken together, this spatial and temporal

expression pattern suggested a critical role for Runx2 as a regulator of osteoblast differentiation (Ducy *et al.*, 1997).

The demonstration that this was the main function of Runx2 came from several lines of molecular and genetic evidence. First, in addition to the *Osteocalcin* promoter, functional OSE2-like elements were identified in the promoter regions of most other genes that are expressed at relatively high levels in osteoblasts, such as *α1(I) collagen, Osteopontin*, and *Bone sialoprotein* (Ducy *et al.,* 1997). Second, and more importantly, the forced expression of *Runx2* in nonosteoblastic cell lines or primary skin fibroblasts induced osteoblast-specific gene expression in these cells, demonstrating that Runx2 acts as a transcriptional activator of osteoblast differentiation *in vitro* (Ducy *et al.*, 1997). Third, the ultimate demonstration that Runx2 is an indispensable transcriptional activator of osteoblast differentiation came from genetic studies in mice and humans.

At the same time, two groups deleted the *Runx2* gene from the mouse genome, both expecting an immunological phenotype based on the assumption that *Runx2* was involved in T-cell differentiation (Komori *et al.*, 1997; Otto *et al.*, 1997). However, unexpectedly, all *Runx2*-deficient mice died immediately after birth owing to respiratory failure caused by the complete absence of endochondral and intramembranous bone formation. Most importantly, there are no osteoblasts in *Runx2*-deficient mice, which was confirmed by the lack of expression of osteoblast marker genes, as demonstrated by *in situ* hybridization.

The critical importance of Runx2 for osteoblast differentiation was further underscored by the finding that mice lacking only one allele of *Runx2* display hypoplastic clavicles and delayed closure of the fontanelles, i.e., defects of intramembranous ossification (Otto *et al.,* 1997). This phenotype is identical to what is seen in the human disease cleidocranial dysplasia (CCD), and subsequent genetic analysis of CCD patients revealed disease-causing heterozygous mutations of the *RUNX2* gene, thereby demonstrating the relevance of Runx2 for osteoblast differentiation also in humans (Lee *et al.,* 1997; Mundlos *et al.,* 1997). Taken together, this overwhelming molecular and genetic evidence has led to the generally accepted view that Runx2 is a master control gene of osteoblast differentiation, providing a molecular switch inducing osteoblast-specific gene expression (Lian and Stein, 2003).

In addition to its prominent role in osteoblast differentiation, Runx2 is also involved in the regulation of bone formation beyond development. This has been demonstrated in several ways. First, transgenic mice expressing a dominant-negative variant of Runx2 specifically in fully differentiated osteoblasts are viable, but develop severe osteopenia caused by a decreased rate of bone formation, in the light of normal osteoblast numbers (Ducy *et al.,* 1999). This phenotype is readily explained by the finding that several Runx2 target genes encoding bone extracellular matrix proteins are expressed at much lower levels. Second, mice lacking *Stat1*, a transcription factor attenuating the nuclear translocation of Runx2, as discussed later, display a high-bone-mass phenotype that is not only explained by increased osteoblast differentiation, but also by increased bone matrix deposition (Kim *et al.,* 2003). Third, a similar, but even more severe phenotype is observed in mice lacking the nuclear adapter protein Shn3. Because Shn3, as discussed later, is involved in the ubiquitination and proteasomal degradation of Runx2, the increased bone formation of the *Shn3*-deficient mice is readily explained by increased Runx2 levels in osteoblasts that in turn lead to enhanced bone matrix deposition (Jones *et al.*, 2006). Given these results, it came as a surprise that another transgenic mouse model, overexpressing intact *Runx2* under the control of an osteoblast-specific *α1(I)-Collagen* promoter fragment, did not display the expected high-bone-mass phenotype, but a severe osteopenia accompanied by an increased fracture risk (Liu *et al.,* 2001). Although these mice had increased numbers of osteoblasts, their bone formation rate was strikingly reduced, which likely illustrates the fact that the dosage of Runx2 needs to be tightly regulated in order to orchestrate proper bone formation *in vivo*.

Runx2 FUNCTIONS DURING SKELETOGENESIS BEYOND OSTEOBLAST DIFFERENTIATION

Although most of these results demonstrating a key role of Runx2 in osteoblasts were already discussed in the last edition of this book, there is accumulating novel evidence that the role of Runx2 in skeletogenesis is much more complex than previously anticipated. The starting point for these findings was the observation that *Runx2*-deficient mice also display defects of chondrocyte hypertrophy in some skeletal elements (Inada *et al.,* 1999; *Kim et al.,* 1999). Moreover, because *Runx2* is transiently expressed in prehypertrophic chondrocytes of mouse embryos, there was a possibility for a function of Runx2 in chondrocyte differentiation. One way to address this possibility was the generation of a transgenic mouse model expressing *Runx2* in nonhypertrophic chondrocytes, using a *α1(II)-Collagen* promoter/enhancer construct (Takeda *et al.*, 2001).

In line with the suspected role of Runx2 as a positive regulator of chondrocyte hypertrophy, these transgenic mice displayed accelerated chondrocyte maturation in the growth plates, but also evidence of ectopic cartilage formation in the rib cage or in the trachea, among other locations. Moreover, the presence of this transgene in a *Runx2*-deficient genetic background prevented the absence of skeletal mineralization that is normally associated with the *Runx2* deficiency. However, the skeleton of these mice only contained hypertrophic cartilage, but no bone matrix, thereby demonstrating that Runx2 induces chondrocyte hypertrophy, but not a transdifferentiation into osteoblasts (Takeda *et al.*, 2001).

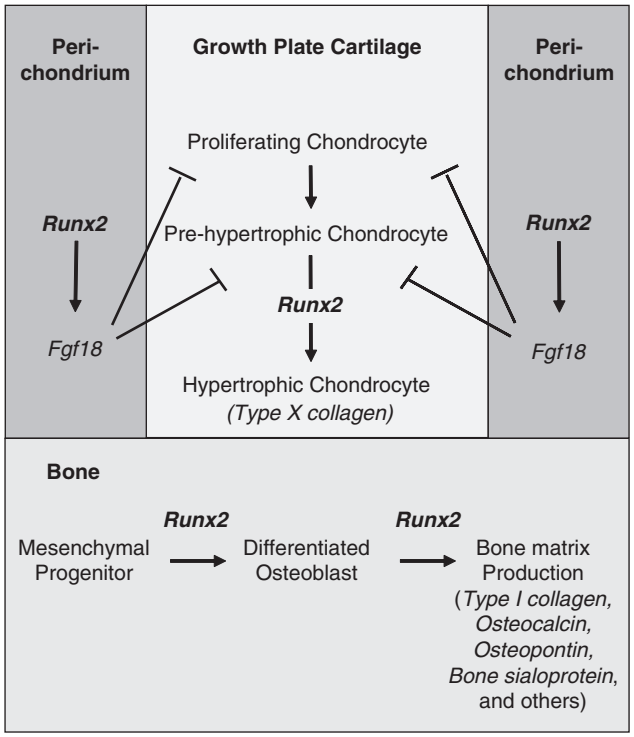

FIGURE 1 Runx2, a major regulator of skeletal development. Trough is transient embryonic expression in prehypertrophic chondrocytes. Runx2 positively regulates chondrocyte hypertrophy by activating the expression of target genes, such as type X collagen (Zheng *et al.*, 2003). Additionally, Runx2 has a negative effect on chondrocyte maturation by increasing the expression of Fgf18 in cells of the perichondium (Hinoi *et al.*, 2007). Besides this regulation of skeletal growth, Runx2 plays a key role in osteoblast differentiation and function, where it activates the expression of several target genes (Ducy *et al.*, 1997; Vaes *et al.*, 2006; Hecht *et al.*, 2007).

Because *Runx2* expression in prehypertrophic chondrocytes is transient, the main function of Runx2 here is probably to establish the growth plate. However, through another site of expression, namely in perichondrial cells, Runx2 has an additional function in the regulation of chondrogenesis. In these cells Runx2 positively regulates the expression of Fgf18, a diffusible molecule that inhibits chondrocyte maturation and osteoblast differentiation (Hinoi *et al.*, 2006; Liu *et al.*, 2002; Ohbayashi *et al.*, 2002). Taken together, these results establish that Runx2 is more than the master gene of osteoblast differentiation, it is, in fact, along with Sox9, the major transcriptional regulator of cell differentiation during skeletogenesis, acting positively and negatively on osteoblast and chondrocyte differentiation (Fig. 1).

REGULATORS OF Runx2 AND THEIR IMPORTANCE FOR SKELETAL BIOLOGY

Given the central role played by Runx2 in skeletal cell differentiation, it is not surprising that other transcription factors playing a role in the regulation of osteoblast differentiation and bone formation exert their functions in a Runx2-dependent manner. Some of these factors regulate, directly or indirectly, transcription of the *Runx2* gene, whereas others, as already mentioned earlier for Stat1 and Shn3, interact with the Runx2 protein and modulate its activity. Although the interplay of these factors is still far from being completely understood, it is increasingly clear, that there are positive and negative influences on Runx2 expression and function, playing a role at different stages of development, but also in different skeletal elements. Therefore, this part of the chapter will focus on some of the best-characterized regulators of Runx2, whose function in skeletal biology was demonstrated by the genetic analysis of mouse models or human patients, as well as by molecular biology experiments.

For instance, there are several lines of evidence showing that certain homeodomain-containing transcription factors are involved in the regulation of *Runx2* expression. One of these proteins is Msx2, whose role in skeletal development was demonstrated through the identification of gain- and loss-of-function mutations in human patients suffering from Boston-type craniosynostosis or enlarged parietal foramina, respectively (Jabs *et al.*, 1993; Wilke *et al.*, 2000). Likewise, *Msx2*-deficient mice display defective ossification of the skull and of bones developing by endochondral ossification (Satokata *et al.*, 2000). Moreover, because the expression of *Osteocalcin* and *Runx2* is strongly reduced in *Msx2*-deficient mice, it appears that Msx2 acts upstream of Runx2 in a transcriptional cascade regulating osteoblast differentiation. A similar observation has been described for mice lacking the homeodomain-containing transcription factor Bpx (Tribioli and Lufkin, 1999). These mice die at birth owing to a severe dysplasia of the axial skeleton, whereas the appendicular skeleton is virtually unaffected. *Runx2* expression in *Bpx*-deficient mice is strongly reduced in osteochondrogenic precursor cells of the prospective vertebral column, thereby indicating that Bpx is required for *Runx2* expression specifically in these skeletal elements.

There are also negative regulators of *Runx2* expression. One of them is the homeodomain-containing transcription factor Hoxa2. *Hoxa2*-deficient mice display ectopic bone formation in the second branchial arch, which is readily explained by an induction of *Runx2* expression exactly in this region (Kanzler *et al.*, 1998). Consistently, transgenic mice expressing *Hoxa2* in craniofacial bones under the control of an *Msx2* promoter fragment lack several bones in the craniofacial area. Beyond development there is at least one factor required to limit *Runx2* expression in osteoblast precursor cells, namely, the high-mobility group containing transcription factor Sox8. *Sox8*-deficient mice display an osteopenia that is caused by accelerated osteoblast differentiation accompanied by enhanced expression of *Runx2* (Schmidt *et al.*, 2005). Likewise, transgenic mice expressing *Sox8* under the control of an osteoblast-specific

α1(I)-Collagen promoter fragment virtually lack differentiated osteoblasts because of decreased expression of *Runx2*.

In addition to the existence of transcriptional regulators of *Runx2* expression, there are also factors interacting with the Runx2 protein, thereby activating or repressing its activity. One recently identified positive regulator of Runx2 action is the nuclear matrix protein Satb2. The importance of this protein in skeletogenesis was first discovered in human patients with cleft palate that carry a heterozygous chromosomal translocation inactivating the *SATB2* gene (Fitzpatrick *et al.*, 2003). The generation of a *Satb2*-deficient mouse model confirmed the importance of this gene in craniofacial development, skeletal patterning, and osteoblast differentiation (Dobreva *et al.,* 2006). The latter function was in part attributed to an increased expression of *Hoxa2*, a negative regulator of bone formation discussed earlier, whose expression is repressed by the binding of Satb2 to an enhancer element of the *Hoxa2* gene.

In addition to this type of action, there is also a Hoxa2-independent influence of Satb2 on the transcription of *Bone Sialoprotein* and *Osteocalcin*. Whereas, in the case of *Bone Sialoprotein,* Satb2 directly binds to an osteoblast-specific element in the promoter of this gene, the activation of *Osteocalcin* expression by Satb2 requires a physical interaction with Runx2. This was demonstrated by cotransfection assays using a *Luciferase* reporter gene under the control of an osteoblast-specific *Osteocalcin* promoter fragment, but also by coimmunoprecipitation experiments. Moreover, the synergistic action of Satb2 and Runx2 in osteoblasts was genetically confirmed by the generation of compound heterozygous mice lacking one allele of each gene (Dobreva *et al.,* 2006). Taken together, these results identified Satb2 as an important regulator of osteoblast differentiation in mice and humans. Moreover, the finding, that Satb2 also interacts with ATF4, another transcription factor involved in osteoblast differentiation and function that will be discussed later, illustrates that the transcriptional network regulating bone formation is much more complex than previously anticipated.

This is underscored by the discovery of other proteins that physically interact with Runx2, thereby attenuating its activity. One of these proteins is Stat1, a transcription factor regulated by extracellular signaling molecules, such as interferons. *Stat1*-deficient mice, as already mentioned, are viable, but develop a high-bone-mass phenotype explained by enhanced bone formation (Kim *et al.,* 2003). The increase of osteoblast differentiation and function in these mice is molecularly explained by the lack of a Stat1-mediated inhibition of the transcriptional activity of Runx2. Interestingly, the physical interaction of both proteins is independent of Stat1 activation by phosphorylation, and it inhibits the translocation of Runx2 into the nucleus. Thus, overexpression of Stat1 in osteoblasts leads to a cytosolic retention of Runx2, and the nuclear translocation of Runx2 is much more prominent in Stat1-deficient osteoblasts (Kim *et al.,* 2003).

Another protein interacting with Runx2, thereby decreasing its availability in the nucleus, is Shn3. Shn3 is a zinc finger adapter protein originally thought to be involved in VDJ recombination of immunoglobulin genes (Wu *et al.*, 1993). Unexpectedly, however, the generation of a *Shn3*-deficient mouse model revealed a major function of this protein in bone formation. In fact, the *Shn3*-deficient mice display a severe adult-onset osteosclerotic phenotype owing to a cell-autonomous increase of bone matrix deposition (Jones *et al*., 2006). Interestingly, although several Runx2 target genes are expressed at higher rates in *Shn3*-deficient osteoblasts, *Runx2* expression itself is not affected by the absence of Shn3. Importantly, however, the Runx2 protein level is strikingly increased in *Shn3*-deficient osteoblasts.

This latter finding is molecularly explained by the function of Shn3 as an adapter molecule linking Runx2 to the E3 ubiquitin ligase WWP1. The Shn3-mediated recruitment of WWP1 in turn leads to an enhanced proteasomal degradation of Runx2, which is best underscored by the finding that RNAi-mediated downregulation of WWP1 in osteoblasts leads to increased Runx2 protein levels and enhanced extracellular matrix mineralization, thus virtually mimicking the defects observed in the absence of Shn3 (Jones *et al*., 2006). Taken together, these data identify Shn3 as a key regulator of Runx2 actions *in vivo*. Moreover, given the postnatal onset of the bone phenotype of the *Shn3*-deficient mice, it is reasonable to speculate that compounds blocking the interaction of Runx2, Shn3, and WWP1 may serve as specific therapeutic agents for the treatment of bone loss diseases, such as osteoporosis.

While Stat1 and Shn3 provide examples for the importance of a negative regulation of Runx2 in postnatal bone remodeling, there is also a need for a negative regulation of Runx2 activity during bone development. This is underscored by the finding that *Runx2* expression in the lateral plate mesoderm is already detectable as early as E10 of mouse development, whereas the expression of molecular markers of differentiated osteoblasts cannot be detected before E13 (Ducy, 2000). A molecular explanation for this delay between *Runx2* expression and osteoblast differentiation came from the functional analysis of Twist proteins that are transiently coexpressed with *Runx2* early during development and inhibit osteoblast differentiation by interacting with Runx2. In essence, the initiation of osteoblast differentiation occurs only when *Twist* gene expression fades away.

That Runx2 expression precedes osteoblast differentiation more than 4 days led to the assumption that Runx2 function must be regulated negatively in *Runx2*-expressing cells. The identification of such a factor relied on human genetic evidence. Haploinsufficiency at the *RUNX2* locus causes a lack of bone in the skull, whereas haploinsufficiency at the *TWIST1* locus causes essentially too much bone in the skull, a condition called craniosynostosis (El Ghouzzi *et al.*, 1997; Howard *et al.* 1997). Because the

same phenotypes are observed in the corresponding mouse models lacking one allele of either gene, it was possible to demonstrate a genetic interaction of *Runx2* and *Twist1* by the generation of compound heterozygote mice. In fact, these mice did not display any detectable defects of skull development and suture fusion (Bialek *et al.*, 2004). In contrast, the defects of clavicle development caused by haploinsufficiency of *Runx2* were not rescued by heterozygosity of *Twist1*, but by heterozygosity of *Twist2*. Thus, both Twist proteins have similar functions in different skeletal elements, which is consistent with their expression pattern in mouse embryos (Bialek *et al.*, 2004).

Both Twist proteins are basic helix-loop-helix transcription factors, yet this function of Twist is not determined by the bHLH domain, but rather by the C-terminal 20 amino acids, the so-called Twist-box, whose sequence is fully conserved in both Twist proteins, in mice and humans. Through the Twist-box, Twist proteins interact with the Runx2 DNA-binding domain and prevent its DNA binding. The importance of this sequence motif for Twist function *in vivo* was confirmed by the existence of a Twist-box mutation within the human *TWIST1* gene that causes a severe form of craniosynostosis (Gripp *et al.*, 2000). Moreover, an ethyl-nitroso-urea-mutagenesis approach in mice led to the identification of an amino acid substitution within the Twist-box of Twist1 that causes premature osteoblast differentiation *in vivo* (Bialek *et al.*, 2004).

Unexpectedly, this mouse model, termed *Charlie Chaplin* (*CC/CC*), also displayed decreased chondrocyte maturation, thereby suggesting an additional physiological role of Twist1, independent of its antiosteogenic function (Hinoi *et al.*, 2006). Because *Twist1* is not expressed in chondrocytes, but in mesenchymal cells of the perichondrium, it appears that it is required to inhibit the induction of *Fgf18* expression in these cells by the action of Runx2, which was described earlier. Indeed, whereas transgenic mice overexpressing *Twist1* under the control of an osteoblast-specific *α1(I)-Collagen* promoter fragment displayed enhanced chondrocyte maturation, the decreased chondrocyte maturation in the *CC/CC* mice was normalized by haploinsufficiency of *Runx2* (Hinoi *et al.*, 2006). Taken together, these data demonstrate that Twist1, through inhibition of Runx2 DNA binding, not only limits osteoblast differentiation and bone formation, but also enhances chondrocyte maturation during skeletal development.

OSTERIX, A Runx2-DEPENDENT OSTEOBLAST-SPECIFIC TRANSCRIPTION FACTOR REQUIRED FOR BONE FORMATION

Besides Runx2, there is at least one more transcription factor, termed Osterix (Osx), whose activity is absolutely required, in mice, for osteoblast differentiation. Osx is a zinc finger-containing transcription factor that is specifically expressed in osteoblasts of all skeletal elements. Inactivation of Osx in mice results in perinatal lethality owing to a complete absence of bone formation (Nakashima *et al.*, 2002). Unlike the *Runx2*-deficient mice, however, whose skeleton is completely nonmineralized, the *Osx*-deficient mice did only lack a mineralized matrix in bones formed by intramembranous ossification. In contrast, the bones formed by endochondral ossification contained mineralized matrix, but this resembled calcified cartilage, and not mineralized bone matrix. This finding shows, that Osx, unlike Runx2, is not required for chondrocyte hypertrophy, thereby demonstrating that it is specifically inducing osteoblast differentiation and bone formation *in vivo*. The comparative expression analysis by *in situ* hybridization further revealed that *Osx* is not expressed in *Runx2*-deficient embryos, and *Runx2* is normally expressed in *Osx*-deficient embryos (Nakashima *et al.*, 2002). These results demonstrated that Osx is acting downstream of Runx2 in a transcriptional cascade of osteoblast differentiation, and its expression is apparently directly regulated by the binding of Runx2 to a responsive element in the promoter of the *Osx* gene (Nishio *et al.*, 2006).

In contrast to the steadily increasing knowledge about the function of Runx2 and its regulation by other molecules, the molecular mechanisms underlying the action of Osx in osteoblasts are less well understood. Moreover, unlike for *RUNX2*, no human mutations of the *OSX* gene have yet been identified that would be associated with decreased bone formation. Nevertheless, there is one recent publication providing evidence for a contribution of Osx to the negative effects of nuclear factor of activated T-cells (NFAT) inhibitors on bone mass (Koga *et al.*, 2005). NFAT inhibitors, such as FK506 or cyclosporin A, are commonly used as immunosuppressants, e.g., after organ transplantation. However, this treatment is often accompanied by the development of osteopenia in the respective patients (Rodino and Shane, 1998). Likewise, treatment of mice with FK506 leads to decreased bone mass owing to impaired bone formation, and the same phenotype was observed in mice lacking the transcription factor Nfatc1. The deduced role of Nfatc1 as a physiological activator of osteoblast differentiation and function can be molecularly explained by an interaction with Osx. In fact, both proteins synergistically activate transcription of a *Luciferase* reporter gene driven by an osteoblast-specific *α1(I)-Collagen* promoter fragment, which is based on the formation of a DNA-binding complex of Nfatc1 and Osx (Koga *et al.*, 2005). Although this is just a first example, it is likely that the complexities of the transcriptional control of osteoblast differentiation will increase further when more Osx-interacting molecules are identified in the future.

ATF4, A TRANSCRIPTIONAL REGULATOR OF OSTEOBLAST FUNCTIONS AND A MEDIATOR OF THE NEURAL REGULATION OF BONE MASS

The role of ATF4 in skeletal biology also arose from a combination of molecular biology and human and mouse genetic data. *RSK2,* which encodes a kinase, is the gene mutated in Coffin–Lowry syndrome, an X-linked mental retardation condition associated with skeletal abnormalities (Trivier *et al.*, 1996). Likewise *Rsk2*-deficient mice display decreased bone mass owing to impaired bone formation (Yang *et al.,* 2004). *In vitro* kinase assays demonstrated that ATF4 is strongly phosphorylated by Rsk2, and that this phosphorylation is undetectable in osteoblasts derived from *Rsk2*-deficient mice. The subsequent analysis of an *ATF4*-deficient mouse model revealed that this transcription factor plays a crucial role in bone formation. In fact, *ATF4*-deficient mice display a delayed skeletal development, and thereafter develop a severe low-bone-mass phenotype caused by decreased bone formation (Yang *et al.*, 2004).

Molecularly, ATF4 was identified as the factor binding to the osteoblast-specific element OSE-1 in the *Osteocalcin* promoter, thereby directly activating the transcription of this gene. Moreover, ATF4 is required for proper synthesis of type I collagen, although this function is not mediated by a transcriptional regulation of *type I collagen* expression. In fact, because type I collagen synthesis in the absence of nonessential amino acids is specifically reduced in primary osteoblast cultures lacking ATF4, it appears that ATF4 is required for efficient amino acid import into osteoblasts, as it has been described for other cell types (Harding *et al.,* 2003). Because a reduced type I collagen synthesis was subsequently also observed in mice lacking Rsk2, these data provided evidence that the diminished ATF4 phosphorylation in the absence of Rsk2 may contribute to the skeletal defects associated with Coffin–Lowry syndrome (Yang *et al.*, 2004).

In addition to its role in bone formation, ATF4, through its expression in osteoblasts, regulates bone resorption (Elefteriou *et al.,* 2005). This function is molecularly explained by the binding of ATF4 to the promoter of the *Rankl* gene, which is expressed by osteoblasts in order to promote osteoclast differentiation (Teitelbaum and Ross, 2003). Likewise, *ATF4*-deficient mice have decreased osteoclast numbers because of reduced *Rankl* expression. Most importantly, however, this function of ATF4 is involved in the control of bone resorption by the sympathetic nervous system. In fact, treatment of normal osteoblasts with isoprotenerol, a surrogate of sympathetic signaling, enhanced osteoclastogenesis of cocultured bone marrow macrophages through an induction of osteoblastic *Rankl* expression (Elefteriou *et al.*, 2005). As expected, this effect was blunted, when the osteoblasts were derived from mice lacking the β2-adrenergic receptor Adrb2. However, the effect of isoprotenerol was also blunted by an inhibitor of protein kinase A, or by using osteoblasts derived from *ATF4*-deficient mice (Elefteriou *et al.*, 2005). Taken together, these results demonstrated that ATF4 is an important mediator of extracellular signals, such as β-adrenergic stimulation, in osteoblasts.

Thus, it is not surprising that the function of ATF4 is mostly regulated post-translationally. For example, as already mentioned, ATF4 is also interacting with other proteins, such as the nuclear matrix protein Satb2 (Dobreva *et al.,* 2006). As described earlier, the proximal *Osteocalcin* promoter contains two osteoblast-specific elements, termed OSE-1 and OSE-2, that serve as binding sites for ATF4 and Runx2, respectively (Ducy and Karsenty, 1995; Ducy *et al.*, 1997; Schinke and Karsenty, 1999; Yang *et al.*, 2004). Because of the proximity of both elements, there is indeed a physical interaction of the two proteins, which is stabilized by Satb2, that acts a scaffold enhancing the synergistic activity of Runx2 and ATF4, which is required for sufficient *Osteocalcin* expression (Xiao *et al.,* 2005; Dobreva *et al.,* 2006).

Other aspects of ATF4 biology are also regulated post-translationally. In fact, even the osteoblast specificity of ATF4 function is not determined by osteoblast-specific *ATF4* expression, but by a selective accumulation of the ATF4 protein in osteoblasts, which is explained by the lack of proteosomal degradation (Yang and Karsenty, 2004). This is best demonstrated by the finding that the treatment of nonosteoblastic cell types with the proteasome inhibitor MG115 leads to an accumulation of the ATF4 protein, thereby resulting in ectopic *Osteocalcin* expression. Taken together, these data provided the first evidence for the achievement of a cell-specific function of a transcriptional activator by a post-translational mechanism. They are therefore of general importance for our understanding of the transcriptional networks controlling cellular differentiation and function.

Remarkably, ATF4 biology further illustrates how the molecular understanding of a disease-causing gene can translate into therapeutic interventions. Indeed, an increased Rsk2-dependent phosphorylation of ATF4 may also be involved in the development of the skeletal abnormalities in human patients suffering from neurofibromatosis (Ruggieri *et al.*, 1999; Stevenson *et al.*, 1999). This disease, which is primarily known for tumor development within the nervous system, is caused by inactivating mutations of the *NF1* gene that encodes a Ras-GTPase-activating protein (Klose *et al.*, 1998). The generation of a mouse model lacking *Nf1* specifically in osteoblasts ($Nf1_{ob-/-}$) led to the demonstration that this gene plays a major physiological role in bone remodeling. In fact, the $Nf1_{ob-/-}$ mice displayed a high-bone-mass phenotype that is caused by increased bone turnover and is accompanied by an enrichment of nonmineralized osteoid (Elefteriou *et al.,* 2006). The further analysis of this

phenotype revealed an increased production of type I collagen in the absence of *Nf1*, which is molecularly explained by an Rsk2-dependent activation of ATF4. Likewise, transgenic mice overexpressing *ATF4* in osteoblasts display a phenotype similar to the $Nf1_{ob-/-}$ mice, and the increased type I collagen production and osteoid thickness in the latter ones is significantly reduced by haploinsufficiency of ATF4 (Elefteriou *et al.*, 2006).

These molecular findings may also have therapeutic implications. Given the previously discussed function of ATF4 in amino acid import, it appeared reasonable to analyze whether the skeletal defects of the $Nf1_{ob-/-}$ mice can be affected by dietary manipulation. Indeed, the increased bone formation and osteoid thickness of $Nf1_{ob-/-}$ mice can be normalized by a low-protein diet, and the same was the case in the transgenic mice overexpressing *ATF4* in osteoblasts (Elefteriou *et al.*, 2006). Likewise, the defects of osteoblast differentiation and bone formation observed in both the *ATF4*- and the *Rsk2*-deficient mice were corrected by feeding a high-protein diet. Taken together, these data not only underscore the importance of ATF4 in osteoblast biology, but they also demonstrate how the knowledge about its specific functions in osteoblasts can be useful for the treatment of skeletal diseases.

AP1 REGULATION OF OSTEOBLAST DIFFERENTIATION AND FUNCTION

Activator protein 1 (AP1) is a heterodimeric transcription factor composed of members of the Jun and Fos family of basic leucine zipper proteins (Karin *et al.*, 1997). These include the Jun proteins c-Jun, JunB, and JunD, as well as the Fos proteins c-Fos, Fra1, Fra2, and Fosb, respectively. Although AP1-transcription factors have been demonstrated to fulfill various functions in different cell types, it is striking that some of the family members play specific roles in bone remodeling, as demonstrated by several loss- or gain-of-function studies in mice (Wagner and Eferl, 2005). For instance, the deletion of *c-Fos* from the mouse genome results in severe osteopetrosis owing to an arrest of osteoclast differentiation, whereas the transgenic overexpression of *c-Fos* results in osteosarcoma development (Grigoriadis *et al.*, 1993, 1994). Moreover, transgenic mice overexpressing either *Fra1*, or *ΔfosB*, a splice variant of *FosB*, display a severe osteosclerotic phenotype caused by increased osteoblast differentiation and function (Jochum *et al.*, 2000; Sabatakos *et al.*, 2000). Likewise, mice lacking Fra1 in extraplacental tissues display an osteopenia associated with reduced bone formation, indicating a physiological role of Fra1 in osteoblasts (Eferl *et al.*, 2004). When the same approach was used to inactivate JunB in extraplacental tissues, thereby circumventing the embryonic lethality caused by a complete genomic deletion of *JunB*, the resulting mice developed a state of low bone turnover, owing to cell-autonomous defects of osteoblast, but also of osteoclast differentiation (Kenner *et al.*, 2004).

Taken together, these data provide evidence for a crucial role of AP1-transcription factors in the regulation of bone formation, although their connection to the other transcriptional regulators described earlier still needs to be further investigated. For instance, it is known from other cell types that Jun proteins can also interact with ATF family members, thus raising the possibility that heterodimerization with ATF4 may be one mechanism by which these proteins can regulate osteoblast-specific gene expression (Chinenov and Kerppola, 2001). Interestingly, it has recently been demonstrated that the osteosarcoma development of *c-Fos* transgenic mice is dramatically decreased in an *Rsk2*-deficient genetic background (David *et al.*, 2005). This observation is molecularly explained by the lack of c-Fos phosphorylation by Rsk2, thereby leading to increased proteosomal degradation. Thus, Rsk2 is apparently not only involved in the physiological regulation of bone formation via phosphorylation of ATF4, but may also have an influence on the development of osteosarcomas via phosphorylation of c-Fos.

Another potential mechanism by which AP1-family members might be involved in the regulation of bone formation came from the analysis of mouse models with impaired circadian regulation. These mice, which lack components of the molecular clock, namely the *Per* or *Cry* genes, display a high-bone-mass phenotype caused by increased bone formation (Fu *et al.*, 2005). Moreover, they respond to intracerebroventricular infusion of leptin by a further increase of bone mass, suggesting that the components of the molecular clock are involved in the regulation of bone formation via the sympathetic nervous system. Interestingly, virtually all genes encoding members of the AP1-transcription factor family were expressed at higher levels in osteoblasts derived from mice lacking either the *Per* genes, or the β2-adrenergic receptor Adrb2 (Fu *et al.*, 2005). This increase was especially pronounced in the case of the *c-Fos* gene, whose expression can also be induced by the addition of isoprotenerol in wild-type osteoblasts. In turn, c-Fos leads to a direct activation of *c-Myc* transcription, thereby indirectly increasing the intracellular levels of cyclin D1 and promoting osteoblast proliferation. Taken together, these data demonstrated that the expression of AP1-components is activated via sympathetic signaling, and that this induction is counteracted by the activity of clock gene products.

TRANSCRIPTION FACTORS ACTING DOWNSTREAM OF WNT SIGNALING

The recent discovery of the *LRP5* gene as a major determinant of bone mass in humans has paved the way to the identification of another class of transcription factors acting downstream of the Wnt signaling pathway (Gong

et al., 2001; Boyden *et al.*, 2002; Little *et al.*, 2002). Lrp5 is a transmembrane protein that acts as a coreceptor for ligands of the Wnt family, thereby triggering a cascade of intracellular signaling events that leads to a nuclear translocation of β-catenin, that in turn activates transcription factors of the Tcf/Lef family (Mao *et al.*, 2001; Huelsken and Birchmeier, 2001). Mice lacking *Lrp5* recapitulate the phenotype of patients with inactivating *LRP5* mutations, namely low bone mass owing to decreased bone formation, and also persistent embryonic eye vascularization (Kato *et al.*, 2002). Because bone resorption is virtually unaffected in the absence of Lrp5, it came as a surprise that mouse models with altered levels of the downstream effector β-catenin in osteoblasts primarily display defects of bone resorption (Glass *et al.*, 2005).

Although an osteoblast-specific mutational activation of *β*-catenin led to an osteopetrotic phenotype, the osteoblast-specific inactivation of *β*-catenin resulted in a low-bone-mass phenotype, caused by increased bone resorption. Because of the strategy used to unravel these functions of *β*-catenin, it was expected that both phenotypes would be explained by a cell-autonomous defect of osteoblasts, which was subsequently confirmed in coculture experiments (Glass *et al.*, 2005). The molecular explanation for the regulation of osteoclast differentiation by *β*-catenin expression in osteoblasts came from the expression analysis of *Osteoprotegerin (Opg)*, a well known inhibitor of bone resorption, blocking the activity of Rankl (Simonet *et al.*, 1997; Yasuda *et al.*, 1998). Surprisingly, although *Opg* expression was markedly increased in osteoblasts from mice expressing the stabilized form of *β*-catenin, its expression was decreased in mice harboring an osteoblast-specific deletion of *β*-catenin (Glass *et al.*, 2005).

One of the transcription factors activated by *β*-catenin in osteoblasts has already been identified as Tcf1, whose importance for the regulation of gene expression in osteoblasts is underscored by several lines of evidence. First, *in situ* hybridization revealed that *Tcf1* is expressed in osteoblasts during bone development and after birth. Second, *Tcf1*-deficient mice display a low-bone-mass phenotype, caused by increased bone resorption. Third, the compound heterozygosity of *Tcf1* and *β-catenin* in osteoblasts also results in low bone mass, which is not observed, when one allele of each gene is inactivated alone. Fourth, *Opg* expression is decreased in osteoblasts of *Tcf1*-deficient mice, and the molecular analysis of the *Opg* promoter revealed the existence of a Tcf-binding site, whose functional activity was subsequently proven by chromatin immunoprecipitation and cotransfection assays (Glass *et al.*, 2005). Thus, although these results raise the question of why the inactivation of Lrp5 does not result in similar abnormalities, they do show that Tcf1 is one transcription factor acting downstream of the Wnt signaling pathway that regulates gene expression in osteoblasts.

PERSPECTIVES

Since the last edition of this book, it is obvious that many new insights into this field have accumulated. These include the recent discoveries of novel transcriptional regulators, such as Osx, ATF4, and others, playing a key role in bone formation. Moreover, the molecular networks between these factors are much better understood than a few years ago, although still more research is necessary to answer the many remaining questions (Fig. 2). These

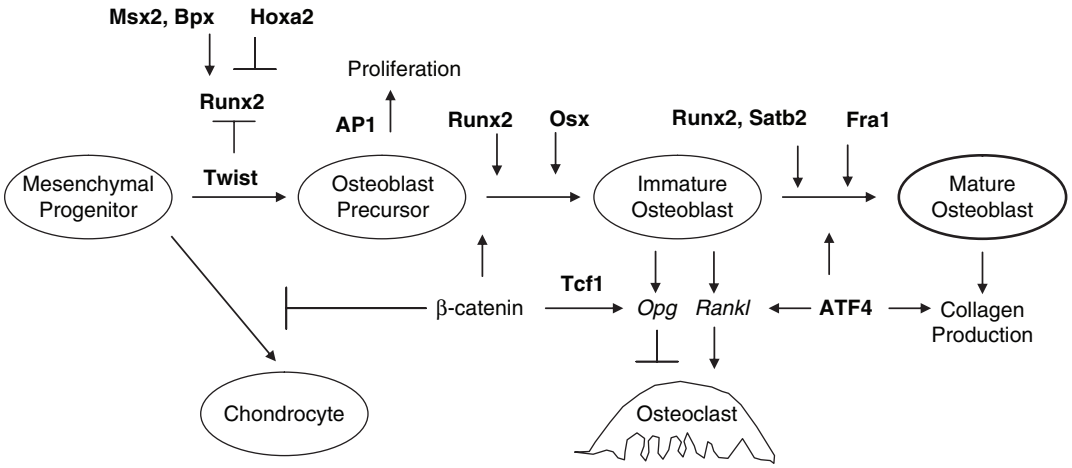

FIGURE 2 Transcriptional control of osteoblast differentiation and function. Runx2 expression in mesenchymal progenitor cells is controlled by homeodomain transcription factors such as Msx2, Bpx, and Hoxa2. The activity of Runx2 is first limited by the action of Twist proteins, whose expression ceases to allow Runx2-mediated differentiation along the osteoblast lineage. Besides Runx2 there are other important transcriptional activators, such as Osx, Satb2, Fra1, and ATF4, that are required for proper osteoblast differentiation and bone matrix deposition. Through the regulation of Opg and Rankl expression by Tcf1 and ATF4, respectively, osteoblasts also control bone resorption by osteoclasts. Moreover, components of the AP1-transcription factor are involved in osteoblast proliferation, and an intact Wnt signaling pathway in mesenchymal progenitor cells is also required to suppress their differentiation into chondrocytes (Day *et al.*, 2005; Hill *et al.*, 2005).

include the definition of specific target genes, the regulation by outside signals, and still a deeper understanding about the interactions of all factors playing a role at various stages of development in the different skeletal elements. Moreover, the most important goal for the future, which should be the major aim of basic research in general, is the use of this accumulating knowledge to define novel therapeutic strategies for the treatment of skeletal diseases.

INTRODUCTION

The past decade has witnessed a literal explosion in our understanding of fundamental biological processes, catalyzed in large part by the human genome project and the vast repertoire of technologies that are now available to identify genes and study gene function. The field of bone biology has certainly benefited from these advances as illustrated by many of the chapters in this book. Not surprisingly perhaps, the genetic dissection of single-gene human disorders that present with skeletal abnormalities has led to advances in our understanding of bone biology, often in directions that could not have been anticipated by the current state of knowledge. The discovery of mutations in the low-density lipoprotein receptor-related protein 5 (LRP5) gene that give rise to conditions of decreased (Gong *et al.*, 2001) or increased bone mass (Little *et al.*, 2002; Boyden *et al.*, 2002) is an example of how fundamental principles are often revealed through the identification of causal mutations underlying inherited human conditions. Prior to these studies the role of Wnt/β-catenin signaling in bone was limited mainly to skeletal development, but because of the explosion of research that occurred as a result of those seminal publications we now appreciate the role of this pathway in bone cell differentiation, proliferation, and apoptosis, bone mass regulation, and the ability of bone to respond to changes in mechanical load. Although Wnts can signal through multiple pathways, in this chapter, the focus will be on what is known about the Wnt/β-catenin signaling pathway and its regulation as it pertains to bone.

Wnt GENES AND PROTEINS

There are currently 19 known *Wnt* genes in humans. Wnt proteins are secreted, highly post-translationally modified proteins that play key roles in development and homeostasis through their involvement in cell differentiation, proliferation, and apoptosis. Nusse and Varmus (1982) first described Wnt as the mouse proto-oncogene integration site/locus (*int-1*) of the murine mammary tumor virus that resulted in breast tumors. Later the *Drosophila* segmentation gene *Wingless* (*Wg*) was shown to be homologous to the *int-1* gene (Cabrera *et al.*, 1987; Rijsewijk *et al.*, 1987) and the name *Wnt* was coined.

The Wnt proteins have proven difficult to study because of their post-translational modifications (glycosylation and palmitoylation) that make them extremely insoluble and, until recently, refractory to purification to any degree. Therefore, much of what we know about Wnt proteins at a structural level is based on their DNA sequence analysis and comparisons. The various Wnt genes share general homology in the range of 35%, although within subgroups the homology can be as high as 83%. The molecular weight of the various Wnt proteins ranges from 39,000 to 46,000. All Wnts contain 23 or 24 conserved cysteine residues that are spaced similarly between proteins, suggesting an important conservation of function, possibly proper folding of the protein, which is required for Wnt activity (Miller, 2001).

Nusse and colleagues successfully purified Wnt3a from mouse L cells (Willert *et al.*, 2003). Subsequently Schulte *et al.* (2005) used a similar strategy to purify Wnt5a. Both groups demonstrated that the addition of a palmitate to the first, most amino-terminally conserved of the cysteine residues is absolutely required for Wnt3a and Wnt5a activity. In *Drosophila* the gene *porcupine* and in *Caenorhabditis elegans* the gene *mom-1* encode acyltransferase enzymes that are strong candidates for the proteins responsible for the palmitoylation of Wnts (Kadowaki *et al.*, 1996; Nusse, 2003). Interestingly, these proteins are membrane bound and found in the endoplasmic reticulum indicating that the palmitoylation occurs intracellularly. Although palmitoylation of secreted proteins is somewhat unusual (Dunphy and Linder, 1998), the hedgehog family of proteins is also palmitoylated and secreted in this manner (Nusse, 2003). Wnts are known to act developmentally as morphogens (Aulehla and Herrmann, 2004; Aulehla *et al.*, 2003; Zecca *et al.*, 1996), but the role of the palmitate in Wnt function

is not clear. Possible roles for the palmitoylation include anchoring the Wnt proteins to the cell surface membrane, binding to a transport protein (unknown) and binding of Wnts to Lrp5/6 and/or frizzled (Miura and Treisman, 2006). Little is known about the role of the glycosylation of Wnts, although this modification is not essential for activity (Mason *et al.*, 1992). Recently, two groups have shown that the multipass transmembrane protein Wntless/Evi, which is located in the Golgi and/or the plasma membrane, is involved in the transport and secretion of Wnt proteins (Banziger *et al.*, 2006; Bartscherer *et al.*, 2006).

COMPONENTS OF THE Wnt/β-CATENIN SIGNALING PATHWAY

A detailed description of the various components of the Wnt/β-catenin signaling pathway can be found at the Wnt homepage website maintained by Roel Nusse (http://www.stanford.edu/~rnusse/) and in several reviews in the literature (Clevers, 2006; Gordon and Nusse, 2006; He, 2003; He *et al.*, 2004a; Johnson and Summerfield, 2005; Kikuchi, 2003; Logan and Nusse, 2004; Mikels and Nusse, 2006; Nusse, 2003; Prunier *et al.*, 2004; Reya and Clevers, 2005). The major players in the Wnt/β-catenin signaling pathway in bone are: (1) the cell surface coreceptors Lrp5/6 and frizzled; (2) the intracellular proteins Dishevelled (Dsh), glycogen synthase kinase-3β (GSK-3β), Axin, and β-catenin; and (3) the TCF/LEF nuclear transcription factors that bind β-catenin and regulate gene expression. In addition, there are a number of other extracellular and intracellular proteins involved in regulation of this pathway that serve to modify the functionality of one of these key proteins. Particularly important are several proteins that bind Lrp5/6 to modulate its binding of Wnt ligand.

The details of the Wnt/β-catenin pathway are illustrated in Figure 1. Ultimately the Wnt/β-catenin signaling pathway controls the intracellular levels of free β-catenin. In the absence of Wnt ligand, the intracellular levels of β-catenin are extremely low because of the activity of a degradation complex composed of Axin, GSK-3β, the adenomatous polyposis coli (APC) protein, and several other proteins. This complex, specifically GSK-3β, is responsible for the phosphorylation of β-catenin, which leads to its ubiquitination and degradation by the 26S proteosome complex (Aberle *et al.*, 1997) (Fig. 1A). Wnt binding to the Lrp5/6-frizzled coreceptors results in Dsh activation and Axin binding to the cytoplasmic tail of Lrp5/6. Dsh activation leads to GSK-3β phosphorylation and inhibition of its activity. β-Catenin is no longer phosphorylated and this, coupled with the binding of Axin to the cytoplasmic tail of Lrp5/6, releases β-catenin. β-Catenin accumulates in the cytoplasm and then translocates into the nucleus where it binds to the TCF/LEF family of transcription proteins and regulates the expression of specific target genes (Fig. 1B).

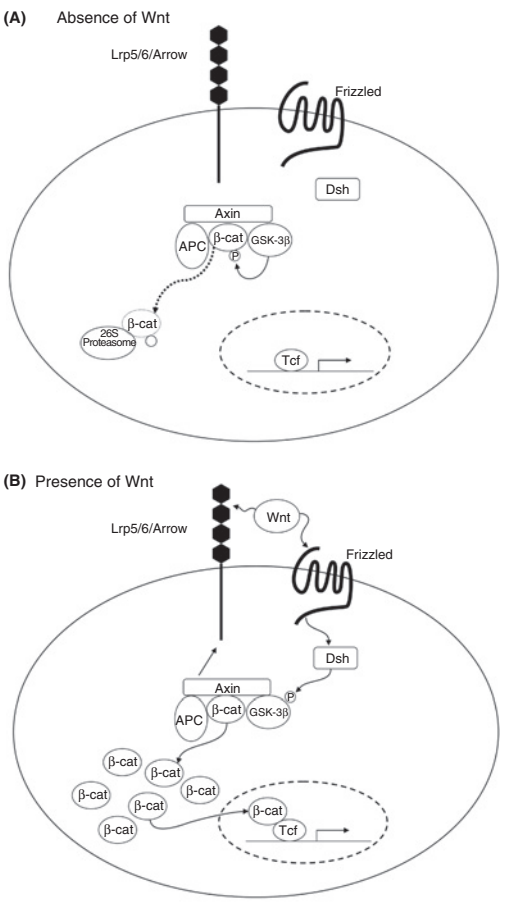

FIGURE 1 The Wnt/β-catenin signaling pathway. The Wnt/β-catenin signaling pathway is controlled by two cell surface coreceptors, Frizzled and one of the low-density lipoprotein receptor-related proteins (Lrp) 5 or 6 in vertebrates, or arrow in *Drosophila* that cooperatively bind the Wnt protein ligand. (**A**) In the absence of Wnt, the degradation complex consisting of the scaffolding protein Axin, adenomatous polyposis coli (APC) and glycogen synthase kinase-3β (GSK-3β), along with several other proteins (not shown), coordinate the phosphorylation of β-catenin, which is then ubiquitinated and degraded by the 26S protesome complex. This serves to keep the intracellular levels of free β-catenin at a low level. (**B**) When Wnt ligand is bound by the Lrp5/6/arrow and frizzled coreceptors the protein Dishevelled (Dsh) is activated, which results in the phosphorylation of GSK-3β, thereby inhibiting its activity. The degradation complex is also induced to bind to the cytoplasmic tail of Lrp5/6/arrow and the combination of events leads to the intracellular accumulation of high levels of free β-catenin. β-Catenin can then translocate into the nucleus and, on binding to the Tcf/LEF family of transcription factors, regulate the expression of a number of target genes.

Lrp5, Lrp6, and Frizzled

Lrp5 and Lrp6 (Arrow in *Drosophila*) are highly homologous proteins that, until their role in bone biology was described, were considered orphan members of the low-density lipoprotein receptor (LDLR) family, which includes at least 13 members (Strickland *et al.*, 2002). One of the hallmark structural characteristics of this family is the presence of tyrosine-tryptophan-threonine-aspartic acid

(YWTD) repeat motifs framed by EGF repeats in the extracellular domain of the proteins. These repeat clusters form β-propellor structures that are important for ligand binding. Based on the amino acid sequence of Lrp5 and Lrp6 derived from cDNA cloning (Brown *et al.*, 1998; Dong *et al.*, 1998; Hey *et al.*, 1998; Kim *et al.*, 1998), Lrp5/6 each contain four of these repeat clusters. However the YWTD motif is degenerate and one of the six repeat sequences comprising each motif in Lrp5 is substituted by leucine-phenylalanine-alanine-asparagine (LFAN) or phenylalanine-phenylalanine-threonine-asparagine (FFTN) sequences (see review by Johnson and Summerfield, 2005). Many of these LDLR family members have a consensus sequence of asparagine-proline-x-tyrosine (NPxY) in their cytoplasmic tail that is required for endocytosis of the receptor (Chen *et al.*, 1990). Lrp5 and Lrp6 lack an NPxY sequence. Also the orientation of the their extracellular domain is reversed relative to other members of the LDLR family in that LDL-type A repeats (complement-like repeats) are adjacent to the transmembrane-spanning region rather than at the amino-terminal end (or clustered throughout the extracellular domain). There are also only three of these LDL-A type repeats in Lrp5 and Lrp6.

Originally human *LRP5* was proposed to be a candidate gene for susceptibility to type I diabetes in the IDDM 4 locus that was mapped to chromosome 11q13 (Figueroa *et al.*, 2000; Twells *et al.*, 2001). However, subsequent genetic association studies failed to confirm this functional role (Twells *et al.*, 2003). At the same time, Arrow (Wehrli *et al.*, 2000) and Lrp6 (Tamai *et al.*, 2000) were shown to mediate Wnt/β-catenin signaling and *Lrp6*$^{-/-}$ mutant mouse embryos displayed skeletal abnormalities similar to those found in mice carrying mutations in different Wnt genes (Pinson *et al.*, 2000). Subsequently, mutations in human *LRP5* were shown to cause osteoporosis pseudoglioma syndrome (OPPG) (Gong *et al.*, 2001), which is characterized by low bone mass and progressive blindness, and the high-bone-mass (HBM) mutation G171V was reported in two separate kindreds (Little *et al.*, 2002; Boyden *et al.*, 2002). At present, a large number of additional mutations that give rise to conditions of increased or decreased bone mass have been reported in the literature (Ai *et al.*, 2005; Jiao *et al.*, 2004; Jin *et al.*, 2004; Johnson *et al.*, 2004; Rickels *et al.*, 2004, 2005; Streeten *et al.*, 2003, 2004; Toomes *et al.*, 2004; Van Wesenbeeck *et al.*, 2003; Whyte *et al.*, 2004). Also, allelic variants of *LRP5* have been shown to contribute to variation in bone mass in several studies, although the relative degree varies and sex differences are noted in many of the studies (Bollerslev *et al.*, 2005; Choudhury *et al.*, 2003; Crabbe *et al.*, 2005; Deng *et al.*, 2002; Ezura *et al.*, 2007; Ferrari *et al.*, 2004; Giroux *et al.*, 2007; Hartikka *et al.*, 2005; Kiel *et al.*, 2007; Koay *et al.*, 2004; Koh *et al.*, 2004; Koller *et al.*, 2005; Mizuguchi *et al.*, 2004; Okubo *et al.*, 2002; Saarinen *et al.*, 2007; van Meurs *et al.*, 2006; Xiong *et al.*, 2007).

The role of LRP6 in human bone density variation has only been studied to a limited degree. One report indicates that the *LRP6* Ile1062Val allele contributes to a higher risk for fragility and vertebral fracture in men and that this allelic variant, in combination with the *LRP5* A1330V allele, accounted for 10% of the fractures in males (van Meurs *et al.*, 2006). It has also been shown that *Lrp6*$^{+/-}$:*Lrp5*$^{-/-}$ mice have lower adult bone mineral density than *Lrp6*$^{+/+}$:*Lrp5*$^{-/-}$ mice, suggesting a role for Lrp6 in bone mass accrual (Holmen *et al.*, 2004). A recent report identified a mutation in LRP6 (LRP6^{R611C}) that is linked to early-onset coronary artery disease in a family and the five mutation carriers that were studied also had low bone densities, confirming a role for LRP6 in bone mass accrual as suggested by the studies in mice (Mani *et al.*, 2007). Also a hypomorphic *Lrp6* mutation in the mouse (called *ringleschwanz*) has been identified and studies in that model have confirmed a role for Lrp6 in somitogenesis and osteogenesis (Kokubu *et al.*, 2004).

Understanding the distinct and/or overlapping functional roles of Lrp5 and Lrp6 remains an important unanswered question in the bone field at this point in time, especially because both appear to be coexpressed in most cells/tissues that have been examined. If Lrp5 and Lrp6 served totally redundant roles then one would expect to observe the dramatic phenotypes observed by either the lose- or gain-of-functions mutations that are known. Clearly, Lrp6 plays an important role in embryonic skeletal patterning (Kokubu *et al.*, 2004; Pinson *et al.*, 2000), whereas Lrp5 seems to play little, if any, role in this aspect of development. Lrp5 seems to be mainly involved in the regulation of adult bone mass, whereas Lrp6 plays only a lesser role. Recently, the role of Lrp5 and the Wnt/β-catenin signaling pathway in the response of bone to mechanical loading has been firmly established. Based on our analysis of the phenotype of affected members of the HBM trait kindred we had speculated that the *LRP5* G171V mutation gene might somehow have altered the sensitivity of the skeleton to mechanical loading (Johnson *et al.*, 2002). Several lines of evidence now support a central role for Lrp5 and the Wnt/β-catenin signaling pathway in the response of bone/bone cells to mechanical loading. Sawakami *et al.* (2006) have shown that the bone-formation response after loading is reduced by 88% in male and 99% in female Lrp5$^{-/-}$ mice compared with wild-type loaded mice. Mice carrying the LRP5 cDNA containing the G171V mutation have increased sensitivity to mechanical loading (Cullen *et al.*, 2004) and these mice lose less bone in response to disuse than wild-type mice (Bex *et al.*, 2003). Changes in the expression of Wnt/β-catenin signaling pathway target genes has been shown to occur both *in vivo* in bone (Robinson *et al.*, 2006) and *in vitro* in bone cells (Lau *et al.*, 2006; Robinson *et al.*, 2006) in response to mechanical loading. Given that Lrp5 is absolutely required for the response of bone to mechanical loading, the question that next needs to be answered is where does Lrp5/Wnt/β-catenin signaling fit into the cellular cascade of events that

occur in response to mechanical loading? A partial answer to this question will be discussed further later in this chapter. Another unanswered question is does Lrp6 play a role in the response to loading? At present, we have no definitive answer, but given the results of the ulna-loading studies performed with the $Lrp5^{-/-}$ mice and that these mice have normal alleles of Lrp6, it would seem that Lrp6 plays little or no role in mechanoresponsiveness in bone.

There are currently 10 known members of the frizzled family of proteins in humans and a homologous protein called smoothened that functions in hedgehog signaling. The frizzled proteins contain a cysteine-rich domain (CRD) at the amino terminus and seven transmembrane-spanning domains. The cysteine-rich domain is responsible for binding of Wnt ligands (Bhanot *et al.*, 1996). The frizzled proteins are generally thought to be coupled to trimeric G-proteins (Katanaev *et al.*, 2005; Sheldahl *et al.*, 1999). It also seems evident that different frizzleds regulate different intracellular signaling cascades. However, the specific combinations are not completely understood. The functioning of specific frizzleds in combination with Lrp5 or Lrp6 in the binding of specific Wnt proteins leads to activation of β-catenin signaling, but some frizzleds acting alone appear to be involved in the activation of three other Wnt signaling pathways. These other Wnt pathways are the planar cell polarity (PCP) (Mlodzik, 2002), the Wnt/Ca^{2+} involving protein kinase C (Kuhl *et al.*, 2000) and a protein kinase A pathway involved in muscle myogenesis (Chen *et al.*, 2005). Dishevelled also appears to be involved in the first two of these frizzled regulated pathways. It is still not clear which of the 10 different frizzleds are involved in the activation of each of the four Wnt pathways. However, it is known that some of the Wnt proteins only activate the β-catenin signaling pathway (e.g., Wnt1 and Wnt3A), whereas other Wnts only activate one of the other pathways (e.g., Wnt5A activates the Wnt/Ca^{2+} signaling pathway) (Miller, 2001).

The discovery that Lrp5/6/Arrow was also required for the activation of the Wnt/β-catenin signaling pathway suggested a model in which Lrp5/6/Arrow and frizzled function as coreceptors (Tamai *et al.*, 2000; Wehrli *et al.*, 2000). The role of Wnt was proposed to perhaps facilitate the association/interaction of the coreceptors and this was the key event leading to pathway activation. Several lines of evidence obtained from the construction of various fusion proteins suggest that this is most likely the case (Holmen *et al.*, 2002, 2005; Tolwinski *et al.*, 2003). Wnt binding and the formation of this ternary complex leads to a frizzled-dependent activation of Dishevelled (Dsh). However, the exact molecular mechanism mediating Dsh activation is not clear. Dsh phosphorylation appears to be one common feature in all of the signaling pathways through which it is known to act. The kinases casein kinase 1 (Peters *et al.*, 1999) and 2 (Willert *et al.*, 1997) and PAR-1 (Sun *et al.*, 2001) are the leading candidates for carrying out the phosphorylation of Dsh, which can occur through both Lrp5/6-dependent (leading to the β-catenin signaling pathway) and -independent mechanisms (Wnt binding to frizzled in the absence of Lrp5/6) (Gonzalez-Sancho *et al.*, 2004). Three different models of how frizzled and Dsh may interact have been proposed (He *et al.*, 2004a), but it is not clear which one functions in conjunction with Wnt and Lrp5/6/Arrow.

One might predict that loss-of-function mutations in the frizzled gene important in bone would lead to a reduction in bone mass similar to loss-of-function mutations in *LRP5*. Mutations in the frizzled family member, *FZD4*, as well as *LRP5* have been identified that result in Familial Exudative Vitreoretinopathy (FEVR), a hereditary disorder that results in blindness (Jiao *et al.*, 2004; Qin *et al.*, 2005; Robitaille *et al.*, 2002; Toomes *et al.*, 2004). In a recent study of patients with FEVR (Qin *et al.*, 2005) it was found that bone density, on average, was much lower in FEVR patients with *LRP5* mutations than in those with *FZD4* mutations. This study of FEVR patients suggests that possibly a different member of the frizzled family of proteins is important in bone mass versus FZD4, which seems to function more specifically perhaps in vision. Nine different frizzleds (Hens *et al.*, 2005) have been detected by RT-PCR in primary murine calvarial cells. However, calvarial cell populations are a heterogeneous mixture and so which frizzled is important in bone cell function and bone mass regulation is an unsolved question at this time.

Dishevelled, Glycogen Synthase Kinase-3β, Axin, and β-Catenin

Dishevelled (Dsh) serves an important intermediary function between frizzled and glycogen synthase kinase-3β in the Wnt/β-catenin signaling pathway. Dsh also serves as an intermediary in the Wnt/Ca^{2+} signaling pathway (Kuhl *et al.*, 2000) and the planar cell polarity (PCP) pathway (Mlodzik, 2002). The PCP pathway is responsible for the proper orientation of wing hairs and thoracic bristles in *Drosophila.* Mutants with hairs/bristles that were improperly oriented led to the identification of the *Frizzled* and *Dishevelled* genes [see review (Adler, 2002)]. Recent evidence suggests that Frizzled signals through the Gαo subunit in both the Wnt/β-catenin pathway and the PCP pathway (Katanaev *et al.*, 2005). Although it is not fully understood how Dsh becomes activated on Wnt binding and how it can discriminate between which pathway(s) to activate, a model has been proposed that suggests that differential intracellular localization of Dsh may be involved in determining some aspects of its function. Dsh associated with cytoplasmic vesicles has been proposed to be linked to signaling through the Wnt/β-catenin pathway, whereas Dsh associated with actin and the plasma membrane is proposed to signal via the PCP pathway (Capelluto *et al.*, 2002; Povelones and Nusse, 2002). It may also be that Frizzled

localization, the specific Frizzled present in the cell, along with the distribution of downstream components and the specific Wnt ligand participating in the initial binding events, are critical as well (Bejsovec, 2005; Katoh, 2005).

The mechanism responsible for the activation of Dsh is not fully understood nor is the mechanism whereby Dsh acts known. There are four domains in Dsh that appear to be critical for its function. There is a DIX domain, which is also found in Axin, a PDZ domain, a conserved stretch of basic amino acids and a DEP domain that is found in other vertebrate proteins that interact with trimeric G-proteins (Cadigan and Nusse, 1997; He *et al.*, 2004a). Activation of Dsh occurs through phosphorylation and this appears to occur in the other Wnt signaling pathways that involve Dsh. The kinases casein kinase 1 (Peters *et al.*, 1999) and 2 (Willert *et al.*, 1997) and PAR-1 (Sun *et al.*, 2001) are the leading candidates to carry out the phosphorylation of Dsh. Gonzalez-Sanchez *et al.* (2004) have recently suggested that Frizzled-Dsh-Axin and Lrp5/6/Arrow-Axin associations occur in parallel and both are required for stabilization of β-catenin. However, much remains to be understood about the role of Dsh in Wnt/β-catenin signaling and in the other Wnt signaling pathways.

Glycogen synthase kinase-3 (GSK-3) has two main isoforms, α and β. Although most of the current evidence implicates GSK-3β in the control of intracellular levels of β-catenin, the GSK-3α isoforms may also play a role (Asuni *et al.*, 2006; McManus *et al.*, 2005). GSK-3β was first identified as playing a key role in the regulation of glycogen synthesis by phosphorylating (and thereby inhibiting) glycogen synthase [see review (Hardt and Sadoshima, 2002)]. GSK-3α and -β are themselves both inhibited by phosphorylation at an amino-terminal serine residue; serine-21 (α) (Sutherland and Cohen, 1994) or serine-9 (β) (Stambolic and Woodgett, 1994; Sutherland *et al.*, 1993). This phosphorylation is known to be catalyzed by a number of different kinases including MAP kinase (Sutherland and Cohen, 1994), protein kinase B (PKB)/Akt (Haq *et al.*, 2000), protein kinase C (Cook *et al.*, 1996), and protein kinase A (Fang *et al.*, 2000). Integrin-linked kinase also regulates GSK-3β, but apparently not through phosphorylation at serine-9 (Delcommenne *et al.*, 1998). Although there are many other regulators of GSK-3β (Hardt and Sadoshima, 2002), the kinases noted earlier all have described roles in bone and, as will be discussed later concerning the Wnt/β-catenin signaling pathway, suggests possible crosstalk between pathways.

The kinase activity of GSK-3β appears to be enhanced by a priming phosphorylation at nearby sites. In proteins such as Lrp5/6, where multiple GSK-3β phosphorylation sites are present in the cytoplasmic tail, then GSK-3β can self-prime. The initial priming phosphorylation of β-catenin needed for the subsequent GSK-3β phosphorylation is carried out by casein kinase I (CKI) (Liu *et al.*, 2002). GSK-3β has also been shown to phosphorylate two sites within Axin (T609 and S614), which is prerequisite for the binding of β-catenin (Jho *et al.*, 1999). It has been proposed that Wnt signaling leads to a dephosphorylation of these sites and this is part of the mechanism leading to the release of β-catenin from the degradation complex. In addition, protein phosphatase 2A (PP2A), which binds to Axin, APC, and Dsh (Hsu *et al.*, 1999; Seeling *et al.*, 1999; Yamamoto *et al.*, 2001) plays an important counterbalancing role opposing GSK-3β. When CK1 phosphorylates its substrates within the degradation complex PP2A dissociates, which favors further net phosphorylation and the release of β-catenin (Gao *et al.*, 2002). Phosphorylated β-catenin is then ubiquitinated and degraded by the 26S proteosome complex (Aberle *et al.*, 1997).

Axin acts as a scaffolding protein directly interacts/binds Dsh, GSK-3β, APC, PP2A, and β-catenin (Behrens *et al.*, 1998; Fagotto *et al.*, 1999; Farr *et al.*, 2000; Hart *et al.*, 1998; Ikeda *et al.*, 1998; Itoh *et al.*, 1998; Nakamura *et al.*, 1998; Sakanaka *et al.*, 1998; Yamamoto *et al.*, 1998). Axin was first identified as the product of the mouse fused locus (Zeng *et al.*, 1997). In vertebrates there are two forms of Axin: Axin 1, which is constitutively expressed and is the main form of the degradation complex, and Axin 2 (also known as Conductin). Axin 2 expression is induced by Wnt signaling and functions as a negative feedback inhibitor of β-catenin signaling (Jho *et al.*, 2002). Axin has several functional domains required for its interactions with the various other proteins of the degradation complex. It appears that amino acids 581 to 616 are responsible for binding β-catenin, whereas the RGS domain interacts with APC, and GSK-3β appears to bind to amino acids 444 to 543 (Nakamura *et al.*, 1998), although GSK-3β was observed only when β-catenin was present. The Armadillo repeats in β-catenin mediate the interaction with Axin, whereas a Dix domain similar to the one found in Dsh likely mediates the interactions between Axin and Dsh. Mutations in the Human AXIN2 gene have been linked to familial tooth agenesis and are predisposing for colon cancer (Lammi *et al.*, 2004).

The collapse of the degradation complex and the release of β-catenin is a complex cascade of poorly understood events. Wnt binding to the coreceptors induces Axin to bind to the cytoplasmic tail of Lrp5/6/Arrow (after the coreceptor is phosphorylated and FRAT-1 binds). When Wnt is not present, β-catenin is bound to APC and APC to Axin as a consequence of specific phosphorylations mediated by GSK-3β (and other kinases). In the presence of Wnt and the activation of Dsh, these phosphorylation events are inhibited and binding of Axin to the cytoplasmic tail of Lrp5/6/Arrow leads to collapse of the complex and release of β-catenin into the cytoplasm.

β-Catenin is highly homologous to the *Drosophila* segment polarity gene *armadillo* (McCrea *et al.*, 1991). The human β-catenin gene (*CTNNB*) is located on Cs 3p21 and encodes a protein of 781 amino acids (~85 kDa). Two

pools of β-catenin exist within the cell; one associated with E-cadherin and the other in the cytoplasm (Nelson and Nusse, 2004). β-Catenin contains a cassette of 12 Armadillo repeats in the middle of the protein that are the interaction sites with E-cadherin, APC, and the nuclear transcription factors (Cadigan and Nusse, 1997; Willert and Nusse, 1998). A number of mutations in β-catenin have been identified that give rise to human cancers. The amino-terminal end of the protein (mainly between amino acids 29 and 49) contains key residues whose phosphorylation by GSK-3β plays a critical role in the subsequent degradation of the protein, and when one or more of these residues are mutated, the protein is more stable and the increased signaling results in tumor formation/growth (Polakis, 2000; Yost *et al.*, 1996). Exactly how β-catenin is translocated from the cytoplasm into the nucleus is not fully understood.

Transcriptional Regulation by β-Catenin

Once inside the nucleus, β-catenin binds to the TCF/LEF family of transcription factors and regulates the expression of a large (and ever increasing) list of target genes. Recently, it has been shown that β-catenin can also interact with the FOXO family of transcriptional regulators and that this association is particularly important during oxidative stress (Essers *et al.*, 2005), which may play a role in age-associated bone loss (Almeida *et al.*, 2006). A consensus TCF/LEF core sequence has been identified that is required for binding of the TCF/LEF proteins [CCTTTGATC] (Korinek *et al.*, 1997). The TCF/LEF proteins have DNA-binding ability but require the transactivating domain of β-catenin (at the C-terminal end) to regulate transcription.

A large number of proteins (see http://www.stanford.edu/~rnusse/ for a detailed listing) participate in the transcriptional regulation mediated by β-catenin. The current model for how β-catenin regulates target gene transcription involves the formation of a larger complex of proteins that induces a change in chromatin structure (Barker *et al.*, 2001). In *Drosophila* when Wnt is not present, TCF acts as a repressor of Wnt/Wg target genes by forming a complex with Groucho (Cavallo *et al.*, 1998), whose repressing ability is regulated by the histone deacetylase enzyme, Rpd3 (Chen *et al.*, 1999). Studies in *Xenopus* have shown that β-catenin interacts with the acetyltransferases p300 and CBP to activate the *siamois* gene promoter (Hecht *et al.*, 2000). Other proteins that control β-catenin signaling include the antagonist Chibby that binds to the C-terminal end (Takemura *et al.*, 2003) and the protein ICAT (Tago *et al.*, 2000) that negatively regulates the interaction between β-catenin and TCF-4. TCF/LEF can also be phosphorylated by the MAP kinase-related protein NLK/Nemo (Ishitani *et al.*, 2003), which reduces the affinity for β-catenin. Considerably less is known about the interaction of β-catenin with the FOXO family of transcription factors, but presumably it also involves the cooperative and repressive interactions with a number of proteins. Also, it is not understood how choices are made as to which interactions are favored under any given set of cellular circumstances.

There are a large number of known Wnt/β-catenin target genes. Interestingly, many of these targets are components of the Wnt signaling pathway (Logan and Nusse, 2004) (see http://www.stanford.edu/~rnusse/ for a more complete listing), which creates a complicated set of feedback loops that can potentially serve to further amplify or inhibit signaling through the pathway. Some of these target genes will be discussed further in the following sections as they play important roles in bone.

Wnt SIGNALING AND BONE CELL FUNCTION

Understanding how the Wnt/β-catenin signaling pathway is regulated and what the role of the pathway in skeletal biology is (are) still unsolved questions, despite considerable progress during the past 5 years. We now know that Wnt/β-catenin signaling regulates osteogenesis through multiple mechanisms. At the level of the mesenchymal precursor cell, Wnts suppress the differentiation pathways that lead to chondrocytes or adipocytes (Day *et al.*, 2005; Hill *et al.*, 2005; Ross *et al.*, 2000). In the case of adipogenesis versus osteoblastogenesis, Wnts work in favor of the osteoblast lineage through blocking the induction of transcription factors such as C/EBPα and PPARγ (Ross *et al.*, 2000). Secreted Frizzled Related Protein-1 (sFRP1) (see discussion following) has been identified as an important negative regulator of Wnt/β-catenin signaling and the progression of chondrocyte differentiation induced by BMP2 (Gaur *et al.*, 2006). Wnt/β-catenin signaling has been shown to promote osteogenesis by direct stimulation of *Runx2* gene expression (Gaur *et al.*, 2005). Activation of Wnt/β-catenin signaling also promotes further osteoblast cell proliferation and mineralization activity, reduces osteoblast apoptosis, and can suppress osteoclast differentiation induced by osteoblasts (Glass *et al.*, 2005) through regulating the expression of OPG (Simonet *et al.*, 1997).

Much of our understanding of the role of Wnt/β-catenin signaling in the control of skeletal development and bone cell differentiation, proliferation, apoptosis, and function is derived from studies of mutations that gave rise to abnormal skeletal phenotypes in both humans and animal models. For example, the Lrp6 knockout mouse (Pinson *et al.*, 2000) displays many of the skeletal patterning defects that were observed in the mice carrying Wnt gene mutations (Greco *et al.*, 1996; Takada *et al.*, 1994; Yoshikawa *et al.*, 1997) and these observations provided the first clue about the role of the Wnt/β-catenin signaling pathway in skeletal development. Subsequently, the identification of mutations in *LRP5* that gave rise to OPPG (Gong *et al.*, 2001)

or increased bone mass (Little *et al.*, 2002; Boyden *et al.*, 2002; Van Wesenbeeck *et al.*, 2003) in human kindreds implicated Wnt/β-catenin signaling in the control of bone mass. The development of Lrp5 and Lrp6 knockout (Kato *et al.*, 2002; Kokubu *et al.*, 2004) and HBM (*LRP5*^{G171V}) transgenic mice (Babij *et al.*, 2003) has also helped to further define the mechanisms by which the pathway regulates bone cell functions. Gong *et al.* (2001) provided initial evidence that LRP5 regulates osteoblast differentiation and proliferation and this was confirmed by studies in the Lrp5$^{-/-}$ mouse (Kato *et al.*, 2002). Adding to the complexity of the affects of Wnt/β-catenin signaling pathway on bone cell activities is the finding that osteoclasts express high levels of LRP6, instead of LRP5 (Spencer *et al.*, 2006), which these investigators suggest raises the possibility that LRP6-mediated signaling may regulate some of the catabolic effects of Wnt/β-catenin signaling in opposition to the anabolic effects mediated by LRP5.

Lrp5$^{-/-}$ mice have a 50% reduction in mineral apposition rate (MAR) (Kato *et al.*, 2002). This could be because of a reduction in the ability of the osteoblast to mineralize or reduced numbers of osteoblasts. Because Lrp5$^{-/-}$ mice have reduced osteoblast numbers in their long bones, which was correlated with a 50% decrease in calvarial osteoblast proliferation, and osteoblast apoptosis and differentiation were not altered, this suggests that the reduced MAR in these mice is likely caused solely by the reduction in osteoblast proliferation rather than a functional deficit in the osteoblast. The HBM transgenic mouse display decreased osteoblast and osteocyte apoptosis (Babij *et al.*, 2003), which also argues in favor of increased osteoblast number as the underlying mechanism behind the increased bone mineral density and strength (Akhter *et al.*, 2004) observed in these mice. As discussed previously, the role of Lrp6 in bone cell function is less understood, but clearly some increment of bone mass is being contributed by the pathway through activation of this coreceptor. In both the Lrp5$^{-/-}$ and HBM transgenic mice osteoclast number appeared to be unaffected. Thus, Wnt/β-catenin signaling clearly plays an important role in osteoblast differentiation, proliferation, and apoptosis.

Activity through the Wnt/β-catenin signaling pathway is controlled by a number of regulatory proteins and these are clearly involved in the regulation of bone cell function. The Dickkopf (Dkk) family of proteins (Krupnik *et al.*, 1999), designated Dkk1, 2, 3, and 4, play important roles in development, bone disease, cancer, and Alzheimer's disease (Niehrs, 2006). Dkks 1, 2, and 4 have been shown to bind to Lrp5/6 (Bafico *et al.*, 2001; Mao *et al.*, 2001; Semënov *et al.*, 2001) and another protein called Kremen (Mao *et al.*, 2002), which is a single-pass transmembrane protein. Formation of the Dkk-Lrp5/6-Kremen complex results in internalization of Lrp5/6 and its subsequent degradation (Mao and Niehrs, 2003; Mao *et al.*, 2002; Rothbacher and Lemaire, 2002). Thus, Dkk removes functional Lrp5/6 from the cell surface. The *LRP5*^{G171V} mutation was initially shown to alter the ability of DKK1 to inhibit the pathway (Boyden *et al.*, 2002). *In vitro*, Dkk1 overexpression has been shown to decrease osteoblast differentiation and maturation, which is Runx2 dependent, and conversely loss of a single *Dkk1* allele in mice results in a high-bone-mass phenotype (Morvan *et al.*, 2006). Deletion of Dkk-2 resulted in decreased osteoblast terminal differentiation and reduced mineralization (Li *et al.*, 2005a). Thus both Dkk1 and Dkk2 play roles in bone formation.

Dkk1 has been shown to be overexpressed in patients who develop lytic bone lesions associated with multiple myeloma (Tian *et al.*, 2003). Overexpression of Dkk1 by myeloma cells is proposed to inhibit osteoblast differentiation and reduced viability of osteoblast stem cells, which in combination with increased RANKL production by the myeloma cells would favor osteoclastogenesis and the development of the lytic bone lesions (Glass *et al.*, 2003; Tian *et al.*, 2003). TNF-α has been shown to regulate Dkk1 as a mechanism for maintaining the equilibrium between bone formation and bone resorption that is disrupted in various joint diseases (Diarra *et al.*, 2007).

Emerging data suggest that the protein product of the *SOST* gene called sclerostin (Brunkow *et al.*, 2001) is an important inhibitor of the Wnt/β-catenin signaling pathway in bone. Sclerostin is produced by osteocytes (Poole *et al.*, 2005; van Bezooijen *et al.*, 2005). The Lrp5^{G171V} mutation has also been shown to interfere with the ability of sclerostin to bind Lrp5 and thereby inhibit Wnt/β-catenin signaling (Ellies *et al.*, 2006; Semenov and He, 2006). The high levels of sclerostin produced by osteocytes implies that the Wnt/β-catenin signaling pathway is held in the "off" position in bone and therefore activation of the pathway requires either a by-pass of the inhibition of Lrp5/6 by sclerostin or a decrease in the levels of sclerostin, thereby permitting Wnt ligand-mediated activation of the pathway. In this regard, it has been proposed that PTH stimulation of bone formation involves a reduction in Sost gene expression (Bellido *et al.*, 2005; Keller and Kneissel, 2005). Mechanical loading has also been shown to decrease sclerostin levels in bone (Robling *et al.*, 2006). Reduction of sclerostin levels by use of a neutralizing antibody has been shown to result in increased bone mass in rats and monkeys, further supporting the concept that the pathway is held in the "off" position by sclerostin and that removal of this "brake" will lead to increased bone formation (Ominsky *et al.*, 2006a, 2006b). This identifies sclerostin as another potential target for the design of anabolic therapies aimed at manipulating the Wnt/β-catenin signaling pathway (see further discussion in subsequent text).

Another class of extracellular regulatory molecules are the secreted frizzled related proteins (sFRPs). The sFRPs have a cysteine rich domain that is highly homologous to the Wnt-binding domain of the frizzled coreceptor and are capable of binding Wnts (Rattner *et al.*, 1997).

sFRPs can act as competitive inhibitors of Wnt-mediated activation of the Wnt/β-catenin pathway (Moon *et al.*, 1997). sFRP-1 has been shown to bind RANKL ligand and therefore is capable of acting as a decoy receptor like OPG and inhibit osteoclastogenesis (Hausler *et al.*, 2001). Studies with a human osteoblast cell line (HOB) demonstrated that sFRP-1 is a negative regulator of osteoblast and osteocyte survival (Mount *et al.*, 2006). Deletion of sFRP-1 results in an increased bone mass phenotype, but unlike the HBM transgenic mice, the effects of sFRP-1 deletion are restricted to trabecular bone and are not manifest in cortical bone (Bodine *et al.*, 2004b). sFRP-1$^{-/-}$ mice have decreased osteoblast and osteocyte apoptosis and increase osteoblast proliferation and differentiation. Unlike the Lrp5$^{-/-}$ mice, the sFRP-1$^{-/-}$ mice had elevated expression of *Runx2* mRNA (Gaur *et al.*, 2005). Deletion of sFRP-1 also has effects on chondrogenesis and endochondral bone formation (Gaur *et al.*, 2006).

Activation of the Wnt/β-catenin signaling pathway leads to changes in the expression of a number of genes. The protein products of many of these genes can act as feedback regulators of the pathway. For example, activation of this pathway is linked to new bone formation in response to mechanical loading, which results in changes in the expression of a number of β-catenin target genes such as Wnt10b, Wnt 1, Wnt 3a, Axin, WISP2, sFRP1, and sFRP4 (Lau *et al.*, 2006; Robinson *et al.*, 2006). Whereas the Wnts would function as stimulators of the pathway, the sFRPs and Axin could serve to inhibit the pathway. Thus, activation of the pathway in response to loading initiates feedback loops that can further activate or inhibit the pathway.

Given this large repertoire of modulators understanding how the pathway is regulated in a coordinated and temporal fashion by these multiple regulators it is somewhat remarkable that mutations in any one of these modulators can have such a dramatic effect on the skeleton. Clearly, we have much more to understand about the complex interplay of the various proteins that regulate the Wnt/β-catenin signaling pathway in bone cells. The function of these regulators of the pathway clearly is often restricted to some aspect of bone cell function and how this occurs is not understood. For example, loss of Axin2 results in increased osteoblast proliferation and differentiation (Yu *et al.*, 2005). However, osteoblast apoptosis was not altered in these mice. In the HBM transgenic mice (Babij *et al.*, 2003), the G171V mutation was associated with decreased osteoblast and osteocyte apoptosis. The G171V mutation has also been shown to reduce the ability of sclerostin (Ellies *et al.*, 2006; Li *et al.*, 2005b; Semenov *et al.*, 2005) and Dkk1 (Boyden *et al.*, 2002) to bind and inhibit Lrp5. It is not known how or whether these might be connected. At still another level, the Wise protein has been shown to be a context-specific activator or inhibitor of Wnt/β-catenin signaling and seems to be more important during embryonic skeletal development (Itasaki *et al.*, 2003). Thus, the picture that is emerging is that different modulators of the pathway may selectively regulate different aspects of bone cell biology and/or specific bone cell types and function during different developmental windows.

INTERACTIONS BETWEEN Wnt/β-CATENIN SIGNALING AND OTHER PATHWAYS IMPORTANT IN BONE MASS REGULATION

The Wnt/β-catenin signaling pathway is not the only pathway that is known to be important in the regulation of bone cell activities and considerable effort is now being focused on understanding how all of these various pathways interact to regulate bone mass. As already discussed, GSK-3β is the critical intracellular enzyme controlling β-catenin levels. Therefore any pathway that can regulate GSK-3β activity has the potential to interact with the Wnt/β-catenin signaling pathway independent of the Lrp5/6-Frizzled coreceptors and any modulators that function at that level.

One set of the well known pathways that have the potential to crosstalk with the Wnt/β-catenin signaling pathway are those pathways that signal through Akt/PKB. Akt/PKB is activated by phosphatidylinositol-3-kinase whose activity is opposed by the PTEN tumor suppressor (Datta *et al.*, 1999; Kandel and Hay, 1999). Akt/PKB has been shown to be stimulated by Wnt and in association with Dsh to phosphorylate GSK-3β (Fukumoto *et al.*, 2001). This raises the potential for several growth factors to potentially crosstalk with the Wnt/β-catenin signaling pathway. Recently it has been shown that the growth of colon cancer cells induced by PGE_2 is partially the result of activation of the Wnt/β-catenin pathway through a dual mechanism involving Akt-mediated phosphorylation of GSK-3β and the $G\alpha_s$ subunit trimeric G-proteins associated with the PGE_2 EP2 receptor binding to axin and thereby promoting dissociation of the degradation complex (Castellone *et al.*, 2005). PGE_2 release/production in bone cells is a well known early response to mechanical loading. Fluid flow shear stress has been shown to increase the phosphorylation of both Akt and GSK-3β in osteoblasts (Norvell *et al.*, 2004). Our laboratory has presented preliminary evidence that in response to fluid flow shear stress there is an initial activation of the β-catenin signaling that is Lrp5 independent and likely mediated through crosstalk with PGE_2 signaling (Kamel *et al.*, 2006). We are currently testing a model in which this initial activation results in a feedback amplification loop that functions at the level of Lrp5 and leads to new bone formation. When Lrp5 is not present, then the amplification loop does not occur and no new bone formation can occur as was observed in the loading studies in the Lrp5$^{-/-}$ mouse (Sawakami *et al.*, 2006). It has also been shown that integrin-linked kinase (ILK) can regulate Akt/PKB and GSK-3β (Delcommenne *et al.*, 1998), which potentially connects the important role of integrins in the response of bone cells to mechanical loading (Pavalko *et al.*, 1998; Wozniak *et al.*, 2000) with

the Wnt/β-catenin signaling pathway through a crosstalk mechanism.

Additionally, signaling pathways regulate the expression of activators or inhibitors (discussed previously) of the Wnt/β-catenin pathway and thereby interact at this level. For example, results of studies with PTH suggest that PTH acts in part through a complementary pathway and not entirely through the Lrp5 Wnt/β-catenin signaling pathway. Continuous PTH treatment of rats *in vivo* or UMR 106 cells in culture results in a downregulation of *Lrp5* and *Dkk1* and an upregulation of *Lrp6* and *Frz*-1 (Kulkarni *et al.*, 2005) and, based on these studies, it was suggested that the effects of PTH are in part mediated by a cAMP-PKA pathway. In studies with the sFRP-1 knockout mouse, it was concluded that PTH and Wnt signaling may share some common components, but PTH action appears to extend beyond the Wnt pathway (Bodine *et al.*, 2004a). However, studies with the $Lrp5^{-/-}$ mouse have shown that Lrp5 is not required for the bone anabolic effects of PTH on bone (Iwaniec *et al.*, 2004; Sawakami *et al.*, 2006). Recently, evidence has been presented that PTH infusion in mice decreases *Sost* mRNA expression and sclerostin levels in osteocytes (Bellido *et al.*, 2005). This finding implies a negative feedback control mechanism in which sclerostin production by osteocytes opposes the actions of Wnts and/or BMPs on osteoblast precursors and PTH by decreasing sclerostin levels indirectly, therefore stimulating osteoblast differentiation and bone formation. Thus the picture that emerges with PTH is complex.

Likewise, several groups have examined potential crosstalk with the BMP signaling pathway and Wnt/β-catenin signaling (Gaur *et al.*, 2006; He *et al.*, 2004b; Liu *et al.*, 2006; Nakashima *et al.*, 2005; Rawadi *et al.*, 2003; Tian *et al.*, 2005; van den Brink, 2004). One model that has been proposed (Liu *et al.*, 2006) for crosstalk between these two pathways in bone marrow stromal cells involves a Dsh-Smad1 interaction in the unstimulated state that becomes disrupted when Wnt is present. When both Wnt and BMP-2 are present the phosphorylation of Smad1 stabilizes the interaction and thereby inhibits Wnt/β-catenin signaling (Liu *et al.*, 2006). In intestinal crypt stem cell self-renewal, BMP inhibitory effects have been proposed to be mediated through suppression of Wnt/β-catenin signaling through a mechanism involving PTEN, PI3-K, and Akt (He *et al.*, 2004b). In bone it has been proposed that BMP-2 increases the expression of Wnt proteins that then activates the Wnt/β-catenin signaling pathway in an autocrine/paracrine feedback loop (Rawadi *et al.*, 2003). It has also been proposed that Wnts induce the expression of BMPs and this induction is necessary for expression of alkaline phosphatase (Winkler *et al.*, 2005). This model also implicated sclerostin as imposing a level of control preferentially at the level of BMP signaling versus Wnt signaling. However, there is now clear evidence for sclerostin being a negative regulator of the Wnt/β-catenin signaling through binding to Lrp5 (Ellies *et al.*, 2006; Semenov and He, 2006). Thus, although it is clear that these two pathways are somehow intertwined, the exact nature of their interaction(s) is not yet fully understood.

As mentioned previously there is now compelling evidence for the involvement of Lrp5 and the Wnt/β-catenin signaling pathway in the formation of new bone induced by mechanical loading of bone. Evidence also indicates that the $LRP5^{G171V}$ mutation may also protect against bone loss related to disuse, but that bone loss owing to estrogen withdrawal is not affected by this mutation (Bex *et al.*, 2003). However, it has been shown that the estrogen receptor, ERα, and β-catenin can/do form a functional interaction and potentially regulate gene expression (Kousmenko *et al.*, 2004). Recently, it has also been suggested that in bone there is a convergence of the ER, kinases, BMP, and Wnt signaling pathways that regulates the differentiation of osteoblasts (Kousteni *et al.*, 2007).

What other pathways might also interact with the Wnt/β-catenin signaling pathway? At present this is an open question, but it is likely that only by understanding the complex interplay of these various pathways will the control, differentiation, proliferation, and function of bone cells be fully appreciated.

THE Wnt SIGNALING PATHWAY AS A TARGET FOR ANABOLIC THERAPY IN BONE

Given the major role of Wnt/β-catenin signaling in skeletal development and adult bone mass regulation it is not surprising that considerable attention is being focused on using key components of the pathway as targets for new drug development (Baron and Rawadi, 2007; Janssens *et al.*, 2006). At the same time we must be cognizant that misregulation of the pathway can lead to numerous diseases (Johnson and Rajamannan, 2006; Moon *et al.*, 2002; Nusse, 2005; Polakis, 2000; Prunier, Hocevar *et al.*, 2004). What hope exists that a bone-specific anabolic agent can be developed without undesirable side effects? Some evidence already exists in the literature that this might be possible, but considerably more study is needed. Another question is what is the best target to focus on for drug development? The majority of pharmaceutical agents target either receptors or specific enzymes. In the Wnt/β-catenin pathway the obvious targets in this regard are the coreceptors Lrp5 and frizzled and GSK-3β, which is the key enzyme controlling intracellular β-catenin levels.

The $LRP5^{G171V}$ mutation results in a high-bone-mass phenotype and a skeleton that is resistant to fracture (Johnson *et al.*, 1997). The affected members of this kindred seem to have no other health consequences related to the presence of this mutation, although in a second kindred with the $LRP5^{G171V}$ mutation affected members all had

torus lesions in the oral cavity to varying degrees (Boyden *et al.*, 2002). It has also been reported that some mutations in *LRP5* may be associated with pathology (Whyte *et al.*, 2004). The findings that this mutation is associated with increased sensitivity to mechanical loading (Johnson *et al.*, 2002; Robinson *et al.*, 2006) suggests a potentially novel pharmaceutical approach. Perhaps one strategy would be to use a pharmaceutical agent that can alter regulation of the pathway (mimicking the effect of the LRP^{G171V} mutation) in combination with an exercise regimen to produce an optimal bone anabolic effect. It might even be possible to use such a combination-therapy approach with a drug dose that by itself has little consequence on bone mass and thus perhaps avoid undesirable side effects. One approach that is currently being tested with success is the use of anti-sclerostin antibodies to overcome the inhibitory effects of sclerostin on Lrp5 (Ominsky *et al.*, 2006a, 2006b). Other inhibitors of the pathway such as Dkk1 (Wang *et al.*, 2007; Yaccoby *et al.*, 2007) and members of the sFRP family (Bodine *et al.*, 2004b; Nakanishi *et al.*, 2006) are potential targets.

Regulation of GSK-3β activity has already been reported to produce a bone anabolic effect. LiCl treatment, which inhibits GSK-3β, restores bone mass in the $Lrp5^{-/-}$ mouse (Clement-Lacroix *et al.*, 2005) and in human users of lithium there appears to be a decreased fracture risk for any fracture and a trend for decreased risk of osteoporotic fractures of the spine and wrist (Colles' fracture) (Vestergaard *et al.*, 2005). GSK-3β inhibitors have also been shown to produce a bone anabolic effect *in vivo* and increase expression of bone formation markers and induce osteoblast cell differentiation *in vitro* (Kulkarni *et al.*, 2006; Robinson *et al.*, 2006). In one study changes in gene expression profile that were obtained from treatment with these agents was virtually identical to changes observed in the HBMtg mouse bones, in bone cells after mechanical loading, and in primary bone cells from affected members of HBM kindred (Robinson *et al.*, 2006). What these studies suggest is that as we learn more about how the Wnt/β-catenin signaling pathway functions in bone, it will be possible to design better and more specific pharmaceutical agents and approaches.

Given the crosstalk between other signaling pathways and the Wnt/β-catenin signaling pathway, it may be that, as we understand more about the nature of these complex interactions, new targets will be revealed. PTH has been proposed to decrease levels of sclerostin produced by osteocytes and thus releases the inhibition of osteoblast differentiation (Bellido *et al.*, 2005). Could it be possible to regulate *Sost* gene expression through other means and thereby influence a bone anabolic effect? BMPs appear to induce the expression of Wnts (and perhaps vice versa) and so understanding what regulates Wnt gene expression in bone may provide a key to new pharmaceutical approaches. The result of β-catenin nuclear translocation is a change in expression of a number of genes, many of which function in a feedback loop as inhibitors or activators of the pathway. As we understand more about the nature of these genes/proteins and how they are regulated it may be possible to design drugs that can alter the activity of these proteins and thereby tip the balance between bone formation and bone resorption in favor of formation and either increase bone mass or prevent bone loss.

Although many of these ideas may be considered fanciful speculation at this point, if we have learned anything in the past 5 years since the discovery of the mutations in *LRP5* that give rise to low and high bone mass, it may simply be that the discoveries of the next 5 years may be even more enlightening in terms of our understanding of the role of Wnt/β-catenin signaling in bone.

Chapter 7

SOST/Sclerostin: An Osteocyte-Derived Inhibitor of Bone Formation that Antagonizes Canonical Wnt Signaling

Rutger L. van Bezooijen*, Socrates E. Papapoulos, Neveen A. T. Hamdy and Clemens W. G. M. Löwik

Department of Endocrinology and Metabolic Diseases, Leiden University Medical Center, Leiden, The Netherlands

INTRODUCTION

Over the past few years, there has been mounting interest in the pathophysiology of the rare sclerosing bone disorders sclerosteosis, van Buchem disease, and high-bone-mass (HBM) phenotype as human models of an imbalance in bone remodeling in favor of increased bone formation.

Identification of the molecular defects at the source of these sclerosing disorders has led to the recognition of the critical role of the low-density lipoprotein receptor-related proteins 5 and 6 (LRP5/6) and of canonical Wnt (Wingless and INT-1) signaling in the regulation of bone formation. Increased bone formation occurs as the result of inactivating mutations in the SOST gene in sclerosteosis and as a result of a large genomic deletion downstream of this gene in van Buchem disease, respectively. HBM phenotype is caused by activating mutations in LRP5 that inhibit the binding and function of antagonists to canonical Wnt signaling, such as dickkopf-1 (Dkk1) and/or the SOST gene protein sclerostin. The known genetic defects in SOST and LRP5 could not be documented, however, in a number of patients reported to have a very similar phenotype, suggesting further as yet unknown mutations in the Wnt signaling pathway.

In this chapter, we focus on two of the known sclerosing disorders: sclerosteosis and van Buchem disease with specific emphasis on the associated genetic defects. We describe the restricted expression pattern and regulation of the SOST gene product sclerostin and the molecular mechanism by which it acts as a negative regulator of bone formation. Finally, we address the possible clinical implications that the discovery of this protein may have for the management of patients with osteoporosis.

SCLEROSTEOSIS AND VAN BUCHEM DISEASE

Sclerosteosis (OMIM 269500) and van Buchem disease (OMIM 239100) are two rare sclerosing bone disorders, first described in the 1950s as distinct clinical entities despite their closely related phenotypes (Truswell, 1958; van Buchem *et al.*, 1955). Sclerosteosis has been reported mainly in Afrikaners of Dutch descent living in South Africa. Although the diagnosis has been established so far in only 70 patients (H. Hamersma, personal communication), the estimated carrier rate among Afrikaners is high, being one in one hundred individuals (Beighton *et al.*, 2004; Hamersma *et al.*, 2003). The vast majority of the patients with a diagnosis of van Buchem disease come from the small isolated fishing village on an island in the IJsselmeer (former Zuiderzee) Urk in The Netherlands. The population remained isolated for centuries until the island was connected to the main land by land reclamation in 1939. About twenty patients have been diagnosed so far, the majority of whom are descendants of a couple who married in 1751 (Vanhoenacker *et al.*, 2003). The carrier rate of van Buchem disease has not been investigated. A few affected individuals and families with the sclerosteosis or van Buchem disease phenotype have been reported in other parts of the world, including Spain, Brazil, United States, Germany, Japan, Switzerland, and Senegal (Hamersma *et al.*, 2003).

The skeletal manifestations of sclerosteosis and van Buchem disease are the result of endosteal hyperostosis and are characterized by progressive generalized osteosclerosis

Principles of Bone Biology, 3rd Edition

(Beighton *et al.*, 1984; Beighton, 1988; Hamersma *et al.*, 2003; van Bezooijen *et al.*, 2005). The manifestations are most pronounced in mandible and skull, with characteristic enlargement of the jaw and facial bones leading to facial distortion, entrapment of cranial nerves often associated with facial palsy, and also eventually potential hearing loss, loss of smell, and increased intracranial pressure. Patients with sclerosteosis present, however, with the additional clinical features of syndactyly, have overall the worst prognosis. Sudden death owing to impaction of the brainstem in the foramen magnum has been described so far only in patients with sclerosteosis (Beighton, 1988; van Bezooijen *et al.*, 2005).

Biochemical and histological data suggest that bone formation is dramatically increased in both sclerosteosis and van Buchem disease (Hill *et al.*, 1986; Stein *et al.*, 1983; van Bezooijen *et al.*, 2004; Wergedal *et al.*, 2003). The newly laid bone is lamellar with no mineralization defect. Data on bone resorption are limited, however, and increase, decrease, or no change in bone resorption has been variably reported in the few patients studied. Bone is overall of very good quality as suggested by increased calculated bone volume and polar moment of inertia in patients with van Buchem disease (Wergedal *et al.*, 2003), increased bone mineral density (BMD) in patients with sclerosteosis (Gardner *et al.*, 2005), and no reported fractures in either disease (Beighton *et al.*, 2004).

Genetic Defects in Sclerosteosis and van Buchem Disease

The search for the gene defect that leads to sclerosteosis succeeded in 2001 with two groups simultaneously identifying mutations in a new gene that was named SOST (sclerosteosis) (Balemans *et al.*, 2001; Brunkow *et al.*, 2001). The SOST gene consists of two exons located at chromosome 17q12-21 and encodes for the protein sclerostin. The coding sequence consists of 642 base pairs that translate into a 213-amino-acid protein of which the first 23 amino acid residues provide a signal peptide for secretion (Fig. 1). Five mutations of the SOST gene have been identified so far in patients with sclerosteosis: the first introduces a premature termination codon in exon 1 (C70T/Gln24X), the second and third introduce premature termination codons in exon 2 (G372A/Trp124X and C376T/Arg126X), and the last two consist of base substitutions in the intron at positions +1 (G→C) and +3 (A→T), resulting in improper splicing of the coded message (Balemans *et al.*, 2001, 2005; Brunkow *et al.*, 2001).

None of these mutations in the SOST gene could be identified in the Dutch patients with van Buchem disease, but the same two groups did identify a 52-kb deletion 35 kb downstream of the SOST gene in these patients (Balemans *et al.*, 2002; Staehling-Hampton *et al.*, 2002). The deleted region was later found to contain regulatory elements for SOST transcription, thus explaining its ability to induce a phenotype closely resembling the sclerosteosis of South African patients, although of a less severe form and with no syndactyly. Genetic differences between the Dutch and South African populations and an incomplete absence of sclerostin in patients with van Buchem disease may explain the difference in severity of clinical symptoms between sclerosteosis and van Buchem disease.

Identification of the different genetic defects underlying the pathophysiology of the endosteal hyperosteosis in

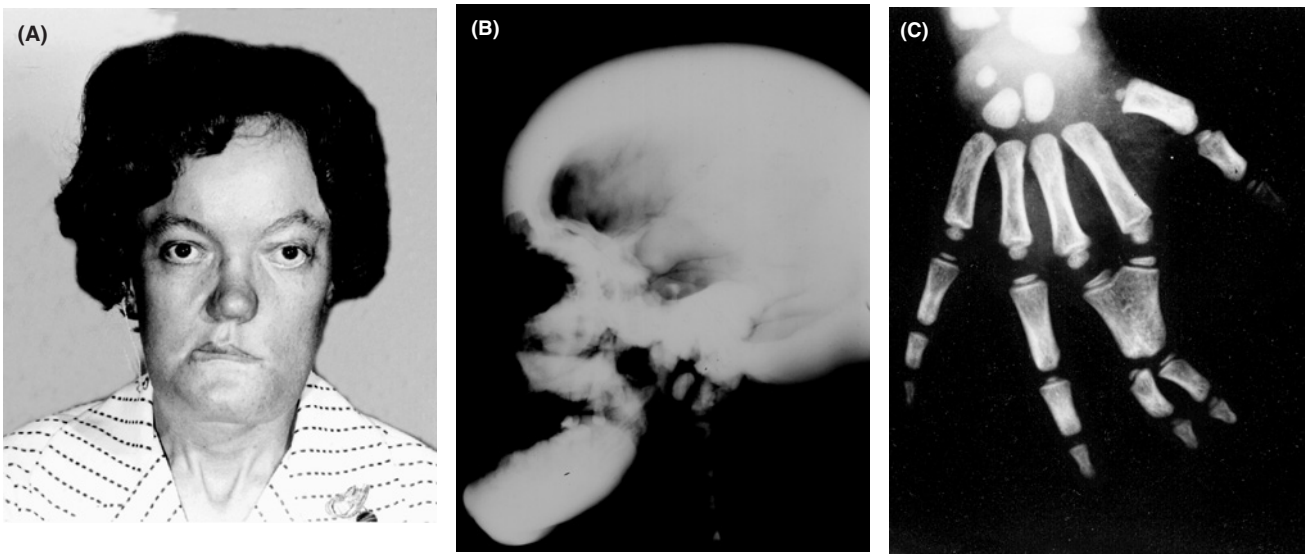

FIGURE 1 Clinical manifestations of sclerosteosis. (**A**) Patient with sclerosteosis with characteristic mandibular overgrowth, facial palsy, tall forehead, and deafness. (**B**) X-ray of the skull of an adult patient with sclerosteosis showing thickening of the skull and mandible. (**C**) X-ray of the hand of a child with sclerosteosis showing syndactyly of the second and third finger (Reprinted from van Bezooijen *et al.*, SOST/sclerostin, an osteocyte-derived negative regulator of bone formation. Cytokine & Growth Factor Reviews 2005 **16**(3) pp. 319–327 with permission from Elsevier).

sclerosteosis, van Buchem disease, and HBM phenotype (mutations in SOST, the van Buchem deletion, and mutations in LRP5, respectively), calls for a reclassification of previously identified patients on the basis of their genetic profile. For example, a patient previously described as having van Buchem disease was found to have a mutation in LRP5 (Van Wesenbeeck *et al.*, 2003), belonging thus to the HBM phenotype group.

SOST/Sclerostin Expression

SOST mRNA is expressed in many tissues, especially during embryogenesis, whereas sclerostin protein is expressed only postnatally in terminally differentiated cells embedded within a mineralized matrix, i.e., osteocytes, mineralized hypertrophic chondrocytes, and cementocytes.

SOST/Sclerostin Expression in Nonmineralized Tissues

SOST mRNA expression can be detected in several tissues other than bone during embryogenesis. Embryonic day 10.5 (E10) of mouse development is the earliest time point for detecting SOST expression that can be demonstrated in the otic vesicle (Ellies *et al.*, 2006). SOST mRNA expression is also found at E13 in the peridigital or interdigital regions of limb buds and it has been speculated that this may be implicated in the pathogenesis of syndactyly in patients with sclerosteosis (Ohyama *et al.*, 2004). A role for SOST in digit formation is further supported by abnormal digit formation in mice overexpressing SOST under its own promoter (Loots *et al.*, 2005).

From E15.5 up to the neonatal period, SOST is expressed within the medial vessel wall of the great arteries containing smooth muscle cells, more specifically in that of the ascending aorta, aortic arch, brachiocephalic artery, common carotids, and pulmonary trunk (van Bezooijen *et al.*, 2007b). In adult mice, however, SOST expression is no longer detected in the great arteries, suggesting that SOST expression is limited to the embryonic and early postnatal stages of cardiovascular development. In contrast, SOST/sclerostin remains expressed in mineralized bone well into adulthood (van Bezooijen *et al.*, 2004; Bellido *et al.*, 2005; Silvestrini *et al.*, 2007). In humans, SOST is expressed in heart and aorta as evaluated by real-time PCR analysis (Balemans *et al.*, 2001; Brunkow *et al.*, 2001). Our group could not detect, however, sclerostin expression in valves or great arteries of human adults (R. L. van Bezooijen, S. E. Papapoulos, N. A. T. Hamdy, and C. W. G. M. Löwik, unpublished observations). In a recent whole-genome expression profiling study, SOST mRNA expression was found to be downregulated in patients with abdominal aortic aneurysms compared with controls (Lenk *et al.*, 2007). Furthermore, high SOST mRNA levels have been reported in human kidney (Balemans *et al.*, 2001; Brunkow *et al.*, 2001) and SOST mRNA expression is expressed in mouse kidney (R. L. van Bezooijen *et al.*, unpublished observations). We did not find, however, any sclerostin protein in the few human renal biopsy specimens analyzed so far, including one previously reported to express SOST mRNA in glomeruli by *in situ* hybridization (Balemans and Van Hul, 2002). SOST mRNA expression has also been reported in fetal and adult human liver biopsies (Brunkow *et al.*, 2001; Kusu *et al.*, 2003). Patients with sclerosteosis or van Buchem disease do not demonstrate kidney abnormalities or clinical or radiological evidence for cardiovascular abnormalities (Hamersma *et al.*, 2003).

SOST/Sclerostin Expression in Mineralized Tissues

In vitro studies of SOST/sclerostin expression are technically difficult because of the current inability to isolate osteocytes from mammalian bones, with osteogenic cell cultures that form mineralized bone nodules being the only available method of generating osteocyte-like cells *in vitro* (Pockwinse *et al.*, 1992). In mouse primary osteogenic bone marrow and mouse mesenchymal KS483 cell cultures, SOST mRNA expression is induced at low levels after onset of bone nodule mineralization. This suggests that SOST is only expressed by a few cells, possibly osteocytes, within the bone nodules (van Bezooijen *et al.*, 2004). However, in mouse primary osteoblastic cultures of embryonic calvaria-derived cells, SOST is already expressed in undifferentiated cells and expression increases with differentiation (Ohyama *et al.*, 2004). In human primary osteogenic cultures that do not form bone nodules, SOST expression has been detected at the undifferentiated stage and increased upon mineralization (Balemans *et al.*, 2001; Sutherland *et al.*, 2004; van Bezooijen *et al.*, 2004; Winkler *et al.*, 2003).

SOST expression in undifferentiated osteoblastic cell lines is cell line dependent and may vary from absent/near absent (C2C12, C3H10T1/2, KS483, MC3T3-E1, OP9, ROS17/2.8, MG63, and TE85 cells) to moderate (Saos-2 and U2-OS cells) or high (UMR106 cells) (Keller and Kneissel, 2005; van Bezooijen *et al.*, 2004; Sevetson *et al.*, 2004). In the murine long-bone osteocyte (MLO) cell lines, reported to represent different stages of osteocyte differentiation (Kato *et al.*, 2001), SOST expression is variable and different from the observed induction of SOST expression upon mineralization. In MLO-Y4 cells that represent mature osteocytes in a mineralized matrix, SOST expression was either low (Bellido *et al.*, 2005) or absent (Keller and Kneissel, 2005), whereas in MLO-A5 cells that represent preosteocytes in osteoid, SOST mRNA levels were high (Bellido *et al.*, 2005).

During mouse embryogenesis, SOST mRNA is expressed in mineralized bones (Ellies *et al.*, 2006; Kusu *et al.*, 2003; van Bezooijen *et al.*, 2004; Winkler *et al.*, 2003; Ohyama *et al.*, 2004). At this early stage of bone

development, it is difficult to determine whether these cells are mineralizing osteoblasts or osteocytes. Sclerostin protein expression has not been reported at the embryonic stage, and we were unable to detect it using several monoclonal antibodies known to act on adult bone tissue (R. L. van Bezooijen *et al.*, unpublished observations). In contrast to the previously described expression of SOST mRNA at the embryonic stage, the earliest time point at which it was possible to detect sclerostin protein expression in mice was 5 days postnatally. In human embryonic bone, sclerostin expression could be detected in osteocytes, but the validity of these data is questionable because samples tested were from embryos with accelerated endochondral and intramembranous ossification in Blomstrand lethal osteochondrodysplasia. In normal human bone, the earliest detection of sclerostin expression so far is in osteocytes of a toe bone biopsy of a one-year-old boy (van Bezooijen *et al.*, 2005). In adult mouse and human bone, sclerostin expression is restricted to osteocytes with diffuse staining, representing dendrites in osteocytic canaliculi (Bellido *et al.*, 2005; Poole *et al.*, 2005; van Bezooijen *et al.*, 2004; Winkler *et al.*, 2003). Similar to the regulation of SOST mRNA *in vitro*, newly embedded osteocytes within unmineralized osteoid do not express sclerostin, but become positive for the protein at, or shortly after, primary mineralization (Poole *et al.*, 2005). The majority of osteocytes in mineralized cortical and cancellous bone are positive for sclerostin, and sclerostin-negative cells are located significantly closer to the surface than sclerostin-positive cells. Osteoclasts, osteoblasts, and bone lining cells do not express sclerostin. As expected, sclerostin is not expressed by osteocytes in bone biopsies of patients with sclerosteosis (van Bezooijen *et al.*, 2004). In addition, no sclerostin expression was found in bone biopsies from patients with van Buchem disease, supporting the notion of the presence of essential regulatory elements for sclerostin expression in bone within the deleted van Buchem region (van Bezooijen *et al.*, 2007a).

During mouse embryogenesis, SOST expression is also observed in odontoblasts that give rise to alveolar bone (Ellies *et al.*, 2006). In contrast, sclerostin expression is restricted to cementocytes in teeth of adult mice and humans (van Bezooijen *et al.*, 2007a). Sclerostin expression was absent in teeth of two patients with van Buchem disease and only a low signal was found in a third patient. It is possible, therefore, that sclerostin is involved in a similar negative feedback mechanism in teeth as in bone and that the protein inhibits cementum formation by cementoblasts. Lack of sclerostin may in turn result in hypercementosis and in a tighter junction between teeth and alveolar bone. No overt changes in cementum thickness were observed, however, by plain radiology of the jaw in patients with sclerosteosis or van Buchem disease.

At birth (P0), SOST mRNA expression can be detected in hypertrophic chondrocytes in mice (Ellies *et al.*, 2006). In human bone, sclerostin protein expression was found in hypertrophic chondrocytes (Winkler *et al.*, 2003), more specifically in mineralized hypertrophic chondrocytes in the growth plate (R. L. van Bezooijen *et al.*, unpublished observations), but it was absent in articular cartilage (van Bezooijen *et al.*, 2004). Although the role of sclerostin in the growth plate remains as yet to be elucidated, it may be responsible for a similar negative feedback mechanism on chondrocyte differentiation and function as on that of osteoblasts. Were this to be confirmed, the lack of sclerostin expression in mineralized hypertrophic chondrocytes may explain the reported tall stature observed in patients with sclerosteosis. Because tall stature is not a feature of Dutch patients with van Buchem disease, it would be very interesting, although technically difficult, to determine whether sclerostin is expressed in the growth plates of these patients.

MECHANISM OF ACTION OF SCLEROSTIN

Sclerostin Inhibits Bone Formation

In patients with sclerosteosis the combination of high bone mass owing to increased bone formation with premature termination codons in the SOST gene suggested an inhibitory effect of the gene product sclerostin on bone formation. Indeed, addition of exogenous sclerostin to osteogenic cultures inhibited proliferation and differentiation of mouse and human osteoblastic cells (Fig. 2) (Sutherland *et al.*, 2004; van Bezooijen *et al.*, 2004; Winkler *et al.*, 2003). It has also been shown that sclerostin may limit the life span of osteoblasts by stimulating their apoptosis (Sutherland *et al.*, 2004). Overexpression of sclerostin, using either the osteocalcin promoter or BAC recombination, induced osteopenia in mice by suppressing bone formation whereas bone resorption was reported to be unaffected (Loots *et al.*, 2005; Winkler *et al.*, 2003).

Sclerostin is a Member of the DAN Family of Glycoproteins

The amino acid sequence of sclerostin contains eight conserved cysteine and one glycine residue suggesting a cystine knot structure (Avsian-Kretchmer and Hsueh, 2004; Balemans *et al.*, 2001; Brunkow *et al.*, 2001; van Bezooijen *et al.*, 2005). Based on the finding of characteristic cysteine and glycine spacing, sclerostin belongs to the DAN (differential screening-selected gene aberrant in neuroblastoma) family of glycoproteins. This family consists of a group of secreted proteins that include wise, cerberus, DAN, coco, caronte, gremlin, dante, and protein related to DAN and cerberus (PRDC), sharing the ability to antagonize bone morphogenetic protein (BMP) activity. Of the BMP antagonists described so far, chordin and noggin have been shown to antagonize BMP signaling by blocking binding of BMPs to their receptors (Piccolo *et al.*, 1999;

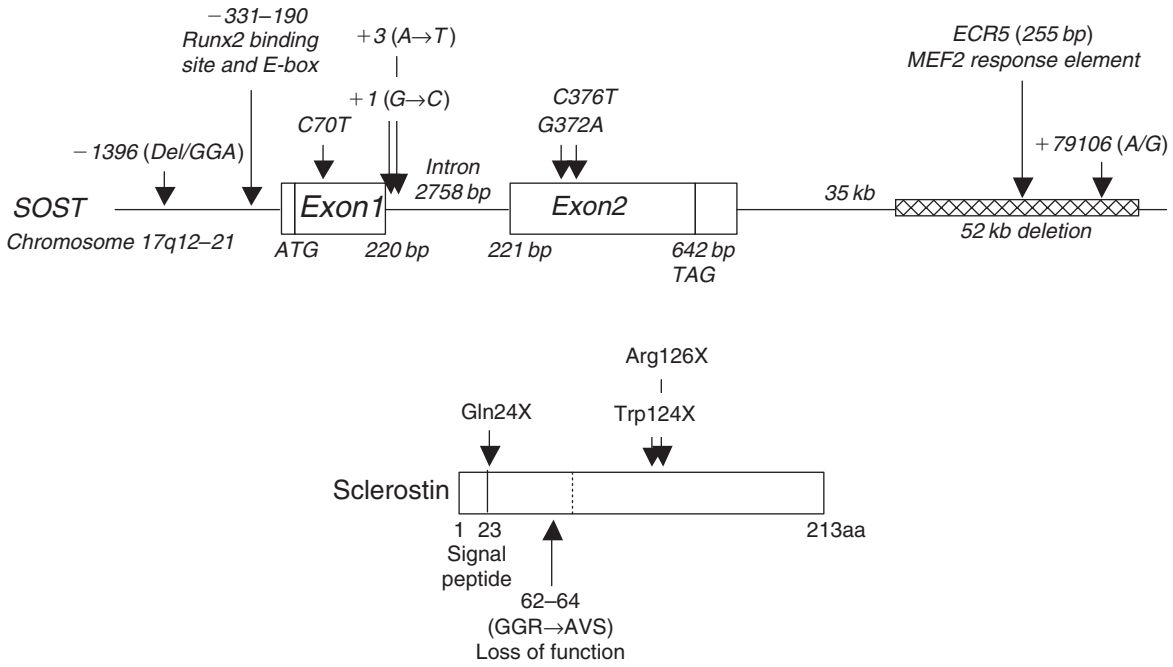

FIGURE 2 Schematic representation of SOST gene and sclerostin protein. The SOST gene is located at chromosome 17q12-21 and consists of 2 exons. In patients with sclerosteosis, three mutations (C70T, G372A, and C376T) have been found in the exons and two mutations (+1 G→C and +3 A→T) in the intron. In Dutch patients with van Buchem disease a 52-kb deletion is found 35 kb downstream of the SOST gene. Two polymorphisms surrounding the SOST gene have been associated with BMD (−1396 del/GGA and +79106 A/G). Regulatory elements of transcription have been identified upstream of the SOST gene (−331–190) and within the region deleted in van Buchem disease (ECR5). MEF2 transcription factors have been shown to bind and stimulate activity of this element. The SOST gene encodes for a 213-amino-acid protein of which the first 23 residues provide a signal peptide for secretion. The three mutations within the exons result in a premature stop of translation at Gln24X, Trp124X, and Arg126X. Amino acids 62–64 are essential for sclerostin function.

Zimmerman *et al.*, 1996). A similar mechanism has been proposed for members of the DAN family.

BMPs are secreted cytokines, originally identified by their ability to induce ectopic bone and cartilage formation (Urist, 1965). BMPs exert their effects through two distinct types of serine/threonine kinase receptors, i.e., type I and type II receptors (Canalis *et al.*, 2003; van Bezooijen *et al.*, 2005). Although having a relative low binding affinity for BMPs, sclerostin was shown to antagonize BMP-stimulated bone formation *in vitro* and *in vivo* (Kusu *et al.*, 2003; van Bezooijen *et al.*, 2004, 2007c; Winkler *et al.*, 2003). The mechanism by which sclerostin antagonizes BMP-stimulated bone formation is different from that of classical BMP antagonists, because it neither antagonizes early BMP responses such as Smad1/5/8 phosphorylation and BMP reporter construct activation nor inhibits stimulation of direct BMP target genes in several osteoblastic cell lines (van Bezooijen *et al.*, 2004, 2007c).

Sclerostin Antagonizes LRP5/6-Mediated Canonical Wnt Signaling

At the turn of the century, human genetic studies provided compelling evidence for a role of gain-of-function mutations in LRP5 in patients with the HBM phenotype (Boyden *et al.*, 2002; Little *et al.*, 2002) and loss-of-function mutations in LRP5 in the osteoporosis pseudoglioma syndrome (OPPG) (Gong *et al.*, 2001). LRP5 is a coreceptor of the canonical Wnt signaling pathway that has been shown to play a pivotal role in bone formation (Baron *et al.*, 2006; Glass and Karsenty, 2007). Wnts are secreted cytokines with pivotal roles in a variety of cellular activities, including cell fate determination, proliferation, migration, polarity, and differentiation (Clevers, 2006). Wnts are distinguished into Wnts that involve β-catenin signaling (canonical pathway) and Wnts that do not (noncanonical pathway). The canonical pathway involves the formation of complexes of Wnts with Frizzled receptors and coreceptors LRP5/6. Upon stimulation, the intracellular signaling molecule β-catenin accumulates and translocates into the nucleus, where it initiates transcription of target genes via complex formation with TCF/Lef1 transcription factors (Fig. 3). Conversely, in the absence of Wnt ligand, β-catenin forms a complex with the tumor suppressor proteins APC and Axin, and the kinases glycogen synthase kinase 3 (GSK3) and casein kinase 1 (CK1), which facilitates phosphorylation and proteosomal degradation of β-catenin.

Wnt signaling is extracellularly regulated by antagonists of which Dkk1 is the best characterized. Dkk1 exerts its

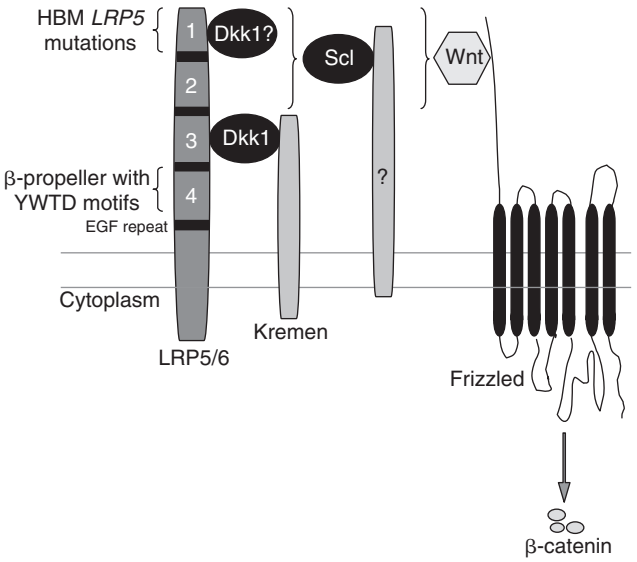

FIGURE 3 Schematic model of antagonized canonical Wnt signaling. Canonical Wnt signaling involves the formation of complexes of Wnts with Frizzled receptors and LRP5/6 coreceptors, resulting in the accumulation of β-catenin in the cytoplasm and translocation into the nucleus. The antagonist Dkk1 inhibits canonical Wnt signaling by the formation of complexes with LRP5/6 and Kremen, resulting in the removal of LRP5/6 from the membrane. Dkk1 binds to the third and probably also the first β-propeller of LRP5/6. The antagonist sclerostin inhibits canonical Wnt signaling by binding to probably the first β-propeller of LRP5/6. Whether sclerostin requires a cofactor like Kremen for Dkk1 to exert its antagonistic effect remains to be established.

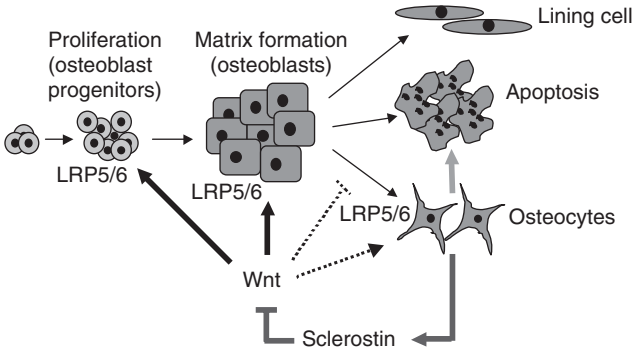

FIGURE 4 Simplified scheme of the inhibitory effect of sclerostin on Wnt-mediated osteoblast development and osteoblast survival. Sclerostin produced and secreted by osteocytes antagonizes LRP5/6-mediated Wnt signaling and inhibits, thereby, the stimulatory effect of Wnts on osteoblast development. In addition, sclerostin may stimulate osteoblast apoptosis.

antagonistic effect by forming a complex with Kremen and LRP5/6 that triggers clearance of these Wnt coreceptors from the membrane by endocytosis (Fig. 4) (Mao *et al.*, 2002). The extracellular part of LRP5/6 consists of four β-propellers that contain YWTD motifs and are separated by EGF-like repeats. The third β-propeller of LRP5/6 was found to be crucial for binding to and for the inhibition by Dkk-1 (Mao *et al.*, 2001; Zhang *et al.*, 2004). However, all ten currently described mutations in patients with HBM are located within the first β-propeller of LRP5 (Balemans and Van Hul, 2007) and have been shown to exhibit reduced binding to and decreased inhibition by Dkk-1, suggesting an additional role for this region in Dkk-1 function (Li *et al.*, 2005; Balemans *et al.*, 2007; Ai *et al.*, 2005; Boyden *et al.*, 2002; Zhang *et al.*, 2004; Bhat *et al.*, 2007).

Three members of the DAN family, i.e., *Xenopus* cerberus, coco, and wise, have been found to antagonize Wnt activity (Bell *et al.*, 2003; Itasaki *et al.*, 2003; Piccolo *et al.*, 1999). Of these antagonists, wise (also known as USAG-1 and ectodin) has the highest amino acid similarity (38%) with sclerostin (Avsian-Kretchmer and Hsueh, 2004). Both genes are missing in the fly and the nematode and a single orthologue is found in *Fugu rubripes* and *Ciona intestinalis*. Both proteins lack a cysteine residue, present in other DAN family members, which is potentially involved in dimerization. Wise appears to be a context-dependent inhibitor and activator of Wnt signaling (Itasaki *et al.*, 2003). In the absence of Wnts, wise binds to the coreceptor LRP6 and may act as a weak agonist to Wnt signaling. In the presence of Wnts, wise competes, however, with Wnt for binding to LRP6 and antagonizes Wnt signaling.

Sclerostin also binds to LRP5/6 and antagonizes Wnt1, Wnt3, Wnt3a, Wnt6, and Wnt10b-stimulated activation of canonical Wnt reporter constructs in human embryonic kidney and mouse osteoblastic cell lines (see Fig. 4) (Li *et al.*, 2005; Semenov *et al.*, 2005; van Bezooijen *et al.*, 2007c; Ellies *et al.*, 2006; Semenov and He, 2006). It was reported that sclerostin did not antagonize Wnt3A-induced β-catenin stabilization in mouse mesenchymal C3H10T1/2 cells (Winkler *et al.*, 2005). We found, however, that sclerostin overexpression decreased Wnt-induced β-catenin nuclear translocation in human embryonic kidney cells (R. L. van Bezooijen *et al.*, unpublished observation). *In vivo*, SOST overexpression inhibits Wnt8-induced duplication of the body axis, and expression of the direct target genes siamois and Xnr3 in *Xenopus* embryos (Ellies *et al.*, 2006; Semenov *et al.*, 2005).

Sclerostin binds to the first two β-propeller domains of LRP5/6 that include the HBM LRP5 mutations (see Fig. 4) (Li *et al.*, 2005; Semenov *et al.*, 2005). Subsequent studies have demonstrated that the binding of sclerostin to some of these HBM LRP5 mutations (G171V, D111Y, R154M, N198S, A214T, and T253I) and the analogous change to LRP5G171V in LRP6 (G158V) is decreased, leading to decreased inhibition of canonical Wnt signaling (Ellies *et al.*, 2006; Semenov and He 2006; Li *et al.*, 2005).

The mechanism by which sclerostin binding to LRP5/6 antagonizes Wnt signaling is intriguing. Although sclerostin and Wnts both bind to the first two β-propellers of LRP5/6, neither appears to compete for LRP5/6 binding (Li *et al.*, 2005). In a Wnt reporter assay, site-directed mutagenesis of amino acids 62–64 of sclerostin by similarly charged amino acids (GGR → AVS) reduced binding of sclerostin to LRP6

and reduced its inhibitory effect, demonstrating the importance of this conserved domain for the function of sclerostin (see Fig. 1) (Ellies *et al.*, 2006). Whether sclerostin requires a coreceptor like Kremen for Dkk1 to induce internalization of LRP5/6 remains to be established. It is, nevertheless, attractive to speculate that mutations in such a cofactor may explain the sclerosteosis-like phenotype in patients who do not demonstrate mutations in SOST or in conserved surrounding regions or in patients who do not have a deletion of the van Buchem region {Balemans, 2007; R. L. van Bezooijen *et al.*, unpublished observations}.

LRP5-mediated canonical Wnt signaling occurs in a wide range of tissues. Nevertheless, patients with activating mutations in LRP5 have a phenotype that is restricted to the skeleton. This can be explained by decreased binding to LRP5 by the antagonist sclerostin of which expression is largely restricted to bone in adults. However, it is currently unclear how decreased binding of the widely expressed antagonist Dkk1 could result in such a restricted skeletal phenotype.

REGULATION OF SOST/SCLEROSTIN EXPRESSION

Regulation of SOST/Sclerostin Expression by Local and Systemic Factors

Osterix and runx-2 are two essential transcription factors in osteoblast differentiation that have been shown to stimulate SOST expression. In primary mouse osteoblastic cultures, osterix expression was found to precede SOST induction and to colocalize in the limb buds, calvaria, and mandibles of mouse embryos, and RNAi silencing of osterix expression downregulated SOST expression (Ohyama *et al.*, 2004). This effect may have been indirect via inhibition of osteoblastic differentiation, because osteocalcin expression was also downregulated. BMPs, BMP-2, 4, and 6, induce SOST expression in mouse and human osteogenic cells, suggesting a protective mechanism to prevent excessive bone formation owing to BMP stimulation (Ohyama *et al.*, 2004; Sutherland *et al.*, 2004).

Parathyroid hormone (PTH) is currently the only available therapy able to stimulate bone formation in patients with osteoporosis (Neer *et al.*, 2001; Shoback, 2007). Although its anabolic effect is well established, the molecular mechanism responsible for this action is not yet fully understood. PTH has recently been shown to inhibit SOST/sclerostin expression *in vitro* and *in vivo*. *In vitro*, PTH decreased SOST transcription within 4 hours and this was not affected by the protein synthesis inhibitor cycloheximide (Keller and Kneissel, 2005; Bellido *et al.*, 2005). SOST mRNA degradation was not affected by PTH. PTH-inhibited SOST expression may involve the cAMP pathway, because addition of the cAMP inducer forskolin also decreased SOST expression. This downregulation is probably not regulated at the proximal SOST promoter site, but involves inhibition of a response element for myocyte enhancer factor 2 (MEF2) transcription factors within the van Buchem deletion (see Fig. 1) (Leupin *et al.*, 2007).

Interpretation of *in vivo* data is more complicated. Consistent with the hypothesis that PTH stimulates bone formation by inhibiting sclerostin expression, daily injections of PTH decreased SOST/sclerostin expression in mice and rats (Keller and Kneissel, 2005; Silvestrini *et al.*, 2007). However, daily PTH injections for 4 days did no affect SOST/sclerostin expression in another study in mice, but a bone catabolic schedule of 4 days of continuous PTH infusion did (Bellido *et al.*, 2005). This difference in response may be because of differences in the time points at which SOST/sclerostin expression analysis was performed, i.e., 15 minutes and 24 hours after the last injection.

Continuous PTH excess and intermittent elevated PTH levels both increase osteoblast (and osteoclast) numbers, but are associated with bone catabolism and anabolism, respectively. SOST/sclerostin downregulation may thus be involved in the stimulation of bone formation in both conditions, whereas other effects of PTH may determine the effect of the hormone on bone resorption. The balance between all these effects will eventually determine the absolute effect on bone mass. Further studies are required to elucidate the precise role of sclerostin in the bone-forming action of PTH.

1,25-Dihydroxyvitamin D3 and glucocorticoids are two other systemic factors that may affect SOST expression. In the human osteosarcoma cell line Saos-2, endogenously expressed SOST is increased by the addition of 1,25-dihydroxyvitamin D3 (Sevetson *et al.*, 2004). In human mesenchymal stem cells, 1,25-dihydroxyvitamin D3 and retinoic acid further stimulated BMP-induced SOST expression (Sutherland *et al.*, 2004). In contrast, dexamethasone abolishes SOST expression in these cells. Because dexamethasone is required to induce human osteogenic cells to differentiate into mature mineralizing cells, this may be another explanation for the low levels of SOST expression in these cultures.

The location of osteocytes and their extensive connected cellular network renders these cells ideal for sensing and translating mechanical signals into cellular adaptive responses (Knothe Tate *et al.*, 2004; Han *et al.*, 2004). Sclerostin's specific expression in osteocytes and its negative regulatory effect on bone formation renders it an attractive candidate for a mechanically modulated osteocyte-derived factor that translates mechanical signals into cellular responses. Preliminary data indicate that mechanical loading decreases both the number and the staining intensity of sclerostin-positive osteocytes in the ulnar diaphysis of mice (Robling *et al.*, 2006). This suggests that stimulation of bone formation by mechanical loading may involve downregulation of sclerostin expression in osteocytes.

SOST Promoter and Regulatory Elements

Alignment of human and mouse SOST nucleotide sequences showed a more than 50% homology within the first 2000 bp upstream of the SOST gene, and this region was found to drive transcription in human and rat osteosarcoma in human embryonic kidney cell lines (Loots *et al.*, 2005; Sevetson *et al.*, 2004). A 142-bp element was identified within this region between nucleotides −331 and −190 relative to the initiation methionine of the SOST coding gene, which was enough to drive SOST transcription in human osteosarcoma Saos-2 cells (see Fig. 1) (Sevetson *et al.*, 2004). Within this element, a runx-2-binding site was essential for its transcriptional activity and runx-2 overexpression stimulated it. In addition, an E-box motif within this element was involved in its transcriptional activity and MyoD overexpression may stimulate it. A C/EBP consensus site, also located within this region, did not appear to regulate transcription. This juxtaposition of Cbfa-1, E-box, and C/EBP within the SOST promoter was suggested to have an intriguing resemblance with the osteocalcin promoter. Osteocalcin is also differentially expressed in the course of osteoblastic differentiation and its deficiency in knockout mice is associated with high bone mass (Ducy *et al.*, 1996).

Analysis of BAC SOST transgenic mice lacking the van Buchem region showed that this region contains regulatory elements essential for SOST expression in bone (Loots *et al.*, 2005). More detailed analysis by stringent alignment between human and mouse sequences (= 80% identity over a 200-bp window) identified seven evolutionarily conserved regions within the van Buchem deletion. One of these regions (ECR5) stimulated transcription specifically in osteoblastic cells and in the skeleton of E14.5 mouse embryos (see Fig. 1). Existence of key regulatory elements within the van Buchem deletion is further supported by the presence of a polymorphism within this region (SRP9, +79106; A/G) that is associated with BMD in elderly men (Uitterlinden *et al.*, 2004). This polymorphism is not within a human–mouse conserved region, but may be in linkage disequilibrium with ECR5. In elderly women, another polymorphism associated with BMD (SRP3, −1396;Del/GGA) is located within the direct upstream promoter region of the SOST gene.

SCLEROSTIN FUNCTION IN BONE MODELING AND REMODELING

Two processes are responsible for construction and reconstruction of the skeleton throughout life, bone modeling and remodeling, respectively. In the process of modeling, bones are shaped and reshaped by the independent actions of osteoblasts and osteoclasts during skeletal development or in response to changes in mechanical loading and aging in adults. Bone remodeling is the process that enables constant renewal of the skeleton. It begins *in utero* and continues throughout life. In this process, bone resorption by osteoclasts and formation by osteoblasts are tightly coupled within a basic multicellular unit (BMU) in which distinct phases of activation, resorption, reversal, and formation can be distinguished.

In the process of remodeling, bone lining cells may be involved in the initiation of bone resorption (Teitelbaum, 2000). The limited data available on patients with sclerostin deficiency indicate, however, that bone resorption is not consistently altered (Hill *et al.*, 1986; Stein *et al.*, 1983; Wergedal *et al.*, 2003), suggesting that an effect of sclerostin on bone resorption is unlikely. It is conceivable that induction of sclerostin expression by newly embedded osteocytes at the onset of mineralization of osteoid may serve as a negative feedback mechanism that would inhibit bone formation by osteoblasts and prevent overfilling of the BMU and uncontrolled bone growth (Fig. 5A) (Poole *et al.*, 2005; van Bezooijen *et al.*, 2004). In this case, absence or downregulation of sclerostin would increase osteoblast numbers and/or prolong the active bone-forming phase of osteoblasts and thereby increase the amount of bone formed.

In the process of bone modeling, it could be hypothesized that sclerostin expression by osteocytes would keep bone lining cells in a state of quiescence (Poole *et al.*, 2005) and may thereby prevent initiation of *de novo* bone

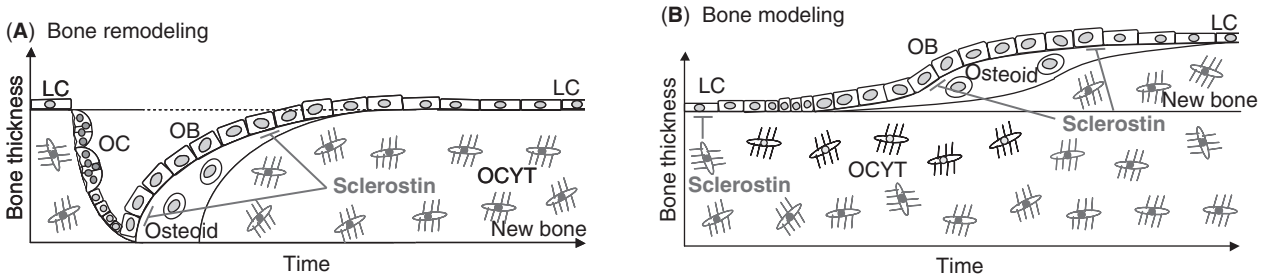

FIGURE 5 Schematic model of the mechanism of action of sclerostin in bone remodeling and modeling. (**A**) In remodeling, sclerostin produced and secreted by newly embedded osteocytes may be transported to the bone surface where it inhibits osteoblastic bone formation and prevents overfilling of the BMU. (**B**) In modeling, sclerostin may serve two actions. First, it may keep bone lining cells in a state of quiescence and prevent, thereby, initiation of *de novo* bone formation. In addition, sclerostin produced and secreted by newly embedded osteocytes may inhibit osteoblastic bone formation similarly to a BMU.

formation (see Fig. 5B). In this model, downregulation of sclerostin expression in osteocytes would induce activation of osteoblasts and stimulate bone formation without previous bone resorption. In addition, sclerostin expressed by osteocytes embedded in new bone formed by bone modeling may demonstrate a similar negative feedback mechanism on bone formation as in a BMU.

Sclerostin produced and secreted by osteocytes may be transported to the bone surface via the canaliculi where it may antagonize LRP5/6 mediated canonical Wnt signaling in osteoblasts, thereby, inhibiting Wnt-stimulated bone formation. Alternatively, sclerostin may antagonize canonical Wnt signaling in osteocytes and regulate another signal that is transported to osteoblasts and inhibits bone formation. In support of this latter view is the observation that Wnt signaling is present in osteocytes in bones of embryonic and adult mice (Hens *et al.*, 2005).

Of the canonical Wnts so far reported to be antagonized by sclerostin, Wnt1, Wnt3, Wnt3a, Wnt6, and Wnt10b, only the last one is expressed in bone. Other Wnts reported to be expressed in bone are Wnt4, Wnt7b, and Wnt9a (formally Wnt14), but the effect of sclerostin on these Wnts is unknown. Interestingly, Wnt10b overexpression, using the adipocyte-specific FABP4 promoter, increased bone mass in mice, whereas mice deficient in Wnt10b had a lower bone mass (Bennett *et al.*, 2005).

Mechanical loading and PTH therapy, two important stimulatory pathways for bone formation, have both been reported to mediate their bone anabolic effect, at least in part, by downregulating SOST/sclerostin expression in osteocytes (Bellido *et al.*, 2005; Keller and Kneissel, 2005; Robling *et al.*, 2006; Silvestrini *et al.*, 2007). Both pathways have been shown to affect bone modeling and remodeling and could, therefore, stimulate bone formation by downregulating sclerostin expression (see Fig. 5A and B).

RELATIONSHIP BETWEEN INHIBITION OF CANONICAL WNT SIGNALING AND THE CLINICAL SPECTRUM OF ENDOSTEAL HYPEROSTOSIS DISORDERS

HBM phenotype is an autosomal dominant condition that resembles sclerosteosis and van Buchem disease and is characterized by increased bone mass owing to enhanced bone formation (Johnson *et al.*, 1997). Although sclerosteosis, van Buchem disease, and the HBM phenotype have similar bone phenotypes, two distinct molecular mechanisms, increased BMP and Wnt signaling, were initially thought to be involved in the pathogenesis of these disorders. The recent discovery that sclerostin antagonizes Wnt signaling rather than BMP signaling suggests, however, that these skeletal disorders are more likely to be caused by increased activity of one and the same signaling pathway, i.e., the canonical Wnt signaling pathway. In the HBM phenotype, mutations within the first propeller of LRP5 result in increased canonical Wnt signaling, resulting in increased bone formation. Whether this results from the decreased ability of Dkk1 and/or sclerostin to inhibit canonical Wnt signaling is as yet unclear. In sclerosteosis and van Buchem disease, absence of sclerostin may result in increased LPR5/6-mediated Wnt signaling and increased bone formation.

The difference in the severity of clinical features between sclerosteosis, van Buchem disease, and HBM phenotype suggests a possible relationship with the degree of inhibition of canonical Wnt signaling (Fig. 6). Within the Afrikaner population in South Africa heterozygote carriers of sclerosteosis have BMD values consistently higher than healthy subjects but have no skeletal manifestations of hyperostosis (Gardner *et al.*, 2005). This suggests that loss of one functional SOST allele may be sufficient to lead to increased canonical Wnt signaling, resulting in increased bone formation and bone mass. Patients with the HBM phenotype have increased bone mass and variable symptomatology, ranging from complete absence of symptoms and signs to jaw enlargement, torus palatinus, cranial nerve entrapment, craniosynostosis, and developmental delay (Balemans and Van Hul, 2007; Levasseur *et al.*, 2005). This variance may be related to the extent by which mutations in LPR5 may affect the negative control of canonical Wnt signaling. Absence of sclerostin staining in bone biopsies of patients with van Buchem disease (van Bezooijen *et al.*, 2007a) and the essential role of the van Buchem region in sclerostin expression in bone (Loots *et al.*, 2005) suggest that in these patients increased bone formation is caused by increased LRP5-mediated Wnt signaling resulting from absence of the canonical Wnt antagonist sclerostin. Sclerostin also binds to LRP6, the other coreceptor involved in canonical Wnt signaling. Absence of sclerostin may, therefore, increase canonical Wnt signaling mediated through both coreceptors. Patients with sclerosteosis have the most severe phenotype. This may be because of the differences in genetic background between patients with van Buchem disease and sclerosteosis, but it may also be because of residual sclerostin in patients with

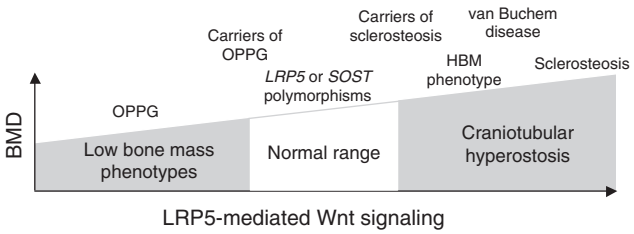

FIGURE 6 Relationship between inhibition of canonical Wnt signaling and clinical spectrum and variations in BMD. Decreased and increased LRP5-mediated canonical Wnt signaling is associated with decreased and increased BMD in humans, respectively.

van Buchem disease. Whereas no sclerostin expression was found in bone biopsies of all six patients with sclerosteosis analyzed so far (van Bezooijen *et al.*, 2004), we found very low levels of sclerostin expression in cementocytes from one of three patients with van Buchem disease (van Bezooijen *et al.*, 2007a). This may indicate that deletion of the van Buchem region does not result in complete absence of sclerostin expression and that the remaining sclerostin levels may still regulate canonical Wnt signaling, thereby, potentially explaining the less severe phenotype of patients with van Buchem disease.

Mutations in LRP6 have not been reported in patients with the HBM phenotype. Although this might be just a matter of time, there may also be a biological explanation for the absence of these mutations. For instance, contribution of LRP6 to the determination of bone mass may be less than that of LRP5. However, LRP5 and LRP6 heterozygote knockout mice demonstrate similar changes in bone mass and in biochemical markers of bone metabolism (Holmen *et al.*, 2004). Alternatively, mutations in LRP6 that decrease sclerostin function may have lethal effects that are not induced by LRP5 HBM mutations.

Mutations in LRP5 other than those in the HBM phenotype have been associated with a decrease in bone mass. Forty-eight mutations in LRP5 have been reported in OPPG, a rare autosomal recessive disorder characterized by severe juvenile-onset osteoporosis, congenital or infancy-onset blindness, and a variable degree of mental retardation, muscular hypotonia, ligamentous laxity, obesity, abnormal hair, seizures, and ventricular septum defects (Balemans and Van Hul, 2007; Levasseur *et al.*, 2005). These mutations are either deleterious (nonsense, frameshift, or splice site mutations) or consist of missense variants shown or expected to result in decreased canonical Wnt signaling. Similar to the allele dose-dependent effect of SOST on BMD in heterozygous carriers of sclerosteosis and homozygotes (Gardner *et al.*, 2005), heterozygous carriers of OPPG are considered phenotypically normal but have decreased BMD and are more susceptible to osteoporotic fractures (Gong *et al.*, 2001).

Variations in BMD within the normal range have been correlated with polymorphisms in both SOST and LRP5. Two polymorphisms in SOST, a 3-bp insertion at position −1396 of the SOST gene and a G-variant in the van Buchem region, have been associated with BMD in elderly whites aged 55 years (Uitterlinden *et al.*, 2004) and several studies have reported an association between polymorphisms in LRP5 and BMD in children, adolescents, and adults (Balemans and Van Hul, 2007). Interestingly, two genetic variations in exons 10 and 18 of LRP5 that are associated with BMD also affect Wnt signaling (Kiel *et al.*, 2007). In addition, these variations affected the relationship between physical activity and BMD in men, suggesting that differences in Wnt signaling owing to variations in LRP5 may play a role in adaptation of bone to mechanical loading, subsequently determining bone mass.

THERAPEUTIC POTENTIAL OF TARGETING SCLEROSTIN

Skeletal disorders are prevalent and associated with significant morbidity and mortality. Independent of etiology, disturbances of bone remodeling constitute the pathophysiological basis of most of the known skeletal diseases. A typical example is osteoporosis in which there is an imbalance between bone resorption and bone formation, in favor of the former, leading to bone loss, disturbed bone microarchitecture, and increased risk of fracture. Correction of the imbalance in bone remodeling either by suppressing bone resorption by using antiresorptive agents such as bisphosphonates or stimulating bone formation by using anabolic agents such as PTH have been shown to significantly reduce the risk of fractures. Antiresorptive agents do not restore already lost bone, however. For this, new therapeutic strategies that stimulate bone formation and induce a positive bone balance are required. In patients with sclerosteosis and van Buchem disease the positive bone balance observed results from the increased formation of bone of excellent quality. Therefore, inhibition of sclerostin production and/or activity may thus provide a therapeutic target for the development of specific bone-forming agents. Moreover, the restricted pattern of sclerostin expression suggests that such agents would be devoid of any extraskeletal effects and thus bear limited risks for side effects.

Inhibition of sclerostin activity by humanized neutralizing monoclonal antibodies has been shown to stimulate bone formation and restore bone mass in preliminary studies in rodents and primates (Ominsky *et al.*, 2006a, 2006b). Recently, preliminary data from a blinded, placebo-controlled, dose-escalating single-dose study in 48 healthy postmenopausal women demonstrated that a single injection of a monoclonal antibody to sclerostin significantly increased the bone formation markers osteocalcin, BSAP, and P1NP, and that therapy was well tolerated (Padhi *et al.*, 2007).

PERSPECTIVES

Identification of sclerostin deficiency as the underlying cause of the two rare skeletal disorders sclerosteosis and van Buchem disease has opened an exciting new field in bone research. Sclerostin's highly restricted expression pattern and its negative regulatory effect on bone formation has identified it as a secreted factor produced by osteocytes that inhibits osteoblast activity and prevents excessive bone formation. Regulating sclerostin expression is

likely to represent a key mechanism in the determination of bone mass. Furthermore, inhibition of sclerostin activity has been shown to stimulate bone formation and increase bone mass in rodents and primates and serum bone formation markers in humans.

Data accumulated during the past 4 years demonstrated that sclerostin antagonizes canonical Wnt signaling through binding to the coreceptors LRP5/6. The precise mechanism by which binding of sclerostin to LRP5/6 interferes with canonical Wnt signaling, however, remains to be elucidated. It also remains unclear whether HBM LRP5 mutations result in increased canonical Wnt signaling owing to decreased Dkk-1 and/or sclerostin function. Nevertheless, the discovery of the mechanism underlying the increased bone formation observed in sclerosteosis and van Buchem disease has revealed increased canonical Wnt signaling as the common affected pathway in these skeletal disorders of high bone mass owing to increased bone formation.

An important challenge will be the identification of regulators of sclerostin/SOST expression that in turn may determine sclerostin's highly restricted expression in pattern. An essential regulatory element within the van Buchem region and its control by MEF2 transcription factors has already been identified.

Characterization of sclerosteosis and van Buchem disease, in combination with the HBM phenotype, has also opened a new research area for therapeutic interventions for the most prevalent of skeletal disorders, osteoporosis. Of particular interest are the consistently higher BMD values of carriers of sclerosteosis without any clinical complications, suggesting that production and/or activity of sclerostin may be titrated without any side effects.

In addition to providing a new basis for the management of individuals with osteoporosis, better understanding of the sclerosing skeletal disorders sclerosteosis and van Buchem disease and of the molecular mechanism of sclerostin action may help in the management of this small group of patients, for whom the only currently available treatment is the hazardous and technically difficult surgical removal of excessive bone in the skull.

ACKNOWLEDGMENTS

We thank Dr. H. Hamersma, Department of Otolaryngology, University of Pretoria, South Africa, for kindly providing pictures and X-rays of patients with sclerosteosis.

INTRODUCTION

The osteocyte is the most abundant cell type of bone. There are approximately 10 times as many osteocytes as osteoblasts in adult human bone (Parfitt, 1977), and the number of osteoclasts is only a fraction of the number of osteoblasts. Our current knowledge of osteocytes lags behind what we know of the properties and functions of both osteoblasts and osteoclasts. However, the striking structural design of bone predicts an important role for osteocytes.

Considering that osteocytes have a very particular location in bone, not on the bone surface but spaced regularly throughout the mineralized matrix, and considering their typical morphology of stellate cells, which are connected with each other via long, slender cell processes, a parallel with the nerve system springs to one's mind. Are the osteocytes the "nerve cells" of the mineralized bone matrix, and if so, what are the stimuli that "excite" the cells? The answers to these questions may very well come from studies in which biomechanical concepts and techniques are applied to bone cell biology. Both theoretical considerations and experimental results have strengthened the notion that osteocytes are the pivotal cells in the biomechanical regulation of bone mass and structure (Cowin *et al*., 1991; Mullender and Huiskes, 1994, 1995; Klein-Nulend *et al*., 1995b). This idea poses many new questions that must be answered. By which mechanism(s) are loading stimuli on bone translated into biochemical stimuli that regulate bone (re)modeling, and what is the nature of these signaling molecules? How and where do the mechanical and hormonal regulatory systems of bone interact? Are osteocytes mere signaling cells, or do they contribute actively to bone metabolic processes such as mineralization, a process that takes place around newly incorporated osteocytes at some distance of the bone matrix formation front?

The development of osteocyte isolation techniques, the use of highly sensitive (immuno)cytochemical and *in situ* hybridization procedures, and the usefulness of molecular biological methods even when only small numbers of cells are available, have rapidly increased our knowledge about this least understood cell type of bone in the recent past and will certainly continue to do so in the future. This chapter compiles and analyzes the most recent findings, and it is hoped that it contributes to the development of new ideas and thoughts about the role of osteocytes in the physiology of bone.

THE OSTEOCYTIC PHENOTYPE

The Osteocyte Network

Mature osteocytes are stellate shaped or dendritic cells enclosed within the lacunocanalicular network of bone. The lacunae contain the cell bodies. From these cell bodies, long, slender cytoplasmic processes radiate in all directions, but with the highest density perpendicular to the bone surface (Fig. 1). They pass through the bone matrix via small canals, the canaliculi. Processes and their canaliculi may be branched. The more mature osteocytes are connected by these cell processes to neighboring osteocytes, the most recently incorporated osteocytes to neighboring osteocytes and to the cells lining the bone surface. Some of the processes oriented to the bone surface, however, appear not to connect with the lining cells, but to pass through this cell layer, thereby establishing a direct contact between the osteocyte syncytium and the extraosseus space. This intriguing observation by Kamioka *et al*. (2001) suggests the existence of a signaling system between the osteocyte and the bone marrow compartment without intervention

of the osteoblasts/lining cells. Osteocytes also appear to be able to retract and extend their dendritic processes, not only between cells in the bone matrix, but also into marrow spaces as shown by dynamic imaging (Veno *et al.*, 2006). This has implications with regards to osteocytes making and breaking communication between cells.

Dramatic changes occur in the distribution of actin-binding proteins during terminal differentiation of osteoblasts to osteocytes (Kamioka *et al.*, 2004). The typical morphology of the osteocyte was originally thought to be enforced on differentiating osteoblasts during their incorporation in the bone matrix. Osteocytes must remain in contact with other cells and ultimately with the bone surface to ensure the access of oxygen and nutrients. Culture experiments with isolated osteocytes have shown, however, that although the cells lose their stellate shape in suspension, they re-express this morphology as soon as they settle on a support (Van der Plas and Nijweide, 1992) (Fig. 2). Apparently, the typical stellate morphology and the need to establish a cellular network are intrinsic characteristics of terminal osteocyte differentiation.

In bone, gap junctions are present between the tips of the cell processes of connecting osteocytes (Doty, 1981). Within each osteon or hemiosteon (on bone surfaces), therefore, osteocytes form a network of gap junction-coupled cells. As the lacunae are connected via the canaliculi, the osteocyte network represents two network systems: an intracellular one and an extracellular one. Gap junctions are transmembrane channels connecting the cytoplasm of two adjacent cells and regulating the passage of molecules less than 1 kD_a (Goodenough *et al.*, 1966; Bennett *et al.*, 1978). Gap junction channels are formed by members of a family of proteins known as connexins. One of these members, Cx43, appears to play an important role in bone cells as Cx43-null mice have delayed ossification, craniofacial abnormalities, and osteoblast dysfunction (Lecanda *et al.*, 2000). It has been proposed that gap junctions function through the propagation of intracellular signals contributing to mechanotransduction in bone, thereby regulating bone cell differentiation (Donahue *et al.*, 2000). A dominant negative mutant of Cx43 diminishes fluid flow-induced release of PGE_2, but not Ca^{2+} responses (Saunders *et al.*, 2001). Fluid flow-induced shear stress stimulates gap junction-mediated intercellular communication and increases Cx43 expression (Cheng *et al.*, 2001), while oscillating fluid flow has been shown to upregulate gap junction communication by an ERK1/2 MAP kinase-dependent mechanism (Alford *et al.*, 2003) in MLO-Y4 osteocyte-like cells.

Recently, hemichannels, unapposed halves of gap junction channels, have been identified in osteocytes localizing at the cell surface, independent of physical contact with adjacent cells (Goodenough *et al.*, 2003). Primary osteocytes and MLO-Y4 osteocyte-like cells (Kato *et al.*, 1997) express very large amounts of Cx43 compared to other cell types such as osteoblasts, yet these cells are only in contact through the tips of their dendritic processes, raising the question regarding function of Cx43 on the rest of the cell

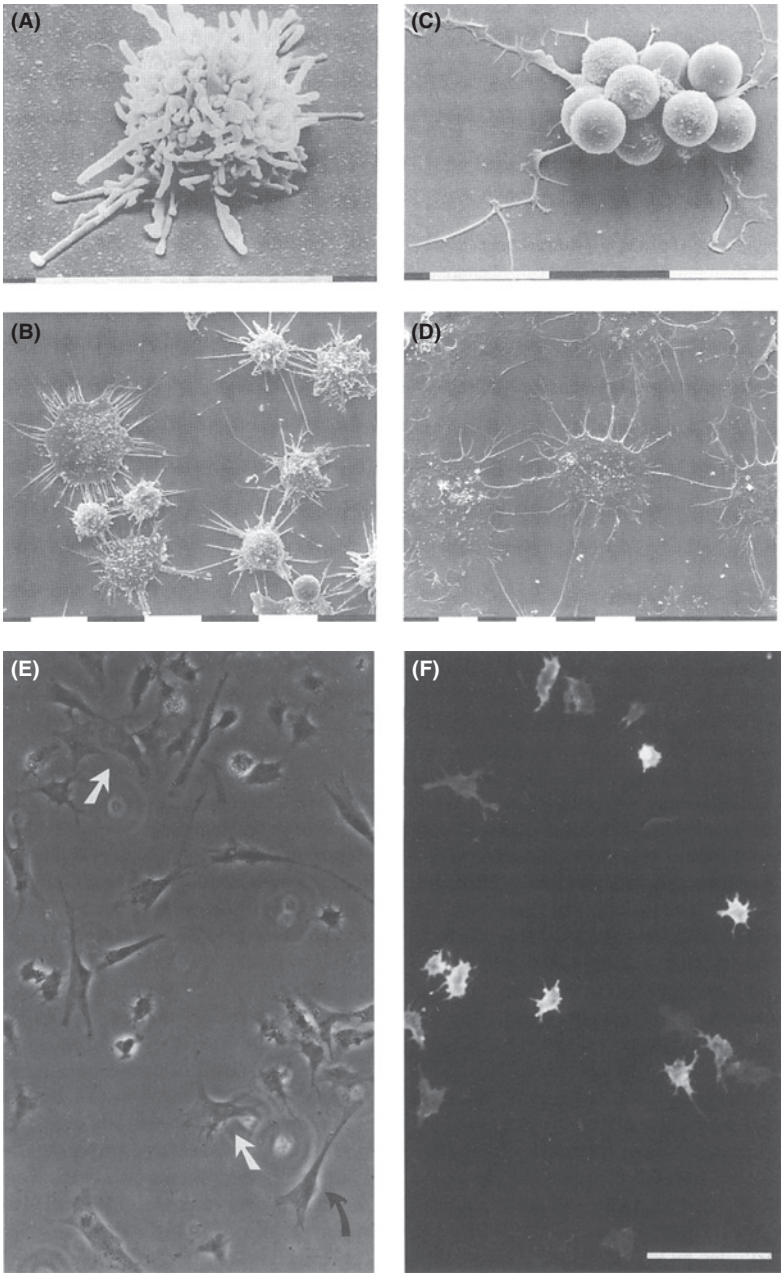

FIGURE 2 Isolated osteocytes in culture. Osteocytes were isolated by an immunodissection method using MAb OB7.3-coated magnetic beads. After isolation the cells were seeded on a glass support, cultured for 5 min **(A)**, 30 min **(B)**, or 24 hr (**C** and **D**) and studied with a scanning electron microscope. Immediately after attachment, osteocytes form cytoplasmic extrusions in all directions **(A)**. During subsequent culture, the cell processes perpendicular on the support disappear, while the processes in the plane of the support elongate **(B)** and ultimately form smooth connections between neighboring cells **(D)**. In **A**, **B**, and **D** the immunobeads were removed from the cells before seeding; in **C** the beads were left on the cells. (Original magnification: **(A)** ×7200, **(B)** ×1400, **(C)** ×2900, and **(D)** ×940; bar: 10 μm). Cells were also isolated from periosteum-free 18-day-old chicken calvariae by collagenase digestion, seeded, and cultured for 24 hr. Subsequently the osteocytes in the mixed population were specifically stained with MAb OB7.3 in combination with biotinylated horse-antimouse IgG and streptavidin-Cy3. **(E)** Phase contrast. **(F)** Immunofluorescence. Black arrows, fibroblast-like cells; white arrows, osteoblast-like cells. (Original magnification: ×300; bar: 100 μm).

membrane. The opening of hemichannels results in ATP and NAD^+ release, which in turn raises intracellular Ca^{2+} levels and wave propagation of Ca^{2+}. It has been shown that oscillating fluid flow activates hemichannels in MLO-Y4 osteocyte-like cells, but not in MC3T3-E1 osteoblast-like cells. This activation involved protein kinase C, and resulted in ATP and PGE_2 release (Genetos *et al.*, 2007). Hemichannels expressed in bone cells such as MLO-Y4 cells appear to function as essential transducers of the anti-apoptotic effects of bisphosphonates (Plotkin *et al.*, 2002)

and serve as a portal for the exit of elevated intracellular PGE_2 in osteocytes induced by fluid flow shear stress (Cherian *et al.*, 2005). Therefore, gap junctions at the tip of dendrites mediate intracellular communication while hemichannels along the dendrite and the cell body mediate extracellular communication within the osteocyte network.

Osteocyte Formation and Death

Osteogenic cells arise from multipotential mesenchymal stem cells (see Chapter 4). These stem cells have the capacity to also differentiate into other lineages, including those of chondroblasts, fibroblasts, adipocytes, and myoblasts (Aubin *et al.*, 1995; Chapter 4). By analogy with hemopoietic differentiation, each of these differentiation lineages is thought to originate from a different committed progenitor, which for the osteogenic lineage is called the osteoprogenitor. Osteodifferentiation progresses via a number of progenitor and precursor stages to the mature osteoblast. An osteoblast has one of three fates: it can embed in its own osteoid and differentiate into an osteocyte, quiescence into a lining cell, or undergo apoptosis (for review see Manalogas (2000). The mechanism by which osteoblasts differentiate into osteocytes is, however, still unknown. Imai *et al*. (1998) found evidence that osteocytes may stimulate osteoblast recruitment and differentiation by expressing osteoblast stimulating factor-1 (OSF-1) (Tezuka *et al.*, 1990). The osteoblasts further differentiate to osteocytes being surrounded by the osteoid matrix that they produce, and they then may become a new source of OSF-1 for the next round of osteoblast recruitment. The expression of OSF-1 in osteocytes may be activated by local damage to bone or local mechanical stress (Imai *et al.*, 1998). Marotti (1996) has postulated that a newly formed osteocyte starts to produce an osteoblast inhibitory signal when its cytoplasmic processes connecting the cell with the osteoblast layer have reached their maximal length. The osteoid production of the most adjacent, most intimately connected osteoblast will be relatively more inhibited by that signal than that of its neighbors. The inactivated osteoblast then spreads over a larger bone surface area, thereby reducing its linear appositional rate of matrix production even further. A second consequence of the widening and flattening of the cell is that it may intercept more osteocytic processes carrying the inhibitory signal. This positive feedback mechanism results in the embedding of the cell in matrix produced by the neighboring osteoblasts. Ultimately, the cell will acquire the typical osteocyte morphology and the surrounding matrix will become calcified. The theory of Marotti is based entirely on morphologic observations. There is no biochemical evidence about the nature or even the existence of the proposed inhibitory factor. Martin (2000) has, however, used the concept successfully in explaining mathematically the changing rates of matrix formation during bone remodeling.

Osteoid-osteocytes were described by Palumbo (1986) to be cells actively making matrix and calcifying this matrix while the cell body reduces in size in parallel with the formation of cytoplasmic processes. Bordier and co-workers (1976) and Nijweide and co-workers (1981) proposed that osteoid-osteocytes play an important role in the initiation and control of mineralization of the bone matrix. During the time an osteoblast has become an osteocyte, the cell has manufactured three times its own volume in matrix (Owen, 1995). Franz-Odendaal and co-workers (2006) proposed that once a cell is surrounded by osteoid that the differentiation process has not ended, but continues.

An enzyme that is produced in high amounts by embedding osteoid-osteocytes and not by osteoblasts, casein kinase II, appears to be responsible for phosphorylation of matrix proteins essential for mineralization (Mikuni-Takagaki *et al.*, 1995). Phosphoproteins appear to be essential for bone mineralization as evidenced by *in vitro* crystal nucleation assays (Boskey, 1996) and *in vivo* by osteomalacia in animal models with deletion of (osteocyte-specific) genes such as dentin matrix protein-1 (DMP1) and PHEX (phosphate-regulating gene with homologies to endopeptidases on the X chromosome) (Strom *et al.*, 1997). The role of these proteins in mineral homeostasis will be discussed later in this chapter. Recently an osteocyte-selective promoter, the 8 kb dentin matrix protein-1 (DMP1), driving GFP has been generated (Kalajzic *et al.*, 2004). With the identification of other markers selective for osteocytes such as E11/gp38 for early osteocytes (Zhang *et al.*, 2006) and sclerostin for late osteocytes (Poole *et al.*, 2006), new tools are on the horizon for the study of osteocyte formation.

The life span of osteocytes is probably largely determined by bone turnover, when osteoclasts resorb bone and either "liberate" or destroy osteocytes. Osteocytes may have a half-life of decades if the particular bone they reside in has a slow turnover rate. The fate of living osteocytes that are liberated by osteoclast action is presently unknown. There is little evidence that osteocytes may reverse their differentiation back into the osteoblastic state (Van der Plas *et al.*, 1994). Some of them, only half released by osteoclastic activity, may be reembedded during new bone formation that follows the resorption process (Suzuki *et al.*, 2000). These osteocytes are then the cells that cross the cement lines between individual osteons, sometimes seen in cross sections of osteonal bone. Most of the osteocytes, however, will probably die by apoptosis and become phagocytosed. Phagocytosis of osteocytes by osteoclasts as part of the bone resorption process has been documented in several reports (Bronckers *et al.*, 1996; Elmardi *et al.*, 1990).

Apoptosis of osteocytes in their lacunae is attracting growing attention because of its expected consequence of decreased bone mechanoregulation, which may lead to osteclastic bone resorption. Osteocyte apoptosis can occur as a result of immobilization, microdamage, estrogen deprivation,

elevated cytokines, glucocorticoid treatment, osteoporosis, osteoarthritis, and aging. The resulting fragility is considered to be due to loss of the ability of osteocytes to signal other bone cells for repair because of a loss of capacity to sense microdamage (Manolagas, 2000; Noble *et al.*, 2003). Apoptotic regions around microcracks were found to be surrounded by surviving osteocytes expressing Bcl-2, whereas dying osteocytes appeared to be the target of resorbing osteoclasts (Verborgt *et al.*, 2000; 2002). Apoptotic changes in osteocytes were shown to be associated with high bone turnover (Noble *et al.*, 1997). However, fatigue-related microdamage in bone may cause decreased osteocyte accessibility for nutrients and oxygen inducing osteocyte apoptosis and subsequent bone remodeling (Burger and Klein-Nulend, 1999; Verborgt *et al.*, 2000). Lack of oxygen elevates hypoxia-inducing factor alpha, HIFa, a transcription activator by inactivation of prolyl hydroxylase leading to apoptosis and induction of the osteoclastogenic factor TNFα and VEGF (Gross *et al.*, 2001) and osteopontin, a mediator of environmental stress and a potential chemoattractant for osteoclasts (Gross *et al.*, 2005).

In contrast to overloading, which induces microdamage, physiological mechanical loads might prevent osteocyte apoptosis *in vivo*. Mechanical stimulation of osteocytes *in vitro*, by means of a pulsating fluid flow, affects TNFα-induced apoptosis. One-hour pulsating fluid flow (0.70 ± 0.30 Pa, 5 Hz) inhibited (25%) TNFα-induced apoptosis in osteocytes, but not in osteoblasts or periosteal fibroblasts (Tan *et al.*, 2006). Although the exact mechanism is not clear, loading-induced nitric oxide production by the osteocytes might be involved in the antiapoptotic effects of mechanical loading.

Also, loss of estrogen (Tomkinson *et al.*, 1998) and chronic glucocorticoid treatment (Weinstein *et al.*, 1998) were demonstrated to induce osteocyte apoptosis, which may, at least in part, explain the bone-deleterious effects of these conditions. Several agents, such as bisphosphonates and calcitonin (Plotkin *et al.*, 1999), CD40 ligand (Ahuja *et al.*, 2003), calbindin-D28k (Liu *et al.*, 2004), and estrogen and selective estrogen receptor modulators (Kousteni *et al.*, 2001), have been found to reduce or inhibit osteoblast and osteocyte apoptosis. Bisphosphonates inhibit apoptosis through interaction with hemichannels and the ERK pathway (Plotkin *et al.*, 2001). Interestingly, the two antiapoptotic agents PTH and MCP-3 have been shown to be selective for apoptosis induced by one particular agent. Unlike the agents listed above, both PTH (Jilka *et al.*, 1999) and MCP-3 will only inhibit glucocorticoid-induced apoptosis, but not TNFα induced apoptosis of MLO-Y4 osteocyte-like cells (Kitase *et al.*, 2006).

Osteocyte viability may play a significant role in the maintenance of bone homeostasis and integrity, yet agents that block apoptosis may exacerbate conditions that require repair and, in addition, might have potentially detrimental effects on tumor formation.

Osteocyte Isolation

Analysis of osteocyte properties and functions has long been hampered by the fact that they are embedded in a mineralized matrix. Although sensitive methods are now available, such as immunocytochemistry and *in situ* hybridization, by which osteocytes can be studied in the tissue in some detail, osteocyte isolation and culture offer a major step forward. This approach became possible by the development of osteocyte-specific antibodies (Fig. 3) directed to antigenic sites on the outside of the cytoplasmic membrane (Bruder and Caplan, 1990; Nijweide and Mulder, 1986). Using an immunodissection method, Van der Plas and Nijweide (1992) subsequently succeeded in the isolation and purification of chicken osteocytes from mixed bone cell populations isolated from fetal bones by enzymatic digestion. Isolated osteocytes appeared to behave *in vitro* like they do *in vivo* in that they reacquired their stellate morphology and, when seeded sparsely, formed a network of cells coupled to one another by long, slender, often branched cell processes (Fig. 2). The cells retained this morphology in culture throughout the time studied (5–7 days) and even reexpressed it when passaged for a second time (Van der Plas and Nijweide, 1992).

Mikuni-Takagaki *et al.* (1995) have isolated seven cell fractions from rat calvariae by sequential digestion. They

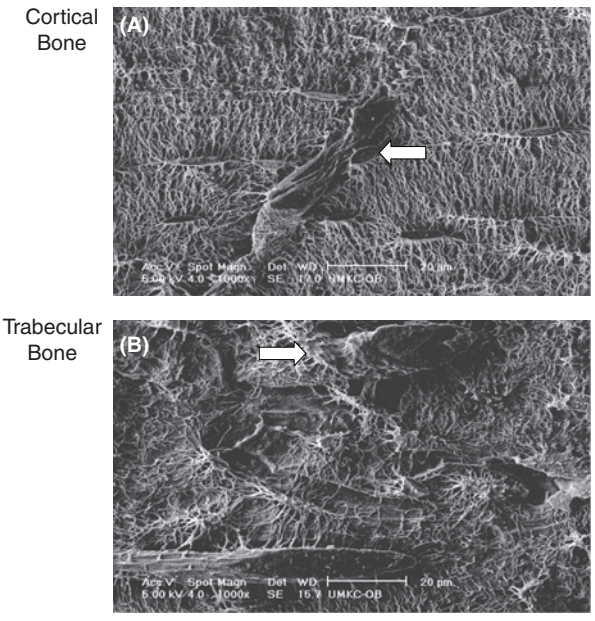

FIGURE 3 Images of acid-etched resin embedded murine cortical **(A)** and trabecular **(B)** bone visualized by scanning electron microscopy showing the complexity of the osteocyte lacuno-canalicular system and the intimate relationship between the lacuno-canalicular system and blood vessels. In the cortical bone, note the linear alignment of the lacunae and the complexity of the canaliculi. In the trabecular bone, the lacunae are not as organized as in the cortical bone. In both sections, note the close relationship of some osteocyte lacunae with blood vessels (arrows).

claimed that the last fraction consisted of osteocytic cells. The cells displayed dendritic cell processes, were negative for alkaline phosphatase, had high extracellular activities of casein kinase II and ecto-5′nucleotidase, and produced large amounts of osteocalcin. After a few days of little change in cell numbers, the cells of fraction VII proliferated, however, equally fast as those of fraction III, the osteoblastic cells, in culture. With the identification of new osteocyte selective markers such as Sost, E11/gp38, Dmp1, Phex and Mepe, it is becoming easier to identify isolated osteocytes (see below).

Osteocyte Markers

In bone, osteocytes are fully defined by their location within the bone matrix and their stellate morphology. One marker for isolated osteocytes is therefore their typical morphology, which they reacquire in culture (Mikuni-Takagaki *et al*., 1995; Van der Plas and Nijweide, 1992). Related to this stellate morphology, osteocytes have a typical cytoskeletal organization, which is important for the osteocyte's response to loading (McGarry *et al.*, 2005). The prominent actin bundles in the osteocytic processes, together with the abundant presence of the actin-bundling protein fimbrin, are exemplary for osteocytes and are retained after isolation (Tanaka-Kamioka *et al*., 1998). In addition, osteocytes are generally found to express osteocalcin, osteonectin, and osteopontin, but show little alkaline phosphatase activity, particularly the more mature cells (Aarden *et al*., 1996b). As stated previously, these metabolic markers have, however, little discriminating value in mixtures of isolated cells. Franz-Odendaal and co-authors (2006) provide a list of molecular markers for the preosteoblast to the osteocyte.

Until recently, no osteocyte-specific markers were known, and only few osteocyte-specific antibodies were available. Examples are the monoclonal antibodies MAb OB7.3 (Nijweide and Mulder, 1986) (Fig. 2), MAb OB37.11 (Nijweide *et al*., 1988), and MAb SB5 (Bruder and Caplan, 1990). All three are specific for avian osteocytes and do not cross-react with mammalian cells. The identities of the three antigens involved have not been reported, although that of OB7.3 has been elucidated and found to be the avian homologue of mammalian Phex (Westbroek *et al.,* 2002). Using an antibody to Phex allowed purification of avian osteocytes from enzymatically isolated bone cells.

Osteoblast/osteocyte factor 45 (OF45) also known as MEPE (matrix extracellular phosphoglycoprotein) is also highly expressed in osteocytes as compared to osteoblasts. Messenger RNA expression for OF45/MEPE begins at E20 in more differentiated osteoblasts that have become encapsulated by bone matrix (Igarashi *et al.*, 2002). *Mepe* was isolated and cloned from a TIO tumor cDNA library (Rowe *et al.*, 2000). Cathepsin D or B can cleave MEPE, releasing the highly phosphorylated C-terminal ASARM region that is a potent inhibitor of mineralization *in vitro* (Bresler *et al.*, 2004; Rowe *et al.*, 2005). OF45/MEPE null mice have increased bone formation, bone mass, and resistance to age-associated trabecular bone loss (Gowen *et al.*, 2003). The authors speculate that osteocytes act directly on osteoblasts through OF45 to inhibit their bone forming activity.

Both Toyosawa (2001) and Feng and colleagues (2006) found dentin matrix protein 1 to be highly expressed in osteocytes with very low expression in osteoblasts. DMP1 is specifically expressed along and in the canaliculi of osteocytes within the bone matrix (Feng *et al.*, 2006). Deletion of this gene in mice results in a phenotype similar if not identical to the hyp-phenotype, suggesting that Dmp1 and Phex are interactive and essential for phosphate metabolism. Potential roles for DMP1 in osteocytes may be related to the post-translational processing and modification resulting in a highly phosphorylated protein and regulator of hydroxyapatite formation. Interestingly, Dmp1 and OF45/MEPE belong to the SIBLING (small, integrin-binding ligand, N-linked glycoprotein) family that also includes bone sialoprotein, osteopontin, and sialophosphoprotein (Fisher, 2003). This family of proteins may function differently in osteocytes compared to other cell types especially upon phosphorylation with casein kinase II, a marker of the osteoblast to osteocyte transition (Mikuni-Takagaki *et al.*, 1995).

Confusion exists regarding the expression of E11/gp38 in bone because Wetterwald (1996) and others (Aubin and Turksen, 1996) have described expression in osteoblasts. However, Schultze (1999) and Zhang (2006) have described expression exclusively in osteocytes and not in osteoblasts *in vivo*. A punctate antibody reaction is observed at the interface between osteoblasts and uncalcified osteoid at the tips and along dendritic processes with less reactivity in osteocytes deeper in the bone matrix. E11/gp38 appears to be responsible for the formation of dendritic processes as reduction in protein expression using an siRNA approach led to a decrease in dendrite extension in MLO-Y4 osteocyte-like cells in response to shear stress (Zhang *et al.*, 2006). E11/gp38 colocalizes with ezrin, radixin, and moesin, ERMs (Scholl *et al.*, 1999), that are concentrated in cell-surface projections where they link the actin cytoskeleton to plasma membrane proteins and are involved in cell motility (Mangeat *et al.*, 1999). CD44 is highly expressed in osteocytes compared to osteoblasts (Hughes *et al.*, 1994), and as E11 is physically associated with CD44 in tumor vascular endothelial cells (Ohizumi *et al.*, 2000), this association most likely occurs in osteocytes to regulate the formation of dendritic processes.

Sclerostin appears to be highly expressed in the mature but not the early osteocyte (Poole *et al.*, 2005). Transgenic mice lacking sclerostin have increased bone mass, and the human condition of sclerostosis is due to a premature

termination of the SOST gene (Balemans *et al.*, 2001). Sclerostin clearly functions as a Wnt antagonist by binding Lrp5 (van Bezooijen *et al.*, 2004). Lrp5 is shown to be an important positive regulator of bone mass (Li *et al.*, 2001). Sclerostin protein may be transported through canaliculi to the bone surface to inhibit bone-forming osteoblasts. Sclerostin is down regulated by mechanical loading (Robling *et al.*, 2006). It has also been proposed that the anabolic effects of PTH are through inhibition of SOST expression (Bellido *et al.*, 2005).

In summary, it is becoming easier to define cells as osteocytic. Even though the E11/gp38 molecule is expressed in other tissues, it is only expressed in osteocytes, not osteoblasts, in bone (Zhang *et al.*, 2006). While E11/gp38 appears to be a marker for the early osteocyte, Sost/sclerostin is a specific marker for the late osteocyte (Poole *et al.*, 2005). Dmp1, Phex, and MEPE, while expressed in low levels in osteoblasts and other tissues, are highly elevated in osteocytes. In addition, a panel of markers for osteocytes is being developed (Franz-Odendaal *et al.*, 2006). Combining these markers with other properties such as dendricity and low or no alkaline phosphatase (see later) can be useful to define not only isolated primary cells, but also cell lines.

Osteocytic Cell Lines

Because the number of primary osteocytes that can be isolated from chickens each time (Van der Plas and Nijweide, 1992) is limited, several groups have tried to establish osteocytic cell lines. Basically, an osteocytic cell line is a contradiction in terms. Osteocytes are postmitotic. However, a cell line of proliferating precursor cells that would differentiate to osteocytes under specific circumstances could prove to be very valuable in the study of osteocyte properties and functions. HOB-01-C1 (Bodine *et al.*, 1996) may meet these requirements. It is a temperature-sensitive cell line, prepared from immortalized, cloned human adult bone cells. It proliferates at 34°C but stops dividing at 39°C. HOB-01-C1 cells display putative osteocytic markers, such as cellular processes, low alkaline phosphatase activity, high osteocalcin production, and the expression of CD44.

MLO-A5 cells, a postosteoblast/preosteocyte-like cell line established from the long bones of 14-day-old mice expressing the large T-antigen driven by the osteocalcin promoter, differentiate into osteoid osteocyte-like cells (Kato *et al.*, 2001). MLO-A5 cells express all of the markers of the late osteoblast such as high alkaline phosphatase, bone sialoprotein, PTH type 1 receptor, and osteocalcin, but begin to express markers of osteocytes such as E11/gp38 as they generate cell processes. MLO-A5 cells begin to express E11/gp38 in culture while generating dendritic processes and generating spherical structures that bud from and mineralize on their developing cellular processes. As the cellular process narrows in diameter, these mineralized structures become associated with and initiate collagen mediated mineralization (Barragan-Adjemian *et al.*, 2006). PTH has been shown to reduce Sost/sclerostin expression in these cells (Bellido *et al.*, 2006).

MLO-Y4 (Kato *et al.*, 1997) is another osteocyte-like cell line in that the cells, when seeded at low density, display complex dendritic processes. They produce high amounts of E11/gp38 (Zhang *et al.*, 2006), CD44, osteocalcin, and osteopontin, and have low alkaline phosphatase activity. Numerous investigators have used these cells to examine gap junctions, hemichannels, and apoptosis and other potential functions of osteocytes (Genetos *et al.*, 2007; Plotkin *et al*, 2005; Vatsa *et al.*, 2006; Vatsa *et al.*, in press; Xiao *et al.*, 2006; Zaman *et al.*, 2006; Zhang *et al.*, 2006; Cherian *et al.*, 2005; Liu *et al.*, 2004; Alford *et al.*, 2003; Ahuja *et al.*, 2003; Zhao *et al.*, 2002; Heino *et al.*, 2002, 2004; Cheng *et al.*, 2001; Yellowley *et al.*, 2000). These cells will support osteoclast formation and activation in the absence of any osteotropic factors (Zhao *et al.*, 2002), and estrogen will reduce support of osteoclast formation by an increase in TGFβ3 (Heino *et al.*, 2002) and, conversely, will also support osteoblast mesenchymal stem cell differentiation (Heino *et al.*, 2004), supporting the hypothesis that osteocytes are orchestrators of both bone resorption and bone formation.

Osteocytic cell lines have also been generated from mice lacking the type 1 PTH/PTHrp receptor (Divieti *et al.*, 2001) and have proved useful to determine the effects of PTH on osteoblasts and osteocytes and for the discovery of a receptor that binds to the carboxy terminus of PTH, CTPH-R (Divieti *et al.*, 2005). CPTH-R is more highly expressed on osteocytes than on other bone cells. Functional studies of CPTH-Rs suggest a role in cell survival and intracellular communication, and in proapoptotic and antiresorptive actions. Investigators using these cell lines cannot assume the cells to be representative of normal osteocytes as they lack the type 1PTH/PTHrp receptor.

Matrix Synthesis

The subcellular morphology of osteocytes and the fact that they are encased in mineralized matrix do not suggest that osteocytes partake to a large extent in matrix production. Osteocytes, especially the more mature, have relatively few organelles necessary for matrix production and secretion. Nevertheless, a limited secretion of specific matrix proteins may be essential for osteocyte function and survival. Several arguments are in favor of such limited matrix production. First, as the mineralization front lags behind the osteoid formation front in areas of new bone formation, osteocytes may be involved in the maturation and mineralization of the osteoid matrix by secreting specific matrix molecules. It is, however, also possible that osteocytes enable the osteoid matrix to be mineralized by phosphorylating certain matrix constituents, as was suggested

by Mikuni-Takagaki *et al.* (1995). Mikuni-Takagaki and colleagues proposed that casein kinase II, produced in high amounts by embedding osteoid osteocytes and not by osteoblasts, is responsible for phosphorylation of matrix proteins essential for mineralization. Therefore, the embedding osteoid cell and the osteocyte probably play roles in the mineralization process and potentially in phosphate metabolism (see later). Osteocytes must inhibit mineralization of the matrix directly surrounding them to ensure the diffusion of oxygen, nutrients, and waste products through the lacunocanalicular system. Osteocalcin, which is expressed to a relative high extent by osteocytes, may play an important role here (Aarden *et al.*, 1996b; Ducy *et al.*, 1996; Mikuni-Takagaki *et al.*, 1995), as does OF45/MEPE and Sost. Osteocytes have been found to be positive for osteocalcin and osteonectin (Aarden *et al.*, 1996b), molecules that are probably involved in the regulation of calcification. Osteopontin, fibronectin, and collagen type I (Aarden *et al.*, 1996b) have also been demonstrated in and immediately around (isolated) osteocytes. These proteins may be involved in osteocyte attachment to the bone matrix (see later). Finally, if osteocytes are the mechanosensor cells of bone (see later), the attachment of osteocytes to matrix molecules is likely of major importance for the transduction of stress signals into cellular signals. Production and secretion of specific matrix molecules offer a possibility for the cells to regulate their own adhesion and, thereby, sensitivity for stress signals.

In addition to collagenous and noncollagenous proteins, the bone matrix contains proteoglycans. These macromolecules consist of a core protein to which one or more glycosaminoglycan (GAG) side chains are covalently bound. Early electron microscopic studies (Jande, 1971) already showed that the osteocyte body, as well as its cell processes, is surrounded by a thin layer of unmineralized matrix containing collagen fibrils and proteoglycans. The proteoglycans were shown to consist of chondroitin 4-sulfate, dermatan sulfate, and keratan sulfate with immunocytochemical methods (Maeno *et al.*, 1992; Smith *et al.*, 1997; Takagi *et al.*, 1997). These observations are supported by the findings of Sauren *et al.* (1992), who demonstrated an increased presence of proteglycans in the pericellular matrix by staining with the cationic dye cuprolinic blue. Of special interest is the reported presence of hyaluronan in osteocyte lacunae (Noonan *et al.*, 1996). CD44, which is highly expressed on the osteocyte membrane, is a hyaluronan-binding protein and also binds to collagen, fibronectin, and osteopontin (Nakamura and Ozawa, 1996; Yamazaki *et al.*, 1999).

The Osteocyte Cytoskeleton and Cell–Matrix Adhesion

As mentioned earlier, the cell–matrix adhesion of osteocytes is of importance for the translation of biomechanical signals produced by loading of bone into chemical signals. Study of the adhesion of osteocytes to extracellular matrix molecules became feasible with the development of osteocyte isolation and culture methods (Van der Plas and Nijweide, 1992). These studies found little difference between the adhesive properties of osteocytes and osteoblasts, although the pattern of adhesion plaques (osteocytes, many small focal contacts, osteoblasts, larger adhesion plaques) was quite different (Aarden *et al.*, 1996a). Both cell types adhered equally well to collagen type I, osteopontin, vitronectin, fibronectin, and thrombospondin. Integrin receptors are involved, as is shown by the inhibiting effects of small peptides containing a RGD sequence on the adhesion to some of these proteins. Adhesion to all aforementioned matrix molecules was blocked by an antibody reacting with the β_1-integrin subunit (Aarden *et al.*, 1996a). The identity of the *a* units involved is yet unknown.

Deformation of the bone matrix upon loading may cause a physical "twisting" of integrins at sites where osteocytes adhere to the matrix. Integrins are coupled to the cytoskeleton via molecules such as vinculin, talin, and *a*-actinin. In osteocytes, especially in the osteocytic cell processes, the actin-bundling protein fimbrin appears to play a prominent role (Tanaka-Kamioka *et al.*, 1998). Mechanical twisting of the cell membrane via integrin-bound beads has been demonstrated to induce cytoskeletal rearrangements in cultured endothelial cells (Wang and Ingber, 1994). The integrin-cytoskeleton complex may therefore play a role as an intracellular signal transducer for stress signals. In addition to the integrins, the nonintegrin adhesion receptor CD44 may attribute to the attachment of osteocytes to the surrounding matrix. CD44 is present abundantly on the osteocyte surface (Hughes *et al.*, 1994; Nakamura and Ozawa, 1995) and is also linked to the cytoskeleton.

Evidence has accumulated recently that underscores the crucial role of the cytoskeleton in a multitude of cellular processes. The cytoskeleton, just like our bony skeleton, provides structure and support for the cell, is actively adapted, and is highly responsive to external physical and chemical stimuli. The cytoskeleton is strongly involved in processes such as migration, differentiation, mechanosensing, and even cell death, and largely determines the material properties of the cell (i.e., stiffness).

For bone cells it has been shown that the production of signaling molecules in response to an *in vitro* fluid shear stress (at 5 and 9 Hz) and vibration stress (5–100 Hz) correlated with the applied stress rate (Bacabac *et al.*, 2004; Bacabac *et al.*, 2006; Mullender *et al.*, 2006). The faster the stress was applied, the stronger the observed response of the cells. Interestingly, high-rate stimuli were found to condition bone cells to be more sensitive for high-frequency, low-amplitude loads (Bacabac *et al.*, 2005). From the field of physics it is known that the effect of stresses applied at different rates at an object are largely determined by the

material properties of that object. This implies that bone cellular metabolic activity (e.g., the production of signaling molecules) and mechanical properties of the cell are related. Bacabac *et al.* (2006b) developed a novel application of two-particle microrheology, for which he devised a three-dimensional *in vitro* system using optical traps to quantify the forces induced by cells on attached fibronectin-coated probes (4 microns). The frequency at which the cells generate forces on the beads is related to the metabolic activity of the cell. This system can also be used to apply controlled forces on the cell using the beads, and enables the study of cells under controlled three-dimensional morphologic configuration, with possibilities for a variety of probe coatings for simulating cell-ECM attachment. Using this setup, the generation of forces by different cells was probed in order to understand the relation between cellular metabolic activities and material properties of the cell. It was shown that, at 37°C, CCL-224 fibroblasts exhibited higher force fluctuation magnitude compared to MLO-Y4 osteocytes (Bacabac *et al.*, 2006b). The force fluctuations on the attached probes reflect intracellular movement, which might include actin (and microtubule) polymerization, as well as motor and crosslinker dynamics. Because cell migration involves these dynamic processes, the lower magnitude of force fluctuation might reflect a lower capacity of osteocytes for motility compared to fibroblasts.

Using the optical trap device, the material properties of round suspended MLO-Y4 osteocytes and flat adherent MLO-Y4 osteocytes were characterized. In addition, the cells were loaded with a nitric oxide (NO) sensitive fluorescent dye (Vatsa *et al.*, 2006) and the NO response of the cells to forces applied on the cell using the attached probes was studied. Osteocytes under round-suspended morphology required lower force stimulation in order to show a NO response, even though they were an order of magnitude more elastic compared to flat-adherent cells (Bacabac *et al.*, 2006b). Apparently, elastic osteocytes seem to require less mechanical forces in order to respond than stiffer cells. On the other hand, flat adherent MLO-Y4 cells, primary chicken osteocytes, MC3T3-E1 osteoblasts, and primary chicken osteoblasts all showed a similar elastic modulus of less than 1 kPa (Bacabac *et al.*, 2006b), even though osteocytes are known to be more responsive to mechanical stress than osteoblasts (Klein-Nulend *et al.*, 1995a). This indicates that differences in mechanosensitivity between cells might not be directly related to the elasticity of the cell, but might be more related to other cell-specific properties (i.e., the presence of receptors or ion-channels in the membrane). Alternatively, the mechanosensitivity of a cell might be related to how cells change their material properties in relation to deformation.

Simultaneous with the increased NO release in response to mechanical stimulation, MLO-Y4 osteocytes showed increased force traction on the attached beads. In other words, the cells started to "pull harder" on the beads and generated a force up to nearly 30 pN, which interestingly is within the order of forces necessary for activating integrins. Whether there was a causal link between loading-induced NO production by the cells and force generation is currently under investigation. Since force generation and cell elasticity are (indirectly) related, these results might indicate that osteocytes adapt their elasticity in response to a mechanical stimulus. Indeed, experiments with an atomic force microscope and optical tweezers have shown that osteocytes become "stiffer" after mechanical loading (Bacabac *et al.*, 2006b; and unpublished observations). This stiffening response was related to actual changes in material properties of the cell, suggesting that the cells actively change their cytoskeleton in response to a mechanical load.

Considering the role of the osteocytes as the professional mechanosensors of bone, and the importance of the cytoskeleton for the response of osteocytes to mechanical loading, much is to be expected from research focusing on the cytoskeletal components of the osteocyte.

Hormone Receptors in Osteocytes

Parathyroid hormone (PTH) receptors have been demonstrated on rat osteocytes *in situ* (Fermor and Skerry, 1995) and on isolated chicken osteocytes (Van der Plas *et al.*, 1994). Administered *in vitro*, PTH was reported to increase cAMP levels in isolated chicken osteocytes (Van der Plas *et al.*, 1994; Miyauchi *et al.*, 2000) and, administered *in vivo*, to increase fos protein (Takeda *et al.*, 1999) and the mRNAs of c-fos, c-jun, and I1-6 in rat osteocytes (Liang *et al.*, 1999). Therefore, although the original theory of osteocytic osteolysis and its regulation by calciotropic hormones such as PTH (Bélanger, 1969) has been abandoned, the presence of PTH receptors on osteocytes and their short-term responses to PTH suggest a role for PTH in osteocyte function. As it is now generally accepted that osteocytes are involved in the transduction of mechanical signals into chemical signals regulating bone (re)modeling, PTH might modulate the osteocytic response to mechanical strain. Injection of PTH in rats was shown to augment the osteogenic response of bone to mechanical stimulation *in vivo*, whereas thyroparathyroidectomy abrogated the mechanical responsiveness of bone (Chow *et al.*, 1998). However, such an approach cannot separate an effect at the level of osteocyte mechanosensing from one at the level of osteoprogenitor recruitment. One mechanism by which PTH may act on osteocytes was suggested by the reports of Schiller *et al.* (1992) and Donahue *et al.* (1995). These authors found that PTH increased Cx43 gene expression and gap junctional communication in osteoblastic cells. In osteocytes, where cell-to-cell communication is so important, a similar effect might lead to more efficient communication within the osteocyte network. Osteocytes also express the receptor

for the carboxy-terminal region of PTH that may play a role in osteocyte viability (Divieti *et al.*, 2001). Activation of receptors for 1,25-dihydroxyvitamin D_3 ($1,25(OH)_2D_3$), which were also shown to be present in osteocytes by immunocytochemistry (Boivin *et al.*, 1987) and by *in situ* hybridization (Davideau *et al.*, 1996), may have similar effects.

Another important hormone involved in bone metabolism is estrogen. Numerous studies have demonstrated that a decrease in blood estrogen levels is accompanied by a loss of bone mass. One explanation for this phenomenon is that estrogen regulates the set point for the mechanical responsiveness of bone (Frost, 1992), i.e., that lowering the ambient estrogen level increases the level of strain in bone necessary for the bone to respond with increased bone formation. If osteocytes are the main mechanosensors of bone, it is reasonable to suppose that osteocytes are the site of set point regulation by estrogen. Estrogen receptors (ER*a*) were demonstrated in osteocytes with immunocytochemistry and *in situ* hybridization (Braidman *et al.*, 1995; Hoyland *et al.*, 1999) in tissue sections. In addition, Westbroek *et al.* (2000b) found higher levels of ER*a* in isolated osteocytes than in osteoblasts or osteoblast precursors. It has been shown that the anabolic response of bone to mechanical loading requires ER*a* (Lee *et al.*, 2003). Recent studies suggested that osteocytes indeed use ER*a* to respond to strain, although the ER*a* content is regulated by estrogen (Zaman *et al.*, 2006).

Receptors for PTH, $1,25(OH)_2D_3$, and estrogen, as well as the androgen receptor (Abu *et al.*, 1997), the glucocorticoid receptor *a* (Abu *et al.*, 2000; Silvestrini *et al.*, 1999), and various prostaglandin receptors (Lean *et al.*, 1995; Sabbieti *et al.*, 1999) have been described in osteocytes. As outlined earlier, glucocorticoids clearly induce osteocyte apoptosis but may have additional effects. Glucocorticoid treatment causes mature osteocytes to enlarge their lacunae and remove mineral from their microenvironment (Lane *et al.*, 2006). Therefore, osteocytes appear to be able to modify their microenvironment in response to certain factors. The prostaglandin receptors, in addition to viability, may be important for communication within the osteocyte network during mechanotransduction (see later).

OSTEOCYTE FUNCTION

Blood–Calcium/Phosphate Homeostasis

The organization of osteocytes as a network of gap junction-coupled cells in each osteon represents such a unique structure that one expects it to have an important function in the metabolism and maintenance of bone. The network offers two advantages that may be exploited by the tissue.

1. A tremendous cell–bone surface contact area, about two orders of magnitude larger than the contact area the osteoblasts and lining cells have (Johnson, 1966).
2. An extensive intracellular and an extracellular communication system between sites within the bone and the bone surface.

The first consideration has led Bélanger (1969) and others to propose the hypothesis that osteocytes are capable of local bone remodeling or osteocytic osteolysis. According to this hypothesis, osteocytes are coresponsible for blood–calcium homeostasis. Later studies (Boyde, 1980; Marotti *et al.*, 1990) supplied alternative explanations for the observations that appeared to support the osteocytic osteolysis theory. The possibility remains, however, that osteocytes are involved in the facilitation of calcium diffusion in and out of the bone (Bonucci, 1990). Although the bulk of calcium transport in and out of the bone is apparently taken care of by osteoblasts and osteoclasts (Boyde, 1980; Marotti *et al.*, 1990), osteocytes may have a function in the fine regulation of blood–calcium homeostasis. The major emphasis of present day thinking is, however, on the role of the osteocyte network as a three-dimensional sensor and communication system in bone.

Osteocytes may also play a major role in phosphate homeostasis. Phex is a metalloendoproteinase found on the plasma membrane of osteoblasts and osteocytes (Ruchon *et al.*, 2000) whose substrate is not known. The precise function of Phex is unclear but it clearly plays a role in phosphate homeostasis and bone mineralization. Pex deletion or loss of function results in X-linked hypophosphatemic rickets (The Hyp Consortium 1995). Nijweide and co-workers (Westbroek *et al.*, 2002) were one of the first to propose that the osteocyte network could be considered a gland that regulates bone phosphate metabolism through expression of Phex.

Other proteins known to regulate mineralization and mineral homeostasis are also highly expressed in osteocytes, such as DMP1, Mepe, and sclerostin. Deletion or mutation of DMP1, a gene that is highly expressed in embedding osteocytes and mature osteocytes, results in hypophosphatemic rickets (Feng *et al.*, 2006), similar to the deletion of Phex. DMP1 is expressed along the canalicular wall, while Phex is expressed on the membrane surface of dendrites and the cell body. Other players in mineral metabolism include MEPE and FGF23, which are also highly expressed in osteocytes (Liu *et al.*, 2006). FGF23 is highly elevated in osteocytes in DMP1 null mice, which results in hypophosphatemia in these animals. The osteocyte network might be viewed as an endocrine gland regulating mineral metabolism. Another fascinating hypothesis is that mineral metabolism is regulated by mechanical loading. DMP1 and Pex gene expression are increased in response to load (Gluhak-Heinrich *et al.*, 2003), Sost expression is inhibited (Robling *et al.*, 2006), while a biphasic response is observed for Mepe expression (Gluhak-Heinrich *et al.*, 2005). Whether FGF23 expression is also regulated by loading is currently unknown.

Functional Adaptation: Wolff's Law

Functional adaptation is the term used to describe the ability of organisms to increase their capacity to accomplish a specific function with increased demand and to decrease this capacity with lesser demand. In the 19th century, the anatomist Julius Wolff proposed that mechanical stress is responsible for determining the architecture of bone and that bone tissue is able to adapt its mass and three-dimensional structure to the prevailing mechanical usage to obtain a higher efficiency of load bearing (Wolff, 1892). For the past century, Wolff's law has become widely accepted. Adaptation will improve an individual animal's survival chance because bone is not only hard but also heavy. Too much of it is probably as bad as too little, leading either to uneconomic energy consumption during movement (for too high bone mass) or to an enhanced fracture risk (for too low bone mass). This readily explains the usefulness of mechanical adaptation as an evolutionary driver, even if we do not understand how it is performed.

Osteocytes as Mechanosensory Cells

In principle, all cells of bone may be involved in mechanosensing, as eukaryotic cells in general are sensitive to mechanical stress (Oster, 1989). However, several features argue in favor of osteocytes as the mechanosensory cells *par excellence* of bone as discussed earlier in this chapter. In virtually all types of bone, osteocytes are dispersed throughout the mineralized matrix and are connected with their neighbor osteocytes via long, slender cell processes that run in slightly wider canaliculi of unmineralized matrix. The cell processes contact each other via gap junctions (Doty, 1981; Donahue *et al.*, 1995), thereby allowing direct cell-to-cell coupling. The superficial osteocytes are connected with the lining cells covering most bone surfaces, as well as the osteoblasts that cover (much-less abundant) surfaces where new bone is formed. From a cell biological viewpoint therefore, bone tissue is a three-dimensional network of cells, most of which are surrounded by a very narrow sheath of unmineralized matrix, followed by a much wider layer of mineralized matrix. The sheath of unmineralized matrix is penetrated easily by macromolecules such as albumin and peroxidase (McKee *et al.*, 1993; Tanaka and Sakano, 1985). However, others have shown that although small tracers (<6 nm) readily pass through the lacunar-canalicular porosity in the absence of mechanical loading, there appears to be an upper limit of size between 6 and 10 nm for molecular movement from bone capillaries to osteocytic lacunae in rat long bone. It was suggested that this range of pore size represents the fiber spacing that has been proposed for the annular space based on the presence of a proteoglycan fiber matrix surrounding the osteocytes (Wang *et al.*, 2004). Therefore, there is an intracellular as well as an extracellular route for the rapid passage of ions and signal molecules. This allows for several manners of cellular signaling from osteocytes lying deep within the bone tissue to surface-lining cells and vice versa (Cowin *et al.*, 1995).

Experimental studies indicate that osteocytes are indeed sensitive to stress applied to intact bone tissue. *In vivo* experiments using the functionally isolated turkey ulna have shown that immediately following a 6-min period of intermittent (1 Hz) loading, the number of osteocytes expressing glucose-6-phosphate dehydrogenase (G6PD) activity was increased in relation to local strain magnitude (Skerry *et al.*, 1989). The tissue strain magnitude varied between 0.05 and 0.2% (500–2000 microstrain) in line with *in vivo* peak strains in bone during vigorous exercise. Other models, including strained cores of adult dog cancellous bone, embryonic chicken tibiotarsi, mouse ulnae, rat caudal vertebrae, and rat tibiae, as well as experimental tooth movement in rats, have demonstrated that osteocytes in intact bone change their enzyme activity and RNA synthesis rapidly after mechanical loading (El Haj *et al.*, 1990; Dallas *et al.*, 1993; Lee *et al.*, 2006; Lean *et al.*, 1995; Forwood *et al.*, 1998; Terai *et al.*, 1999). These studies show that intermittent loading produces rapid changes of metabolic activity in osteocytes and suggest that osteocytes may indeed function as mechanosensors in bone. The mechanical environment of the stress-sensitive osteocyte varies with the geometry of the osteocyte lacuna (McCreadie *et al.*, 2004). Computer simulation studies of bone remodeling, assuming this to be a self-organizational control process, predict a role for osteocytes, rather than lining cells and osteoblasts, as stress sensors of bone (Mullender and Huiskes, 1995, 1997; Huiskes *et al.*, 2000; Ruimerman *et al.*, 2005). A regulating role of strain-sensitive osteocytes in basic multicellular unit (BMU) coupling has been postulated by Smit and Burger (2000). Using finite-element analysis, the subsequent activation of osteoclasts and osteoblasts during coupled bone remodeling was shown to relate to opposite strain distributions in the surrounding bone tissue. In front of the cutting cone of a forming secondary osteon, an area of *decreased* bone strain was demonstrated, whereas a layer of *increased* strain occurs around the closing cone (Smit and Burger, 2000). Osteoclasts therefore attack an area of bone where the osteocytes are underloaded, whereas osteoblasts are recruited in a bone area where the osteocytes are overloaded. Hemiosteonic remodeling of trabecular bone showed a similar strain pattern (Smit and Burger, 2000). Thus, bone remodeling regulated by load-sensitive osteocytes can explain the maintenance of osteonic and trabecular architecture as an optimal mechanical structure, as well as adaptation to alternative external loads (Huiskes *et al.*, 2000; Smit and Burger, 2000).

If osteocytes are the mechanosensors of bone, how do they sense mechanical loading? This key question is, unfortunately, still open because it has not yet been established

unequivocally how the loading of intact bone is transduced into a signal for the osteocytes. The application of force to bone during movement results in several potential cell stimuli. These include changes in hydrostatic pressure, direct cell strain, fluid flow, and electric fields resulting from electrokinetic effects accompanying fluid flow (Pienkowski and Pollack, 1983). Evidence has been increasing steadily for the flow of canalicular interstitial fluid as the likely stress-derived factor that informs the osteocytes about the level of bone loading (Cowin *et al.*, 1991, 1995; Cowin, 1999; Weinbaum *et al.*, 1994; Klein-Nulend *et al.*, 1995b; Knothe-Tate, 2000; Burger and Klein-Nulend, 1999; You *et al.*, 2000). In this view, canaliculi are the bone porosity of interest, and the osteocytes the mechanosensor cells.

Canalicular Fluid Flow and Osteocyte Mechanosensing

In healthy, adequately adapted bone, strains as a result of physiological loads (e.g., resulting from normal locomotion) are quite small. Quantitative studies of the strain in bones of performing animals (e.g., galloping horses, fast-flying birds, even a running human volunteer) found a maximal strain not higher than 0.2–0.3% (Rubin, 1984; Burr *et al.*, 1996). This poses a problem in interpreting the results of *in vitro* studies of strained bone cells, where much higher deformations, in the order of 1–10%, were needed to obtain a cellular response (for a review, Burger and Veldhuijzen, 1993). In these studies, isolated bone cells were usually grown on a flexible substratum, which is then strained by stretching or bending. For instance, unidirectional cell stretching of 0.7% was required to activate prostaglandin E_2 production in primary bone cell cultures (Murray and Rushton, 1990). However, in intact bone, a 0.15% bending strain was already sufficient to activate prostaglandin-dependent adaptive bone formation *in vivo* (Turner *et al.*, 1994; Forwood, 1996). If we assume that bone organ strain is somehow involved in bone cell mechanosensing, then bone tissue seems to possess a lever system whereby small matrix strains are transduced into a larger signal that is detected easily by osteocytes. The canalicular flow hypothesis proposes such a lever system. Indeed, *in vitro* experiments that relate the effects of fluid flow and substrate straining have shown that fluid flow-induced shear stress induces higher release of signaling molecules (McGarry *et al.*, 2005). A numerical study showed that the deformation of cells on a two-dimensional substrate caused by fluid flow is fundamentally different from that induced by substrate straining (McGarry *et al.*, 2005). Fluid shear stress had a larger overturning effect on the bone cells, while substrate strain predominantly affected cell-substrate attachments. Whether these observations can be extrapolated towards osteocytes that are embedded in a three-dimensional matrix is a matter of debate, but they clearly indicate that substrate deformation and a flow of interstitial fluid could have differential effects on cells.

The flow of extracellular tissue fluid through the lacuno-canalicular network as a result of bone tissue strains was made plausible by the theoretical study of Piekarski and Munro (1977) and has been shown experimentally by Knothe-Tate and colleagues (1998, 2000). This strain-derived extracellular fluid flow may help keep osteocytes healthy, particularly the deeper ones, by facilitating the exchange of nutrients and waste products between the Haversian channel and the osteocyte network of an osteon (Kufahl and Saha, 1990). However, a second function of this strain-derived interstitial fluid flow could be the transmission of "mechanical information" (Fig. 4). The magnitude of interstitial fluid flow through the lacunocanalicular network is directly related to the amount of strain of the bone organ (Cowin *et al.*, 1991). Because of the narrow diameter of the canaliculi, bulk bone strains of about 0.1% will produce a fluid shear stress in the canaliculi of roughly 1 Pa (Weinbaum *et al.*, 1994), enough to produce a rapid response in endothelial cells (Frangos *et al.*, 1985; Kamiya and Ando, 1996).

Experimental studies *in vitro* have demonstrated that osteocytes are indeed quite sensitive to the fluid shear stress of such a magnitude compared to osteoblasts and osteo-progenitor cells (Klein-Nulend *et al.*, 1995a,b; Ajubi *et al.*, 1996; Westbroek *et al.*, 2000; Westbroek *et al.*, 2001). These results suggest that the combination of the cellular three-dimensional network of osteocytes and the accompanying porous network of lacunae and canaliculi acts as the mechanosensory organ of bone. Different loading-induced canalicular flow patterns around cutting cone and reversal zone during remodeling could, for instance, explain the typical alignment of haversian canals (Burger *et al.*, 2003). Volumetric strain in the bone around a BMU cutting cone has been related to canalicular fluid flow (Smit *et al.*, 2002), and the predicted area of low canalicular flow around the tip of the cutting cone was proposed to induce local osteocyte apoptosis. Unloading-induced osteocytes apoptosis has been shown in rat bone, and was highly associated with osteoclastic bone resorption (Basso *et al.*, 2006). Osteocyte apoptosis at the tip of the cutting cone would attract osteoclasts, leading to further excavation of bone in the direction of loading. Importantly, mechanical loading by fluid shear stress have been shown to promote osteocyte survival (Bakker *et al.*, 2004). The model by Smit *et al.* (2002) further predicts that at the base of the cutting cone and further down the reversal zone, osteocytes receive enhanced fluid shear stress during loading. This could prevent osteocyte apoptosis, but may also promote the retraction and detachment of osteoclasts from the bone surface. These two mechanisms, attraction of osteoclasts to the cutting cone tip and induction of osteoclast detachment from the cutting cone base, together explain the mechanically meaningful behaviour of osteoclasts during remodeling.

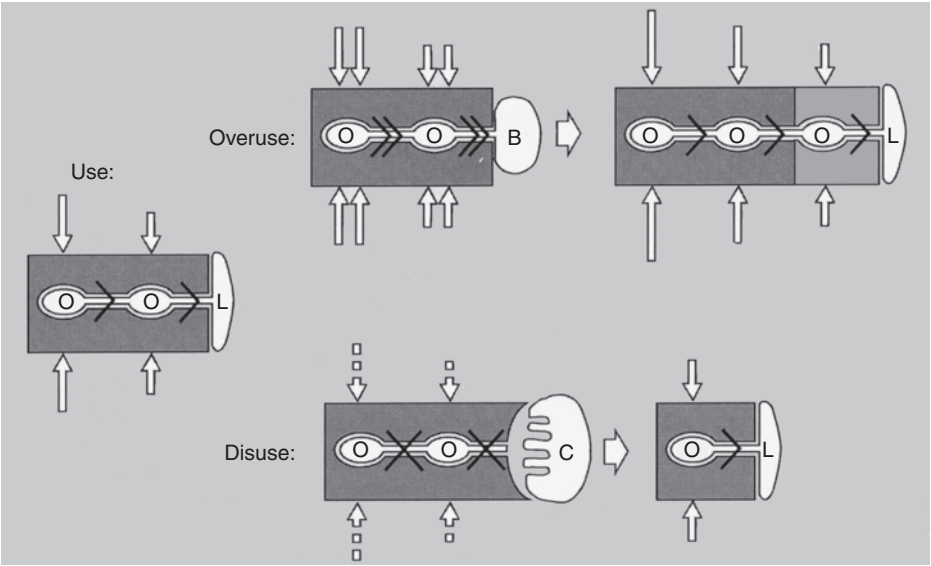

FIGURE 4 Schematic representation of how the osteocyte network may regulate bone modeling. In the steady state (USE), normal mechanical use ensures a basal level of fluid flow through the lacunocanalicular porosity, indicated by an arrowhead through the canaliculi. This basal flow keeps the osteocytes viable and also ensures basal osteocyte activation and signaling, thereby suppressing osteoblastic activity as well as osteoclastic attack. During (local) overuse (OVERUSE), osteocytes are overactivated by enhanced fluid flow (indicated by double arrowheads), leading to the release of osteoblast-recruiting signals. Subsequent osteoblastic bone formation reduces the overuse until normal mechanical use is reestablished, thereby reestablishing the steady state of basal fluid flow. During (local) disuse (DISUSE), osteocytes are inactivated by lack of fluid flow (indicated by crosses through canaliculi). Inactivation leads to a release of osteoclast-recruiting signals, to a lack of osteoclast-suppressing signals, or both. Subsequent osteoclastic bone resorption reestablishes normal mechanical use (or loading) and basal fluid flow. O, osteocyte; L, lining cell; B, osteoblast; C, osteoclast; dark-gray area, mineralized bone matrix; light-gray area, newly formed bone matrix; white arrows represent direction and magnitude of loading. Adapted from Burger and Klein-Nulend (1999).

The flow of interstitial fluid through the bone canaliculi will have two effects: a mechanical one derived from the fluid shear stress and an electrokinetic one derived from streaming potentials (Pollack *et al.*, 1984; Salzstein and Pollack, 1987). Either of the two, or both in combination, might activate the osteocyte. For instance, streaming potentials might modulate the movement of ions such as calcium across the cell membrane (Hung *et al.*, 1995, 1996), whereas shear stress will pull at the macromolecular attachments between the cell and its surrounding matrix (Wang and Ingber, 1994). Both ion fluxes and cellular attachment are powerful modulators of cell behavior and therefore good conveyors of physical information (Sachs, 1989; Ingber, 1991). *In vitro* experiments using bone cells subjected to a flow of fluid of increasing viscosity suggest that fluid shear stress is the major activator of the bone cell response to loading (Bakker *et al.*, 2001). However, care should be taken when extrapolating results obtained with cells seeded on a two-dimensional surface to the three-dimensional *in vivo* situation.

Mechanosensation and the resulting mechanotransduction of biochemical signals may be a complex event (Bonewald, 2006). Perturbation of dendrites, the cell body, and even primary cilia could be involved in combination or sequentially in this response. The osteocytes' response to different kinds of mechanical loading has predominantly been studied in cell cultures or entire bone, while knowledge of mechanosensing in osteocytes single-cell level is essential for understanding the complex process of bone adaptation. For instance, the mechanosensitive part of the osteocytes, the cell body or the cell processes, has not yet been determined. More information is needed on the single osteocyte's response to a localized mechanical stimulation.

It has been suggested that fluid flow over dendrites in the lacunar-canalicular porosity can induce strains in the actin filament bundles of the cytoskeleton that are more than an order of magnitude larger than tissue level strains. Using the latest ultrastructural data for the cell process cytoskeleton and the tethering elements that attach the process to the canalicular wall, a realistic three-dimensional model was created for the osteocyte process. Using this model, the deformed shape of the tethering elements and the hoop strain on the central actin bundle as a result of loading induced fluid flow was predicted. It was found that tissue-level strains of $>$1,000 microstrain at 1 Hz resulted in a hoop strain of $>$0.5%. The tethering elements of the osteocyte process can thus act as a strain-amplifier (Han *et al.*, 200).

Recent publications have shown that osteocytes express a single primary cilia (Xiao *et al.*, 2006). These authors also showed that PKD1/PC1, a known mechanosensory protein in the kidney, does play a role in normal bone structure. Primary cilia in other cells clearly function as sensors

of odors, light, and movement (Singla and Reiter, 2005). It remains to be determined whether the bone defect in animals with defective PKD1 function is due to defective function of PKD1 in cilia, or whether PKD1 has a function in another location in the cell. Very recent, early data suggest that loss of cilia results in decreased sensitivity to fluid flow shear stress (Malone *et al.*, 2006). Determining the function of PKD1 and/or cilia should lend insight into mechanotransduction in osteocytes.

The osteocyte has either been viewed as a quiescent cell acting as a "placeholder" in bone or as a mechanosensory cell as outlined in this chapter. Most observations using static two-dimensional imaging suggest that the dendritic processes are somewhat permanently anchored to the lacunar wall. Dallas and co-workers have shown cell body movement and the extension and retraction of dendritic processes over time using dynamic imaging of living osteocytes within their lacunae (Veno *et al.*, 2006). Calvarial explants from transgenic mice with green fluorescent protein (GFP) expression targeted to osteocytes revealed that, far from being a static cell, the osteocyte is highly dynamic. Therefore dendrites, rather than being permanent connections between osteocytes and with bone surface cells, may have the capacity to connect and disconnect and reconnect. With this new information, theories regarding shear stress within lacunae and osteocyte signaling will require modification.

Response of Osteocytes to Fluid Flow *in Vitro*

The technique of immunodissection, as discussed earlier in this chapter, made it possible to test the canalicular flow hypothesis by comparing the responsiveness of osteocytes, osteoblasts, and osteoprogenitor cells to fluid flow. The strength of the immunodissection technique is that three separate cell populations with a high (90%) degree of homogeneity are prepared, representing (1) osteocytes with the typical "spider-like" osteocyte morphology and little matrix synthesis, (2) osteoblasts with a high synthetic activity of bone matrix-specific proteins, and (3) (from the periosteum) osteoprogenitor cells with a fibroblast-like morphology and very high proliferative capacity (Nijweide *et al.*, 1986). Because the cells are used within 2 days after isolation from the bone tissue, they may well represent the three differentiation steps of osteoprogenitor cell, osteoblast, and osteocyte. In contrast, mixed cell cultures derived from bone that are generally used to represent "osteoblastic" cells likely contain cells in various stages of differentiation. Therefore, changes in mechanosensitivity related to progressive cell differentiation cannot be studied in such cultures. The development of differentiation stage specific bone-cell lines have facilitated the comparison in cell-type specific responses to mechanical loading. Recently Ponik *et al.* (2007) have described significant differences in the response to fluid shear between MC3T3-E1 osteoblasts and MLO-Y4 osteocytes. Stress fibers were formed and aligned within osteoblasts after 1 h of unidirectional fluid flow, but this response was not observed until greater than 5 h of oscillatory fluid flow (Ponik *et al.*, 2007). However, owing to their clonal selection, cell lines do not necessarily express the whole range of bone-specific genes characteristic of primary bone cells. Therefore, the use of primary bone cells can be preferred over the use of cell lines when comparing the behavior of osteoblasts and osteocytes.

Using immunoseparated primary cell populations, osteocytes were found to respond far stronger to fluid flow than osteoblasts and these stronger than osteoprogenitor cells (Klein-Nulend *et al.*, 1995a,b; Ajubi *et al.*, 1996; Westbroek *et al.*, 2000a). Osteocytes also appeared to be more responsive to fluid flow than osteoblasts or osteoprogenitor cells with respect to the production of soluble signaling molecules affecting osteoblast proliferation and differentiation (Vezeridis *et al.*, 2005). The release of these soluble factors was at least partially dependent on the activation of a nitric oxide (NO) pathway in osteocytes in response to fluid flow. Pulsating fluid flow (PFF) with a mean shear stress of 0.5 Pa (5 dynes/cm^2) with a cyclic variation of plus or minus 0.2 Pa at 5 Hz stimulated the release of NO and prostaglandin E_2 and I_2 (PGE_2 and PGI_2) rapidly from osteocytes within minutes (Klein-Nulend *et al.*, 1995a; Ajubi *et al.*, 1996). Osteoblasts showed less response, and osteoprogenitor cells (periosteal fibroblasts) still less. Intermittent hydrostatic compression (IHC) of 13,000 Pa peak pressure at 0.3 Hz (1 sec compression followed by 2 sec relaxation) needed more than a 1-hr application before prostaglandin production was increased, again more in osteocytes than in osteoblasts, suggesting that mechanical stimulation via fluid flow is more effective than hydrostatic compression (Klein-Nulend *et al.*, 1995b). A 1-hr treatment with PFF also induced a sustained release of PGE_2 from the osteocytes in the hour following PFF treatment (Klein-Nulend *et al.*, 1995b). This sustained PGE_2 release, continuing after PFF treatment had been stopped, could be ascribed to the induction of prostaglandin G/H synthase-2 (or cyclooxygenase 2, COX-2) expression (Westbroek *et al.*, 2000a). Again, osteocytes were much more responsive than osteoblasts and osteoprogenitor cells, as only a 15-min treatment with PFF increased COX-2 mRNA expression by threefold in osteocytes but not in the other two cell populations (Westbroek *et al.*, 2000). Upregulation of COX-2 but not COX-1 by PFF had been shown earlier in a mixed population of mouse calvarial cells (Klein-Nulend *et al.*, 1997) and was also demonstrated in primary bone cells from elderly women (Joldersma *et al.*, 2000), whereas the expression of COX-1 and -2 in osteocytes and osteoblasts in intact rat bone has been documented (Forwood *et al.*, 1998). These *in vitro* experiments on immunoseparated cells suggest that as bone cells mature, they increase their capacity to produce

prostaglandins in response to fluid flow (Burger and Klein-Nulend, 1999). First, their immediate production of PGE_2, PGI_2, and probably PGF_2a (Klein-Nulend *et al.*, 1997), in response to flow, increases as they develop from osteoprogenitor cell, via the osteoblastic stage into osteocytes. Second, their capacity to increase expression of COX-2 in response to flow, and thereby to continue to produce PGE_2 even after the shear stress has stopped (Westbroek *et al.*, 2000a), increases as they reach terminal differentiation. Because induction of COX-2 is a crucial step in the induction of bone formation by mechanical loading *in vivo* (Forwood, 1996), these results provide direct experimental support for the concept that osteocytes, the long-living terminal differentiation stage of osteoblasts, function as the "professional" mechanosensors in bone tissue.

Pulsating fluid flow also rapidly induced the release of NO in osteocytes but not in osteoprogenitor cells (Klein-Nulend *et al.*, 1995a). Rapid release of NO was also found when whole rat bone rudiments were mechanically strained in organ culture (Pitsillides *et al.*, 1995) and in human bone cells submitted to fluid flow (Sterck *et al.*, 1998). In line with these *in vitro* observations, inhibition of NO production inhibited mechanically induced bone formation in animal studies (Turner *et al.*, 1996; Fox *et al.*, 1996). NO is a ubiquitous messenger molecule for intercellular communication and is involved in many tissue reactions where cells must collaborate and communicate with each other (Koprowski and Maeda, 1995). The intracellular upregulation of NO after mechanical stimulation has been shown in single bone cells using DAR-4M AM chromophore (Vatsa *et al.*, in press). It was shown that a single osteocyte can disseminate a mechanical stimulus to its surrounding osteocytes via extracellular soluble signaling factors, which reinforces the putative mechanosensory role of osteocytes, and demonstrates a possible mechanism by which a single mechanically stimulated osteocyte can communicate with other cells in a bone multicellular unit, which might help to better understand the intricacies of intercellular interactions in BMUs and thus bone remodeling (Vatsa *et al.*, in press). Another interesting example of the involvement of NO in tissue reactions where cells must collaborate and communicate with each other is the adaptation of blood vessels to changes in blood flow. In blood vessels, enhanced blood flow, e.g., during exercise, leads to widening of the vessel to ensure a constant blood pressure. This response depends on the endothelial cells, which sense the increased blood flow, and produce intercellular messengers such as NO and prostaglandins. In response to these messengers, the smooth muscle cells around the vessel relax to allow the vessel to increase in diameter (Kamiya and Ando, 1996). The capacity of endothelial cells to produce NO in response to fluid flow is related to a specific enzyme, endothelial NO synthase or ecNOS. Interestingly, this enzyme was found in rat bone lining cells and osteocytes (Helfrich *et al.*, 1997; Zaman *et al.*, 1999) and in cultured bone cells derived from human bone (Klein-Nulend *et al.*, 1998). Both endothelial and neuronal NOS isoforms are present in osteocytes (Cabbalero-alias *et al.*, 2004). The rapid release by mechanically stressed bone cells makes NO an interesting candidate for intercellular communication within the three-dimensional network of bone cells. Treatment with pulsatile fluid flow increased the level of ecNOS RNA transcripts in the bone cell cultures (Klein-Nulend *et al.*, 1998), a response also described in endothelial cells (Busse and Fleming, 1998; Uematsu *et al.*, 1995). Enhanced production of prostaglandins is also a well-described response of endothelial cells to fluid flow (Busse and Fleming, 1998; Kamiya and Ando, 1996). It seems, therefore, that endothelial cells and osteocytes possess a similar sensor system for fluid flow and that both cell types are "professional" sensors of fluid flow.

Mechanotransduction starts by the conversion of physical loading-derived stimuli into cellular signals. Several studies suggest that the attachment complex between intracellular actin cytoskeleton and extracellular matrix macromolecules, via integrins and CD44 receptors in the cell membrane, provides the site of mechanotransduction (Wang *et al.*, 1993; Watson, 1991; Ajubi *et al.*, 1996, 1999; Pavalko *et al.*, 1998). An important early response is the influx of calcium ions through mechanosensitive ion channels in the plasma membrane and the release of calcium from internal stores (Hung *et al.*, 1995, 1996; Ajubi *et al.*, 1999; Chen *et al.*, 2000; You *et al.*, 2000). The rise in intracellular calcium concentration activates many downstream signaling cascades such as protein kinase C and phospholipase A_2 and is necessary for activation of calcium/calmodulin dependent proteins such as NOS. The activation of phospholipase A_2 results among others in the activation of arachidonic acid production and PGE_2 release (Ajubi *et al.*, 1999). Other genes whose expression in osteocytes is modified by mechanical loading include c-fos, MEPE and IGF-I (Lean *et al.*, 1995; 1996).

Many steps in the mechanosignaling cascade are still unknown in osteocytes as well as other mechanosensory cells. Recently, it has been shown that the Wnt family of proteins strongly modulate the anabolic response of bone to mechanical loading (Robinson *et al.*, 2006). More research will need to be conducted to elucidate the physiological role of Wnts in bone cell mechanotransduction. Undoubtedly, in the mean time new players in the field of bone cell mechanotransduction will be identified.

SUMMARY AND CONCLUSION

Tremendous progress has been made in discerning the function of osteocytes since this chapter was first written about seven or eight years ago. One only has to search the term "osteocytes" on *PubMed* to see the dramatic increase in references to and studies of this elusive bone cell. Markers for osteocytes have been expanded to delineate early to late

stages of osteocyte differentiation and the critical role of mineralization in this process. Genomic profiling of osteocytes is a storehouse of information regarding the potential functions of these cells and their response to strain.

Molecular mechanisms and pathways involved in osteocyte mechanosensation have been identified and expanded significantly. Although some investigators hold to the concept of a single mechanoreceptor initiating a linear cascade of events, new theories suggesting simultaneous triggering events in response to load are being investigated. It remains to be determined what makes these cells more responsive to shear stress than to osteoblasts and what role the cell body, dendrites, and even cilia may play in this response.

These cells make up 90–95% of all bone cells in the adult skeleton. Collectively, any minor modulation of the entire population could have significant local and systemic effects, not only on bone, but also on other organs. Although it was postulated several decades ago that osteocytes could potentially play a role in calcium metabolism, it appears that this cell may have a more important role in phosphate metabolism. It remains to be determined how factors produced by osteocytes can enter the circulation suggesting an intimate connection between the lacuno-canalicular system and the blood supply.

One reason for the dramatic expansion in knowledge in the field of osteocyte biology is the generation of new tools and the advancement of technology. No longer is this cell safe within its mineralized cave from "prying eyes." Transgenic technology has targeted the osteocyte with fluorescent markers and generated conditional deletions. Cell lines, osteocyte selective and specific antibodies, and probes have been generated. Advanced instrumentation such as Raman spectroscopy and atomic force microscopy can probe and characterize the osteocyte microenvironment. Dynamic imaging has revealed osteocyte movement within their lacuna and canaliculi.

Even with these advances, we may still only be seeing "the tip of the iceberg" with regards to osteocyte function. It has been proposed that the osteocyte could be the orchestrator of bone remodeling in the adult skeleton that directs both osteoblast and osteoclast function. The future looks exciting and full of new discoveries with regards to the biology of the osteocyte and its role in mechanosensation.

ACKNOWLEDGMENTS

The authors would like to acknowledge the pioneering leadership in the field of osteocyte biology of Drs. Els Burger and Peter Nijweide, original authors of this chapter. These two individuals laid the foundation upon which the present authors have founded their research. The authors wish to thank Dr. Astrid Bakker for critically reading the manuscript.

The authors would also like to acknowledge funding support from the National Institutes of Health AR-46798 (L.F.B.), The Netherlands Foundation for Fundamental Research on Matter (ALW/FOM/NWO project no. 01FB28/2) (J.K.N.) and The Netherlands Institute for Space Research (SRON grant no. MG-055) (J.K.N.).

INTRODUCTION

Osteoclasts, the multinucleated giant cells that resorb bone, develop from hematopoietic cells of the monocyte-macrophage lineage. We developed a mouse coculture system of osteoblasts/stromal cells and hematopoietic cells in which osteoclasts are formed in response to bone-resorbing factors such as 1α,25-dihydroxyvitamin D_3 [1α,25$(OH)_2D_3$], parathyroid hormone (PTH), prostaglandin E_2 (PGE_2), and interleukin 11 (IL-11). A series of experiments using this coculture system established the concept that osteoblasts/stromal cells are crucially involved in osteoclast development. Cell-to-cell contact between osteoblasts/stromal cells and osteoclast progenitors is necessary for inducing osteoclast differentiation in the coculture system. Studies on macrophage colony-stimulating factor (M-CSF, also called CSF-1)-deficient *op/op* mice have shown that M-CSF produced by osteoblasts/stromal cells is an essential factor for inducing osteoclast differentiation from monocyte-macrophage lineage cells. Subsequently, another essential factor for osteoclastogenesis, receptor activator of nuclear factor κB ligand (RANKL) was molecularly cloned in 1998. RANKL [also known as osteoclast differentiation factor (ODF)/osteoprotegerin ligand (OPGL)/tumor necrosis factor (TNF)-related activation-induced cytokine (TRANCE)] is a member of the TNF-ligand family, which is expressed as a membrane-associated protein in osteoblasts/stromal cells in response to many bone-resorbing factors. Osteoclast precursors that possess RANK (receptor activator of nuclear factor κB), a TNF receptor family member, recognize RANKL through cell–cell interaction with osteoblasts/stromal cells and differentiate into osteoclasts in the presence of M-CSF. Mature osteoclasts also possess RANK, and RANKL induces their bone-resorbing activity. Osteoprotegerin [OPG, also called osteoclastogenesis inhibitory factor (OCIF)] mainly produced by osteoblasts/stromal cells is a soluble decoy receptor for RANKL. OPG has been shown to function as an inhibitory factor for osteoclastogenesis *in vivo* and *in vitro*. Mutations of OPG, RANK, and RANKL have been detected in humans. TNFα and IL-1 directly induce differentiation and function of osteoclasts, respectively, by a mechanism independent of the RANKL–RANK interaction. This chapter describes the history of the discovery of RANKL and its development afterward.

ROLE OF OSTEOBLASTS/STROMAL CELLS IN OSTEOCLAST DIFFERENTIATION AND FUNCTION

Role of Osteoblasts/Stromal Cells in Osteoclast Differentiation

Development of osteoclasts proceeds within a local microenvironmental milieu of bone. This process can be reproduced *ex vivo* in a coculture of mouse calvarial osteoblasts and hematopoietic cells (Takahashi *et al.*, 1988; Suda *et al.*, 1992; Chambers *et al.*, 1993). Multinucleated cells formed

TABLE I Osteoclast Formation in Cocultures with hIL-6R Transgenic Mice or Mice Carrying the Disrupted Genes of VDR, PTHR1, or EP4

	Coculture system[a]			
Osteotropic factor	Osteoblasts	Hematopoietic cells	Osteoclast formation	Reference
hIL-6	wt	hIL-6R tg	−	Udagawa *et al.* (1995)
	hIL-6R tg	wt	+	
PTH	PTHR1(−/−)	wt	−	Liu *et al.* (1998)
	wt	PTHR1(−/−)	+	
PGE_2	EP4(−/−)	wt	−	Sakuma *et al.* (2000)
	wt	EP4(−/−)	+	
$1\alpha,25(OH)_2D_3$	VDR(−/−)	wt	−	Takeda *et al.* (1999)
	wt	VDR(−/−)	+	

[a]*Osteoblasts or hematopoietic cells obtained from human* IL-6R (*h*IL-6R) *transgenic* (*tg*) *mice,* VDR *knockout* [VDR(−/−)] *mice,* PTHR1 *knockout* [PTHR1(−/−)] *mice, or* EP4 *knockout* [EP4(−/−)] *mice were cocultured with their counterparts (osteoblasts or hematopoietic cells) obtained from wild-type* (*wt*) *mice.*

in the coculture exhibit major characteristics of osteoclasts, including tartrate-resistant acid phosphatase (TRAP) activity, expression of calcitonin receptors, c-Src (p60c-Src), vitronectin receptors ($\alpha_v\beta_3$), and the ability to form resorption pits on bone and dentine slices (Suda *et al.*, 1992). Some mouse stromal cell lines, such as MC3T3-G2/PA6 and ST2, are able to support osteoclastogenesis when cultured with mouse spleen cells (Udagawa *et al.*, 1989). In this coculture, osteoclasts are formed in response to various osteotropic factors, including $1\alpha,25(OH)_2D_3$, PTH, PGE_2, and IL-11. Cell-to-cell contact between osteoblasts/stromal cells and osteoclast progenitors is required to induce osteoclastogenesis. Subsequent experiments established that the target cells of osteotropic factors for inducing osteoclast formation *in vitro* are osteoblasts/stromal cells (Table I).

IL-6 exerts its activity via a cell surface receptor that consists of two components: a ligand-binding IL-6 receptor (IL-6R) and a non-ligand-binding but signal-transducing protein gp130. The genetically engineered soluble IL-6R (sIL-6R), which lacks both transmembrane and cytoplasmic domains, has been shown to mediate IL-6 signals through gp130 in response to IL-6. Neither recombinant IL-6 nor sIL-6R alone induced osteoclast formation in coculture, but osteoclasts were formed in response to IL-6 in the presence of sIL-6R (Tamura *et al.*, 1993). This suggests that a signal(s) mediated by gp130 is involved in osteoclast development, and that osteoblasts/stromal cells do not have enough membrane-bound IL-6R. Using transgenic mice constitutively expressing human IL-6R, it was shown that the expression of human IL-6R in osteoblasts was indispensable for inducing osteoclast recruitment (Udagawa *et al.*, 1995) (see Table I). When osteoblasts obtained from human IL-6R transgenic mice were cocultured with normal spleen cells, osteoclast formation was induced in response to human IL-6 without adding human sIL-6R. Indeed, cytokines such as IL-11, oncostatin M, and leukemia inhibitory factor (LIF), which transduce their signals through gp130 in osteoblasts/stromal cells, induced osteoclast formation in the coculture. These results established for the first time the concept that bone-resorbing cytokines using gp130 as a common signal transducer act directly on osteoblasts/stromal cells but not on osteoclast progenitors to induce osteoclast formation.

Requirement of PTH/PTHrP receptors (PTHR1) in the osteoblast was confirmed by using cocultures of osteoblasts and spleen cells obtained from PTHR1 knockout mice (Liu *et al.*, 1998). Osteoblasts obtained from PTHR1(−/−) mice failed to support osteoclast development in cocultures with normal spleen cells in response to PTH (see Table I). Osteoclasts were formed in response to PTH in cocultures of spleen cells obtained from PTHR1(−/−) mice and normal calvarial osteoblasts. This suggests that the expression of PTHR1 in osteoblasts/stromal cells is critical for PTH-induced osteoclast formation *in vitro*.

PGE_2 exerts its effects through PGE receptors (EPs) that consist of four subtypes (EP1, EP2, EP3, and EP4). Intracellular signaling differs among the receptor subtypes: EP1 is coupled to Ca^{2+} mobilization and EP3 inhibits adenylate cyclase activity, whereas both EP2 and EP4 stimulate adenylate cyclase activity. It was reported that 11-deoxy-PGE_1 (an EP4 and EP2 agonist) stimulated

osteoclast formation more effectively than butaprost (an EP2 agonist) and other EP agonists in the coculture of primary osteoblasts and bone marrow cells, suggesting that EP4 is the main receptor responsible for PGE_2-induced osteoclast formation (Sakuma *et al.*, 2000). Furthermore, the PGE_2-induced osteoclast formation was not observed in the coculture of osteoblasts from EP4(−/−) mice and spleen cells from wild-type mice, whereas osteoclasts were formed in the coculture of wild-type osteoblasts and EP4(−/−) spleen cells (Sakuma *et al.*, 2000) (see Table 1). These results indicate that PGE_2 enhances osteoclast formation through the receptor subtype EP4 on osteoblasts. Li *et al.* (2000b) used cells from mice in which the EP2 receptor had been disrupted to test the role of EP2 in osteoclast formation. The response to PGE_2 for osteoclast formation was also reduced in cultures of bone marrow cells obtained from EP2(−/−) mice. In mouse calvarial organ cultures, the EP4 agonist stimulated bone resorption markedly, but its maximal stimulation was less than that induced by PGE_2 (Suzawa *et al.*, 2000). The EP2 agonist also stimulated bone resorption, but only slightly. EP1 and EP3 agonists showed no effect on bone resorption. These findings suggest that PGE_2 stimulates bone resorption by a mechanism involving cAMP production in osteoblasts/stromal cells, mediated mainly by EP4 and partially by EP2.

The other known pathway used for osteoclast formation is that stimulated by $1\alpha,25(OH)_2D_3$. Using $1\alpha,25(OH)_2D_3$ receptor (VDR) knockout mice, Takeda *et al.* (1999) clearly showed that the target cells of $1\alpha,25(OH)_2D_3$ for inducing osteoclasts in the coculture were also osteoblasts/stromal cells but not osteoclast progenitors (see Table 1). Spleen cells from VDR(−/−) mice differentiated into osteoclasts when cultured with normal osteoblasts in response to $1\alpha,25(OH)_2D_3$. In contrast, osteoblasts obtained from VDR(−/−) mice failed to support osteoclast development in coculture with wild-type spleen cells in response to $1\alpha,25(OH)_2D_3$. These results suggest that the signals mediated by VDR are also transduced into osteoblasts/stromal cells to induce osteoclast formation in the coculture.

Thus, the signals induced by almost all of the bone-resorbing factors are transduced into osteoblasts/stromal cells to recruit osteoclasts in the coculture. Therefore, we proposed that osteoblasts/stromal cells express ODF, which was hypothesized to be a membrane-bound factor in promoting the differentiation of osteoclast progenitors into osteoclasts through a mechanism involving cell-to-cell contact (Suda *et al.*, 1992) (Fig. 1). Chambers *et al.* (1993) also proposed a similar hypothesis, in which stromal osteoclast-forming activity (SOFA) is expressed by osteoblasts/stromal cells to support osteoclast formation.

Discovery of M-CSF as an Essential Factor for Osteoclastogenesis

Experiments with the *op/op* mouse model established the role of M-CSF for osteoclast formation. Yoshida *et al.*

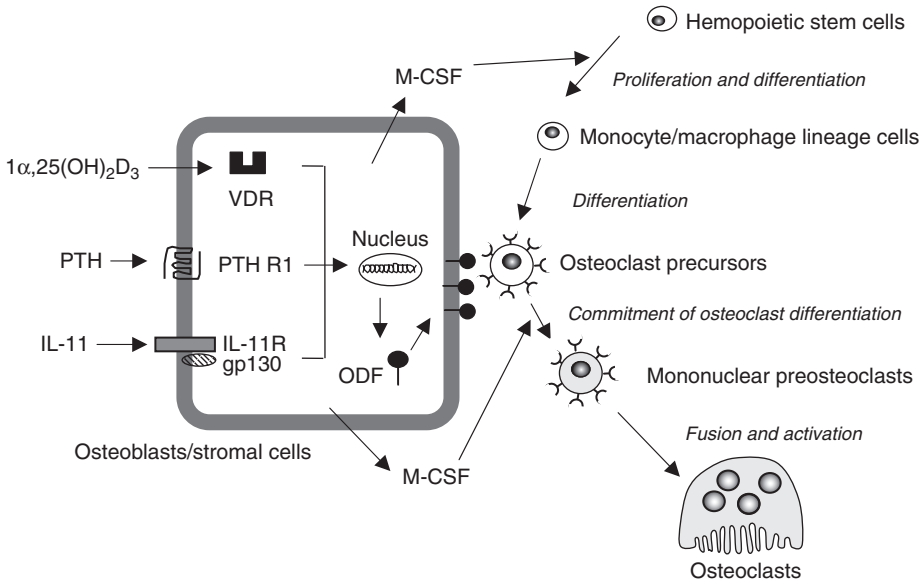

FIGURE 1 A hypothetical concept of osteoclast differentiation and a proposal for osteoclast differentiation factor (ODF). Osteotropic factors such as $1\alpha,25(OH)_2D_3$, PTH, and IL-11 stimulate osteoclast formation in mouse cocultures of osteoblasts/stromal cells and hematopoietic cells. The target cells of these osteotropic factors are osteoblasts/stromal cells. Three independent signaling pathways mediated by $1\alpha,25(OH)_2D_3$-VDR, PTH-PTHR1, and IL-11-IL-11R/gp130 interactions induce ODF as a membrane-associated factor in osteoblasts/stromal cells in similar manners. Osteoclast progenitors of the monocyte-macrophage lineage recognize ODF through cell–cell interaction with osteoblasts/stromal cells and differentiate into osteoclasts. M-CSF produced by osteoblasts/stromal cells is a prerequisite for both proliferation and differentiation of osteoclast progenitors. This hypothetical concept has been proved molecularly by the discovery of the RANKL–RANK interaction.

(1990) demonstrated that there is an extra thymidine insertion at base pair 262 in the coding region of the M-CSF gene in *op/op* mice. This insertion generated a stop codon (TGA) 21 bp downstream, suggesting that the M-CSF gene of *op/op* mice cannot code for the functionally active M-CSF protein. In fact, administration of recombinant human M-CSF restored the impaired bone resorption of *op/op* mice *in vivo* (Felix *et al.*, 1990; Kodama *et al.*, 1991). Calvarial osteoblasts obtained from *op/op* mice could not support osteoclast formation in cocultures with normal spleen cells, even in the presence of $1\alpha,25(OH)_2D_3$ (Takahashi *et al.*, 1991). The addition of M-CSF to the coculture with *op/op* osteoblastic cells induced osteoclast formation from normal spleen cells in response to $1\alpha,25(OH)_2D_3$. In contrast, spleen cells obtained from *op/op* mice were able to differentiate into osteoclasts when cocultured with normal osteoblasts. It was shown that M-CSF is involved in both proliferation of osteoclast progenitors and their differentiation into osteoclasts (Tanaka *et al.*, 1993; Felix *et al.*, 1994).

Begg *et al.* (1993) investigated age-related changes in osteoclast activity in *op/op* mice. Femurs of newborn *op/op* mice were infiltrated heavily with bone, and the marrow hemopoiesis was reduced significantly. However, the femoral marrow cavity of *op/op* mice enlarged progressively with the concomitant appearance of tartrate-resistant acid phosphatase (TRAP, a marker enzyme of osteoclasts)-positive osteoclasts, and by 22 weeks of age the marrow hemopoiesis was comparable to that of controls. Niida *et al.* (1999) reported that a single injection in *op/op* mice with recombinant human vascular endothelial growth factor (VEGF) induced osteoclast recruitment. VEGF receptor 1 (VEGFR-1/Flt-1) is a high-affinity tyrosine kinase (TK) receptor for VEGF and regulates angiogenesis as well as monocyte/macrophage functions. It was also reported that when a VEGFR-1 signaling deficiency [Flt1(TK)(−/−)] was introduced into *op/op* mice, the double mutant [*op/op* Flt1(TK)(−/−)] mice exhibited severer osteoclast deficiency (Niida *et al.*, 2005). These results suggest that factors other than M-CSF, including VEGF, can be substituted for M-CSF to induce osteoclast formation under special occasions.

Role of Osteoblasts/Stromal Cells in Osteoclast Function

One of the major technical difficulties associated with the analysis of mature osteoclasts is their strong adherence to plastic dishes. A collagen gel-coated culture using mouse bone marrow cells and osteoblasts/stromal cells was developed to obtain a cell preparation containing functionally active osteoclasts (Suda *et al.*, 1997a). The purity of osteoclasts in this preparation was only 2–3%, contaminated with numerous osteoblasts. However, this crude osteoclast preparation proved to be useful for establishing a reliable resorption pit assay on dentine slices. The crude osteoclast preparation was further purified using a 30% Percoll solution (Jimi *et al.*, 1996). Interestingly, these highly purified osteoclasts (purity: 50–70%) cultured for 24 hours on dentine slices failed to form resorption pits. Resorptive capability of the purified osteoclasts was restored when osteoblasts/stromal cells were added to the purified osteoclast preparation. Similarly, Wesolowski *et al.* (1995) obtained highly purified mononuclear and binuclear prefusion osteoclasts using echistatin-treated cocultures of mouse bone marrow cells and osteoblastic MB 1.8 cells. These enriched prefusion osteoclasts failed to form resorption pits on bone slices, but their bone-resorbing activity was induced when both MB 1.8 cells and $1\alpha,25(OH)_2D_3$ were added to the prefusion osteoclast cultures. These results suggested that osteoblasts/stromal cells play an essential role not only in the stimulation of osteoclast differentiation, but also in the activation of mature osteoclasts to resorb bone, which also depends on a cell-to-cell contact-dependent process (Suda *et al.*, 1997b).

RANKL–RANK INTERACTION FOR OSTEOCLASTOGENESIS

Discovery of OPG

OPG was cloned as a member of the TNF receptor superfamily in an expressed sequence tag cDNA project (Simonet *et al.*, 1997). Interestingly, OPG lacked a transmembrane domain and presented as a secreted form (Fig. 2). Hepatic expression of OPG in transgenic mice resulted in severe osteopetrosis. Osteoclastogenesis inhibitory factor (OCIF), which inhibited osteoclast formation in the coculture of osteoblasts and spleen cells, was isolated as a heparin-binding protein from the conditioned medium of human fibroblast cultures (Tsuda *et al.*, 1997). The cDNA sequence of OCIF was identical to that of OPG (Yasuda *et al.*, 1998a). OPG/OCIF contains four cysteine-rich domains and two death domain homologous regions (see Fig. 2). The death domain homologous regions share structural features with "death domains" of TNF type I receptor (p55) and Fas, both of which mediate apoptotic signals. Analysis of the domain deletion mutants of OPG revealed that the cysteine-rich domains are essential for inducing biological activity *in vitro*. Although the biological significance of the death domain homologous regions in the OPG molecule has to be elucidated in the future, the cysteine residue at position 400 (Cys-400) is necessary for homodimerization (Yamaguchi *et al.*, 1998).

OPG strongly inhibited osteoclast formation induced by $1\alpha,25(OH)_2D_3$, PTH, PGE_2, or IL-11 in cocultures. Analyses of transgenic mice overexpressing OPG and animals injected with OPG have demonstrated that this factor increases bone mass by suppressing bone resorption

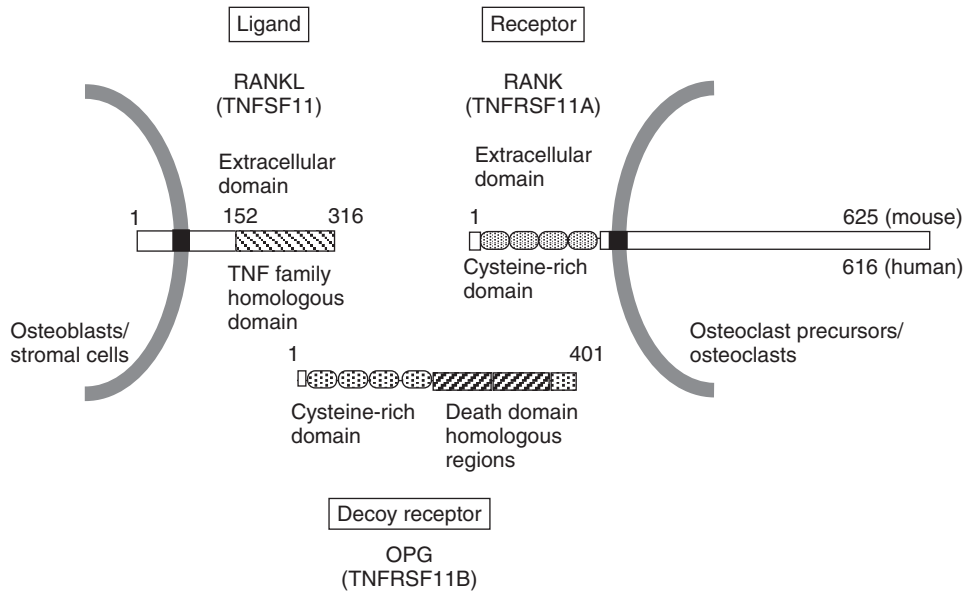

FIGURE 2 A diagrammatic representation of the ligand, receptor, and decoy receptor of the newly discovered TNF receptor-ligand family members essentially involved in osteoclastogenesis. RANKL is a type II transmembrane protein composed of 316 amino acid residues. The TNF homologous domain exists in Asp^{152}-Asp^{316}. Mouse RANK is a type I transmembrane protein of 625 amino acid residues. Human RANK composed of 616 amino acid residues. Four cysteine-rich domains exist in the extracellular region of the RANK protein. OPG, a soluble decoy receptor for RANKL, is composed of 401 amino acid residues without a transmembrane domain. OPG also contains four cysteine-rich domains and two death domain homologous regions. The cysteine-rich domains but not the death domain homologous regions of OPG are essential for inhibiting osteoclast differentiation and function. RANKL, RANK, and OPG are also named TNFSF11, TNFRSF11A, and TNFRSF11B, respectively.

(Simonet *et al.*, 1997; Yasuda *et al.*, 1998a). The physiological role of OPG was investigated further in OPG-deficient mice (Bucay *et al.*, 1998; Mizuno *et al.*, 1998). These mutant mice were viable and fertile, but adolescent and adult OPG(−/−) mice exhibited a decrease in bone mineral density (BMD) characterized by severe trabecular and cortical bone porosity, marked thinning of parietal bones of the skull, and a high incidence of fractures. Interestingly, osteoblasts derived from OPG(−/−) mice strongly supported osteoclast formation in coculture without adding any bone-resorbing agents (Udagawa *et al.*, 2000). These results indicate that OPG produced by osteoblasts/stromal cells functions as an important negative modulator in osteoclast differentiation and activation *in vivo* and *in vitro*.

RANKL–RANK Interaction in Osteoclast Differentiation and Function

Using OPG as a probe, Yasuda *et al.* (1998b) cloned a cDNA with an open reading frame encoding 316 amino acid residues from an expression library of the mouse bone marrow-derived stromal cell line ST2. The OPG-binding molecule was a type II transmembrane protein of the TNF ligand family. Because the OPG-binding molecule satisfied major criteria of ODF, this molecule was renamed ODF. Lacey *et al.* (1998) also succeeded in the molecular cloning of the ligand for OPG (OPGL) from an expression library of the murine myelomonocytic cell line 32D. Molecular cloning of ODF/OPGL demonstrated that it was identical to TRANCE (Wong *et al.*, 1997b) and RANKL (Anderson *et al.*, 1997), which had been identified independently by other research groups. A new member of the TNF receptor family, termed "RANK," was cloned from a cDNA library of human dendritic cells (Anderson *et al.*, 1997). The mouse RANK cDNA encodes a type I transmembrane protein of 625 amino acid residues with four cysteine-rich domains in the extracellular region. The N-terminal region of RANK has a similar structure to that of OPG, a decoy receptor for RANKL (see Fig. 2).

A genetically engineered soluble form of RANKL, together with M-CSF, induced osteoclast formation from spleen cells in the absence of osteoblasts/stromal cells. Treatment of calvarial osteoblasts with $1\alpha,25(OH)_2D_3$, PTH, PGE_2, or IL-11 upregulated the expression of RANKL mRNA. Survival, fusion, and pit-forming activity of mouse osteoclasts formed *in vitro* are also induced by RANKL (Jimi *et al.*, 1999a). RANKL also increased bone resorption by isolated rat authentic osteoclasts (Burgess *et al.*, 1999; Fuller *et al.*, 1998). These results suggested that osteoblasts/stromal cells are essentially involved in both differentiation and activation of osteoclasts through the expression of RANKL as a membrane-associated factor (Fig. 3).

Polyclonal antibodies against the extracellular domains of RANK (anti-RANK Ab) induced osteoclast formation in

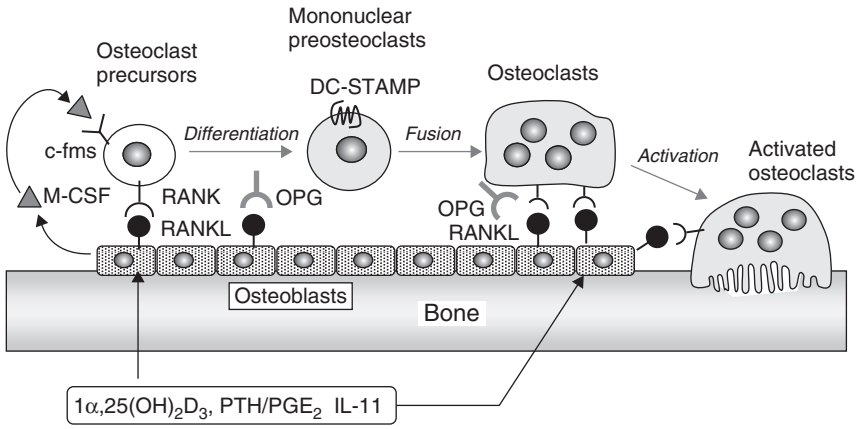

FIGURE 3 A schematic representation of osteoclast differentiation and function regulated by RANKL and M-CSF. Osteotropic factors such as $1\alpha,25(OH)_2D_3$, PTH, and IL-11 stimulate expression of RANKL in osteoblasts/stromal cells. Osteoblasts/stromal cells constitutively express M-CSF. The membrane-associated form of RANKL expressed by osteoblasts/stromal cells is responsible for the induction of osteoclast differentiation in the coculture. Osteoclast precursors express c-Fms and RANK, and recognize RANKL through cell–cell interaction with osteoblasts/stromal cells and differentiate into mononuclear preosteoclasts in the presence of M-CSF. Mononuclear preosteoclasts express DC-STAMP. RANKL also directly stimulates fusion and activation of osteoclasts. DC-STAMP plays a role in fusion of mononuclear preosteoclasts to form multinucleated osteoclasts. Osteoclasts express RANKL, which stimulates bone-resorbing activity of osteoclasts. Mainly osteoblasts/stromal cells produce OPG, a soluble decoy receptor of RANKL. OPG strongly inhibits the entire differentiation, fusion, and activation processes of osteoclasts induced by RANKL.

spleen cell cultures in the presence of M-CSF (Hsu *et al.*, 1999; Nakagawa *et al.*, 1998). In contrast, the anti-RANK antibody, which lacks the Fc fragment (the Fab fragment), completely blocked the RANKL-mediated osteoclastogenesis (Nakagawa *et al.*, 1998). Transgenic mice expressing a soluble RANK-Fc fusion protein showed osteopetrosis, similar to OPG transgenic mice (Hsu *et al.*, 1999). Taken together, these results suggest that RANK acts as the sole signaling receptor for RANKL in inducing differentiation and subsequent activation of osteoclasts (see Fig. 3). Thus, ODF, OPGL, TRANCE, and RANKL are different names for the same protein, which is important for the development and function of T cells, dendritic cells and osteoclasts. The terms RANKL, RANK, and OPG are used in this chapter in accordance with the guidelines of the American Society for Bone and Mineral Research President's Committee on Nomenclature (2000). According to the nomenclature of TNF and TNF receptor (TNFR) super family (SF) members, RANKL, RANK, and OPG are also named TNFSF11, TNFRSF11A, and TNFRSF11B, respectively (see Fig. 2).

Phenotypes of RANKL- and RANK-Deficient Mice

The physiological role of RANKL was investigated by generating RANKL-deficient mice (Kong *et al.*, 1999b). RANKL(−/−) mice lacked osteoclasts but had normal osteoclast progenitors that can differentiate into functionally active osteoclasts when cocultured with normal osteoblasts/stromal cells. Osteoblasts obtained from RANKL(−/−) mice failed to support osteoclast formation in the coculture with wild-type bone marrow cells even in the presence of $1\alpha,25(OH)_2D_3$ and PGE_2. RANKL(−/−) mice exhibited defects in early differentiation of T and B lymphocytes. In addition, RANKL(−/−) mice showed normal splenic structure and Peyer's patches, but lacked all lymph nodes.

The physiological role of RANK was also investigated by generating RANK-deficient mice (Dougall *et al.*, 1999). The phenotypes of RANK(−/−) mice were essentially the same as those of RANKL(−/−) mice. Like RANKL-deficient mice, RANK(−/−) mice were characterized by severe osteopetrosis resulting from an apparent block in osteoclast differentiation. RANK(−/−) mice also exhibited a marked deficiency of B cells in the spleen. RANK(−/−) mice retained mucosal-associated lymphoid tissues, including Peyer's patches, but completely lacked all the other peripheral lymph nodes. Li *et al.* (2000a) further showed that RANK(−/−) mice had a profound defect in bone resorption and remodeling and in the development of the cartilaginous growth plates of endochondral bone. Osteopetrosis observed in RANK(−/−) mice was rescued by the transplantation of bone marrow from rag1 (recombinase-activating gene 1)(−/−) mice, indicating that RANK(−/−) mice have an intrinsic defect in osteoclast lineage cells. Osteoclastogenesis in RANK(−/−) mice was also rescued by the transferring the RANK cDNA back into hematopoietic precursors. These data indicate that RANKL–RANK interaction is an absolute requirement not only for osteoclast development, but also in lymphocyte development and lymph node organogenesis.

Discovery of DC-STAMP as a Cell Fusion Factor in Osteoclast Generation

Multinucleated osteoclasts are formed by cell–cell fusion of mononuclear preosteoclasts. Recent studies have shown that the dendritic cell-specific transmembrane protein (DC-STAMP), a seven-transmembrane protein, is responsible for the cell–cell fusion of osteoclasts (Kukita *et al.*, 2004; Yagi M *et al.*, 2005). DC-STAMP expression in osteoclast precursors was upregulated during differentiation into osteoclasts. No multinucleated osteoclasts were observed in DC-STAMP knockout mice, but many mononuclear preosteoclasts expressing osteoclast-specific markers were detected in those bone tissues. Bone-resorbing activity was considerably lower in DC-STAMP(−/−) osteoclasts than in the wild-type osteoclasts (Yagi M *et al.*, 2005). DC-STAMP(−/−) mice developed mild osteopetrosis. These results suggest that DC-STAMP is an essential molecule for osteoclast fusion, and multinucleated osteoclasts have higher bone-resorbing activity than mononuclear preosteoclasts. Thus, osteoclasts are the specifically differentiated multinucleated cells specialized for bone resorption.

Modulators of RANK Signals

Molecules That Stimulate ITAM Signals

Immunoreceptor tyrosine-based activation motif (ITAM) is an important signaling component for a number of immunoglobulin-like receptors including T-cell receptors, B-cell receptors, NK-cell receptors, and Fc receptors. Kim *et al.* (2002) succeeded in the molecular cloning of a new member of such receptors expressed by osteoclasts and named it "the osteoclast-associated receptor (OSCAR)." Subsequently, Koga *et al.* (2004) reported that molecules containing ITAM such as DNAX-activating protein 12 (DAP12) and Fc receptor common γ chain (FcRγ) play important roles in osteoclastogenesis. Deficiency in both FcRγ and DAP12 caused osteopetrotic phenotypes in mice. FcRγ and DAP12 are adaptor molecules that associate with immunoglobulin-like receptors such as OSCAR, triggering receptor expressed on myeloid cells 2 (TREM2), signal-regulatory protein β1 (SIRPβ1), and paired immunoglobulin-like receptor A (PIR-A). ITAM-mediated signals cooperate with RANK to stimulate calcium oscillation. This signal is crucial for the robust induction of nuclear factor of activated T cells, cytoplasmic 1 (NFATc1), that leads to osteoclastogenesis (Takayanagi, 2007). NFATc1 is a transcription factor essential for osteoclastogenesis, and the role of NFATc1 in osteoclastogenesis is described in detail in Chapter 9. The ligands for these receptors are not yet known, but will have to be identified in the future.

TGF-β

Bone is a major storage site for transforming growth factor β (TGF-β). Osteoclastic bone resorption releases TGF-β from bone matrix. Receptors for TGF-β superfamily members are a family of transmembrane serine/threonine kinases and are classified as type I and type II receptors according to their structural and functional characteristics. Formation of a type I–type II receptor complex is required for the ligand-induced signals. Sells Galvin *et al.* (1999) reported that TGF-β enhanced osteoclast differentiation in cultures of mouse bone marrow cells stimulated by RANKL and M-CSF. Fuller *et al.* (2000) also showed that osteoclast formation induced by RANKL was abolished completely by adding soluble TGF-β receptor type II, suggesting that TGF-β is an essential cofactor for osteoclastogenesis. These results support the previous findings (1) that transgenic mice expressing TGF-β_2 developed osteoporosis owing to enhanced osteoclast formation (Erlebacher and Derynck, 1996) and (2) that osteoclast formation was reduced in transgenic mice expressing a truncated TGF-β type II receptor in the cytoplasmic domain (Filvaroff *et al.*, 1999). Fox *et al.* (2000) and Quinn *et al.* (2001) independently reported that TGF-β directly promoted TNFα-induced osteoclast formation in bone marrow macrophage cultures, suggesting that TGF-β released from bone matrix acts as a costimulatory factor in osteoclast formation. (For more detail on the role of TNFα in osteoclast differentiation, see "RANKL-Independent Osteoclast Differentiation and Activation.") However, TGF-β has been shown to strongly inhibit osteoclast formation in the coculture of osteoblasts and bone marrow cells (Quinn *et al.*, 2001; Thirunavukkarasu *et al.*, 2001). These results suggest that TGF-β is a critical modulator for the control of physiological and pathophysiological osteoclastogenesis.

PGE_2

PGE_2 synergistically enhanced RANKL-induced osteoclastic differentiation of precursor cells through EP2 and EP4 (Wani *et al.*, 1999; Kobayashi *et al.*, 2005). RANKL-induced degradation of IκBα and phosphorylation of MAPKs in RAW264.7 cells were upregulated by PGE_2 in a cAMP/protein kinase A (PKA)-dependent manner, suggesting that PGE_2 signals crosstalk with RANK signals (Kobayashi *et al.*, 2005). TGF-β-activated kinase 1 (TAK1) possesses a PKA recognition site at amino acids 409–412. PKA directly phosphorylated TAK1 in RAW264.7 cells transfected with wild-type TAK1 but not with $Ser^{412}Ala$ mutant TAK1. $Ser^{412}Ala$ TAK1 served as a dominant-negative mutant in PKA-enhanced degradation of IκBα, phosphorylation of p38 MAPK, and PGE_2-enhanced osteoclast differentiation in RAW264.7 cells. Furthermore, forskolin enhanced TNFα-induced osteoclastic differentiation and IκBα degradation in RAW264.7 cells. Indeed, $Ser^{412}Ala$ TAK1 abolished the stimulatory effects of forskolin on osteoclast differentiation induced by TNFα. These results suggest that the phosphorylation of the Ser^{412} residue in TAK1 is essential for cAMP/PKA-induced

upregulation of osteoclast differentiation induced by RANKL and TNFα (Kobayashi *et al.*, 2005). PGE_2 produced at the inflammatory environment may directly enhance osteoclast formation.

REGULATION OF RANKL AND OPG EXPRESSION

Osteoblasts/Stromal Cells

Treatment of calvarial osteoblasts with osteotropic factors such as $1\alpha,25(OH)_2D_3$, PTH, PGE_2, or IL-11 upregulated the expression of RANKL mRNA. O'Brien *et al.* (1999) reported that the expression of dominant-negative signal transducer and activator of transcription (STAT) 3 or dominant-negative gp130 suppressed RANKL expression in a stromal/osteoblastic cell line (UAMS-32) and osteoclast formation-supporting activity stimulated by IL-6 together with soluble IL-6 receptor, oncostatin M, or IL-11 but not by PTH or $1\alpha,25(OH)_2D_3$. The gp130-dependent signals use at least two intracellular pathways: STAT 1/3 pathway and Src homology 2 domain-containing protein tyrosine phosphatase 2 (SHP2)/ras/mitogen-activated protein kinase(MAPK) pathway. To define the role of gp130 signals *in vivo*, Sims *et al.* (2004) analyzed mice in which gp130 signaling via either STAT1/3 or SHP2/ras/MAPK pathway was attenuated. They found that the STAT1/3 pathway was involved in the differentiation and function of osteoblasts and chondrocytes, whereas the SHP2/ras/MAPK pathway directly inhibited osteoclastogenesis in a cell lineage-autonomous manner. These results suggest that the gp130/STAT1/3 signaling pathway induces RANKL expression in osteoblasts.

The involvement of PGE receptor subtypes in PGE_2-induced RANKL expression in osteoblasts/stromal cells was examined using specific agonists for the EPs. Both the EP2 agonist and the EP4 agonist induced cAMP production and expression of RANKL mRNA in osteoblastic cells (Suzawa *et al.*, 2000). Sympathetic signaling via β2-adrenergic receptors (β2AR) expressed in osteoblasts has been shown to control bone formation downstream of leptin (Ducy *et al.*, 2000; Takeda *et al.*, 2002). Using β2AR-deficient mice, Elefteriou *et al.* (2005) reported that the sympathetic nervous system favors bone resorption by increasing expression in osteoblasts/stromal cells of RANKL. This sympathetic function requires cAMP/PKA signaling, followed by phosphorylation of activating transcription factor 4 (ATF4), a cell-specific cAMP response element binding protein (CREB)-related transcription factor, that enhances osteoblast differentiation and function. These results further confirm that cAMP-PKA signaling induces RANKL expression in osteoblasts/stromal cells.

Compounds that have a capacity of elevating intracellular calcium, such as ionomycin, cyclopiazonic acid, and thapsigargin, also induced osteoclast formation in mouse cocultures of bone marrow cells and primary osteoblasts (Takami *et al.*, 1997). Similarly, high calcium concentrations of the culture medium induced osteoclast formation in the cocultures. Treatment of primary osteoblasts with these compounds or high medium calcium stimulated the expression of RANKL mRNA (Takami *et al.*, 2000). Phorbol 12-myristate 13-acetate (PMA), an activator of protein kinase C (PKC), also stimulated the expression of RANKL mRNA in primary osteoblasts. PKC inhibitors, such as calphostin and staurosporin, suppressed ionomycin- and PMA-induced expression of RANKL mRNA in primary osteoblasts. Thus, calcium/PKC signals induce RANKL expression in osteoblasts/stromal cells. The calcium/PKC signal is proposed to be the fourth signal pathway involved in the induction of RANKL mRNA expression, which in turn stimulates osteoclast formation. It was also shown that lipopolysaccharide (LPS) and IL-1 stimulate RANKL expression in osteoblasts through calcium/PKC signals (Kikuchi *et al.*, 2001; Suda *et al.*, 2004).

These results suggest that at least four signals are independently involved in RANKL expression by osteoblasts/stromal cells: VDR-mediated signals, cAMP/PKA-mediated signals, gp130/STAT3-mediated signals, and calcium/PKC-mediated signals (Fig. 4). Treatment of primary osteoblasts with $1\alpha,25(OH)_2D_3$, PTH, PGE_2, and IL-11 suppressed OPG mRNA expression, suggesting that the balance between RANKL and OPG expression regulates osteoclast formation.

T Lymphocytes

RANKL expression in T cells is induced by antigen receptor engagement. Kong *et al.* (1999a) reported that activated T cells directly triggered osteoclastogenesis through RANKL expression. RANKL was detected on the surface of activated T cells. Activated T cells also secreted soluble RANKL into culture medium (Gillespie, 2007). Systemic activation of T cells *in vivo* also induced a RANKL-mediated increase in osteoclastogenesis and severe bone loss. In a T-cell-dependent model of rat adjuvant arthritis characterized by severe joint inflammation, treatment with OPG at the onset of the disease prevented bone and cartilage destruction but not inflammation. These results suggest that both systemic and local T-cell activation can lead to RANKL production and subsequent bone loss. Horwood *et al.* (1999) also reported that human peripheral blood-derived T cells, prepared with anti-CD3 antibody-coated magnetic beads, supported osteoclast differentiation from mouse spleen cells in the presence of concanavalin A together with IL-1 or TGF-β in the coculture. The expression of RANKL mRNA was stimulated in peripheral blood-derived T cells treated with the same factors. In synovial tissue sections with lymphoid infiltrates from patients with rheumatoid

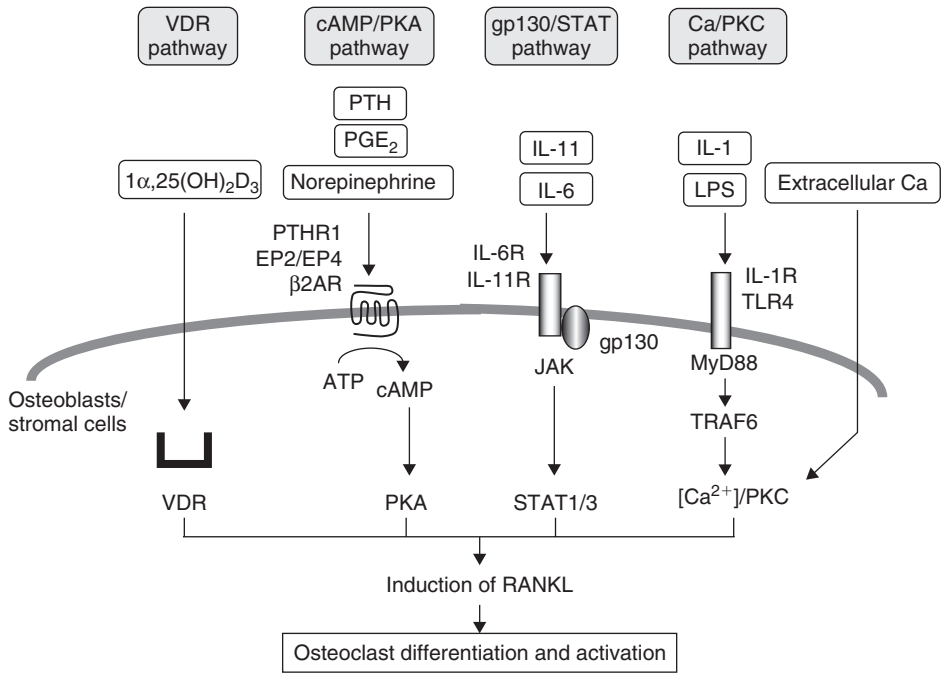

FIGURE 4 Signaling pathways for the induction of RANKL in osteoblasts/stromal cells. Three independent signals have been proposed to induce RANKL expression in osteoblasts/stromal cells: VDR-mediated signals by $1\alpha,25(OH)_2D_3$, cAMP/PKA-mediated signals by PTH, PGE-2 and β2AR agonists such as norepinephrine, gp130-mediated signals by IL-11 and IL-6. The calcium/PKC signal in osteoblasts/stromal cells, which is induced by ionomycin or high calcium concentrations of the culture medium, is now proposed to be the fourth signaling pathway involved in the induction of RANKL mRNA expression. LPS and IL-1 stimulate RANKL expression in osteoblasts through the calcium/PKC signal. RANKL expression induced by these four signals in osteoblasts/stromal cells in turn stimulates osteoclast differentiation and function.

arthritis, the expression of RANKL was demonstrated in CD3-positive T cells. The ability of activated T cells to support osteoclast formation may provide a mechanism for the potentiation of osteoclast formation and bone destruction in diseases such as rheumatoid arthritis and periodontitis. Using specific inhibitors, Kong *et al.* (1999a) showed that the induction of RANKL by T cells depends on PKC, phosphoinositide-3 kinase, and calcineurin-mediated signaling pathways. These results suggest that calcium/PKC signals are involved in RANKL expression by activated T cells.

The inflammation recruits hematopoietic and immune cells such as activated T cells at the site. Teng *et al.* (2000) transplanted human peripheral blood lymphocytes from periodontitis patients into NOD/SCID mice. Human CD4(+) T cells, but not CD8(+) T cells or B cells, were identified as essential mediators of alveolar bone destruction in the transplanted mice. Stimulation of CD4(+) T cells by *Actinobacillus actinomycetemcomitans*, a well-known gram-negative anaerobic microorganism that causes human periodontitis, induced production of RANKL. *In vivo* inhibition of RANKL function with OPG diminished alveolar bone destruction and reduced the number of periodontal osteoclasts after microbial challenge. In addition to the ability of T cells to directly support osteoclastogenesis, T cells also secrete inflammatory cytokines such as IL-1, IL-6, and IL-17, each of which can stimulate RANKL expression by osteoblasts/stromal cells. Recent studies have revealed that the IL-17-producing helper T-cell subset (Th17) is responsible for bone destruction in autoimmune arthritis (Sato *et al.*, 2006). Th17 cells are responsive to IL-23, which regulates their expansion and survival. The importance of IL-17 and IL-23 in rheumatoid arthritis and other inflammatory diseases was highlighted in studies using IL-17- and IL-23-deficient mice (Nakae *et al.*, 2003; Murphy *et al.*, 2003). Both IL-17-deficient mice and IL-23-deficient mice showed marked resistance to autoimmune responses. These results suggest that Th17 cells function as important immunomodulators of osteoclastic bone resorption in autoimmune arthritis.

Wnt Signals

Wnt proteins (Wnts) are palmitoylated and glycosylated ligands that play a central role in early development of organs and tissues. The discovery that loss-of-function mutations in low-density lipoprotein receptor-related protein 5 (LRP5), a Wnt coreceptor, brought about a low bone mass in humans and revealed the possible role of Wnt signaling in the regulation of bone remodeling (Gong *et al.*, 2001). There are two pathways of Wnt signaling: β-catenin-dependent canonical and -independent noncanonical pathways. Wnts act on osteoblast precursor cells

and promote their differentiation into mature osteoblasts through the β-catenin-dependent canonical pathway (Kato *et al.*, 2002). In addition, Wnts suppress bone resorption by regulating RANKL/OPG ratio through the same pathway in mature osteoblasts. Wnt3a strongly inhibits $1\alpha,25(OH)_2D_3$-induced osteoclast formation in cocultures of stromal ST2 cells and bone marrow cells (Yamane *et al.*, 2001). However, Wnt3a fails to inhibit RANKL-induced osteoclast formation in bone marrow macrophage cultures. These results suggest that the inhibitory effect of Wnt3a on osteoclast formation is mediated by osteoblasts/stromal cells. Glass *et al.* (2005) developed mice expressing a stabilized form of β-catenin in osteoblasts (β-catenin mutant mice), and reported that the β-catenin mutant mice developed osteopetrosis with the defect of tooth eruption and the decreased number of osteoclasts. Microarray analysis to compare gene expression in LRP5(−/−) mice and β-catenin mutant mice showed that OPG mRNA is upregulated in osteoblasts in those mice. When β-catenin was inactivated selectively in mature osteoblasts using α1(I) collagen Cre mice, the bone mass was decreased owing to the enhancement of bone resorption (Glass *et al.*, 2005). Activation of the canonical Wnt pathway was shown to stimulate OPG expression in osteoblasts. In addition, the canonical Wnt pathway suppresses the expression of RANKL in MC3T3E1 cells and MG-63 cells (Spencer *et al.*, 2006). These results suggest that the activation of the canonical Wnt pathway in osteoblasts suppresses bone resorption through upregulation of OPG expression and downregulation of RANKL expression.

Regulation of Shedding of RANKL

OPG(−/−) mice exhibit severe osteoporosis because of enhanced osteoclast differentiation and function. The serum concentration of RANKL was elevated in OPG(−/−) mice (Yamamoto *et al.*, 2006). A homozygous deletion of the OPG gene was found in patients with juvenile Paget's disease, and the serum level of RANKL was markedly elevated in one such a patient as well (Whyte *et al.*, 2002). Osteoblasts obtained from OPG(−/−) mice released a large amount of RANKL. When OPG was added to the culture of OPG(−/−) osteoblasts, the release of RANKL into the culture medium was strikingly inhibited. Activated T cells from WT mice also released a large amount of RANKL. Similarly, the release of RANKL from activated T cells was inhibited by adding OPG. These results suggest that activated T cells release RANKL because of the lack of OPG production, and that the binding of OPG to membrane-associated RANKL expressed by either osteoblasts or activated T cells suppresses the shedding of RANKL. OPG(−/+) and T-cell-double-deficient mice were created by cross-breeding of OPG(−/−) mice and athymic nude (Fox n1nu/nu) mice (Nakamichi *et al.*, 2007). Serum levels of RANKL in OPG(−/−) and T cell-double-deficient mice were as high as those in OPG(−/−) mice. These results suggest that the high levels of serum RANKL detected in OPG(−/−) mice are not derived from T cells but from bone tissues. Hikita *et al.* (2006) also reported that matrix metalloproteinase (MMP) 14 and a disintegrin and metalloproteinase (ADAM) 10 have strong RANKL-shedding activity. Suppression of MMP14 in primary osteoblasts increased membrane-bound RANKL and promoted osteoclastogenesis in cocultures with macrophages. These results suggest that some proteases such as MMP 14 and ADAM 10 are involved in the RANKL shedding and the binding of OPG to the membrane-associated RANKL protects RANKL against attack by those proteases.

MUTATIONS OF RANK, OPG, AND RANKL FOUND IN HUMANS

RANK Mutation

Discovery of the RANKL/OPG/RANK signaling pathway has led the identification of some bone diseases in humans (Fig. 5). In 2000, Hughes *et al.* reported for the first time that the gene responsible for familial expansile osteolysis and familial Paget's disease of bone was mapped to the gene encoding RANK (TNFRSF11A). So far, four different insertion mutations in the gene encoding RANK (TNFRSF11A) have been described. Familial expansile osteolysis is a rare autosomal dominant disorder of bone characterized by focal areas of increased bone remodeling. The osteolytic lesions, which usually develop in the long bones during early adulthood, show increased activities for both osteoblasts and osteoclasts. Two mutations of the heterozygous insertion were detected in the first exon of the RANK gene in affected members of four families. One mutation was a duplication of 18 bp (84dup18) and the other a duplication of 27 bp (75dup27), both of which affected the signal peptide (SP) region of the RANK molecule (Hughes *et al.*, 2000; Palenzuela *et al.*, 2002). Nakatsuka *et al.* (2003) reported the clinical and radiographic features of individuals with the 75dup27 mutation. Whyte and Hughes (2002) found a 15-bp duplication in the RANK gene (84dup15) in a mother and a daughter affected by expansile skeletal hyperphosphatasia. Johnson-Pais *et al.* (2003) also identified an 18-bp tandem duplication (83dup18) in the RANK gene in two patients with familial expansile osteolysis.

Expression of recombinant forms of the mutant RANK proteins revealed perturbations in the expression levels and lack of normal cleavage of the signal peptide (Hughes *et al.*, 2000). Both mutations caused an increase in RANK-mediated NF-κB signaling *in vitro*, consistent with the presence of an activating mutation. Thus, activating mutations in RANK cause familial expansile osteolysis and

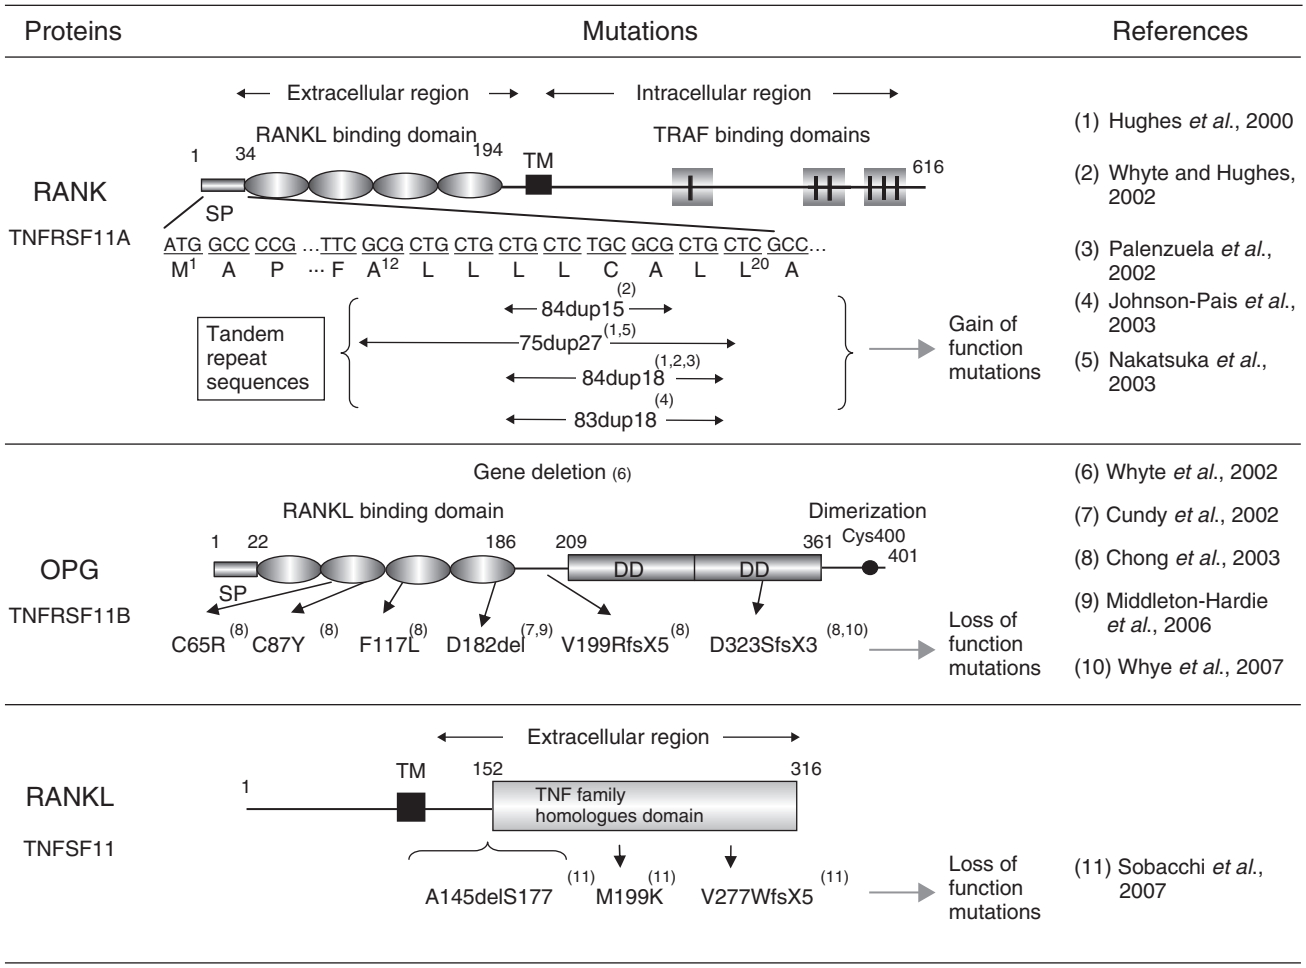

FIGURE 5 Mutations of RANK, OPG, and RANKL found in humans. Three different insertion mutations have been identified in the signal peptide (SP) region of the RANK (TNFRSF11A) gene. These three mutations lead to the gain-of-function mutations. The total deletion and six different mutations have been identified in the OPG (TNFRSF11B) gene. The six mutations found in the OPG gene result in the loss-of-function mutations. In the RANKL (TNFSF11) gene, three mutations have been identified in the extracellular region. These three mutations lead to the loss of function of RANKL. Figures in the shoulder parentheses indicate references. The expression, like that of "fsX5," means the frame shift and appearance of a new stop codon after four new amino acids.

expansile skeletal hyperphosphatasia, both of which show hyperphosphatasia with increased bone remodeling.

OPG Mutation

Juvenile Paget's disease, an autosomal recessive osteopathy, is characterized by rapidly remodeling woven bone, osteopenia, fractures, and progressive skeletal deformity. Whyte *et al.* (2002) found defects in the gene encoding OPG defects in the two Navajo patients with juvenile Paget's disease. Both patients had a homozygous deletion of the OPG gene. Serum levels of OPG were undetectable, but those of soluble RANKL were markedly increased. Cundy *et al.* (2002) subsequently reported that mutations of the OPG gene cause idiopathic hyperphosphatasia (also known as Juvenile Paget's disease) (see Fig. 5). Three affected siblings showed the same homozygous mutation of a 3-bp inframe deletion in exon 3 of the OPG gene, resulting in the loss of an aspartate residue (D182del). Recombinant mutant OPG failed to inhibit bone resorption *in vitro*. Middleton-Hardie *et al.* (2006) also studied the characteristics of OPG (D182del) in more detail. OPG (D182del) inhibited osteoclast formation less effectively than wild-type OPG and had a reduced ability to bind to RANKL. In addition, the mutant OPG was retained within the cells, probably because of the change in the folding structure. These results suggest that deletion of aspartate 182 in OPG is the loss-of-function mutation.

Chong *et al.* (2003) evaluated the relationships between phenotypes and genotypes of the OPG gene in patients of nine families with idiopathic hyperphosphatasia. They found homozygous mutations in the OPG gene in affected members from six of nine families with idiopathic hyperphosphatasia. Four of the six mutations occurred in the cysteine-rich ligand-binding domain (C65R, C87Y, F117L, and D182del). One mutation was found to be a deletion

mutation/insertion at the junction of exon 3 and intron 3. This mutation is predicted to produce a truncated protein consisting of amino acids 1–198 of the wild type with six additional nonnatural amino acids at the C terminus (V199RfsX5). The other mutation is the insertion/deletion mutation at the C-terminal end of the protein (D323SfsX3). The severity of the phenotype was related to the predicted effects of the mutations on OPG function. Three mutations occurred in and near the cysteine-rich ligand-binding domain (C65R, C87Y, and V199RfsX5) and were predicted to disrupt the binding of OPG to RANKL. These mutations result in severe phenotypes. Noncysteine missense mutations in the ligand-binding domain (F117L and D182del) were associated with an intermediate phenotype. A mutation at the C-terminal end of the protein (D323SfsX3) was associated with the mildest phenotype (Chong *et al.*, 2003; Whyte *et al.*, 2007). Thus, mutations in the OPG gene account for the majority of, but not all, cases of idiopathic hyperphosphatasia, and there are distinct genotype–phenotype relationships.

The effects of recombinant OPG were investigated in two adult siblings with juvenile Paget's disease (D182del) (Cundy *et al.*, 2005). Bone resorption (assessed by N-telopeptide excretion) was markedly suppressed by once-a-week subcutaneous doses of 0.3 to 0.4 mg per kg body weight. Plasma alkaline phosphatase activity and osteocalcin levels were similarly suppressed into a normal range. After 15 months of treatment, radial bone mass was increased in one patient by 9% and in the other, by 30%. Apart from mild hypocalcemia and hypophosphatemia, no apparent adverse events occurred. These results provide corroborative evidence that juvenile Paget's disease is indeed the result of OPG deficiency and confirms the critical role of OPG in regulating bone turnover in humans.

RANKL Mutation

Autosomal recessive osteopetrosis is usually associated with normal or elevated numbers of nonfunctional osteoclasts. Sobacchi *et al.* (2007) reported mutations in the gene encoding RANKL in six individuals with autosomal recessive osteopetrosis whose bone biopsy specimens lacked osteoclasts (see Fig. 5). These individuals did not show any obvious defects in immunological parameters. The mutation of the RANKL gene was found in four families of the six families examined. Family 1 showed the deletion of amino acids 145–177 in RANKL. Families 2 and 4 had the substitution of Met to Lys at 199 of RANKL (M199K). Family 3 had the deletion of the 828–829 nucleotides, which results in the appearance of a stop codon at 281 (V277WsfX5). Osteoclast progenitors appear to be normal, because RANKL induced formation of functional osteoclasts from monocytes of the patients. Hematopoietic stem cells were transplanted into three patients. All three patients showed good levels of hematological engraftment, but no improvement in bone remodeling was observed in those patients after hematopoietic stem cell transplantation. This suggests that the defect is not intrinsic to osteoclasts. Hematopoietic stem cell transplantation apparently did not provide sufficient donor stromal precursors or mesenchymal stem cells to correct the bone defect. It is also suggested that RANKL expressed by hematopoietic cells including T cells cannot functionally cure osteopetrosis in normal bone metabolism. Taken together, these results demonstrate that mutations in the gene encoding RANKL lead to an osteoclast-poor form of osteopetrosis. These findings confirm the notion that RANKL expressed by osteoblasts/stromal cells also plays an essential role in osteoclast differentiation and function in humans.

RANKL-INDEPENDENT OSTEOCLAST DIFFERENTIATION AND ACTIVATION

Accumulating evidence has shown that RANKL is important not only for physiological bone development, but also for pathological bone destruction in postmenopausal osteoporosis, rheumatoid arthritis, periodontal diseases, and tumor-induced osteolysis. In addition, recent studies have shown that RANKL is not the sole factor responsible for osteoclast differentiation and function. TNFα stimulates osteoclast differentiation and IL-1 stimulates osteoclast function in the absence of the RANKL–RANK interaction.

RANKL-Independent Regulation of Osteoclast Differentiation

The cytoplasmic tail of RANK interacts with TNF receptor-associated factor 1 (TRAF1), TRAF2, TRAF3, TRAF5, and TRAF6 (Darnay *et al.*, 1998; Galibert *et al.*, 1998; Schneeweis *et al.*, 2005). TRAF6-mediated signals appear to be important for osteoclast differentiation and function, because TRAF6(−/−) mice develop severe osteopetrosis (Lomaga *et al.*, 1999; Naito *et al.*, 1999). Azuma *et al.* (2000) and Kobayashi *et al.* (2000) independently found that TNFα stimulates osteoclast differentiation in the absence of the RANKL–RANK interaction. Osteoclast formation induced by TNFα was inhibited by the addition of antibodies against TNF receptor type I (TNFRI, p55) and TNF receptor type II (TNFRII, p75), respectively, but not by OPG. Osteoclasts induced by TNFα formed resorption pits on dentine slices only in the presence of IL-1. Kim *et al.* (2005) reported that hematopoietic precursors from RANKL(−/−), RANK(−/−), or TRAF6(−/−) mice differentiated into osteoclasts *in vitro* when they were stimulated with TNFα in the presence of cofactors such as TGF-β. These results suggest that RANK/TRAF6-mediated signals are not essentially required for osteoclast differentiation induced by TNFα.

TNFRI and TNFRII use TRAF2 as a common signal transducer in the target cells, suggesting that TRAF2-mediated signals play a role in osteoclast differentiation.

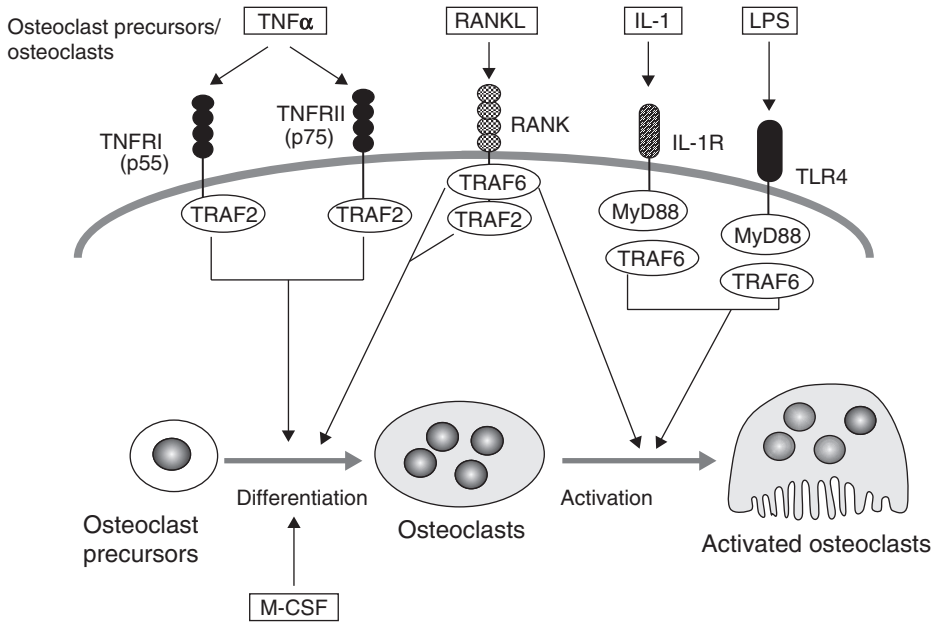

FIGURE 6 A schematic representation of RANKL-dependent and -independent regulation of osteoclast differentiation and function. The binding of RANKL to RANK induces association of RANK and TRAF family members including TRAF2 and TRAF6. TNFα and RANKL stimulate osteoclast differentiation independently. Osteoclast differentiation induced by TNFα occurs via TNFRI (p55) and TNFRII (p75) expressed by osteoclast precursors. RANKL induces osteoclast differentiation through RANK-mediated signals. M-CSF is a common factor required for both TNFα- and RANKL-induced osteoclast differentiation. TNFRI and TNFRII use TRAF2 as a common signal transducer in the target cells, suggesting that TRAF2-mediated signals play important roles in osteoclast differentiation. Activation of osteoclasts is induced by RANKL, IL-1, and LPS through RANK, IL-1 receptor (IL-1R), and TLR4, respectively. Both TLR4 and IL-1R use common signaling molecules such as MyD88 and TRAF6. Osteoclast function appears to require preferentially TRAF6-mediated signals.

Kanazawa and Kudo (2005) examined the involvement of TRAF2 in osteoclast differentiation by using TRAF2-deficient mice. RANKL-induced osteoclastogenesis gave a reduction of 20% in the progenitors from TRAF2-deficient mice compared with that of the cells from littermate wild-type mice, whereas TNFα-induced osteoclastogenesis was severely impaired in the cells from the TRAF2-deficient mice. TRAF2 overexpression induced differentiation of osteoclast progenitors from wild-type mice into osteoclasts. It has been reported that when osteotropic factors such as $1\alpha,25(OH)_2D_3$, PTH, and IL-1 were administered into RANK(−/−) mice, neither TRAP-positive cell formation nor hypercalcemia was induced (Li *et al.*, 2000a). In contrast, administration of TNFα into RANK(−/−) mice induced TRAP-positive cells near the site of injection even though the number of TRAP-positive cells induced by TNFα was not large. These results suggest that TRAF2 plays an important role in TNFα-induced osteoclastogenesis (Fig. 6).

Lam *et al.* (2000) reported that differentiation of macrophages into osteoclasts was dramatically enhanced by TNFα, when macrophages were pretreated with a small amount of RANKL, suggesting that osteoblasts/stromal cells are somehow involved in osteoclastogenesis in TNFα-induced osteoclastogenesis. To evaluate the role of osteoblasts/stromal cells in TNFα-driven osteoclast formation *in vivo*, Kitaura *et al.* (2005) generated chimeric mice in which wild-type (WT) bone marrow-derived osteoclast precursors are transplanted into lethally irradiated mice deleted of both TNFRI and TNFRII [TNFRI/II(−/−)], and in which bone marrow cells derived from TNFRI/II(−/−) mice are transplanted into lethally irradiated WT mice. WT to WT and TNFRI/II(−/−) to TNFRI/II(−/−) irradiated and transplanted mice were used as positive and negative controls, respectively. Those chimeras were administered daily with TNFα and sacrificed on day 5. As expected, TNFRI/II(−/−) to TNFRI/II(−/−) mice failed to respond to TNFα, whereas WT to WT mice generated osteoclasts in a dose-dependent manner. Although the increase in the number of osteoclasts induced by TNFα was observed in both chimeric mice, the responsiveness to TNFα was higher in TNFRI/II(−/−) to WT mice than WT to TNFRI/II(−/−) mice. These results indicate that TNF receptors expressed by osteoblasts/stromal cells contribute more than those by osteoclast progenitors to TNF-induced osteoclastogenesis *in vivo*. Nevertheless, these results also suggest that TNFα directly induces differentiation of osteoclast precursors into osteoclasts. TNFα appears to be a more convenient target in arresting inflammatory osteolysis.

RANKL-Independent Regulation of Osteoclast Function

IL-1 stimulates osteoclast function through IL-1 receptor type I (Jimi *et al.*, 1999b). As described earlier, purified osteoclasts placed on dentine slices failed to form resorption

pits. When IL-1 or RANKL was added to the purified osteoclast cultures, resorption pits were formed on dentine slices within 24 hours (Jimi *et al.*, 1999b). Osteoclasts express IL-1 type 1 receptors, and IL-1 activated NF-κB rapidly in purified osteoclasts. The pit-forming activity of osteoclasts induced by IL-1 was inhibited completely by adding IL-1 receptor antagonist (IL-1ra) but not by OPG (Jimi *et al.*, 1999a). Fuller *et al.* (2006) carefully examined the role of humoral agents, including RANKL, TGF-β, IL-1α, and TNFα in murine osteoclast formation *in vitro*. They reported that IL-1α and TNFα substituted for RANKL for stimulation of bone-resorbing activity of osteoclasts, but the potency of TNFα to induce osteoclast function was much weaker than that of IL-1. These results suggest that IL-1 directly stimulates osteoclast function through IL-1 type 1 receptors in mature osteoclasts.

LPS, a major constituent of gram-negative bacteria, has been proposed to be a potent stimulator of bone resorption in inflammatory bone diseases including periodontal diseases. Toll-like receptor (TLR) family members are recognition receptors for a diverse group of microbial ligands, including components of bacteria, fungi, and viruses. TLR4 is a critical receptor for LPS. The cytoplasmic signaling cascade of TLR4 is quite similar to that of the IL-1 receptor, because both receptors possess cytoplasmic Toll/IL-1 receptor (TIR) domains. Both TLR4 and IL-1 receptors use common signaling molecules such as myeloid differentiation factor 88 (MyD88) and TRAF6 (Akira and Takeda., 2004). LPS and IL-1 enhanced the survival of osteoclasts and pit-forming activity of osteoclasts even in the presence of OPG (Kikuchi *et al.*, 2001; Suda *et al.*, 2004). The stimulatory effects of LPS and IL-1 on the pit-forming activity were not observed when MyD88-deficient osteoclasts were cultured on dentine slices (Sato *et al.*, 2004). In contrast, RANKL stimulated pit-forming activity of MyD88-deficient osteoclasts. These results suggest that LPS and IL-1 commonly use MyD88 and TRAF6 to induce osteoclast function, whereas RANKL uses TRAF6 to induce osteoclast function (see Fig. 6). TNFα failed to induce pit-forming activity of osteoclasts. These results suggest that TRAF6 signals are preferentially used for activation of osteoclasts. Thus, IL-1 and some bacterial components directly stimulate osteoclast function independent of the RANK-mediated pathway (see Fig. 6).

CONCLUSION

The discovery of the RANKL–RANK interaction now opens a wide new area in bone biology focused on the investigation of the molecular mechanism of osteoclast development and function. Osteoblasts/stromal cells, through the expression of RANKL and M-CSF, are involved throughout the osteoclast lifetime of their differentiation, survival, fusion, and activation. OPG produced by osteoblasts/stromal cells is an important negative regulator of osteoclast differentiation and function. Both RANKL(−/−) mice and RANK(−/−) mice show similar features of osteopetrosis with a complete absence of osteoclasts in bone. Gain-of-function mutations of RANK have been found in patients suffering from familial expansile osteolysis and familial Paget's disease of bone. Loss-of-function mutation of OPG also results in juvenile Paget's disease in bone. Loss-of-function mutations in the gene encoding RANKL were found in patients with autosomal recessive osteopetrosis whose bone biopsy specimens lacked osteoclasts. These findings confirm that the RANKL–RANK interaction is indispensable for osteoclastogenesis, not only in mice, but also in humans. Studies have also shown that inflammatory cytokines, TNFα and IL-1, can substitute for RANKL in inducing osteoclast differentiation and function. These results suggest that in addition to RANKL, inflammatory cytokines play important roles in osteoclastic bone resorption under pathological conditions.

Chapter 10

Osteoclast Function: Biology and Mechanisms

INTRODUCTION

There is a unanimous consensus among biologists that the main function of osteoclasts is to resorb mineralized bone, dentine, and calcified cartilage. Actually, according to our current knowledge, this seems to be the only function for those large and multinucleated cells that reveal several unique features. However, their close relationship with immune cells as well as mesenchymal stem cells in a bone marrow environment may indicate also new, previously unrecognized functions (Kollet *et al.*, 2006). Resorption of mineralized tissues is obligatory for normal skeletal maturation, including bone growth and remodeling, as well as tooth eruption.

In evolution the appearance of osteoclasts opened a totally new strategy for skeletal development. However, it is very difficult to know exactly why natural selection during evolution has favored the development of osteoclasts in the first place. Was it because of the obvious advantages they offered for the flexible use of the skeleton? Perhaps the development of osteo- (chondro)clast-like cells was favored by natural selection because of the advantages of the effective regulation of calcium homeostasis. The third possibility could be the need and pressure for the development of a safe environment for the hematopoietic tissue. No firm conclusions can be drawn from the current evidence and knowledge. Given the importance of calcium homeostasis and hematopoiesis, one might speculate that resorptive cells were originally developed not at all for skeletal purposes, but to support those vital functions.

It is not known either for sure whether functional osteoclasts were originally developed for the resorption of bone or calcified cartilage. It also remains to be clarified at what stage of the evolution resorbing osteoclasts appeared. Most probably this took place more than 300 million years ago.

BONE RESORPTION IS THE ONLY RELIABLE CHARACTERIZATION FOR OSTEOCLASTS

During skeletal growth, osteoclasts are needed for the resorption of calcified cartilage and modeling of growing bone. In adult bone, resorptive cells are responsible for remodeling. If necessary, they fulfill the requirements of calcium homeostasis via excessive resorption beyond normal remodeling. In addition to osteoclasts, tumor cells, monocytes, and macrophages have been suggested to have bone-resorbing capacity. However, later studies have not been able to confirm that tumor cells can resorb bone directly. Instead they can induce recruitment, as well as activity of osteoclasts, by secreting a large number of osteoclast regulating factors (Ralston, 1990). Bone resorption by macrophages has been demonstrated only in vitro and is probably due to the phagocytosis of bone particles rather than the more specialized mechanisms used by the osteoclasts. It is also possible that mineralized bone per se can induce monocytes and tissue macrophages to differentiate into osteoclasts under culture conditions. A recent study by Kim *et al.* (2006b) indicated that in addition to receptor activator of NFκB ligand (RANKL), monocyte chemotactic peptide-1 together with macrophage colony-stimulating factor (M-CSF) was also able to induce multinuclear tartrate-resistant acid phosphatase (TRACP)-positive cells from circulating monocytes. Although these cells were positive for calcitonin receptor and revealed several other osteoclastic markers they were not able to resorb bone.

At present it is thus generally accepted that the osteoclast is the only cell that is able to resorb mineralized

Principles of Bone Biology, 3rd Edition

bone. Both mononuclear and multinuclear osteoclasts can resorb bone, but larger cells seem to be more effective than smaller ones, although there is no direct relationship between the resorption capacity and the number of nuclei (Piper *et al.*, 1992). Large osteoclasts predominate at sites of aggressive, pathological bone resorption and they may even be more sensitive to extracellular stimulating factors (Trebec *et al.*, 2007). The number of nuclei in osteoclasts also varies among species, being higher in birds than in mammals.

Osteoclasts in different types of bone have been thought to be similar. Some differences have been observed especially in their content of proteolytic enzymes between different bone locations. Lee *et al.* (1995) described mononuclear cells with ruffled borders on uncalcified septa of the growth plate cartilage and proposed that these septoclasts probably resorb transversal septa of the growth plate just before chondroclasts start resorption of longitudinal calcified septa. According to present knowledge, chondroclasts that resorb calcified cartilage are similar to osteoclasts, but there are perhaps also other types of resorbing cells present in specific areas of the growing skeleton.

LIFE SPAN OF THE OSTEOCLAST AND THE RESORPTION CYCLE

In the adult, stem cells for osteoclasts originate from the hematopoietic tissue (for review, see Chapter 7). They share a common differentiation pathway with macrophages and dendritic cells until the final differentiation steps. Differentiation is characterized by the sequential expression of different sets of genes. Several cytokines and growth factors are known to affect the differentiation pathway of the osteoclasts, and studies have confirmed the central role of the receptor activator of NFκB (RANK)-RANKL-osteoprotegerin (OPG) pathway in this process.

After proliferating in bone marrow, mononuclear preosteoclasts are guided to bone surfaces by mechanisms, which are so far unknown. It is not known in detail where and when fusion of mononuclear precursors to multinuclear osteoclasts actually takes place and what are the molecular mechanisms regulating fusion. There are certainly several types of molecular interactions between the membranes of two cells undergoing fusion. Some of these have recently been revealed. Yagi *et al.* (2005) demonstrated a critical role of dendritic cell–specific transmembrane protein (DC-STAMP) in the fusion process. They showed that osteoclast cell fusion was abrogated in DC-STAMP –/– mice and could be restored by retroviral induction of the gene. These results are in accordance with a conclusion that DC-STAMP is one of the key molecules in the osteoclast fusion, although it might not be the actual fusion protein. Earlier in vitro studies have suggested that proteolipid part of V-ATPase may have a role in membrane fusion (Peters *et al.*, 2001). It is thus of special interest that impaired fusion ability of preosteoclasts was observed in mice that were deficient in V-ATPase V0 subunit d2 (Lee *et al.*, 2006). Because there are only very limited numbers of multinucleated cells in the adult body, the cell fusion process may offer interesting new molecular targets to regulate bone resorption. However, cell type specificity of the fusion process may still appear to be a difficult challenge.

The fusion of mononuclear precursors into multinucleated osteoclasts in the bone marrow takes place mainly in the vicinity of bone surfaces, because multinuclear osteoclasts are seldom observed far away from the bone surface. Somehow, precursors are guided near to those sites that are determined to be resorbed. How this happens, how these sites are determined, and which cells actually make the decision where and when, for instance, a new remodeling unit is initiated are not known. Strongest candidates for this role are osteocytes and bone lining cells.

Both negative and positive regulation between osteocytes and osteoclasts could exist. In vitro osteoclasts resorb devitalized bone with a much higher efficiency than bone where osteocytes are alive (Gu *et al.*, 2005b). In addition, it has been shown that healthy osteocytes secrete a partially estrogen dependent biological activity that inhibits osteoclasts differentiation. At least part of this biological activity is transforming growth factor (TGF) β3 (Heino *et al.*, 2002). Thus, it is possible that healthy osteocytes secrete a factor or factors that prevent osteoclast differentiation and activation, whereas dying osteocytes promote osteoclast activity. There is indirect evidence, indeed, that such mechanisms are operating in vivo. Kurata *et al.* (2006) showed, using a 3-D coculture model, that local damage of osteocytes induces differentiation of bone marrow precursors that are near to the damaged area. In bone, osteocytes form an internal network that could sense the whole bone as a single unit (Aarden *et al.*, 1994) and are the most obvious cells to act as gatekeepers for the local remodeling processes. Learning the molecular details of this complicated biological cross-talk between osteocytes and osteoclasts remains a major challenge for bone biologists. It may well be a key to understand regulation of the bone remodeling.

It is also possible that bone matrix may undergo time- or stress-related changes that can regulate osteoclast activity. However, at present somewhat controversial data exist about these changes. During ageing, matrix molecules, especially collagen, undergo nonenzymatic glycation, which leads to the accumulation of advanced glycation end (AGE) products into the bone matrix. A receptor for AGE products, RAGE, a member of the immunoglobulin superfamily, has several ligands and has been suggested to have a role in several diseases. Osteoclasts can detect AGE products because they express RAGE (Zhou *et al.*, 2006). RAGE –/– mice have increased bone mass and decreased resorption capacity of their osteoclasts, suggesting that AGE products can, via RAGE, activate signaling pathways

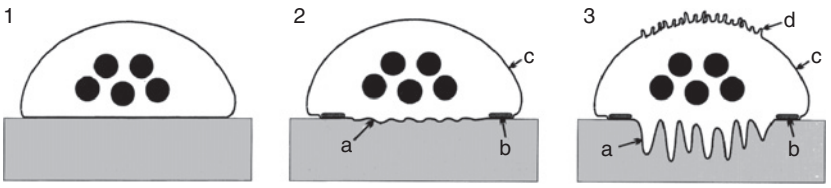

FIGURE 1 The nonresorbing osteoclast is polarized (1), but immediately after attachment for resorption it shows three different membrane domains (2): ruffled border (a), sealing zone (b), and basal membrane (c). Once matrix degradation has started (3), the fourth membrane domain, a functional secretory domain (FSD), appears in the basal membrane (d).

leading to osteoclast activation. This is in agreement with a study of Henriksen *et al.* (2007) showing that osteoclasts prefer aged bone. In contrast, Valcourt *et al.* (2007) have shown that AGE modifications inhibited osteoclasts, both their differentiation and activity. In conclusion, there is evidence, although indirect at this time, that osteocytes and bone matrix may both have a role in targeting osteoclasts to a correct resorption site.

Although it is not known exactly how resorption sites are determined, it is known that the first sign of a forthcoming resorption place on the endosteal surface is the retraction of bone-lining cells (Jones and Boyde, 1976). This retraction uncovers osteoid and after its removal by osteoblasts the osteoclasts can attach to the mineralized surface. The sequence of cellular events needed for bone resorption is called the resorption cycle (see Figs. 1 and 4). One resorption cycle of any individual osteoclast thus involves complicated multistep processes, which include osteoclast attachment, formation of the sealing zone, plasma membrane polarization, and resorption itself with final detachment and cell death (Lakkakorpi and Väänänen, 1995; Väänänen *et al.*, 2000). On the basis of in vitro studies, one osteoclast can undergo several consecutive resorption cycles before entering the apoptosis pathway (Kanehisa and Heerche, 1988). Following is a short description of each particular phase of the resorption cycle.

FORMATION OF THE SEALING ZONE AND CYTOSKELETAL CHANGES DURING THE RESORPTION CYCLE

The initial attachment of osteoclasts to bone matrix is mediated by integrins of heterodimeric adhesion receptors. So far five integrins have been identified in osteoclasts. $\alpha_v\beta_3$ (a classical vitronectin receptor), $\alpha_v\beta_5$, $\alpha_2\beta_1$ (collagen receptor), and $\alpha v\beta_1$, which binds to a variety of extracellular matrix proteins, including vitronectin, collagen, osteopontin, and bone sialoprotein (Nesbitt *et al.*, 1993). The latest one is $\alpha_9\beta_1$, which binds to ADAM8, a disintegrin and metalloproteinase (Rao *et al.*, 2006). The interactions between these integrins and bone matrix are functional important for osteoclast activation. Antibodies against the vitronectin receptor, Arg-Gly-Asp (RGD) mimetics, and RGD peptides, which block the attachment of the vitronectin receptor to RGD-containing bone matrix proteins, inhibit bone resorption in vitro (Sato *et al.*, 1990; Horton *et al.*, 1991; Lakkakorpi *et al.*, 1991) and in vivo (Fisher et al., 1993; Engelman et al., 1997). β_3- and α_9-integrin null mice have dysfunctional osteoclasts and impaired bone resorption (McHugh *et al.*, 2000; Rao *et al.*, 2006).

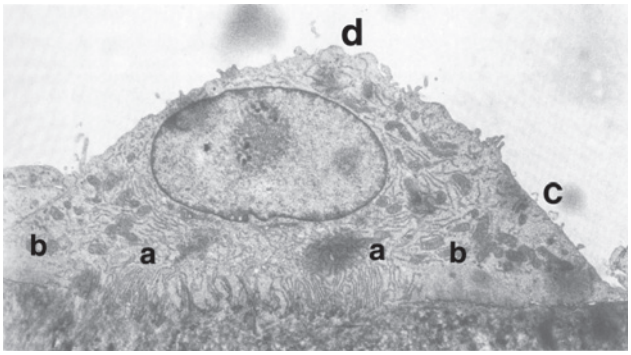

FIGURE 2 A transmission electron microscopic image of a bone-resorbing osteoclast. a, ruffled border; b, sealing zone; c, basal membrane; d, functional secretory domain. Original magnification: ×2500.

During osteoclast activation, the matrix-derived signals, transduced mainly through integrins, induce dramatic cytoskeleton and plasma membrane reorganization resulting in the formation of a ringlike structure of microfilaments known as the *actin ring* at the sealing zone (Lakkakorpi *et al.*, 1989). This structure surrounds a specialized plasma membrane domain, the ruffled border, thus forming an isolated resorptive microenvironment between the osteoclast and the underlying bone matrix (Väänänen *et al.*, 2000). The ultrastructure of a resorbing osteoclast (Fig. 2) clearly shows that the plasma membrane of resorbing osteoclast at the sealing zone is tightly bound to the matrix, offering a good diffusion barrier between the resorption lacuna and extracellular fluid (Väänänen and Horton, 1995). It has been demonstrated that a pH gradient really exists (Baron *et al.*, 1985), indicating that the sealing around the resorption lacuna is tight enough to maintain the low pH that is essential for bone mineral dissolution and

the optimized activities of bone degradating enzymes (see Fig. 3). The permeability of the sealing zone is dynamically regulated during the resorption cycle (Stenbeck and Horton, 2000). This is the case not only in vitro; osteoclasts in bone also have a similar type of actin ring around the resorption lacuna (Sugiyama and Kusuhara, 1994).

The pioneer in vitro studies of osteoclasts on bone or dentine slices in late 1980s and early 1990s revealed that the microfilament pattern in osteoclasts undergoes rapid changes when preparing for resorption (Fig. 4) (Kanehisa *et al.*, 1990; Lakkakorpi *et al.*, 1989; Zambonin-Zallone *et al.*, 1988). In osteoclasts that are not resorbing, polymerized actin is accumulated in podosome-type structures throughout the whole bone-facing surface of the osteoclast. Gradually, an intense accumulation of podosomes to the local areas of the bone-facing membrane takes place (Lakkakorpi and Väänänen, 1991). Next, podosomes are collected into a large circular structure(s) and simultaneously the density of podosomes increases. At the last step, actin forms a dense beltlike structure where individual podosomes cannot be recognized under a light microscope. This dynamic process of podosome organization has been monitored in more detail recently by live confocal imaging and fluorescence recovery after photobleaching (FRAP) analysis in a monocytic cell line expressing an actin-green fluorescent protein (Destaing *et al.*, 2003). In individual podosomes, the polymerized actin is organized into a 300-nm dense actin core and a 500-nm "actin cloud," which correspond to the thick core bundle of actin fibers and a domelike radial meshwork of less densely packed actin fibers under the electron microscope, respectively (Luxenburg *et al.*, 2007). During osteoclast differentiation, these individual podosomes evolve from clusters in early stages, to dynamic rings at intermediate stages, to belts organized at the cell periphery in mature osteo-

matrix, isolated podosomes fuse into a continuous sealing zone. Because podosomes and the sealing zone have been exclusively detected in osteoclasts on collagen or plastic and those on mineralized matrix, respectively, Saltel *et al.* (2006) argue that the sealing zone is not derived from podosomes. However, by careful examination of cultured osteoclasts with high-resolution scanning electron microscopy, Luxenburg *et al.* (2007) found that the organization of individual podosomes in osteoclast on glass and bone as well as macrophages is similar, indicating a generalized basic structure of podosomes, independent of substrate or cell type. In all states of podosome organization, including the sealing zone, individual podosomes could still be detected. The sealing zone differs from individual or clustered podosomes mainly in their densities and degree of interconnectivity of podosomes. Although there is no direct evidence, the higher order of podosomes may physically segregate the sealing zone into two distinct regions governing barrier and adhesion functions, respectively.

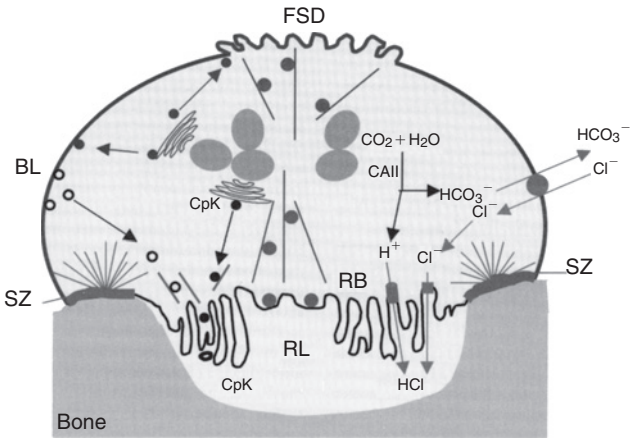

FIGURE 3 Schematic illustration of a bone-resorbing osteoclast. Intensive intracellular membrane trafficking is involved in the establishment of specific plasma membrane domains and resorption processes. Cathepsin K and protons are secreted vectorially to the resorption lacunae. Transcytotic vesicles are presented as brown full circles. BL, basolateral domain; CAII, carbonic anhydrase II; CpK, cathepsin K; FSD, functional secretory domain; RB, ruffled border; RL, resorption lacunae; SZ, sealing zone.

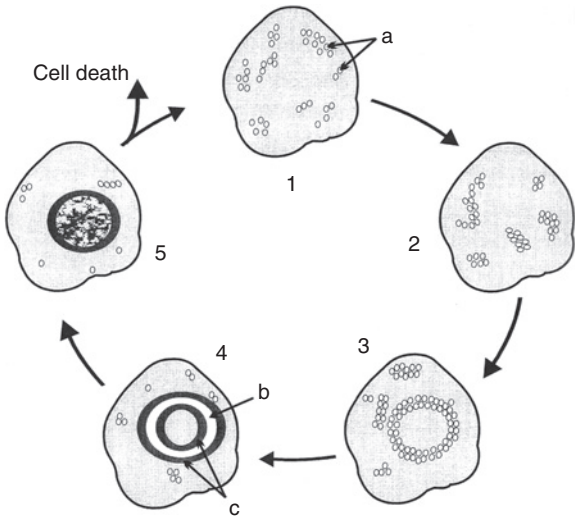

FIGURE 4 Organization of microfilaments in osteoclasts can be used to recognize different phases of the resorption cycle. When a nonresorbing cell (1) is induced to resorb, podosome-type structures (a) gather to certain areas of bone-facing surface (2) and finally form a large circular collection of podosomes (3). In the following step, the individual podosome-type structure disappears (4) and a distinct dense actin ring (b) appears between two broad vinculin rings (c). The vitronectin receptor is tightly colocalized with vinculin in those rings as well as in podosomes. After resorption, cytoskeletal rings disappear in a certain order (5) and the cell can either undergo apoptosis or return to the resting phase.

At the fully developed sealing zone, $\alpha_v\beta_3$ integrin and its associated proteins, such as talin, vinculin, and paxillin, form broad bands around the actin core (Lakkakorpi *et al.*, 1991). This distribution pattern suggests that molecules other than integrins are directly linking the actin core to

the plasma membrane, although the signals derived from $\alpha_v\beta_3$ integrin are required for inducing actin reorganization and the sealing zone formation (McHugh *et al.*, 2000). This notion is also supported by observations from echistatin-treated mice (Masarachia *et al.*, 1998; Yamamoto *et al.*, 1998), which did not reveal changes in the sealing zone or ruffled borders.

A single podosome represents a unit of multiprotein complexes with F-actin and its regulators such as Arp2/3, WASP, cortactin, and gelsolin at the core, which is surrounded by integrins and their associated proteins (paxillin, talin, vinculin), adaptor proteins (Cbl, SH3BP2, and others), kinases (c-Src, Pyk2 and PI-3Ks), Rho GTPases (cdc42, Rho and Rac), enzymes (MT1-MMP, MMP-9), and endocytic regulators (e.g., dynamin) (Linder and Aepfelbacher, 2003; Linder and Kopp, 2005). The important role of many of these components in podosome and sealing zone formation in osteoclasts has been characterized during the past few years (see Table 1 and references therein). In addition to the regulating mechanisms at the podosome level, upstream signaling pathways induced by osteoclast activating cytokines are also critical for promoting cytoskeleton reorganization and the sealing zone formation. However, some of these cytokines, such as M-CSF and RANKL, are also required for osteoclast differentiation, making it very difficult to dissect their direct role in osteoclast cytoskeleton organization. To overcome this difficulty, Kim *et al.* (2006a) and Fuller *et al.*(2002) have developed an in vitro washaway-recovery system, in which actin rings in mature osteoclasts are disrupted quickly by cytokine starvation and allowed to re-form under stimulation by individual cytokines. This transient manipulation does not change the total number of osteoclasts on bone slices and does not induce apoptosis. Using this system we have revealed that M-CSF, RANKL, TNF and interleukin (IL)-1, but not culture medium alone, can directly stimulate actin-ring formation (Fig. 5). Because these cytokines do not induce sealing zone formation in osteoclasts cultured on plastic or glass, the data support the concept that signaling pathways downstream of both integrin and the cytokine receptors coordinately activate osteoclasts (Nakamura *et al.*, 2001; Faccio *et al.*, 2003).

Baron and Duong and their colleagues have identified a signaling complex, consisting of Pyk2/Src/Cbl/PI-3K, which links $\alpha_v\beta_3$-integrin signaling to actin-ring formation in osteoclasts (Sanjay *et al.*, 2001; Duong *et al.*, 1998). More recently, a novel protein complex mediating $\alpha_v\beta_3$-integrin's function in osteoclasts has been identified (Zou *et al.*, 2007). In this model, protein tyrosine kinases, c-Src and Syk, bind directly to the cytoplasmic tail of β_3-integrin and form a complex with immune receptors with ITAMs (immunoreceptor tyrosine-based activation motifs), FcRγ and Dap12. The complex then activates Vav3, which is a GEF (guanine exchange factor) of small GTPase Rac and promotes actin cytoskeleton organization and function of osteoclasts (Faccio *et al.*, 2005). In both models, c-Src plays a central role in $\alpha_v\beta_3$-integrin mediated osteoclast activation. c-Src-deficient mice, which suffer from osteoporosis, have a normal number of osteoclasts, which attach to bone but do not form a normal sealing zone and the ruffled border (Boyce *et al.*, 1992; Soriano *et al.*, 1991). Although the osteoclast phenotypes can be genetically rescued by kinase-deficient mutants of c-Src, the c-Src kinase activity, at least in vitro, is required for podosome and the sealing zone formation (Miyazaki *et al.*, 2004). Calpain, an intracellular cysteine protease, has recently been identified as regulating osteoclast cytoskeleton organization by selectively cleaving talin, which links integrin to the actin cytoskeleton (Hayashi *et al.*, 2005). Both IL-1 and RANKL can directly stimulate cytoskeleton organization and the sealing zone formation in osteoclasts (see Fig. 5 and Nakamura *et al.*, 2002; Burgess *et al.*, 1999). The cytoskeletal effects of both cytokines are likely mediated by a common downstream effector, TRAF6. IL-1 induces a TRAF6/c-Src complex formation in osteoclasts (Nakamura *et al.*, 2002), whereas gene rescuing experiments in RANK- and TRAF6-deficient osteoclasts have demonstrated that TRAF6, especially its RING finger domain, is essential for osteoclast cytoskeletal organization and resorptive function (Armstrong *et al.*, 2002; Kobayashi *et al.*, 2001).

Compared to what we know for actin, much less is known about the changes in the organization of microtubules and intermediate filaments during the resorption cycle. In osteoclasts cultured on glass, each nucleus preserves its own microtubule-organizing center during fusion (Moudjou *et al.*, 1989). However, in resorbing mammalian osteoclast, individual centrioles are eliminated and microtubules are radiating from perinuclear area (Mulari *et al.*, 2003b). In resorbing osteoclasts, microtubules form thick bundles in the middle of the cell, originating from the top of the cell and converging toward the ruffled border (Lakkakorpi and Väänänen, 1995). Data suggest that these microtubules actually extend from the ruffled border to the functional secretory domain and are most probably mediating transcytotic trafficking. Even less is known about the organization of intermediate filaments and their possible changes during the polarization of osteoclasts.

RESORBING OSTEOCLASTS ARE HIGHLY POLARIZED AND SHOW FOUR DIFFERENT MEMBRANE DOMAINS

Osteoclasts cycle between resorbing and nonresorbing phases, which are accompanied by drastic changes in their polarization (see Figs. 1 to 4). Resorbing osteoclasts are highly polarized cells containing several different plasma membrane domains, whereas those osteoclasts that are not resorbing do not reveal clear morphological features of polarity. In resorbing cells the sealing zone itself forms one distinctive membrane domain and simultaneously separates two

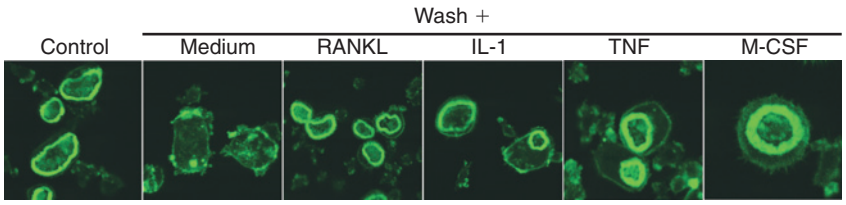

FIGURE 5 Mature osteoclasts were generated from bone marrow macrophages with M-CSF and RANKL for 5 days. The cells were either untreated (control) or washed with cold medium followed by culturing with medium alone (medium) or medium plus 100 ng/mL RANKL, 10 ng/mL IL-1, 10 ng/mL TNF, and 50 ng/mL M-CSF, respectively, for 60 minutes. The cells were then fixed and F-actin was stained with Alexa-488–phalloidin. (See plate section)

other membrane domains, the ruffled border (RB) and the basolateral domain (see Figs. 1 and 2). In addition to these three membrane domains, morphological and functional studies have revealed a distinct membrane domain in the basal membrane, namely a functional secretory domain (FSD; Salo *et al.*, 1996). This membrane domain has some characteristic features of the apical membrane domain in epithelial cells. Viral proteins that are usually targeted to the apical domain are, in osteoclasts, targeted to this domain. In addition, FSD is morphologically different from the rest of the membrane, and it has been also shown to be a target for transcytotic vesicles carrying bone degradation products (Salo *et al.*, 1997; Nesbitt and Horton, 1997). In resorbing osteoclasts, thick bundles of microtubules connect the RB and the FSD (Mulari *et al.*, 2003a), and a specific type of exocytotic vesicles, clastosomes, have been described in close association to the FSD (Salo, 2002). At present it is not known how formation of FSD is regulated.

The ruffled border membrane forms the actual "resorbing organ." The characteristics of this unique membrane domain do not perfectly fit any other known plasma membrane domain described so far. The ruffled border membrane is formed by the rapid fusion of acidic intracellular vesicles (Palokangas *et al.*, 1997). Many of the proteins reported to be present at the ruffled border are also found in endosomal and/or lysosomal membranes, including the vacuolar proton pump, mannose-6-phosphatase receptor, rab7, and 1 gp 110 (Baron *et al.*, 1988; Väänänen *et al.*, 1990; Palokangas *et al.*, 1997). Functional experiments, for instance, with labeled transferring and dextran, have further supported the conclusion that the ruffled border represents a plasma membrane domain with typical features of the late endosomal compartment (Palokangas *et al.*, 1997).

A small GTPase, rab7, regulates targeting and docking of acidic vesicles to the ruffled border (Zhao *et al.*, 2002). On their way to the ruffled border acidic vesicles are translocated from the microtubule-mediated trafficking to actin filaments (Mulari *et al.*, 2003a), and this transition could happen via specific protein–protein interaction between rab 7 and another small GTPase, Rac1 (Sun *et al.*, 2005).

Several membrane proteins reveal a nonhomogeneous distribution at the ruffled border. For instance, the vacuolar proton pump (Mattsson *et al.*, 1997), as well as rab7, is concentrated at the lateral edges of the ruffled border (Palokangas *et al.*, 1997). Our functional experiments have also shown that exocytotic vesicles in resorbing osteoclasts are found at the lateral areas of the ruffled border, and endocytotic vesicles mainly bud from the central area of the ruffled border (Zhao *et al.*, 2001). The ruffled border is thus composed of two different domains—lateral and central—where exocytosis and endocytosis occur, respectively. This allows simultaneous proton and enzyme secretion and the endocytosis of degradation products.

In order to create and maintain specialized membrane domains, as well as to transport products of biosynthetic or secretory machinery, the cell has distinct intracellular trafficking routes, originating from one compartment and reaching another. Intracellular vesicular routes shown to be operating in the resorbing osteoclasts were presented schematically in Fig. 3. It is obvious that these events could be highly specific and may offer new potential targets to inhibit or stimulate bone resorption. In addition to its role in the organization of membrane domains, the cytoskeleton also undergoes drastic reorganization during cell polarization. By following transferrin traffic in osteoclasts during different stages of the resorption cycle, one can see how dynamic membrane trafficking in osteoclasts actually is. In bone-resorbing cells, the bulk of the endocytosed transferrin is rapidly targeted to the ruffled border (Mulari *et al.*, 2003a), whereas in osteoclasts that are moving on the bone surface transferrin is mainly targeted via perinuclear recycling compartment to the leading edge (Sun *et al.*, unpublished).

HOW OSTEOCLASTS DISSOLVE BONE MINERAL

Bone mineral is mainly crystalline hydroxyapatite, and there are not many biological processes that could be responsible for the solubilization of crystals. In fact, the only process that has been suggested to be able to solubilize hydroxyapatite crystals in the biological environment is low pH. Thus the idea that bone resorption is facilitated by local acidification has been discussed among bone biologists for

a long time, and Fallon *et al.* (1984) demonstrated that the resorption lacuna is really acidic. This observation was also confirmed later by other investigators who used the accumulation of acridine orange in acidic compartments as an indicator of low pH (Baron *et al.*, 1985).

The first experiments to explain the molecular mechanism of lacunar acidification suggested the presence of gastric-type proton pumps in osteoclasts (Baron *et al.*, 1985; Tuukkanen and Väänänen, 1986). However, it soon became clear that the main type of proton pump in the ruffled border of osteoclasts is a V-type ATPase (Bekker and Gay, 1990a; Blair *et al.*, 1989; Väänänen *et al.*, 1990).

V-type ATPases are electrogenic proton pumps that contain several different subunits forming two independently assembled complexes: cytoplasmic and membrane bound. (For a review, see Drory and Nelson, 2006.) V-type ATPases are found in all mammalian cells, and they are responsible for the acidification of various intracellular compartments, including endosomes, lysosomes, secretory vesicles, and synaptic vesicles. The membrane-bound complex is composed of at least five different subunits, and the soluble catalytic complex contains at least eight different subunits. Each pump contains several copies of each subunit, and two or even more isoforms for several subunits have been described. In addition to the marked differences in expression level in different cells and tissues, different isoforms are specifically expressed in certain cells, giving, at least in theory, a good possibility for a remarkable cell and tissue specificity.

Heterogeneity of the 116-kDa a3 subunit has turned out to be of special importance for bone biology. Four different isoforms of this subunit that stabilize the soluble complex to the membrane complex have been characterized. It has been shown that a marked number of patients suffering from malignant osteopetrosis have a mutation in the a3 subunit of vacuolar type ATPase (Kornak *et al.*, 2000; Frattini *et al.*, 2000). Further evidence for the importance of this particular subunit is provided by the severe osteopetrotic phenotype in knockout mice of this specific subunit (Li *et al.*, 2000) and also by the fact that oc/oc osteopetrotic mice have a deletion in this subunit (Scimeca *et al.*, 2000). Antisense oligonucleotides and siRNAs against different subunits of the proton pump complex have also been used to confirm the role of the proton pump in osteoclast function (Laitala and Väänänen, 1994; Hu *et al.*, 2005).

The low pH in the resorption lacuna is achieved by the action of the proton pump both at the ruffled border and in intracellular vacuoles. Cytoplasmic acidic vacuoles disappear at the time when the ruffled border appears, during the polarization of the cell. Thus the initial acidification of the subcellular space is achieved by the direct exocytosis of acid during the fusion of intracellular vesicles to form the ruffled border. This ensures rapid initiation of mineral dissolution, and further acidification may be obtained by the direct pumping of protons from the cytoplasm to the resorption lacuna. As mentioned above small GTPases Rab7 and Rac1 regulates targeting of acidic vesicles to the ruffled border. This targeting is obviously also partially mediated via subunit B of V-ATPase since direct interaction between subunit B and actin filament has also been described in osteoclasts (Zuo *et al.*, 2006).

In vitro studies with isolated osteoclasts and bafilomycin A1 were first used to show the functional importance of the proton pump for mineral dissolution (Sundquist *et al.*, 1990). An elegant in vivo study using local administration of bafilomycin A1 confirmed that inhibition of the vacuolar proton pump can potentially be used to inhibit bone resorption (Sundquist and Marks, 1995). The development of new types of vacuolar proton pump inhibitors with improved specificity and selectivity has opened a whole new opportunity for treating osteoporosis and other bone metabolic bone diseases (for review, see Niikura, 2006). However, it is still not known whether any present inhibitor is suitable for the clinical use.

In addition to the proton pump, several other molecules have critical functions in the acidification of the resorption lacuna. Minkin and Jennings (1972) showed that bone resorption in mouse calvarial cultures could be inhibited by carbonic anhydrase (CA) inhibitors and decrease of CA II expression by using antisense technology leads to the inhibition of bone resorption in cultured rat osteoclasts (Laitala and Väänänen, 1994). In humans, Ca II deficiency causes nonfunctional osteoclasts and osteopetrosis (Sly and Hu, 1995), and aging CA-II deficient mice also show mild osteopetrosis (Peng *et al.*, 2000). In addition to soluble CA II at least two membrane-bound carbonic anhydrases, namely CA IV and CA XIV, are expressed in osteoclasts (Riihonen *et al.*, 2006).

Pumping of protons through the ruffled border is balanced by the secretion of anions (see Fig. 3). The presence and functional importance of a high number of chloride channels in the ruffled border membrane have been shown by demonstrating that loss of the chloride channel isoform CIC-7 leads to osteopetrosis both in patients and mice (Kornak *et al.*, 2001). CIC-7 is associated with another membrane protein, Ostm1, a protein of unknown function (Lange *et al.*, 2006), and it is of interest that mutations in this gene lead to osteopetrosis both in mice (grey-lethal mice) and in humans (Ramirez *et al.*, 2004). Polymorphisms of the same gene are associated with bone mineral density (Pettersson *et al.*, 2005). It is not thus surprising that CIC-7 is considered as one of the most interesting drug targets for osteoporosis (Schaller *et al.*, 2005).

In addition to the proton pump and chloride channel, the ruffled border also seems to have K+/Cl-cotransporter KCC1, which participates somehow in proton extrusion (Kajiya *et al.*, 2006). The outflow of chloride anions through the ruffled border is most likely compensated by the action of a HCO_3/Cl exchanger in the basal membrane. The basolateral membrane of resorbing osteoclasts also contains a high concentration of Na/K-ATPase (Baron *et al.*, 1986) and Ca-ATPase (Bekker and Gay, 1990b).

HOW OSTEOCLASTS DEGRADE ORGANIC MATRIX

After solubilization of the mineral phase, the organic matrix is degraded and removed from the resorption lacuna. The roles of two major classes of proteolytic enzymes—lysosomal cysteine proteinases and matrix metalloproteinases (MMPs)—have been studied most extensively. The question of the role of proteolytic enzymes in bone resorption can be divided into at least four subquestions. First, what are the proteolytic enzymes, which are needed to remove unmineralized osteoid from the site of future resorption? Second, what are the proteolytic enzymes, which take part in the degradation of organic matrix in the resorption lacuna? Third, is there intracellular matrix degradation in osteoclasts, and what proteolytic enzymes, if any, are responsible for the intracellular degradation process? Fourth, where and how are different proteolytic enzymes targeted during the resorption process?

Sakamoto and Sakamoto (1982) and Chambers *et al.* (1985) suggested that osteoblast-derived collagenase (MMP-1) plays a major role in the degradation of bone covering osteoid. Removal of the osteoid layer seems to be a necessary or even obligatory step for the future action of osteoclasts. Although the role of osteoblasts seems to be essential in this early phase of bone resorption, it has not been shown definitively that osteoblasts in situ are responsible for the production of all proteolytic enzymes necessary for osteoid degradation. The possibility cannot be ruled out that some proteinases necessary for matrix degradation have already been produced and stored in the matrix during bone formation.

In addition to MMP-1, a membrane-bound matrix metalloproteinase (MT1-MMP) clearly has a role in bone turnover. MT1-MMP-deficient mice develop dwarfism and osteopenia among other connective-tissue disorders (Holmbeck *et al.*, 1999). The analysis of deficient mice, however, suggests that the primary defects are in bone-forming cells rather than in osteoclasts, although some studies have also indicated a high expression on MT1-MMP in osteoclasts (Sato *et al.*, 1997; Pap *et al.*, 1999). It appears to be localized in specific areas of cell attachment, but at the moment there are no direct data pointing to the specific function of MT1-MMP in the resorption process. In conclusion, it is evident that several MMPs that are in osteoblastic cells play an important role in the regulation of bone turnover, but specific mechanisms remain to be elucidated.

It is obvious that a substantial degradation of collagen and other bone matrix proteins during bone resorption takes place in the extracellular resorption lacuna. Two enzymes, cathepsin K and MMP-9, have been suggested to be important in this process. Data that cathepsin K is a major proteinase in the degradation of bone matrix in the resorption lacuna are now very convincing. First of all, it is highly expressed in osteoclasts and is also secreted into the resorption lacuna (Everts *et al.*, 2006; Troen, 2006). Second, it has been shown that it can degrade insoluble type I collagen, and inhibition of its enzymatic activity in in vitro and in vivo models prevents matrix degradation (Bossard *et al.*, 1996; Votta *et al.*, 1997). Third, deletion of the cathepsin K gene in mice leads to osteopetrosis (Saftig *et al.*, 1998; Gowen *et al.*, 1999). Finally, human gene mutations of cathepsin K lead to pyknodysostosis (Gelb *et al.*, 1996; Johnson *et al.*, 1996).

These data have encouraged several researchers and pharmaceutical companies to try to develop specific inhibitors of cathepsin K to be used in the treatment of osteoporosis (Kumar *et al.*, 2007; Palmer *et al.*, 2005). Because mineral dissolution is not prevented by such inhibitors, it is possible that inhibition of this enzyme could lead to the accumulation of an unmineralized matrix. This is supported by a recent finding of Li *et al.* (2006) showing increased bone fragility despite high bone mass in mice lacking cathepsin K. This may be an important contraindication to the long-term use of cathepsin K inhibitors in the treatment of bone diseases.

Osteoclasts are also rich in cystatin B, a natural inhibitor of cysteine proteinases. Addition of cystatin B to the culture medium of bone marrow cells cultured on bone slices protected osteoclasts from experimentally induced apoptosis (Laitala-Leinonen *et al.*, 2006), suggesting that as in neuronal cells, a balance of cysteine proteinases and their natural inhibitors regulates cell survival. This hypothesis is further supported by Chen *et al.* (2007), who demonstrated that cathepsin K –/– mice showed premature cell senescence. A number of other lysosomal cysteine proteinases—cathepsins B, D, L, and S—have been suggested to play a role in osteoclasts, and data exist showing that at least B and L are also secreted into the resorption lacuna (Goto *et al.*, 1994). An interesting proteomic analysis of lysosomal acid hydrolases secreted by osteoclasts indicated that almost all known cathepsins were produced by Raw 264.7 cell derived osteoclasts (Czupalla *et al.*, 2006). These results also suggest that osteoclasts target several lysosomal hydrolases for secretion and do not release them only by fusion of endosomes/lysosomes to the ruffled border.

MMP-9 is highly expressed in osteoclasts and secreted into the resorption lacuna. MMP-9 knockout mice show an interesting phenotype of transient osteopetrosis (Vu *et al.*, 1998) suggesting that it is mainly needed in the degradation of calcified cartilage during animal growth. Fuller *et al.* (2007) recently demonstrated that inhibitors of MMPs had no effect on CTX-I release in in vitro resorption assay with human osteoclasts. These studies together with some previous in vitro studies (Everts *et al.*, 1998) support the conclusion that MMP-9 is not important in the resorption process of bone matrix as such but plays a role, for example, during migration and attachment of osteoclasts, and

perhaps in the resorption of calcified cartilage. Some other studies suggest that the role of MMP-9 in different populations of osteoclasts could be different, and furthermore that osteoclasts may be a more heterogeneous cell population than previously thought (Everts *et al.*, 2006).

In conclusion, evidence indicates that several MMPs and lysosomal proteinases, especially cathepsin K and some other cysteine proteinases, play a major role in the matrix degradation (Everts *et al.*, 2006; Fuller *et al.*, 2007). The coordinated action of several proteinases may be needed to solubilize completely fibrillar type I collagen and other bone matrix proteins. Some of these proteinases obviously act mainly extracellularly and some intracellularly or both. Extracellular matrix degradation may be further enhanced by production of free oxygen radicals and this may continue also during the transcytosis through the cell. In addition, osteoclasts may produce and target several lysosomal enzymes not only to the resorption lacuna and intracellular compartments but also to other membrane domains than the ruffled border for secretion (Czupalla *et al.*, 2006). Specific function(s) of these secreted enzymes remain to be found.

HOW BONE DEGRADATION PRODUCTS ARE REMOVED FROM THE RESORPTION LACUNA

During bone resorption the ruffled border membrane is continuously in very close contact with the bone matrix. Thus, it is somewhat misleading to speak about a resorption lacuna, which is only a very narrow space between the cell membrane and the matrix components. This tentatively suggests that degradation products must be somehow removed continuously from the resorption space in order to allow the resorption process to continue. Theoretically, there are two different routes for resorption products. They can either be released continuously from the resorption lacuna beneath the sealing zone or be transcytosed through the resorbing cell.

Salo *et al.* (1994) provided the first evidence for the transcytosis of bone degradation products in vesicles through the resorbing osteoclasts from the ruffled border to the functional secretory domain of the basal membrane. This finding was later confirmed by demonstrating fragments of collagen and other matrix proteins in the transcytotic vesicles (Salo *et al.*, 1997; Nesbit *et al.*, 1997). When matrix degradation products are endocytosed, it is possible that further degradation of matrix molecules takes place during the transcytosis. Experiments where bone degradation products and cathepsin K were localized simultaneously in resorbing osteoclasts revealed that they exist in a same pool of transcytotic vesicles (Vääräniemi *et al.*, 2004). Results further showed that TRACP-containing vesicles were fused into matrix and cathepsin K–containing vesicles on their way to the functional secretory domain. On the other hand it has been shown that TRACP can generate highly destructive reactive oxygen species (ROS) that are able to destroy collagen and other proteins (Halleen *et al.*, 1999). In addition, cleavage of TRACP with cathepsin K increases its activity for ROS formation (Fagerlund *et al.*, 2006). All these results together suggest a new function for TRACP in the final destruction of matrix components during the transcytosis. The observed phenotype of mild osteopetrosis in TRACP knockout mice (Hayman *et al.*, 1996) is in good agreement with this.

In addition to collagen and other protein fragments, calcium and phosphate also have to be removed from the resorption lacuna. Our initial observations with tetracycline-labeled bone matrix suggested that calcium is also transcytosed from the resorption lacuna (Salo *et al.*, 1997). A recent study by Yamaki *et al.* (2006) supports this suggestion, demonstrating the presence and transport of calcium in vesicles towards the functional secretory domain. However, until now it has not been possible to exclude a leakage of calcium and phosphate directly from the resorption lacuna to the extracellular medium. This mechanism would at least consume less energy than vesicular transcytosis. In addition to these two routes, there is also some evidence to suggest that a nonvesicular transcytosis could be a possibility, although the evidence is still rather vague. This possibility is supported by the finding that a high amount of Ca-channel TRPV5 is located at the ruffled border, and when the gene is knocked out, osteoclasts lose the capacity to resorb bone (van der Eerden, 2005). This option would also involve the active participation of cytoplasmic calcium binding proteins such as calmodulin. Only a very limited number of indirect data are available about phosphate transport from the resorption lacuna during bone resorption. Ito *et al.* (2005) found, using osteoclast-like cells, that these cells had Na-dependent phosphate transport that was induced by acidic pH.

Stenbeck and Horton (2000) suggested that the sealing zone is a more dynamic structure than previously thought and could be loose enough to allow the diffusion of molecules from the extracellular fluid into the resorption lacuna. On the basis of their findings, the authors concluded that the sealing zone may also allow diffusion of the resorption products out from the lacuna. It remains to be seen whether all these three mechanisms are operational and if one of them is more important than others.

WHAT HAPPENS TO OSTEOCLASTS AFTER RESORPTION

In vitro studies have shown that an osteoclast can go through more than one resorption cycle (Kanehisa and Heersche, 1988; Lakkakorpi and Väänänen, 1991). Unfortunately, we do not yet know if this also happens in vivo or if the osteoclast continues its original resorption cycle as long as it is

functional. Regardless, there must be a mechanism that destroys multinucleated osteoclasts in situ. There are at least two different routes that the multinucleated osteoclast can take after it has fulfilled its resorption task. It can undergo fission into mononuclear cells or it can die.

Very little evidence exists to support the idea that multinucleated cells are able to undergo fission back to mononuclear cells. It is thus very likely that all osteoclasts die via apoptosis. It is becoming more evident that changing the osteoclast life span is a major mechanism to regulate bone resorption activity. Many physiological as well as pharmacological agents seem to use this particular mechanism of action.

At present many physiological as well as pharmacological agents are known to induce apoptosis in osteoclasts, for instance, bisphosphonates, which are widely used to inhibit bone resorption and prevent bone loss. Clodronate and aminobisphosphonates both induce apoptosis, but their mechanisms of action are different. Aminobisphosphonates inhibit protein prenylation by blocking an enzyme, farnesyl pyrophosphate synthetase (Russell, 2006), and this inhibition leads to disturbances of intracellular vesicular trafficking and finally to cell death (Luckman *et al.*, 1998). In clodronate-treated cells apoptosis is due to the inhibition of mitochondrial function, and the target molecule is mitochondrial ADP/ATP translocase (Lehenkari *et al.*, 2002). Another example of drug-induced apoptosis is reveromycin A, which is an acid-activated isoleucyl-tRNA synthetase inhibitor with a remarkable specificity to osteoclasts in experimental animals (Woo *et al.*, 2006).

In addition to bisphosphonates, estrogen and calcitonin have been suggested to regulate osteoclast apoptosis (Hughes *et al.*, 1996; Selander *et al.*, 1996a). It is quite evident that cell–matrix interactions are also important signals for osteoclast survival. The importance of the right extracellular milieu for the osteoclast phenotype and for survival is seen clearly when one compares their sensitivity to extracellular calcium. A moderate concentration of extracellular calcium has been shown to promote apoptosis in osteoclasts cultured on an artificial substrate (Lorget *et al.*, 2000), whereas if cultured on bone, the cells can tolerate high concentrations of extracellular calcium (Lakkakorpi *et al.*, 1996).

A good example of a prolonged life span of osteoclasts on the bone metabolism is SHIP–/– mice (Takeshita *et al.*, 2002) which shows a marked osteoporosis due to increased number of hyperactive osteoclasts. A study by Kim *et al.* (2006a), with targeted knockout of glucocorticoid receptor in osteoclasts, suggests that osteoclasts are a primary target of glucocorticoids and may even regulate bone formation via an osteoclast-mediated pathway. Another animal model, targeted overexpression of 11-β-hydroxysteroid dehydrogenase 2, an enzyme that inactivates glucocorticoids, seems to support also a direct effect on osteoclasts (Jia *et al.*, 2006).

It is most likely that the molecular pathways leading to apoptosis in osteoclasts are similar to those described in other cells. It is possible, however, that the highly specific phenotype of the osteoclast also includes cell-specific features of cell survival and death (Tanaka *et al.*, 2006). If this turns out to be a case, it will open a number of new strategies to regulate osteoclast activity in various bone diseases.

Chapter 11

Receptor Activator of NF-κB (RANK) Signaling

Hiroshi Takayanagi

Department of Cell Signaling, Graduate School, Tokyo Medical and Dental University, Yushima 1-5-45, Bunkyo-ku, Tokyo 113-8549, Japan, Phone: +81-3-5803-5471, Fax: +81-3-5803-0192, E-mail: taka.csi@tmd.ac.jp

INTRODUCTION

Osteoclasts are multinucleated cells of monocyte/macrophage origin that degrade bone matrix. Congenital lack or dysfunction of osteoclasts causes osteopetrosis, the investigation of which has provided insights into the essential molecules for osteoclast differentiation and function (Asagiri and Takayanagi, 2007; Teitelbaum and Ross, 2003). Naturally occurring or genetically modified osteopetrotic mice have provided information on the molecules essential for osteoclastogenesis, including receptor activator of nuclear factor (NF)-κB (RANK), RANK ligand (RANKL), and macrophage colony-stimulating factor (M-CSF). Osteoclasts are generated *in vitro* from bone marrow cells stimulated with recombinant RANKL and M-CSF. This osteoclast differentiation system allows a rough but extremely useful visualization of the differentiation process, and the cells undergoing differentiation can then be subjected to extensive molecular analyses. Here we focus on studies of the intracellular signal transduction of RANK, and summarize recent progress in the understanding of the mechanisms of osteoclastogenesis.

LESSONS FROM OSTEOPETROTIC MICE

Osteopetrotic mice revealed a number of genes essential for osteoclast differentiation, which are categorized into two types (Fig. 1): genes involved in the generation of osteoclast precursor cells and those involved in the promotion of the differentiation process. The first group of genes includes *M-CSF* (Yoshida *et al.*, 1990), *Csf1r/c-Fms* (encoding M-CSF receptor) (Dai *et al.*, 2002), and the transcription factor *PU.1* (Tondravi *et al.*, 1997), which are involved in the generation of common progenitors for macrophages and osteoclasts. The deletion of these genes results in the lack of both macrophages and osteoclasts. M-CSF induces the proliferation of osteoclast precursor cells, supports their survival, and upregulates RANK expression, which is a prerequisite for their further differentiation (Ross and Teitelbaum, 2005; Arai *et al.*, 1999). The transcription factor PU.1 binds to the promoter region of *Csf1r* and positively regulates transcription (Zhang *et al.*, 1994), and mice deficient in *PU.1* display an osteopetrotic phenotype similar to *op/op* mice (Tondravi *et al.*, 1997). MITF is activated by M-CSF signaling (Weilbaecher *et al.*, 2001) and binds to the *Bcl-2* promoter (McGill *et al.*, 2002). MITF regulates the expression of the anti-apoptotic protein Bcl-2 in the osteoclast lineage (McGill *et al.*, 2002), and both *mi/mi* mice (carrying a mutation at the *MITF* locus) and *Bcl-2*-deficient mice exhibit osteopetrosis (McGill *et al.*, 2002; Hodgkinson *et al.*, 1993).

The second group includes *RANKL* (Kong *et al.*, 1999), *RANK* (Dougall *et al.*, 1999; Li *et al.*, 2000), *TRAF6* (Kobayashi *et al.*, 2003; Lomaga *et al.*, 1999; Naito *et al.*, 1999), *c-Fos* (Johnson *et al.*, 1992; Wang *et al.*, 1992), *NF-κB (p50/p52)* (Franzoso *et al.*, 1997; Iotsova *et al.*, 1997), *NFATc1* (Asagiri *et al.*, 2005), and *Fc receptor common γ subunit* (*FcRγ*)/*DNAX-activating protein 12* (*DAP12*) (Koga *et al.*, 2004; Mocsai *et al.*, 2004), the deficiency of which leads to the loss of multinucleated osteoclasts despite a normal (or increased) number of macrophages. *DC-STAMP* (Yagi *et al.*, 2005), *Gab2* (Wada *et al.*, 2005), and *IKKβ* (Ruocco *et al.*, 2005) are also included in this group, but the osteopetrotic phenotype that develops with a deficiency of these genes is less severe. In a culture system, *Syk* (Koga *et al.*, 2004; Mocsai *et al.*, 2004), *NIK* (Novack *et al.*, 2003), and *IKKα* (Ruocco *et al.*, 2005) have also been shown to be included in this group. Despite the long list of molecules possibly involved in RANK signaling, we cannot fully understand the differentiation process until sequential molecular events activated by RANK are revealed.

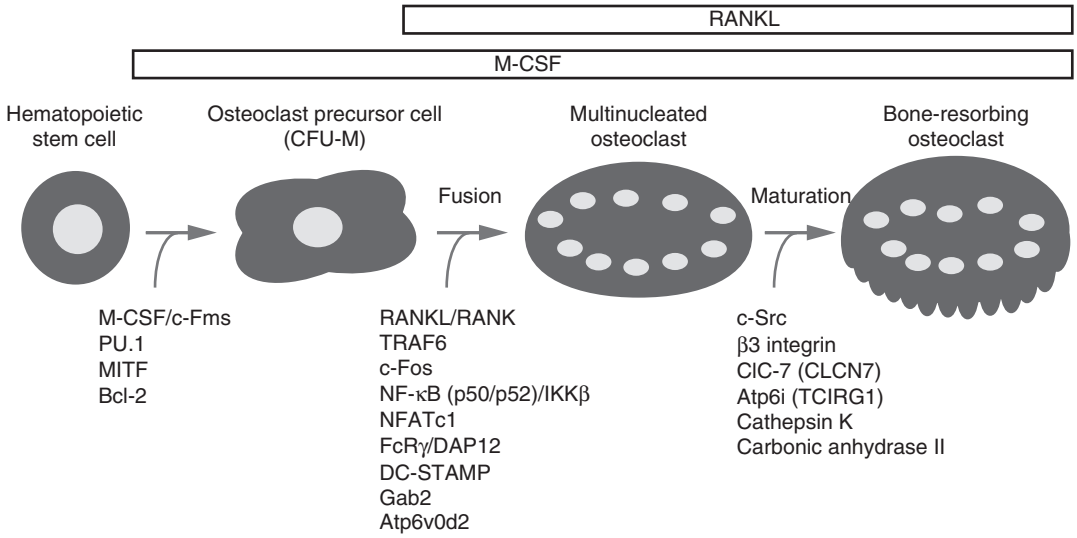

FIGURE 1 Key molecules for osteoclast differentiation. Osteoclast differentiation requires two major cytokines, M-CSF and RANKL, at certain indicated periods. Hematopoietic stem cells undergo differentiation into macrophage colony-forming units (CFU-M), which are the common precursor cells of macrophages and osteoclasts. The differentiation step from CFU-M to multinucleated osteoclasts is characterized by cell–cell fusion, which is mainly induced by RANKL. Mature osteoclasts acquire bone-resorbing activity, which is also dependent on M-CSF and RANKL.

Another set of genes is comprised of *c-Src* (Lowe *et al.*, 1993; Soriano *et al.*, 1991), *ClC-7 (CLCN7)* (Kornak *et al.*, 2001), *Atp6i (TCIRG1)* (Frattini *et al.*, 2000; Li *et al.*, 1999), and *cathepsin K* (Saftig *et al.*, 1998). Mice deficient in these molecules have osteoclasts with no or very little bone-resorbing activity, indicating these molecules are crucial for osteoclast function.

TRAF6

RANK lacks intrinsic enzymatic activity in its intracellular domain, and the analyses of molecules associating with the cytoplasmic domain of RANK revealed that it transduces signaling by recruiting adaptor molecules such as the TRAF family of proteins (Darnay *et al.*, 1998; Galibert *et al.*, 1998; Wong *et al.*, 1999; Wong *et al.*, 1998). The TRAF family contains seven members (TRAFs 1, 2, 3, 4, 5, 6, and 7) and mainly mediates signals induced by the TNF family of cytokines and pathogen-associated molecular patterns (PAMPs) (Bouwmeester *et al.*, 2004; Inoue *et al.*, 2000). The cytoplasmic tail of RANK contains three TRAF6-binding sites, and the phenotype of knockout mice revealed TRAF6 to be the major adaptor molecule linking RANK to osteoclastogenesis (Lomaga *et al.*, 1999; Naito *et al.*, 1999; Gohda *et al.*, 2005). In contrast to the essential role of TRAF6 in osteoclastogenesis, the contributions of other TRAF members seem to be relatively limited.

The binding of TRAF6 to RANK induces the trimerization of TRAF6, leading to the activation of NF-κB and mitogen-activated kinases (MAPKs), including Jun N-terminal kinase (JNK) and p38 (Wong *et al.*, 1998; Kobayashi *et al.*, 2001). TRAF6 contains an N-terminal RING finger domain and a stretch of predicted zinc finger domains (Kobayashi *et al.*, 2001). The ubiquitin ligase activity mediated by the RING finger motif of TRAF6 has been shown to be important for NF-κB activation in immune cells (Deng *et al.*, 2000) as well as osteoclasts (Lamothe *et al.*, 2007). However, deletion analysis indicated that the RING finger domain of TRAF6 is dispensable for the formation of tartrate-resistant acid phosphatase (TRAP)-positive multinucleated cells (Kobayashi *et al.*, 2001). Further studies are needed to resolve this discrepancy. TRAF6 forms a signaling complex containing RANK and TAK-1-binding protein (TAB) 2, which results in TGFβ-activated kinase (TAK)1 activation (Mizukami *et al.*, 2002). Dominant negative forms of TAK1 and TAB2 inhibit the NF-κB activation induced by RANKL, and endogenous TAK1 has been shown to be activated in response to RANKL stimulation in RAW 264.7 cells (Mizukami *et al.*, 2002). Thus, *in vitro* experiments suggest that TAK1 is involved in the TRAF6-mediated activation of NF-κB and MAPKs during osteoclastogenesis.

TRAF6 was originally identified as an adaptor molecule that binds CD40, but CD40 has only one TRAF6-binding site. However, the osteoclastogenic activity of RANK, which contains three binding sites is 100 times higher than CD40 (Gohda *et al.*, 2005). Therefore, there appear to exist qualitative differences between RANK and other receptor signaling events. It is still not clear the mechanisms by which RANK alone among the TRAF6-binding receptors is able to stimulate osteoclastogenesis so powerfully. One possible explanation is that RANK has specific adaptor protein(s) not associated with other TRAF6-binding receptors. For example, Gab2 has been shown to be associated with RANK and

to play an important role in its signal transduction (Wada *et al.*, 2005). Atypical PKC (aPKC)-interacting protein p62 is one of the candidate molecules putatively involved in the regulation of TRAF6 (Duran *et al.*, 2004).

NF-κB

NF-κB activation is among the very early molecular events induced by RANK (Anderson *et al.*, 1997) and is mediated by TRAF6. NF-κB is a family of dimeric transcription factors that include Rel (cRel), RelA (p65), RelB, NF-κB 1 (p50), and NF-κB 2 (p52, which is processed from its precursor, p100). Whereas the Rel proteins contain transcriptional activation domains, such domains are absent in p50 or p52, the activation function of which depends on heterodimerization with any of the three Rel proteins (Ghosh and Karin, 2002; Hayden and Ghosh, 2004). Mice doubly deficient in *p50* and *p52* develop osteopetrosis because of a defect in osteoclast differentiation, indicating that NF-κB (p50 and p52) plays an indispensable role in osteoclastogenesis (Franzoso *et al.*, 1997; Iotsova *et al.*, 1997).

NF-κB activation depends on classical and noncanonical pathways. The classical NF-κB signaling pathway involves activation of the inhibitor of the κB (IκB) kinase (IKK) complex that phosphorylates and degrades the IκB, which retains most of the NF-κB dimer, including p50:RelA, in the cytoplasm (Ghosh and Karin, 2002; Hayden and Ghosh, 2004). The alternative pathway induces the p52:RelB dimer, which are generated through the processing of the p100:RelB complex by NF κB-inducing kinase (NIK) (Ruocco *et al.*, 2005; Novack *et al.*, 2003; Ghosh and Karin, 2002; Hayden and Ghosh, 2004). If p50 and p52 are exclusively involved in the classical and alternative pathways, respectively, the phenotype of *p50/p52*-deficient mice suggests that both pathways are important for osteoclastogenesis. However, osteoclast formation is not completely abrogated in mice lacking NIK (Novack *et al.*, 2003). Targeted disruption of *IKKα*, which is important in the alternative pathway, results in an impairment of osteoclastogenesis only *in vitro*, not *in vivo*, while targeted disruption of *IKKβ*, which is an essential catalytic IKK in the classical pathway, results in the impairment of osteoclastogenesis both *in vitro* and *in vivo* (Ruocco *et al.*, 2005). These results suggest that the classical, not the alternative pathway, is crucial for osteoclastogenesis; however, this is not completely consistent with the finding that *p50*-deficient mice exhibit no bone abnormalities. Thus, the precise roles of the two NF-κB activation pathways and the function of each NF-κB component in osteoclastogenesis are at present not entirely clear.

NFATc1

The NFAT transcription factor family was originally identified in T cells, and is comprised of five members. Among all the known transcription factors, the mRNA of NFATc1 (NFAT2) is the most strongly induced by RANKL (Takayanagi *et al.*, 2002). The necessary and sufficient role of *NFATc1* in osteoclastogenesis was suggested by the *in vitro* observation that *NFATc1*$^{-/-}$ embryonic stem cells do not differentiate into osteoclasts, and that ectopic expression of NFATc1 causes bone marrow-derived precursor cells to undergo osteoclast differentiation in the absence of RANKL (Takayanagi *et al.*, 2002). The activation of NFATc1 is mediated by a specific phosphatase, calcineurin, which is activated by calcium/calmodulin signaling. Consistent with this, calcineurin inhibitors such as FK506 and cyclosporin A potently inhibit osteoclastogenesis (Takayanagi *et al.*, 2002; Ishida *et al.*, 2002). Although *in vivo* analysis of *NFATc1*-deficient mice has been hampered by embryonic lethality (de la Pompa *et al.*, 1998; Ranger *et al.*, 1998), the adoptive transfer of hematopoietic stem cells to osteoclast-deficient mice and blastocyst complementation experiments have made it possible to fully demonstrate the critical function of NFATc1 in osteoclastogenesis *in vivo* (Asagiri *et al.*, 2005).

c-Fos and AP-1

The essential role of c-Fos in osteoclastogenesis has long been established (Grigoriadis *et al.*, 1994). The AP-1 transcription factor is a dimeric complex composed of the Fos (c-Fos, FosB, Fra-1, Fra-2), Jun (c-Jun, JunB, JunD), and ATF (ATFa, ATF2, ATF3, ATF4, B-ATF) proteins (Eferl and Wagner, 2003; Wagner and Eferl, 2005). RANK activates the transcription factor complex AP-1 partly through an induction of its critical component, c-Fos (Takayanagi *et al.*, 2002; Wagner and Eferl, 2005), but it is unclear whether RANK signaling is involved in the functional modification of c-Fos. The expression of c-Fos is actually increased after RANKL stimulation, but the molecular mechanism underlying its induction has yet to be fully understood.

NFATc1 induction by RANKL is completely abrogated in *c-Fos*-deficient cells (Takayanagi *et al.*, 2002; Matsuo *et al.*, 2004) and overexpression of NFATc1 rescues osteoclastogenesis in *c-Fos*-deficient cells (Matsuo *et al.*, 2004). ChIP experiments have shown c-Fos is recruited to the *NFATc1* promoter after RANKL stimulation (Asagiri *et al.*, 2005). Thus, c-Fos plays an essential role in osteoclastogenesis by functioning as a direct transcriptional regulator of NFATc1. Another member of the Fos family, Fra-1, which is a transcriptional target of c-Fos during osteoclast differentiation, compensates for the loss of *c-Fos* both *in vivo* and *in vitro*, but *Fra-1*-deficient mice do not exhibit osteopetrosis (Eferl *et al.*, 2004). This suggests that Fra-1 has an ability to compensate for the loss of *c-Fos* but is not the exclusive downstream molecule. It is reported that transgenic mice expressing dominant negative c-Jun (which inhibits all AP-1 dimers) under the control of the

TRAP promoter exhibit osteopetrosis, clearly indicating that AP-1 activity is critical for osteoclastogenesis (Ikeda *et al.*, 2004).

In contrast to the critical role of c-Fos, the Jun family of proteins, which are partners of the Fos family of proteins in the context of AP-1, play a redundant role. Mice lacking Jun family proteins such as c-Jun and JunB are embryonically lethal, but conditional knockout mice revealed that a deficiency in JunB or c-Jun leads to a considerable decrease in osteoclast formation, but not to the complete blockade of this process, suggesting that Jun members can substitute for each other during osteoclastogenesis (Wagner and Eferl, 2005; David *et al.*, 2002; Kenner *et al.*, 2004).

Role of NF-κB in the NFATc1 induction

As mentioned earlier, NFATc1 is the most important transcriptional target of c-Fos. What is the role of NF-κB in the regulation of c-Fos and NFATc1? Since NFATc1 induction was shown to be impaired in *TRAF6*$^{-/-}$ cells (Takayanagi *et al.*, 2002), it has been suggested that the induction of NFATc1 by RANKL requires NFκB activation. This idea was also supported by the observation that an NF-κB inhibitor was shown to suppress RANKL-stimulated induction of NFATc1 (Takatsuna *et al.*, 2005) and that NFATc1 induction is also impaired in *p50/p52*-deficient cells (Yamashita *et al.*, 2007). These results collectively indicate that the RANKL-mediated induction of NFATc1 is dependent on NF-κB.

Is NFATc1 the direct transcriptional target of NF-κB? Chromatin immunoprecipitation (ChIP) experiments revealed that NF-κB is recruited to the *NFATc1* promoter immediately after RANKL stimulation (Asagiri *et al.*, 2005). In fact, the *NFATc1* promoter contains κB sites and NF-κB overexpression activated the *NFATc1* promoter in a luciferase reporter gene assay (Asagiri *et al.*, 2005). However, osteoclastogenesis in *p50/p52*-deficient cells was shown to be rescued by the overexpression of c-Fos as well as NFATc1 (Yamashita *et al.*, 2007). In addition, the induction of c-Fos was impaired in *p50/p52*-deficient cells (Yamashita *et al.*, 2007). Although it is not clear whether NF-κB is directly recruited to the *c-fos* promoter, these results do suggest that NF-κB contributes to the induction of NFATc1 through the induction of c-Fos, at least in part. It is likely that NF-κB contributes to the induction of NFATc1 by both directly acting on the *NFATc1* promoter, and indirectly, through c-Fos induction.

Another molecule that is recruited to the *NFATc1* promoter is NFATc2, a member of the NFAT family of transcription factors. NFATc2 is present prior to RANKL stimulation and is recruited to the *NFATc1* promoter at the same time as NF-κB. NFATc2 and NF-κB cooperatively activate the *NFATc1* promoter within minutes of RANKL stimulation (Asagiri *et al.*, 2005). Physiologically, this (initial induction of NFATc1) is an important step toward the robust induction of NFATc1 at the next stage of differentiation. However, because NFATc2 is dispensable for osteoclastogenesis *in vivo* (Asagiri *et al.*, 2005), the initial induction of NFATc1, which is dependent on NF-κB and NFATc2, is not absolutely essential for osteoclastogenesis.

Autoamplification of NFATc1 and Epigenetic Regulation

Because NFATc1 and NFATc2 play a redundant role in the immune system (Peng *et al.*, 2001), the question arises as to how NFATc1 plays such an exclusive function in osteoclastogenesis. An interesting observation was obtained from rescue experiments using *NFATc1*$^{-/-}$ osteoclast precursor cells: osteoclast formation in *NFATc1*$^{-/-}$ cells was recovered not only by forced expression of NFATc1 but also by that of NFATc2 (Asagiri *et al.*, 2005). How are we to reconcile the indispensable *in vivo* role of NFATc1 in osteoclastogenesis with the observation that *NFATc1* deficiency is compensated for by forced expression of NFATc2? We considered the following explanation: the NFATc1 and NFATc2 proteins have a similar function of inducing osteoclastogenesis if and when they are ectopically expressed at a similarly high level. Therefore, the essential role of NFATc1 is not achieved by the unique function of the protein, but by an NFATc1-specific gene regulatory mechanism.

Accordingly, we analyzed the mRNA expression of *NFATc1* and *NFATc2* genes during osteoclastogenesis. The mRNA of *NFATc1* is induced selectively and potently by RANKL, while *NFATc2* mRNA is expressed constitutively in precursor cells at a low level (Asagiri *et al.*, 2005; Takayanagi *et al.*, 2002). Importantly, FK506, which suppresses the activity of NFAT through an inactivation of calcineurin, downregulates the induction of *NFATc1,* but not *NFATc2*. This suggests that *NFATc1* is selectively autoregulated by NFAT during osteoclastogenesis. As expected, ChIP experiments revealed that NFATc1 is recruited to the *NFATc1* but not the *NFATc2* promoter 24 h after RANKL stimulation, and the occupancy persists during the terminal differentiation of osteoclasts, indicating the autoamplification mechanism by NFATc1 is specifically operative in the *NFATc1* promoter (Asagiri *et al.*, 2005).

Why does this autoamplification occur only in *NFATc1* gene regulation? If NFAT-binding sites are only found in the *NFATc1* promoter, the selective recruitment would be easily explained. However, NFAT-binding sites are in fact found in both the *NFATc1* and the *NFATc2* promoters; thus, the promoter sequence cannot be the answer. Histone acetylation is a marker of the transcriptionally active chromatin structure, and transcriptional coactivators such as CBP and PCAF have histone acetylase activity (de la Serna *et al.*, 2006; Ansel *et al.*, 2006). Investigation of

the recruitment of CBP and PCAF to the *NFATc1* promoter yielded positive results. The rate of histone acetylation in the *NFATc1* promoter increased gradually after RANKL stimulation, and methylation of histone H3 lysine 4, which is characteristic of a transcriptionally active locus, is also upregulated exclusively in the *NFATc1* promoter; however, this was not observed in the *NFATc2* promoter (Asagiri *et al.*, 2005). Conversely, the *NFATc2* promoter is constantly associated with methylated DNA-binding proteins, such as methyl-CpG-binding protein 2 (MeCP2), suggesting epigenetic modification of the *NFATc2* promoter is responsible for the muted pattern of gene expression (Asagiri *et al.*, 2005; Robertson, 2002). Thus, contrasting epigenetic modification of the *NFATc1* and the *NFATc2* promoters might account for their unique spatiotemporal induction pattern during osteoclastogenesis. In conclusion, the essential role of the *NFATc1* gene is determined not only by the function of the encoded protein, but also by an NFATc1-specific gene regulatory mechanism. It remains an issue to be pursued in future work to determine the reason such a specific epigenetic regulation is evidently at work only in osteoclasts.

Transcriptional Targets and Partners of NFATc1

Accumulating evidence indicates that a number of osteoclast-specific genes are directly regulated by NFATc1. Based on promoter and/or ChIP analyses, the *TRAP* (Takayanagi *et al.*, 2002; Matsuo *et al.*, 2004; Kim *et al.*, 2005), *calcitonin receptor* (Takayanagi *et al.*, 2002; Matsuo *et al.*, 2004; Kim *et al.*, 2005; Anusaksathien *et al.*, 2001), *cathepsin K* (Kim *et al.*, 2005; Matsumoto *et al.*, 2004), *β3 integrin* (Crotti *et al.*, 2006), and osteoclast-associated receptor (OSCAR) have all been shown to be regulated by NFATc1 (Kim *et al.*, 2005; Kim *et al.*, 2005). It is not understood how the target genes of NFATc1 promote the differentiation process, but it is notable that the genes involved in osteoclast fusion are also regulated by NFATc1. DC-STAMP, a putative seven-transmembrane spanning protein, is essential for the cell–cell fusion of osteoclasts (Yagi *et al.*, 2005; Kukita *et al.*, 2004). Its expression is rapidly induced in osteoclast precursor cells by RANKL and forced expression of DC-STAMP induces the formation of TRAP-positive multinucleated cells. Because the RANKL-mediated induction of *NFATc1* in *DC-STAMP*$^{-/-}$ cells is normal (Yagi *et al.*, 2005), DC-STAMP may function downstream of NFATc1 to promote multinucleation. In fact, a recent report showed that DC-STAMP is regulated by NFATc1(Yagi *et al.*, 2007). The D2 isoform of the vacuolar (H(+)) ATPase (v-ATPase) V(0) domain (Atp6v0d2), which was also found to be crucial for osteoclast fusion, was revealed to be a transcriptional target of NFATc1(Kim *et al.*, 2007).

The AP-1 complex is known to be a transcriptional partner of NFAT in lymphocytes, and crystal structure analysis revealed the formation of the NFAT:AP-1 complex to be crucial for DNA binding (Chen *et al.*, 1998). Likewise, an NFAT:AP-1 complex is important for the induction of the *TRAP* and *calcitonin receptor* genes as well as the robust autoamplification of NFATc1 (Takayanagi *et al.*, 2002). It has also been shown that NFATc1 cooperates with PU.1 and MITF on the *cathepsin K* and the *OSCAR* promoters (Kim *et al.*, 2005; Matsumoto *et al.*, 2004). It is noteworthy that both PU.1 and MITF, which are thought to be important for the survival of osteoclast precursor cells, also participate in osteoclast-specific gene induction at the terminal stage of differentiation. Thus, NFATc1 forms an osteoclast-specific transcriptional complex containing AP-1 (Fos/Jun), PU.1, and MITF for the efficient induction of osteoclast-specific genes (Asagiri *et al.*, 2005). It should also be noted that the components of the NFATc1 complex are not always the same: the cooperation between NFATc1 and PU.1/MITF was not observed on the *calcitonin receptor* promoter, suggesting that the differential composition of the transcriptional complex contributes to the spatiotemporal expression of each gene during osteoclastogenesis (Kim *et al.*, 2005).

Sequential Molecular Events During Osteoclastogenesis

The process of osteoclast differentiation can be effectively divided into three stages in the context of transcriptional control by NFATc1, as shown in Fig. 2: (i) The binding of RANKL to RANK results in the recruitment of TRAF6, leading to the activation of downstream molecules such as NF-κB. NFATc2 is recruited to the *NFATc1* promoter at a very early phase. Cooperation of NFATc2 and NF-κB initiates the induction of *NFATc1*. (ii) Stimulated by calcium signaling, NFATc1 is activated and binds its own promoter. This leads to the robust induction of *NFATc1* (i.e., autoamplification). AP-1 (containing c-Fos) is critical for this autoamplification. RANKL induces selective recruitment of NFATc1 to the promoter of *NFATc1*, but not to that of *NFATc2*, which is explained by epigenetic regulation. (iii) A number of osteoclast-specific genes such as *cathepsin K*, *TRAP*, *calcitonin receptor,* and *OSCAR* are activated by a transcriptional complex containing NFATc1 and cooperators such as AP-1, PU.1, and MITF.

MAPKs

In vitro experiments have suggested that MAPKs play an important role in osteoclastogenesis, but corroborating *in vivo* evidence has yet to be obtained. MAPKs are involved in the activation of AP-1 components (Chang and Karin, 2001) and therefore may have a role in osteoclastogenesis by modulating AP-1 activity, but the detailed molecular

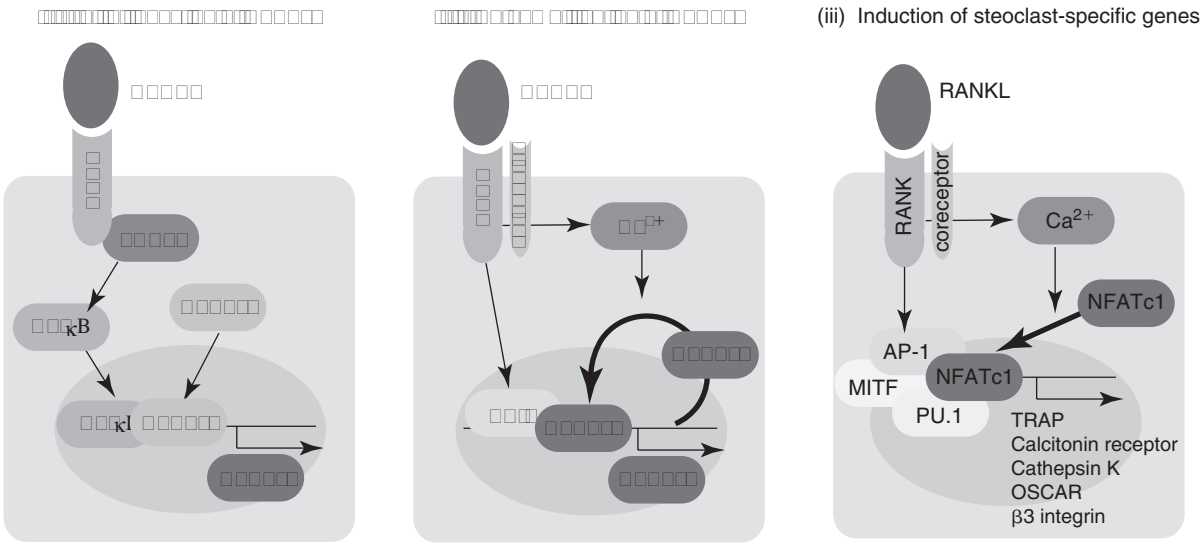

FIGURE 2 RANKL-mediated osteoclast differentiation and the induction of NFATc1. (i) The binding of RANKL to its receptor RANK results in the recruitment of TRAF6, which activates NF-κB. NF-κB and NFATc2 are involved in the initial induction of NFATc1. (ii) NFATc1 expression is autoamplified by its binding to the own promoter. The AP-1 component c-Fos is essential for the robust induction of NFATc1. Costimulatory receptors for RANK mediate the activation of the calcium signaling required for the nuclear localization and activation of NFATc1. (iii) NFATc1 in cooperation with partner transcription factors activates the induction of osteoclast-specific genes.

mechanisms of this action are not well elucidated. Mammals express at least four distinctly regulated groups of MAPKs, p38-MAPKs (p38α/β/γ/δ), JNK1/2/3, ERK1/2, and ERK5 (Chang and Karin, 2001). Many of the MAPKs have been shown to be activated downstream of RANK. Based on the effect of a specific inhibitor of p38α and β (SB203580) in RAW 264.7 cells, it was suggested that p38α and/or β are involved in osteoclast formation (Matsumoto *et al.*, 2000). It has also been shown that p38 is important for the induction of the *cathepsin K* gene (Matsumoto *et al.*, 2004). The functions of the other p38-MAPK isoforms, p38γ and δ, remain to be determined. MEKs (ERK1/2 kinases) are also activated by RANKL; however, inhibition of ERK activity by a MEK inhibitor did not suppress osteoclastogenesis (Matsumoto *et al.*, 2000) but rather potentiated it (Hotokezaka *et al.*, 2002), suggesting that the ERK pathway negatively regulates osteoclastogenesis. Although mice with *JNK1/2/3* genes individually inactivated are viable and do not display obvious bone abnormalities, an *in vitro* study has indicated that at least JNK1 is involved, albeit partially (David *et al.*, 2002). More detailed *in vivo* analyses are needed to obtain conclusive evidence on the role of the MAPKs in osteoclastogenesis.

Costimulatory Signals for RANK

It has been suggested that the RANK and M-CSF receptor together transmit signals that are sufficient for osteoclastogenesis (Boyle *et al.*, 2003). In addition, a novel type of receptor was identified in osteoclasts. OSCAR is an immunoglobulin-like receptor involved in the cell–cell interaction between osteoblasts and osteoclasts (Kim *et al.*, 2002). OSCAR associates with an adaptor molecule, FcRγ (Koga *et al.*, 2004; Merck *et al.*, 2004), which harbors an immunoreceptor tyrosine-based activation motif (ITAM) critical for the activation of calcium signaling in immune cells (Reth, 1989). Another ITAM-harboring adaptor, DAP12, has been reported to be involved in the formation and function of osteoclasts (Kaifu *et al.*, 2003). Notably, mice doubly deficient in FcRγ and DAP12 exhibit severe osteopetrosis owing to the differentiation blockade of osteoclasts, demonstrating that the immunoglobulin-like receptors associated with FcRγ and DAP12 are essential for osteoclastogenesis (Koga *et al.*, 2004; Mocsai *et al.*, 2004). These receptors include OSCAR, triggering receptor expressed in myeloid cells (TREM)-2, signal-regulatory protein (SIRP) β1, and paired immunoglobulin-like receptor (PIR)-A, although the ligands and exact function of each of these receptors remain to be determined. The importance of the ITAM-harboring adaptors and the receptors associated with them in bone metabolism is also underscored by reports that mutations in the *DAP12* and *TREM-2* genes cause severe skeletal and behavior abnormalities known as Nasu–Hakola disease (Paloneva *et al.*, 2000; Paloneva *et al.*, 2002).

ITAM-mediated signals cooperate with RANK to stimulate calcium signaling through ITAM phosphorylation and the resulting activation of Syk and PLCγ. Therefore, these signals should properly be called costimulatory signals for RANK (Fig. 3). Initially characterized in natural killer and myeloid cells, the immunoglobulin-like receptors

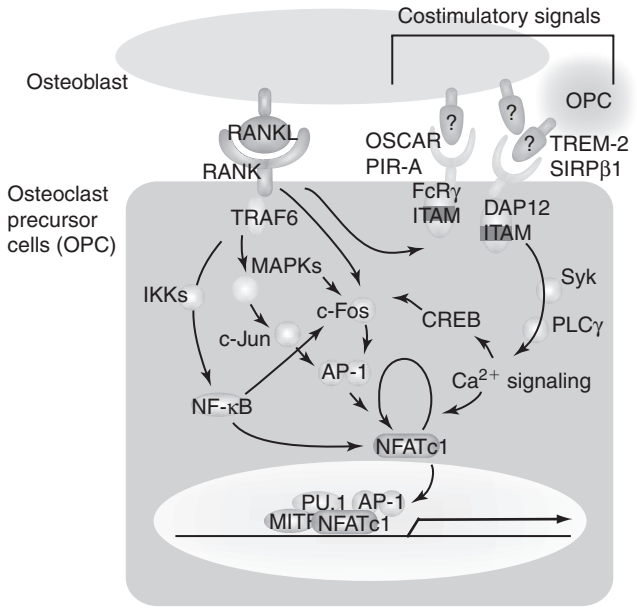

FIGURE 3 Cooperation of RANK and immunoreceptor tyrosine-based activation motif (ITAM) signals in osteoclastogenesis. RANK activates the NF-κB and c-Fos pathways that stimulate the induction of NFATc1. Immunoglobulin-like receptors associate with Fc receptor common γ subunit (FcRγ) and DNAX-activating protein 12 (DAP12), both of which contain the ITAM motif. RANK and ITAM signaling cooperate to phosphorylate phospholipase Cγ(PLCγ) and activate calcium signaling, which is critical for the autoamplification of NFATc1.

associated with FcRγ or DAP12 are thus identified as unexpected but nevertheless essential partners of RANK during osteoclastogenesis (Koga *et al.*, 2004; Baron, 2004; Takayanagi, 2005). It is not fully understood how RANK can specifically induce osteoclastogenesis in cooperation with ITAM signaling, but it is partly explained by the observation that phosphorylation of ITAM is upregulated by RANKL (Koga *et al.*, 2004). In addition, RANKL stimulation results in an increased expression of immunoreceptors such as OSCAR, thereby augmenting the ITAM signal (Kim *et al.*, 2005; Kim *et al.*, 2005). It is also conceivable that RANK activates an as yet unknown pathway that specifically synergizes with or upregulates ITAM signaling. Recent studies showed that RGS10 is activated by RANK and mediates calcium oscillation. We have recently unpublished results suggesting that Tec family tyrosine kinases such as Btk and Tec are activated by RANK and are involved in the phosphorylation of PLCγ (Shinohara *et al.*, 2008).

The role of inhibitory type receptors containing immunoreceptor tyrosine-based inhibitory motif (ITIM) in osteoclast differentiation remains elusive, but osteoclastogenesis is enhanced in mice lacking phosphatases such as Src homology (SH)-2-containing protein tyrosine phosphatase (SHP)-1 (Aoki *et al.*, 1999; Umeda *et al.*, 1999) or SH-2-containing inositol 5′,-phosphatase (SHIP)-1 (Takeshita *et al.*, 2002), which counterbalance the ITAM signal in the immune system.

Calcium/calmodulin signaling is related not only to phosphatases such as calcineurin, but also to kinases, including calcium/calmodulin-dependent kinases. These kinases are thus also activated during RANKL-induced osteoclastogenesis and participate in the activation of RANK signaling mainly by upregulating c-Fos expression through CREB (Sato *et al.*, 2006). The regulation of c-Fos has been enigmatic, but recent studies suggest that RANK induction of c-Fos is under the control of multiple transcriptional regulators including NF-κB (Yamashita *et al.*, 2007), CREB (Sato *et al.*, 2006), and PPARγ (Wan *et al.*, 2007) as well as MAPKs.

CONCLUSION

The discovery of RANKL and RANK has greatly enriched our understanding of the mechanisms of osteoclast differentiation, activation, and survival. Much attention and effort have been paid to RANK signaling from both the biological and therapeutic points of view. Despite this progress, it is still not clear why only RANK induces osteoclastogenesis. The signaling events activated by RANK are integrated by NFATc1, but nothing is known about the downstream molecules that orchestrate the late phase of the differentiation process. Therefore, much work remains to be done in this field, but the tremendous effort entailed will surely be rewarded because the rationality of targeting RANK signaling in therapy has already been demonstrated by the efficacy of anti-RANKL antibody in several human trials against bone diseases (McClung *et al.*, 2006).

INTRODUCTION

Skeletal growth and repair during adult life occurs via bone remodeling, a coordinated and tightly regulated process. The maintenance of normal bone mass depends on maintaining the appropriate balance between bone formation and bone resorption. The current view on normal bone remodeling is that the processes of bone resorption and formation are tightly coupled, so that a change in either usually leads to a subsequent compensating change in the other (Martin and Sims, 2005). However, normal age-related physiological changes and certain pathological conditions result in excessive bone resorption, leading to osteoporosis.

Bone resorption is carried out by osteoclasts, which are multinucleated, terminally differentiated cells derived from the monocyte/macrophage lineage (Roodman, 1999; Suda *et al.*, 1999; Teitelbaum, 2000). Each bone remodeling cycle begins with a resorption phase, in which osteoclasts are recruited to a remodeling site on the bone surface, where the cells excavate bone surface over a period of 2 to 4 weeks. This is followed by a reversal phase, when the osteoclasts move away from the resorption site and mononuclear precursors are recruited and differentiated into osteoblasts. During the subsequent 2- to 4-month-long formation phase, mature osteoblasts deposit an organic matrix that then becomes mineralized (Grey and Reid, 2005; Rodan, 1998).

The rate of bone resorption varies as a function of changes in both the number and activity of osteoclasts, the only cells capable of resorbing bone (Baron, 1989). Osteoclastogenesis is controlled by the proliferation and homing of the progenitors to bone and their differentiation and fusion to form multinucleated cells. A comprehensive review of the regulation of osteoclast generation has been presented in a previous chapter.

Osteoclast function starts with adhesion to the bone matrix, which initiates a polarization of the cell that involves cytoskeletal reorganization and the formation of a tight sealing zone that is enriched in filamentous actin and encloses the resorption lacuna (Duong *et al.*, 2000). The cytoskeletal organization associated with osteoclastic bone resorption is also discussed in another chapter. Within the area surrounded by the sealing zone, targeted insertion of intracellular transport vesicles into the plasma membrane forms a deeply folded membrane, the ruffled border, which secretes protons and hydrolytic enzymes into the resorption lacuna. The acidification of the lacuna by the secreted protons demineralizes the bone matrix, exposing the organic components, primarily collagen type I, which are subsequently degraded by the secreted lysosomal proteolytic enzymes (Baron *et al.*, 1988, 1985; Väänänen *et al.*, 2000; Fig. 1).

Current antiresorptive therapies, which predominantly target osteoclast development and survival, include bisphosphonates, selective estrogen receptor modulators (SERMs),

Principles of Bone Biology, 3rd Edition

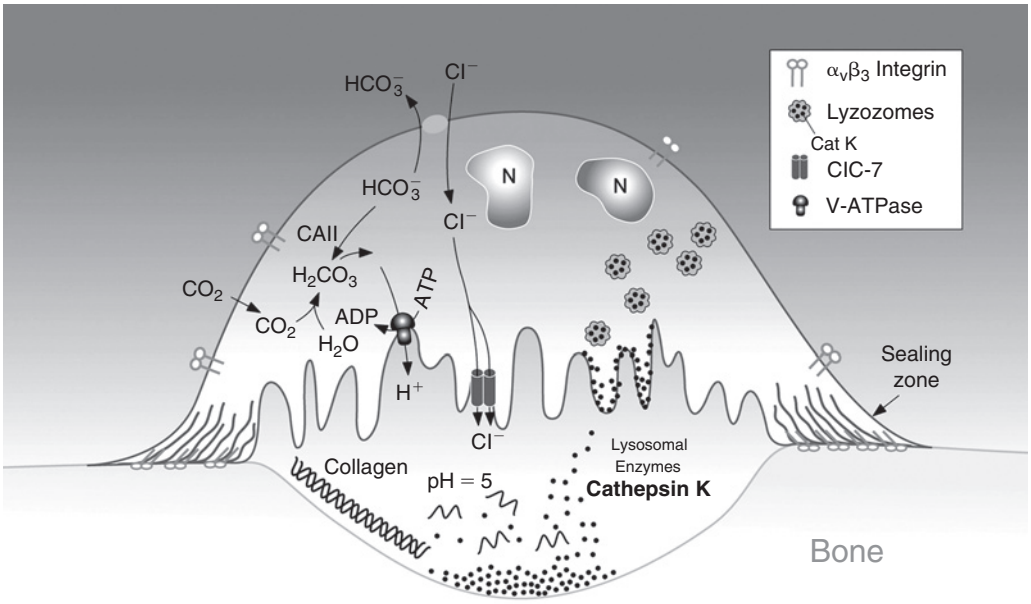

FIGURE 1 Schematic illustration of a bone-resorbing osteoclast. Several targets are genetically and pharmacologically validated as rate-limiting in regulating osteoclast bone resorption activity including the adhesion receptor $\alpha_v\beta_3$ integrin for osteoclast polarization and movement; carbonic anhydrase II (CAII), V-ATPase, and chloride channel CIC-7 for acidification; and cathepsin K for the removal of organic bone matrix in the resorption lacunae.

and anti–receptor activator of NFκB (RANK) ligand (Boyce *et al.*, 2006; Grey and Reid, 2005; Rodan and Martin, 2000). However, pharmacological or genetic methods used to disrupt osteoclast function (Rodan and Martin, 2000; Teitelbaum, 2000) identified many molecules that are involved either in the degradation of bone matrix proteins such as cathepsin K or metalloproteinases (MMPs), or in the regulation of acidification, including carbonic anhydrase type II, tartrate-resistant acid phosphatase (TRAP), the a3 subunit of the vacuolar H^+-ATPase, and the CIC-7 chloride channel, which can be targeted for therapeutic regulation of osteoclast activity (Frattini *et al.*, 2000; Kornak *et al.*, 2001; Li *et al.*, 1999; Scimeca *et al.*, 2000). A new generation of antiresorptive agents has been developed to specifically interfere with osteoclast bone-resorbing activity (Boyce *et al.*, 2006; Rodan and Martin, 2000; Vasiljeva *et al.*, 2007). These antiresorptives include agents that directly compromise osteoclast activation by modulating cellular polarization and secretion, including calcitonin, $\alpha_v\beta_3$ integrin antagonists, and Src kinase inhibitors, as well as agents that either directly inhibit acidification of the resorption lacunae by blocking the osteoclast-specific subtype of carbonic anhydrase type II or the V-ATPase or the CIC-7 chloride channel, or block degradation of bone matrix proteins, such as inhibitors of cathepsin K. This chapter discusses the signal transduction pathways mediated by integrin and calcitonin receptor in the context of their regulation of cytoskeletal reorganization during osteoclastic bone resorption, as well as the role of cathepsin K in bone resorption.

ADHESION AND CYTOSKELETAL ORGANIZATION IN OSTEOCLASTS—$\alpha_v\beta_3$ INTEGRINS

Osteoclastic bone resorption is a process requiring physical intimacy between resorptive cell and bone matrix. Thus, cell matrix attachment molecules, particularly integrins, play a central role in the capacity of osteoclasts to degrade bone (Carron *et al.*, 2000; Feng *et al.*, 2001). Integrins, a superfamily of heterodimeric transmembrane receptors, mediate cell–matrix and cell–cell interaction. Integrin-mediated adhesion and signaling regulate a variety of cell processes (Clark and Brugge, 1995; Giancotti and Ruoslahti, 1999; Schlaepfer *et al.*, 1999). In addition to cell adhesion, integrin assembly also organizes extracellular matrices, modulates cell shape changes, and participates in cell spreading and motility (Wennerberg *et al.*, 1996; Wu *et al.*, 1996).

Integrin signaling is bidirectional. Extracellular matrix molecules interact with the integrin external domain and stimulate outside-in signaling that induces changes in cytoskeletal organization and intracellular signaling, whereas inside-out signaling induced by the interaction with cytoskeletal proteins or actions of intracellular signaling effectors prompt conformational changes in the integrin's ligand binding site (Takagi *et al.*, 2002) that alter its affinity, thereby modulating its binding capabilities and, ultimately intracellular events (Butler *et al.*, 2003; Geiger *et al.*, 2001; Pelletier *et al.*, 1995).

$\alpha_v\beta_3$-Mediated Osteoclast Function

Adhesion of osteoclasts to the bone surface involves the interaction of integrins with the extracellular matrix proteins within bone. Bone consists mainly of type I collagen (>90%) and of non-collagenous proteins interacting with a mineral phase of hydroxyapatite. Osteoclasts express very high levels of the vitronectin receptor, $\alpha_v\beta_3$ (Duong *et al.*, 2000; Horton, 1997; Rodan and Martin, 2000). Mammalian osteoclasts also express lower levels of collagen/laminin receptor $\alpha_2\beta_1$ and the vitronectin/fibronectin receptor $\alpha_v\beta_1$, whereas osteoclast precursors express $\alpha_2\beta_2$ and $\alpha_v\beta_5$ (Athanasou and Quinn, 1990; Lane *et al.*, 2005). $\alpha_v\beta_3$, like all members of the α_v integrin family, recognizes the amino acid Arg-Gly-Asp (RGD), which is present in a variety of bone matrix proteins, including osteopontin and bone sialoprotein. Osteoclasts attach to and spread on these substrates in an RGD-dependent manner and, most important, competitive ligands arrest bone resorption *in vivo* (Engleman *et al.*, 1997; Murphy *et al.*, 2005; Yamamoto *et al.*, 1998). Additionally, osteoclastic bone resorption *in vitro* can be inhibited by RGD-containing peptides and disintegrins or by antibodies that block $\alpha_v\beta_3$ binding.

Whereas $\alpha_v\beta_3$ is abundantly expressed on mature osteoclasts and is a marker of their phenotype (McHugh *et al.*, 2000), it is absent in marrow macrophages, which express $\alpha_v\beta_5$. With exposure to receptor activator of NFκB ligand (RANKL), the β_5 subunit disappears and is replaced by β_3 (Ross and Teitelbaum, 2005). Ovariectomy of $\beta_5^{-/-}$ mice induces increased osteoclastogenesis and more bone loss than in their wild-type counterparts (Lane *et al.*, 2005). Thus, although $\alpha_v\beta_3$ and $\alpha_v\beta_5$ are compositionally similar, they are differentially expressed in response to RANKL and exert different effects on osteoclast function.

Attachment of $\alpha_v\beta_3$ to the matrix induces signaling events that include changes in intracellular calcium, protein tyrosine phosphorylation, and cytoskeletal reorganization (Duong *et al.*, 1998; Duong and Rodan, 2000; Eliceiri *et al.*, 1998; Faccio *et al.*, 2003; Sanjay *et al.*, 2001b). The importance of $\alpha_v\beta_3$ in osteoclast function is underscored by the fact that the targeted disruption of the β_3 integrin subunit results in a progressive increase in the bone mass due to osteoclast dysfunction. Osteoclasts isolated from these $\beta_3^{-/-}$ mice fail to spread, do not form actin rings, and have abnormal ruffled membranes and exhibit reduced bone resorption activity *in vivo* (McHugh *et al.*, 2000). In echistatin-treated mice, where bone resorption was inhibited, the number of osteoclasts on the bone surface was unchanged rather than decreased, suggesting that osteoclast inhibition by $\alpha_v\beta_3$ integrin antagonists is not due to the detachment of osteoclasts from the bone surface (Masarachia *et al.*, 1998; Yamamoto *et al.*, 1998). Consistent with this observation, the number of osteoclasts in the bones of $\beta_3^{-/-}$ mice was normal, but the formation of the ruffled border was impaired (McHugh *et al.*, 2000). These data suggest, as indicated by the analysis of the integrin repertoire of osteoclasts, that in the absence of functional $\alpha_v\beta_3$ receptors, adhesion per se is not compromised and that other integrins, or different attachment proteins, participate in this process. However, some unique and not completely characterized signaling properties of $\alpha_v\beta_3$ may well be critical for cell motility and for the formation of the ruffled border (McHugh *et al.*, 2000; Nakamura *et al.*, 2001; Sanjay *et al.*, 2001b). Thus, $\alpha_v\beta_3$ plays a role in the adhesion and spreading of osteoclasts on bone and the subsequent resorptive process by transmitting bone matrix–derived signals, ultimately activating intracellular events that regulate cytoskeletal reorganization that are essential for osteoclast migration and polarization.

Research has focused on characterizing the $\alpha_v\beta_3$-regulated signaling cascade and identifying structural proteins required for this cytoskeletal reorganization. Studies using both genetic and biochemical approaches, such as immunolocalization and co-precipitation, have partially elucidated the $\alpha_v\beta_3$-induced signaling in osteoclasts, identifying complexes that includes Pyk2, Src, Cbl, dynamin, and Syk as potentially important components.

Pyk2 Couples $\alpha_v\beta_3$ Integrins to Src in Osteoclasts

The engagement of the matrix by either $\alpha_v\beta_3$ or $\alpha_v\beta_2$ initiates a signaling mechanism in osteoclasts and osteoclast precursors that activates the nonreceptor tyrosine kinase, Pyk2 (Duong *et al.*, 1998; Faccio *et al.*, 2003; Lakkakorpi *et al.*, 2003; Miyazaki *et al.*, 2004; Nakamura *et al.*, 1998; Sanjay *et al.*, 2001b), a member of the focal adhesion kinase (FAK) family, by a mechanism that involves an increase in cytosolic free Ca^{2+} and the binding of Pyk2 to the cytoplasmic domain of the β integrin subunit (Duong and Rodan, 2000; Faccio *et al.*, 2003; Pfaff and Jurdic, 2001; Sanjay *et al.*, 2001b). Pyk2 is highly expressed in osteoclasts (Duong *et al.*, 1998), where it colocalizes with the podosomes in osteoclasts plated on glass and in sealing zones of resorbing osteoclasts on bone (Duong *et al.*, 1998; Gil-Henn *et al.*, 2007; Sanjay *et al.*, 2001b; Zhang *et al.*, 2002).

Pyk2 is required for normal osteoclast function. $Pyk2^{-/-}$ mice are osteopetrotic, and $Pyk2^{-/-}$ osteoclasts and osteoclasts infected with Pyk2 antisense-expressing adenovirus resorb bone less efficiently and exhibit defects in cell adhesion, spreading, and sealing zone organization (Duong *et al.*, 2001; Gil-Henn *et al.*, 2007; Sims *et al.*, 1999). Following integrin engagement, integrin-induced phosphorylation of Pyk2 Tyr^{402} creates a binding site for Src, another nonreceptor tyrosine kinase, and the Src-associated adaptor/ubiquitin ligase Cbl (Duong *et al.*, 1998; Lakkakorpi *et al.*, 2003; Miyazaki *et al.*, 2004).

Pyk2's kinase activity, Tyr^{402}, and focal adhesion targeting (FAT) domain, which targets Pyk2 to adhesion complexes

(Schaller and Sasaki, 1997), are all required to one degree or another for normal Pyk2 function in osteoclasts. Mutating Tyr^{402} or disabling the catalytic site reduces but does not eliminate the ability of recombinant Pyk2 to restore the bone-resorbing activity of $Pyk2^{-/-}$ osteoclasts, while deleting the FAT domain essentially eliminates the normalization of bone resorbing activity (Gil-Henn *et al.*, 2007). Interestingly, $Pyk2^{Y402F}$ has a powerful dominant-negative effect when overexpressed in wild-type osteoclasts, while kinase-dead Pyk2 has little negative effect (Lakkakorpi *et al.*, 2003; Miyazaki *et al.*, 2004), notwithstanding the similar efficacies of these two mutants in restoring $Pyk2^{-/-}$ osteoclast bone resorbing activity (Gil-Henn *et al.*, 2007).

Deleting the β_3 integrin gene or disabling the Pyk2-binding site on β_3 integrin results in a dramatic reduction in the attachment-induced interaction of Src with Pyk2 and Src and Cbl phosphorylation (Faccio *et al.*, 2003), indicating that Pyk2 couples $\alpha_v\beta_3$ to the Src-Cbl signaling cascade (discussed later). Interestingly, attachment-induced phosphorylation of Pyk2 Tyr^{402} in osteoclasts generated *in vitro* is affected more by eliminating the β_2 integrin than by eliminating the β_3 integrin (Faccio *et al.*, 2003), suggesting that Pyk2 performs both Src/Cbl-dependent and Src/Cbl-independent attachment-induced functions in osteoclasts downstream of different integrins, and that a yet-to-be-identified integrin-specific factor regulates the binding of Src to Pyk2 phosphotyrosine 402.

The binding of Src by Pyk2 is also regulated by the large GTPase dynamin, which reduces the phosphorylation level of Pyk2 Tyr^{402} by an as yet incompletely characterized mechanism, thereby eliminating the Src binding site (Bruzzaniti *et al.*, 2005a). The process involves the binding and/or hydrolysis of GTP by dynamin and appears to be induced by Src-catalyzed phosphorylation of dynamin, suggesting that the process acts as a feedback loop by which Src limits the duration of the Pyk2-Src association.

Pyk2 also associates with phospholipase C-γ (Nakamura *et al.*, 2001), leupaxin (Gupta *et al.*, 2003), $p130^{Cas}$ (Lakkakorpi *et al.*, 1999), and gelsolin (Wang *et al.*, 2003) in osteoclasts and promotes the formation of the peripheral podosome belt by a microtubule-dependent mechanism (Gil-Henn *et al.*, 2007). Both $Pyk2^{Y402F}$ and kinase-dead Pyk2 normalize podosome belt formation in $Pyk2^{-/-}$ osteoclasts but not bone resorption, indicating that Src-Pyk2 association is required for bone resorption even when podosome organization is normal. Thus, Pyk2's ability to recruit Src and its associated proteins to sites of $\alpha_v\beta_3$ integrin activation appears to be a required function of Pyk2 in coupling downstream of activated $\alpha_v\beta_3$.

c-Src Regulates $\alpha_v\beta_3$-Mediated Cytoskeletal Organization and Cell Motility

Src is a key signaling effector that couples $\alpha_v\beta_3$-initiated signals to multiple signaling pathways and cellular responses (Faccio *et al.*, 2003; Miyazaki *et al.*, 2004; Sanjay *et al.*, 2001b; Zou *et al.*, 2007). Src has been reported to play multiple roles in integrin signaling, in the regulation of the cell cytoskeleton and in cell migration (Alper and Bowden, 2005; Frame, 2004; Playford and Schaller, 2004). $Src^{-/-}$ mice are osteopetrotic (Soriano *et al.*, 1991) to a greater extent than the $Pyk2^{-/-}$ mice, and mice that lack both Src and Pyk2 are more osteopetrotic than either the $Src^{-/-}$ or the $Pyk2^{-/-}$ mice (Sims *et al.*, 1999). Src appears to play a unique role in osteoclasts, because the absence of other Src family kinases that are normally expressed in osteoclasts (c-Fyn, c-Yes, Hck, and Fgr; Horne *et al.*, 1992; Lowell *et al.*, 1996) fails to produce osteopetrosis (Lowell *et al.*, 1996; Stein *et al.*, 1994), although $Src^{-/-}{\cdot}Hck^{-/-}$ double mutant mice are significantly more osteopetrotic than the $Src^{-/-}$ animals (Lowell *et al.*, 1996), suggesting that Hck may partially compensate for the absence of Src. Re-expressing Src in $Src^{-/-}$ osteoclasts *in vitro* restores bone-resorbing activity (Miyazaki *et al.*, 2004), and targeting re-expression of Src to osteoclasts in the $Src^{-/-}$ mouse reverses the osteopetrotic phenotype (Schwartzberg *et al.*, 1997).

$Src^{-/-}$ osteoclasts fail to spread normally on extracellular matrix, exhibit abnormal organization of F-actin-containing adhesion complexes, and are significantly less mobile than wild-type osteoclasts (Lakkakorpi *et al.*, 2001; Sanjay *et al.*, 2001b). The notable absence of a ruffled border in $Src^{-/-}$ osteoclasts (Boyce *et al.*, 1992) suggests that Src also contributes to the regulation of exocytic and/or endocytic vesicle trafficking in osteoclasts, as it appears to do in other types of cells (Ahn *et al.*, 1999; Foster-Barber and Bishop, 1998). The absence of the ruffled border could also be a consequence of the defects in attachment and motility, because attachment to the bone surface and establishment of the sealing zone must precede the formation of the ruffled border and secretion into the resorption compartment. The formation of the ruffled border is therefore likely to be induced by signals emanating from attachment complexes in the sealing zone (outside-in signaling), which may require Src.

Src activation is associated with the formation of the podosome adhesion structures (Tarone *et al.*, 1985) that characterize osteoclasts and other highly motile cells (Linder and Aepfelbacher, 2003; Marchisio *et al.*, 1988, 1984). Podosomes contain a dense central column of F-actin, the actin core, surrounded by a more loosely organized F-actin meshwork called the podosome cloud (Collin *et al.*, 2006; Destaing *et al.*, 2003). Numerous adaptor and regulatory proteins, including Pyk2, Src, Cbl, paxillin, vinculin, integrins, talin, dynamin2, the Arp2/3 complex, Wasp, and cortactin, colocalize with the podosome core and/or cloud (Bruzzaniti *et al.*, 2005b; Destaing *et al.*, 2003; Luxenburg *et al.*, 2006b; Ochoa *et al.*, 2000; Pfaff and Jurdic, 2001; Tehrani *et al.*, 2006). Actin polymerizes continuously into the podosome core and cloud throughout

the brief (2- to 4-minute) life span of the podosome (Destaing *et al.*, 2003), revealing the dynamic nature of these specialized attachment structures.

Deletion or inhibition of Src leads to reduced osteoclast motility and alterations of the osteoclast cytoskeleton (Sanjay *et al.*, 2001b), including fewer podosomes, a reduced rate of actin polymerization within the podosome (measured as the recovery from photobleaching), and an increased podosome life span (Destaing *et al.*, 2003, 2008; Luxenburg *et al.*, 2006b). Src's tyrosine kinase activity and adaptor function are both required for normal podosome organization and dynamics, because neither kinase-dead Src nor a Src mutant with both the SH2 and SH3 binding domains disabled rescue podosome function (Destaing *et al.*, 2008; Luxenburg *et al.*, 2006b). Thus, Src is involved in regulating multiple aspects of podosome structure, organization, and dynamics. Pyk2 also modulates the podosome organization. The rate of actin polymerization within podosomes of Pyk2$^{-/-}$ osteoclasts is reduced, with the time of recovery from photobleaching increasing by a factor of 2, although podosome life span is largely unaffected (Gil-Henn *et al.*, 2007), suggesting that Src may regulate actin polymerization in cooperation with Pyk2 but regulate podosome life span by a Pyk2-independent mechanism.

The key Src substrates in the regulation of podosome assembly and function remain to be identified. Src phosphorylates several actin regulatory proteins that contribute to podosome formation and functions, including N-Wasp (Park *et al.*, 2005; Torres and Rosen, 2003), dynamin2 (Ochoa *et al.*, 2000; Werbonat *et al.*, 2000), and cortactin (Lua and Low, 2005; Martinez-Quiles *et al.*, 2004). Silencing cortactin expression in osteoclasts inhibits podosome formation (Tehrani *et al.*, 2006), and mutating cortactin's Src-phosphorylated tyrosine residues causes defective podosome formation (Tehrani *et al.*, 2006) and affects podosome life span (Luxenburg *et al.*, 2006a). Src could therefore regulate actin polymerization and life span of podosomes at least in part by regulating cortactin activity. Src could also modulate podosome activity by promoting the dynamin-induced dephosphorylation of Pyk2 (discussed earlier) or by regulating the interaction of the PI(4,5)P2 modifying enzyme PIPKI-γ90 with talin (Lee *et al.*, 2005).

The Role(s) of Cbl Downstream of the Integrin-Pyk2-Src Complex

As noted previously, the Pyk2-Src signaling complex that forms in response to the engagement of $\alpha_v\beta_3$ to the matrix includes the adaptor protein Cbl, which is phosphorylated by Src (Sanjay *et al.*, 2001b; Tanaka *et al.*, 1996). Cbl and the highly homologous Cbl-b also function as ubiquitin ligases within multiprotein signaling complexes, targeting receptor tyrosine kinases and other signaling proteins for ubiquitylation (Sanjay *et al.*, 2001a; Swaminathan and Tsygankov, 2006; Thien and Langdon, 2001). The single deletions of either the Cbl or the Cbl-b gene cause relatively mild but distinctly different bone phenotypes (Chiusaroli *et al.*, 2002, 2003; Murphy *et al.*, 1998).

Deletion of Cbl induces a mild reduction in bone resorption that is transiently detected primarily during endochondral bone formation at the stage of formation of the marrow cavity and is thought to be the result of reduced osteoclast motility, observed both *in vitro* and *in vivo* (Chiusaroli *et al.*, 2003; Sanjay *et al.*, 2001b). The reduced osteoclast motility may be due in part to the loss of Cbl-mediated ubiquitylation, because expression on a Cbl$^{-/-}$ background of a Cbl with a disabling point mutation in the RING domain (c-Cbl$^{C379A/-}$; Thien *et al.*, 2005) results in osteoclasts with reduced motility, and the motility defect is rescued by re-expressing wild-type c-Cbl (Itzstein *et al.*, 2006). Thus, Cbl-dependent mechanisms promote the motility of osteoclasts *in vitro*, consistent with the role of Cbl in the regulation of cell adhesion, spreading, and migration via mechanisms that involve Src and phosphatidylinositol 3-kinase (PI3K; Feshchenko *et al.*, 1999; Meng and Lowell, 1998; Scaife and Langdon, 2000) and contribute to the osteoclast's ability to invade and resorb bone and mineralized cartilage *in vivo* (Chiusaroli *et al.*, 2003). The moderate and transient Cbl$^{-/-}$ bone phenotype suggests that Cbl-b might largely compensate for the absence of c-Cbl.

The bone phenotype of Cbl-b$^{-/-}$ mice is distinctly different from the Cbl$^{-/-}$ phenotype and more pronounced, with significantly reduced bone mass (Chiusaroli *et al.*, 2002). Bone formation is unaltered in these mice, but urine deoxypyridinoline crosslinks, a marker of bone resorption, are increased, as is *in vitro* bone resorbing activity (Sanjay *et al.*, 2004), suggesting that the osteopenia results from increased osteoclast activity. Expressing recombinant Cbl-b in the Cbl-b$^{-/-}$ osteoclasts restores *in vitro* resorbing activity to normal via a mechanism that requires both the phosphotyrosine-binding TKB domain and the ubiquitin conjugating enzyme-binding RING domain, whereas overexpressing c-Cbl has no effect (Nakajima *et al.*, 2006). These different phenotypes suggest that Cbl and Cbl-b each perform some unique functions in osteoclasts, presumably as a consequence of the differences in the specific regulatory proteins that bind to each Cbl protein.

In contrast to the distinct but relatively mild phenotypes of the single Cbl gene deletions, the simultaneous depletion of both Cbl and Cbl-b disrupts the podosome belt, reduces migration and bone resorption, and increases osteoclast apoptosis (Purev, unpublished observation), indicating that these homologous Cbl proteins also redundantly perform certain key functions in osteoclasts, as they do in other cells (Naramura *et al.*, 2002). These common functions of Cbl and Cbl-b may be required for the Src-dependent signaling mechanisms downstream of integrin activation that are responsible for the reduced bone resorbing activity of Src$^{-/-}$ osteoclasts. The fact that overexpressing Cbl

proteins with reduced binding to Src or PI3K reduces the bone-resorbing activity of wild-type osteoclasts (Miyazaki *et al.*, 2004; Sanjay *et al.*, 2006), in contrast to the effects of deleting either Cbl (no change) or Cbl-b (increased resorption), supports this possibility.

$\alpha_v\beta_3$-Dependent Activation of Phosphatidylinositol 3-Kinase

Phosphatidylinositol 3-kinase (PI3K) is a key signaling effector that associates with activated $\alpha_v\beta_3$ and Src in osteoclasts (Hruska *et al.*, 1995). Activation of $\alpha_v\beta_3$ increases PI3K activity and its association with gelsolin-containing cytoskeleton complexes (presumably the podosomes; Chellaiah *et al.*, 1998; Hruska *et al.*, 1995). Inhibiting PI3K disrupts the actin ring and interferes with osteoclast attachment, spreading, and bone-resorbing activity (Lakkakorpi *et al.*, 1997; Nakamura *et al.*, 1995). In adhering and spreading osteoclasts and macrophages, PI3K is activated and translocates to the membrane and/or actin cytoskeleton (Lakkakorpi *et al.*, 1997; Meng and Lowell, 1998). Attachment of macrophages to the matrix induces Src family kinase-dependent phosphorylation of Cbl and Cbl's association with PI3K (Meng and Lowell, 1998). Src-catalyzed phosphorylation of Cbl Tyr^{731} creates a binding site for PI3K (Ueno *et al.*, 1998). Overexpressing Cbl^{Y731F}, which is unable to bind to PI3K, reduces *in vitro* bone resorbing activity of osteoclasts by 80% (Miyazaki *et al.*, 2004) and fails to restore either the basal or the M-CSF-induced motility of Cbl-deficient osteoclasts, in contrast to the complete rescue by wild-type Cbl (Sanjay, unpublished observation), suggesting that the binding of PI3K to Cbl is required for normal osteoclast migration and bone resorption.

$\alpha_v\beta_3$-Dependent Activation of Syk and Vav

Another more recently reported signaling mechanism downstream of the β_3 integrin-induced activation of Src involves the nonreceptor tyrosine kinase Syk and the Rho family guanine nucleotide exchange factor Vav (Zou *et al.*, 2007). Following the RANK ligand-induced phosphorylation of immunoreceptor tyrosine-based activation motifs (ITAMs) on DAP12 and FcRγ, two receptors that are required for the fusion of mononuclear preosteoclasts to form active multinucleated osteoclasts (Koga *et al.*, 2004; Mocsai *et al.*, 2004), Syk binds via its tandem SH2 domains to the phosphorylated ITAMs (Mocsai *et al.*, 2004). Integrin engagement induces the activation of Src, which then binds to and phosphorylates the ITAM-associated Syk, activating Syk (Zou *et al.*, 2007). The activated Syk in turn phosphorylates and activates Vav3 (and possibly Vav1 and Vav2, which are also expressed in osteoclasts) (Faccio *et al.*, 2005). The Vav proteins are known to regulate cytoskeleton organization by activating Rho family GTPases, especially Rac, as well as by Rho family-independent mechanisms (Hornstein *et al.*, 2004). The importance of this pathway in osteoclasts is indicated by the findings that deletion of any of the genes that encode DAP12, FcRγ, Syk, and Vav3 interferes with the formation of multinuclear osteoclasts and bone resorption (Faccio *et al.*, 2005; Kaifu *et al.*, 2003; Koga *et al.*, 2004; Mocsai *et al.*, 2004).

Although Cbl proteins have not been demonstrated to modulate this signaling pathway in osteoclasts, they interact with and downregulate Syk and Vav in a number of cellular systems (Bustelo *et al.*, 1997; Lupher *et al.*, 1998; Miura-Shimura *et al.*, 2003). Interestingly, the deletion of Cbl-b uncouples tyrosine phosphorylation of Vav1 in T-cells from the requirement for co-stimulation by CD28 (Bachmaier *et al.*, 2000; Chiang *et al.*, 2000), suggesting that a similar effect of the absence of Cbl-b on Vav activation downstream of DAP12 and FcRγ in osteoclast precursors and mature osteoclasts might contribute to the enhanced osteoclast activity and low bone mass in the $Cbl\text{-}b^{-/-}$ mice.

Thus, integrins expressed by the osteoclast, particularly the $\alpha_v\beta_3$ integrin, play critical roles in osteoclast biology. These include adhesion itself as well as mediating outside-in signaling, which ensures proper organization of the cytoskeleton, and inside-out signaling, which modulates the affinity of the receptors for their substrates. These two regulatory modes are essential in ensuring the assembly and disassembly of the adhesion structures (podosomes), a cyclic process that is necessary for efficient cell motility.

CALCITONIN AND THE CYTOSKELETON

Because of its potent inhibitory effects on osteoclast activity, calcitonin has long been recognized as a potential therapeutic agent for the treatment of diseases that are characterized by increased bone resorption, such as osteoporosis, Paget's disease, and late-stage malignancies. Signaling mechanisms downstream of the calcitonin receptor have therefore been of great interest. A comprehensive discussion of calcitonin-induced signaling appears elsewhere in this volume, and we focus here on what is known of the interaction of calcitonin-activated signaling events with attachment-related signaling.

In situ, calcitonin causes reduced contact of osteoclasts with the bone surface and altered osteoclast morphology (Holtrop *et al.*, 1974; Kallio *et al.*, 1972), whereas osteoclasts treated with calcitonin *in vitro* retract and become less mobile (Chambers and Magnus, 1982; Chambers *et al.*, 1984; Zaidi *et al.*, 1990). These effects suggest that some of the key targets of calcitonin signaling are involved in integrin-related signaling, cell attachment, and cytoskeletal function.

The calcitonin receptor, a G protein–coupled receptor that has been cloned from several species and cell types, couples to multiple heterotrimeric G proteins (G_s, $G_{i/o}$, and G_q; Chabre *et al.*, 1992; Chen *et al.*, 1998; Force *et al.*, 1992; Shyu *et al.*, 1996, 1999). Because it couples to multiple G proteins, the proximal signaling mechanisms that are activated by calcitonin include many classical GPCR-activated effectors, such as adenylyl cyclase and protein kinase A (PKA); phospholipases C, D, and A2; and protein kinase C (PKC). For technical reasons, much of the initial characterization of signaling downstream of the calcitonin receptor has been conducted in cells other than osteoclasts, particularly cell lines that express recombinant calcitonin receptor. In HEK 293 cells that express the calcitonin receptor, calcitonin induces the phosphorylation and activation of the extracellular signal-regulated kinases, Erk1 and Erk2 (Chen *et al.*, 1998; Raggatt *et al.*, 2000), via mechanisms that involve the $\beta\gamma$ subunits of pertussis toxin-sensitive G_i as well as pertussis toxin-insensitive signaling via phospholipase C, PKC, and elevated intracellular calcium ($[Ca^{2+}]_i$).

Treatment of the calcitonin receptor–expressing HEK 293 cells with calcitonin induces the tyrosine phosphorylation and association of three components of cellular adhesion complexes, FAK, paxillin, and HEF1, a member of the $p130^{Cas}$ family (Zhang *et al.*, 1999). Interestingly, the HEK 293 cells express both HEF1 and $p130^{Cas}$, but only HEF1 is affected by calcitonin treatment. These calcitonin-induced changes are independent of adenylyl cyclase/PKA and of pertussis toxin–sensitive mechanisms and appear to be mediated by the pertussis toxin-insensitive PKC/$[Ca^{2+}]_i$ signaling pathway and to require integrin attachment to the substratum and an intact actin cytoskeleton (Zhang *et al.*, 2000). Calcitonin also induces the phosphorylation of FAK and paxillin in osteoclasts (Zhang *et al.*, 2002), although the calcitonin-induced signaling mechanisms appear to differ to some degree in the osteoclasts and the HEK293 cells. Thus, the calcitonin-induced tyrosine phosphorylation of paxillin and HEF1 in the HEK 293 cells is enhanced by the overexpression of c-Src and strongly inhibited by the overexpression of a dominant negative kinase-dead Src, suggesting that c-Src is required at some point in the coupling mechanism (Zhang *et al.*, 2000). In contrast, the coupling occurs equally well in osteoclast-like cells derived from wild-type and $Src^{-/-}$ mice (Zhang *et al.*, 2002). Similarly, calcitonin treatment of the calcitonin receptor-expressing HEK293 cells increases the phosphorylation of Pyk2, the other member of the FAK family, but reduces Pyk2 phosphorylation in osteoclasts by way of a mechanism that appears to also disrupt attachment complexes and reduce osteoclast attachment (Shyu *et al.*, 2007; Zhang *et al.*, 2002). Finally, calcitonin was recently shown to reduce osteoclast motility, spreading and bone resorbing activity in part by inhibiting calpain activity via a protein kinase C-dependent mechanism (Marzia *et al.*, 2006).

CATHEPSIN K AS A NOVEL ANTIRESORPTIVE TARGET

Degradation of Bone Matrix

Cathepsin K (Cat K) is a member of the CA1 family of lysosomal cysteine proteases. This family comprises 11 human members (cathepsins B, C [J, dipeptidyl peptidase I], F, H, K [O-2], L, O, S, V [L2], W [lymphopain], X [P, Y, Z]), which share a common papain-like structural fold and a conserved active site Cys-Asn-His triad of residues (Rossi *et al.*, 2004; Turk *et al.*, 2001; Vasiljeva *et al.*, 2007; Yasuda *et al.*, 2005). These enzymes are synthesized as preproenzymes and are converted from the catalytically inactive zymogen to the active form in an acidic environment as found in the late endosome or lysosome. Traditionally, cysteine cathepsins were thought to exclusively function as nonspecific proteases in the lysosome. However, there is growing evidence that cathepsins are also secreted in the active form to acidic extracellular compartments. Collectively, cathepsins participate in important physiological as well as pathological processes, including activation of precursor proteins (proenzymes and prohormones), bone remodeling, MHC-II-mediated antigen presentation, keratinocyte differentiation, hair cycle morphogenesis, and apoptosis. They have also been implicated in tumor progression and metastasis, inflammatory diseases, arthrosclerosis, and periodontitis (Lipton, 2005; Stoka *et al.*, 2005; Vasiljeva *et al.*, 2007). The role of cathepsin K in regulating skeletal remodeling and in other bone diseases is discussed here (Lipton, 2005; Vasiljeva *et al.*, 2007; Wang and Bromme, 2005; Yasuda *et al.*, 2005).

Bone is approximately 60% calcium hydroxyapatite and approximately 40% proteins. Collagen type I, which forms trimeric helices that involve all but the extreme N- and C-terminal regions (telopeptides), accounts for about 90% of the bone matrix protein. Both dissolution of minerals and degradation of collagen I are required for normal bone resorption. Early studies on the roles of cysteine proteases in bone matrix degradation examined the effects of various nonselective cysteine protease inhibitors including leupeptin and E-64 (Everts *et al.*, 1988). Treatment of osteoclasts on bone with E-64 results in accumulation of undigested collagen fibrils in late endosome/lysosome vacuoles suggesting an important role of these enzymes in the degradation of matrix collagen (Delaisse *et al.*, 1984). Cat K cDNAs encoding proteins of 329 amino acid residues with 94% sequence homology were cloned from rabbit osteoclast cDNA and human osteoarthritic hip bone cDNA libraries, respectively, and originally designated cathepsin O-2 (Tezuka *et al.*, 1994; Inaoka *et al.*, 1995). Cat K is most closely related to Cat S (48% homology) and most distantly related to Cat B (20% homology; Turk *et al.*, 2001). More recently, Cat K mRNA or protein has been detected in other tissues, including embryonic lung

and thyroid gland, macrophages, synovial fibroblasts, neonatal dermal fibroblasts, and activated chondrocytes, and in breast and prostate tumors (Buhling *et al.*, 2000; Littlewood-Evans *et al.*, 1997; Morko *et al.*, 2004; Runger *et al.*, 2007; Tepel *et al.*, 2000).

Cat K is unique in its ability to cleave at multiple sites within the native collagen trimer in both the nonhelical and the proteolytically resistant helical regions (Kafienah *et al.*, 1998). The human disease characterized by cathepsin K (*CSTK*) gene mutations is known as pyknodysostosis, a rare autosomal-recessive osteochondrodysplasia (Gelb *et al.*, 1996). These patients typically exhibit an osteopetrotic phenotype with skeletal dysplasia, including short stature, skeletal fragility, acro-osteolysis of the distal phalanges, clavicular dysplasia, delayed closure of the cranial sutures, and spondylolysis of the lumbar vertebrae (Schilling *et al.*, 2007). There are at least 15 known mutations in the *CSTK* gene that inactivate Cat K or result in early termination of protein synthesis (Fratzl-Zelman *et al.*, 2004; Gelb *et al.*, 1996; Schilling *et al.*, 2007). Targeted deletion of Cat K in mice reproduced the high bone mass phenotype of pyknodysostosis with normal numbers of differentiated osteoclasts on the bone surface, supporting the pivotal role of Cat K in osteoclast activity (Kiviranta *et al.*, 2005; Li *et al.*, 2006; Saftig *et al.*, 1998). Histological analysis revealed that osteoclasts from patients with pyknodysostosis or from Cat K–deficient mice exhibit a morphology similar to that of cells treated with E-64 (Everts *et al.*, 2003; Fratzl-Zelman *et al.*, 2004; Saftig *et al.*, 2000). Because of the lack of proteolytic activity, these cells contain large cytoplasmic vacuoles with undigested collagen and form demineralized matrix fringes on the bone surface (Fratzl-Zelman *et al.*, 2004). In contrast, overexpression of Cat K by its own promoter in transgenic mice resulted in an osteopenic phenotype associated with an increased rate of turnover in metaphyseal trabecular bone and increased porosity of diaphyseal cortical bone (Kiviranta *et al.*, 2001; Morko *et al.*, 2005a). Pharmacological inhibition of Cat K both in *in vitro* osteoclast-based bone resorption assays and in animals and humans results in a reduction in bone resorption and an increase in bone mass, consistent with the premise that Cat K is a promising therapeutic target for the treatment of diseases involving inappropriately rapid bone turnover, including osteoporosis, Paget's disease, arthritis, and metastatic bone disease (Lipton, 2005; Vasiljeva *et al.*, 2007).

Regulation of CSTK Expression

Consistent with the critical role of receptor activator of NFκB (RANK) ligand (RANKL) in the induction of osteoclast differentiation from myeloid precursors (Asagiri and Takayanagi, 2007), RANKL stimulates Cat K mRNA and protein expression in human osteoclasts and in isolated mature rat osteoclasts (Corisdeo *et al.*, 2001; Shalhoub *et al.*, 1999). RANKL appears to stimulate the transcription of the Cat K gene via a number of TRAF6-mediated mechanisms. The activation of NFκB and p38 and the induction of c-Fos expression all promote Cat K gene expression (Asagiri and Takayanagi, 2007; Troen, 2006). NFκB and c-Fos induce the expression of NFATc1 (NFAT2), which activates Cat K expression. Overexpression of NFATc1 markedly stimulates the rat Cat K promoter. Phosphorylation of NFATc1 by p38 kinase further enhances *CTSK* gene expression and promoter activity.

Activated p38 kinase also induces phosphorylation of the microphthalmia transcription factor (Mitf; Matsumoto *et al.*, 2004), a member of the helix-loop-helix (HLH) leucine zipper family. Mutations in the microphthalmia gene (mi/mi) selectively affect osteoclast development and/or function and lead to osteopetrosis (Motyckova and Fisher, 2002). Dominant negative mutations of Mitf exhibit osteopetrosis and lack Cat K mRNA and protein. Mitf binds directly to three E-box motifs in the human *CTSK* promoter, and mutation of any one of these significantly impairs stimulation of promoter activity by Mitf (Steingrimsson *et al.*, 2002). Furthermore, Mitf and PU.1, another transcription factor mediating early osteoclastogenesis (Tondravi *et al.*, 1997), synergistically potentiate NFATc1-induced stimulation of human *CTSK* promoter activity.

Other physiological activators or inhibitors of osteoclast bone resorption also stimulate or inhibit Cat K gene expression (Troen, 2006). Some of these known regulators are various members of the AP-1 transcription factor family, osteoprotegerin (OPG), estrogen, parathyroid hormone (PTH), interleukin (IL)-1α, IL-6, or tumor necrosis factor (TNF)-α. However, it is unclear whether the regulation of Cat K gene expression is simply correlated with osteoclast differentiation or activation or if these factors are intrinsically capable of regulating Cat K synthesis, thereby leading to enhancement of bone resorption in the mature osteoclast. Thus, there have been tremendous advances in our understanding of the effect of Cat K inhibition on bone remodeling.

THERAPEUTIC IMPLICATIONS

Inhibition of Bone Resorption without Affecting Bone Formation

Under normal conditions, bone resorption and formation are tightly coupled events. Although bisphosphonates, estrogen/SERMs, and more recently anti-RANKL reduce bone resorption via inhibition of osteoclastogenesis or survival, the rate of bone formation subsequently falls, thereby reducing the long-term therapeutic effect. To support this line of evidence on the coupling of bone resorption and

formation, PTH action on bone formation seems to require osteoclast activation. In PTH-treated ovariectomized (OVX) rats, co-treatment with either estrogen or risedronate reduced histomorphometrically assessed bone formation parameters (Wronski *et al.*, 1993). When sheep were treated with PTH for 3 months, the anabolic effects were significantly reduced when tiludronate was coadministered (Delmas *et al.*, 1995). This evidence from animal studies is supported by recent clinical studies, which showed that treatment of osteoporosis patients with alendronate significantly blunted the anabolic response to PTH (Black *et al.*, 2003; Finkelstein *et al.*, 2003; Khosla, 2003).

Recent evidence suggests that a number of agents that inhibit osteoclastic bone resorption while preserving osteoclast secretory activity may have less effect on bone formation. Evidence from genetically distinct osteopetrotic phenotypes suggests that activated osteoclasts could be the source of a factor that promotes bone formation. Most forms of osteopetrosis (as in *c-fos*$^{-/-}$ mice, for example, which cannot generate osteoclasts; Grigoriadis *et al.*, 1994) are characterized by decreased bone formation in addition to defective bone resorption, due to the coupling processes. In contrast, humans with autosomal dominant osteopetrosis, due to inactivating mutations in the chloride-7 channel (CIC-7) or in ATP6i, have increased osteoclast numbers, but deficient activity due to the decreased acidification of resorption lacunae (Cleiren *et al.*, 2001; Taranta *et al.*, 2003). Bone formation appeared normal in these patients, but without true age-matched controls and with limited biopsies available, the significance of this observation was uncertain (de Vernejoul and Benichou, 2001). In mice, disruption of the CIC-7 chloride channel or the a3 V-ATPase subunit also results in the inhibition of bone resorption accompanied by a significant increase in osteoclast numbers but no change in the rate and extent of bone formation (Karsdal *et al.*, 2005; Xu *et al.*, 2007). Similarly, there are several mouse lines in which the Cat K gene has been deleted; all exhibit defects in bone resorption with normal or enhanced osteoclast numbers (Chen *et al.*, 2007; Gowen *et al.*, 1999; Kiviranta *et al.*, 2005; Li *et al.*, 2006; Saftig *et al.*, 1998). Histomorphometric analysis of cancellous regions of femoral bones from Cat K-deficient mice shows an increased bone formation rate. An intermediate effect was observed for the female heterozygotes (Kiviranta *et al.*, 2005; Li *et al.*, 2006). This suggests that the osteoclasts may still be generating factor(s) that promote bone formation, even though they do not resorb bone because of a failure to remove bone matrix.

More recently, pharmacological evaluation of Cat K inhibitors in OVX animals has provided evidence to support the hypothesis that Cat K inhibition has less effect on bone formation than bisphosphonates. In an OVX-rabbit model, both a Cat K inhibitor (L-006235) or alendronate (ALN) completely blocked the bone loss observed in vehicle-treated animals. ALN also reduced the bone formation rate of both cancellous and endocortical bone. In contrast, no reduction in bone formation rate was observed at either site in the L-006235 group (Pennypacker *et al.*, 2006). Similarly, studies of the effects of Cat K inhibitors (balicatib, relacatib) in ovariectomized cynomolgus monkeys studies suggest that Cat K inhibitors may suppress both resorption and formation in cancellous bone, but may stimulate periosteal cortical bone deposition (Novartis, 2003; Stroup *et al.*, 2005, 2001), possibly by transiently increasing plasma levels of PTH (Stroup *et al.*, 2006a).

Similar observations of the effects of balicatib on bone formation markers in humans have also been reported. A 1-year dose-ranging study of balicatib in postmenopausal women found a 61% decrease in serum and urinary collagen crosslinks (a marker of bone resorption) at the highest dose. Serum osteocalcin and bone-specific alkaline phosphatase, markers of bone formation, were similar to placebo after 1 year of treatment (Adami *et al.*, 2006). This apparent decoupling of bone resorption and bone formation, based on bone turnover markers, distinguishes Cat K inhibitors from other antiresorptives such as bisphosphonates, denosumab, and SERMs, all of which suppress markers for both resorption and formation. Increases in bone mineral density were also observed at the highest dose, providing the first clinical evidence that this mechanism is effective at increasing bone mineral density (BMD) in humans. The clinical validation of the effect of Cat K inhibition on bone mineral density, plus the provocative data suggesting a decoupling of bone resorption and formation provide a compelling framework for further development of Cat K inhibitors for the treatment of osteoporosis.

Other Indications for the Therapeutic Use of Cat K Inhibitors in Bone-related Disease

There is mounting evidence that Cat K may also play a role in other pathologies. In addition to the known high expression of Cat K in osteoclasts, its expression has been documented more recently in a number of other tissues including, but not limited to, cartilage (Morko *et al.*, 2004), atherosclerotic plaques (Lutgens *et al.*, 2006; Platt *et al.*, 2007), adipose tissue (Xiao *et al.*, 2006), lung (Buhling *et al.*, 2000), and skin (Runger *et al.*, 2007). However, levels in these tissues are generally orders of magnitude lower than that in osteoclasts.

Although the ability of Cat K inhibitors to prevent the progression of osteoarthritis (OA) in preclinical models has not yet been reported, they may be beneficial in the treatment of OA via either of two mechanisms (Felson and Neogi, 2004). First, OA has recently been viewed as a whole-organ disease, and not a disease of only articular cartilage. In this view, subchondral bone may play a key role in the triggering and progression of OA. Increased bone turnover and microfracture could increase the stiffness of subchondral bone, transmitting increased stress to

the cartilage thus increasing degradation of the cartilage. Furthermore, the formation of osteophytes, or bone spurs, in the joints of OA patients is likely related to increased endochondral bone formation. Second, Cat K has been demonstrated to efficiently degrade collagen type II, the major matrix constituent of cartilage (Kafienah *et al.*, 1998). This enzyme is thus suggested to play a direct role, along with metalloproteinases, in articular cartilage degradation (Wang and Bromme, 2005; Yasuda *et al.*, 2005). Increased Cat K expression has been documented in cartilage samples from human OA patients as well as in synovial tissue and articular chondrocytes (Hou *et al.*, 2002; Morko *et al.*, 2004). The observation that overexpression of CatK under its own promoter in transgenic mice results in spontaneous development of synovitis and cartilage degradation (Morko *et al.*, 2005b) further strengthens the argument that Cat K plays a role in the development of OA.

Another potentially useful application of Cat K inhibitors may be in treating metastatic bone disease, which is characterized by very high levels of bone turnover in proximity to the tumor (Rodan, 2003; Roodman, 2004). Bone resorption inhibitors such as bisphosphonates represent the current standard of care for the treatment of bone metastases, primarily due to breast, prostate or multiple myeloma, and it has been proposed that other strong antiresorptives such as Cat K inhibitors could also be useful in the treatment of bone metastases. Support for this possibility comes from the observation that treatment with a Cat K inhibitor significantly reduced the area of breast cancer-mediated osteolytic lesions in the tibia following the implantation of human breast cancer cells into nude mice (Stroup *et al.*, 2006b). In a separate study, an additive effect of a Cat K inhibitor and zoledronic acid on the reduction of tumor-induced osteolysis was found (Waltham *et al.*, 2006). Similarly, treatment with a Cat K inhibitor both prevented and diminished the progression of cancer growth in bone when prostate cancer cells were injected into the tibia of SCID mice (Lu *et al.*, 2005).

Integrin-Related Signaling

The findings that gene deletion of $\alpha_v\beta_3$ integrin and its downstream effectors, as well as the use of inhibitors of this integrin, results in inhibition of bone resorption *in vivo* in rodent models point to these molecules as potential therapeutic targets for osteoporosis therapy. $\alpha_v\beta_3$ integrin is highly and somewhat selectively expressed in osteoclasts across species. $\beta_3^{-/-}$ mice appear to have normal development and growth, besides the defects related to $\alpha_v\beta_3$ integrin associated osteopetrosis and $\alpha_{IIb}\beta_3$ integrin-associated bleeding. Orally active RGD mimetics have been reported to successfully block bone resorption in rodents without notable adverse effects. Although early clinical studies have uncovered some side effects, particularly in skin, it is not clear if this is an effect of the specific compound or of the entire class. However, the possibilities still exist of developing safe and effective therapeutic agents for osteoporosis based on interfering with the interaction of the osteoclast $\alpha_v\beta_3$ integrin with its physiological ligands. Moreover, antagonists to integrin receptors may play a role in preventing the homing of metastatic cancer cells to the skeleton (Zhao *et al.*, 2007).

Calcitonin

Although the mechanism and action of calcitonin in blocking osteoclast function are not fully understood, the relative selective expression of the calcitonin receptor in osteoclasts and its well-accepted role in regulating osteoclastic cytoskeleton have made calcitonin an attractive therapeutic agent for many years. Human, pig, salmon, and eel calcitonin has been used in both injected and intranasal form in the treatment of osteoporosis and Paget's disease. However, calcitonin-induced downregulation of the receptors in osteoclasts has been observed, resulting in the hormone-induced resistance of osteoclasts to inhibition of bone resorption. It therefore remains to be seen whether this problem can be overcome for therapeutic application of this class of receptor. Identification of the downstream signaling pathway of calcitonin receptor would further our understanding of how calcitonin blocks bone resorption and regulates calcium hemostasis. As discussed here, it is possible that many of the effects of calcitonin on the osteoclast are due to its ability to generate intracellular signals that interfere with the normal regulation of the cytoskeleton, adhesion, and/or cell motility, thereby converging on similar functional targets as the integrin signaling pathways.

INTRODUCTION

Apoptosis was defined by Kerr and Wyllie as a series of morphological changes in nuclear chromatin and cytoplasm, leading to specific and controlled deletion of cells, that is, the functional opposite of mitosis (Kerr *et al.*, 1972; Wyllie *et al.*, 1980). It is now established that apoptosis is controlled by a variety of physiological and pathological factors and is involved in the control of cell number not only during development but also during the repair and maintenance of regenerating epithelial tissues such as skin, cornea, the alimentary canal, and the hematopoietic system. Since the previous version of this chapter appeared in 2002, it has become increasingly clear that apoptosis plays an important role in the growth and maintenance of the skeleton. Moreover, dysregulation of apoptosis is a feature of the most common diseases of the skeleton and may in fact represent a therapeutic target.

After briefly describing general features of apoptosis and its regulation, we will concentrate on the occurrence and control of apoptosis in chondrocytes, osteoclasts, osteoblasts, and osteocytes. We will place emphasis on the role of apoptosis of osteoclasts and osteoblasts during remodeling by the basic multicellular unit (BMU), the role of osteocyte apoptosis in adaptation to mechanical strain, and the significance of bone cell apoptosis in the pathophysiology of bone disease and its treatment.

GENERAL FEATURES AND REGULATION OF APOPTOSIS

Apoptotic cells exhibit several specific morphological changes including cytoplasmic shrinkage due to dehydration, nuclear chromatin condensation, DNA degradation, cytoplasmic blebbing, loss of contact with neighboring cells, detachment from the extracellular matrix, and fragmentation into so-called apoptotic bodies (Kerr *et al.*, 1972; Fig. 1). Phosphatidylserine, normally present only in the inner leaflet of the plasma membrane, is transferred to the outer leaflet and is recognized by phagocytes that quickly ingest the apoptotic bodies, ensuring that the process occurs without surrounding tissue edema or recruitment of inflammatory cells. Thus, apoptotic cells vanish without a trace in a manner so efficient that they are often difficult to find in typical tissue sections. The entire process, from initiation to the complete disappearance of the cell, lasts anywhere from 2 or 3 hours up to 1 or 2 days depending on the cell type (Bursch *et al.*, 1990; Pompeiano *et al.*, 1998). Apoptotic cells are interspersed with viable cells. In contrast, cell death due to necrosis occurs in clumps of adjacent cells. Unlike apoptotic cells, necrotic cells are characterized by increased intracellular water and cloudy swelling of the cytoplasm, calcium precipitation, and zones of surrounding hyperemia and inflammatory cell infiltration (Anderson, 1966).

Apoptosis is the default fate of most nucleated cells and is triggered by two distinct pathways: the extrinsic pathway, which is activated by death receptor signaling, and the intrinsic pathway, which is initiated by loss of mitochondrial integrity (Kroemer *et al.*, 2007). As summarized in Figure 2, both pathways culminate in the activation of a family of normally latent proteolytic enzymes called caspases that, once activated, cleave specific intracellular proteins, leading to the morphological changes that characterize apoptosis (Kumar, 2006). There are two types of caspases. The initiator caspases −2, −8, −9, and −10 undergo autoactivation following recruitment to the signaling complexes that form in response to extrinsic or intrinsic stimulation. The proteolytically active forms of the initiator caspases then cleave and activate the latent effector caspases −3, −6, and −7, which execute the death program.

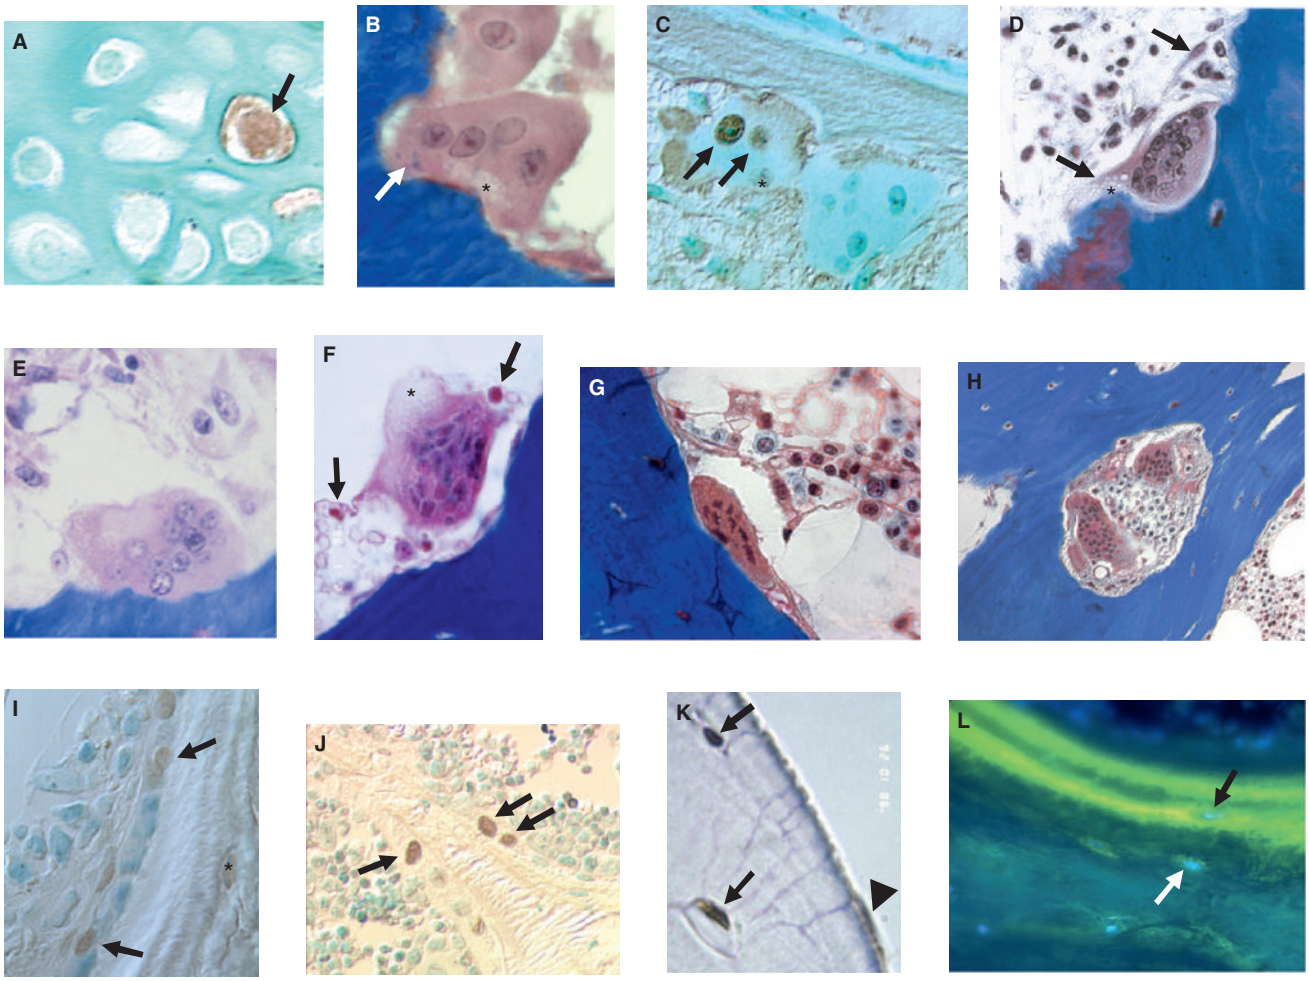

FIGURE 1 Apoptosis of bone cells. **A**, Chondrocyte apoptosis with positive ISEL staining, shrinkage, and nuclear fragmentation is noted (*arrow*). Toluidene blue counterstain, ×630. **B**, A normal osteoclast is shown with a distinct sealing zone and lysosomal-rich clear area (*) at the bone surface. Note the prominent nucleoli. Tiny fragments of blue resorbed mineralized bone can be seen inside the cell (*arrow*). Masson stain, ×1000. **C**, Human osteoclast apoptosis in a dialysis patient with secondary hyperparathyroidism. With just two distinct apoptotic nuclei (*arrows*), the upper left osteoclast remains attached to bone but in situ nick-end labeling defines the cell as apoptotic. Another nuclear profile does not exhibit staining (*). The osteoclast on the right has no ISEL staining and is viable. ISEL staining with toluidene blue counterstain, ×630. **D**, A morphological sign of osteoclast apoptosis is blebbing (*arrows*) and vacuolization (*). The changes were induced by alendronate treatment of Paget's disease of bone. Blebbing is a later event during the process of apoptosis than the ISEL staining shown in **C.** Masson stain, ×400. **E**, In normal osteoclasts, the nuclei are polarized away from the bone surface and the clear zone is immediately adjacent to the ruffled border (see **B**). However, in the osteoclast shown here, the clear zone is away from, and the nuclei are adjacent to, the bone surface. This section was taken from a patient with postmenopausal osteoporosis treated with alendronate. This extent of abnormal osteoclast architecture is a later feature of apoptosis than blebbing and vacuolization shown in panel **D**. Masson stain, ×400. **F**, End-stage alendronate-induced human osteoclast apoptosis in Paget's disease of bone. The osteoclast has detached from the bone surface, contracted, and the nuclei are condensed and fragmented. Prominent cytoplasmic blebbing and vacuolization at the top of the cell (*) and formation of apoptotic bodies at the left and right sides can be seen (*arrows*). This stage of osteoclast apoptosis is rarely seen because of the fleeting existence of apoptotic osteoclasts before they are swept away by phagocytosis. Masson stain, ×630. **G**, This osteoclast is still attached to the bone surface, but the nuclei are pyknotic and the clear zone is absent in this section from a patient receiving long-term treatment with alendronate. Nuclear detail in the surrounding bone marrow is intact. Masson stain, ×630. **H**, Giant osteoclasts, detached from the bone surface and containing 15 to 30 nuclei, are noted after long-term treatment with alendronate in postmenopausal osteoporosis. Masson stain, ×400. **I**, Apoptotic osteoblasts are identified by the brown ISEL staining (arrows) and nuclear condensation in this section taken from a patient receiving long-term treatment with prednisone. An apoptotic osteocyte is present at the right side of the photomicrograph (*). The apoptotic osteoblasts are interspersed with unaffected viable (blue) members of the osteoblast team. Counterstained with methyl green and viewed by Nomarski differential interference contrast microscopy, ×630; modified from Weinstein et al. (1998). **J**, Murine osteoblast apoptosis on cancellous bone. Normal blue-green osteoblasts are interspersed between the brown apoptotic cells (*arrows*). ISEL staining with toluidene blue counterstain, ×250. **K**, Chronic glucocorticoid therapy causes the accumulation of markedly pyknotic apoptotic osteocytes (*arrows*) and lining cells (*arrowhead*) in this section of a femoral head obtained during total hip replacement because of glucocorticoid-induced osteonecrosis. Note that the lacunar-canalicular system now links dead cells. ISEL staining with toluidene blue counterstain and viewed by Nomarski differential interference contrast microscopy, ×1600; modified from Weinstein and Manolagas (2000). **L**, Transiliac biopsy from a patient with glucocorticoid-induced osteoporosis stained with Höescht dye. Note the apoptotic condensed osteocytes recently buried in (*black arrow*) and below (*white arrow*) a new packet of bone outlined by yellow tetracycline labeling. Epifluorescent photomicrograph, ×630. (See plate section)

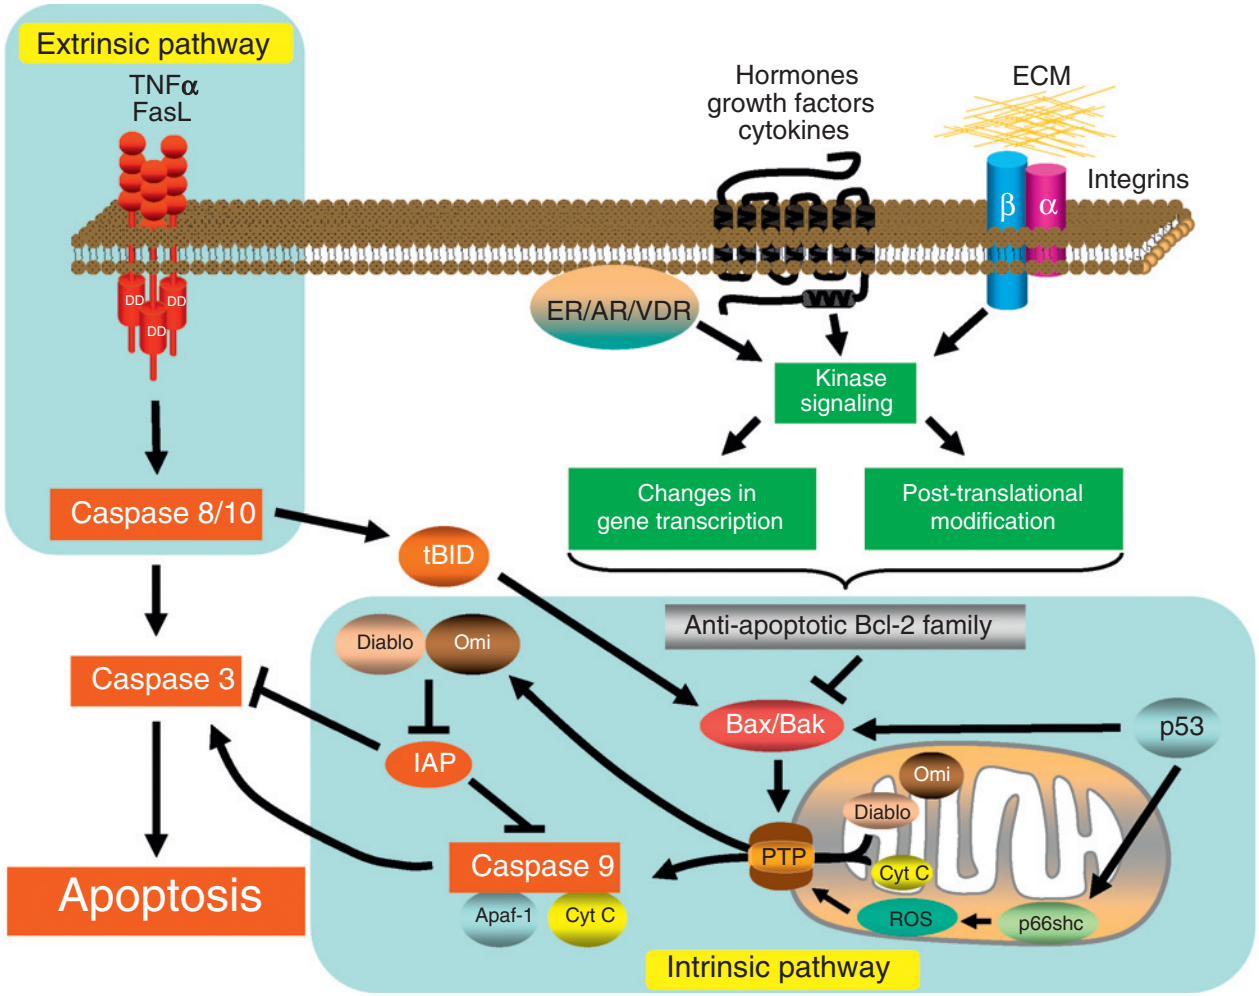

FIGURE 2 Basic mechanisms of the regulation of apoptosis. See text for details. AR, androgen recepto; ; Apaf-1, apoptotic protease activating factor-1; cytc, cytochrome c; DD, death domain; ECM, extracellular matrix; ER, estrogen receptor; IAP, inhibitor of apoptosis protein; PTP, permeability transition pore; VDR, vitamin D receptor. (See plate section)

Activation of Apoptosis

The extrinsic pathway is activated by death receptors residing at the cell surface. These receptors comprise a family of transmembrane proteins, including Fas, and receptors for tumor necrosis factor (TNF)-α and TNF-related apoptosis-inducing factor (TRAIL), which possess a death domain in the intracellular portion of the receptor. Binding of cognate ligands promotes assembly of the death inducing signaling complex at the death domain, resulting in recruitment and activation of caspase-8 or caspase-10 (see Fig. 2). This pathway has been studied mainly in cells of the immune system and is responsible for deletion of autoreactive T-cells. TNF-α also activates antiapoptotic pathways that are mediated by NFκB—a phenomenon that may be important for osteoclast survival, as will be discussed later.

The intrinsic pathway represents the most common apoptotic mechanism in vertebrates and is activated by an increase in the permeability of the outer mitochondrial membrane (Kroemer *et al.*, 2007). The integrity of this membrane is controlled by the pro- and antiapoptotic members of the Bcl-2 family of proteins (Kim *et al.*, 2006). As illustrated in Figure 3, the level of pro-apoptotic sensor Bcl-2 proteins is increased by diverse stimuli, including genotoxic agents, locally produced growth factors, cytokines, systemic hormones, oxidative stress, diminished ATP levels, and loss of kinase-mediated survival pathways. The increase in these sensor proteins overcomes the inhibitory actions of antiapoptotic Bcl-2 family proteins, culminating in the opening of the permeability transition pore of the outer mitochondrial membrane by the proapoptotic Bcl-2 family members Bax and Bak. This results in the release of cytochrome *c*, Omi, and Diablo proteins from the space between the outer and inner mitochondrial membranes into the cytoplasm (see Fig. 2). Death signals also activate $p66^{Shc}$, a protein that interferes with the electron transport

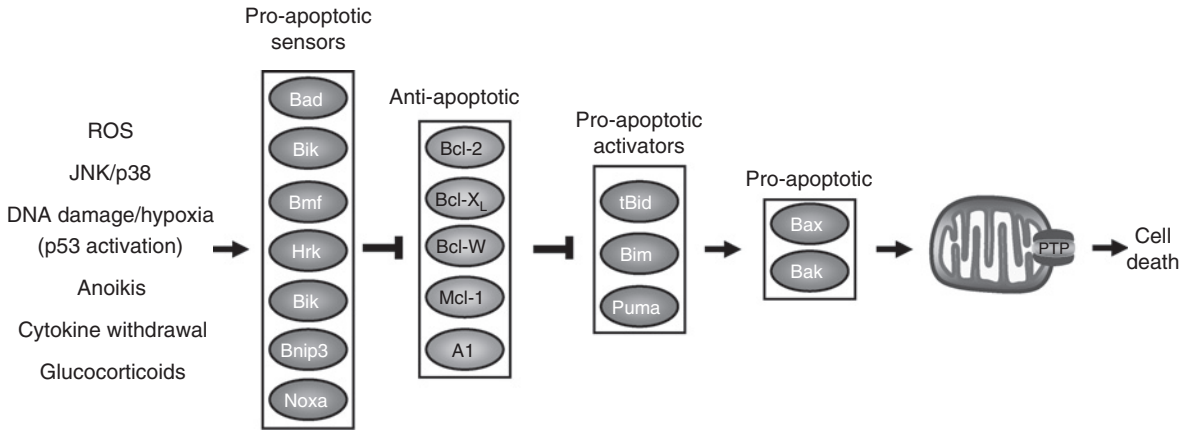

FIGURE 3 Control of mitochondrial membrane permeability by members of the Bcl-2 family of proteins. Apoptosis is triggered when the level of proapoptotic "sensor" members of the Bcl-2 family of proteins exceeds that of the antiapoptotic Bcl-2 family members. Proapoptotic stimuli increase the synthesis of "sensor" Bcl-2 proteins, reduce their sequestration or proteasomal degradation, and decrease the synthesis of antiapoptotic Bcl-2 proteins (Willis and Adams, 2005). The "sensor" Bcl-2 proteins activate apoptosis by binding to, and thereby inhibiting the function of, antiapoptotic Bcl-2 proteins, which normally prevent the actions of members of the proapoptotic "activator" Bcl-2 family (Kim et al., 2006). The resulting increase in the level of "activator" Bcl-2 proteins facilitate the homo-oligomerization of a third set of proapoptotic Bcl-2 proteins, Bax and Bak, which bind to the outer mitochondrial membrane and open the permeability transition pore (PTP). Modified from Galonek and Hardwick (2006).

machinery of the inner mitochondrial membrane and generates reactive oxygen species (ROS) that also contribute to permeabilization of the outer mitochondrial membrane (Giorgio *et al.*, 2005). Upon release of cytochrome *c* into the cytoplasm, it interacts with apoptotic protease activating factor-1 (Apaf-1) which causes the activation of caspase-9 (Kumar, 2006). Omi and Diablo promote apoptosis by blocking the activity of members of the inhibitor of apoptosis (IAP) family, which normally prevent caspase activation. A connection between the extrinsic and intrinsic pathways is provided by caspase-8 cleavage of Bid to generate a truncated form (tBid) that increases the permeability of the outer mitochondrial membrane (see Fig. 2).

Cells are kept alive by hormones and locally produced growth factors and cytokines that activate various kinase cascades leading to increased synthesis of antiapoptotic members of the Bcl-2 and IAP proteins and/or sequestration or degradation of proapoptotic sensor Bcl-2 proteins. Survival signals are also generated by the interaction of integrins with extracellular matrix proteins, which promote the formation of focal adhesion complexes within the cell comprising cytoskeletal proteins, focal adhesion kinase (FAK), and members of the Src family of kinases. Phosphorylation of FAK activates the PI3-kinase and the MAP kinase cascades, which prevent apoptosis.

Detection and Quantification of Apoptosis

Quantification of cells undergoing apoptosis in tissues has relied mainly on methods that detect the presence of degraded DNA (Gavrieli *et al.*, 1992; Wijsman *et al.*, 1993; Ansari *et al.*, 1993). These methods are known by a number of acronyms that are often used interchangeably, the most common being TUNEL (terminal deoxynucleotidyl transferase mediated dUTP nick-end-labeling) and ISEL (in situ end-labeling) (see Figs. 1A, C, I–K). The procedure involves attachment of a labeled nucleotide to hydroxyl groups at the 3′ end of DNA using either terminal deoxynucleotidyl transferase or the Klenow fragment of DNA polymerase I. Use of the Klenow enzyme detects cells with fewer DNA strand breaks, and labeling with this enzyme is less susceptible to artifact because it lacks exonuclease activity (Wijsman *et al.*, 1993). The incorporated labeled nucleotides are usually visualized with peroxidase staining in tissue sections. The technique is sensitive enough to detect the few DNA strand breaks that occur in the earliest stages of apoptosis (Pompeiano *et al.*, 1998). As in any quantitative histologic procedure, detection of degraded DNA in apoptotic cells requires standardization and the use of appropriate negative and positive controls during each staining procedure (Jilka *et al.*, 2007). Table 1 lists guidelines for obtaining reproducible estimates of apoptotic osteoblasts.

Other methods have been developed for detection of apoptotic cells in tissues and/or in culture, including histologic or enzymatic detection of active caspases, staining of DNA with fluorescent dyes such as acridine orange, Höescht dyes (see Fig. 1L), and propidium iodide, as well as detection of phosphatidylserine on the cell surface (Bellido and Plotkin, 2007). Fragmented nuclei can also be detected in cells transfected with green fluorescent protein containing a nuclear localization sequence—a useful tool for studying apoptosis in cells co-transfected with genes of interest for mechanistic studies (Bellido and Plotkin, 2007).

TABLE I Guidelines for the Detection of Apoptotic Osteoblasts

1. Section thickness must be less than 10μm to allow access of reagents into all cells.
2. Exposure of fragmented DNA in nondecalcified sections after removal of the plastic is best accomplished by pretreatment with in 10 mM citrate buffer using laboratory-grade microwave irradiation (such as the H2800 Microwave Processor, Energy Beam Sciences, Inc., East Granby, Conn.) followed by incubation with pepsin or proteinase K that are free of contaminating nuclease activity (Negoescu *et al.*, 1996). Treatment must be brief to prevent loss of tissue morphology and to avoid false positive results.
3. Identically fixed and processed bone tissue serves as the best positive control. Weaned breast tissue (included as a positive control in apoptosis kits) is not useful for optimizing staining of apoptotic osteoblasts because it is easier to obtain positive staining in this tissue than in bone (Tidball and Albrecht, 1998).
4. Efforts to increase the sensitivity of the staining procedure by increasing the duration of (a) proteinase pretreatment, (b) exposure to the transferase or Klenow enzyme, or (c) incubation with reagents to intensify color development can lead to nonspecific staining that can go unrecognized unless a standard specimen with a known coefficient of variation for osteoblast apoptosis is available for comparison (Labat-Moleur *et al.*, 1998).
5. Morphological changes such as discretely condensed chromatin and nuclear fragmentation or peripheral beading on the nuclear membrane should accompany the positive staining. Apoptotic osteoblasts should be juxtaposed to osteoid and interspersed with normal osteoblasts and show a cuboidal morphology to distinguish them from nearby marrow and lining cells (see Figs. 1I, J).

APOPTOSIS OF CHONDROCYTES DURING ENDOCHONDRAL OSSIFICATION

Chondrocyte apoptosis plays a major role in the shaping of long bones during development. In the growth plate, chondrocytes undergo a series of highly regulated transformations leading to the replacement of the cartilage template by bone. During this process, known as endochondral ossification, chondrocytes proliferate, produce type II collagen, and form a columnar cell layer. Subsequently they undergo cell cycle arrest, differentiation, and hypertrophy, which is followed by mineralization of the surrounding matrix. At this point, the chondrocytes die by apoptosis and, after blood vessel invasion, the cartilage is replaced with bone (Gibson *et al.*, 1995).

Apoptotic hypertrophic chondrocytes are easily recognized at the lateral margins of the growth plate with TUNEL or ISEL staining (see Fig. 1A). Although some investigators have reported that ISEL- or TUNEL-positive chondrocytes are rare (Roach *et al.*, 2004), classical ISEL-positive chondrocytes are so commonly found that they are useful as internal positive controls for apoptosis staining of other bone cells.

Chondrocyte apoptosis may begin well before the dramatic and massive death that characterizes hypertrophic chondrocytes as some chondrocytes exhibit TUNEL staining during the proliferative stage (Cruickshank *et al.*, 2005). As chondrocytes progress from the late proliferative stage toward the mature stage, there is a decrease in the permeability of the mitochondrial membrane and the level of Bcl-2, whereas binding of Bax to mitochondria increases (Amling *et al.*, 1997; Pucci *et al.*, 2007). These changes are associated with increased sensitivity to proapoptotic stimuli, such as elevated concentrations of inorganic phosphate (Pucci *et al.*, 2007). ROS are elevated in hypertrophic chondrocytes and may be involved in the initiation of apoptosis, because administration of the antioxidant *N*-acetylcysteine (NAC) reduces ROS and inhibits hypertrophy and apoptosis of these cells (Morita *et al.*, 2007).

Parathyroid hormone related peptide (PTHrP) and Indian hedgehog (Ihh) play central roles in the regulation of endochondral ossification and are involved in the maintenance of chondrocyte survival during this process (Kronenberg, 2003). Ihh is secreted by chondrocytes that have just stopped proliferating and it stimulates the synthesis of PTHrP, which restrains apoptosis (Lee *et al.*, 1996; Amizuka *et al.*, 1996; Weir *et al.*, 1996). As chondrocytes become more distant from the site where PTHrP is produced during hypertrophy, PTHrP-induced survival signaling diminishes. The antiapoptotic effect of PTHrP on chondrocytes is mediated in part by increased Bcl-2 expression (Amling *et al.*, 1997) and by Nkx3.2, a member of the NK family of homeoprotein transcriptional regulators (Provot *et al.*, 2006). Expression of Nkx3.2 is high in proliferating chondrocytes, but diminishes thereafter. NKX3.2 is absent in PTHrP-deficient mice. Interestingly, the antiapoptotic activity of Nkx3.2 appears unrelated to its function as a transcriptional regulator. Nkx3.2 enhances chondrocyte survival in a cell-autonomous fashion by activating NFκB, apparently in a ligand independent fashion (Park *et al.*, 2007). The mechanism by which NFκB inhibits apoptosis in chondrocytes is unknown, but in other tissues it upregulates the expression of antiapoptotic members of the Bcl-2 family, as well as members of the inhibitors of apoptosis family of proteins, such as c-IAP and XIAP (Dutta *et al.*, 2006).

A second factor that restrains chondrocyte apoptosis is the transcription factor hypoxia-inducible factor 1α (HIF-1α). At normal oxygen tension HIF-1α levels are low

because proline hydroxylases utilize molecular oxygen to hydroxylate specific proline residues in HIF-1α, which results in its degradation by proteasomes (Wenger *et al.*, 2005). Under the low oxygen tension condition that prevails at the center of the growth plate, HIF-1α levels are high, leading to increased synthesis of several factors that prevent apoptosis including Bcl-2, glycolytic enzymes that maintain the level of ATP, and vascular endothelial growth factor (VEGF; Schipani *et al.*, 2001; Cramer *et al.*, 2004). VEGF induces vascularization and restrains chondrocyte apoptosis as indicated by increased apoptosis in the center of the proliferative and upper hypertrophic zones of the growth plate in mice with chondrocyte-specific deletion of VEGF (Zelzer *et al.*, 2004). Proline hydroxylase levels are increased in hypertrophic chondrocytes, suggesting that the consequent decline of HIF-1α levels contributes to apoptosis of these cells (Terkhorn *et al.*, 2007). This notion is supported by *in vitro* studies showing that diminished levels of HIF-1α in mature chondrocytes are associated with increased sensitivity to the proapoptotic effects of ROS (Terkhorn *et al.*, 2007).

Wnt proteins influence cell proliferation, differentiation, and survival in many tissues by binding to Frizzled, and low-density lipoprotein receptor-related protein 5 (LRP5) or LRP6 co-receptors. This causes accumulation of β-catenin in the nucleus where it activates the TCF/LEF family of transcription factors (Bodine and Komm, 2006). Wnt/β-catenin-induced signaling is involved in the maintenance of chondrocyte viability because deletion of β-catenin specifically in chondrocytes results in a dramatic increase in apoptosis of differentiated chondrocytes (Mak *et al.*, 2006). Although less severe, this growth plate phenotype resembles that of mice lacking HIF-1α or VEGF in chondrocytes. The increased chondrocyte death of mice lacking β-catenin in chondrocytes is rescued by induction of hedgehog signaling, suggesting that hedgehog-induced survival signaling is downstream of Wnt/β-catenin activation.

OSTEOCLAST APOPTOSIS

The life span of osteoclasts in cancellous bone has been estimated to be as long as 11 to 15 days in dogs (Jaworski *et al.*, 1981) and as short as 1 to 2 days at the end of lactation in rats (Miller and Bowman, 2007). Yet the lifetime of the BMU in either of these species, or in humans, is much longer, lasting several weeks to months (Parfitt, 1996). This has two important implications for the function of the BMU. First, for orderly progression of the BMU there must be a constant supply of new osteoclasts to replace those lost by apoptosis. Second, osteoclast life span controls the depth of resorption. Indeed, prolongation of osteoclast life span causes teams of osteoclasts to resorb to greater depths than normal, leading to the perforation of trabeculae and loss of connectivity (Parfitt *et al.*, 1996).

Compared to other bone cell types, osteoclasts are rare: 10-fold fewer than osteoblasts and 100-fold fewer than osteocytes. This fact hinders the detection of apoptotic osteoclasts in bone sections unless overall osteoclast number is increased and/or apoptosis is stimulated. The earliest morphological abnormalities seen in apoptotic osteoclasts are prominent cytoplasmic blebs (see Fig. 1D). Next, the ruffled border is disrupted (see Figs. 1E, G), the nuclei become pyknotic, and the cell detaches from the bone surface (see Figs. 1F–H; Weinstein and Manolagas, 2000). In mice treated with high levels of bisphosphonates (BPs), all of the nuclei exhibit condensed chromatin and TUNEL staining, as well as more intense cytoplasmic staining for tartrate-resistant acid phosphatase due to cytoplasmic contraction (Hughes *et al.*, 1995). Osteoclasts in which all of the nuclei are stained with TUNEL have also been observed in bone of estrogen-treated rats (Faloni *et al.*, 2007) and in mice after lactation (Ardeshirpour *et al.*, 2007). With the more sensitive ISEL method that permits visualization of the early stages of DNA degradation, some osteoclast nuclei are stained but others are not (see Fig. 1C).

As will be described later, numerous factors regulate osteoclast apoptosis. The regulation of osteoclast life span represents an elegant and sensitive mechanism by which rapid changes in osteoclast number, and thus bone resorption, can be accomplished. For example, stimulation of osteoclast apoptosis may rapidly reduce bone resorption once increased demand for calcium has ended, such as at the end of lactation. Conversely, a rapid increase in the demand for bone resorption, such as dietary calcium deficiency, may be met in part by inhibition of osteoclast apoptosis.

Fas ligand stimulates osteoclast apoptosis. This may be an important signal for the control of osteoclast number, because mice lacking Fas have increased osteoclasts and lower bone mass (Wu *et al.*, 2003). High extracellular calcium concentrations, similar to those that occur locally during bone resorption, can also induce osteoclast apoptosis *in vitro* (Lorget *et al.*, 2000), possibly via activation of the calcium sensing receptor (Mentaverri *et al.*, 2006). Detachment of osteoclasts *in vitro* induces apoptosis, presumably by disrupting integrin-mediated survival signaling (Villanova *et al.*, 1999). Calcitonin inhibits the resorptive activity of osteoclasts and also promotes detachment from the bone surface. However, it does not induce apoptosis due to compensatory cAMP-mediated survival signaling (Selander *et al.*, 1996).

Osteoclast differentiation depends on production of macrophage colony-stimulating factor (M-CSF) and RANKL by stromal cells, and these cytokines, as well as TNF-α and IL-1, also promote osteoclast survival (Fuller *et al.*, 1993; Lacey *et al.*, 2000). Many of these cytokines utilize the same signaling pathways to accomplish this function, and the details of these pathways have been recently reviewed (Xing and Boyce, 2005). Therefore, the present

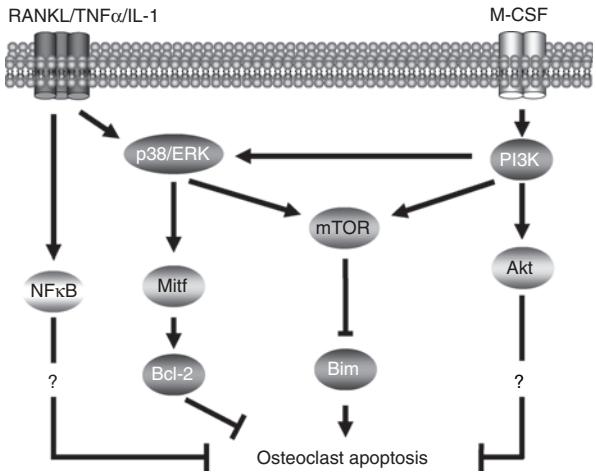

FIGURE 4 Summary of cytokine-activated pathways that promote osteoclast survival. Although RANKL, TNF-α, and IL-1 bind to distinct receptors, a generic receptor is shown in the diagram. See text for details. Akt, thymoma viral proto-oncogene; ERK, extracellular signal-regulated kinase; IL-1, interleukin-1; M-CSF, macrophage colony-stimulating factor; Mitf, microphthalmia-associated transcription factor; mTOR, mammalian target of rapamycin; NFκB, nuclear factor-kappa B; RANKL, receptor activator of NFκB ligand; PI3K, phosphoinositide-3 kinase; TNFα, tumor necrosis factor α.

discussion will focus on the common aspects of these survival pathways, which are illustrated in Figure 4.

M-CSF, RANKL, TNF-α, and IL-1 each activate extracellular signal-regulated kinases (ERKs) that activate antiapoptosis signaling in osteoclasts, as blockade of ERK activation blocks the ability of IL-1 or TNFα to promote osteoclast survival (Miyazaki *et al.*, 2000; Lee *et al.*, 2001). Phosphatidylinositol 3-kinase (PI3K) activity is also required for the anti-apoptotic action of each of these cytokines (Wong *et al.*, 1999; S. E. Lee *et al.*, 2001; Z. H. Lee *et al.*, 2002; Fukuda *et al.*, 2005). While some evidence suggests that PI3K promotes osteoclast survival via activation of the survival kinase Akt (Lee *et al.*, 2001; Lee *et al.*, 2002; Gingery *et al.*, 2003), a more recent study employing short-hairpin RNAs (shRNAs) to reduce Akt indicates that Akt is required for osteoclast differentiation but not for survival (Sugatani and Hruska, 2005). Mammalian target of rapamycin (mTOR) is a target of PI3K activity, and activation of this kinase is required for the antiapoptotic actions of M-CSF, RANKL, and TNF-α in osteoclasts (Glantschnig *et al.*, 2003). Thus, although the role of Akt in cytokine-mediated osteoclast survival remains to be clarified, each of these cytokine activated pathways appears to converge on mTOR activation as a critical determinant of their ability to promote osteoclast survival.

The transcription factor NFκB is activated by RANKL, TNF-α, and IL-1 and has been shown to oppose cell death induced by TNF-α in a variety of systems (Beg and Baltimore, 1996; Varfolomeev and Ashkenazi, 2004). Suppression of NFκB subunit expression via antisense RNA blocks the ability of IL-1 to support osteoclast survival (Jimi *et al.*, 1998), and decoy oligonucleotides that block NFκB binding to DNA induce osteoclast apoptosis *in vitro* and *in vivo* (Penolazzi *et al.*, 2003, 2004, 2006). Nonetheless, osteoclast precursors lacking NFκB subunits have normal survival (Xing *et al.*, 2002) and inhibition of NFκB activation via a dominant-negative IKK2 did not affect the ability of IL-1 to promote osteoclast survival (Miyazaki *et al.*, 2000). The reasons underlying these different results are unclear but may be related to off-target actions of some methods used to suppress NFκB activation (Miyazaki *et al.*, 2000).

The downstream effectors of prosurvival signaling in osteoclasts are best characterized in the case of M-CSF. M-CSF activates the Mitf transcription factor, which then stimulates transcription of Bcl-2 (Hershey and Fisher, 2004). The importance of this pathway is illustrated by the osteopetrotic phenotype of mice lacking either Mitf or Bcl-2 (McGill *et al.*, 2002), and the rescue of the osteopetrotic phenotype of M-CSF-deficient mice by overexpression of Bcl-2 (Lagasse and Weissman, 1997). The pro-apoptotic Bcl-2 family member Bim is also involved in the regulation of osteoclast survival as M-CSF promotes the proteasomal degradation of this factor (Akiyama *et al.*, 2003).

Besides cytokines, lipopolysaccharide (LPS) stimulates bone resorption (Abu-Amer *et al.*, 1997). LPS is a strong inducer of all of the cytokines mentioned earlier. However, LPS promotes survival of differentiated osteoclasts *in vitro* in the presence of OPG or IL-1 receptor antagonists, or in cells derived from TNF-α receptor-deficient mice, via activation of both the NFκB and PI3K pathways (Suda *et al.*, 2002). Thus, LPS can promote osteoclast survival both indirectly via stimulation of cytokines and directly via activation of survival pathways.

Sex steroids, glucocorticoids and BPs also influence osteoclast apoptosis as listed in Table II. Their effects will be discussed in detail in Section VII.

OSTEOBLAST APOPTOSIS

Apoptosis, the means of culling osteoblast number, appears to begin at the early stages of osteoblast differentiation and continues throughout all stages of the working life of this cell. Thus, apoptotic mesenchymal progenitors have been detected near the primary spongiosa of developing chick and rabbit long bones (Palumbo *et al.*, 2003), the osteogenic front of developing murine calvarial bone (Rice *et al.*, 1999), at sites of fracture healing (Landry *et al.*, 1997; Li *et al.*, 2002), and near the newly forming bone that develops during distraction osteogenesis—a process in which long bones are cut and gradually stretched, resulting in *de novo* bone formation within the expanding gap (Li *et al.*, 2003).

Apoptotic osteoblasts with positive TUNEL or ISEL staining are first recognized by russet-brown nuclear

TABLE II Changes in Bone Cell Apoptosis during Pathologic Bone Remodeling and Response to Therapy

Condition/ Treatment	Osteoclast Apoptosis	Osteoblast Apoptosis	Osteocyte Apoptosis	Bone Mass	Bone Strength

Intermittent PTH	?	↓	↓	↑	↑
Bisphosphonates	↑	↓	↓	↑	↑

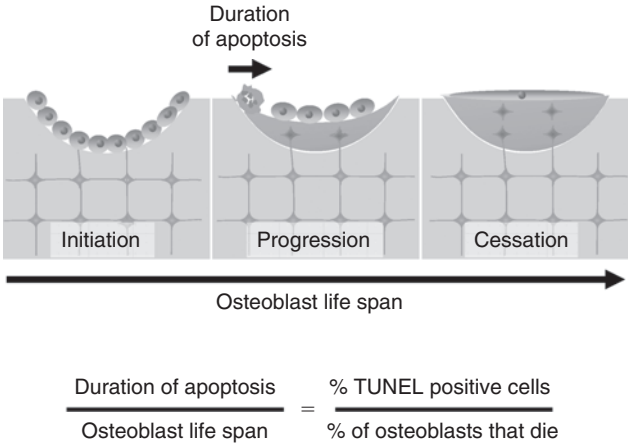

FIGURE 5 Estimation of osteoblast apoptosis. A team of osteoblasts assembles at the floor of the resorption cavity at the beginning of the bone formation process ("initiation"). During matrix synthesis ("progression"), some osteoblasts become entombed as osteocytes and some die by apoptosis. When matrix synthesis ceases ("cessation"), all that remains of the original team of osteoblasts are osteocytes and lining cells. The equation allows calculation of the fraction of osteoblasts that die by apoptosis based on the observed prevalence of osteoblasts exhibiting degraded DNA as detected by TUNEL or ISEL, osteoblast life span, and the length of time that apoptotic osteoblasts exhibit staining for TUNEL or ISEL. Osteoblast life span can be determined by dividing the wall width (the histologic measure of the amount of bone made by a team of osteoblasts) by the mineral apposition rate. For osteoblasts in cancellous bone of normal adult mice this is about 12 days (Weinstein *et al.*, 1998). It is unknown how long the DNA fragmentation phase of apoptosis lasts in dying osteoblasts, but in liver cells the duration of this particular phase is 2 to 3 hours when visualized with the terminal deoxynucleotidyl transferase method (Bursch *et al.*, 1990). There is no reason to expect that this phenomenon would substantially vary among cell types. Therefore, if the prevalence of murine osteoblast apoptosis is 0.6%, it can be calculated that 60% to 90% of osteoblasts die by apoptosis, the rest becoming osteocytes or lining cells.

pigmentation and small balls of chromatin rimming the nuclear membrane (see Figs. 1I, J). Later, cell shrinkage becomes evident, but detachment from the bone surface appears to be a late phenomenon and probably a fleeting one due to rapid phagocytosis after detachment (Weinstein *et al.*, 1998, 2004). In vertebral cancellous bone of adult mice, 0.5% to 1.0% of osteoblasts exhibit DNA strand breaks when analyzed with the terminal deoxynucleotidyl transferase enzyme (Jilka *et al.*, 1998; Silvestrini *et al.*, 1998; Weinstein *et al.*, 1998). Using the more sensitive Klenow enzyme the prevalence of apoptotic osteoblasts increases to as much as 5% to 10%; see Fig. 1J). Longitudinal sections of lumbar vertebrae (L1–L4) of adult mice are particularly advantageous samples for quantifying osteoblast apoptosis because they typically contain 800 to 1200 osteoblasts for inspection. This situation allows statistically meaningful estimates of the prevalence of apoptosis.

How can a phenomenon of such low prevalence be important? The phase of apoptosis that can be detected by TUNEL staining represents only a tiny fraction of the cell's life span, analogous to the brevity of a 6-month-long terminal illness as compared to the entire life of a 75-year-old human. Tidball and Albrecht have estimated that an entire tissue could die of apoptosis in 20 days if only 0.4% of the nuclei in the tissue were detectably apoptotic (using the terminal deoxynucleotidyl transferase enzyme; Tidball and Albrecht, 1998). This calculation is based on the assumption that there is a 2-hour period of detectability of the phenomenon, that apoptosis occurs at a constant rate, and that no mitosis occurs during this period. Based on the fact that in the snapshot of a biopsy the fraction of cells exhibiting apoptotic features is equal to the corresponding fraction of time spent in apoptosis, one can calculate the percentage of cells that undergo apoptosis in mice is 60% to 90% (Fig. 5). This estimate is very similar to the estimate of Parfitt (1990) for the number of osteoblasts that die by apoptosis in human bone.

Despite the seeming parity between humans and mice with respect to the proportion of osteoblasts that die, the actual prevalence of osteoblast apoptosis in human bone is much lower compared to mice. Indeed, no apoptotic osteoblasts were seen in transiliac biopsies taken from 12 normal

subjects using the less sensitive TUNEL enzyme (Weinstein *et al.*, 1998). The more sensitive Klenow enzyme was used to search for apoptotic osteoblasts in biopsies from 23 placebo-treated post-menopausal women in another study (Weinstein *et al.*, 2003), but none were found (R. S. Weinstein, unpublished observations). The different prevalence of apoptotic osteoblasts in murine and human cancellous bone is due to the fact that human osteoblasts live longer and are fewer in number compared to their murine counterparts because bone turnover in humans is lower. Specifically, whereas the average osteoblast life span is about 12 days in normal adult mice (Weinstein *et al.*, 1998), the average life span of normal human osteoblasts is about 150 days (Parfitt *et al.*, 1997)—a 12.5-fold difference. Therefore, a 0.6% prevalence of osteoblast apoptosis in mice corresponds to a prevalence of 0.05% in humans. Furthermore, whereas the average bone formation rate in Swiss-Webster mice is about $0.150\,\mu m^2/\mu m/day$ (Weinstein *et al.*, 1998), the corresponding value in healthy humans is about $0.038\,\mu m^2/\mu m/day$ (Han *et al.*, 1997)—a 4-fold difference. There is no reason to suspect that the duration of the morphologic features of apoptosis is different in the two species. Likewise, in both species the rate of bone formation is inexorably proportional to the number of osteoblasts (Parfitt *et al.*, 1995). That is to say, the higher the number of osteoblasts present in a defined area of bone, the greater the chance to detect an apoptotic one. If the relationship between osteoblast number and bone formation rate is similar in the two species (once again there is no reason to suspect that it is different), the 12-fold difference in life span between them needs to be multiplied by the fold difference in bone formation rate. This simple calculation makes the chance of detecting an apoptotic osteoblast in a section of human bone about 50 times lower than in a section of murine bone.

The total number of osteoblasts present in a longitudinal section obtained from a transiliac biopsy from humans is only 20 to 50 (Weinstein *et al.*, 2003) as compared to the 800 to 1200 cells present in a single longitudinal section of four murine vertebrae. If one were to estimate the prevalence of apoptosis relying on the inspection of 20–50 cells present in a section from a human biopsy, one will fail to find a single apoptotic cell most of the time because the phenomenon is predicted to occur in 0.01% to 0.1% of the entire osteoblast population. In other words, to achieve comparable statistical power for estimating the prevalence of osteoblast apoptosis in a human bone section as in a murine section, one would have to prepare 100 sections and stain them with the more sensitive Klenow enzyme. Such sections are usually 5 to 7 μm thick (the optimal usable thickness for staining and microscopy) and must be nonadjacent because the osteoblast height is 12 to 20 μm. Unfortunately, this is practically impossible to achieve with a normal-sized human transiliac biopsy of 7 mm diameter.

There are only two scientifically valid ways of estimating rare events such as apoptosis. The first is enumeration of a vast number of cells in which the sparse phenomenon may happen. The second is reliance on a simulation model based on a predetermined estimate of the probability of the rare event happening, which is the only practical option for human biopsies—perhaps with the exception of conditions, such as glucocorticoid excess, in which the prevalence of the phenomenon increases dramatically. But the sine qua non conditions under which such a model can be relied on is that the apoptotic events must be randomly spaced and independent of each other. Unfortunately, neither condition is certain. In fact, osteoblast apoptosis seems to occur in particular regions of bone. As elegantly explained in the case of the detection of another rare occurrence in bone samples—namely microcracks—frequency distributions are typically skewed with a few specimens exhibiting many events but most having only a few or none (Martin *et al.*, 2007). Therefore, if only a few apoptotic osteoblasts are identified in a specimen, it is a warning sign that the sample size is not large enough to estimate the prevalence of the phenomenon in the entire skeleton of an experimental group. An a priori estimate of the prevalence of apoptosis in advance of an experiment, together with the appropriate positive and negative controls, must be used to derive a reliable estimate of the required sample size.

Most if not all major regulators of skeletal homeostasis influence the apoptosis of osteoblasts as illustrated in Figure 6. Importantly, genetic factors that determine bone mass also control osteoblast apoptosis as evidenced by the inverse relationship between bone formation rate and osteoblast apoptosis in high bone mass C3H/HeJ mice, compared to low bone mass C57BL/6 mice (Sheng *et al.*, 2006). Osteoblast apoptosis is highly regulated during fracture repair and during the closing of skeletal defects in rodent models (Landry *et al.*, 1997; Olmedo *et al.*, 2000; Li *et al.*, 2002). Interestingly, in mice with partial deficiency in HIF-1α the callus of experimentally induced femoral fractures is larger and osteoblast apoptosis is decreased (Komatsu *et al.*, 2007). Thus, regulation of osteoblast apoptosis during fracture healing appears to play a role in modulating the pace of bone regeneration.

Bone morphogenetic proteins (BMPs) not only play an important role in osteoblast differentiation, but also induce apoptosis of mesenchymal osteoblast progenitors in interdigital tissues during the development of hands and feet (Zou and Niswander, 1996). Interestingly, BMP-2 induces apoptosis of cultured osteoblastic cells in a manner that is independent of its pro-differentiating effect (Hay *et al.*, 2004). Several other factors including Fas ligand, IL-1, and tumor necrosis factor, on the other hand, also stimulate apoptosis of cultured osteoblastic cells (Jilka *et al.*, 1998; Tsuboi *et al.*, 1999); but at present there is no evidence that they are involved in the regulation of osteoblast apoptosis *in vivo*.

Wnt signaling has a profound effect on bone as exemplified by the high bone mass phenotype of mice and

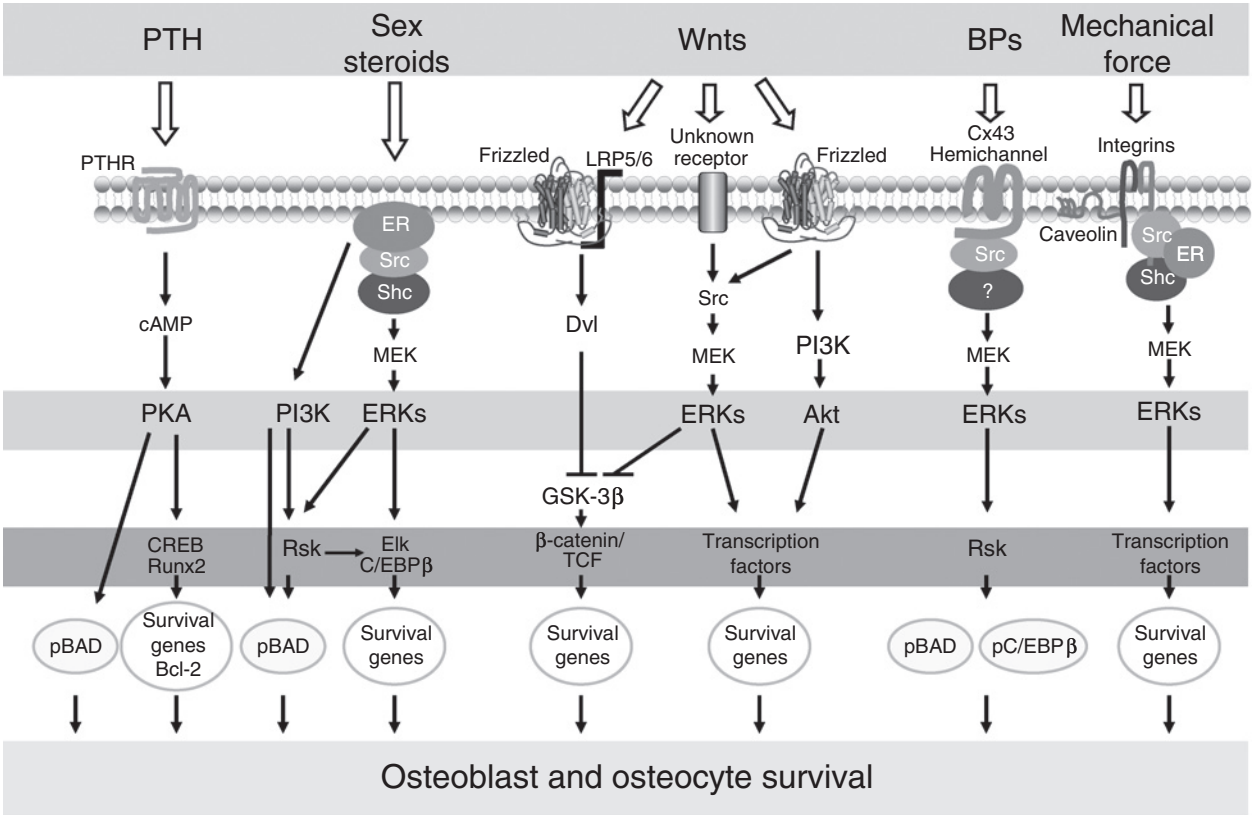

FIGURE 6 Antiapoptotic signaling pathways activated by hormones, cytokines, and mechanical forces in osteoblasts and osteocytes. Akt, thymoma viral proto-oncogene; BP, bisphosphonates; c/EBPβ, CCAAT/enhancer binding protein β; CREB, cAMP response element-binding; Dvl, disheveled; ER, estrogen receptor; Elk, ETS oncogene family; ERK, extracellular signal-regulated kinase; LRP5/6, low-density lipoprotein receptor-related protein 5 or LRP6; MEK, ERK kinase; PI3K, phosphoinositide-3 kinase; PKA, protein kinase A; PTH, parathyroid hormone; PTHR, PTH receptor; rsk, ribosomal S6 kinase; Runx2, runt related transcription factor 2; TCF, T cell factor.

humans with activating mutations of LRP5, which acts as a co-receptor with members of the Frizzled protein family of receptors for Wnt ligands (Bodine and Komm, 2006). Besides their well-established role in the proliferation and differentiation of osteoblast progenitors, Wnts are involved in the control of osteoblast and osteocyte apoptosis (see Fig. 6). Thus, the increased bone formation exhibited by mice lacking the Wnt antagonist secreted frizzled related protein-1 (SFRP-1) is associated with decreased osteoblast and osteocyte apoptosis (Bodine *et al.*, 2004). Likewise, the prevalence of osteoblast and osteocyte apoptosis is decreased in mice expressing the high bone mass activating mutation of LRP5 (G171V; Babij *et al.*, 2003). This LRP5 mutant exhibits reduced ability to bind sclerostin (Ellies *et al.*, 2006)—the Wnt antagonist specifically secreted by osteocytes (Bellido *et al.*, 2005). Consistent with this, *in vitro* studies have shown that sclerostin induces osteoblast apoptosis *in vitro* (Sutherland *et al.*, 2004). As will be discussed later, the ability of PTH and mechanical loading to reduce sclerostin synthesis could contribute to their ability to stimulate osteoblast differentiation and prolong osteoblast life span (Bellido *et al.*, 2005; Robling *et al.*, 2006).

Consistent with this *in vivo* evidence, direct activation of Wnt signaling *in vitro* prevents apoptosis of uncommitted C2C12 osteoblast progenitors and more differentiated MC3T3-E1 and OB-6 osteoblastic cell models (Almeida *et al.*, 2005). Thus, Wnt3a and Wnt1, which activate the so-called canonical pathway leading to β-catenin mediated transcription, as well as Wnt5a that does not activate β-catenin, were all able to prevent apoptosis. Remarkably, both classes of Wnts activate Src/ERK and PI3/AKT kinases, which are required for the antiapoptotic effect of these ligands. The mechanism by which Wnts activate these survival kinases is unknown. However, it might result from Wnt association with other receptors, such as Ryk—an atypical member of the receptor tyrosine kinase family that binds Wnts and can either form a complex with Frizzled to activate canonical Wnt signaling or transduce noncanonical Wnt signals via Frizzled-independent pathways that involve downstream activation of ERKs (Katso *et al.*, 1999).

Despite evidence that Wnt signaling suppresses osteoblast apoptosis, the reduced osteoblast number in mice lacking LRP5 is apparently not associated with increased osteoblast apoptosis (Kato *et al.*, 2002), although

osteoblastic calvaria cells isolated from such mice do exhibit increased apoptosis (Clement-Lacroix *et al.*, 2005). Likewise, osteoblast apoptosis is not reduced when canonical Wnt signaling is increased by deletion of Axin2, an intracellular inhibitor of the canonical Wnt signaling pathway (Yu *et al.*, 2005). Moreover, reduction of β-catenin levels does not affect osteoblast numbers, suggesting a lack of an effect on osteoblast apoptosis (Holmen *et al.*, 2005; Glass *et al.*, 2005). These findings are consistent with *in vitro* evidence that expression of an active form of β-catenin alone does not prevent osteoblast apoptosis, and that β-catenin-mediated transcription was only permissive for the antiapoptotic effects of canonical Wnts but it was dispensable for the antiapoptotic action of the noncanonical Wnt5a (Almeida *et al.*, 2005). Thus, activation of Src/ERK and PI3K/Akt pathways (and potentially other signaling molecules) appears to be primarily responsible for the anti-apoptotic effects of Wnts on osteoblasts.

PTHrP, produced by early osteoblast progenitors (Walsh *et al.*, 1995) as well as osteocytes (Chen *et al.*, 2005b), is an important member of the locally produced cytokines and growth factors that regulate osteoblast apoptosis (Miao *et al.*, 2004, 2005). Specific deletion of PTHrP in cells of the osteoblast lineage caused a reduction in bone mass that was associated with increased osteoblast apoptosis (Miao *et al.*, 2005). Other factors include transforming growth factor-β (TGF-β), insulin-like growth factor-I (IGF-I), fibroblast growth factor-2 (FGF-2), and interleukin-6 (IL-6) type cytokines (Jilka *et al.*, 1998; Bellido *et al.*, 1998; Hurley *et al.*, 1999; Grey *et al.*, 2003). *In vivo* evidence that TGF-β provides tonic antiapoptotic signaling is provided by the decreased bone mass associated with increased osteoblast apoptosis in mice lacking Smad-3, which mediates TGFβ-signaling (Borton *et al.*, 2001). Additional evidence is provided by studies of mice lacking PTEN, a phosphatase that dephosphorylates PI(3,4,5)trisphosphate generated by PI3Kinase—a survival pathway activated by many growth factors including IGF-I. Mice with deletion of PTEN in osteoblasts exhibit high bone mass, and removal of PTEN from cultured osteoblasts attenuates their apoptosis, although the prevalence of osteoblast apoptosis in bone of PTEN- deficient mice was not determined (Liu *et al.*, 2007).

Interaction of cultured osteoblastic cells with the extracellular matrix generates antiapoptotic signals via integrins (Globus *et al.*, 1998; Verderio *et al.*, 2003). Moreover, mice expressing a matrix metalloproteinase (MMP)-resistant mutant of type I collagen exhibit increased osteoblast and osteocyte apoptosis. Thus, MMP-mediated release of growth factors from the extracellular matrix or exposure of cryptic integrin binding sites in the matrix must also contribute to antiapoptotic signaling in these cells (Zhao *et al.*, 2000).

Some of the pathways affecting osteoblast apoptosis discussed earlier are regulated by systemic hormones and pharmacotherapeutic agents as listed in Table 2 and discussed in Section VII.

OSTEOCYTE APOPTOSIS

The Osteocyte Network

Osteocytes are former osteoblasts entombed individually in lacunae of the mineralized matrix. They display multiple (50 on average) cytoplasmic dendritic processes that radiate from the cell body. These processes run along narrow canaliculi and are linked by gap junctions with processes of neighboring osteocytes, the lining cells, and osteoblasts at the bone surface, as well as cellular elements of the bone-marrow endothelial cells of the marrow vasculature (Marotti *et al.*, 1990). Osteocytes uniquely synthesize proteins such as sclerostin that are capable of modulating osteoblast and osteoclast differentiation. Thus, osteocytes are ideally suited for sensing and responding to mechanical strain and provide a means by which bone adjusts to load by changing in mass, shape, or microarchitecture, and a means for initiating repair of microdamage (Martin *et al.*, 1998). The crucial role of osteocytes in the adaptation of bone to reduced mechanical strain is supported by recent evidence that mice in which osteocytes have been ablated fail to lose bone in response to hindlimb unloading (Tatsumi *et al.*, 2007).

Whereas osteoblasts and osteoclasts are relatively short-lived and transiently present on only a small fraction of the bone surface, osteocytes are long-lived and present throughout the skeleton. Unlike osteoblasts, which begin to die by apoptosis almost as soon as they are born, most osteocytes remain alive until the bone in which they reside is replaced. Nonetheless, some osteocytes do die by apoptosis, because the prevalence of the phenomenon under physiologic conditions is 2% to 5% when visualized with ISEL (Aguirre *et al.*, 2006). Apoptotic osteocytes are deep brown colored with TUNEL or ISEL, are markedly pyknotic, and occupy an eccentric position with their lacunae (see Fig. 1K). The pyknosis is particularly noteworthy when stained by DNA-specific bisbenzimide dyes such as Hoechst 33258 (Weinstein *et al.*, 2000; see Fig. 1L). Osteocyte apoptosis is cumulative because osteocytes are isolated from macrophages, and it requires extensive degradation to small molecules to dispose of the cells through the narrow canaliculi. Indeed, degraded DNA can be detected in osteocyte lacunae of necrotic human bone long after the initial apoptotic insult (Weinstein *et al.*, 2000; see Fig. 1K).

Significance of Osteocyte Apoptosis and Its Regulation by Mechanical Strain

Physiological levels of load imposed on bone *in vivo* decrease the number of apoptotic osteocytes (Noble *et al.*,

2003). On the other hand, lack of mechanical stimulation induced by unloading of bone leads to an increased number of hypoxic osteocytes (Basso and Heersche, 2006) as well as apoptotic osteocytes (Aguirre *et al.*, 2006). The hypoxic effect is reversed by loading, suggesting that mechanical forces facilitate oxygen diffusion and thereby osteocyte survival (Dodd *et al.*, 1999). Osteocytes interact with the extracellular matrix (ECM) in the pericellular space through discrete sites in their membranes, which are enriched in integrins and vinculin (Gohel *et al.*, 1995; Aarden *et al.*, 1996), as well as through transverse elements that tether osteocytes to the canalicular wall, as elegantly demonstrated by Schaffler and co-workers (You *et al.*, 2004). Fluid movement in the canaliculi resulting from mechanical loading might induce ECM deformation, shear stress, and/or tension in the tethering elements. The resulting changes in circumferential strain in osteocyte membranes might be converted into intracellular signals by integrin clustering and integrin interaction with cytoskeletal and catalytic proteins at focal adhesions (Giancotti, 1997). Indeed, physiological levels of mechanical strain imparted by stretching or pulsatile fluid flow prevent apoptosis of cultured osteocytes (Bakker *et al.*, 2004; Plotkin *et al.*, 2005a).

Mechanical forces are transduced into intracellular signals through integrins and a signalsome comprising actin filaments, microtubules, FAK, and Src kinases, resulting in activation of the ERK pathway and attenuation of osteocyte apoptosis (Plotkin *et al.*, 2005a; see Fig. 6). Intriguingly, a ligand-independent function of the estrogen receptor (ER) is indispensable for mechanically induced ERK activation in both osteoblastic and osteocytic cells (Aguirre *et al.*, 2007). This observation is consistent with reports that mice lacking the ERα and ERβ exhibit a poor osteogenic response to loading (Lee *et al.*, 2004a).

The disruption of the integrity of the osteocyte network that results from apoptosis serves as a signaling mechanism for bone's ability to self-repair and perhaps also to adapt to mechanical strains in a spatially defined pattern. Thus, in ulnae of adult rats, osteocyte apoptosis induced by bone fatigue is localized to regions of bone that contain microcracks and occurs in proximity to the subsequent osteoclastic resorption (Verborgt *et al.*, 2000, 2002). Likewise, osteocyte apoptosis induced by osteotomy in chicken radii temporally precedes an increase in osteoclasts (Clark *et al.*, 2005). Moreover, within 3 days of tail suspension, mice exhibit an increased incidence of osteocyte apoptosis in both trabecular and cortical bone (Aguirre *et al.*, 2006). This change is followed 2 weeks later by increased osteoclast numbers and cortical porosity, reduced trabecular and cortical width, and decreased spinal bone mineral density and vertebral strength. Importantly, whereas in ambulatory animals apoptotic osteocytes are randomly distributed, in unloaded mice apoptotic osteocytes are preferentially sequestered in endosteal cortical bone, the site that was subsequently resorbed. Furthermore, in rabbit tibia midshaft, osteocyte apoptosis and density exhibit a quantitative regional and linear association with remodeling (Hedgecock *et al.*, 2007). The conclusion from all these lines of evidence is that diminished mechanical forces eliminate signals that maintain osteocyte viability, thereby leading to apoptosis. Dying osteocytes in turn become the beacons for osteoclast recruitment to the vicinity and the resulting increase in bone resorption and bone loss (Manolagas, 2006). This contention is supported by the recent evidence that inducible and specific killing of osteocytes is sufficient to initiate bone resorption in mice (Tatsumi *et al.*, 2007).

The nature of the osteoclastogenic signals generated by the apoptotic osteocytes are, at this stage, only a matter of conjecture. Nonetheless, the oxygen deprivation that occurs with disuse enhances the expression of HIF-1α in osteocytes (Gross *et al.*, 2001). This transcription factor is a potent inducer of the angiogenic and osteoclastogenic factor VEGF. It is unknown whether increased HIF-1α also protects some anoxic osteocytes from apoptosis as it does in chondrocytes of the growth plate, or whether it promotes apoptosis in osteocytes as it does in other cell types by stabilizing p53 (Greijer and van der Wall, 2004).

Other mechanism(s) by which reduced mechanical forces trigger osteocyte apoptosis have been proposed. A deficit in nitric oxide (NO) production has been suggested as a potential culprit (Burger *et al.*, 2003). Consistent with this hypothesis, mechanical stimulation increases the production of NO by osteocytes (Klein-Nulend *et al.*, 1995; Pitsillides *et al.*, 1995; Zaman *et al.*, 1999). Mechanical stimulation of chicken and canine bone also increases the production of prostaglandin E_2 (Rawlinson *et al.*, 1991; Ajubi *et al.*, 1996), an agent known to inhibit bone cell apoptosis (Machwate *et al.*, 2001), raising the possibility that prostaglandins and perhaps other autocrine/paracrine soluble factors are also involved in the maintenance of osteocyte viability.

Similar to osteoblasts, signals for osteocyte survival may also be provided by the ECM itself as indicated by the increase in the prevalence of osteocyte apoptosis in transgenic mice expressing collagenase-resistant collagen type-I (Zhao *et al.*, 2000). It is thought that exposure of cryptic sites of ECM proteins by MMPs is required for the maintenance of cell–ECM interactions that result in "outside-in" integrin signaling that preserves osteocyte (and osteoblast) viability. This scenario is consistent with the observation that physiological levels of mechanical strain promote survival of osteocytic cells via a mechanism mediated by integrins (Plotkin *et al.*, 2005a). Besides mechanical forces, systemic hormones and pharmacotherapeutic agents affect osteocyte apoptosis in a manner analogous to osteoblasts (see Table 2) using similar pathways (see Fig. 6), as discussed in Section VII.

Several clinical conditions, ranging from complete motor paralysis to temporary immobilization such as bed rest, cause different degrees of bone loss, named disuse

osteopenia (Bikle *et al.*, 1997, 2003). Bone loss is also a consequence of spaceflights and represents a significant hindrance for long-term space flying (Bikle *et al.*, 1997). The evidence that mechanical forces regulate the life span of osteocytes raises the possibility that preservation of the function of the osteocyte network by maintaining osteocyte viability represents a powerful means for the prevention of the dramatic bone loss that ensues with weightlessness.

IMPLICATIONS FOR THE PATHOGENESIS AND TREATMENT OF BONE DISEASE

The pathophysiology of osteoporosis is due to excessive osteoclasts relative to the need for bone remodeling, too few osteoblasts relative to the need created by bone resorption, or a combination of both conditions (Manolagas, 2000). In addition to derangements in the genesis of bone cells, conditions leading to loss of bone mass and strength are associated with prolonged osteoclast life span and shortened osteoblast and osteocyte life span (summarized in Table 2). Not surprisingly, chronic diseases of the joint are also associated with dysregulated apoptosis.

Degenerative and Inflammatory Joint Disease

Osteoarthritis is characterized by progressive loss of articular cartilage leading to inflammation, subchondral bone formation, and the development of osteophytes at the joint margins. A prominent histologic feature of the cartilage in osteoarthritis is a decrease in the number of chondrocytes, which are normally responsible for the repair and regeneration of articular cartilage (Hashimoto *et al.*, 1998; Kim and Blanco, 2007). With increasing severity of osteoarthritis, there is continued loss of chondrocytes associated with increased numbers of apoptotic chondrocytes. Although it is unclear whether apoptosis represents the event that initiates the development of osteoarthritis, available evidence supports the notion that chondrocyte death and matrix loss are part of a vicious cycle leading to disease progression (Kim and Blanco, 2007).

In vitro studies have shown that chondrocyte apoptosis is stimulated by factors known to be present in osteoarthritic lesions including nitric oxide, ROS, TNF-α, Fas ligand, and TRAIL (Lotz *et al.*, 1999; Lee *et al.*, 2004b). Loss of matrix attachment, increased mechanical force, and increased levels of pyrophosphate also stimulate chondrocyte apoptosis (Johnson *et al.*, 2001; Islam *et al.*, 2002). That apoptosis plays a fundamental role in the development of the disease is indicated by the ability of caspase inhibitors to reduce both chondrocyte apoptosis and the severity of osteoarthritic changes seen in appropriate animal models (D'Lima *et al.*, 2006).

Rheumatoid arthritis is characterized by joint destruction due to accumulation of synovial fibroblasts and macrophages that produce proinflammatory cytokines and matrix degradative enzymes, as well as lymphocytes that invade the area to produce additional cytokines. Interestingly, it has been proposed that the synovial fibroblast hyperplasia is the result of insufficient apoptosis (Liu and Pope, 2003). Indeed, induction of apoptosis of these cells with Fas ligand (Yao *et al.*, 2000) or TRAIL (Terzioglu *et al.*, 2007) reduced inflammation and associated joint destruction. Chondrocyte viability was unaffected, presumably due to the lack of vascularization.

RANKL is produced by synovial cells and T cells in the arthritic joint. It has recently been shown that this cytokine plays a important role in the development and recruitment of osteoclasts that resorb the adjacent bone surfaces, resulting in destruction and weakening of the joint (Takayanagi, 2005). TNF-α is also increased and may prolong osteoclast life span and stimulate osteoblast apoptosis in rheumatic joints either directly, or indirectly by stimulating the synthesis of the Wnt antagonist Dkk1 (Diarra *et al.*, 2007).

Osteoporosis Associated with Sex Steroid Deficiency

Sex steroids preserve bone mass by attenuating bone turnover and maintaining a focal balance between the rate of bone formation and resorption. Attenuation of bone turnover is the result of suppressive effects of sex steroids on the generation of both osteoblast and osteoclast progenitor cells. Maintenance of a focal balance between bone resorption and formation is due to an antiapoptotic action of estrogens and androgens on osteoblasts/osteocytes and a proapoptotic effect on osteoclasts (Manolagas, 2000). Estrogen deficiency also increases the prevalence of osteocyte apoptosis in humans (Tomkinson *et al.*, 1997), rats (Tomkinson *et al.*, 1998), and mice (Kousteni *et al.*, 2001). Increased osteocyte apoptosis and the resulting disruption of the osteocyte network may contribute to bone fragility that follows estrogen deficiency.

Sex steroids act directly on osteoblasts to induce survival signals via a kinase-mediated action of the ER, independent of the DNA binding actions of the receptor (Kousteni *et al.*, 2001; see Fig. 6). Extensive *in vitro* studies have shown that the antiapoptotic effects of 17β-estradiol (E_2) on osteoblastic and osteocytic cells are mediated by transient activation of the Src/Shc/ERKs, as well as modulation of the PI3K and JNK signaling pathways. Moreover, activation of cytoplasmic kinases by estrogens in osteoblast cell culture and murine bone promotes the activation of key transcription factors downstream of ERKs such as Elk-1, CCAAT enhancer binding protein-b (C/EBPβ), cyclic adenosine monophosphate-response element binding protein (CREB), and the suppression of

c-Jun (Kousteni *et al.*, 2003). And, activation of these transcription factors is required for the antiapoptotic effects of estrogens. The evidence that direct receptor–DNA interaction is dispensable for the regulation of osteoblast apoptosis by E_2 is further supported by evidence that mice lacking the DNA-binding function of the ERα (NERKI) show increased osteoblast apoptosis following ovariectomy, whereas replacement with E_2 prevents this effect (M. Almeida, unpublished observations).

In contrast to the antiapoptotic effects of estrogens and androgens on osteoblasts and osteocytes, these hormones exert proapoptotic effects on mature osteoclasts and their precursors. This latter effect is associated with reduced expression of IL-1R1 mRNA and increased IL-1 decoy receptor expression (Sunyer *et al.*, 1999). In murine bone marrow cocultures, the proapoptotic effect of estrogen is mediated by TGF-β produced by osteoblastic cells (Hughes *et al.*, 1996). The proapoptotic actions of E_2 on osteoclasts may also involve E_2-induced downregulation of cytokines such as M-CSF, TNF-α, and RANKL that promote osteoclast survival (Eghbali-Fatourechi *et al.*, 2003; Syed and Khosla, 2005), and increased synthesis of OPG that blocks the actions of RANKL (Hofbauer *et al.*, 1999).

E_2 has direct proapoptotic effects on osteoclasts mediated by ERKs (Chen *et al.*, 2005a). E_2-induced ERK phosphorylation in osteoclasts was sustained for at least 24 hours following exposure to the hormone, in contrast to its transient effect on ERK phosphorylation in osteoblast and osteocytic cells. Interestingly, the proapoptotic effect of E_2 on osteoclasts was abrogated by conversion of sustained ERK phosphorylation to transient (Chen *et al.*, 2005a). Moreover, 4-estren-3α,17β-diol (estren), a synthetic ligand of the ER or androgen receptor that reproduces the nongenotropic effects of classical sex steroids with minimal effects on classical transcription, was as potent as E_2 or 5α-dihydrotestosterone (DHT) not only in protecting osteoblasts/osteocytes from apoptosis but also in promoting osteoclast apoptosis (Kousteni *et al.*, 2002). Conversely, 1,2,5-tris(4-hydroxylphenyl)-4-proylpyrazole, an ER ligand with potent classical transcriptional activity but minimal effects on ERK or JNK kinases, did not affect osteoclast (or osteoblast) apoptosis. Moreover, osteoclasts generated from the bone marrow of mice with ERα lacking the ability to bind to DNA ($ER\alpha^{NERKI/-}$) also underwent apoptosis upon E_2 treatment (Kousteni *et al.*, 2005). Taken together, the foregoing evidence indicates that the proapoptotic effect of sex steroids on osteoclasts, similar to their antiapoptotic effect on osteoblasts and osteocytes, results from a kinase-mediated mechanism of receptor action.

Antioxidant actions of sex steroids are critical for their effects on the life span of osteoclasts and osteoblasts. Loss of sex steroids promotes an increase in oxidative stress in bone that is rescued by treatment with E_2, DHT, or the antioxidant NAC. Importantly, NAC was as effective as E_2 or DHT in preventing the decrease in bone mineral density (BMD; Lean *et al.*, 2003), as well as the increase in osteoblast and osteocyte apoptosis caused by gonadectomy (Almeida *et al.*, 2007). The proapoptotic effect of both sex steroids on osteoclasts is associated with increased levels of glutathione reductase (GSR), consistent with evidence that osteoclasts utilize reactive oxygen species for survival signaling (Almeida *et al.*, 2007). GSR defends against oxidative damage by acting in concert with glutathione peroxidase and glutathione to convert peroxides into harmless alcohols (Dickinson and Forman, 2002). Thus, drugs such as buthionine sulfoximine (BSO) or diethylmaleate (DEM) that deplete the cells of glutathione abrogate E_2- or DHT-induced osteoclast apoptosis *in vitro* (Almeida *et al.*, 2007). Further, the effects of E_2 or DHT on GSR levels in osteoclasts were abrogated by specific inhibitors of Src and MEK kinases. BSO or DEM also abrogated the antiapoptotic effects of E_2 or DHT on osteoblastic OB-6 cells and calvaria cells.

The mechanism by which sex steroids modulate the redox status of osteoblasts is unclear; however, it seems that increased GSR synthesis is not involved (M. Almeida *et al.*, unpublished observation). Instead, E_2 or DHT appears to suppress H_2O_2-induced $p66^{shc}$ phosphorylation (required for transduction of oxidant stress signals into apoptosis) via activation of the Src/ERK signaling (Almeida *et al.*, 2007). Thus, stimulation of osteoclast and attenuation of osteoblast apoptosis by E_2 involve nonprotein thiol metabolism and are the result of actions mediated via cytoplasmic kinases and probably downstream transcriptional control (Kousteni *et al.*, 2003).

Glucocorticoid-Induced Osteoporosis

Growth retardation due to glucocorticoid excess is characterized by increased apoptosis of both proliferating and terminal hypertrophic chondrocytes resulting in decreased width of the growth plate (Chrysis *et al.*, 2003). The increase in chondrocyte apoptosis is accompanied by increased immunoreactivity for caspase-3 and decreased immunoreactivity for the antiapoptosis proteins, Bcl-2 and Bcl-X, as well as decreased immunoreactivity for PTHrP.

Glucocorticoid excess also increases the prevalence of osteoblast and osteocyte apoptosis in both adult murine vertebrae and human iliac bone (Weinstein *et al.*, 1998; Gohel *et al.*, 1999; see Figs. 1I–L). This may explain, at least in part, the decrease in osteoblast number and bone formation rate caused by glucocorticoid excess. Glucocorticoid-induced osteoporosis in humans is often complicated by the *in situ* death of portions of bone, associated with abundant apoptotic osteocytes juxtaposed to the subchondral fracture crescent—a ribbon-like zone of collapsed trabeculae (Weinstein *et al.*, 2000). Osteocytes with condensed chromatin have been observed between the tetracycline labeling that demarcates sites of bone formation,

indicating that these cells died immediately after entombment (see Fig. 1L). In this situation, osteocyte apoptosis represents a cumulative and unrepairable defect that would disrupt the mechanosensory osteocyte–canalicular network and prevent repair of microfractures. This situation would promote collapse of the femoral head and explain the correlation between total steroid dose and the incidence of avascular necrosis of bone (Felson and Anderson, 1987), as well as the occurrence of osteonecrosis after cessation of steroid therapy.

The proapoptotic effect of glucocorticoids on osteoblasts and osteocytes is direct as overexpression of 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2), an enzyme that inactivates glucocorticoids, specifically in osteoblasts and osteocytes prevents the steroid-induced increase in apoptosis (O'Brien *et al.*, 2004). Moreover, osteoblast number, osteoid area, and bone formation rate are significantly higher in glucocorticoid-treated 11β-HSD2 transgenic mice compared to glucocorticoid-treated wild-type controls. Overexpression of 11β-HSD2 also preserves osteocyte viability and bone strength despite loss of bone mass (O'Brien *et al.*, 2004), suggesting that osteocytes contribute to bone strength independently of bone mass. Although the mechanism(s) involved have not been established, disruption of the lacunocanalicular system that occurs with osteocyte apoptosis can lead to changes in bone material properties (Weinstein *et al.*, 2006).

Glucocorticoid-stimulated apoptosis of cultured osteoblastic and osteocytic cells is strictly dependent on the glucocorticoid receptor (GR; Gohel *et al.*, 1999; Plotkin *et al.*, 2007b), and osteoblast-specific deletion of the GR prevents glucocorticoid-induced osteoblast apoptosis (Tuckermann *et al.*, 2005). Strikingly, in an osteocytic cell model (MLO-Y4) the proapoptotic effect of glucocorticoids is preceded by cell detachment due to interference with FAK-mediated survival signaling generated by integrins. In this mechanism, Pyk2 (a member of the FAK family) becomes phosphorylated and subsequently activates proapoptotic JNK signaling (Plotkin *et al.*, 2007b). In addition, the proapoptotic actions of glucocorticoids may involve suppression of the synthesis of locally produced antiapoptotic factors including IGF-I and IL-6 type cytokines, as well as MMPs (Canalis and Delany, 2002), and stimulation of the proapoptotic Wnt antagonist SFRP-1 (Wang *et al.*, 2005).

As in the case of sex steroids, the effects of glucocorticoids on osteoclast life span are the opposite of that on osteoblasts (see Table 2). However, the rat appears to be an exception as there is a glucocorticoid-induced increase in cancellous bone mass and decrease in osteoclasts (King *et al.*, 1996), possibly due to increased apoptosis (Dempster *et al.*, 1997). In mice receiving excess glucocorticoids, osteoclast progenitors are reduced, but cancellous osteoclast number does not decrease, presumably because of the ability of glucocorticoids to prolong osteoclast life span (Jia *et al.*, 2006). This effect may account for the early transient increase in bone resorption in patients with exogenous or endogenous hyperglucocorticoidism. The prosurvival effect of glucocorticoids on osteoclasts is powerful enough to antagonize the proapoptotic effect of BPs (Weinstein *et al.*, 2002).

The antiapoptotic actions of glucocorticoids on osteoclasts are also direct, because mice expressing 11β-HSD2 specifically in osteoclasts exhibit a reduction in osteoclast number following administration of glucocorticoids, consistent with suppressive effects of the steroid on progenitors and prevention of steroid-induced survival signaling in osteoclasts (Jia *et al.*, 2006). In accord with this decrease in osteoclast number, the loss of bone density observed in wild-type mice was strikingly prevented in these transgenic mice. Nevertheless, the expected glucocorticoid-induced decrease in osteoblast number and bone formation and increasein the prevalence of osteoblast apoptosis were still observed.

Age-Related Involutional Osteoporosis

Age-related loss of bone mass and strength is an invariable feature of human biology. Recent population-based longitudinal studies demonstrate that substantial trabecular bone loss begins as early as the 20s in young adult women and men, long before any hormonal changes (Riggs *et al.*, 2008). In bone of aging dogs, there is an accumulation of microdamage (Frank *et al.*, 2002), and in humans there is a decline in osteocyte density (Vashishth *et al.*, 2000; Qiu *et al.*, 2002) accompanied by decreased prevalence of osteocyte-occupied lacunae (Qiu *et al.*, 2003), an index of premature osteocyte death. Furthermore, osteocyte death is associated with hip fractures in aging humans (Dunstan *et al.*, 1990). In view of the evidence discussed earlier for the role of osteocytes in microfracture repair, age-related loss of osteocytes due to apoptosis could be partially responsible for the disparity between bone quantity and quality that occurs with aging (Hui *et al.*, 1988).

Both female and male C57BL/6 mice lose bone strength and mass progressively between the ages of 4 and 31 months. These changes are temporally associated with a decreased rate of remodeling as evidenced by decreased osteoblast and osteoclast numbers and decreased bone formation rate, as well as decreased wall width and increased osteoblast and osteocyte apoptosis (Almeida *et al.*, 2007). Increased levels of ROS may contribute to this increase in apoptosis as evidenced by a temporal linkage with increased ROS and decreased activity of GSR in the bone marrow, and a corresponding increase in the phosphorylation of p53 and $p66^{Shc}$. In addition, aged mice exhibit a twofold increase in serum corticosterone, adrenal weight, and bone mRNA for 11β-HSD1, the enzyme that amplifies glucocorticoid action (Weinstein *et al.*, unpublished data). Thus, local amplification of endogenous glucocorticoids may also contribute to increased osteoblast and osteocyte apoptosis.

Increased production of PPARγ-activating oxidized lipids could also contribute in view of evidence that this transcription factor exerts tonic suppression of bone formation (Akune *et al.*, 2004; Klein *et al.*, 2004) and that administration of the PPARγ ligand rosiglitazone to mice decreases bone formation and increases the number of apoptotic osteoblasts (Soroceanu *et al.*, 2004). Finally, the decline in physical activity with old age could stimulate apoptosis of osteoblasts and osteocytes because of reduced skeletal loading.

Bone Anabolism by Intermittent PTH

Daily injections of parathyroid hormone (PTH) increase bone mass and reduce the incidence of fracture in postmenopausal women, in elderly men, and in women with glucocorticoid-induced osteoporosis (Hodsman *et al.*, 2005). In humans receiving daily injections of PTH for 28 days (Lindsay *et al.*, 2006) or for 12 to 24 months (Ma *et al.*, 2006), most of the increase in bone formation occurred within preexisting BMUs. New bone formation also took place on surfaces adjacent to the BMU, perhaps due to spillage of osteoblasts outside the boundary of the bone surface being remodeled. Thus, PTH overrides the mechanisms that normally limit the number of osteoblasts in the BMU to that needed to replace the bone previously excavated by osteoclasts. The increase in osteoblast number appears to be due to both increased osteoblast differentiation and decreased osteoblast apoptosis (Jilka, 2007). In view of the prodifferentiating and prosurvival effects of locally produced PTHrP discussed earlier (Miao *et al.*, 2005), it is possible that daily injections of PTH simply add to existing osteogenic signals arising from PTHrP-induced activation of PTHR1.

Studies in mice have shown that increased survival is a major contributor to the increase in osteoblast number caused by intermittent PTH. Daily administration of 3 to 300 ng/g/d of PTH for 28 days to adult mice caused a dose-dependent increase in the BMD of the spine and hindlimb that was associated with a reduction in osteoblast apoptosis at both skeletal sites (Bellido *et al.*, 2003). Moreover, the same doses of PTH that inhibited osteoblast apoptosis also increased osteoblast number, bone formation rate, and the amount of cancellous bone. The prevalence of osteoblast apoptosis in this experiment was inversely correlated with circulating osteocalcin, bone formation rate, and osteoblast number. A decline in the number of apoptotic osteoblasts was detected after only two injections. After four injections, there was a 50% reduction in the prevalence of apoptotic osteoblasts, and osteoblast number increased two-fold.

In contrast, a 50% increase in apoptotic osteoblasts was observed in the primary spongiosa of the distal femur of 1-month-old rats after 7 and 21 days, but not after 28 days, of PTH injections (Stanislaus *et al.*, 2000). Nevertheless, these investigators also reported that the activity of caspases 2, 3, and 7 was dramatically decreased in extracts of the femoral metaphyseal bone, which included both primary and secondary spongiosa. This result is consistent with an antiapoptotic effect of daily hormone injections on osteoblasts in the secondary spongiosa, and perhaps on the preosteoblasts that are prevalent in the metaphysis during growth (Onyia *et al.*, 1997).

In a recent study of transiliac biopsies from postmenopausal women receiving daily injections of PTH for 28 days, Lindsay *et al.* (2007) found an increase in osteoblast apoptosis in cancellous bone, as well as a positive correlation between osteoblast apoptosis and bone formation rate. It seems highly unlikely that a species difference can account for this incongruent result. The absolute number of apoptotic osteoblasts could increase with the stimulation of osteoblastogenesis in response to intermittent PTH as Lindsay *et al*. suggest, yet the prevalence of apoptosis could well be unaffected or reduced when expressed per number of osteoblasts. However, osteoblast apoptosis expressed per millimeter of osteoblast surface, as was done in the study of Lindsay *et al*., does not permit estimation of prevalence because it ignores the variation in osteoblast size that occurs during their transition from plump cuboidal, at the beginning of the refilling of a resorption cavity, to bricklike rectangular, near the end of the process (Parfitt, 1990). Other methodologic issues could also be responsible for the discrepancy (Jilka *et al.*, 2007). Indeed, as discussed earlier, apoptotic osteoblasts in humans are quite rare. Thus, it may be necessary to examine the role of apoptosis in the anabolic effect of intermittent PTH in humans under conditions in which the baseline prevalence of the phenomenon is substantially increased (e.g., glucocorticoid excess) to facilitate detection of the effects of pharmacologic manipulation.

PTH and PTHrP inhibit apoptosis in cultures of rat, murine and human osteoblastic cells (Jilka *et al.*, 1998; Bellido *et al.*, 2003; Chen *et al.*, 2002) via cAMP-activated protein kinase A and inactivation of the proapoptotic protein Bad, as well as increased transcription of survival genes such as Bcl-2 (Bellido *et al.*, 2003; see Fig. 6). The increased synthesis of survival genes requires cAMP response element-binding protein and Runx2. Besides PTH and PTHrP, other hormones that stimulate cAMP production in osteoblastic cells, including calcitonin and prostaglandin E, inhibit apoptosis of osteoblastic cells (Plotkin *et al.*, 1999; Machwate *et al.*, 2001).

In cultured osteoblastic cells, the antiapoptotic effect of PTH lasts only about 6 hours because of PTH-induced activation of proteasomal degradation of Runx2 (Bellido *et al.*, 2003) and termination of PKA-mediated gene expression downstream of receptor desensitization by protein kinase inhibitor γ (Chen *et al.*, 2007). Consistent with short-lived PTH-induced survival signaling, a reduction in osteoblast apoptosis is not observed after 6 days of continuous elevation of PTH in mice by infusion, or after

2 days of hormone elevation caused by feeding a calcium-deficient diet (Bellido *et al.*, 2003). Hence, the decrease in apoptotic osteoblasts seen in mice receiving intermittent PTH appears to be due to short bursts of survival signaling resulting in repeated delays of apoptosis.

Locally produced factors may also mediate the effects of intermittent PTH on osteoblast apoptosis. Experiments with genetically modified mice have shown that the anabolic effect of intermittent PTH depends upon growth factors with anti-apoptotic properties, such as IGF-I and FGF-2, that are known to be increased by intermittent PTH administration (Miyakoshi *et al.*, 2001; Bikle *et al.*, 2002; Yamaguchi *et al.*, 2005; Hurley *et al.*, 2006). Moreover, PTH decreases the expression of Wnt antagonists SFRP-2 and sclerostin, suggesting that intermittent PTH increases Wnt signaling, which not only stimulates differentiation but also inhibits apoptosis as discussed earlier. Consistent with this notion, daily PTH injections increased vertebral cancellous bone in male wild-type mice, but not in male LRP5-null mice (Kharode *et al.*, 2006); nevertheless, the anabolic response to PTH in cortical bone is not affected by LRP5 deficiency (Kharode *et al.*, 2006; Sawakami *et al.*, 2006; Iwaniec *et al.*, 2007).

The Therapeutic Efficacy of Bisphosphonates

Bisphosphonates greatly attenuate the bone loss induced by glucocorticoid excess, sex steroid deficiency, and immobilization, and they are also used for the treatment of multiple myeloma and Paget's disease, as well as the management of the skeletal complications of cancer (Lipton, 2005). Decreased osteoclast progenitor development, decreased osteoclast recruitment, impairment of osteoclast function, and promotion of apoptosis of mature osteoclasts (see Figs. 1C–H) each contribute to the antiresorptive actions of BPs (Fleisch, 1998).

Nonamino- and aminobisphosphonates both lead to increased osteoclast apoptosis, although by distinct molecular mechanisms (Rogers, 2004). The nonamino derivatives, such as etidronate, clodronate and tiludronate, are metabolized to nonhydrolyzable ATP-like molecules. Intracellular accumulation of these metabolites inhibits the ATP-dependent enzyme adenine nucleotide translocase, a component of the mitochondrial permeability transition pore, leading to increased permeability of the outer mitochondrial membrane, caspase 3 activation, and osteoclast apoptosis (Rogers, 2004). This proapoptotic effect of nonaminobisphosphonates appears to be the primary mechanism for inhibition of resorption, because inhibition of caspases abolishes the antiresorptive effect of clodronate and etidronate *in vitro* (Halasy-Nagy *et al.*, 2001).

On the other hand, aminobisphosphonates, such as alendronate, risedronate, and zoledronate, suppress bone resorption and induce osteoclast apoptosis by inhibiting farnesyl diphosphate synthase (FPPS), an enzyme of the mevalonate metabolic pathway crucial for posttranslational prenylation and membrane targeting of proteins (Rogers, 2004). Accumulation of unprenylated molecules, in particular small GTPases that control cytoskeletal reorganization and vesicular trafficking, is an important cause of the decreased resorption, because bypassing aminobisphosphonate-dependent inhibition of FPPS restores resorption (Halasy-Nagy *et al.*, 2001). Loss of actin rings as well as defective ruffled border formation, trafficking of lysosomal enzymes and transcytosis of resorption products induced by aminobisphosphonates is eventually followed by osteoclast apoptosis. However, apoptosis may not be the mechanism responsible for the anti-resorptive activity of aminobisphosphonates. Indeed, unlike the case with nonamino- bisphosphonates, the anti-resorptive action of alendronate and risedronate is unaffected by caspase inhibitors (Halasy-Nagy *et al.*, 2001). This may explain observations from human studies that the reduction of bone resorption by aminobisphosphonates occurs in the face of unchanged osteoclast number (Chavassieux *et al.*, 1997, 2000).

Long-term treatment of human and nonhuman primates with BPs increases wall thickness, an index of focally increased osteoblast numbers or activity, resulting in more complete refilling of resorption cavities (Storm *et al.*, 1993; Balena *et al.*, 1993; Chavassieux *et al.*, 1997). This evidence raises the possibility that BPs do more than simply reduce remodeling space and that they also have a positive effect on this particular aspect of bone formation. Albeit, overall bone formation declines, as measured by serum markers, because of the decreased rate of remodeling. Moreover, the antifracture efficacy of BPs is disproportionate to their effect on bone mass (Cummings *et al.*, 2002), suggesting an additional effect on bone strength unrelated to effects on bone resorption or bone formation. In addition, the initial increase in bone resorption characteristic of glucocorticoid-induced bone loss is not prevented by BPs (Weinstein *et al.*, 2002). This evidence indicates that the actions of BPs on osteoclasts do not explain all aspects of their bone protective effects.

A series of studies has revealed that BPs prevent osteoblast and osteocyte apoptosis *in vitro* and *in vivo* (Plotkin *et al.*, 1999; Kogianni *et al.*, 2004; Follet *et al.*, 2007), providing a potential explanation for the increased wall thickness associated with BP therapy. Prevention of apoptosis of osteocytes and osteoblasts by BPs is exerted via activation of ERKs via a novel paradigm of signal transduction (Plotkin *et al.*, 1999; see Fig. 6). Specifically, hexameric connexin-43 (Cx43) hemichannels are essential transducers of the ERK-activating/antiapoptotic effects of BPs; however, the gap junctions formed by two Cx43 hemichannels are not. The signal-transduction property of Cx43 requires not only the pore-forming domain of Cx43, but also the C-terminal portion of the protein, which is physically

associated with the kinase Src. Consistent with this, Src expression and activity, as well as its interaction with Cx43, are indispensable for the antiapoptotic effects of BPs on osteoblasts and osteocytes. Unlike most ERK-activating stimuli that require nuclear functions of ERKs leading to gene transcription, BPs promote survival through ERK functions that are restricted to the cytoplasm. Such extranuclear functions require the activity of the kinase Rsk, the subsequent inactivation of the proapoptotic protein Bad, and the creation of a functional caspase inhibitory domain in C/EBPβ independent of its transcriptional effects (Plotkin *et al.*, 2005b). This evidence adds Cx43 to the list of transmembrane proteins capable of transducing survival signals in response to extracellular cues and raises the possibility that Cx43 may serve in this capacity for endogenously produced molecules or even other drugs.

Prevention of osteocyte apoptosis by BPs represents yet another potential mechanism for the inhibition of bone remodeling by these agents, beyond the well-established direct inhibition of osteoclast development and function. As discussed earlier, osteocyte apoptosis may initiate a targeted remodeling response. Therefore, prevention of osteocyte apoptosis by BPs might inhibit remodeling indirectly by decreasing osteoclast recruitment.

SUMMARY

Apoptosis of chondrocytes, osteoclasts, osteoblasts, and osteocytes plays a critical role in the development of the skeleton and in the maintenance of bone mass and strength throughout life. Dysregulation of bone cell apoptosis contributes to joint disease, as well as to the development of osteoporosis that occurs with sex steroid deficiency, glucocorticoid excess, and aging. Furthermore, apoptosis may be an important therapeutic target because the beneficial effects of intermittent PTH, as well as BPs, are associated with a reduction in osteoblast and osteocyte apoptosis. Future innovations that facilitate detection of this important event in human bone, as well as a deeper understanding of the factors and signaling pathways that control bone cell survival, should provide a better appreciation of the role of apoptosis in bone physiology, pathophysiology, and treatment. And, they may lead to new and improved therapeutic strategies. This potential is highlighted by recent work from our group showing that aminobisphosphonates that lack antiresorptive/antiremodeling activity, but retain the antiapoptotic property of BPs on osteoblast and osteocytes, preserve bone strength (Plotkin *et al.*, 2007a).

INTRODUCTION

Skeletal development and bone remodeling require stringent control of gene activation and suppression in response to physiological cues. The fidelity of skeletal gene expression necessitates integrating a broad spectrum of regulatory signals that govern the commitment of osteoprogenitor stem cells to the bone cell lineage and proliferation and differentiation of osteoblasts, as well as maintenance of the bone phenotype in osteocytes residing in a mineralized bone extracellular matrix. To accommodate the requirements for short-term developmental and sustained phenotypic expression of cell growth and bone-related genes, it is necessary to identify and functionally characterize the promoter regulatory elements as well as cognate protein–DNA and protein–protein interactions that determine the extent to which genes are transcribed. However, it is becoming increasingly evident that the catalogue of regulatory elements and proteins is insufficient to support transcriptional control in the nucleus of intact cells and tissues. Rather, gene regulatory mechanisms must be understood within the context of the subnuclear organization of nucleic acids and regulatory proteins.

There is growing appreciation that transcriptional control, as it is operative *in vivo*, requires multiple levels of nuclear organization. It is essential to package 2.5 yards of DNA as chromatin within the limited confines of the nucleus. Gene promoter elements must be rendered competent for protein/DNA and protein/protein interactions in a manner that permits binding and functional activities of primary transcription factors as well as coactivators and co-repressors. Less understood but pivotally relevant to physiological control is the localization of the regulatory machinery for gene expression, replication, and repair at subnuclear sites where the macromolecular complexes that support DNA and RNA synthesis are localized.

This chapter focuses on contributions by several indices of nuclear architecture to the control of gene expression in bone cells. We present cellular, biochemical, molecular, genetic, and epigenetic evidence for linkages of developmental and tissue-specific gene expression with the organization of transcriptional regulatory machinery in subnuclear compartments. Using skeletal genes as a paradigm, this chapter addresses mechanisms that functionally organize the regulatory machinery for transcriptional

†Present address: Institute of Oral Health Research, School of Dentistry, University of Alabama at Birmingham, Alabama 35294

activation and suppression as well as cell fate and lineage commitment during skeletal development and remodeling. It also provides evidence for consequences that result from perturbations in nuclear structure: gene expression interrelationships that are associated with skeletal disease and tumors that metastasize to bone.

GENE EXPRESSION WITHIN THE THREE-DIMENSIONAL CONTEXT OF NUCLEAR ARCHITECTURE: MULTIPLE LEVELS OF NUCLEAR ORGANIZATION SUPPORT FIDELITY OF GENE REGULATION

Although the mechanisms that control gene expression remain to be formally defined, there is growing awareness that the fidelity of gene regulation necessitates the coordination of transcription factor metabolism and the spatial organization of genes and regulatory proteins within the three-dimensional context of nuclear architecture. The components of nuclear organization include the sequence of gene regulatory elements, chromatin structure, and higher order organization of the transcriptional regulatory machinery into subnuclear domains. All of these parameters involve mechanisms that include transcription factor synthesis, nuclear import and retention, post-translational modifications of factors, and directing factors to subnuclear sites that support the organization and assembly of regulatory machinery for gene expression. Remodeling of chromatin and nucleosome organization to accommodate requirements for protein–DNA and protein–protein interactions at promoter elements are essential modifications for both activation of genes and physiological control of transcription. This is a key component of epigenetic control that mediates competency for gene activation or suppression and conveys phenotype and lineage commitment to progeny cells during mitosis. The reconfiguration of gene promoters and assembly of specialized subnuclear domains reflect the orchestration of both regulated and regulatory mechanisms. There are analogous and complex regulatory requirements for processing of gene transcripts. Here it has been similarly demonstrated that the regulatory components of splicing and export of messenger RNA to the cytoplasm are dependent on the architectural organization of nucleic acids and regulatory proteins. There is growing evidence that the focal localization of regulatory machinery in nuclear microenvironments supports the integration of regulatory signals in a manner that facilitates competency for physiological responsiveness.

From a biological perspective, each parameter of factor metabolism requires stringent control and must be linked to structure–function interrelationships that mediate transcription and processing of gene transcripts. However, rather than representing regulatory obstacles, the complexities of nuclear biochemistry and morphology provide the required specificity for physiological responsiveness to a broad spectrum of signaling pathways to modulate transcription under diverse circumstances. Equally important, evidence is accruing that modifications in nuclear architecture and nuclear structure–function interrelationships accompany and appear to be causally related to compromised gene expression under pathological conditions.

Multiple levels of genomic organization that contribute to transcription are illustrated schematically in Figure 1. Additional levels of nuclear organization are reflected by the subnuclear localization of factors that mediate transcription, processing of gene transcripts, DNA replication, DNA repair at discrete domains, and retention of regulatory factors with target gene promoters during mitosis to epigenetically maintain phenotype in progeny cells.

Sequence Organization: A Blueprint for Responsiveness to Regulatory Cues

Appreciation is accruing for the high density of information in both regulatory and mRNA-coding sequences of cell growth and phenotypic genes. The modular organizations of promoter elements provide blueprints for responsiveness to a broad spectrum of regulatory cues that support competency for transient developmental and homeostatic control as well as sustained commitments to tissue-specific gene expression. Overlapping recognition elements expand the options for responsiveness to signaling cascades that mediate mutually exclusive protein–DNA and protein–protein interactions. Splice variants for gene transcripts further enhance the specificity of gene expression. However, it must be acknowledged that the linear order of genes and flanking regulatory elements is necessary but insufficient to support expression in a biological context. There is a requirement to integrate the regulatory information at independent promoter elements and selectively utilize subsets of promoter regulatory information to control the extent to which genes are activated and/or suppressed.

Transcription of the osteocalcin (OC) gene is controlled by a modularly organized promoter with proximal basal regulatory sequences and distal hormone responsive enhancer elements (reviewed in Lian *et al.*, 2004). The OC gene is not expressed in nonosseous cells, nor is it transcribed in osteoprogenitor cells or early-stage proliferating osteoblasts. Following the postproliferative onset of osteoblast differentiation, transcription of the OC gene is regulated by Runx2 (Fig. 2). Maximal levels of transcription are controlled by the combined activities of the vitamin D response element, C/EBP site, AP-1 regulatory elements, and the OC box. Linear organization of the OC gene promoter reveals proximal regulatory elements that control basal and tissue-specific activity. These include the OC box for homeodomain protein binding and an osteoblast-specific complex, the TATA domain, a Runx site, and a C/EBP site. The distal promoter contains a vitamin D responsive

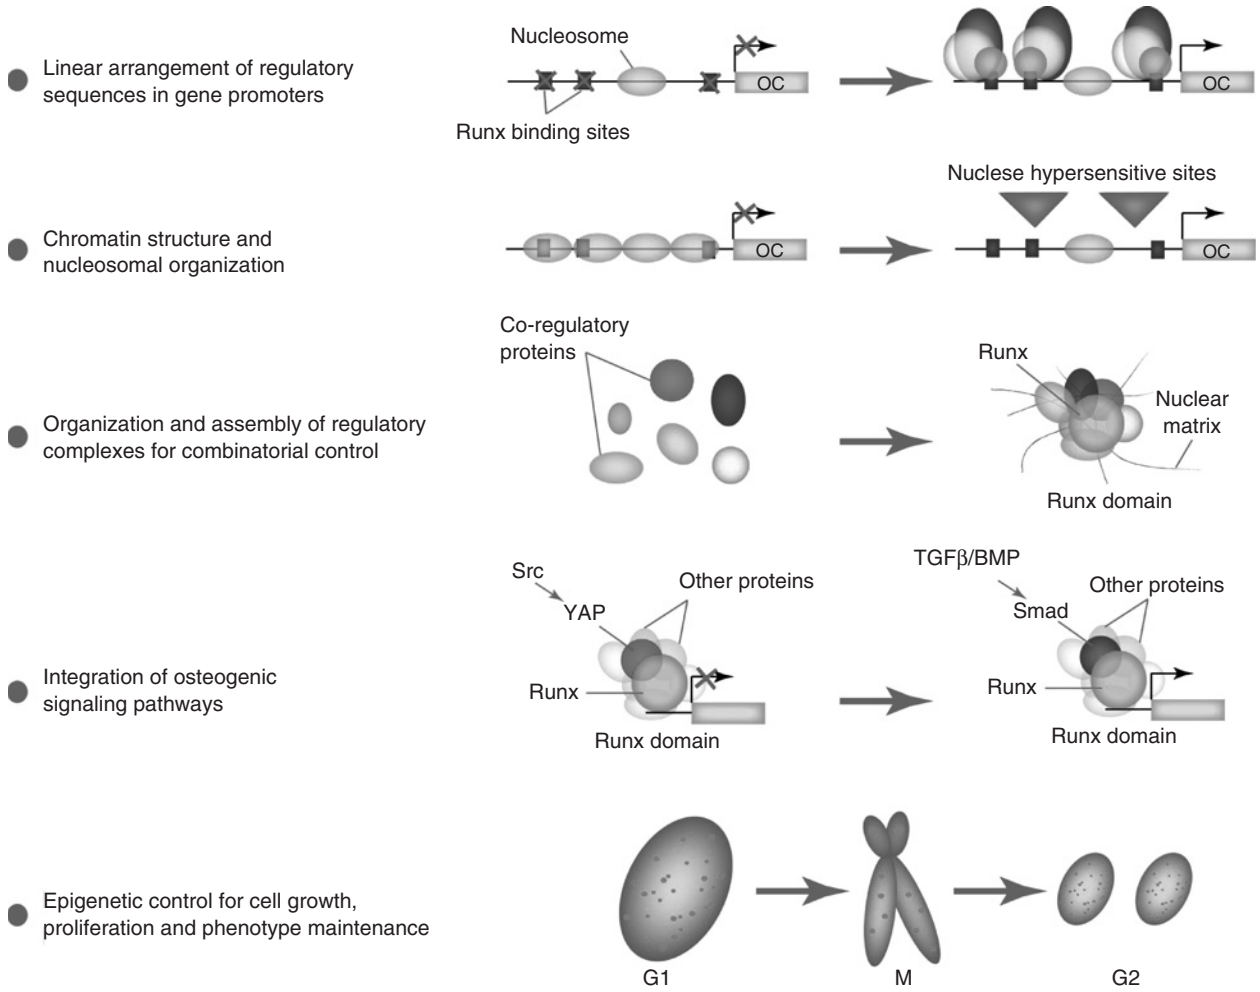

FIGURE 1 Multiple levels of nuclear organization. The linear placement of DNA-regulatory elements in gene promoters constitutes the primary level of nuclear organization. The distance between these regulatory sites is intricately regulated by the packaging of DNA into nucleosomes and higher order chromatin structures. Scaffolding nuclear proteins, such as RUNX, provide structural platforms for the assembly of multiprotein supercomplexes to facilitate the combinatorial control of gene expression. Genes and macromolecular regulatory complexes together give rise to dynamic microenvironments within the nucleus. RUNX nuclear microenvironments contain various co-regulatory proteins that are involved in combinatorial control of gene activation, as well as repression, chromatin remodeling and cellular signaling. In addition, Runx nuclear microenvironments are equally partitioned during mitosis to epigenetically regulate cell growth and phenotypic properties.

enhancer element (VDRE) that is flanked by Runx sites. The control of transcription is dependent on protein–DNA interactions in the basal and upstream elements that are in part dependent on the accessibility of cognate regulatory sequences and additionally on the consequences of mutually exclusive protein–DNA interactions.

Chromatin Reorganization: Packaging Genomic DNA in a Manner that Controls Access to Genetic Information

Chromatin structure and nucleosome organization provide architectural linkages between gene organization and components of transcriptional control. Within the eukaryotic nucleus the DNA is organized into a highly structured nucleoprotein complex named chromatin. The nucleosome is the fundamental unit of chromatin and is composed of a 147-bp DNA fragment wrapped around a core of histone proteins (two each of histones H2A, H2B, H3, and H4; Ramakrishnan, 1997; Richmond and Davey, 2003). Chromatin structure and nucleosome organization reduce distances between regulatory sequences, contributing to cross talk between promoter elements, and render elements competent for interactions with positive and negative regulatory factors.

The presence of nucleosomes has been generally considered to block accessibility of most transcription factors to their cognate binding sequences. Moreover, gene activity is usually accompanied by alterations in the nucleosomal array, as evidenced by increased nuclease hypersensitivity at specific promoter and enhancer elements (Li *et al.*, 2007; Narlikar *et al.*, 2002). Thus, nuclease digestion has

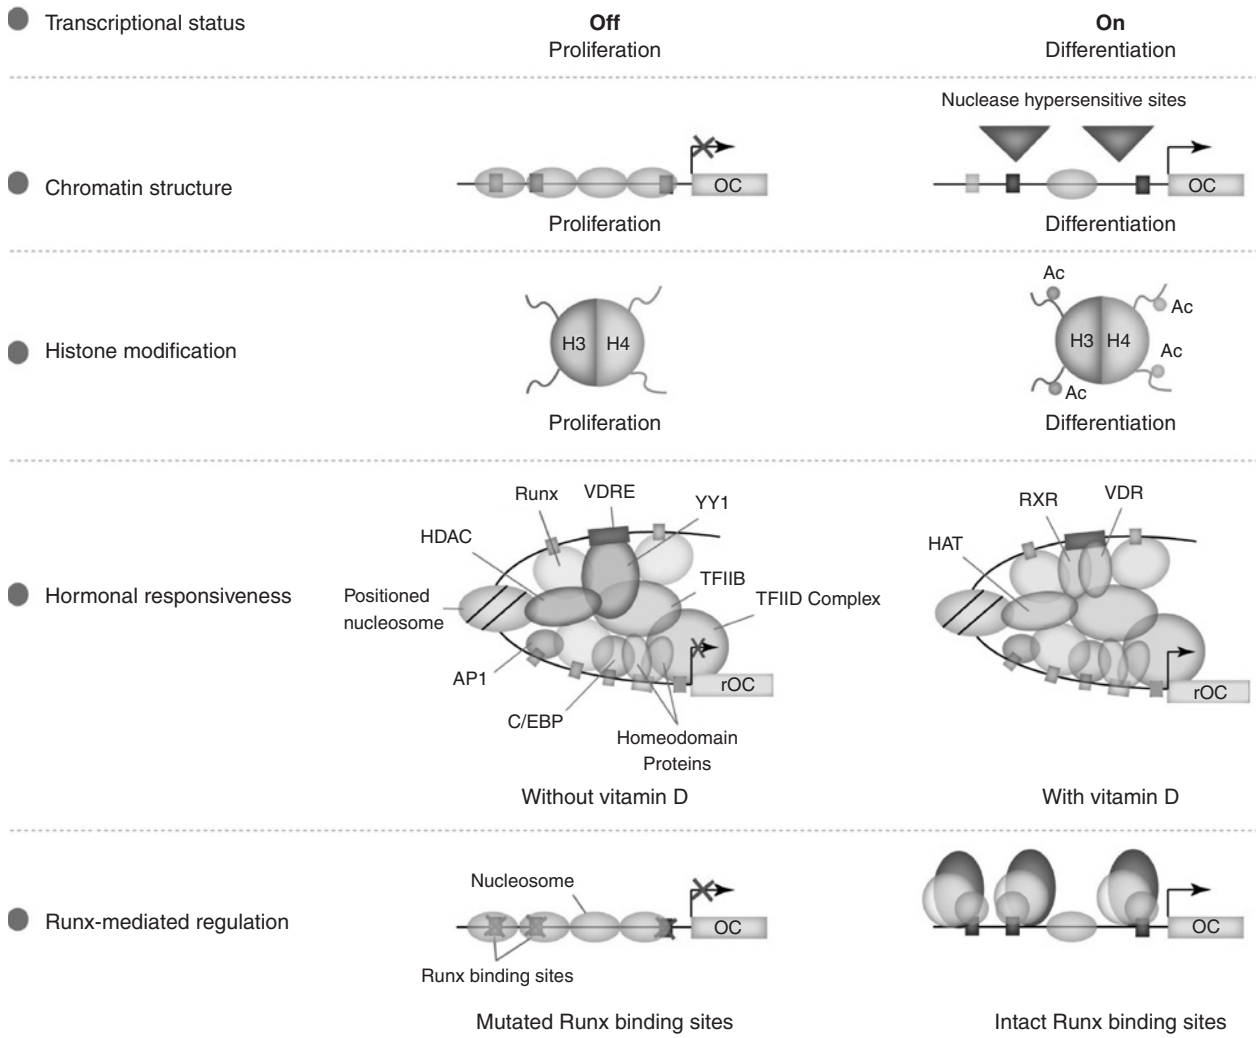

FIGURE 2 Runx-dependent regulation of the bone specific osteocalcin gene at multiple levels of nuclear organization. Osteocalcin is actively transcribed during osteoblast differentiation. This transcriptional upregulation is accompanied by Runx-dependent chromatin remodeling, histone modifications, and steroid hormone responsiveness. Intact Runx binding sites are required for transcriptional regulation of the osteocalcin gene; mutations in Runx binding sites result in a closed chromatin conformation, presence of transcriptional inhibitory histone modifications, and recruitment of repressor complexes.

been widely used to probe spatial organization of chromatin both *in vitro* and *in vivo* based on the premise that chromatin accessibility to nuclease activity reflects chromatin access to nuclear regulatory molecules. Chromatin immunoprecipitation (ChIP) assays that utilized antibodies to covalently modified histones or transcription regulators provide the basis for defining the dynamic association of protein complexes with chromatin domains that exhibit particular patterns of epigenetic markers. Multiple studies have established that there are intrinsic differences in the nucleosome binding capacity among transcription factors. Although several transcription factors cannot bind when their sites are assembled into nucleosomes, others can recognize and interact with nucleosome-engaged binding elements (Li *et al.*, 2007; Narlikar *et al.*, 2002), albeit with different degrees of affinity.

Changes in chromatin organization have been documented under many biological conditions where modifications of gene expression are necessary for the execution of physiological control. Transient changes in chromatin structure accompany and are linked functionally to developmental and homeostatic-related control of gene expression. Long-term changes occur when the commitment to phenotype-specific gene expression occurs with differentiation. Superimposed on the remodeling of chromatin structure and nucleosome organization that renders genes transcriptionally active are additional alterations in the packaging of DNA as chromatin support steroid hormone-responsive enhancement or dampening of transcription.

A large family of protein complexes that promote transcription by altering chromatin structure in an ATP-dependent manner have been described (Becker and Horz, 2002; de la Serna *et al.*, 2006; Narlikar *et al.*, 2002; Peterson, 2002). Among them is the SWI/SNF subfamily, which is composed of several subunits and has been implicated in

a wide range of cellular events, including gene regulation, cell cycle control, development, and differentiation (Becker and Horz, 2002; de la Serna *et al.*, 2006; Li *et al.*, 2007; Peterson, 2002). The mammalian SWI/SNF complexes contain a catalytic subunit that can be either BRG1 or BRM, each of which includes ATPase activity. Mutations in the ATPase domain of BRG1 or BRM that abrogate the ability of these proteins to bind ATP result in the formation of inactive SWI/SNF complexes (de la Serna *et al.*, 2000, 2001a, 2001b). Furthermore, expression of mutant BRG1 or BRM proteins in NIH3T3 cells impairs the ability of these cells to activate endogenous stress response genes in the presence of arsenite (de la Serna *et al.*, 2000) and to differentiate into muscle or adipocytic cells (de la Serna *et al.*, 2000, 2001a, 2001b; Salma *et al.*, 2004). In addition, we have recently shown that the presence of the mutant BRG1 protein in these NIH3T3 cell lines inhibits BMP2-induced differentiation into the osteoblast lineage (Young *et al.*, 2005). Similarly, expression of mutant BRG1 in osteoblastic cells exhibiting a differentiated phenotype inhibits the expression of genes associated with this terminally differentiated stage (Villagra *et al.*, 2006).

A highly debated feature of ATP-dependent chromatin remodelers is their ability to catalyze *in vitro* nucleosome mobilization along the DNA (sliding), to reposition the histone octamer to a nucleosome-free DNA, or to transiently expose nucleosomal DNA (Becker and Horz, 2002; de la Serna *et al.*, 2006; Li *et al.*, 2007; Narlikar *et al.*, 2002; Peterson, 2002). It has been proposed that the varied outcomes observed in these studies are related to the different experimental conditions used during the analyses. Although considerable scientific effort has been dedicated during the past few years to establishing the molecular mechanisms by which ATP-dependent, and in particular SWI/SNF, complexes remodel nucleosomal organization, only limited attention has been given to the contribution of the DNA sequence to chromatin structure and chromatin remodeling (Thastrom *et al.*, 2004). Our group has reported that promoter sequences can be critical components of the regulatory mechanisms that control chromatin remodeling and gene transcription (Gutierrez *et al.*, 2000, 2007a; Paredes *et al.*, 2002). Using as a model system the promoter region of the rat OC gene reconstituted *in vitro*, we demonstrated that SWI/SNF complexes induce histone octamer mobilization to preferential positions within the promoter sequence, leading to a nucleosomal organization that resembles that found in intact bone cells expressing the OC gene. This SWI/SNF-mediated preferential nucleosome positioning is primarily determined by the presence of both nucleosome positioning and nucleosome excluding sequences that are conveniently distributed within the proximal promoter domain of the OC gene (Gutierrez *et al.*, 2007a).

An increasing body of evidence also indicates that the activity of SWI/SNF chromatin remodeling complexes involves nucleosome eviction (Boeger *et al.*, 2004; Gutierrez *et al.*, 2007b; Korber *et al.*, 2006; Liu *et al.*, 2006; Reinke and Horz, 2003). Recent pulse-chase experiments show that there is a dynamic turnover of histones at transcriptionally active genes (reviewed by Clayton *et al.*, 2006). Similarly, histone H2A/H2B dimers are dynamically exchanged between nucleosomes (reviewed by Workman, 2006). Interestingly, the presence of a transcription factor bound to its target sequence enhances SWI/SNF-mediated nucleosome eviction (Gutierrez *et al.*, 2007b). Therefore, it has been proposed that interaction of transcriptional activators with their cognate elements is one of the first determinants leading to targeted remodeling by ATP-dependent complexes (Gutierrez *et al.*, 2007b). Consequently, the position of the cognate binding sites for these SWI/SNF-targeting factors, relative to the translational position of the nucleosomes within a given promoter, becomes a key element during the chromatin remodeling process that leads to transcription activation.

Histone modifications also play a major role in regulating chromatin structure and gene transcription in eukaryotic cells (for a recent review, see Kouzarides, 2007). These modifications may alter chromatin organization by disrupting intranucleosomal and/or internucleosomal histone–DNA interactions (e.g., histone acetylation). In addition, these post-translational modifications provide specific docking domains on the nucleosomal surfaces, enhance recognition by proteins, modify chromatin structure, and regulate transcription (e.g., histone methylation). An important breakthrough in addressing the physiological role of histone modifications experimentally came with the identification and cloning of enzymes that catalyze these modifications *in vivo* (Bernstein *et al.*, 2007; Kouzarides, 2007). Thus, it has been shown that nuclear histone modifying enzymes are critical during steroid hormone-dependent transcriptional activation.

Vitamin D, a sec-steroid, provides a paradigm for understanding molecular mechanisms involved in bone metabolism. Vitamin D directly regulates the expression of genes that support bone formation during development and bone remodeling throughout life. Therefore, osteoblast differentiation is a model for understanding developmental responsiveness to vitamin D (Christakos *et al.*, 2003; van Driel *et al.*, 2004).

Vitamin D exerts its genomic effects through the vitamin D receptor (VDR), which is a member of the superfamily of nuclear receptors (Rachez and Freedman, 2000; Xu and O'Malley, 2002). As in other nuclear receptors, binding of the ligand induces conformational changes in the C-terminal ligand-binding domain (LBD) of the VDR. The changes establish competency for VDR interaction with coactivators of the p160/SRC family, including SRC-1/NCoA-1, SRC-2/NCoA-2/GRIP/TIF2, and SRC-3/ACTR. These complexes are critical for transcriptional activation (Christakos *et al.*, 2003; Rachez and Freedman, 2000; Xu and O'Malley, 2002). p160/SRC coactivators

form high-molecular-weight complexes by interacting with other coactivator proteins including p300, its related homologue CBP, and P/CAF (Goodman and Smolik, 2000). Moreover, p160/SRC coactivators have been shown to recruit CBP/p300 and P/CAF to ligand-bound nuclear receptors. Multiprotein complexes containing different activities are functionally linked to ligand-dependent transcriptional regulation (Rachez and Freedman, 2000). Coactivators such as SRC-3/ACTR, SRC-1/NCoA-1, CBP/p300, and P/CAF contain intrinsic histone acetyltransferase (HAT) activity. Therefore, protein complexes including independent HAT activities can be recruited to gene promoters by nuclear receptors in a ligand-dependent manner (Rachez and Freedman, 2000). Once bound to these promoters, the HAT activities contribute to chromatin remodeling events that increase access of additional regulatory factors to their cognate elements (Narlikar *et al.*, 2002).

The multisubunit DRIP (VDR-Interacting Protein) complex also binds to VDR in response to the ligand vitamin D (Rachez *et al.*, 1999). This interaction occurs through the LBD of VDR in the same manner as the p160/SRC coactivators, resulting in transcriptional enhancement (Rachez *et al.*, 2000). In contrast to p160/SRC coactivators, DRIP is devoid of HAT and other chromatin remodeling activities and interacts with nuclear receptors through a single subunit designated DRIP205, which anchors other subunits to the receptor LBD. Several of these subunits are also present in the Mediator complex, which interacts with the C-terminal domain (CTD) of RNA polymerase II, forming the holoenzyme complex (Kornberg, 2005). Therefore, the DRIP complex appears to function as a transcriptional coactivator by forming a molecular bridge between the VDR and the basal transcription machinery, reflecting the importance of three-dimensional promoter organization to regulatory activity.

In the past few years various investigators have shown that coactivator complexes including p160/SRC and DRIP are recruited to steroid hormone-regulated genes by nuclear receptors in a sequential and mutually exclusive manner (Burakov *et al.*, 2002; Kim *et al.*, 2005; Metivier *et al.*, 2003; Sharma and Fondell, 2002). The ordered association of transcriptional regulators exhibits binding kinetics with periods of 40 to 60 minutes. These results provided the basis for a model in which cyclical association of different coactivator complexes reflects the dynamics of the transcription activation process of nuclear receptor-regulated genes (Metivier *et al.*, 2006; Xu and O'Malley, 2002). Alternatively, recent reports indicate that occupancy at the target gene regulatory regions by nuclear receptor-associated coactivator complexes may also occur gradually and at a significantly lower rate (Oda *et al.*, 2003; Wang *et al.*, 2005). Thus, it has been shown that during keratinocyte differentiation, there is a specific utilization of p160/SRC or DRIP205/Mediator coactivator complexes to regulate vitamin D–dependent genes (Oda *et al.*, 2003). The proposed model indicates that both coactivator complexes have important roles during early stages of keratinocyte differentiation, but a subsequent decrease in major DRIP/Mediator components leads to a predominant role for p160/SRC in the later stages of differentiation.

The bone-specific OC gene and skeletal-restricted Runx2 transcription factor serve as examples of obligatory relationships between nuclear structure and vitamin D–mediated physiological control of skeletal gene expression (Montecino *et al.*, 2007). It appears that there are similar relationships between nuclear organization and other bone-related vitamin D-responsive genes (e.g., osteopontin and 24-hydroxylase). However, we will largely confine our consideration of nuclear structure–gene expression relationships to the OC gene.

The rat OC gene encodes a 10-kDa bone-specific protein that is induced in osteoblasts with the onset of mineralization at late stages of differentiation (Owen *et al.*, 1990). Modulation of OC gene expression during bone formation and remodeling requires physiologically responsive accessibility of proximal and upstream promoter sequences to regulatory and co-regulatory proteins, as well as protein–protein interactions that integrate independent promoter domains. The chromatin organization of the OC gene illustrates dynamic remodeling of a promoter to accommodate requirements for phenotype-related developmental and vitamin D–responsive activity (Montecino *et al.*, 2007).

Transcription of the OC gene is controlled by modularly organized basal and hormone-responsive promoter elements (see Fig. 2), located within two DNase I–hypersensitive sites (distal site, positions −600 to −400; proximal site, positions −170 to −70) that are only nuclease accessible in bone-derived cells expressing this gene. A key regulatory element that controls OC gene expression is recognized by the VDR complex on ligand stimulation. This vitamin D responsive element (VDRE) is located in the distal region (Fig. 3A) of the OC promoter (positions −465 to −437) and functions as an enhancer to increase OC gene transcription (Montecino *et al.*, 2007). The retention of a nucleosome between the proximal and upstream enhancer domains reduces the distance between the basal regulatory elements and the VDRE and supports a promoter configuration that is conducive to protein–protein interactions between VDR-associated proteins and components of the RNA polymerase II–bound complex (see Fig. 3B). Interaction of the VDR at the distal promoter region of the OC gene requires nucleosomal remodeling (Montecino *et al.*, 1999; Paredes *et al.*, 2002).

Another key regulator of OC gene expression is the nuclear matrix-associated transcription factor Runx2, a member of the Runt homology family of proteins that has been shown to contribute to the control of skeletal gene expression (Lian *et al.*, 2004). Runx2 proteins serve as a scaffold for the assembly and organization of co-regulatory proteins that mediate biochemical and architectural control

of promoter activity. The rat OC gene promoter contains three recognition sites for Runx2 interactions, site A (−605 to −595), site B (−438 to −430), and site C (−138 to −130). Mutation of all three Runx2 sites results in significantly reduced OC expression in bone-derived cells (Javed *et al.*, 1999). We have recently shown that within the OC gene promoter context there is a tight functional relationship between Runx2 and the vitamin D-dependent pathway (Paredes *et al.*, 2004). Runx2 and VDR are components of the same nuclear complexes, colocalize at punctate foci within the nucleus of osteoblastic cells, and interact directly in protein–protein binding assays *in vitro* (Paredes *et al.*, 2004). Additionally, mutation of the distal Runx2 sites A and B (which flank the VDRE; see Fig. 3) abolishes vitamin D–enhanced OC promoter activity (Paredes *et al.*, 2004). In contrast to most nuclear receptors, the VDR does not contain an N-terminal AF-1 transactivation domain and thus is unable to interact with coactivators through this region (Rachez and Freedman, 2000). Therefore, Runx2 plays a key role in the vitamin D–dependent stimulation of the OC gene promoter in osteoblastic cells by directly stabilizing binding of the VDR to the VDRE. Runx2 also allows recruitment of the coactivator p300 to the OC promoter (see Fig. 3(A), which results in upregulation of both basal and vitamin D–enhanced OC gene transcription (Sierra *et al.*, 2003). Based on these results, we have postulated that Runx2-mediated recruitment of p300 may facilitate the subsequent interaction of p300 with the VDR on ligand stimulation (Paredes *et al.*, 2004).

The rate of recruitment of p160/SCR-1 and DRIP coactivators to the OC gene in response to vitamin D has recently been studied (Carvallo *et al.*, 2007). It has been found that the VDR and SRC-1 rapidly and stably interact with the distal region of the OC promoter encompassing the VDRE (see Fig. 3B). The interaction of SRC-1 and VDR directly correlates with vitamin D–mediated transcriptional enhancement of the OC gene, increased association of the RNA polymerase complex, and vitamin D–stimulated histone H4 acetylation (Shen *et al.*, 2002).

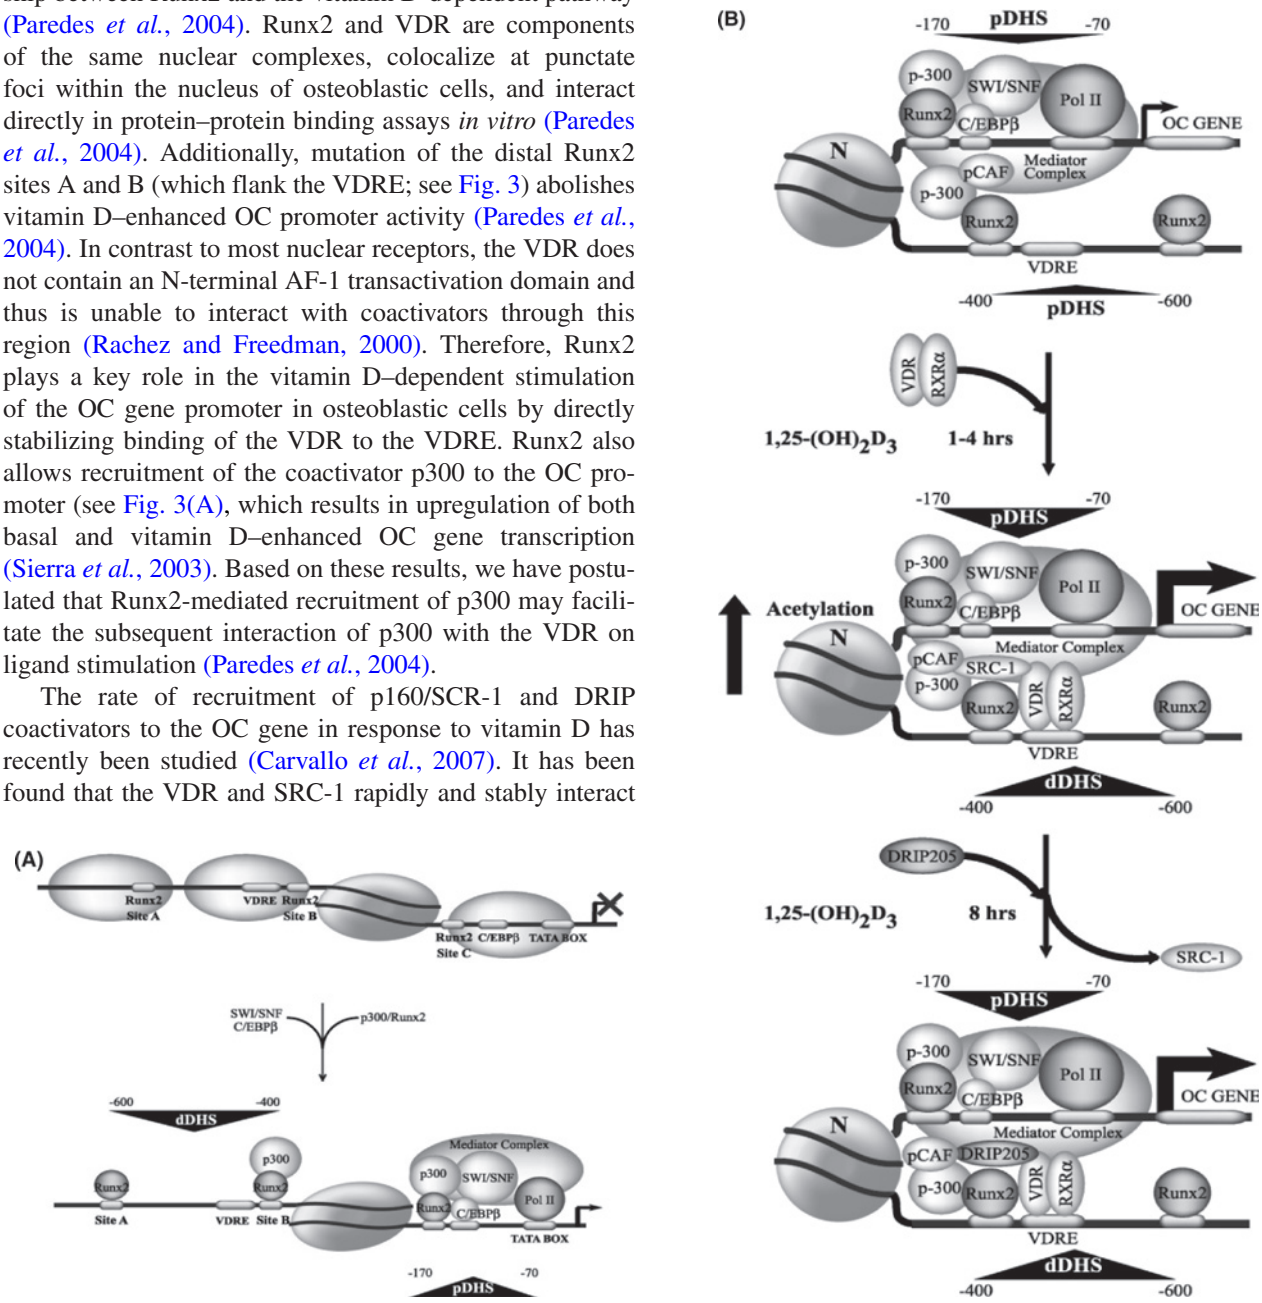

FIGURE 3 The rat osteocalcin gene promoter and the chromatin remodeling process that accompanies basal and vitamin D–enhanced osteocalcin transcription in osteoblastic cells. The principal regulatory elements, cognate transcription factors and associated co-regulators bound to the osteocalcin (OC) gene promoter, are indicated. The filled circles represent nucleosomes assembled along the first 800 bp of the OC promoter and the arrow indicates the transcription start site and direction of transcription. The presence of the distal (dDHS, −600 to −400) and proximal (pDHS, −170 to −70) DNase I hypersensitive sites is also marked. **A**, Linear representation of the OC promoter. **B**, Proposed three-dimensional organization of the OC gene promoter when transcribing at basal or vitamin D–enhanced (after treatment of osteoblastic cells expressing OC with vitamin D for 4 and 8 hours) conditions. The size of the arrow indicates the level of transcription. The increase in histone acetylation that accompanies vitamin D–enhanced transcription is also marked.

Interestingly, DRIP205 was found to bind to the OC promoter only after several hours of continuous treatment with vitamin D, concomitant with release of SRC-1 (see Fig. 3B). Based on these results it has been postulated that this preferential recruitment of SRC-1 to the OC gene promoter is based on the specific distribution of regulatory elements at the distal region of the promoter. This organization may lead to the formation of a stable complex at the distal region that includes Runx2, p300, VDR, and SRC-1. Once established, this complex may mediate an increase in acetylation of histones H3 and H4 and directly stimulate the basal transcription machinery bound to an OC promoter actively engaged in transcription.

The general relevance of vitamin D–mediated chromatin-based mechanisms of promoter activity, accessibility, and crosstalk between regulatory domains is further illustrated by the vitamin D responsiveness of the osteopontin and 24-hydroxylase genes. Recent studies have established that vitamin D induces a rapid and cyclical association of the VDR/RXR heterodimer with the proximal mouse 24(OH)ase gene promoter in osteoblastic cells (Kim *et al.*, 2005). Vitamin D treatment also induces a rapid recruitment of coactivators such as p160/SRC and p300/CBP, which leads to acetylation of histone H4. DRIP205/Mediator is also recruited to the proximal promoter region concomitantly with the interaction of RNA polymerase II. Together, these results support a model in which highly dynamic association of the VDR with chromatin occurs during vitamin D–dependent induction of the 24(OH)ase gene in osteoblasts (Kim *et al.*, 2005).

Carlberg and co-workers have also monitored the spatiotemporal regulation of the human 24(OH)ase gene (Vaisanen *et al.*, 2005). They have evaluated 25 contiguous genomic regions spanning the first 7.7 kb of the human 24(OH)ase promoter and found that in addition to the proximal VDREs, three further upstream regions are associated with the VDR on vitamin D stimulation. Interestingly, only two of these regions contain sequences resembling known VDREs that are transcriptionally responsive to this hormone. The other VDR-associated upstream promoter region does not contain any recognizable classical VDRE that could account for the presence of the VDR protein. However, simultaneous association of the VDR, RXR, p160/SRC, and DRIP/Mediator coactivators, as well as RNA polymerase, was detected in all four vitamin D–responsive sequences after the addition of the ligand (Vaisanen *et al.*, 2005). Remarkably, despite participating in the same process, all four chromatin regions displayed individual vitamin D–dependent patterns of interacting proteins. Based on these results, the authors propose that these upstream vitamin D–responsive regions may have a role in the implementation of gene activation, as they raise their vitamin D–dependent histone H4 acetylation status earlier than that of the proximal promoter VDREs (Vaisanen *et al.*, 2005). It has also been suggested that the simultaneous communication of the individual promoter regions with the RNA polymerase II complex occurs through a particular three-dimensional organization of the chromatin at the 24(OH)ase promoter. This arrangement could be facilitating close contact between distal and proximal regulatory regions.

On the other hand, Pike and co-workers have described that on vitamin D treatment of osteoblastic cells, there is a rapid and cyclical association of the VDR with the osteopontin (OP) promoter (Kim *et al.*, 2005). This increased binding of the VDR parallels vitamin D–mediated transcriptional enhancement of the OP gene and additionally involves cyclical, sequential, and mutually exclusive recruitment of the coactivators p160/SRC, p300/CBP, and DRIP/Mediator. Interestingly and in contrast to the OC and 24(OH)ase genes, p160/SRC–p300/CBP binding does not result in increased histone H4 acetylation. These results further confirm that in osteoblastic cells different promoters are regulated by distinct mechanisms in response to vitamin D.

The transcription factor C/EBPβ is also a principal transactivator of the OC gene that binds within the proximal promoter region (−106 to −99; see Fig. 3A) and synergizes with Runx2 to enhance basal and tissue-specific OC gene transcription (Gutierrez *et al.*, 2002). C/EBPβ has been recently shown to recruit the SWI/SNF complex to the OC promoter (see Fig. 3A), where it is required for both formation of the proximal nuclease hypersensitive site and transcriptional activation of this gene in osteoblastic cells (Villagra *et al.*, 2006). Therefore, it is postulated that binding of C/EBPβ and Runx2 to the proximal promoter region of the OC gene in differentiated osteoblasts allows recruitment of both SWI/SNF and HAT-containing chromatin remodeling activities, and that together, these activities catalyze the changes in chromatin structure that facilitate transcription (see Fig. 3). Interestingly, both C/EBPβ and Runx2 are bound to the OC promoter in differentiated osteoblastic cells that are not transcribing the OC gene because of an inhibition of SWI/SNF-mediated chromatin remodeling (Villagra *et al.*, 2006). This result indicates that interaction of both factors with the OC promoter is, at least partially, independent of SWI/SNF activity and therefore prior to the formation of the proximal DNase I hypersensitive site.

Higher Order Nuclear Organization: Interrelationships of Transcriptional Regulatory Machinery with Nuclear Architecture

The necessity for both nuclear architecture and biochemical control to regulate gene expression is becoming increasingly evident. An ordered organization of nucleic acids and regulatory proteins to assemble and sustain macromolecular complexes that provide the machinery for transcription

requires stringent, multistep mechanisms. Each component of transcriptional control is governed by responsiveness to an integrated series of cellular signaling pathways. Each gene promoter selectively exercises options for regulating factor interactions that activate or repress transcription. All transcriptional control is operative *in vivo* under conditions where, despite low representation of promoter regulatory elements and cognate factors, a critical concentration is essential for a threshold that can initiate sequence-specific interactions and functional activity.

Historically, there was a dichotomy between pursuit of nuclear morphology and transcriptional control. However, the growing experimental evidence indicating that components of gene regulatory mechanisms are associated architecturally strengthens the nuclear structure–function paradigm. Are all regulatory events that control gene expression linked architecturally? Can genetic evidence formally establish consequential relationships between nuclear structure and transcription? What are the mechanisms that direct genes and regulatory factors to subnuclear sites that support transcription? How are boundaries established that compartmentalize components of gene expression to specific subnuclear domains? Can the regulated and regulatory parameters of nuclear structure–function interrelationships be distinguished? These are key questions that must be addressed experimentally to validate components of gene expression that have been implicated as dependent on nuclear morphology. From a biological perspective, it is important to determine if breaches in nuclear organization are related to compromised gene expression in diseases that include cancer where incurred mutations abrogate transcriptional control.

Nuclear Matrix: A Scaffold for the Architectural Organization of Regulatory Complexes

The identification and *in situ* visualization of the nuclear matrix, together with the characterization of a chromosome scaffold, were bases for pursuing the control of gene expression within the three-dimensional context of nuclear architecture.

The anastomosing network of fibers and filaments that constitute the nuclear matrix supports the structural properties of the nucleus as a cellular organelle and accommodates modifications in gene expression associated with proliferation, differentiation, and changes necessary to sustain phenotypic requirements in specialized cells (Fig. 4; Bidwell *et al.*, 1994; Dworetzky *et al.*, 1990). Regulatory functions of the nuclear matrix include but are by no means restricted to DNA replication (Berezney and Coffey, 1975), gene location (Zeng *et al.*, 1997), imposition of physical constraints on chromatin structure that support formation of loop domains, concentration and targeting of transcription factors (Cai *et al.*, 2006; Dobreva *et al.*, 2006; van Wijnen *et al.*, 1993), RNA processing and transport of gene transcripts (Blencowe *et al.*, 1994), and post-translational modifications of chromosomal proteins, as well as imprinting and modifications of chromatin structure (Davie, 1997; Drobic *et al.*, 2006). Additional evidence for participation of the nuclear matrix in gene expression came from reports of qualitative and quantitative changes in the representation of nuclear matrix proteins during the differentiation of normal diploid cells and in tumor cells associated with a spectrum of cancers. More direct evidence for functional linkages between nuclear architecture and transcriptional control was provided by demonstrations that cell growth and phenotypic regulatory factors are nuclear matrix associated and by modifications in the partitioning of transcription factors between the nuclear matrix and the nonmatrix nuclear fraction when changes in gene expression occur (reviewed in Stein *et al.*, 2003; Zaidi *et al.*, 2007).

Contributions of the nuclear matrix to control of gene expression is further supported by involvement in regulatory events that mediate histone modifications, chromatin remodeling, and processing of gene transcripts (de la Serna *et al.*, 2006; Zink *et al.*, 2004). Instead of addressing chromatin remodeling and transcriptional activation as complex but independent mechanisms, it is biologically meaningful to investigate the control of genome packaging and expression as interrelated processes that are operative in relation to nuclear architecture. Taken together with findings that indicate important components of the machinery for both gene transcription and replication are confined to nuclear matrix-associated subnuclear domains, the importance of nuclear architecture to intranuclear compartmentalization of regulatory activity is being pursued.

Subnuclear Domains: Nuclear Microenvironments Provide a Structural and Functional Basis for Subnuclear Compartmentalization of Regulatory Machinery

An understanding of interrelationships between nuclear structure and gene expression necessitates knowledge of the composition, organization, and regulation of sites within the nucleus that are dedicated to DNA replication, DNA repair, transcription, and processing of gene transcripts. During the past several years there have been developments in reagents and instrumentation to enhance the resolution of nucleic acid and protein detection by *in situ* hybridization and immunofluorescence analyses. We are beginning to make the transition from descriptive *in situ* mapping of genes, transcripts, and regulatory factors to visualization of gene expression from the three-dimensional perspective of nuclear architecture. Figure 4 displays components of gene regulation that are associated with the nuclear matrix. Initially, *in situ* approaches were utilized primarily for the intracellular localization of nucleic acids. Proteins that contribute to control of gene expression were first identified by biochemical analyses. We are

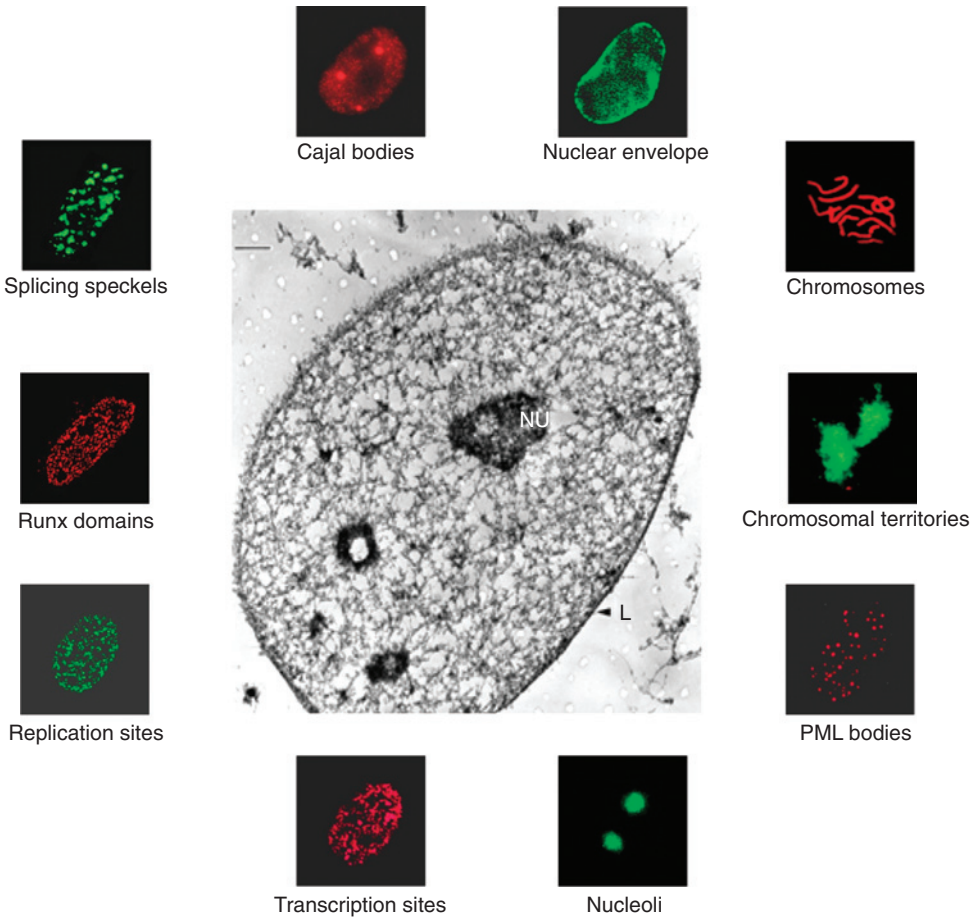

FIGURE 4 The nuclear architecture is functionally linked to the organization and sorting of regulatory information. Immunofluorescence microscopy of the nucleus *in situ* has revealed the distinct nonoverlapping subnuclear distribution of vital nuclear processes, including DNA replication sites; structural parameters of the nucleus (e.g., the nuclear envelope, chromosomes, and chromosomal territories); and Runx transcription factor domains for chromatin organization and transcriptional control of tissue-specific genes, as well as RNA synthesis and processing, involving, for example, transcription sites, SC35 domains, Cajal bodies, and nucleoli. These domains are associated with the nuclear matrix (the electron micrograph shown in the center). (See plate section)

now applying high-resolution *in situ* analyses for the primary identification and characterization of gene regulatory mechanisms under *in vivo* conditions.

We are increasing our understanding of the significance of nuclear domains to the control of gene expression. These local nuclear environments that are generated by the multiple aspects of nuclear structure are tied to the developmental expression of cell growth and tissue-specific genes. Historically, the control of gene expression and characterization of structural features of the nucleus were pursued conceptually and experimentally as minimally integrated questions. At the same time, however, independent pursuit of nuclear structure and function has occurred in parallel with the appreciation that several components of nuclear architecture are associated with parameters of gene expression or control of specific classes of genes.

For the most part, biochemical parameters of replication and transcription have been studied independently. However, paradoxically, from around the turn of the last century it was recognized that there are microenvironments within the nucleus where regulatory macromolecules are compartmentalized in subnuclear domains. Chromosomes and the nucleolus provided the initial paradigms for the organization of regulatory machinery within the nucleus. Also, during the past several decades, linkages have been established between subtleties of chromosomal anatomy and replication as well as gene expression. Regions of the nucleolus are understood in relation to ribosomal gene expression. The organization of chromosomes and chromatin is well accepted as a reflection of functional properties that support competency for transcription and the extent to which genes are transcribed. It has been generally recognized that chromosomes are nonrandomly organized in the interphase nucleus as chromosomal territories. Location of genes within chromosomal territories has been associated with transcriptional status (Cremer *et al.*, 2006). Recently, it has been shown that chromosomal territories intermingle with each other in the interchromatin space (Branco and Pombo, 2007). Chromosomal organization in the interphase nucleus may have implications for coordinated

timing of replication at intranuclear sites for DNA duplication that appear to persist from one S-phase to the next (Sadoni *et al.*, 2004).

There is a broad-based organization of regulatory macromolecules within discrete nuclear domains. Examples of intranuclear compartmentalization now include but by no means are restricted to SC35 RNA processing sites, PML bodies, the structural and regulatory components of nuclear pores that mediate nuclear-cytoplasmic exchange (Moir *et al.*, 2000), coiled (Cajal) bodies, and replication foci, as well as defined sites where steroid hormone receptors and transcription factors reside (see Fig. 4; Glass and Rosenfeld, 2000; Leonhardt *et al.*, 2000; McNally *et al.*, 2000). The integrity of these subnuclear microenvironments is indicated by structural and functional discrimination between each architecturally defined domain. Corroboration of structural and functional integrity of each domain is provided by the uniqueness of the intranuclear sites with respect to composition, organization, and intranuclear distribution in relation to activity (Hirose and Manley, 2000; Kosak and Groudine, 2004; Lemon and Tjian, 2000; Taatjes *et al.*, 2004).

We are now going beyond mapping regions of the nucleus that are dedicated to replication and gene expression. We are gaining insight into interrelationships between the subnuclear organization of the regulatory and transcriptional machinery with the dynamic assembly and activity of macromolecular complexes that are required for biological control during development, differentiation, maintenance of cell and tissue specificity, homeostatic control, and tissue remodeling. Equally important, it is becoming evident that the onset and progression of cancer and neurological disorders are associated with and potentially functionally coupled with perturbations in the subnuclear organization of genes and regulatory proteins that relate to aberrant gene replication, repair, and transcription (reviewed in Zaidi *et al.*, 2007).

Intranuclear Trafficking to Subnuclear Destinations: Directing Skeletal Regulatory Factors to the Right Place at the Right Time

The traditional experimental approaches to transcriptional control have been confined to the identification and characterization of gene promoter elements and cognate regulatory factors. However, the combined application of *in situ* immunofluorescence together with molecular, biochemical, and genetic analyses indicates that several classes of transcription factors exhibit a punctate subnuclear distribution. This punctate subnuclear distribution persists after the removal of soluble nuclear proteins and nuclease-digested chromatin. We propose that the intranuclear organization of regulatory proteins could be linked functionally to their competency to affect gene expression (e.g., Guo *et al.*, 1995; Htun *et al.*, 1996; Nguyen and Karaplis, 1998; Stenoien *et al.*, 1998; Verschure *et al.*, 1999; Zeng *et al.*, 1997). Therefore, one fundamental question is the mechanism by which this compartmentalization of regulatory factors is established within the nucleus. This compartmentalization could be maintained by the nuclear matrix, which provides an underlying macromolecular framework for the organization of regulatory complexes (Berezney and Jeon, 1995; Berezney and Wei, 1998; Penman, 1995). However, one cannot dismiss the possibility that nuclear compartmentalization is activity driven (Misteli, 2000, 2004; Pederson, 2000; Spector, 2001).

Insight into architecture-mediated transcriptional control can be gained by examining the extent to which the subnuclear distribution of gene regulatory proteins affects their activities. We and others observed that members of the Runx/Cbfa family of hematopoietic and bone tissue-specific transcription factors (Banerjee *et al.*, 1997; Chen *et al.*, 1998; Merriman *et al.*, 1995; Zaidi *et al.*, 2001; Zeng *et al.*, 1997, 1998) exhibit a punctate subnuclear distribution and are associated with the nuclear matrix (Zeng *et al.*, 1997). Biochemical and *in situ* immunofluorescence analyses established that a 31-residue segment designated the nuclear matrix targeting signal (NMTS) near the C terminus of the Runx factor is necessary and sufficient to mediate association of these regulatory proteins to nuclear matrix-associated subnuclear sites at which transcription occurs (Zaidi *et al.*, 2001; Zeng *et al.*, 1997, 1998). The NMTS functions autonomously and can target a heterologous protein to the nuclear matrix. Furthermore, the NMTS is independent of the DNA-binding domain as well as the nuclear localization signal, both of which are in the N-terminal region of the Runx protein. The unique peptide sequence of the Runx NMTS (Zaidi *et al.*, 2001; Zeng *et al.*, 1997, 1998) and the defined structure obtained by x-ray crystallography (Tang *et al.*, 1998a, 1999) support the specificity of this targeting signal. These data are compatible with a model in which the NMTS functions as a molecular interface for specific interaction with proteins and/or nucleic acids that contribute to the structural and functional activities of nuclear domains. However, at present we cannot formally distinguish whether this interaction between the NMTS and its putative nuclear acceptor strictly reflects targeting or retention.

The idea that specific mechanisms direct regulatory proteins to sites within the nucleus is reinforced by the identification of targeting signals in the glucocorticoid receptor (Htun *et al.*, 1996; Tang *et al.*, 1998b; van Steensel *et al.*, 1995), PTHrP (Nguyen and Karaplis, 1998), the androgen receptor (van Steensel *et al.*, 1995), PIT1 (Stenoien *et al.*, 1998), SATB2 (Dobreva *et al.*, 2006), and YY1 (Guo *et al.*, 1995; McNeil *et al.*, 1998). These targeting signals do not share sequence homology with each other or with the Runx/Cbfa transcription factors. Furthermore, the proteins each exhibit distinct subnuclear distributions. Thus, a series of trafficking signals are responsible for directing

regulatory factors to nonoverlapping sites within the cell nucleus. Collectively, the locations of these transcription factors provide coordinates for the activity of gene regulatory complexes.

The importance of architectural organization of regulatory machinery for bone-restricted gene expression is evident from the intranuclear localization of Runx2 co-regulatory proteins that control OC gene expression. For example, TLE/Groucho, a suppressor of Runx-mediated transcriptional activation, colocalizes with Runx2 at punctate subnuclear sites (Javed *et al.*, 2000). The Yes-associated protein represents another example of a Runx co-regulatory factor that is directed to Runx subnuclear sites when associated with Runx (Zaidi *et al.*, 2004).

Intranuclear targeting of regulatory factors is a multistep process, and we are only beginning to understand the complexity of each step. However, biochemical and *in situ* analyses have shown that at least two trafficking signals are required: The first supports nuclear import (the nuclear localization signal) and the second mediates interactions with specific sites associated with the nuclear matrix (the nuclear matrix-targeting signal). Given the multiplicity of determinants for directing proteins to specific destinations within the nucleus, alternative splicing of messenger RNAs might generate different forms of a transcription factor that are targeted to specific intranuclear sites in response to diverse biological conditions. Furthermore, the activities of transcription complexes involve multiple regulatory proteins that could facilitate the recruitment of factors to sites of architecture-associated gene activation and suppression.

Intranuclear Informatics

Recently, mathematical algorithms, designated intranuclear informatics, have been developed to identify and assign unique quantitative signatures that define regulatory protein localization within the nucleus (Young *et al.*, 2004). Quantitative parameters that can be assessed include nuclear size and variability in domain number, size, spatial randomness, and radial positioning (Fig. 5).

The significance and implication of intranuclear informatics can be shown by three distinct biological examples (see Figs. 5B–D). Regulatory proteins with different activities can be subjected to intranuclear informatics analysis, which assigns each protein a unique architectural signature. The overlap between the architectural signatures of different proteins is often correlated to their functional overlap. Alternatively, the subnuclear organization of a protein domain can be linked with subnuclear targeting, biological function, and disease. For example, Runx2 and its subnuclear targeting defective mutant (mSTD) show distinct architectural signatures, indicating that the biological activity of a protein can be defined and quantified as subnuclear organization. Finally, the data can be used to define functional conservation: For example this technique can be used to show that the postmitotic restoration of the spatially ordered Runx subnuclear organization is functionally conserved.

Integration of Osteogenic Signaling Pathways

Gene expression during skeletal development and bone remodeling is controlled by a broad spectrum of regulatory signals that converge at promoter elements to activate or repress transcription in a physiologically responsive manner. The subnuclear compartmentalization of transcription machinery necessitates a mechanistic explanation for directing signaling factors to sites within the nucleus where gene expression occurs under conditions that support integration of regulatory cues. The interactions of YAP and SMAD co-regulatory proteins with C-terminal segments of the Runx2 transcription factor permits assessment of requirements for recruitment of c-Src and BMP/TGF-mediated signals to skeletal target genes. Our findings indicate that nuclear import of YAP and SMAD co-regulatory factors is agonist dependent. However, there is a stringent requirement for fidelity of Runx subnuclear targeting for recruitment of these signaling proteins to active subnuclear foci transcriptionally. Our results demonstrate that the interactions and spatial-temporal organization of Runx and SMAD as well as YAP co-regulatory proteins are essential for the assembly of transcription machinery that supports expression or repression of skeletal genes (Zaidi *et al.*, 2004). Competency for intranuclear trafficking of Runx proteins has similarly been functionally linked with the subnuclear localization and activity of TLE/Groucho co-regulatory proteins (Javed *et al.*, 2000). These findings are consistent with Runx proteins serving as scaffolds for combinatorial interactions with co-regulatory proteins that contribute to biological control and a requirement for intranuclear trafficking to complete the transduction and implementation of regulatory signals that are requisite for physiological responsiveness.

Epigenetic Control of Cell Growth, Proliferation, and Sustained Phenotype

Postmitotic gene expression requires restoration of nuclear organization and assembly of regulatory complexes. In addition, skeletal development as well as osteoblast cell growth and function require stringent control of ribosomal biogenesis. Genetic alterations that deregulate ribosome production (e.g., Treacher Collins syndrome) result in craniofacial bone defects and growth retardation. Using *in situ* immunofluorescence microscopy, we have demonstrated that Runx2 remains associated with mitotic chromosomes at target gene loci to support lineage-specific transcription and is quantitatively distributed into postmitotic progeny cells (Young *et al.*, 2007b; Zaidi *et al.*, 2003). These findings suggest an epigenetic function of Runx2 at mitotic

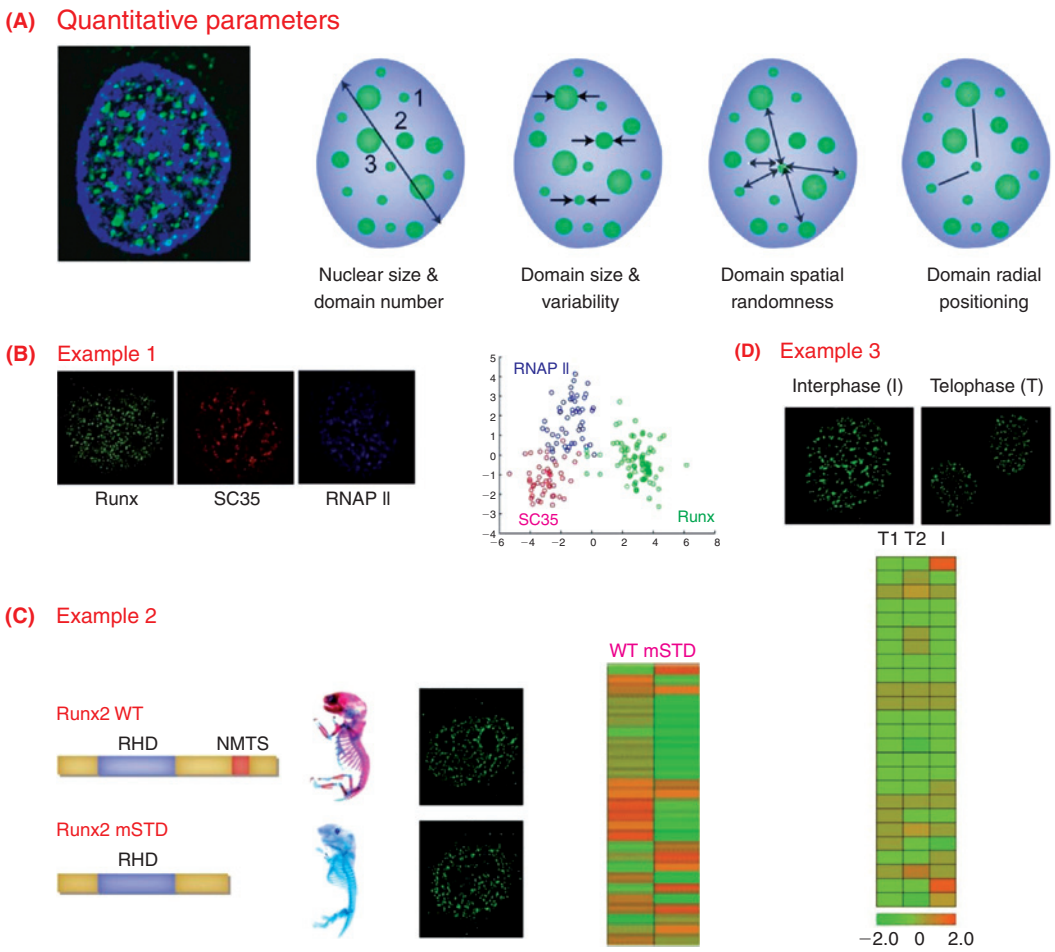

FIGURE 5 Intranuclear informatics. **A**, The conceptual framework for the quantitation of subnuclear organization by intranuclear informatics. The four main groups of parameters examined are based on inherent biological variability. **B**, Regulatory proteins with different activities can be subjected to intranuclear informatics analysis, which assigns each protein a unique architectural signature. The overlap between the architectural signatures of different proteins is often correlated with their functional overlap. Shown in **B** are Runx transcription factor (green), SC35 splicing protein (red), and RNA polymerase II (blue). These data obtained from intranuclear informatics can be presented in various forms such as a graph (shown in **B**) comparing two parameters: domain spatial randomness (on the *x*-axis) and domain radial positioning (on the *y*-axis). One hundred nuclei (each represented as one circle on the graph) co-stained for RUNX2, SC35, and RNA pol II were analyzed. As shown here, each of the three regulatory proteins (Runx, SC35, RNA polymerase II) exhibits distinct properties for the two parameters represented. We attribute these unique architectural signatures to distinct functional properties of these proteins. **C**, The subnuclear organization of Runx domains is linked with subnuclear targeting, biological function and disease. Biologically active RUNX2 and an inactive subnuclear targeting defective mutant of RUNX2 (mSTD) show distinct architectural signatures, indicating that the biological activity of a protein can be defined and quantified as subnuclear organization. The wild-type and mSTD RUNX2 proteins are schematically depicted in **C**. Alizarin red (bone) and alcian blue (cartilage) staining of skeletons from mice homozygous for wild-type and mSTD RUNX2 show a complete absence of mineralized bone in mSTD RUNX2 knock-in mice. Although both proteins exhibit similar patterns of subnuclear organization *in situ* in whole cell preparations (shown by the green fluorescence), intranuclear informatics shows that each protein exhibits a distinct architectural signature. All 28 quantitative parameters analyzed by intranuclear informatics are presented as hierarchical clusters. The green color represents the presence and red color represents absence of a specific nuclear feature. **D**, Postmitotic restoration of the spatially ordered subnuclear organization of Runx is functionally conserved. ROS 17/2.8 osteosarcoma cells were subjected to *in situ* immunofluorescence microscopy for endogenous RUNX2. RUNX2 is distributed at punctate subnuclear domains throughout the interphase and telophase nuclei. Subnuclear organization parameters were computed from deconvolved images for RUNX2 for interphase nuclei (I), and both progeny telophase nuclei, denoted arbitrarily as telophase nucleus 1 (T1) or telophase nucleus 2 (T2). A color map has been applied to the standardized data assigning red to higher values and green to lower values. (See plate section)

chromosomes. This epigenetic role of Runx2 at M/G1 transition is further confirmed by the association of Runx2 with phenotypic genes during mitosis (Fig. 6). In addition to controlling phenotypic genes at M/G1 transition, ribosomal RNA biosynthesis is also regulated by the bone-related Runx2 transcription factor that controls the proliferative potential of osteoprecursors and osteogenic lineage commitment (Fig. 7; Young *et al.*, 2007a). We find that reduction of Runx2 levels in human Saos-2 cells by siRNA modulates rRNA transcription, indicating that ribosomal gene production is indeed Runx2 responsive. Furthermore, a bioinformatics analysis reveals the presence of multiple Runx binding elements within regulatory regions of rRNA genes. Chromatin immunoprecipitation (ChIP) analysis

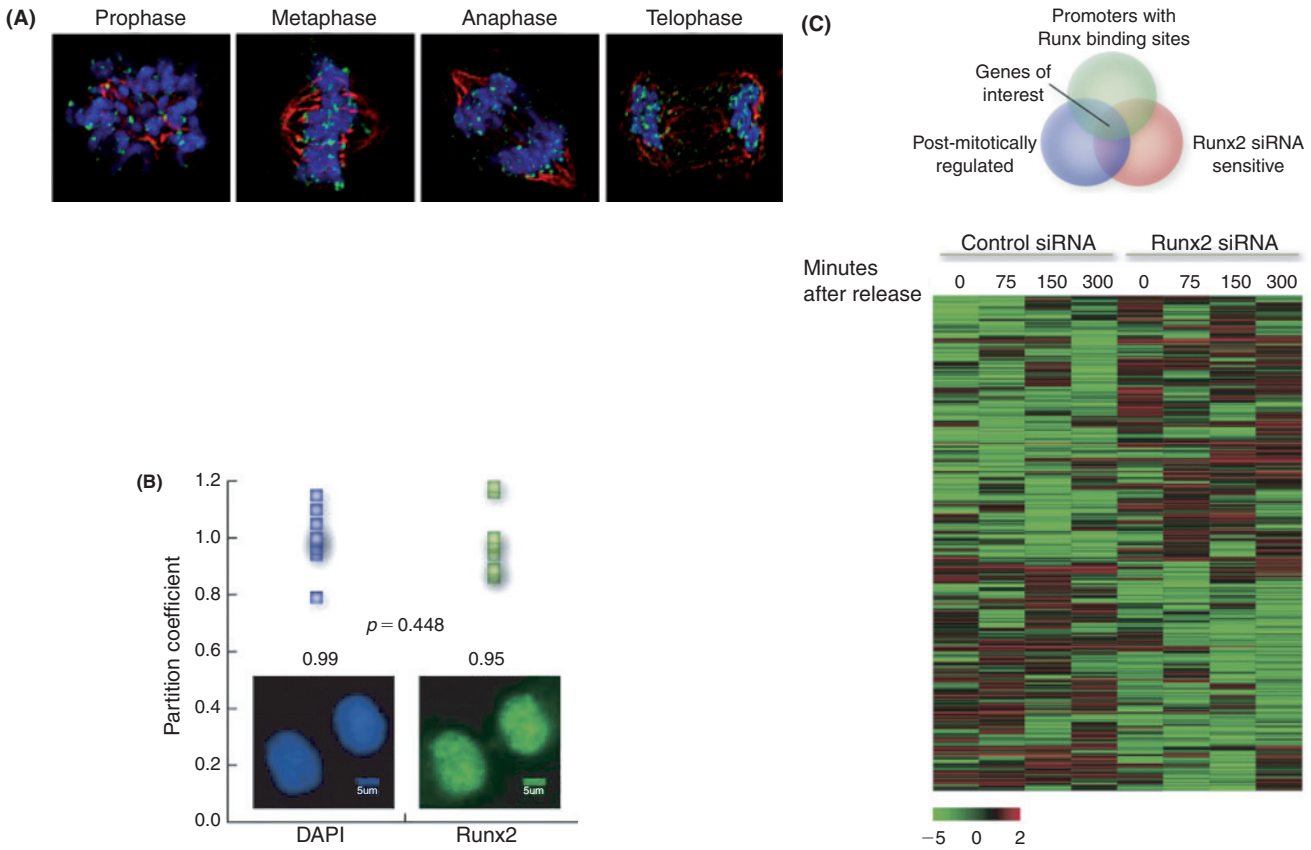

FIGURE 6 Runx2 confers phenotype commitment from parental to progeny cells by associating with phenotypic genes during mitosis. **A**, Asynchronously growing Saos-2 cells were fixed and stained for DNA using DAPI and for Runx2 using a rabbit polyclonal antibody. Mitotic cells were identified by chromosome morphology. High-resolution images obtained by three-dimensional deconvolution algorithms reveal that Runx2 (green) is localized in mitotic chromosomes. A subset of Runx2 colocalizes with the microtubules, labeled by α-tubulin staining (red). **B**, Runx2 protein partitions equivalently to progeny cells following cell division. A quantitative image analysis was applied to determine the relative levels of Runx in nuclei of the telophase cells ($n = 10$; *lower*). We defined a PC that reflects the ratio of integrated signal intensities between progeny nuclei. Runx2 exhibited a PC equivalent to that of DNA, demonstrating that this factors is equally segregated in progeny cells after cell division. Student's *t* test was performed to assess the significance of observed differences. **C**, Genome-wide identification of Runx2–sensitive gene expression patterns during the mitosis to G1 transition. Runx2 and control siRNA-treated cells were synchronized by nocodazole and mitotic shakeoff. Mitotic cells were isolated at shakeoff (0 hours), and remaining cells were replated and released for progression into G1 (1.25, 2.5, and 5 hours). Using an empirical Bayes linear modeling approach, we identified 500 genes significantly altered by siRNA treatment. A heat map illustrating hierarchical cluster analysis is shown. Two main clusters reflect genes that are repressed and activated by Runx2 knockdown. (See plate section)

establishes that Runx2 directly associates with ribosomal RNA genes. Both immunofluorescence and immunoelectron microscopy reveal that a subset of Runx2 is localized to nucleoli where ribosomal genes reside and ribosomal biogenesis occurs. Interestingly, we find that during the mitotic silencing of gene expression, Runx2 is localized at chromosomal foci that are associated with open chromatin at nucleolar organizing regions and colocalize with the RNA polymerase I transcription factor and upstream binding factor (UBF1). Functional linkage between Runx2 and ribosomal gene expression is further established by enhanced ribosomal RNA synthesis in primary cells isolated from the calvarial tissue of Runx2 null mice compared with wild-type Runx2 counterparts. Notably, induction of Runx2 in uncommitted mesenchymal cells directly represses ribosomal biogenesis, and this repression of ribosomal gene expression by Runx2 is associated with cell growth inhibition and expression of osteoblast-specific genes (Young *et al.*, 2007a, 2007b; Zaidi *et al.*, 2003). These results indicate that the function of Runx2 as a master regulator of osteoblast differentiation is coupled to its ability to modulate the anabolic function of osteoblasts.

ARCHITECTURAL REQUIREMENT OF NUCLEAR ORGANIZATION FOR FORMATION OF OSTEOLYTIC LESIONS BY METASTATIC TUMORS

A striking feature of tumor that metastasize to bone is the upregulation of skeletal genes that include OC, OP, and ON. Consequently, understanding of the regulatory

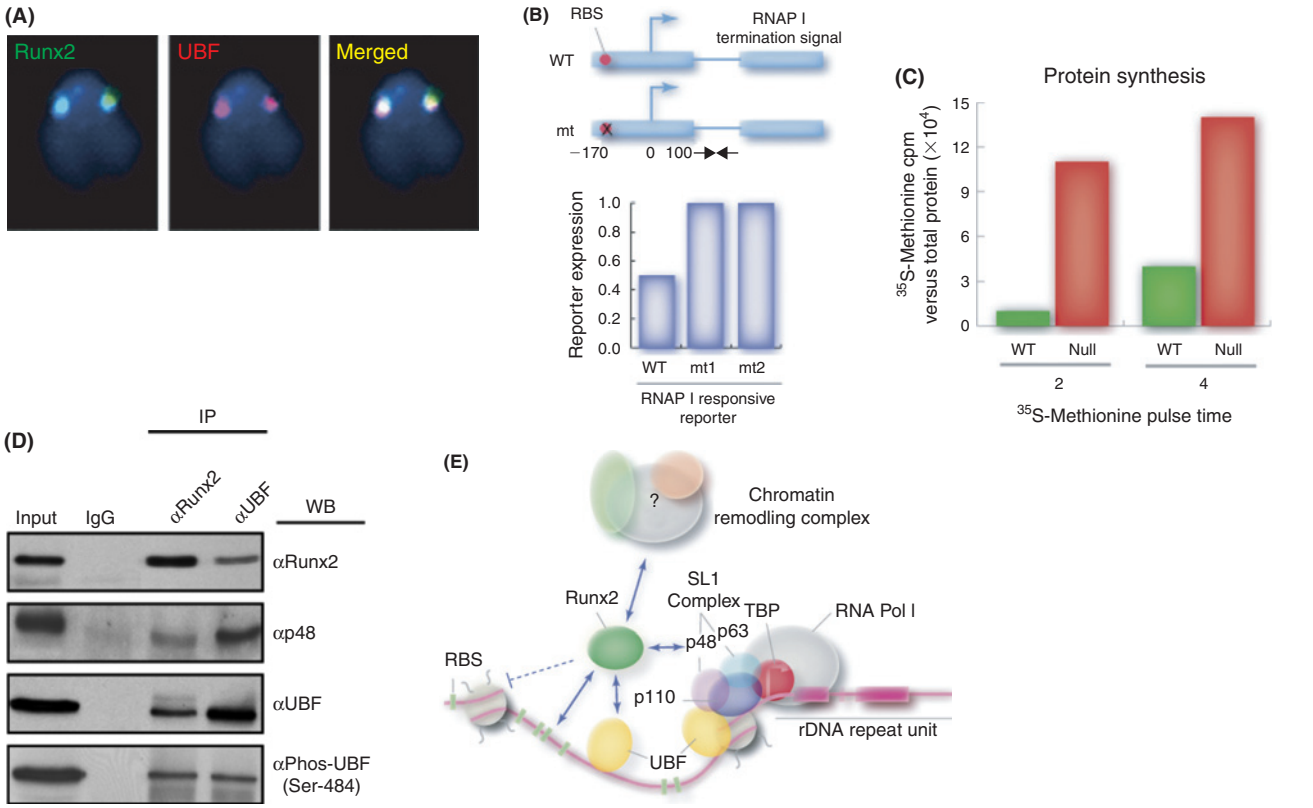

FIGURE 7 Runx2 regulates ribosomal RNA genes. (**A**) Immunofluorescence microscopy for Runx2 (green) and UBF1 (red) with DAPI staining (blue) and overlay for colocalization. Mitotic chromosome spreads from MCF-10A show that Runx2 colocalizes with nucleolar organizing regions (NORs). (**B**) Schematic of the rDNA-promoter reporters (wild-type [WT] and mutant [mt]) are shown with Runx binding site in red circle. RT-qPCR based reporter assay shows Runx2 inhibition of rDNA transcription. MC3T3 cells were transfected with hemagglutinin (HA) tagged *Runx2*. **C**, Primary calvarial cells from homozygous mouse embryos (17.5 days postcoitus) with WT or null Runx2 alleles. Total protein synthesis was measured by ^{3}H-methylmethionine incorporation at 0.5, 1, 2 and 4 hours using autoradiography. Incorporation of ^{35}S-methionine into proteins was measured by scintillation counting and normalized to total protein. **D**, Immunoprecipitates (IP) of endogenous Runx2 and UBF1 from osteoblastic cells react with antibodies against Runx2, UBF1, phospho-UBF1, or the p48 subunit of the SL1 complex in Western blots (WB). **E**, Diagram depicts lineage-specific regulation of rRNA synthesis. (See plate section)

mechanisms that control skeletal gene expression in tumors can provide insight into strategies for treatment. Our lab has demonstrated that transcription of skeletal genes in metastatic breast/prostate cancer cells is controlled by Runx2. We therefore determined the requirement for fidelity of Runx subnuclear localization for expression of bone proteins in breast/prostate cancers. The significance of intranuclear targeting is provided by single amino acid substitutions in the NMTS of lineage-specific Runx regulatory proteins. These mutations modify subnuclear targeting of Runx proteins and prevent osteolytic activity of metastatic breast cancer cells *in vivo* (Fig. 8). These findings suggest that therapeutic restoration of altered regulatory protein subnuclear targeting in leukemia and solid tumors may enhance capabilities for diagnosis and/or targeted treatment of cancer. The effectiveness of this strategy requires further understanding of the extent to which other regulatory proteins exhibit modified subnuclear targeting in metastatic cancers. Consistent with the subnuclear localization for tumor-related osteolysis or formation of osteoblastic lesions, perturbations in competency for subnuclear localization of Runx1 in myeloid progenitor cells leads to expression of a transformed phenotype (Barnes *et al.*, 2004; Javed *et al.*, 2005; Vradii *et al.*, 2005).

Runx2 Contributes to the Sequence of Metastatic Events through Regulation of Target Genes

One of the earliest indications of Runx2 involvement in the metastatic process was the characterization of the spectrum of matrix proteins, extracellular matrix signaling factors, and enzymes involved in bone turnover that are directly activated by Runx2 and are factors that have long been characterized as associated with stages of tumor progression and metastatic events. For example, Runx2 activates integrins in breast and prostate cancer cells (Pratap *et al.*, 2006). The vascular endothelial growth factor, essential for vascularization of the growth plate, has been shown to require Runx2 for activation during normal bone development (Zelzer *et al.*, 2001). Runx2 contributes to BSP and

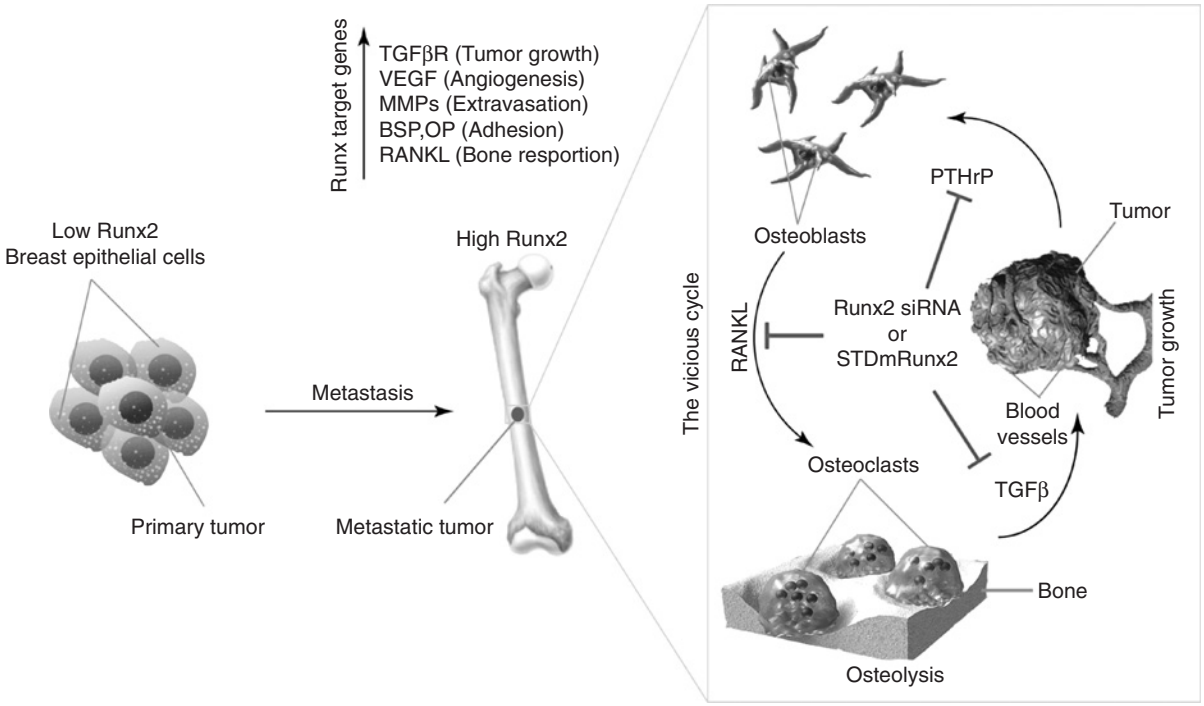

FIGURE 8 Vicious cycle of metastatic bone disease between breast cancer cells and bone. Once cancer cells arrive in bone, the four major participants in this vicious cycle include the cancer cells, osteoblasts, osteoclasts, and mineralized bone matrix, a major source of immobilized growth factors. Prostate cancer cells secrete factors that stimulate osteoblasts to proliferate, differentiate, and secrete growth factors. These factors are deposited into the bone matrix and also enrich the local microenvironment of the tumor cells. Tumor cells secrete osteolytic factors, most of which act via osteoblast production of the osteoclast differentiation factor RANKL. Growth factors released from the mineralized bone matrix as a consequence of osteoclastic bone resorption further enrich the local milieu. These interactions reinforce each other to accelerate cancer progression. Several of these factors are direct targets of Runx2 transcription factor, which is upregulated in highly aggressive prostate and breast cancer. When cancer cells expressing the mSTD Runx2 are introduced in mice, these cells lack the expression of cancer growth-promoting factors and do not form osteolytic lesions.

OPN, which have been observed in cancers with a high propensity for forming bone metastases, and these proteins are associated with poor survival (Bellahcene *et al.*, 1996; Bramwell *et al.*, 2006; Sharp *et al.*, 2004). Thus, high levels of Runx2 expression in the primary tumor may contribute to early events of tumor vascularization and modulate invasive properties of metastatic and nonmetastatic cancer cells (Pratap *et al.*, 2005).

Matrix metalloproteinases (MMPs) have long been implicated in tumor invasion and metastasis (Egeblad and Werb, 2002). Runx2 directly activates MMP genes, MMP9 and MMP13 (Pratap *et al.*, 2005; Selvamurugan *et al.*, 2004). We have reported that Runx2 siRNA knockdown decreases MMP9 expression in bone metastatic MDA-MB-231 breast cancer cells and reduces their invasive potential through matrigel (Pratap *et al.*, 2005). Furthermore, overexpression of Runx2 in poorly metastatic MCF-7 cells results in a significant increase in invasiveness in the matrigel invasion assay, concomitant with increased expression of several markers of metastasis (MMP2, MMP9, MMP13, and VEGF). Thus Runx2 represents a viable candidate for therapeutic targeting in primary tumors to block expression of many genes related to metastasis to bone.

Subnuclear Targeting Supports Metastasis and Osteolytic Bone Disease

Direct evidence for a functional role for Runx2 in metastatic cell lines was provided by inhibition of tumor growth, and osteolytic disease in the intratibial model of bone metastasis. The highly aggressive MDA-MB-231 cell lines were modified with stably integrated mutant Runx2 mutant proteins. MDA-MB-231 cells express high levels of Runx2 in striking contrast to MCF-7, the nonmetastatic breast cell line. Two Runx2 mutant proteins, either a dominant negative (Runx2 Δ230) or a point mutation protein that is defective in intranuclear targeting of Runx2 to transcriptionally active subnuclear domains (targeting deficient [TD] mRunx2 R398A/Y428A) when expressed in MDA-MB-231, decrease functional activity of the endogenous Runx2 in MDA-MB-231, breast cancer cells. As a result, *in vitro* invasive and *in vivo* bone osteolytic properties of the parental cells were blocked (Barnes *et al.*, 2004; Javed *et al.*, 2005). These findings suggest that fidelity of Runx2 intranuclear organization is obligatory for expression of target genes that mediate the osteolytic activity of metastatic breast cancer cells (Javed *et al.*, 2005).

Runx2 organization of regulatory complexes in the nuclear microenvironment of cancer cells can promote the end stage of metastasis to bone as a result of the formation of Runx2 protein–protein complexes. Of the many signaling proteins secreted by cancer cells, TGFβs and BMPs have long been implicated in early events of both tumorigenesis and metastasis as well as facilitating tumor growth and the osteolytic disease (Grimm and Rosen, 2006; Guise and Chirgwin, 2003; Yoneda *et al.*, 2001). TGFβ signals through both the Smad pathway and the mitogen-activated protein (MAP) kinase pathways and stimulates PTHrP secretion (Kakonen *et al.*, 2002). Runx2 protein is a downstream target of both pathways and plays a central role as a transcriptional mediator of Smad signaling (Chang *et al.*, 2002; Ji *et al.*, 2001; Kang *et al.*, 2005). This appears to be a critical component of the Runx2 activity in facilitating metastatic bone disease as tumor cells in the bone environment respond to TGFβ to continue the vicious cycle of tumor growth and osteolytic diseases (Chirgwin *et al.*, 2004; Feeley *et al.*, 2005; Fizazi *et al.*, 2003). PTHrP is stimulated by TGFβ (Kakonen *et al.*, 2002) and is now established as one of the principal factors responsible for activating the process of bone loss. Runx2 is also linked to RANKL production as well as inhibition of osteoprotegerin, an antagonist of osteoclast differentiation, thereby contributing to the osteolytic disease (Enomoto *et al.*, 2003). Thus identification of a master regulatory transcription factor Runx2, which mediates the TGFβ signaling pathway and controls the expression of genes directly linked to stages of tumor metastasis to bone and the accompanying bone disease, provides an opportunity to target an upstream regulator of many tumorigenic activities.

FUNCTIONAL INTERRELATIONSHIPS BETWEEN NUCLEAR STRUCTURE AND SKELETAL GENE EXPRESSION

The regulated and regulatory components that interrelate nuclear structure and function must be established experimentally. A formidable challenge is to define further the control of transcription factor targeting to acceptor sites associated with the nuclear matrix. It will be important to determine whether acceptor proteins are associated with a preexisting core filament structural lattice or whether a compositely organized scaffold of regulatory factors is assembled dynamically.

An inclusive model for all steps in the targeting of proteins to subnuclear sites cannot yet be proposed. However, this model must account for the apparent diversity of intranuclear targeting signals. It is also important to assess the extent to which regulatory discrimination is mediated by subnuclear domain-specific trafficking signals. Furthermore, the checkpoints that monitor the subnuclear distribution of regulatory factors and the sorting steps that ensure both structural and functional fidelity of nuclear domains in which replication and expression of genes occur must be defined biochemically and mechanistically.

There is emerging recognition that the placement of regulatory components of gene expression must be coordinated temporally and spatially to facilitate biological control. The consequences of breaches in nuclear structure–function relationships are observed in an expanding series of diseases that include cancer (McNeil *et al.*, 1999; Rogaia *et al.*, 1997; Rowley, 1998; Tao and Levine, 1999; Weis *et al.*, 1994; Yano *et al.*, 1997; Zeng *et al.*, 1998; Zhang *et al.*, 2000) and neurological disorders (Skinner *et al.*, 1997). Findings indicate the requirement for the fidelity of Runx/Cbfa/AML subnuclear localization to support regulatory activity for skeletogenesis *in vivo.* Although many of the human mutations in Runx2 associated with cleidocranial dysplasia occur in the DNA-binding domain, several mutations have been identified in the C terminus, which disrupt nuclear matrix association (Zhang *et al.*, 2000). As the repertoire of architecture-associated regulatory factors and cofactors expands, workers in the field are becoming increasingly confident that nuclear organization contributes significantly to the control of transcription. To gain increased appreciation for the complexities of subnuclear organization and gene regulation, we must continue to characterize mechanisms that direct regulatory proteins to specific transcription sites within the nucleus and sustain regulatory complex association with gene loci on mitotic chromosomes for epigenetic control of lineage and phenotype for these proteins to be in the right place at the right time.

INTRODUCTION

It has been almost 150 years since the term "collagen" was first adopted in the English language. This rope-like structure that yields gelatin upon boiling made its early appearance in evolution in primitive animals such as jellyfish, coral, and sea anemones (Bergeon, 1967). Today, the collagen family of proteins has grown to 28 different types and is used as a versatile biomaterial for delivery of drugs as well as for cosmetic purposes.

During those 150 years our understanding of collagen has evolved with advances in techniques and technology. The work of Nageotte in the early 1920s used acid solubilization to reveal the fibers that histologists had earlier described in sections of connective tissues (Nageotte, 1927); x-ray diffraction and then electron microscopy characterized those fibers that made up the collagen molecule. In addition to collagens involved in fibril formation, several other groups of nonfibrillar collagen have been discovered. Among these, some are involved in membrane formation that surrounds tissues such as basement and Descemet's membranes, cuticle of worms, and skeleton of sponges.

In this chapter, we are focusing on fibrillar collagens and, in particular, collagen type I, the most abundant extracellular protein, especially in bone, where it is essential for bone strength. We will discuss the structure and biosynthesis of type I collagen and associated proteins that maintain its homeostasis and recent results into the organization of regulatory elements in type I collagen genes, many of which are based on studies in transgenic mice. Then we will address how collagen synthesis is regulated by cytokines and growth factors.

The accepted definition of collagens is: "structural proteins of the extracellular matrix which contain one or more domains harboring the conformation of a collagen triple helix" (Myllyharju and Kivirikko, 2004; van der Rest and Garrone, 1991). The triple-helix motif is composed of three polypeptide chains whose amino acid sequence consists of Gly-X-Y repeats. Because of this particular peptide sequence, each chain is coiled in a left-handed helix, and the three chains assemble in a right-handed triple helix, where Gly residues are in the center of the triple helix and where the lateral chains of X and Y residues are on the surface of the helix (van der Rest and Garrone, 1991). In about one-third of the cases, X is a proline and Y is a hydroxyproline; the presence of hydroxyproline is essential to stabilize the triple helix and is a unique characteristic of collagen molecules. At the time of this review, 28 different types of collagens have been described, which are grouped in subfamilies depending on their structure and/or their function. The roman numerals denoting collagen types follow the order in which they were reported. For each collagen type, the alpha chains are identified with Arabic numerals (Myllyharju and Kivirikko, 2001). Although a standard nomenclature has been agreed on, the representation of the collagen names can be sometimes confusing. Throughout this chapter, we will address the unassembled collagen molecules as procollagens, the mouse gene as *Col1a1* or *Col1a2* (lower case) and the human in capital letters (*COL1A1* or *COL1A2*).

FIBRILLAR COLLAGENS

Types I, II, III, V, and XI and the newly described types XXIV and XXVII collagens (Boot-Handford *et al.*, 2003; Koch *et al.*, 2003) form the group of fibrillar collagens. The characteristic feature of fibrillar collagens is that they consist of a long continuous triple helix that self-assembles

Principles of Bone Biology, 3rd Edition

into highly organized fibrils. These fibrils have a very-high-tensile strength and play a key role in providing a structural framework for body structures such as skeleton, skin, blood vessels, intestines, or fibrous capsules of organs. Type I collagen, which is the most abundant protein in vertebrates, is present in many organs and is a major constituent of bone, tendons, ligaments, and skin. Type III collagen is less abundant than type I collagen, but its distribution essentially parallels that of type I collagen with the exception of bones and tendons, which contain virtually no type III collagen. Moreover, type III collagen is relatively more abundant in distensible tissues, such as blood vessels, than in nondistensible tissues. Type V collagen is present in tissues that also contain type I collagen. Type II collagen is a major constituent of cartilage and is also present in the vitreous body. Like type II, type XI and type XXVII collagens are present in cartilage. However, unlike other collagens, type XXVII appear to express in epithelial cells of cochlea, lung, gonad, and stomach (Boot-Handford *et al.*, 2003), suggesting that its function in these epithelial layers can not depend on the copolymerization with other collagens. Collagen type XXIV displays unique structural features of invertebrate fibrillar collagens and is expressed predominantly in bone tissue (Matsuo *et al.*, 2006).

Bone formation is a complex and tightly regulated genetic program that involves two distinct pathways at different anatomical locations (de Crombrugghe *et al.*, 2001; Karsenty and Wagner, 2002; Olsen *et al.*, 2000). In intramembranous ossification, mesenchymal cells condense and differentiate directly into mainly collagen type I producing osteoblasts, whereas in endochondral bone formation, a cartilage model that is initially rich in type II and type XI collagens, which are secreted by chondrocytes, is replaced by an osteum rich in collagen type I matrix. Cartilage formation in endochondral skeletal elements is initiated by the condensation of chondrogenic mesenchymal cells followed by the overt differentiation of cells in these condensations. After undergoing a unilateral form of proliferation, these cells gradually become hypertrophic. At the same time, cells around the condensations form the perichondrial layer that gives rise to the osteoblast-forming periosteum and ultimately to cortical bone. The process of cartilage replacement by a bone matrix involves invasion by preosteoblasts in the periosteum as well as blood vessels and hematopoietic cells of the zone of hypertrophic chondrocytes. Expression of the genes for collagen type I and those for collagen types II and XI follow distinct transcriptional codes that control osteoblastogenesis and chondrogenesis (Bridgewater *et al.*, 1998; de Crombrugghe *et al.*, 2001; Karsenty and Wagner, 2002; Lefebvre *et al.*, 2001; Lefebvre and de Crombrugghe, 1998). In addition to fibrillar collagens, collagen type X has been implicated in the morphogenic events of hypertrophic cartilage prior to their replacement by bone. Although knockout mice for collagen X showed no apparent phenotype (Rosati *et al.*, 1994), significant reduction in the amount and quality of bone minerals was evident (Paschalis *et al.*, 1996).

Collagen types XXIV and XXVII display mutually exclusive patterns of expression in the developing and adult mouse skeleton. Gene expression studies have shown that whereas *Col24a1* transcripts accumulate at ossification centers of the craniofacial, axial, and appendicular skeleton, *Col27a1* activity is instead confined to the cartilaginous anlagen of skeletal elements (Boot-Handford *et al.*, 2003; Koch *et al.*, 2003; Pace *et al.*, 2003). Additionally, structural considerations have suggested that collagens XXIV and XXVII are likely to form distinct homotrimers (Koch *et al.*, 2003). Together these observations have been interpreted to indicate that these newly discovered fibrillar collagens may participate in the control of important physiological processes in bone and cartilage, such as collagen fibrillogenesis and/or matrix calcification and mineralization (Boot-Handford *et al.*, 2003; Koch *et al.*, 2003; Pace *et al.*, 2003).

STRUCTURE, SYNTHESIS, AND ASSEMBLY OF TYPE I COLLAGEN

Structure

Fibril-forming collagens are synthesized in precursor form, procollagens. Each molecule of type I collagen is typically composed of two α1 chains and one α2 chain [$\alpha1(I)_2$–$\alpha2(I)$] coiled around each other in a characteristic triple helix. Both the α1 chain and the α2 chain consist of a long helical domain preceded by a short N-terminal peptide and followed by a short C-terminal peptide (for reviews, see Myllyharju and Kivirikko, 2001, 2004, and van der Rest and Garrone, 1991).

The mechanism that controls the 2:1 stoichiometry of the collagen chains in type I collagen is not well understood. It is evident that a number of type I collagen molecules can be formed by three α1 chains [$\alpha1(I)_3$]. The homotrimeric type I collagen isotype containing three pro α1(I) collagen chains [$\alpha1(I)_3$] is a minor isotype, whose role is not well understood. Homotrimers are found embryonically (Jimenez *et al.*, 1977; Rupard *et al.*, 1988) in small amounts in skin (Uitto, 1979), in certain tumors and cultured cancer cell lines (Moro and Smith, 1977; Rupard *et al.*, 1988), and also during wound healing (Haralson *et al.*, 1987). Mesangial cells, which do not synthesize collagen type I *in vivo*, produce homotrimeric type I collagen in culture, further suggesting that homotrimers play a role in wound healing (Johnson *et al.*, 1992). The collagen I α2-deficient mouse, otherwise known as the oim mouse (osteogenesis imperfecta model) is homozygous for a spontaneous nucleotide deletion in the *Col1a2* gene, resulting in a frameshift altering the carboxy-propeptide of the pro Col1a2 chain. Although the carboxy-propeptide is not present in

mature type I collagen, it is responsible for association of the Col1a2 chain with the Col1a1 chains during assembly of the triple helix (Chipman *et al.*, 1993; Deak *et al.*, 1983; McBride *et al.*, 1997) (see sections on collagen diseases).

Type I collagen is secreted as a propeptide, but the N telopeptide and the C telopeptide are cleaved rapidly by specific proteases, ADAMTS 2 and BMP1, respectively, in order that shorter molecules assemble to form fibrils (Canty and Kadler, 2005). In fibrils, molecules of collagen are parallel to each other (Fig. 1); they overlap each other by multiples of 67 nm (distance D), with each molecule being 4.4 D (300 nm) long; there is a 40-nm (0.6 D) gap between the end of a molecule and the beginning of the other (see Fig. 1). This quarter-staggered assembly explains the banded aspect displayed by type I collagen fibrils in electron microscopy. In tissues, type I collagen fibrils can be parallel to each other and form bundles (or fibers), as in tendons, or they can be oriented randomly and form a complex network of interlaced fibrils, as in skin. In bone, hydroxyapatite crystals seem to lie in the gaps between collagen molecules.

Transcription

In humans the gene coding for the α1 chain of type I collagen is located on the long arm of chromosome 17 (17q21.3-q22), (chromosome 11 in mouse) and the gene coding for the α2 chain is located on the long arm of chromosome 7 (7q21.3-q22) (chromosome 6 in mouse). Both genes have a very similar structure (Chu *et al.*, 1984; D'Alessio *et al.*, 1988), and this structure is also very similar to that of genes coding for other fibrillar collagens (Vuorio and de Crombrugghe, 1990). The difference in size between the two genes (18 kb for the *Col1a1* gene and 38 kb for the *Col1a2* gene) is explained by differences in the size of the introns.

The triple helical domain of the α1 chain is coded by 41 exons, which code for Gly-X-Y repeats, and by two so-called joining exons. These joining exons code in part for the telopeptides and in part for Gly-X-Y repeats, which are part of the triple helical domain. The triple helical domain of the α2 chain is coded by 42 exons, plus two joining exons. Each of the corresponding exons coding for the triple helical domain of the α1 chain and for the triple helical domain of the α2 chain has a similar length (Table I). The only exception is that exons 34 and 35 in the *Col1a2*, which are 54 bp long each, correspond to a single 108-bp 34/35 exon in the α1 gene. Except for the two joining exons, each exon starts exactly with a G codon and ends precisely with a Y codon, and all the exons are 54, 108 (54 × 2), 162 (54 × 3), 45, or 99 bp long (see Table I). This organization suggests that exons coding for triple helical domains could have originated from the amplification of a DNA unit containing a 54-bp exon embedded in intron

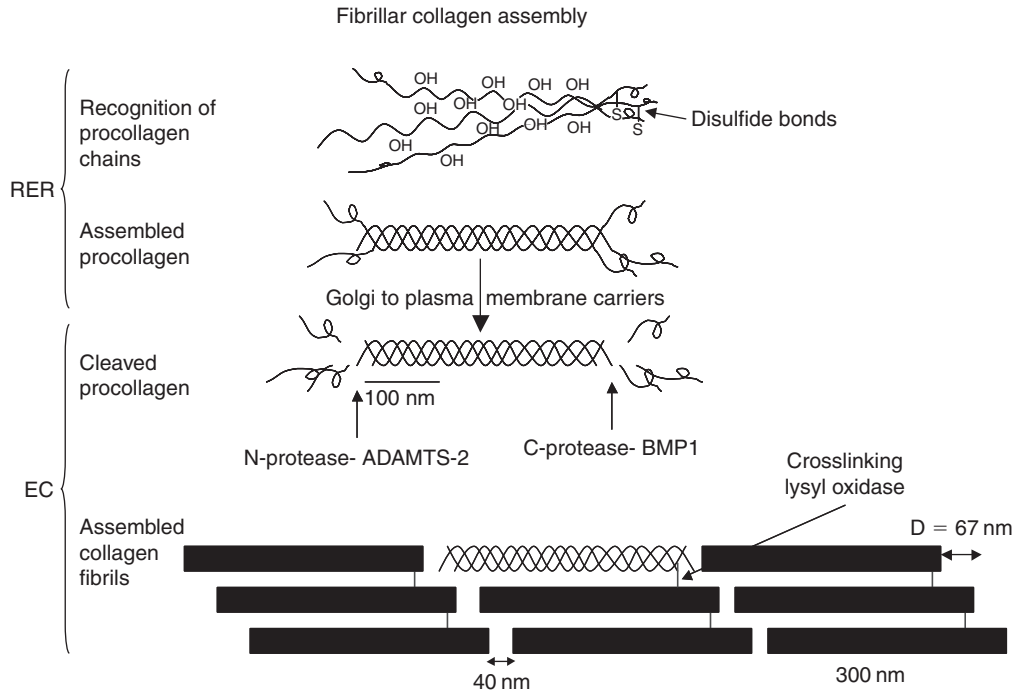

FIGURE 1 Schematic diagram of collagen assembly depicting the recognition of the alpha chains in the rough endoplasmic reticulum (RER) and the helix formation strengthened by the hydroxylated proline and lysine residues (OH). The collagen is then transported by Golgi to plasma membrane vesicles to extracellular space (EC) where the propeptides are removed by proteinases and the fibrils are assembled into collagen fibers that are cross-linked by lysyl oxidase.

TABLE I Size of Exons Coding for the Triple Helical Domain of Type I Collagen*

Exon	Size (bp)	Exon	Size (bp)	Exon	Size (bp)
7	45	21	108	35	54
8	54	22	54	36	54
9	54	23	99	37	108
10	54	24	54	38	54
11	54	25	99	39	54
12	54	26	54	40	162
13	45	27	54	41	108
14	54	28	54	42	108
15	45	29	54	43	54
16	54	30	45	44	108
17	99	31	99	45	54
18	45	32	108	46	108
19	99	33	54	47	54
20	54	34	54	48	108

*In the pro-α 1(I) collagen gene, exons 33 (54 bp) and 34 (54 bp) are replaced by a single 108-bp 33/34 exon. The two joining exons (exons 6 and 49) are not considered in this table (see text for details).

sequences. One hundred and eight- and 162-bp exons would result from a loss of intervening introns. Forty-five- and 99-bp exons would result from recombinations between two 54-bp exons (Vuorio and de Crombrugghe, 1990).

For both the α1 chain and the α2 chain, the C propeptide plus the C telopeptide are coded by 4 exons (exons 48 to 51 of the *Col1a1* gene, exons 49 to 52 of the *Col1a2* gene). The first of these exons code for the end of the triple helical domain, the C-terminal telopeptide, and the beginning of the C-terminal propeptide. The three other exons code for the rest of the C-terminal propeptide. The C-terminal propeptide has a globular structure that is stabilized by two intrachain disulfide bonds (see Fig. 1). It contains three (α2 chain) and four (α1 chain) additional cysteine residues that form interchain disulfide bonds. The formation of disulfide bonds precedes the triple helix formation and plays an essential role in the intracellular assembly of the three a chains (see sections on translational and posttranslational modifications).

The signal peptide, the N propeptide, and the N telopeptide of the α1 chain, as well as of the α2 chain, are coded by the first six exons. The N propeptide of the α1 chain contains a cysteine-rich (10-cysteine residue) globular domain, a short triple helical domain, and a short globular domain, which harbors the N-terminal peptidase cleavage site (see Fig. 1). The N-terminal propeptide of the α2 chain does not contain a cysteine-rich domain but a short globular domain. The 3′-untranslated region of both the *Col1a1* gene and the *Col1a2* gene contains more than one polyadenylation site, which explains that mRNAs with different sizes will be generated. As in many other genes, the functional role of the different polyadenylation sites is still unknown.

Translation

After being transcribed, the pre-mRNA undergoes exon splicing, capping, and addition of a poly(A) tail, which gives rise to a mature mRNA. These mature mRNAs are then translated in polysomes, and the resulting proteins undergo extensive post-translational modifications before being assembled in a triple helix and released in the extracellular space (for reviews, see Lamande and Bateman, 1999; Myllyharju and Kivirikko, 2001).

Signal peptides are cleaved from the chains when their N-terminal end enters the cisternae of the rough endoplasmic reticulum. Both the pro-α1 chain and the pro-α2 chain undergo hydroxylation and glycosylation, and these modifications are essential for the assembly of type I collagen chains in a triple helix. About 100 proline residues in the Y position of the Gly-X-Y repeats, a few proline residues in the X position, and about 10 lysine residues in the Y position undergo hydroxylation, respectively, by a prolyl 4-hydroxylase, a prolyl 3-hydroxylase, and a lysyl hydroxylase. Hydroxylation of proline to hydroxyproline is critical to obtain a stable triple helix, and at 37°C, stable folding in a triple helical conformation cannot be obtained before at least 90 prolyl residues have been hydroxylated. These hydroxylases have different requirements to be active, and, in particular, they can act only when prolyl or lysyl residues occupy the correct position in the amino acid sequence of the a chain and when peptides

are not in a triple helical configuration. Moreover, these enzymes require ferrous ions, molecular oxygen, α-ketoglutarate, and ascorbic acid to be active. This requirement for ascorbic acid could explain some of the consequences of scurvy on wound healing. When lysyl residues become hydroxylated, they serve as a substrate for a glycosyltransferase and for a galactosyltransferase, which add glucose and galactose, respectively, to the ε-OH group. As for hydroxylases, glycosylating enzymes are active only when the collagen chains are not in a triple helical conformation. Glycosylation interferes with the packaging of mature molecules into fibrils, and increased glycosylation tends to decrease the diameter of fibrils.

While hydroxylations and glycosylations described previously occur, after a mannose-rich oligosaccharide is added to the C propeptide of each pro α chain, C propeptides from two α1 chains and one α2 chain associate with the formation of intrachain and interchain disulfide bonds. After prolyl residues have been hydroxylated, and the three C propeptides have associated, a triple helix will form at the C-terminal end of the molecule and then extend toward the N-terminal end (see Fig. 1). This propagation of the triple helical configuration occurs in a "zipper-like fashion" (Prockop, 1990). If prolyl residues are not hydroxylated or if interchain disulfide bonds are not formed between the C propeptides, the a chain will not fold in a triple helix. Although the functions of the C-terminal sequences, which have been associated with initiation of triple helix formation, are thought to be well established, those of the N-terminal propeptide are poorly understood (Bornstein, 2002). The N propeptide of type I procollagen, as released physiologically by procollagen N-protease (ADAMTS 2), contains a globular domain largely encoded by exon 2 in the *Col1a1* gene, and a short triple helix that terminates in a non-triple-helical telopeptide sequence, which separates this helix from the major collagen helix. Bornstein and colleagues generated a mouse with a targeted deletion of exon 2 in the *Col1a1* gene, thus replicating the type IIB splice form of type II procollagen in type I procollagen (Bornstein *et al.*, 2002), surprisingly, homozygous mutant mice were essentially normal. In particular, none of the steps in collagen biogenesis thought to be dependent on the N propeptide were defective. However, there was a significant, but background-dependent, fetal mortality, which suggested a role for the type I collagen N propeptide in developmental processes.

Toman and colleagues have gone even further to demonstrate that propeptide may not be necessary for the selection and folding of procollagen. They engineered type I collagen genes that encode the N and C telopeptides with the entire triple helical domain and show that these sequences are sufficient for assembly of a triple helix in *Saccharomyces cerevisiae* (Olsen *et al.*, 2001). Other fibrillar collagens (types II, III, V, and XI) have a similar structure and thus would be expected to fold into triple helices without the propeptide regions in an analogous system.

Intracellular Transport

The newly formed triple-helical forms are then stabilized by Hsp47, a molecular chaperone of type I collagen molecules (Nagai *et al.*, 2000; Tasab *et al.*, 2000). This protein belongs to the serine protease inhibitor (serpin) superfamily containing a serpin signature sequence. Hsp47 resides in the endoplasmic reticulum (ER), as inferred from the presence of a carboxyl-terminal RDEL sequence similar to the ER retrieval signal, KDEL. Hsp47 binds to nascent procollagen chains in the ER of collagen-secreting cells and dissociates from them before reaching the *cis*-Golgi apparatus. Disrupting the *hsp47* gene in mice resulted in embryonic lethality in mice by 11.5 days postcoitus and caused a molecular abnormality in procollagens (Nagai *et al.*, 2000). Type I procollagen chains containing propeptides accumulated in the tissues, but the mature collagen chains normally processed were scarcely observed, suggesting that HSP47 is essential as a collagen-specific molecular chaperone for the proper processing of procollagen molecules, and the *hsp47* gene is needed for the normal development of mouse embryo (Nagai *et al.*, 2000). The Golgi complex with its associated Trans Golgi Network (TGN) consists of a complex network of anastomosing tubules. The TGN mediates the final modification of N-linked oligosaccharides to the complex and is involved in both the transport and sorting of membrane and secretory proteins (Griffiths and Simons, 1986). Previous works have shown that green fluorescent protein (GFP) fusion proteins are transported from the Golgi to the cell surface in tubular-saccular compartments that travel along microtubules (Hirschberg *et al.*, 1998; Polishchuk *et al.*, 2000; Puertollano *et al.*, 2003; Toomre *et al.*, 1999). These pleiomorphic Golgi to Plasma Membrane carriers (GPCs) can be 0.5 to 1.7 μm in length and have also been called transport containers (Toomre *et al.*, 1999) and post-Golgi carriers (Hirschberg *et al.*, 1998). A recent *in vitro* study has shown that exit from the TGN occurs by the formation of a tubular-reticular TGN domain that is a precursor structure to the release of tubular-saccular GPCs (Polishchuk *et al.*, 2003).

For the majority of cells, procollagen is secreted in the extracellular space, where a specific procollagen aminopeptidase (ADAMTS 2) and a specific procollagen carboxypeptidase (BMP1) cleave the propeptides, thereby triggering spontaneous self-assembly of collagen molecules into fibrils, giving rise to mature collagen molecules (Kadler, 2004; Kadler *et al.*, 1990). Cleavage of the propeptide decreases the solubility of collagen molecules dramatically. Thus a major extracellular function of C propeptides is thought to prevent fibril formation, while N propeptide influence fibril shape and diameter (Hulmes, 2002).

The free propeptides are believed to be involved in feedback regulation of collagen synthesis of types I and III collagens by fibroblasts in culture (Wiestner *et al.*, 1979). However, the mechanism of this inhibition remained elusive despite attempts by several groups to characterize it.

Fibrillogenesis

In the extracellular space, the molecules of mature collagen assemble spontaneously into quarter-staggered fibrils; this assembly is directed by the presence of clusters of hydrophobic and of charged amino acids on the surface of the molecules. Fibril formation has been compared with crystallization in that it follows the principle of "nucleated growth" (Prockop, 1990). Once a small number of molecules have formed a nucleus, it grows rapidly to form large fibrils. During fibrillogenesis, some lysyl and hydroxylysyl residues are deaminated by a lysine oxidase, which deaminates the ε-NH_2 group, giving rise to aldehyde derivatives. These aldehydes will associate spontaneously with ε-NH_2 groups from a lysyl or hydroxylysyl residue of adjacent molecules, forming interchain cross-links. These cross-links will increase the tensile strength of the fibrils considerably (see Fig. 1). *In vitro* studies have shown that procollagen molecules and their various structural domains have a remarkable capacity to control all stages of collagen assembly, from intracellular assembly to extracellular suprafibrillar assembly at a micrometer scale. The *in vivo* process is much more complex but we are beginning to understand some of this in particular cell types. Kadler and coworkers have recently shown that GPCs are indeed present *in vivo* in embryonic tendon fibroblasts and that some GPCs contain 28-nm-diameter collagen fibrils. Moreover, GPCs are targeted to novel plasma membrane protrusions, which they have termed "fibripositors" (fibril depositors). What was intriguing in this study is the fact that procollagen can be converted to collagen within the confines of the cell membrane, which is consistent with the observation of collagen fibrils in some GPCs and the known intracellular activation of BMP-1. In addition, fibripositors were shown to be always oriented along the tendon axis, which establishes a link between intracellular transport and the organization of the ECM (Canty *et al.*, 2004). Interestingly, fibripositor formation is not a constitutive process in procollagen-secreting cells. It is absent in postnatal development despite active procollagen synthesis, but occurs only during a narrow window of embryonic development when tissue architecture is being established. It is not known whether this phenomenon occurs in other types of specialized collagen-secreting cells (Canty and Kadler, 2005).

Assembly

The final assembly of fibrillar collagen involves the direct interaction of several molecules, which include other collagens, small leucine-rich proteoglycan (SLRP), and others. These interactions shape the diameter of the fibrils (Kuc and Scott, 1997; Vogel and Trotter, 1987) and patterning of the final matrix. SLRPs are a group of secreted proteins that includes decorin, biglycan, fibromodulin, lumican, and keratocan, among others, that play major roles in tissue development and assembly, especially in collagen fibrillogenesis (Iozzo, 1999). Biglycan and decorin are highly expressed in extracellular bone matrix and there is now substantial evidence to support an increasing role for biglycan and decorin in influencing bone cell differentiation and proliferative activity (Waddington *et al.*, 2003). The ability of decorin and biglycan to interact with collagen molecules and to facilitate fibril formation has implicated these macromolecules in important roles in the provision of a collagenous framework in bone, which eventually allows for mineral deposition. Initial mineral deposition is proposed to occur within or near the gap zones along the collagen fibers, and the structural architecture of the collagen fibers along with interacting noncollagenous proteins are likely to play a key role in directing placement of the mineral crystals (Dahl and Veis, 2003).

Molecular modeling techniques have lead to the proposal that decorin and biglycan adopt an open-horseshoe structure (Weber *et al.*, 1996) where the inner cavity interacts with a single triple helical molecule. The generation of mutated forms of decorin has demonstrated the importance of leucine-rich sequences 4 to 6 in mediating this interaction (Kresse *et al.*, 1997). In addition, reduction in the disulfide bridges at the C- and N-terminal of decorin also abolished interaction with type I collagen (Ramamurthy *et al.*, 1996) and this led to the proposal that the disulfide loop at the C terminal binds to adjacent collagen fibrils, thereby facilitating the lateral assembly and stabilization of the fibrils.

Interestingly, recent molecular analysis data have put forward the idea that decorin exists as a dimer in solution (Scott *et al.*, 2003), and if this is the case *in vivo,* then the nature of this interaction will be important when considering the mechanistic role of decorin in fibril assembly. The glycoseaminoglycan (GAG) moiety of decorin and biglycan have also been deemed to play an important role in collagen fibrillogenesis, where the interaction of glycosylated forms of these SLRPs with collagen appeared to be greater than nonglycosylated forms (Bittner *et al.*, 1996).

Further evidence for the role of decorin and biglycan in bone formation is provided by targeted deletion of the genes. The biglycan knockout (*Bgn* −/−) mouse (Xu *et al.*, 1998), unlike the *Dcn* −/− mouse (Danielson *et al.*, 1997), showed no gross skin abnormalities but rather a reduction in bone density. These mice were seen to develop an osteoporotic phenotype, failing to achieve peak bone mass owing to decreased bone formation with significantly shorter femurs (Ameye *et al.*, 2002). Within these animals lower osteoblast numbers and osteoblast activity were observed. *In vitro* experiments demonstrated that the number and responsiveness of bone marrow stromal cells to TGF-β, and hence osteogenic precursor cells, decreased dramatically with age, but apoptosis rates increased (Chen *et al.*, 2002a). The effects were not confined only to the skeletal tissues. Within the teeth the transition of predentin

to dentin appeared to be impaired and the thickness of the enamel was dramatically increased (Goldberg *et al.*, 2002). Taken together these results would suggest that biglycan plays an important role in the formation of mineralized tissue. Furthermore, despite high sequence identity and somewhat similar patterns of localization, decorin and biglycan are not interchangeable in function and do not have the ability to rescue each other's knockout phenotypes. Notably, *Bgn* −/− and *Dcn* −/− double-knockout animals revealed that the effects of both gene deficiencies were additive in the dermis and synergistic in bone (Corsi *et al.*, 2002). The lack of both genes caused a phenotype with severe skin fragility and osteopenia, resembling a rare progeroid variant of Ehlers–Danlos syndrome.

Consequences of Genetic Mutations on Type I Collagen Formation

Osteogenesis imperfecta (also known as "brittle bone disease") is a genetic disease characterized by an extreme fragility of bones. Genetic studies have shown that it is due to a mutation in the coding sequence of either the pro *COL1A1* gene or the pro *COL1A2* gene, and more than 150 mutations have been identified (for review, see Byers, 2001) Most severe cases of osteogenesis imperfecta result from mutations that lead to the synthesis of normal amounts of an abnormal chain, which can have three consequences (Marini *et al.*, 2007). First, the structural abnormality can prevent the complete folding of the three chains in a triple helix, e.g., if a glycine is substituted by a bulkier amino acid that will not fit in the center of the triple helix. In this case, the incompletely folded triple helical molecules will be degraded intracellularly, resulting in a phenomenon known as "procollagen suicide." Second, some mutations appear not to prevent folding of the three chains in a triple helix, but presumably prevent proper fibril assembly. For example, Prockop's group has shown that a mutation of the *pro Col1a1* gene that changed the cysteine at position 748 to a glycine produced a kink in the triple helix (Kadler *et al.*, 1991). Finally, some mutations will not prevent triple helical formation or fibrillogenesis but might modify the structural characteristic of the fibrils slightly and thus affect their mechanical properties. In all these cases, the consequence on the mechanical properties of bone is probably similar. Mild forms of osteogenesis imperfecta most often result from a functionally null allele, which decreases the production of normal type I collagen. Null mutations are usually the result of the existence of a premature stop codon or of an abnormality in mRNA splicing. In these cases, the abnormal mRNA appears to be retained in the nucleus (Johnson *et al.*, 2000). A mouse model of osteogenesis imperfecta has been obtained by using a knockin strategy that introduced a Gly^{349}→Cys mutation in the pro *Col1a1* gene (Forlino *et al.*, 1999). This model faithfully reproduced the human disease. Another spontaneous mouse mutation the *oim*/*oim* mouse, analogous to human type III OI, carries a spontaneous deletion of G at nucleotide 3983 in the α2 chain of collagen type I, which alters the reading frame to result in the final 48 amino acids of the COOH-terminal propeptide generating a new stop codon, with addition of an extra amino acid (Chipman *et al.*, 1993). In these mice, collagen type I is made of $a(I)_3$ homotrimers in place of the normal $\alpha1(I)_2$ $\alpha2(I)_1$ heterotrimers.(Chipman *et al.*, 1993; Kuznetsova *et al.*, 2004; Miles *et al.*, 2002) which results in marked skeletal fragility, with thinning of the long bones and reduced mechanical strength.(Chipman *et al.*, 1993; Pereira *et al.*, 1995) An additional organ pathology has been recently described by Phillips and coworkers, namely a glomerulopathy characterized by abnormal renal collagen deposition (Brodeur *et al.*, 2007; Phillips *et al.*, 2002).

Ehlers–Danlos syndrome type VIIA and VIIB are two rare dominant genetic diseases characterized mainly by an extreme joint laxity. They result from mutations in the pro *COL1A1* gene (Ehlers–Danlos syndrome type VIIA) or in the pro *COL1A2* gene (Ehlers–Danlos syndrome type VIIB) that interfere with the normal splicing of exon 6, and a little less than 20 mutations have been described. These mutations can affect the splice donor site of intron 7 or the splice acceptor site of intron 5; in the latter case, there is efficient recognition of a cryptic site in exon 6 (Byers *et al.*, 1997). Thus, these mutations induce a partial or complete excision of exon 6. They do not appear to affect the secretion of the abnormal procollagen molecules, but they are responsible for the disappearance of the cleavage site of the N-terminal propeptide and thus for the presence of partially processed collagen molecules in fibrils that fail to provide normal tensile strength to tissues (Byers, 2001). Nevertheless, these mutations seem to affect the rate of cleavage of the N-terminal propeptide rather than to completely prevent it, which explains that the phenotype is less severe than for patients who do not have a functional N-proteinase (Ehlers–Danlos syndrome type VIIC).

Collagen Type I and Osteoporosis

Because type I collagen is the most abundant protein in bone and because mutations in the *COL1A1* gene are a major cause of osteogenic imperfecta, this gene has been considered a strong candidate for susceptibility to osteoporosis (Ralston and de Crombrugghe, 2006). Indeed polymorphisms in both the promoter (Garcia-Giralt *et al.*, 2002) and in the first intron of *COL1A1* (Grant *et al.*, 1996) have been associated with changes in bone mineral density (BMD). The polymorphism of intron 1 is located in a binding site for the transcription factor Sp1 and has been associated with various osteoporosis-related symptoms such as bone density and fractures (Grant *et al.*, 1996; Uitterlinden

et al., 1998), postmenopausal bone loss (Harris *et al.*, 2000; MacDonald *et al.*, 2001), bone geometry (Qureshi *et al.*, 2001), bone quality (Mann *et al.*, 2001), and bone mineralization (Stewart *et al.*, 2005). The osteoporosis-associated Sp1 polymorphism causes increased Sp1 binding, enhanced transcription, and abnormally high production of *COLIA1* mRNA and protein (Mann *et al.*, 2001), which result in an imbalance between the *COLIA1* and *COLIA2* chains. This is thought to lead to impairment of bone strength and reduced bone mass in carriers of the Sp1 polymorphism (Stewart *et al.*, 2005). Retrospective meta-analyses of previous studies have indicated that the Sp1 polymorphic allele is associated with reduced BMD and with vertebral fractures (Efstathiadou *et al.*, 2001; Mann and Ralston, 2003). In a recent large prospective meta-analysis of more than 20,000 participants from several European countries of the GENOMOS study, homozygotes for the Sp1 polymorphism were found to be associated with lower BMD at the lumbar spine and femoral neck and a predisposition to vertebral fractures (Ralston *et al.*, 2006). In this study, however, the BMD association was only observed for homozygotes of the Sp1 polymorphism, in contrast to previous studies where heterozygotes also showed a reduction in BMD (Mann and Ralston, 2003). It should be noted that the association between *COLIA1* alleles and vertebral fracture reported in GENOMOS and other studies was not fully accounted for by the reduced bone density, suggesting that the Sp1 allele may also be a measure of bone quality. Furthermore, the existence of an extended haplotype defined by the Sp1 polymorphism and other promoter polymorphisms has been proposed to exert stronger effects on BMD than the individual polymorphisms (Garcia-Giralt *et al.*, 2002; Stewart *et al.*, 2006). Evidence has been presented that suggests that the promoter polymorphism at position −1663 interacts with the transcription factor NMP4, which plays a role in osteoblast differentiation by interacting with Smads (Garcia-Giralt *et al.*, 2005).

Transcriptional Regulation of Type I Collagen Genes

Expression of the *pro Col1a1* gene and the *pro Col1a2* gene is coordinately regulated in a variety of physiological and pathological situations. In many of these instances it is likely that the control of expression of these two genes is mainly exerted at the level of transcription, suggesting that similar transcription factors control the transcription of both genes.

This section considers successively the proximal promoter elements of these genes and then the nature of cell-specific enhancers located in other areas of these genes including intronic sequences. Information about the various DNA elements has come from transient expression experiments in tissue culture cells, *in vitro* transcription experiments, and experiments in transgenic mice. *In vitro* transcription experiments and, in large measure, transient expression experiments identify DNA elements that have the potential of activating or inhibiting promoter activity. These DNA elements can be used as probes to detect DNA-binding proteins. However, transient expression and *in vitro* transcription experiments do not take into account the role of the chromatin structure in the control of gene expression. Transgenic mice are clearly the most physiological system to identify tissue-specific elements; the DNAs that are tested are integrated into the mouse genome and their activities are presumably also influenced by their chromatin environment. In transgenic mice experiments, reporter genes such as green fluorescent protein (GFP, luciferase or the *Escherichia coli* β-galactosidase offer the advantage that their activity is indicative of promoter activation and location of the expression. All three transgenes can be detected *in vivo* without having to kill the mouse. In addition, X-Gal histochemical stain for β-galactosidase can identify the cell types in which the transgene is active by histology.

Transient transfection experiments using various sequences upstream of the transcription start site of either the pro α1(I) or the pro α2(I) promoter, cloned upstream of a reporter gene, and introduced in fibroblasts, have delineated positive *cis*-acting regulatory segments in these two sequences that were designated as minimal proximal promoters. Footprint experiments and gel-shift assays performed using these regulatory elements as DNA templates have also characterized sequences that interact with DNA-binding proteins to modulate the expression of the two genes.

Proximal Promoters of Type I Collagen Genes

Transcription Factors Binding to the pro α1(I) Proximal Promoter

In the pro α1(1) collagen gene, a close homology exists between human and mouse promoters. Brenner and colleagues demonstrated by progressively deleting the mouse *pro-Col1a1* promoter that sequences downstream of −181 bp are needed for high-level transient transfection (Brenner *et al.*, 1989). Therefore, the sequence between −220 and +110 has been used as the proximal promoter (Fig. 2) and contains binding sites for DNA-binding factors that also bind to the proximal *pro Col1a2* promoter (Ghosh, 2002). These DNA elements in the mouse pro *Col1a1* proximal promoter include a binding site for CBF between −90 and −115 (Karsenty and de Crombrugghe, 1990). A second CCAAT box located slightly more upstream is, however, unable to bind CBF, suggesting that sequences surrounding the CCAAT motif also have a role in CBF binding. Similar results were observed in the human *COL1A1* promoter (Saitta *et al.*, 2000). DNA transfection experiments with

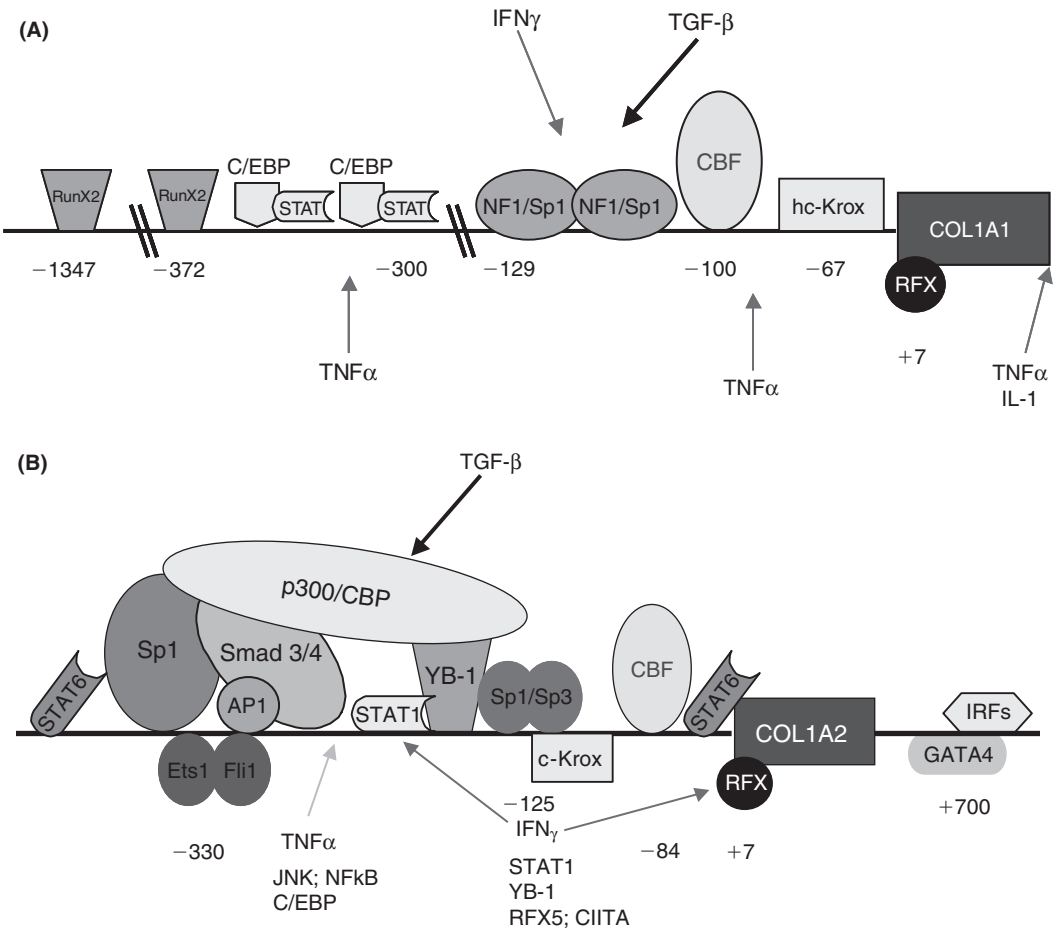

FIGURE 2 Schematic diagram illustrating the known transcription factors that bind to the proximal promoter of the human and murine *Col1a1* (**A**) and *Col1a2* (**B**) promoters. Also shown are the cytokines that modulate the expression of these genes. The data are accumulated from several papers as cited in the text.

the *pro Col1a1* promoter showed that point mutations in the CBF-binding site decreased promoter activity (Karsenty and de Crombrugghe, 1990). The CBF-binding site is flanked by two identical 12-bp repeat sequences that are binding sites for Sp1 and probably other GC-rich binding proteins (Nehls *et al.*, 1991). In transient transfection experiments, a mutation in the binding site that prevents the binding of Sp1 surprisingly increased the activity of the promoter, and overexpression of Sp1 decreased the activity of the promoter (Nehls *et al.*, 1991). It is possible that several transcription factors with different activating potentials bind to overlapping binding sites and compete with each other for binding to these sites; the overall activity of the promoter could then depend on the relative occupancy of the different factors on the promoter DNA. Substitution mutations in two apparently redundant sites between −190 and −170 and between −160 and −130 that abolished DNA binding resulted in an increase in transcription (Karsenty and de Crombrugghe, 1990). Formation of a DNA–protein complex with these two redundant elements in the pro *Col1a1* promoter was also shown to be completed by the sequence of the *pro Col1a2* promoter between −173 and −143, suggesting that both type I promoters contained binding sites for a similar (Karsenty and de Crombrugghe, 1991). A member of the Krox family, designated c-Krox, binds to these two sites in the pro *Col1a1* promoter (Galera *et al.*, 1994). In addition, c-Krox binds to a site located near the CCAAT box in the pro *Col1a1* promoter and to three GC-rich sequences in the pro *Col1a2* proximal promoter, located between −277 and −264 bp, between −175 and −143 bp, and near the CCAAT box, respectively (Galera *et al.*, 1996). More recently, c-Krox has been shown to exert its action by synergistic association with SP1 (Kypriotou *et al.*, 2007).

The *Col1a1* promoter region spanning base pairs −9 to −56 bound purified recombinant YY1 and the corresponding binding activity in nuclear extracts was supershifted using a YY1-specific antibody. Mutation of the TATA box to TgTA enhanced YY1 complex formation. YY1 functions as a positive regulator of constitutive activity in fibroblasts. Although YY1 is not sufficient for transcriptional

initiation, it is a required component of the transcription machinery in this promoter (Riquet *et al.*, 2001).

A *RunX2/Cbfa1*-binding element is present in the *Col1a1* promoter of mouse, rat, and human at approximately position −372 (Kern *et al.*, 2001). This site binds *RunX2/Cbfa1*only weakly and does not act as a *cis*-acting activator of transcription when tested in DNA transfection experiments. These may interact with the upstream osteoblast-specific element (OSF2) site at −1347 (Kern *et al.*, 2001) as discussed in the section on "upstream element in the pro *Col1a1*" later.

It is likely that the transcriptional function of various transcription factors and eventually their DNA-binding properties offer opportunities for regulation by intracellular signaling pathways. These pathways are triggered by a variety of cytokines such as TNFα, which exerts its inhibitory action on *Col1a1* expression through NF-κB (Rippe *et al.*, 1999).

Factors Binding to the pro-COL1A2 *Proximal Promoter*

Several functional *cis*-acting elements have been identified in the approximately 400-bp proximal promoter of the mouse pro *Col1a2* gene (+54 to −350 bp) and the human minimal sequence between +52 and −378bp. The first transcription factor found to bind to this promoter was the ubiquitous CCAAT-binding protein, CBF. This transcription factor is formed by three separate subunits, named A, B, and C, which have all been cloned and sequenced (Maity and de Crombrugghe, 1998). All three subunits are needed for CBF to bind to the sequence containing the CCAAT box located between −84 and −80 and activate transcription in both human and mouse genes (see Fig. 2B). *In vitro* data suggest that the A and C subunits first associate to form an A–C complex and that this complex then forms a heteromeric molecule with the B subunit (Sinha *et al.*, 1995). Mutations in the CCAAT box that prevent the binding of CBF decrease the transcriptional activity of the pro *Col1a2* proximal promoter three to five times in transient transfection experiments of fibroblastic cell lines (Coustry *et al.*, 1995). Purified CBF as well as CBF composed of its three recombinant subunits also activate the pro Col1a2 promoter in cell-free nuclear extracts previously depleted of CBF (Coustry *et al.*, 1995). Two of the three subunits of CBF contain transcriptional activation domains. More recently, a single substitution of T to an A *in vivo* in the presence of an upstream enhancer of the human sequence suggested that CBF is involved in patterning of the collagen type I expression in the dorso-ventral as well as the rostro-caudal axis of mouse skin fibroblasts (Tanaka *et al.*, 2004).

In addition to the binding site for CBF, footprinting experiments and gel-shift studies identified other binding sites in the first 350 bp of the mouse *pro Col1a2* promoter. Three GC-rich sequences, located at about −160 bp (between −176 and −152 bp) and −120 bp (between −131 and −114 bp) have been shown to interact with DNA-binding proteins by footprint experiments and gel-shift assays (Hasegawa *et al.*, 1996). A deletion in the mouse promoter encompassing these three foot-printed sequences completely abolished the transcriptional activity of the *pro Col1a2* proximal promoter in transient transfection experiments using fibroblastic cell lines. The corresponding regions in the human *pro COL1A2* promoter were also protected in *in vivo* and *in vitro* footprinting experiments (Ihn *et al.*, 1996) and bound transcriptional activators. However, gel-shift assays performed using the human *pro COL1A2* promoter have suggested that a *cis*-acting element located at −160 bp represents a repressor element (Ihn *et al.*, 1996), implying that interactions between proteins interacting with the activator elements at −300, −125, and −80 bp and proteins binding to a repressor element at −160 bp regulate this gene. Spl and Sp3 have been shown to bind the TCCTCC motif located between −123 and −128 bp; both transcription factors activate this promoter (Ihn *et al.*, 2001) (see Fig. 2B). Furthermore, proteins that bind to the two proximal segments also bind to the most upstream GC-rich segment, at −300 bp, with the exception of CBF, suggesting a redundancy among functionally active DNA segments of the pro *COL1A2* proximal promoter.

TGF-β mediates its action in the human promoter through the combination of the ubiquitous transcription factor Sp1, the Smad3/4 complex, and the coactivators p300/CBP in what is termed a TGF-β-responsive element (TbRE) (Zhang *et al.*, 2000). This segment contains three GC-rich motifs between −330 and −255, capable of binding Sp1, C/EBP, AP1, and Smad complexes (Chen *et al.*, 1999, 2000a; Kanamaru *et al.*, 2003; Tamaki *et al.*, 1995; Zhang *et al.*, 2000). Interaction among these nuclear factors is synergistic and requires binding of Sp1 and Smad3/4 to the GC-rich elements and the downstream CAGAC Smad site, respectively (Ghosh *et al.*, 2000; Poncelet and Schnaper, 2001; Zhang *et al.*, 2000).

Tumor necrosis-alpha (TNFα) and interferon-γ (IFNγ) suppress matrix production. In contrast to the single DNA element that mediates TGF-β stimulation of the COL1A2 proximal promoter, both TNFα and IFN-γ have been shown to inhibit COL1A2 transcription by interfering with the formation of the TGF-β-induced complex, and by stimulating the interaction of negative factors with responsive DNA elements located 5′ and 3′ of it. This so called: "cytokine responsive element" plays an important role in maintaining homeostasis. Involvement of AP1 and NF-κB in transducing the inhibitory action of TNFα on *COL1A2* gene expression has been shown using immortalized fibroblasts from mice that lack either the AP1 activator JNK1 or the NF-κB essential modulator NEMO. Specifically, the loss of JNK1 prevented the TNFα antagonism of TGF-β, but preserves TNFα inhibition of constitutive *COL1A2*

expression. TGF-β antagonism by TNFα involves JNK1 phosphorylation of c-jun leading to off-DNA competition of the latter molecule for Smad3 binding to the cognate DNA site and/or for interaction with the p300/CBP coactivators (Kouba *et al.*, 1999; Verrecchia *et al.*, 2001, 2002).

Binding of INF-γ to its receptors leads to tyrosine phosphorylation of JAK tyrosine kinases and this in turn results in STAT1 phosphorylation. In *COL1A2*, STAT1 activation results in competition with Smad3 for interaction with p300/CBP (Inagaki *et al.*, 2003). In addition, JAK1 can also activate transcription factor YB-1; this activation results in both inhibition of constitutive promoter activity through YB-1 binding the −125 TC-box, and antagonism of TGF-β signals through YB-1 competition with Smad3 and/or p300/CBP (Ghosh *et al.*, 2001; Higashi *et al.*, 2003). For more details, see "Growth Factors" and "Cytokines."

Est1/Fli1, have also been shown to bind the same sequence with an opposite effects on collagen type I transcription. A functional Ets transcription factor was identified in *COL1A2* in close proximity of Sp1 sites. Ets1 stimulated, whereas Fli1 inhibited promoter activity. Sp1 binding was essential for inhibition of Fli1. Moreover, overexpression of Fli1 in dermal fibroblasts led to decrease in *COL1A2* mRNA and protein levels (Czuwara-Ladykowska *et al.*, 2001). Furthermore, TGF-β treatment of dermal fibroblasts leads to dissociation of Ets1 from the CBP/p300 complexes and alters their responses to TGF-β in favor of matrix degradation (Czuwara-Ladykowska *et al.*, 2002).

Furthermore a CpG motif at +7 has been shown to be preferentially methylated and bound by RFX proteins in cells acquiring a collagen I-negative state. Cell transfection experiments in conjunction with DNA-binding assays have assigned positive or negative properties to each of the proteins binding to the proximal promoter of *pro COL1A2* (Sengupta *et al.*, 2002). The degree of methylation at the +7 CpG site, on the other hand, has been shown to modulate the binding affinity of RFX proteins and, consequently, their ability to downregulate promoter activity by recruiting associated proteins that interfere with the assembly of positively acting transcriptional complexes (Xu *et al.*, 2003, 2004).

Organization of Upstream Segments of Type I Collagen Genes

Upstream Elements in the pro Col1a1 Gene

In complete contrast with its high-level activity in transient expression and *in vitro* transcription experiments, the 220-bp *pro Col1a1* proximal promoter is almost completely inactive in stable transfection experiments and in transgenic mice (Rossert *et al.*, 1996). By increasing the length of this promoter, evidence from different groups showed that the 2.3-kb human promoter linked to different transgenes resulted in a high degree of tissue-specific expression of the reporter gene in bone, tail, and skin. However, this expression of the transgene was not identical to that of the endogenous gene (Slack *et al.*, 1991). Indeed, in latter experiments using embryos from the same mice, *in situ* hybridization assays showed no expression of the transgene in perichondrium and in skeletal muscle, implying that additional sequences might be needed to obtain expression of the gene in all type I-collagen producing cells (Liska *et al.*, 1994), In newborn mice carrying a 3.6-kb rat *Col1a1* promoter linked to a CAT reporter gene, high levels of transgene expression were found in extracts of bone, tooth, and tendon (Bogdanovic *et al.*, 1994; Pavlin *et al.*, 1992). Similarly, the mouse 3.6-kb promoter fused to β-galactosidase transgene resulted in a similar pattern, but localized to three distinct *cis*-acting sequences that directed expression in the skin, bone, and tendon (Rossert *et al.*, 1995). The skin element was between −220 bp and −900 bp. The bone element was further delineated to 117 bp between −1656 bp and −1540 bp, and the tendon to a sequence between −2300 bp and −3600 bp (Rossert *et al.*, 1996) (Fig. 3), These experiments suggested a modular arrangement of separate *cis*-acting elements that activate the pro *Col1a1* gene in different type I collagen-producing cells. The direct consequence of such a modular arrangement is that it should be possible to selectively modulate the activation of type I collagen genes in well-defined subpopulations of type I collagen-producing cells. Perhaps the best illustration of *cis*-acting element responsible for the activation of the mouse pro *Col1a1* gene is the osteoblast element. This 117-bp segment is very well conserved amongst species. In the mouse promoter, located between −1656 and −1540 bp, is a minimal sequence able to induce high levels of expression of the reporter gene exclusively in osteoblasts. In these mice the transgene becomes active at the same time during embryonic development when osteoblasts first appear in the different ossification centers. This so-called "osteoblast-specific element" can be divided into three subsegments that have different functions. The 29-bp A segment, which is located most 5′ (−1656 to −1628 bp), is required to activate the gene in osteoblasts. A deletion of the A element or a 4-bp mutation in the TAAT sequence of this segment completely abolished the expression of the reporter gene in osteoblasts of transgenic mice. The C segment, which is located at the 3′ end of the 117-bp sequence (−1575 to −1540 bp), is required to obtain consistent high-level expression of the reporter gene in transgenic mice (Rossert *et al.*, 1996). When this C segment was deleted, the *lacZ* gene was expressed at very low levels and only in a small proportion of transgenic mice. The function of the intermediary segment (B segment) is still poorly understood, but it could be to prevent a promiscuous expression of the gene and, in particular, expression of the gene in the nervous system.

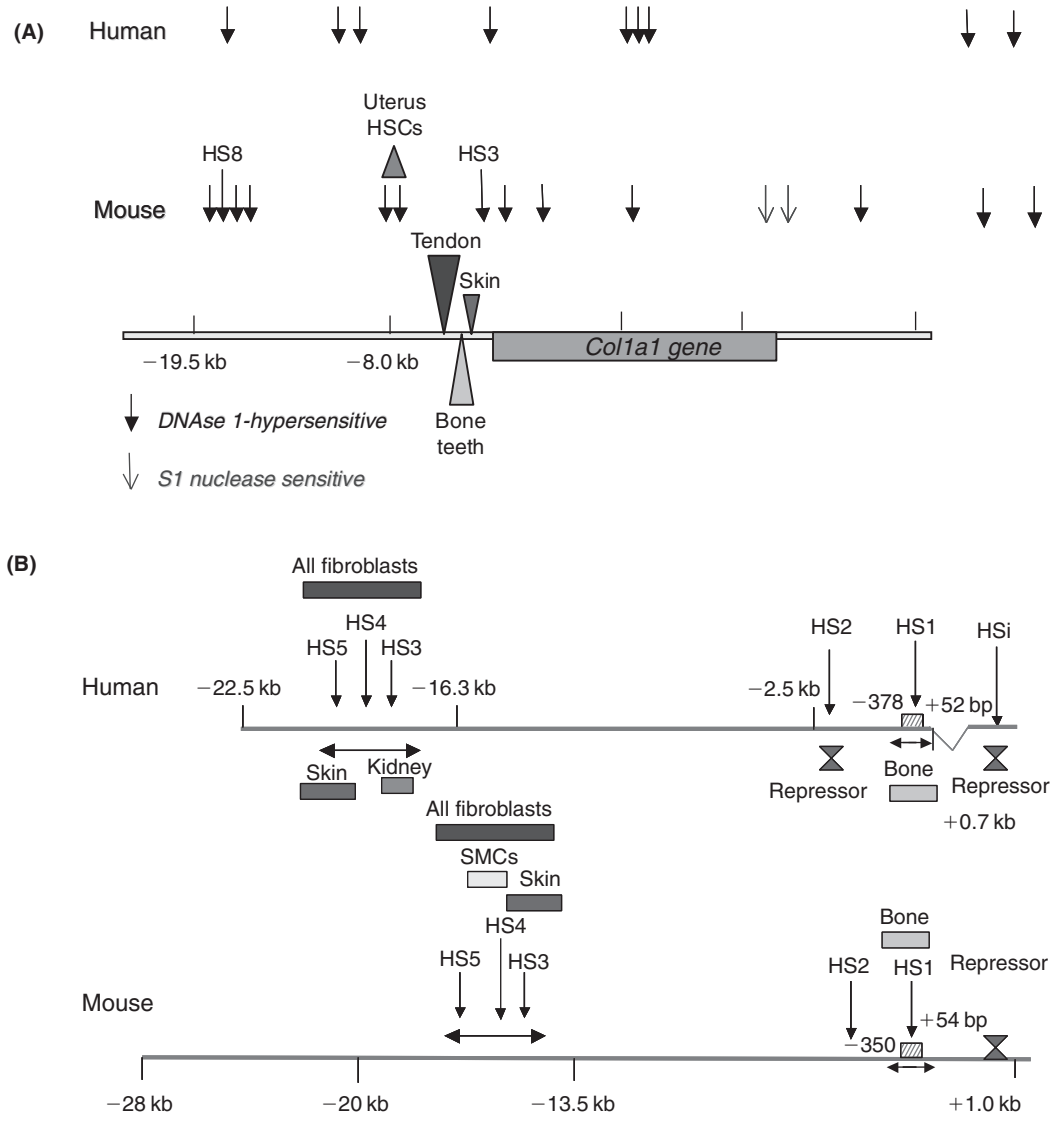

FIGURE 3 DNaseI hypersensitive sites (HS) of the human and murine *Col1a1* (**A**) and *Col1a2* (**B**) genes depicted by vertical arrows, which indicate the position within the gene where the sequence may be involved in transcriptional regulation. Areas of high homology in the promoter (>85%) are indicated by horizontal arrows. Also indicated are the regions in which *cis*-acting sequences have been shown to express in transgenic mice and the tissues or cells in which they are expressed and called "elements."

In addition to the 117-bp region, a consensus Cbfa1-binding site, termed OSE2, is present at approximately −1347 bp of the rat, mouse, and human genes (Kern *et al.*, 2001). *RunX2/Cbfa1* can bind to this site, as demonstrated by electrophoretic mobility shift assay and supershift experiments using an anti-Cbfa1 antibody. Mutagenesis of the *Col1a1* OSE2 at −1347 bp reduces the activity of a *Col1a1* promoter fragment 2- to 3-fold. Moreover, multimers of this OSE2 at −1347 bp confer osteoblast-specific activity to a minimum *Col1a1* collagen promoter fragment in DNA transfection experiments. However, this region did not confer expression in transgenic mice, suggesting that other specific factors contribute to collagen expression of collagen type I in osteoblasts. Indeed osterix, a zinc finger transcription factor, was found to be essential for bone formation and to act downstream of *RunX2/Cbfa1*. It was shown to bind to segment C of the osteoblast element. The tendon element was found to be a combination of sequences between −3.2 and −3.6 kb termed TSE1 and TSE2 (Terraz *et al.*, 2002). Gel-shift experiments of this region showed that scleraxis, which is a basic helix-loop-helix transcription factor that is expressed selectively in tendon fibroblasts, binds TSE2, whereas TSE1 binds NFATc transcription factors (Lejard *et al.*, 2007).

In pursuit of the controlling regions of this gene, a chromatin structure analysis of the human *COL1A2* gene has revealed the presence of several proximal and distal 5′ and 3′ DNase I hypersensitive sites (HS) (Barsh *et al.*, 1984).

Breindl's team used the same technique and mapped a 55-kb sequence spanning the mouse gene, including 24 kb of 5′- and 13 kb of 3′-flanking sequences (Salimi-Tari *et al.*, 1997). Nine HS sites were found, seven of which were in the promoter sequence (HS3–HS9) up to −20 kb (see Fig. 3A). All of these hypersensitive sites were present in collagen type I-producing cells except for HS8. When these sequences were fused to a reporter gene in transgenic animals, they revealed an additional *cis*-acting sequence in uterine smooth muscle cells between −7 to −8 kb (Krempen *et al.*, 1999) and liver stellate cells (Yata *et al.*, 2003).

Upstream Elements of the Mouse pro Col1a2 *gene*

The activity of the mouse 350-bp *pro Col1a2* proximal promoter in transgenic mice is very low compared with that of the corresponding endogenous gene. Although this low-level activity appears to be present selectively in fibroblasts and mesenchymal cells (Niederreither *et al.*, 1992), the precise sequences and the factors responsible for this tissue specificity have not yet been identified. An element located 13.5 to 17 kb upstream of the start site of transcription, and named "far-upstream enhancer," increased the levels of expression of the *lacZ* and luciferase reporter genes considerably when it was cloned upstream of the 350-bp mouse *pro Col1a2* proximal promoter. Moreover, this element by itself contributed to the tissue-specific expression of a reporter gene. Indeed, when it was cloned upstream of a minimal promoter that has no tissue-specific expression by itself, i.e., first 220 bp of the *pro Col1a1* proximal promoter, it conferred a tissue-specific expression to the *lacZ* reporter gene in transgenic mice (Bou-Gharios *et al.*, 1996).

Interestingly, in transgenic mice harboring the *lacZ* reporter gene cloned downstream of a *pro Col1a2* promoter segment containing the far-upstream enhancer, fibroblastic cells expressed the *lacZ* reporter gene at very high levels, but only a subset of osteoblastic cells expressed this reporter gene, whereas odontoblasts and fully differentiated tendon fibroblasts did not (Bou-Gharios *et al.*, 1996), suggesting that a *cis*-acting element active in all osteoblasts is missing from this promoter/enhancer sequence. Besides this heterogenous expression of the *lacZ* reporter gene in bone, the lack of expression of the *lacZ* gene in odontoblasts suggests that other elements exist that control expression in these cells and strongly supports a modular organization of different regulatory domains in the mouse *pro Col1a2* promoter, as described for the *pro Col1a1* promoter.

In order to verify the transgene-staining results, both luciferase and β-galactosidase activity in tissue homogenate were measured because the transgenic line used harbored both β-galactosidase and luciferase transgenes. Although β-galactosidase staining was no longer present in many tissues by the time transgenic mice are weaned, luciferase activity of the same tissues remained significantly higher than in controls. The endogenous mRNA level followed the overall trend of the transgene and very little transgene mRNA was detected by three months of age. The skin showed the highest level of endogenous mRNA during development, which was matched by transgene expression (Ponticos *et al.*, 2004a), and although mRNA level drops by day 10 after birth, the transgene remains significantly high until three weeks of age, suggesting perhaps a specific role of this enhancer in the dermis.

The role of the enhancer in the regulation of the collagen type I gene was also revealed by measuring activation of the transgenes after injury to tissues either by injection of fibrogenic cytokines such as TGFβ-1 or by physical injury. Such challenge appears to stimulate a significant increase in transcription of both the endogenous collagen gene and the transgenes. Although mRNA levels of collagen has been shown to diminish in many tissues after birth and throughout adulthood (Goldberg *et al.*, 1992), acute injury reactivates the *lacZ* transgene to a level that is visually apparent (Ponticos *et al.*, 2004a). This finding makes such transgenic animals an important tool and provides a model to address questions about the nature of cells that are active in fibrosis. For example, in muscular dystrophy where fibrosis bears the hallmark of the disease (Morrison *et al.*, 2000), this model can be used to identify those cells that are active in producing collagen type I as shown with glomerulosclerosis (Chatziantoniou *et al.*, 1998) and the Tsk mouse model bred with these transgenic mice (Denton *et al.*, 2001). More importantly, this will allow us to test the direct effects of various antifibrotic agents on the cells that are actively synthesizing collagen type I.

In the human *COL1A2* gene, six distinct DNase I-hypersensitive sites were mapped within 22 kb upstream and around the start site of transcription. Their spatial arrangement, cell type specificity, and relative availability to DNase I digestion are comparable to those of the mouse gene (Antoniv *et al.*, 2001). The more striking finding of the chromatin survey was the identification of three strong cell-type-specific hypersensitive sites (HS3–5), at a location comparable to those of the mouse far-upstream enhancer and residing within nearly identical sequences (see Fig. 3B). DNase I footprinting correlated areas of sequence identity with twelve distinct binding sites of nuclear proteins, the majority of which are likely not to be tissue-specific. Using transgenic analysis, it was found that the proximal −378 promoter contains elements that drive tissue-specific transcription in subsets of fibroblastic and osteoblastic cells, and this activity is significantly augmented when the proximal promoter is linked to the far-upstream enhancer. The results of the human transgenes thus indicate that the predominant function of the upstream element is to broaden and intensify tissue-specific transcription from the proximal promoter. Unlike the mouse enhancer that was only active in a subset of osteoblasts, the

human sequence was active in all osteoblasts and it is most likely that the osteoblast element resides in the proximal promoter (Antoniv *et al.*, 2001).

Mode of Action of Tissue-Specific Elements

The mode of action of the different lineage-specific transcription elements and their postulated cognate-binding proteins is still unknown, but a study of hypersensitive sites (Antoniv *et al.*, 2001; Bou-Gharios *et al.*, 1996) and *in vivo* footprinting experiments (Chen *et al.*, 1997) strongly suggest that the chromatin structure of discrete areas in the regulatory regions of type I collagen genes is different in cells when these genes are being transcribed actively compared with cells in which they are silent. These experiments suggest that, in intact cells, transcription factors such as CBF bind to the proximal promoters of type I collagen genes only in cells in which the genes are transcribed actively (Coustry *et al.*, 2001). Although *in vivo* footprint experiments show a protection of the CCAAT box in different fibroblastic cell lines, such a protection does not exist in cell lines that do not produce type I collagen. Similarly, hypersensitive sites corresponding to the far-upstream enhancer of the *pro Col1a2* promoter can be detected only in cells that express type I collagen. The importance of chromatin structure is also highlighted by comparison of transient and stable transfection experiments. When a chimeric construct harboring the *pro Col1a1* osteoblast-specific element cloned upstream of a minimal promoter and of the *lacZ* reporter gene was transfected stably in different cell lines, it was expressed in the ROS17/2 osteoblastic cell line, but not in two fibroblastic cell lines or in a cell line that does not produce type I collagen. In contrast, in transient transfection experiments, the same chimeric construction was expressed at high levels by all cell lines. These results suggest a model where the binding of a lineage-specific transcription factor to specific enhancer segments of type I collagen genes would result in opening the chromatin around the promoter and allow ubiquitous transcription factors to bind to the proximal promoter and to activate transcription of the genes.

The discovery of the far-upstream enhancer raised the question of whether the enhancer could confer tissue specificity on its own, and if individual elements of the proximal promoter contribute differently to *COL1A2* transcription *in vivo*. A series of mutations introduced in each of the transcription factors binding sites within the proximal promoter such as the three Sp1 sites, GC-rich Sp1/Sp3-binding sites, and the CBF-binding site reduced transgene activity suggesting strong evidence that these protein interactions operate *in vivo* as well, and in concert with the enhancer-bound complex (Tanaka *et al.*, 2004). The unique expression pattern of transgenic mice harboring mutations in the binding site of transcription factor CBF/NFY lead to loss of *LacZ* expression in the ventral and head regions of the dermis, as well as in the muscles of the forelimbs. The patterning of specific cell lineages implies that CBF/NFY may be essential for *COL1A2* activity in those cells that do not express the transgene. These transgenic data therefore raise the intriguing possibility that CBF/NFY may be implicated in patterning COL1A2 expression in some mesenchyme cell lineages through a yet-to-be-defined mechanism. The results suggested cooperativity between the far-upstream enhancer and proximal promoter in assembling tissue-specific protein complexes. They confirmed *in vitro* observations indicating that interactions among proximal promoter elements are required for optimal transcription. They also indicated that transcription factors binding to individual promoter elements are responsible for distinct properties of *COL1A2* expression *in vivo* (Ramirez *et al.*, 2006).

In the enhancer sequence of the mouse *Col1a2* gene, the first tissue-specific element to be characterized was a vascular smooth muscle cells (vSMC) element; a 100-bp sequence at about −16.6 kb upstream of the transcription start site regulates collagen expression exclusively in vSMC (Ponticos *et al.*, 2004b). This expression was shown to be activated through the binding of the homeodomain protein Nkx2.5, and further potentiated by the presence of GATA6. In contrast, this element was repressed by the binding of the zinc finger protein delta-EF1/ZEB1. A model of regulation where the activating transcription factor, Nkx2.5, and the repressor,, delta-EF1/ZEB1 compete for an overlapping DNA-binding site. This element is important in understanding the molecular mechanisms of vessel remodeling and is a potential a target for intervention in vascular diseases where there is excessive deposition of collagen in the vessel wall.

First Intron Elements

First Intron of the pro COL1A1 *Gene*

Different negative or positive regulatory segments have been identified within the first intron, but most of the transcription factors binding to these regulatory segments are still unknown. A sequence of the first intron of the human *COL1A2* gene located about +600 bp downstream of the transcription start site binds AP-1, and a mutation that abolished this binding diminished the expression of a reporter gene in transient transfection experiments (Liska *et al.*, 1990) This AP-1 was also found to mediate the repressive effect of ras in fibroblasts (Slack *et al.*, 1995). Another segment of the first intron of the human gene, which extends from 820 to 1093 bp, has been shown to inhibit the activity of a reporter gene in transient transfection experiments (Liska *et al.*, 1992). This sequence contains two binding sites for an Sp1-like transcription factor, and mutations in these two Sp1-binding sites tended to increase the activity of the reporter gene (Liska *et al.*, 1992). An Sp1-binding site is also located at about 1240 bp, in the human gene, and

a frequent G→T polymorphism in this Sp1-binding site (G1242T) has been linked with low bone mineral density and increased risk of osteoporotic vertebrate fracture (Grant *et al.*, 1996), which suggests that it may be important for normal levels of type I collagen synthesis by osteoblasts.

The phenotype of Mov 13 mice suggested that the first intron of the pro α1(I) collagen gene could play a role in the expression of this gene. These mice, which harbor a retrovirus in the first intron of the *pro Col1a1* gene (Harbers *et al.*, 1984), express this gene in osteoblasts and odontoblasts, but not in fibroblastic cells (Schwarz *et al.*, 1990). Nevertheless, the presence of tissue-specific regulatory elements in the first intron of the *pro Col1a1* gene has long been controversial. Two groups have reported that, in transgenic mice harboring the proximal promoter of either the human or the rat *pro Col1a1* gene, the pattern of expression of the reporter gene was the same whether or not these mice harbored the first intron of the *pro Col1a1* collagen gene (Sokolov *et al.*, 1993). In contrast, data obtained by *in situ* hybridization in transgenic mice harboring 2.3 kb of the human *pro Col1a1* proximal promoter suggested that the first intron of this gene was necessary to obtain high-level expressions of the transgene in the dermis of skin (Liska *et al.*, 1994). Only mice harboring the first intron, in addition to the 2.3-kb proximal promoter segment, expressed the human growth hormone reporter gene at high levels in skin. In order to clarify this issue, Bornstein's group generated knockin mice with a targeted deletion of most of the first intron (Hormuzdi *et al.*, 1998). Mice homozygous for the mutated allele developed normally and showed no apparent abnormalities. Nevertheless, in heterozygous mice, the mutated allele was expressed at normal levels in skin, but at lower levels in lung and muscle, and its levels of expression decreased with age in these two tissues more than in wild type mice. Thus, the first intron does not play a role in the tissue-specific expression of the *pro Col1a1* gene, but it seems to be important for maintaining normal transcriptional levels of this gene in certain tissues (Hormuzdi *et al.*, 1999).

First Intron of the pro COL1A2 *Gene*

The first intron of the mouse *pro Col1a2* gene has also been shown to contain a tissue-specific enhancer in transient transfection experiments (Rossi and de Crombrugghe, 1987). In transgenic mice, however, the presence of this tissue-specific enhancer apparently had no effect on the pattern of expression of a CAT reporter gene (Goldberg *et al.*, 1992). However, recent transgenic analysis of the human gene suggested that despite the homologies between the two genes, species-specific differences have been reported regarding the function of individual *cis*-acting elements, such as the first intron sequence (Antoniv *et al.*, 2005). *In vitro* DNase I footprinting of the sequence corresponding to the open chromatin site identified a cluster of three distinct areas of nuclease protection that span from nucleotides +647 to +759 of the *COL1A2* gene. These areas contain consensus sequences for GATA and IRF transcription factors. Gel mobility shift and chromatin immunoprecipitation assays corroborated this finding by documenting binding of GATA-4 and IRFs 1and 2 to the first intron sequence (Antoniv *et al.*, 2005). Moreover, a short sequence encompassing the three footprints was found to inhibit expression of transgenic constructs containing the *COL1A2* proximal promoter and far-upstream enhancer in a position-independent manner. Mutations inserted into each of the footprints restored transgenic expression to different extents. These results therefore indicated that the intronic sequence corresponds to a repressor element, the activity of which seems to be mediated by the concerted action of GATA and IRF proteins (see Fig. 2B). Furthermore, GATA4 was found to bind the promoter sequence of HS2 at −2.3 kb in the COL1A2 gene. Overexpression of this transcription factor inhibited the expression of the transgene as well as endogenous gene in fibroblasts (Wang *et al.*, 2005). The presence of a common repressor transcription factor in both HS2 and HS intron led to the suggestion that the "switch-off" of collagen in adults may occur by cooperation of the intronic sequence and HS2 to block the enhancer activity from exerting its effect through its cooperation with the proximal promoter in (HS1) (Ramirez *et al.*, 2006).

Post-transcriptional Regulation of Type I Collagen

Even if the control of expression of type I collagen genes appears to be mainly exerted at the level of transcription, type I collagen production is also be regulated at a post-transcriptional level. For example, TGF-β and IFN-γ modulate not only the levels of transcription of type I collagen genes, but also the stability of the corresponding mRNAs. Similarly, activation of hepatic stellate cells is associated with a dramatic increase in the stability of the *pro Col1a1* mRNA. Run-on experiments have shown that the half-life of this mRNA was increased about 15-fold in activated rat hepatic stellate cells when compared with quiescent ones (Stefanovic *et al.*, 1997). Several lines of evidence indicate that expression of the genes coding for the two collagens I and III is controlled predominantly post-transcriptionally at the mRNA level, as the 3′-UTR of the collagen family mRNA has been shown to be a target for mRNA-binding protein. hnRNP A1, E1, and K substantially participate in the coordinative upregulation of collagen I and III synthesis, which is involved in mRNA stabilization (Lindquist *et al.*, 2000). Indeed, all three *COL1A1*, *1A2*, and *3A1* 3′-UTRs, contain hnRNP K-like consensus motifs and do actually bind it. *COL1A1* and *COL1A2* contain a classical CU-rich hnRNP E1-binding site and it is also able to bind hnRNP E1, although not *COL3A1*, which lacks a more extended

CU-rich region. Furthermore, these mRNA-binding proteins have been shown to increase in fibrotic conditions and are suggested to coordinate expression of type I and III collagens by common post-transcriptional mechanisms targeted at the mRNA 3′-UTR level (Thiele *et al.*, 2004).

The sequence of the mouse pro *Col1a1* mRNA surrounding the start codon could also play a role in regulating mRNA stability. This sequence has been shown to form a stem-loop structure, and mutations that prevent its formation decreased the stability of the mRNA dramatically (Stefanovic *et al.*, 1999). Indeed, the 5′-UTR of *COL1A1*, *COL1A2*, and *COL3A1* mRNAs are involved in such translational control. These 5′ stem loops, together with their cognate binding proteins, should help coordinate translation and couple the translation apparatus to the rest of the collagen biosynthetic pathway (Stefanovic and Brenner, 2003).

FACTORS INVOLVED IN TYPE I COLLAGEN GENE REGULATION

Different cytokines, hormones, vitamins, and growth factors can modify type I collagen synthesis by osteoblasts and/or fibroblasts. The effects of these molecules have been studied mainly *in vitro* by using either bone organ cultures or cell cultures. However, in some instances the *in vivo* effects of these factors on type I collagen synthesis have also been studied. A degree of complexity is due to the fact that some factors can act on type I collagen synthesis but can also act indirectly by modifying the secretion of other factors, which will themselves affect type I collagen synthesis. For example, TNF-α will inhibit type I collagen production through the NF-κB pathway, but it will also induce the secretion of prostaglandin E_2 (PGE_2) and of IL-1, which themselves affect type I collagen production. Furthermore, PGE_2 will induce the production of IGF-1, which also modifies the rate of type I collagen synthesis.

Transforming Growth Factor β

In mammals, the TGF-β family consists of three members (TGF-β1, TGF-β2, and TGF-β3), which have similar biological effects but different spatial and temporal patterns of expression. These three molecules are part of a large family, the TGF-β superfamily, which also contains proteins such as bone morphogenetic proteins (BMPs), activins/inhibins, growth and differentiation factors (GDFs), as well as Nodal and its related proteins (Chang *et al.*, 2002; Massague and Chen, 2000). Members of the TGF-β family are multifunctional proteins that regulate cell proliferation and differentiation, extracellular matrix modification, angiogenesis, apoptosis, and immunosuppression (Feng and Derynck, 2005; Jones *et al.*, 2006; Schier and Shen, 2000). A TGF-β protein exerts its function by binding to and bringing together on the cell surface type I and II receptors to form a ligand–receptor complex (Leask and Abraham, 2004). Five members of type II and seven members of type I receptors [Activin receptor-like kinase (ALK) 1–7] have been characterized in mammals (Graham and Peng, 2006). Upon phosphorylation by the type II receptor, the type I receptor phosphorylates and activates Smads, which are intracellular signaling molecules for members of the TGF-β superfamily. Phosphorylated Smads are released from the receptors and form oligomeric complexes with a common-partner Smad, Smad4, and translocate into the nucleus where they bind to specific DNA sequences called Smad-binding elements, and act as transcription factors to regulate the transcription of target genes. Smad2 and Smad3 respond to TGF-βs, Activins, Nodal and Lefty, whereas Smad1, Smad5, and Smad8 mediate BMP signaling (Miyazawa *et al.*, 2002). Several transcription factors and transcriptional coactivators have been shown to cooperate with Smad complexes, such as Sp1, AP-1, PEBP2/CBF, TFE-3, ATF-2, or CBP/p300 (reviewed in Attisano and Wrana, 2000).

TGF-βs are secreted by many cell types, including monocytes/macrophages, lymphocytes, platelets, fibroblasts, osteoblasts, and osteoclasts (Leask and Abraham, 2004). Synthesis by bone cells is quantitatively important because, *in vivo*, the highest levels of TGF-β are found in platelets and bone (Seyedin *et al.*, 1985). Nearly all cells, including osteoblasts and fibroblasts, have TGF-β receptors (Verrecchia and Mauviel, 2007).

The three mammalian TGF-β isoforms are synthesized as homodimeric proproteins (proTGF-β) that have a mass of 75 kDa. The dimeric propeptides are cleaved from the mature TGF-β 24-kDa dimer in the *trans*-Golgi by furin-type enzymes. Mature TGF-β1 then associates noncovalently with a dimer of its N-terminal propeptide (also called LAP, for latency-associated peptide). This complex is referred to as the small latent complex (Annes *et al.*, 2003). Early in the assembly of TGF-β and LAP, disulfide linkages are formed between cysteine residues of LAP and specific cysteine residues in another protein, the latent-TGF-β binding protein (LTBP) to form the Large Latent Complex (Annes *et al.*, 2003). The LTBP is removed extracellularly by either proteolytic cleavage by various proteases such as plasmin, thrombin, plasma transglutaminase, or endoglycosylases, or by physical interactions of the LAP with other proteins, such as *thrombospondin-1*, which is able to transform latent TGF-β1 into active TGF-β1 *in vitro*. Analysis of mice harboring a targeted disruption of the thromobspondin-1 gene suggests that it likely plays an important role *in vivo* (Crawford *et al.*, 1998). In particular, the phenotype of thrombospondin-1-null mice was relatively similar to the one of TGF-β1-null mice, and fibroblasts isolated from the former mice had a decreased ability to activate TGF-β1. Nevertheless, thrombospondin-1 is probably not the only molecule that activates TGF-β *in vivo* (Abdelouahed *et al.*, 2000).

The four latent TGF-β binding proteins (LTBP1–4) belong to the LTBP/fibrillin family of large extracellular glycoproteins (Todorovic *et al.*, 2005). LTBP1, LTBP3, and LTBP4 form a subgroup within the family, because they covalently interact with latent TGF-β and have an important role as regulators of TGF-β function: LTBPs facilitate the secretion of latent TGF-β, direct its localization in the ECM, and regulate the activation of the cytokine. In mice ablation of the *Ltbp3* gene and attenuation of *Ltbp4* expression both result in developmental defects associated with reduced TGF-β activity (Dabovic *et al.*, 2002; Sterner-Kock *et al.*, 2002), further demonstrating that *Ltbp3* and *Ltbp4* modulate extracellular TGF-β levels in a specific and nonredundant manner.

The role of TGF-β on type I collagen synthesis has been demonstrated both *in vivo* and *in vitro*. *In vivo*, subcutaneous injections of platelet-derived TGF-β in newborn mice increased type I collagen synthesis by dermal fibroblasts with formation of granulation tissue (Roberts *et al.*, 1986). Injections of platelet-derived TGF-β onto the periostea of parietal bone of newborn rats stimulated bone formation, and thus accumulation of extracellular matrix (Noda and Camilliere, 1989). Transgenic mice that overexpressed mature TGF-β1developed hepatic fibrosis and renal fibrosis (Sanderson *et al.*, 1995). Increased expression of TGF-β2 in osteoblasts in transgenic mice resulted in an osteoporosis-like phenotype with progressive bone loss. The bone loss was associated with an increase in osteoblastic matrix deposition and osteoclastic bone resorption (Erlebacher and Derynck, 1996). Conversely, expression of a dominant-negative TGF-β receptor mutant in osteoblasts led to decreased bone remodeling and increased trabecular bone mass (Filvaroff *et al.*, 1999). In humans, mutations in the latency-associated peptide of TGF-β1 (LAP) causes Camurati–Engelmann disease, a rare sclerosing bone dysplasia inherited in a autosomal-dominant matter. It is unclear whether these mutations impair the ability of the LAP to inhibit TGF-β activity or whether the mutations cause accelerated degradation of TGF-β (Janssens *et al.*, 2000; Kinoshita *et al.*, 2000).

More recently, transgenic mice expressing a kinase-deficient type II TGF receptor (T-RIIΔk) in fibroblasts demonstrated unexpected skin and lung fibrosis (Denton *et al.*, 2003). Moreover, the fibrotic phenotype of explanted dermal fibroblasts from the T-RIIDk-deficient transgenic mice showed that expression of the mutant receptor leads to multilevel activation of the TGF-β ligand–receptor axis and that activation depends on endogenous T-RI receptor kinase activity (Denton *et al.*, 2005). This paradoxical increased acivity of the TGF-β-ligand–receptor axis in these transgenic mice occurs despite previous findings that the kinase-deficient TGF-β receptors are dominant negative inhibitors of signaling in several experimental systems, when expressed at high expression levels compared with wild-type receptors. Further evidence that TGF-β and its signaling pathways significantly influence collagen gene regulation is manifested in Smad3 −/− mice exposed to a single dose of 30 to 50 Gy of gamma-irradiation; these mice showed significantly less epidermal acanthosis and dermal influx of mast cells, macrophages, and neutrophils and decreased expression of TGF-β than skin from wild-type littermates suggesting that inhibition of Smad3 could decrease tissue damage and reduce fibrosis after exposure to ionizing radiations (Flanders *et al.*, 2002). Conversely, C57BL/6 mice with bleomycin-induced lung fibrosis receiving an intratracheal injection of a recombinant adenovirus expressing Smad7 demonstrated suppression of Type 1 procollagen mRNA, reduced hydroxyproline content, and no morphological fibrotic responses in the lungs, indicating that gene transfer of Smad7 prevents bleomycin-induced lung fibrosis (Nakao *et al.*, 1999). More recently, using mice with a targeted deletion of Smad3, Roberts *et al.* (2006) demonstrated that lack of Smad3 prevents the epithelial-to-mesenchymal transition of lens epithelial cells following injury, and attenuates the development of fibrotic sequelae. Together, these various experimental approaches demonstrate the direct implication of Smad3 and TGF-β in fibrotic diseases.

In vitro, TGF-β stimulates the synthesis of most of the structural components of the extracellular matrix by fibroblasts and osteoblasts, including type I collagen (for a review, see Leask and Abraham, 2004). It also decreases extracellular matrix degradation by repressing the synthesis of collagenases and stromelysins and by increasing the synthesis of tissue inhibitors of metalloproteinases (TIMPs). It increases lysyl-oxidase activity, which may favor interchain cross-linking in collagen fibrils (Feres-Filho *et al.*, 1995). Finally, it stimulates the proliferation of both fibroblasts and osteoblasts, in contrast to its inhibitory effect on the proliferation of epithelial cells. Moreover, TGF-β may have a role in controlling the lineage-specific expression of type I collagen genes during embryonic development, because there is an excellent temporal and spatial correlation between activation of type I collagen genes and the presence of immunoreactive TGF-β in the extracellular environment (Niederreither *et al.*, 1992).

One way in which TGF-β exerts its action is at a pretranslational level, by increasing mRNA levels of the *pro Col1a1* and *pro Col1a2* transcripts. This increase in type I collagen mRNA levels can be caused by an increase in the transcription rate of type I collagen genes and/or by an increase in procollagen mRNA stability, with the relative contribution of these two mechanisms depending on cell types and on culture conditions. The second effect is through Smad proteins as indicated later: The effect of TGF-β on transcription of the human pro *COL1A2* gene involves Smad complexes reviewed by Ramirez *et al.* (2006). This effect is mediated through a sequence of the promoter located between −378 and −183 bp upstream of the start site of transcription and is called TGF-β-responsive element (TβRE), as demonstrated by transfection experiments

(Inagaki *et al.*, 1994). Footprinting experiments performed with this sequence revealed two distinct segments interacting with DNA-binding proteins (Inagaki *et al.*, 1994). It contains two binding sites for Sp1, as well as a binding site for C/EBP (Greenwel *et al.*, 1997; Inagaki *et al.*, 1994). The DNA sequence between −271 and −250 contains a CAGA box that binds Smad 3/Smad 4 complexes (Chen *et al.*, 1999; Zhang *et al.*, 2000), as well as a binding site for AP-1 (Chung *et al.*, 1996). Data have shown that Smad 3/Smad 4 complexes can bind to CAGA box and mediate TGF-β induced stimulation of the *pro COL1A2* gene, in cooperation with Sp1 proteins (Zhang *et al.*, 2000). Other studies have suggested a role of AP-1 in mediating the effects of TGF-β (Chung *et al.*, 1996). This Smad/AP1 interaction was later found to take place "off DNA" (Verrecchia *et al.*, 2001). The transcriptional coactivator CBP/p300, which can bind to Smad complexes, also plays an important role in mediating the effects of TGF-β on the transcriptional activity of the *pro COL1A2* gene (Ghosh *et al.*, 2000). Thus, TGF-β probably activates the transcription of the *pro COL1A2* gene through the binding of a multimeric complex, which includes Smad 3/Smad 4, Sp1, CBP/p300, and possibly AP-1. More recently, using Affymetrix microarrays to detect cellular genes, whose expression is regulated by TGF-β through Smad3, identified the gene for an early growth response factor-1 (EGR-1) as a Smad3-inducible gene (Chen *et al.*, 2006a). It was also found that TGF-β enhanced endogenous Egr-1 interaction with a consensus Egr-1-binding site element and with GC-rich DNA sequences of the human *COL1A2* promoter *in vitro* and *in vivo*. Furthermore, forced expression of Egr-1 by itself caused dose-dependent upregulation of *COL1A2* promoter activity and further enhanced the stimulation induced by TGF-β (Chen *et al.*, 2006a). Other transcriptional coactivators such as the steroid receptor coactivator-1 may also participate in TGF-β effects (Dennler *et al.*, 2005).

In the rat *pro Col1a1* gene, a TGF-β response element has been described at about 1.6 kb upstream of the start site of transcription (Ritzenthaler *et al.*, 1993) and between −174 and −84 bp in the human pro α1 collagen gene (Jimenez *et al.*, 1994). The latter sequence contains an Sp1-like binding site, but none of these two sequences seems to contain a potential Smad-binding site. In addition to direct action of TGF-β, part of the profibrotic properties may be indirect, mediated by an increased production of a cysteine-rich protein called connective tissue growth factor (Leask and Abraham, 2003).

Connective tissue growth factor (CTGF, CCN2)

CTGF (also called CCN2), a member of the CCN family of matricellular proteins, has long been known to promote differentiation and proliferation of chondrocytes and osteoblasts (for a review, see Takigawa *et al.*, 2003). CCN2 promotes fibroblast proliferation, matrix production, and granulation tissue formation, as well as cell adhesion and migration. Experiments using recombinant CTGF and neutralizing antibodies targeting CTGF have suggested that CTGF mediates at least some of the effects of TGF-β on fibroblast proliferation, adhesion, and ECM production, including collagen and fibronectin (Crean *et al.*, 2002; Weston *et al.*, 2003). Moreover, an expression vector encoding CTGF transfected into fibroblasts can activate a reporter driven by the type I collagen promoter, suggesting that a CTGF response element exists in the promoter of type I collagen (Shi-wen *et al.*, 2000). Perhaps the most significant recent insights into the specific physiological roles of the CCN2 have come from the generation of mutant mice lacking CCN2 (Ivkovic *et al.*, 2003). *Ccn2* −/− mice display severely malformed ribcages and die soon after birth owing to a failure to breathe. These mice exhibit impaired chondrocyte proliferation and proteoglycan production within the hypertrophic zone. Excessive chondrocytic hypertrophy and a concomitant reduction in endochondral ossification are also observed. Further support for the idea that CCN2 regulates bone formation in development comes from studies of transgenic mice that overproduce CCN2 under the control of the mouse type XI collagen promoter. These mice develop normally but show dwarfism within a few months of birth owing to a reduced bone density (Nakanishi *et al.*, 2001). The molecular basis for this deformity has not yet been explored; however, a possible explanation is that CCN2 overexpression results in abnormally premature ossification, before proper chondrocyte maturation.

CCN2 is constitutively expressed in fibrotic and embryonic fibroblasts independently of TGF-β (Chen *et al.*, 2006b; Holmes *et al.*, 2001, 2003). Experiments using *Ccn2* −/− MEFs have shown that loss of CCN2 results in an inability of TGF-β to induce expression of approximately one-third of those mRNAs induced in *Ccn2* +/+ MEFs (Shi-wen *et al.*, 2006). Consistent with the fact that CCN2 is required only for a subset of TGF responses, *Ccn2* −/− MEFs show no impairment of the generic Smad pathway, emphasizing the relative selectivity of CCN2-dependent action. In contrast to the lack of effect of loss of CCN2 expression on basal type I collagen and alpha-smooth muscle actin expression, the ability of TGF-β to induce these proteins is impaired in *Ccn2* −/− MEFs (Shi-wen *et al.*, 2006).

Expression of the *CTGF* gene in fibroblasts is strongly induced by TGF-β but not by other growth factors, and intradermal injections of TGF-β in neonatal mice induced an overexpression of *CTGF* in skin fibroblasts (Frazier *et al.*, 1996; Igarashi *et al.*, 1993). The ability of TGF-β to induce CCN2 also requires protein kinase C and the Ras/MEK/ERK MAP kinase cascade (Chen *et al.*, 2002b; Stratton *et al.*, 2002). As in the case of other TGF-β-responsive promoters that do not require the transcription factor AP-1, the induction of CCN2 by TGF-β is

antagonized by hyperactive AP-1 or Jun N-terminal kinase (JNK) (Leask *et al.*, 2003) because of the ability of active Jun to bind to Smads off DNA and inhibit Smads from interacting with the target DNA sequences (Verrecchia *et al.*, 2001).

Although a specific CTGF receptor has yet to be identified, CTGF appears to perform many of its functions through integrins, heparin sulfate-containing proteoglycans, and the low-density lipoprotein receptor-related protein (Gao and Brigstock, 2003; Segarini *et al.*, 2001; Weston *et al.*, 2003).

Growth Factors

Fibroblast Growth Factor

FGFs comprise a family of 23 genes encoding structurally related proteins divided into six subfamilies of FGFs (Ornitz and Marie, 2002). The most recent member is FGF23, which is mainly produced by osteocytes in bone and acts as a hormone primarily to inhibit phosphate reabsorption in the proximal tubules of the kidney (Liu *et al.*, 2007; Razzaque and Lanske, 2007). Most members of the FGF family bind to four distinct FGF receptor tyrosine kinase molecules (FGFR) and activate the receptors. Historically, FGF2 (basic fibroblast growth factor) was the first FGF ligand to be isolated from growth plate chondrocytes (Sullivan and Klagsbrun, 1985). Subsequently, *Fgf2* gene expression has also been observed in periosteal cells and in osteoblasts (Hurley *et al.*, 1999; Sabbieti *et al.*, 1999). FGF signaling affects the expression and activity of several transcription factors that are required for calvarial osteogenesis. In rat or mouse calvarial cells, FGF2 activates osteocalcin transcription. This activity is inhibited by the transcription factor MSX2 and is activated by DLX5 (Newberry *et al.*, 1997, 1999). FGF2 can up-regulate *Twist* expression in mouse calvarial mesenchyme (Rice *et al.* 2000). *Twist* heterozygous mice show altered FGFR protein expression (Rice *et al.*, 2000), suggesting that Twist acts upstream of FGF signaling pathways. Additionally, Twist could be a potential transcriptional regulator that mediates the negative effect of FGF2 on type I collagen expression in calvarial cells (Fang *et al.*, 2001). Thus, FGF/FGFR, MSX, and Twist functionally interact to control cranial suture development in a coordinated manner. FGF_2 production by calvarial osteoblasts is upregulated by FGF2 itself, and by parathyroid hormone, PGE_2, and TGF-β. Thus, the balance between high and low levels of endogenous FGF2 may constitute a mechanism to control proliferation and ensure normal cranial vault development (Moore *et al.*, 2002).

Bone resorption by osteoclasts is required to maintain the shape of craniofacial bones during development. It is therefore significant that FGF2 can increase the formation of osteoclast-like cells and activate mature osteoclasts through FGFR1 (Chikazu *et al.*, 2000). In addition, FGF2 increases the expression of metalloproteinases, collagenases 1 and 3 (Newberry *et al.*, 1997; Tang *et al.*, 1996; Varghese *et al.*, 2000) tissue inhibitors of metalloproteinases (TIMP) 1 and 3 (Varghese *et al.*, 1995) and stromelysin-3, which regulates collagenase activity in calvarial cells (Delany and Canalis, 1998). These mechanisms may control bone matrix degradation and remodeling by FGFs during calvarial expansion. Targeted deletion of FGF2 causes a relatively subtle defect in osteoblastogenesis, leading to decreased bone growth and bone density. However, no defects in chondrogenesis were observed (Montero *et al.*, 2000).

Insulin-like Growth factor

Insulin-like growth factor I (IGF-I) is synthesized by many cells, including cells of the osteoblastic lineage, as well as chondroblasts and osteoclasts (Rajaram *et al.*, 1997). IGF-I plays an important role in regulating peak bone mineral density and bone size (Mohan and Baylink, 2005; Mohan *et al.*, 2003). The IGFs interact with specific cell surface receptors, designated type I and type II IGF receptors (IGF-IR and IGF-IIR). Most of the actions of IGF-I and IGF-II are mediated by the IGF-IR, which is a transmembrane receptor with tyrosine kinase activity.

The IGFs in serum and other extracellular environments are bound to specific IGF-binding proteins (IGFBPs), which represent a family of six secreted proteins with a common domain organization. Each IGFBP has unique properties and exhibits specific functions. IGFBPs 2 to 5 are present in bone; IGFBP-4 and -5 are expressed at the highest levels. Unlike IGFBP-4, which has an inhibiting effect on IGF actions, IGFBP-5 has a potentiating effect, both *in vivo* and *in vitro*, probably by binding directly to sites that are independent of the IGF receptor (Govoni *et al.*, 2005).

IGF-I and IGF-II can stimulate osteoblast and fibroblast proliferation and increase type I collagen production by these cells. Their effect on type I collagen production by osteoblasts has been demonstrated by using both fetal rat calvariae and osteoblastic cells, and it is related to an increase in corresponding mRNA transcripts (McCarthy *et al.*, 1989; Thiebaud *et al.*, 1994; Woitge and Kream, 2000).

In vivo, administration of IGF-I to hypophysectomized rats increased mRNA transcripts for pro *Col1a1* and pro *Col1a2* genes in parietal bones (Schmid *et al.*, 1989). Furthermore, in calvaria of mice, in which the *IgfI* gene was disrupted, there was a reduced rate of collagen synthesis. Using the *Cre-LoxP* model to disrupt IGF-I in all *Col1a2*-expressing cells demonstrated that locally produced IGF-I plays a critical role in embryonic and postnatal growth. Local IGF-I from *Col1a2*-producing cells is required for bone matrix mineralization during embryonic development and postnatal growth (Govoni *et al.*, 2007). Moreover, to determine the effects of locally expressed IGF-I on bone remodeling, a transgene was produced in

which murine IGF-I cDNA was cloned downstream of a gene fragment comprising 3.6 kb of 5′ upstream regulatory sequence and most of the first intron of the rat *Col1a1* gene. Transgenic calvaria showed an increase in osteoclast numbers per bone surface, as well as increased collagen synthesis and cell proliferation. Femur length, cortical width, and cross-sectional area were also increased in transgenic femurs, whereas femoral trabecular bone volume displayed little change. Thus, broad overexpression of IGF-I in cells of the osteoblast lineage increased indices of bone formation and resorption (Jiang *et al.*, 2006). Furthermore, in calvaria of mice, in which the IGF-1 gene is disrupted, there was a reduced rate of collagen synthesis (Woitge and Kream, 2000).

Cytokines

Tumor Necrosis Factor alpha

Tumor necrosis factor α (TNF-α) is a cytokine secreted mainly by monocytes/macrophages, but osteoblasts seem to be able to produce TNF-α under certain conditions (Gowen *et al.*, 1990). After being cleaved from its propeptide, TNF-α undergoes trimerization and binds to type I receptors, which transduce most of the effects of TNF-α, or to type II receptors,which activate them and transmit signals to the nucleus via different transcription factors.

TNF-α levels are elevated in various bone disorders such as rheumatoid arthritis and osteoporosis (Beutler and Cerami, 1988; Pacifici, 1996). In bone tissue, TNF-α inhibits osteoblast function and increases osteoclastogenesis, thus favoring net matrix destruction (Centrella *et al.*, 1988; Chou *et al.*, 1996; Panagakos *et al.*, 1996). Similarly, TNF-α stimulates fibroblast and osteoblast proliferation, inhibits the production of extracellular matrix components, including type I collagen and its modifying enzyme, lysyl oxidase (Kouba *et al.*, 1999; Pischon *et al.*, 2004; Verrecchia *et al.*, 2000), as well as that of the transcription factor Sox9 (Murakami *et al.*, 2000), and increases collagenase production and thus extracellular matrix degradation (Iraburu *et al.*, 2000).

In vivo, inoculation of nude mice with TNF-α-producing cells decreased type I collagen production in skin and liver, impaired wound healing, and decreased TGF-β1 synthesis in skin (Houglum *et al.*, 1998). TNF-α also increases PGE_2 and interleukin 1 production by osteoblasts and fibroblasts, which themselves modulate type I collagen synthesis.

In dermal fibroblasts, inhibition of collagen synthesis in fibroblasts by TNF-α is associated with a decrease in mRNA levels for the *pro Col1a1* and *pro Col1a2* transcripts and in the transcription of type I collagen genes (Solis-Herruzo *et al.*, 1988). Inagaki *et al* (1995) showed that TNF-α increases binding of a protein complex that recognizes the negative *cis*-acting element located immediately next to the TβRE, and postulated that TNF-α counteracts the TGF-β elicited stimulation of collagen gene expression through overlapping nuclear signaling pathways. Kouba *et al.* (1999) characterized this specific TNF-α response element and termed it (TaRE) between nucleotides −271 and −235 relative to the transcription initiation site. Electrophoretic mobility supershift assays identified the NF-κB family members NF-κB1 and RelA as transcription factors binding the TaRE and mediating TNF-α repression of *COL1a2* promoter activity. By using a gene knockout approach, the same group showed that, in primary fibroblasts from NF-κB essential modulator (NEMO) knockout mice, lack of NF-κB activation prevented repression of basal *COL1a2* gene expression by TNF-α. Similar regulatory mechanisms take place in dermal fibroblasts, transfected with dominant negative forms of IKK-a, a critical kinase upstream of NF-κB (Verrecchia *et al.*, 2002). More interestingly, the antagonist activities of TGF-β and TNF-α in *COL1a2* may be the result of steric interactions between transcription factors binding to TβRE and TaRE, respectively (Greenwel *et al.*, 2000; Verrecchia *et al.*, 2001).

The inhibitory effects of TNF-α on the rat *pro Col1a1* proximal promoter was shown to be mediated by a sequence located between −378 and −345 bp through the binding of proteins of the C/EBP family, such as C/EBP delta and p20C/EBP beta (Iraburu *et al.*, 2000). Other TNF-α response elements have been identified within the *pro Col1a1* gene between −101 and −38 bp and between 68 and 86 bp, in dermal fibroblasts and hepatic stellate cells, respectively (Hernandez *et al.*, 2000; Mori *et al.*, 1996). The latter *cis*-acting element binds proteins of the Sp1 family, whereas the proteins binding to the former one have not been identified (Hernandez *et al.*, 2000; Mori *et al.*, 1996). Using two lines of transgenic mice harboring a growth hormone reporter gene under the control of either, at 2.3 kb, the human *pro COL1A1* proximal promoter plus the first intron, or at 440 bp of this promoter plus the first intron, Chojkier's group reported that different *cis*-acting elements mediate the inhibitory effects of TNF-α, depending on the tissue (Houglum *et al.*, 1998). In skin, the inhibitory effect of TNF-α on the activity of the reporter gene was mediated through a *cis*-acting element located between −2.3 kb and −440 bp (Buck *et al.*, 1996). In contrast, this inhibitory effect of TNF-α was mediated in liver through an element located between −440 and +1607 bp (Houglum *et al.*, 1998).

Interferon γ

Interferon γ (IFN-γ) is a cytokine produced both by monocytes/macrophages and by type I helper T cells. IFN-γ binds to the IFN-γ receptor complex (IFNGR1 and IFNGR2), followed by the activation of receptor-associated janus kinase (JAK), which in turn phosphorylates and activates the signal transducer and activator of

transcription (STAT1). Once phosphorylated, STAT1 molecules dimerize and translocate to the nucleus where they modulate target gene transcription either by direct interaction with specific sequences or through protein–protein interactions (Darnell *et al.*, 1994; Horvai *et al.*, 1997).

In vitro, IFN-γ decreases osteoblast and fibroblast proliferation and type I collagen synthesis by these cells. This latter effect seems to be caused both by a decrease in type I collagen mRNA stability (Czaja *et al.*, 1987; Kahari *et al.*, 1990) and by a decrease in the transcription rate of the pro *Col1a1* gene (Diaz and Jimenez, 1997; Yuan *et al.*, 1999). Transfection studies using different segments of the human pro *COL1A1* proximal promoter have shown the existence of an IFN-γ response element between −129 and −107 bp that can bind transcription factors NF1 and members of the Sp1 family (Yuan *et al.*, 1999). However, mutations in NF1 and Sp1 sites, which abrogate the binding of these factors, repress the basal *COL1A1* promoter activity but are unable to abrogate the IFN-γ-mediated inhibition, suggesting that NF1 and Sp1 are not involved in this inhibitory action of IFN-γ (Yuan *et al.*, 1999).

In the human *COL1A2* gene, an IFN-γ response element has been identified between −161 and 125 bp by using transfection experiments in dermal fibroblasts (Higashi *et al.*, 1998). Simlarly to the action of TNF-α, Ulloa *et al.* (1999) reported that IFN-γ abrogates the TGF-β stimulation of TGF-β responsive element containing reporter constructs in fibrosarcoma cells by inducing the level of Smad7 via the JAK-STAT1 signaling pathway. To account for the antagonistic action of IFN-γ and TGF-β on expression of the *COL1a2* gene, however, evidence suggests another mechanism involving p300/CBP. This evidence indicates that IFN-γ activated STAT1 sequesters the endogenous p300 and reduces its interaction with Smad3, thus inhibiting the TGF-β/Smad-induced collagen gene transcription (Ghosh *et al.*, 2001). Moreover, Higashi *et al.* (2003) showed that Y-box binding factor (YB-1) binds to the IFN-γ responsive element at −165 to −150 and mediates transcriptional repression of *COL1A2*. The use of YB-1 as a therapeutic target was successfully used to downregulate collagen type I, as a strategy to treat liver fibrosis *in vivo*. This effect was potentiated by the addition of exogenous IFN-γ (Inagaki *et al.*, 2005).

Other Cytokines

Interleukin 1

Interleukin 1 (IL-1) is a cytokine secreted mainly by monocytes/macrophages, but also by other cells, including fibroblasts, osteoblasts, synoviocytes, and chondrocytes. Two forms of IL-1 have been described, IL-1 a and IL-1β, which have little primary structure homology but bind to the same receptor and have similar biological activities (Stylianou and Saklatvala, 1998).

IL-1 modulates the type I collagen synthesis at different levels, and the variations may be owing to cell type, species, and age differences but, at present, the molecular mechanisms by which IL-1 modulates the type I collagen gene transcription are not clear. *In vitro*, IL-1 has an inhibitory effect on type I collagen production by osteoblasts, which is owing to an inhibition of type I collagen gene transcription (Harrison *et al.*, 1990). Nevertheless, it can be masked when low doses of IL-1 are used, as this cytokine stimulates the production of PGE_2, which in turn can modulate type I collagen synthesis. Slack *et al.* (1995) have suggested that the inhibitory effects of IL-1 on the transcription of the human pro *COL1A1* collagen gene by osteoblasts could be mediated through the binding of AP-1 to the first intron of the gene (Slack *et al.*, 1995), but this has not been confirmed. *In vitro*, IL-1β inhibits the expression of the *COL1A2* in human lung fibroblasts at the transcriptional level by a PGE_2-independent effect, as well as through the effect of endogenous fibroblast PGE_2 released under the stimulus of the cytokine (Diaz *et al.*, 1993). More recently, in SSc fibroblasts, pre-IL-1 a was shown to form a complex with IL-1α-binding proteins that are translocated into the nuclei of fibroblasts via HAX-1 (HS1-associated protein X-1) and IL-1 receptor type II in order to increase production of collagen and IL-6 (Kawaguchi *et al.*, 2006). In contrast, the biological impact of IL-1β on tendon fibroblasts showed that the presence of IL-1β significantly decreased the level of collagen type I mRNA. These effects were found to be mediated by selective upregulation of EP(4) receptor, which is a member of G-protein-coupled receptor that transduces the PGE_2 signal via the p38 MAPK pathway (Thampatty *et al.*, 2007).

Interleukin 13

Interleukin 13 (IL-13) is a major inducer of fibrosis. Indeed, IL-13 induces expression of TGF − β1 in macrophages. The increase in TGF-β expression requires both TNF-α and signaling through IL-13 receptor α2 to activate an AP-1 variant, which stimulates the TGF-β promoter. Prevention of IL-13Ra2 expression, IL-13Ra2 gene silencing, or blockade of IL-13Ra2 signaling lead to marked downregulation of TGF-β1 production and collagen deposition in bleomycin-induced lung fibrosis (Fichtner-Feigl *et al.*, 2006). Thus, IL-13R a2 signaling during prolonged inflammation could be an important therapeutic target for the prevention of TGF-β1-mediated fibrosis.

Interleukin 4

Interleukin-4 (IL-4) is secreted by type 2 helper T cells and by mastocytes. *In vitro*, IL-4 increases type I collagen production by human fibroblasts by increasing both transcriptional levels of type I collagen genes and stability of the corresponding mRNAs (Serpier *et al.*, 1997). In bronchial fibroblasts, IL-4 positively regulates *pro COL1A1*

transcription by direct promoter activation and increases the TIMP-2/MMP-2 ratio, thereby supporting the profibrotic effect of this cytokine. Furthermore, a combined action of SP1, NF-κB, and STAT6 contribute to the IL-4 mediated *COL1A2* gene activation. An AP2 site adjacent to a STAT6 consensus motif TTC N(3/4) GCT is located within 205 bases from the transcription start site and seems to support the moderate IL-4-induction of COL1A1 gene expression (Bergeron *et al.*, 2003; Buttner *et al.*, 2004).

Other Interleukins

Interleukin 6 (IL-6) has been shown to induce collagen type I and is elevated in patients with systemic sclerosis (Kawaguchi *et al.*, 1999) and in cultured hepatic stellate cells (Nieto, 2006).

Interleukin 10 (IL-10) is secreted mainly by monocytes/macrophages, inhibits type I collagen genes transcription and type I collagen production by skin fibroblasts (Reitamo *et al.*, 1994).

Oncostatin M is produced mainly by activated T cells and monocytes/macrophages and belongs to the hematopoietic cytokine family. It is mitogenic for fibroblasts and stimulates type I collagen production by fibroblasts by increasing transcriptional levels of type I collagen genes (Ihn *et al.*, 1997). Transfection studies performed using different segments of the human pro α2(I) collagen gene have shown that a 12-bp segment located between −131 and −120 bp, and that contains a TCCTCC motif, mediated the stimulatory effects of oncostatin M (Ihn *et al.*, 1997).

Arachidonic Acid Derivatives

PGE_2, a product of the cyclooxygenase pathway, is synthesized by various cell types, including endothelial cells, monocytes/macrophages, osteoblasts, and fibroblasts. Its production by the fibroblasts is increased by IL-1 and TNF-α. PGE_2 has a biphasic effect on type I collagen synthesis by bone organ cultures and by osteoblastic cells (Ono *et al.*, 2005). At low concentration, it increases type I collagen synthesis, whereas at higher concentrations it decreases type I collagen synthesis. PGE_2 induces the production of IGF-I by osteoblastic cells, and part of the stimulatory effect of low doses of PGE_2 on type I collagen production seems to be indirect, mediated by a stimulation of IGF-I production (Raisz *et al.*, 1993b). Nevertheless, part of this stimulatory effect is independent of IGF-I production and persists after blocking the effects of IGF-I (Raisz *et al.*, 1993a). It is notable that when PGE_2 is added to fibroblasts in culture, it inhibits type I collagen synthesis and decreases the levels of the corresponding mRNAs. Most of the effects of PGE_2 are mediated through an increase in cAMP levels (Sakuma *et al.*, 2004) and the activation of collagen synthesis by low doses of PGE_2 could be caused by such a mechanism, because cAMP analogues can also increase collagen synthesis in bone (Fall *et al.*, 1994). In contrast, the inhibitory effect of PGE_2, which has been shown to be caused by an inhibition of transcription of type I collagen genes, is not mediated through a cAMP-dependent pathway but through a pathway involving the activation of protein kinase C (Sakuma *et al.*, 2004). A study using an osteoblastic cell line transfected stably with various segments of the rat pro Col1a1 promoter cloned upstream of a CAT reporter gene has shown that PGE_2 acts through an element located more than 2.3 kb upstream of the start site of transcription (Raisz *et al.*, 1993b). A more recent study using fibroblasts transfected transiently with a construct containing 220 bp of the mouse *pro Col1a1* proximal promoter has shown that PGE_2 can also act through a *cis*-acting element located within this promoter segment (Riquet *et al.*, 2000).

Hormones and Vitamins

Corticosteroids

It has been known for many years that the administration of corticosteroids to patients results in osteoporosis and growth retardation. In mice, corticosteroids have also been shown to decrease collagen production in calvariae (Advani *et al.*, 1997). *In vitro*, incubation of fetal rat calvariae with high doses of corticosteroids, or with lower doses but for a prolonged period of time, decreased the synthesis of type I collagen (Canalis, 1983; Dietrich *et al.*, 1979); this inhibitory effect could also be observed with osteoblastic cell lines (Hodge and Kream, 1988). Moreover, cortisol increases interstitial collagenase transcript levels by post-transcriptional mechanisms in osteoblastic cells (Delany *et al.*, 1995b). Nuclear run-off experiments performed using osteoblasts derived from fetal rat calvariae showed that glucocorticoids downregulate transcriptional levels of the *pro Col1a1* gene, as well as stability of the corresponding mRNA (Delany *et al.*, 1995a). Because corticosteroids inhibit the secretion of IGF-I, part of their inhibitory effect on type I collagen synthesis could be indirect, but calvariae from IGF-I-null mice maintain their responsiveness to glucocorticoids (Woitge and Kream, 2000).

When added to fibroblasts in culture, corticosteroids usually decrease type I collagen synthesis by acting at a pretranslational level, which is in agreement with their *in vivo* effect on wound healing (Cockayne *et al.*, 1986). Stable transfection experiments using the mouse pro *Col1a2* proximal promoter fused to a CAT reporter gene and transfected into fibroblasts have shown that sequences located between −2048 and −981 bp and between −506 and −351 bp were important for the corticosteroid-mediated inhibition of transcription (Perez *et al.*, 1992). However, the *cis*-acting element(s) responsible was not sufficient to block the effect alone (Meisler *et al.*, 1995),

and further experiments from the same group indicated that glucocorticoids coordinately regulate procollagen gene expression through TGF-β elements. Depression of procollagengene expression by glucocorticoids through the TGF-β element is mediated by decreased TGF-β secretion, possibly involving a secondary effect on regulatory proteins encoded by noncollagenous protein genes (Cutroneo and Sterling, 2004).

Bone mineral density (BMD) decreases by 2% to 4.5% after just 6 months of glucocorticoid administration to healthy men, but subsequently the rate of bone loss declines (LoCascio *et al.*, 1990). Considerable evidence indicates that glucocorticoid-induced bone loss occurs in two phases in both humans and mice: an early, rapid phase in which bone mass is lost because of excessive bone resorption and a slower, later phase in which bone is lost because of inadequate bone formation (LoCascio *et al.*, 1990; Weinstein *et al.*, 1998). Transgenic mice overexpressing 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2) using the osteoclast-specific murine tartrate-resistant acid phosphatase (TRAP) promoter (Reddy *et al.*, 1995) exhibited decreased cancellous osteoclasts after glucocorticoid administration and were protected from the glucocorticoid-induced early, rapid loss of BMD (Jia *et al.*, 2006), suggesting that direct effects of glucocorticoids on osteoclasts are more important than these mediators in the early, rapid loss of bone mass that follows glucocorticoid administration. Similarly, when an osteoblast-specific 2.3-kb *Col1a1* promoter drives (11β-HSD2) expression in mature osteoblasts, 11β-HSD2 should metabolically inactivate endogenous glucocorticoids in the targeted cells, thereby reducing glucocorticoid signaling; collagen synthesis rates were lower in calvarial organ cultures of transgenic mice than in wild type. Furthermore, the inhibitory effect of 300 n*M* hydrocortisone on collagen synthesis was blunted in transgenic calvariae. Trabecular bone parameters measured by microcomputed tomography were also reduced in L3 vertebrae, but not femurs, of 7- and 24-week-old transgenic females. This effect was not seen in male mice, suggesting that endogenous glucocorticoid signaling is required for normal vertebral trabecular bone volume and architecture in female mice (Sher *et al.*, 2004).

Thyroid Hormones

Thyroid hormones have been shown to inhibit type I collagen production by cardiac fibroblasts, and this effect was associated with a decrease in the levels of pro *Col1a1* mRNA (Chen *et al.*, 2000b). Transfection studies have shown that thyroid hormones modulate transcriptional levels of the *pro Col1a1* gene through a *cis*-acting element located between −224 and 115 bp (Chen *et al.*, 2000b). In addition, thyroid hormone (T3) regulates the FGFR1 promoter in osteblasts through a thyroid receptor-binding site at position −279/−264 (O'Shea P *et al.*, 2007).

Parathyroid Hormone

Parathyroid hormone (PTH) binds to specific receptors in osteoblasts and upregulates RANKL expression, a protein essential for osteoclast development and survival. PTH signaling occurs via a PTH receptor /1/cAMP/ protein kinase A/CREB cascade. Runx2 may contribute to the osteoblast specificity of PTH signaling (Fu *et al.*, 2006) by downregulating OPG expression (Boyle *et al.*, 2003). *In vitro*, parathyroid hormone inhibits type I collagen synthesis by osteoblastic cell lines as well as by bone organotypic cultures (Kream *et al.*, 1986). This inhibitory effect is associated with a decrease in the levels of procollagen mRNAs (Kream *et al.*, 1986). When calvariae of transgenic mice harboring a 1.7-, 2.3-, or 3.6-kb segment of the rat *pro Col1a1* proximal promoter were cultured in the presence of parathyroid hormone, there was a parallel decrease in the incorporation of [^{3}H]proline and in the activity of the reporter gene, suggesting that the *pro Col1a1* promoter contains a *cis*-acting element located downstream of −1.7 kb, which mediates the inhibition of the *pro Col1a1* gene expression induced by parathyroid hormone (Bogdanovic *et al.*, 2000; Kream *et al.*, 1993). Furthermore, the effect of parathyroid hormone on the levels of expression of the reporter gene were mimicked by cAMP and potentiated by a phosphodiesterase inhibitor, suggesting that the inhibitory effects of parathyroid hormone are mediated mainly by a cAMP-signaling pathway (Bogdanovic *et al.*, 2000).

Vitamin D

The classic role of the vitamin D endocrine system is to stimulate calcium absorption in the intestine, thus maintaining normocalcemia and indirectly regulating bone mineralization (van Driel *et al.*, 2004). The actions of vitamin D are mediated through the vitamin D receptor (VDR), which acts as a ligand-activated transcription factor to regulate the expression of target genes. The VDR heterodimerizes with retinoid X receptor (RXR) and associates with the transcriptional complex on promoters of target genes. *In vitro*, the active metabolite of vitamin D_3, $1,25(OH)_2D_3$, has been shown to inhibit type I collagen synthesis by bone organ cultures and by osteoblastic cells, and this inhibitory effect is caused by an inhibition of the transcription of type I collagen genes (Bedalov *et al.*, 1998; Harrison *et al.*, 1989). Transfection studies performed with the rat pro *Col1a1* proximal promoter led to the identification of a vitamin D responsive element between −2.3 and −1.6 kb (Pavlin *et al.*, 1994). Nevertheless, when transgenic mice, harboring a 1.7-kb segment of the rat pro *Col1a1* promoter cloned upstream of a CAT reporter gene, were treated with $1,25(OH)_2D_3$, the levels of expression of the CAT reporter gene decreased, which suggests that a vitamin D response element is located downstream of −1.7 kb (Bedalov *et al.*, 1998). Similarly, when calvariae from these transgenic mice

were cultured in the presence of $1,25(OH)_2D_3$, it inhibited reporter gene expression (Bedalov *et al.*, 1998). It is of note that part of the effects of vitamin D on type I collagen could be mediated through an inhibition of the production of IGF-I, because vitamin D has been shown to inhibit IGF-I production and increases the concentrations of inhibitory IGFBP-4 (Scharla *et al.*, 1991). Indeed, effects of $1,25-(OH)_2D_3$ on release of the IGFs were independent of bone resorption and support the conclusion that $1,25-(OH)_2D_3$ modulated the production and secretion of IGF-I and IGF-II in calvarial cells (Linkhart and Keffer, 1991). The results of these studies and similar studies on PTH in calvarial cells suggest that PTH, TGF-β, and $1,25-(OH)_2D_3$ differentially regulate mouse calvarial cell IGF-I and IGF-II production. Furthermore, IGFBP-5 has been shown to reduce the effects of $1,25(OH)_2D_3$ by blocking cell cycle progression at G_0/G_1 in osteoblasts and by decreasing the expression of cyclin D1. Moreover, IGFBP-5 can interact with VDR to prevent RXR:VDR heterodimerization and IGFBP-5 may attenuate the $1,25(OH)_2D_3$-induced expression of bone differentiation markers (Schedlich *et al.*, 2007).

Chapter 16

Collagen Cross-Linking and Metabolism

INTRODUCTION

In constituting about 90% of the matrix protein of bone, collagen clearly plays an important role in determining the characteristic of the tissue. Much of the research on collagen has focused on the extensive post-ribosomal modifications that occur during biosynthesis of the molecule, as these intracellular changes have major influences on the assembly, cross-linking, mineralization, and degradation of collagen fibrils. The aim of this chapter is to bring together current knowledge on the mechanisms of collagen cross-linking and how these are influenced by specific post-ribosomal modifications. These changes are also viewed in the context of collagen metabolism, with particular reference to the utilization of certain collagen metabolites as markers of bone metabolism.

Although 27 genetically distinct collagen types are known (Myllyharju and Kivirikko, 2004), bone contains predominantly the principal fibrillar form, collagen type I, but with small amounts of collagens V and III. Collagen V interacts with type I fibrils (Birk *et al.*, 1988; Chanut-Delalande *et al.*, 2001) and may have some regulatory role on fibril diameter and orientation, as has been shown for cornea. Collagen III in bone is generally limited to anatomically distinct regions, such as tendon insertion sites (Keene *et al.*, 1991). Thus, for the purposes of this chapter, the properties of collagen type I will be considered, as these dominate the primarily structural function of collagen in bone.

CROSS-LINK FORMATION

Collagen type I fibrils form spontaneously within the extracellular space once the N- and C-terminal propeptides of procollagen have been removed by specific proteases. During fibrillogenesis, the final enzymatic modification of collagen occurs: conversion of lysine or hydroxylysine residues within both N- and C-terminal telopeptides to aldehydes by lysyl oxidase. Subsequently, all collagen cross-linking steps occur spontaneously by virtue of the specific alignment of molecules within the fibrils.

As indicated in an overview of the cross-linking process (Fig. 1), the hydroxylation state of telopeptide lysine residues is crucial in determining the pathway of collagen cross-linking; this step is determined by an intracellular modification during collagen biosynthesis.

Hydroxylation of telopeptide lysine residues is known to be accomplished by a separate enzyme to the one that act on lysines in the central chain portion destined to become the helix, and further research in this area has expanded our knowledge of the tissue-specific control of collagen cross-linking. Following preliminary evidence for a telopeptide lysyl hydroxylase from studies *in vitro* (Royce and Barnes, 1985; Uzawa *et al.*, 1999), and from a rare form of osteogenesis imperfecta, Bruck syndrome (Bank *et al.*, 1999), the long form of lysyl hydroxylase-2, a splice variant of the enzyme also known as procollagen-lysine, 2-oxoglutarate, 5-dioxygenase-2 (PLOD-2), was shown to accomplish hydroxylation of telopeptide lysine residues (Mercer *et al.*, 2003; van der Slot *et al.*, 2003). Initially, PLOD-2, which has been localized to chromosome 3, was thought to be an unlikely candidate for the defect in Bruck syndrome, known to be located on chromosome 17 (Bank *et al.*, 1999), but subsequent studies demonstrated the heterogeneity of this disorder, with some variants being derived from PLOD-2 deficiency (Ha-Vinh *et al.*, 2004). Further studies have confirmed that, of the three known PLOD enzymes, the long splice variant of lysyl hydroxylase 2 (LH2b) directs the pathways of collagen cross-linking in MC3T3-E1 cells (Pornprasertsuk *et al.*, 2004), and that there appears to be tissue-specific control of this (Walker *et al.*, 2005) and other lysyl hydroxylase enzymes (Eyre *et al.*, 2002). Some studies of telopeptide hydroxylation have associated increased

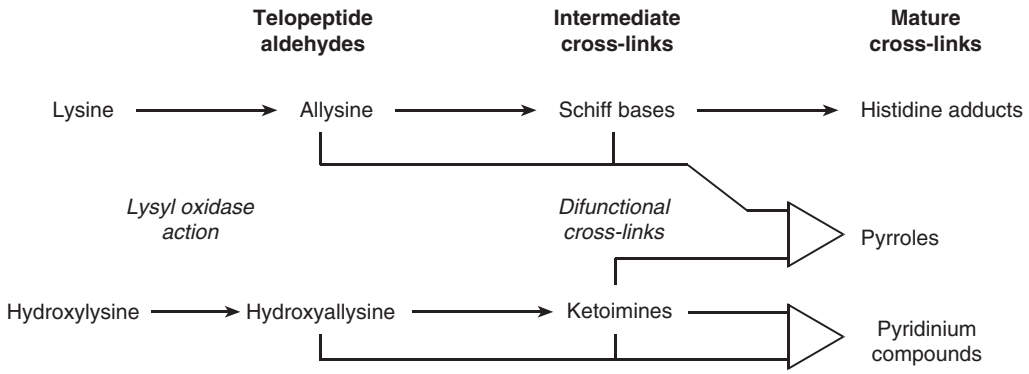

FIGURE 1 Formation of collagen cross-links from lysine- or hydroxylysine-derived telopeptide aldehydes giving rise to Schiff base or ketoimine difunctional bonds, respectively. On maturation, the Schiff bases are converted primarily to nonreducible, histidine adducts, whereas the ketoimines react with hydroxylysine aldehyde or a second ketoimine to give pyridinium cross-links. Pyrrole cross-link formation requires the presence of both lysine- and hydroxylysine-derived products.

expression of LH2b generally with fibrosis, particularly in skin (van der Slot *et al.*, 2003; van der Slot *et al.*, 2004), leading to attempts at enzyme inhibition as a therapeutic target (Zuurmond *et al.*, 2005). The hypothesis prompting this approach, that the presence of hydroxylysine-derived cross-links results in intractable collagen, has yet to be verified experimentally, and other data now indicate that the association of LH2 with fibrosis may, at least in part, result directly from elevated collagen synthesis in response to overexpression of LH2 (Wu *et al.*, 2006).

All of the three known lysyl hydroxylase isoenzymes were shown to hydroxylate collagenous sequences *in vitro* but LH2 exhibited no activity against 23- or 29-residue synthetic peptide substrates corresponding to the C- or N-terminal telopeptide domains, respectively; this enzyme appeared to require a full length α-chain as substrate (Takaluoma *et al.*, 2007). LH3 is a multifunctional enzyme that, in addition to lysyl hydroxylation, has galactosyltransferase and glucosyltransferase activities (Heikkinen *et al.*, 2000); the latter appears to be the predominant function of LH3 (Ruotsalainen *et al.*, 2006; Salo *et al.*, 2006) providing intriguing new insights into possible functions of O-glycosylation of collagen hydroxylysine (Sipila *et al.*, 2007).

CROSS-LINK STRUCTURE

Intermediate Cross-Links

The preponderance of hydroxylysine aldehydes in bone collagen telopeptides ensures that most of the difunctional cross-links initially formed are relatively stable bonds. Thus, in contrast to tissues such as skin, where the telopeptide lysine aldehydes interact with adjacent molecules to give Schiff base (–N ═ CH–) cross-links, the presence of the hydroxyl group allows an Amadori rearrangement to a more stable, ketoimine form. Both the Schiff base and the ketoimine forms of cross-link are reducible by borohydride, a technique that enabled the Schiff base compounds to be stabilized for identification (Bailey *et al.*, 1974). Although the ketoimine bonds are sufficiently stable to allow isolation of peptides containing these bonds, the cross-links are quantified after reduction with borohydride to the well-characterized compounds dihydroxylysinonorleucine (DHLNL) and hydroxylysinonorleucine (HLNL).

The reducible, bifunctional cross-links are referred to as intermediates because of their conversion during maturation of the tissue to nonreducible compounds, which are generally trivalent. Such a process can therefore be considered to provide additional stability to the fibrillar network, although, because of some ambiguities in the mechanisms involved, this has not been demonstrated directly.

Pyridinium Cross-Links

One of the first maturation products of the intermediate cross-links to be identified was pyridinoline (PYD) or hydroxylysyl pyridinoline (HP), a trifunctional 3-hydroxy-pyridinium compound (Fujimoto *et al.*, 1978). An analogue, deoxypyridinoline (DPD) or lysyl pyridinoline (LP), has also been identified in bone (Ogawa *et al.*, 1982). Both of these compounds (Fig. 2) are derived from intermediate ketoimines by reaction either with another difunctional cross-link (Eyre and Oguchi, 1980) or with a free hydroxylysine aldehyde group (Robins and Duncan, 1983). The chemistry of these two proposed mechanisms is very similar, but there are implications in terms of structural function of the cross-links. The involvement of two difunctional compounds results in a cross-link among three collagen molecules, whereas the alternative mechanism seems more likely to link only two molecules (as shown in Fig. 2). The difunctional, reducible cross-links necessarily link adjacent molecules within a pentafilament microfibril

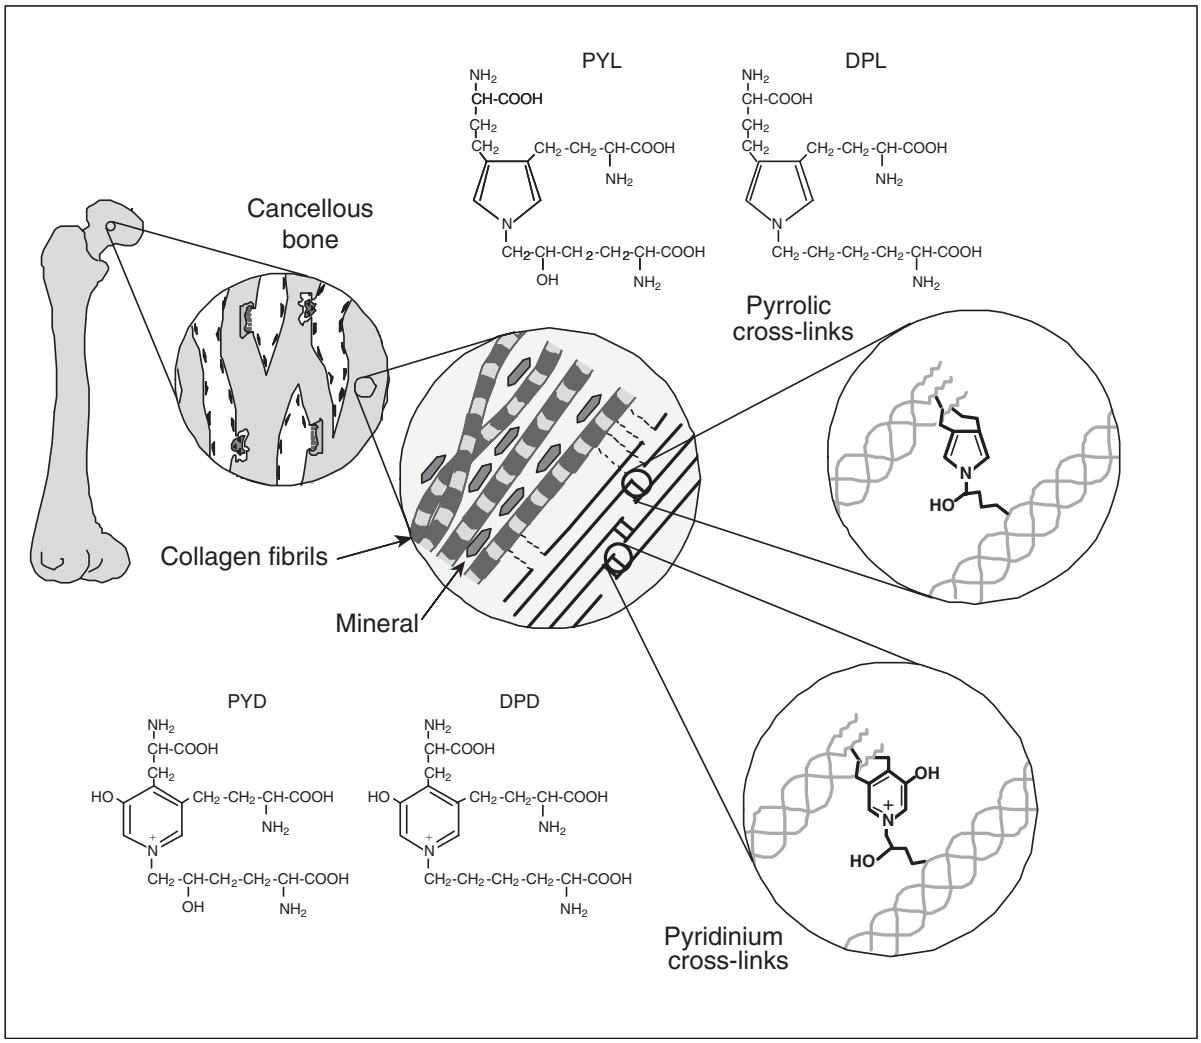

FIGURE 2 Stabilization of bone matrix by pyridinium and pyrrolic cross-links. Slightly higher concentrations of the mature cross-links are present in cortical compared with remodeling cancellous bone (inset) showing schematically mineralized collagen fibrils having a banded appearance arising from the precise alignment of collagen molecules in a quarter-staggered array. The overlap is stabilized by cross-links at both N- and C-terminal ends. (Insets) Pyridinium and pyrrole compounds linking N-terminal telopeptides to an adjoining helix: cross-linking may also involve telopeptides from two different molecules in register. Pyridinium cross-links are present at both N- and C-terminal sites, but pyrroles are located predominantly at the N terminus. Depending on the degree of hydroxylation of the helical lysine residue, two analogues of both the pyridinium and the pyrrolic cross-links are formed.

(Orgel *et al.*, 2006), whereas modeling studies suggest that conversion to mature, trifunctional bonds is accompanied by the formation of a transverse network of inter-microfibrillar bonds (Malone *et al.*, 2004; Robins, 2006).

Pyrroles

Based on the observation that tissues solubilized by enzyme treatment gave a characteristic pink color with *p*-dimethylaminobenzaldehyde, Scott and colleagues (Scott *et al.*, 1981) suggested that collagen contained pyrrolic cross-links. These compounds were termed Ehrlich chromogens (EC) and, in later experiments, diazo-affinity columns were used to bind covalently the pyrrole-containing peptides from enzyme digests of bone (Scott *et al.*, 1983) and skin (Kemp and Scott, 1988); these were partially characterized by amino acid analysis. A similar affinity chromatography approach was used to demonstrate that Ehrlich chromogen cross-links were present at the same loci as the pyridinium cross-links in bovine tendon (Kuypers *et al.*, 1992). This work culminated in a proposed structure and mechanism of formation for pyrroles analogous to that for pyridinium cross-link formation: this mechanism involves reaction of a difunctional, ketoimine cross-link with a lysyl aldehyde-derived component rather than hydroxylysyl aldehyde-derived component (Kuypers *et al.*, 1992), where the latter may be a second difunctional cross-link (Hanson and Eyre, 1996).

Isolation and characterization of the pyrrolic cross-link(s) were hampered by the instability of the pyrrole to acid or alkali hydrolysis. The use of repeated enzyme digestion of decalcified bone matrix to isolate pyrrole-containing peptides was not possible because, as these peptides were reduced in size and enriched, the pyrrole tended to oxidize or polymerize. By synthesizing new Ehrlich reagents, however, it was possible to both stabilize the pyrrolic cross-links and facilitate their isolation and characterization by mass spectrometry (Brady and Robins, 2001). Both predicted analogues of the pyrrole (Fig. 2) were identified as the derivatized cross-link. Consistent with previous nomenclature, the trivial names pyrroloLine (PYL) and deoxypyrroloLine (DPL) have been proposed for the underivatized cross-links, and a convergent total chemical synthesis of DPL has been described (Adamczyk *et al.*, 2001).

Location of Cross-Links

Within the quarter-staggered, fibrillar array of collagen molecules, almost all cross-links have been shown to be located at the 4D overlap position (see Fig. 2). Thus, N-telopeptide-derived cross-links are linked to the C-terminal part of the helix [residue 930 in the α1(I) chain], whereas C-telopeptide-derived cross-links are adjacent to the N-terminal end of the helix at residue 87. Because there is no oxidizable lysine in the C-telopeptide of the α2(I) chain, a more restricted number of cross-links is possible at this site compared to the N-terminal end. It has been established that the pyridinium and pyrrole cross-links are both located at these sites but that there are differences in their relative amounts. Thus, in bone collagen, the pyrrolic cross-links involve predominantly the N-terminal telopeptide (Hanson and Eyre, 1996), although there is some evidence for their location at the C-terminal end (Brady and Robins, 2001). Pyridinium cross-links are present at both ends of the molecule (Hanson and Eyre, 1996; Robins and Duncan, 1987) but, in human tissue, there is more DPD relative to PYD at the N terminus compared with the C-telopeptide-derived cross-linking region (Hanson and Eyre, 1996). The helical Hyl residue toward the N-terminal end (residue 87) is much more likely to be glycosylated than its C-terminal counterpart so that glycosylated pyridinium cross-links are relatively common, whereas glycosylated pyrrolic cross-links have not yet been detected.

Spectrum of Cross-Linking

The variations in telopeptide lysine hydroxylation give rise to a spectrum of different cross-linking patterns (Fig. 3). Bone collagen occupies a central position in this spectrum by virtue of the partial hydroxylation within the telopeptides, resulting in the formation of both pyridinium and pyrrolic cross-links. In cartilage, where telopeptide hydroxylation is essentially complete, only pyridinium cross-links

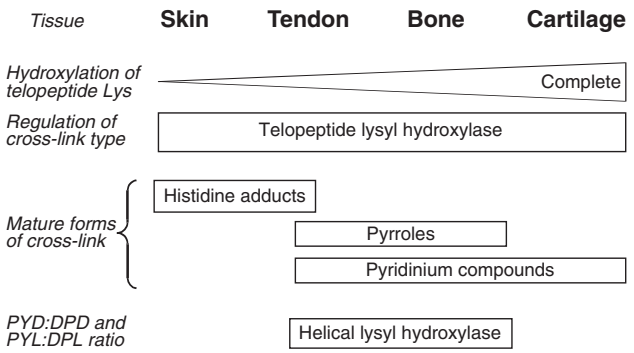

FIGURE 3 Spectrum of tissue-specific cross-linking resulting from the activity of telopeptide lysyl hydroxylase to give complete hydroxylation in cartilage but no significant hydroxylation of telopeptide lysine in skin collagen. The action of this intracellular enzyme regulator leads to the differences shown in mature cross-links. Pyrrolic cross-links are absent at the extremes of activity but are major components of bone and some tendons. The action of the intracellular enzyme, helical lysyl hydroxylase, regulates the relative proportions of mature pyridinium and pyrrolic cross-links in bone and tendon.

are present with no pyrrolic forms. At the opposite end of the spectrum, skin also has no pyrrolic cross-links because of the absence of any telopeptide lysyl hydroxylase activity in this tissue. Helical lysyl hydroxylase activity, predominantly accomplished by the LH1 enzyme, has a much less profound effect on cross-link composition (Fig. 3) but does control the relative proportions of PYD:DPD and PYL:DPL. These cross-link changes are exemplified by the kyphoscoliotic type of Ehlers-Danlos syndrome (EDS VIA) or Nevo syndrome in which LH1 deficiency results in a change of over twofold in the PYD:DPD ratio in urine, reflecting mainly that in bone (Giunta *et al.*, 2005).

Age-Related Changes in Lysyl Oxidase-Derived Cross-Links

The conversion of the intermediate, bifunctional cross-links to pyridinium compounds is well documented, but the stoichiometry is less clear. Studies of the aging *in vitro* of bone indicated a 2:1 molar ratio of the ketoimine precursor to the pyridinium cross-link (Eyre, 1981), an observation that is consistent with the proposed mechanism of formation of the trivalent cross-link (Eyre and Oguchi, 1980). The maturation of bifunctional cross-links to the pyrrolic cross-links is extremely difficult to follow owing to instability of the pyrrole during isolation. In addition, as a relatively reactive species, pyrrolic cross-links have the potential to undergo further interactions within the fibril during the maturation process, although there appears to be little change in total bone pyrrole concentrations during aging (Bailey *et al.*, 1999).

In most soft tissues, the content of intermediate, reducible bonds is very low after the cessation of growth (Robins *et al.*, 1973), but bone is unusual in retaining a relatively large proportion of reducible bonds. One possible reason for this is the continual turnover through the remodeling of bone, resulting in a higher proportion of recently formed fibrils compared with other tissues. In support of this view, low bone turnover in osteopetrotic rats was found to be associated with high concentrations of pyridinium cross-links in cancellous and compact bone, which were partially normalized by the restoration of osteoclast formation with colony-stimulating factor 1 treatment (Wojtowicz *et al.*, 1997). The ultimate concentrations of pyridinium cross-links attained in these experiment were, however, not markedly different and it is unclear whether the observed differences in kinetics play an important part *in vivo*. Studies from samples obtained *in vivo* show that, although the overall collagen content of bone decreases, there appears to be no dramatic change in mature enzymatic cross-link concentrations with age (Bailey *et al.*, 1999; Nyman *et al.*, 2006). The situation may be confounded by subtle differences between areas that are undergoing active remodeling and sites containing older bone (Hernandez *et al.*, 2005; Nyman *et al.*, 2006) but again the relative differences in cross-link content are small.

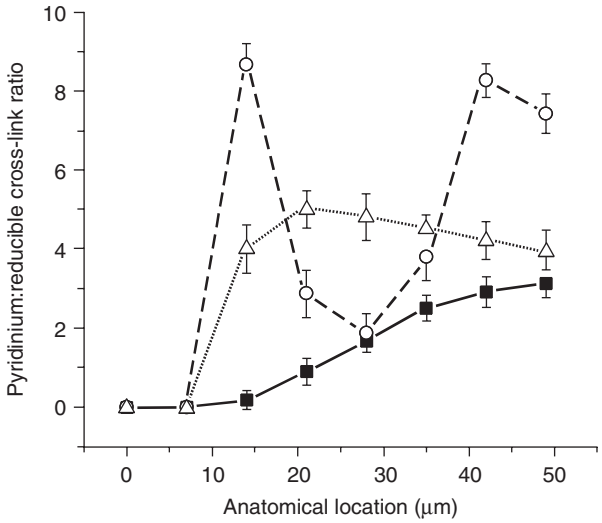

FIGURE 4 The spatial variation in pyridinium: reducible collagen cross-link ratio at bone-forming trabecular bone surfaces as a function of the anatomical distance from the outer edge of the osteoid surface (Paschalis *et al.*, 2004). The data depict measurements in iliac crest biopsy samples taken from patients with high-turnover osteoporosis (open circles) and low-turnover osteoporosis (open triangles) in comparison with healthy controls of similar age (solid squares), at equivalent anatomical locations (Paschalis *et al.*, 2004). Adapted with permission of the American Society for Bone and Mineral Research from Paschalis *et al.* (2004).

Direct Measurement of Cross-link Maturation in Tissues

The rates of conversion of intermediate to mature cross-links in tissues have generally been assessed by rather time-consuming and laborious analysis of individual cross-links in borohydride-reduced tissues. Such analyses do not, of course, give any indication of the localization of the different cross-links within the tissue. By using a newly developed application of Fourier transform infrared (FTIR) spectroscopy combined with imaging techniques, it has been possible to visualize within bone tissue sections the relative abundance of intermediate and mature cross-links (Paschalis *et al.*, 2001).

Bands in the amide I spectral region had been used previously for FTIR analysis of collagen, but by analyzing the spectra of isolated bone peptides containing either PYD or DHLNL, Paschalis *et al.* (2001) were able to assign a band at $\sim 1660\,cm^{-1}$ primarily to the mature, trifunctional cross-link and another at $\sim 1690\,cm^{-1}$ to intermediate cross-links characterized by DHLNL. Thus, by measuring the 1660:1690 band ratio, the relative proportions of mature and immature cross-link could be measured in a spatially resolved manner in thin sections of undecalcified bone. In bone trabeculae, the mature:intermediate cross-link ratio was much higher in the geometric center compared with lower ratios at the periphery and in osteoid-containing regions, consistent with the growth patterns in bone (Paschalis *et al.*, 2003). This technique does not measure the cross-links directly but assesses their presence from characteristic perturbations in the amide I part of the spectrum: it is likely that little distinction can be made with these methods between any of the trifunctional, mature cross-links, or between any of the intermediate, difunctional compounds. The method is, however, extremely valuable in facilitating imaging of the spatial distribution of collagen cross-link maturation, as evidenced by the differences in maturation patterns (Fig. 4) in iliac crest biopsies between normal postmenopausal women and those prone to fracture (Paschalis *et al.*, 2004).

Age-Related Changes in Sugar-Derived Cross-links

Although there are numerous sugar-derived modifications known to occur in collagens from all tissues, in bone pentosidine is the only well-characterized cross-link studied *in vivo* mainly owing to its stability to acid hydrolysis. Pentosidine is the glucose-mediated cross-link formed between a modified lysine residue and arginine (Sell and Monnier, 1989) and recent studies have revealed some intriguing correlations between the age-related changes in concentration of this cross-link and the physical properties of the bone, both *in vitro* and *in vivo*. Many studies have shown an increase in pentosidine concentrations with age (Odetti *et al.*, 2005; Nyman *et al.*, 2006; and a

concomitant decrease in mechanical bone quality (Wang *et al.*, 2002). Using postmortem vertebrae, regression analysis showed significant negative correlations between pentosidine concentrations and vertebral failure load and work to fracture after accounting for bone mineral density (Viguet-Carrin *et al.*, 2006) suggesting an association of these cross-links with increased fragility. In an attempt to assess the potential effect on fracture, femoral necks from a group of fracture patients were compared to postmortem age-matched controls in compartments with high and low degrees of mineralization. The results showed that pentosidine content was significantly higher in fracture patients in the areas of low mineral density and elevated in the high-density areas (Saito *et al.*, 2006). Incubation *in vitro* of fetal bovine cortical bone at 37°C in phosphate buffered saline induced marked increases in enzymatic cross-links, but to levels much lower than those found *in vivo* (Garnero *et al.*, 2006). How an increase in intermolecular cross-linking might have a deleterious effect on quality is less clear with the only evidence being associative; in this study, there was a large increase (55-fold) in pentosidine but only to very low concentrations of cross-link (10 mmol/mol). In fact, in all of these studies the relative quantities of measured pentosidine is in the order of 20–40 mmol/mol of collagen, at least an order of magnitude lower than the combined lysyl oxidase-mediated cross-links, which can approach the mol/mol level in bone. It is difficult therefore, to envisage how such small amounts could affect bone collagen strength directly. One possibility, however, is that other sugar-derived lysine-arginine cross-links, which are not stable to acid hydrolysis, may be more important, but would be expected to correlate to the more readily detectable pentosidine. The difficulty in measuring these cross-links is that they need to be isolated by enzymatic digestion, which is extremely difficult for bone. Concentrations of these acid unstable cross-links have been measured in soft collagenous tissues and can reach levels that may conceivably affect collagen stiffness and strength; glucosepane measured in the skin of diabetic subjects reached concentrations of about 1 mol/mol collagen by the ninth decade of life (Sell *et al.*, 2005).

Other Age-Related Changes

Changes in protein structure owing to age-related modifications such as progressive deamidation, racemization, or, as discussed in the previous section, nonenzymatic glycosylation of specific amino acid residues are well recognized. These changes have profound effects on the functional properties of the matrix and may alter interactions with cells and other matrix constituents, thus affecting the metabolism of the protein. Although a detailed discussion of the many protein modifications that occur during aging is beyond the scope of this chapter, specific changes because of isomerization and racemization of aspartyl residues in collagen telopeptides are discussed because of their implications for the measurement of collagen metabolites as bone resorption markers.

Isomerization and Racemization of Asp in Telopeptides

The racemization of amino acids in proteins has long been used as a means of assessing the "age" of proteins (Helfman and Bada, 1975). Different amino acids racemize at different rates, but aspartyl (or asparaginyl) residues racemize particularly rapidly because of the association with isomerization events. Conversion to a D-aspartyl or -asparaginyl residue occurs more readily when this residue is adjacent to a glycine, thus allowing the formation of a succinimide intermediate, which leads to L- and D-isomers of both α and β forms. The presence of isomeric forms of -Asp-Gly- bonds in collagen telopeptides was recognized by Fledelius and colleagues (Fledelius *et al.*, 1997), who showed that the proportion of β-aspartyl residues within the C-terminal telopeptide of α1(I) increased with age in human and animal tissues. Measurements in urine reflected similar age changes, with higher α/β ratios detected in children compared with adults (Fledelius *et al.*, 1997). Later studies of the Asp-Gly bond in the N-telopeptide of the α2(I) chain revealed that isomerization also occurs at this end of the molecule (Brady *et al.*, 1999), although there were some differences between N- and C-terminal telopeptides in the relative α/β ratios in bone and urine.

The isomerization and racemization of aspartyl residues in telopeptides potentially have applications in monitoring the relative rates of metabolism of different pools of bone. A systematic study of the kinetics of isomerization and racemization of C-telopeptide aspartyl residues using synthetic peptides aged *in vitro* indicated that the ratio most discriminatory in terms of indicating biological age was αL/βD (Cloos and Fledelius, 2000). Analysis of these ratios in bone samples using immunoassays specific for each form of CTX indicated that children and patients with Paget's had a turnover time of 2–3 months, whereas those from healthy adults and patients with osteoporosis had longer half-lives. In an extension to these studies, analyses of the relative rates of turnover of a wide range of human tissues using the specific CTX immunoassays (Gineyts *et al.*, 2000) suggested that collagen turnover in most of the soft tissues examined, including arteries, heart, lung, and skeletal muscle, was much higher than that in bone. These rather surprising results probably arise because of the limited solubilization of the tissue with trypsin, although the amounts solubilized were not reported (Gineyts *et al.*, 2000). Without heat denaturation before trypsinization, however, only younger, less cross-linked tissue will be extracted, leading to an overestimate of the turnover rate.

There are now several available assays to assess serum, urine, and cell culture α and β C-terminal peptides (see Table I). Other assays differentiating among the αL, αD

TABLE I Various forms of the C-terminal telopeptide of collagen type I detected by the commercially available assays

Assay	Telopeptide fragment detected
αCTX RIA	αCTX; αCTX-x-αCTX; αCTX-x-βCTX
Urinary CTX	βCTX; βCTX-x-αCTX; βCTX-x-βCTX
Serum CTX (CrossLaps; Roche Elecsys)	βCTX-x-βCTX
ααCTX ELISA	αCTX-x-αCTX

βL, and βD also have been used but discriminating among the three altered forms added little more value than comparing alpha and any isomerized or racemized fragment when used as a direct estimate of resorption (Cloos *et al.*, 2003b). Comparison of the αL-CTX isoform to the kinetically slowest form, αD-CTX may represent useful "extremes" of the young-old profile when assessing metastases (Cloos *et al.*, 2003a).

The β telopeptide serum assays have been widely used to indicate increased bone resorption in various conditions expected to be associated with increased resorption of mature bone (Cloos *et al.*, 2003b), including menopause and fracture (Kawana *et al.*, 2002) and bone loss in hemodialysis patients (Okuno *et al.*, 2005). The β peptides also appear to reflect attenuation of resorption in therapies such as hormone replacement (HRT), bisphosphonates (Byrjalsen *et al.*, 2007; Okabe *et al.*, 2004), and calcitonin (Zikan and Stepan, 2002).

The α-peptide assays, or preferably α/β ratios generated from measuring both forms of the peptide, can provide additional information on metabolism rates. The rate of turnover would be expected to have a direct effect on the maturity of collagen in bone, as slowing down resorption should allow more time for alpha to beta maturation; therefore, the collagen fragments detected would be expected to show a more mature profile. An example of this is a study using both urinary α-α and β-β peptide assays to monitor the effects of antiresorptive therapies (Byrjalsen *et al.*, 2007). Although all of the treatments (alendronate, ibandronate, HRT, and raloxifene) significantly reduced both α-α peptides and β-β peptides compared to placebo, only the bisphosphonates significantly changed the ratio, demonstrating an increased maturation of bone allowed by the decreased turnover.

Measuring α fragments may also provide an improved index of bone loss from areas of intense remodeling of immature bone that has had insufficient time to isomerize. As discussed previously, in Paget's disease there is a significant increase in α/β ratio (Garnero *et al.*, 1997; Alexandersen *et al.*, 2005) but the α/β ratio also responds extremely sensitively to antiresorptive therapy and may indicate an increase in bone maturation with treatment (Alexandersen *et al.*, 2005). Metastatic bone cancer is another condition where rapid remodeling may result in non-isomerized peptide fragments being released into the serum and urine through resorption of more immature areas of bone. Measuring α-α alone or as an α-α/β-β ratio provided significant discrimination between breast cancer patients with or without bone metastases (Cloos *et al.*, 2004), as was comparison of the aging extremes of the isomerization process, αL/αD, although α-α alone was still the best at differentiating those subjects with metastases (Cloos *et al.*, 2003a). The number of bone metastases also correlated with urinary α-αCTX measurements, as demonstrated in another study of patients with primary breast cancer (Leeming *et al.*, 2006).

In addition to representing an opportunity to estimate the age of bone being resorbed at any given time, the presence of isomerized aspartyl residues may be postulated as a mechanism *in vivo* for targeting older bone for local remodeling. This nonstochastic or targeted remodeling is suggested to occur primarily at load-bearing areas in response to micro-damage (Han *et al.*, 1997). In an *in vitro* study using both young and aged bone, it was shown that osteoclastogenesis and total resorption was accelerated in older bone (Henriksen *et al.*, 2007). Although the α/β ratio of the peptides released was used as a marker to differentiate between the two samples and to monitor relative resorption of old versus new bone, it is tempting to speculate that such modifications may be used *in vivo* to recognize mature bone that is fit for remodeling.

DEGRADATIVE PATHWAYS

Action of Osteoclastic Cells

The major role of osteoclasts in bone resorption has been discussed extensively in this volume and will not be described here in detail. Of the many proteases expressed by osteoclasts, current evidence indicates that the cysteine proteinase, cathepsin K, plays a major role in degrading bone matrix. Initially cloned from rabbit osteoclasts (Tezuka *et al.*, 1994), cathepsin K was subsequently shown to be expressed predominantly in this cell type for other

mammalian species. Studies of human osteoclastic cells showed that cathepsin K inhibition with antisense probes markedly decreased the resorptive activity measured by pit assay (Avnet *et al.*, 2006). Unlike other cathepsins, recombinant cathepsin K was shown to be capable of solubilizing demineralized, fibrillar bone collagen (Garnero *et al.*, 1998a). The importance of cathepsin K for bone metabolism *in vivo* was demonstrated by the discovery that pycnodysostosis, an autosomal recessive skeletal dysplasia, resulted from mutations in this enzyme (Gelb *et al.*, 1996). The lack of cathepsin K resulted in decreased bone turnover measured by histomorphometry as well as poor bone quality and structural characteristics revealed by quantitative backscattered electron imaging and small angle X-ray scattering (Fratzl-Zelman *et al.*, 2004). This disorder was also associated with the accumulation of phagocytosed collagen fragments in lysosomal vacuoles (Everts *et al.*, 2003). Changes in the patterns of urinary bone markers occurred in pycnodysostosis (Nishi *et al.*, 1999), and studies *in vitro* confirmed that cathepsin K activity influenced the fragments produced from both N-terminal (Atley *et al.*, 2000) and C-terminal (Sassi *et al.*, 2000) sites of collagen type I.

Although cathepsin K clearly has an important function in osteoclastic bone resorption, there are many other enzymes that may play a role. Matrix metalloproteinases (MMPs), which are abundant in bone (Knott *et al.*, 1997), include collagenases with the ability to cleave native collagen fibrils, although less effectively than cathepsin K (Garnero *et al.*, 1998), and gelatinases able to degrade further the denatured chain fragments produced. Some debate continues on the relative roles of cathepsin K and MMPs in osteoclastic bone resorption. Although osteoclast activity assays *in vitro* suggested that MMPs contribute little resorptive activity (Fuller *et al.*, 2007), these enzymes may have more indirect roles through, for example, modifying osteoclast migration and recruitment (Delaisse *et al.*, 2003). As the major bone-resorbing enzyme, however, cathepsin K constitutes a primary therapeutic target for attenuating bone resorption (Kumar *et al.*, 2007).

EXTRASKELETAL PROCESSING OF COLLAGEN FRAGMENTS

Hepatic and Renal Influences

There is currently little evidence on whether the liver plays a significant role in the further processing of collagen fragments. Early studies showed that ^{125}I-labeled monomeric α1(I) chains injected into rats were taken up rapidly by liver endothelial and Kupffer cells (Smedsrod *et al.*, 1985). For the endothelial cells at least, this process was receptor mediated and was accompanied by lysosomal degradation of the denatured collagen chains. Whether the relatively small fragments of collagen that emanate from bone will be similarly sequestered and metabolized by the liver is unknown.

In contrast, there is good evidence that the kidney has an important role in controlling the patterns of collagen degradation products from bone and other tissues. Initially, evidence was again obtained from animal experiments in which immunostaining of rat kidney sections with antibodies recognizing only denatured collagen showed large accumulations of collagen fragments in proximal renal tubules (Rucklidge *et al.*, 1986). Subsequent studies following the fate of injected ^{3}H-labeled collagen fragments by autoradiography showed rapid uptake by proximal tubule epithelial cells and vacuolar transport to lysosomes (Rucklidge *et al.*, 1988) where antibody reactivity was lost, presumably through degradation of the peptides.

Analyses of serum and urinary concentrations of pyridinium cross-link components in children provided evidence that free pyridinium cross-links were in part produced in the kidney (Colwell and Eastell, 1996). This study showed that the proportion of free DPD in serum was about half that in urine. Analysis of free DPD in serum for older children revealed a negative correlation with the total cross-link output (Colwell and Eastell, 1996) and a similar correlation was noted in urine for a group of pre- and postmenopausal women (Garnero *et al.*, 1995). These data led to the hypothesis that the renal processing of collagen fragments was a saturable process whereby increased collagen turnover resulted in a progressive decrease in the proportion of free cross-links and a corresponding increase in their peptide forms (Colwell and Eastell, 1996; Garnero *et al.*, 1995; Randall *et al.*, 1996). This hypothesis is probably an oversimplification, however, as an analysis of the results for a wide range of healthy individuals and patients with metabolic bone diseases indicated only a weak correlation between the proportion of free DPD and total cross-link output (Robins, 1998). Comparisons of serum and urinary immunoassays for telopeptide markers indicated a greater degree of renal processing of the N-terminal relative to C-terminal components (Fall *et al.*, 2000), although it is unclear whether this is related to the increased protease resistance of C-telopeptides imparted by the presence of isoaspartyl residues. Several studies have established that the patterns of collagen cross-link-containing components can be affected by various treatments for disease (Garnero *et al.*, 1995; Robins, 1995; Kamel *et al.*, 1995), and the effects of amino-bisphosphonates have received most attention in this respect.

Effects of Bisphosphonates

Much interest in this aspect was created by a report that measurements of free and peptide-bound cross-links in patients receiving acute, intravenous treatment with pamidronate for three days showed essentially no changes in free pyridinium cross-link concentrations, whereas there were large decreases in telopeptide-based assays and, to a lesser extent, in HPLC measurements of total cross-links (Garnero *et al.*, 1995). Although these finding appeared

to overestimate the bisphosphonate effects compared with another similar study (Delmas, 1993), subsequent investigations of the effects of longer term bisphosphonate treatment have confirmed that there are changes in the patterns of collagen degradation components. Treatment of postmenopausal women with the amino-bisphosphonate, neridronate, over a four-week period resulted in a significant increase in the proportion of free DPD, with an apparently greater response to therapy in the peptide-bound fraction (Tobias *et al.*, 1996). This study also showed that there were no changes in the proportion of free PYD, leading to an increased PYD/DPD ratio in the peptide fraction. The changes in cross-link ratio were initially thought to represent altered tissue contributions to the cross-links, but, as DPD is more prevalent at the N-terminal portion of collagen (Hanson and Eyre, 1996), these changes probably indicate differential effects on proteolytic degradation of the N- and C-telopeptide cross-linked regions.

Bisphosphonates appear to inhibit bone resorption through several mechanisms involving direct effects on osteoclasts and their precursors (Flanagan and Chambers, 1991; Murakami *et al.*, 1995; Hughes *et al.*, 1995) or indirectly through effects on osteoblasts (Sahni *et al.*, 1993). Two classes of these compounds may be distinguished pharmacologically; the more potent, nitrogen-containing bisphosphonates act by inhibiting farnesyl diphosphate synthase, an enzyme of the mevalonate pathway, thereby preventing prenylation of small GTPase-signaling proteins required for normal cellular osteoclast function (Coxon *et al.*, 2006). Amino-bisphosphonates have also been shown to activate caspase-3-like enzymes, the cysteine proteinases that act as the main executioner enzymes during apoptosis (Benford *et al.*, 2001). It is conceivable, therefore, that these compounds may also affect the activity of enzymes involved in the degradation of collagen fragments. Whether this occurs in bone, which seems likely in view of the accumulation of bisphosphonates in this tissue, or in other organs involved in peptide processing is at present unknown. Thus, in addition to inhibiting bone resorption, bisphosphonates may also alter the patterns of collagen degradation products, a fact that is crucial in interpreting biochemical monitoring of these processes (see Disturbances of Degradative Metabolism).

Gastrointestinal Effects

Studies have shown that bone resorption is influenced by nutrient intake (Bjarnason *et al.*, 2002; Clowes *et al.*, 2002a), and some of these effects may have been interpreted previously as circadian or diurnal variations. Insulin clamp studies indicated that postprandial hyperinsulinemia was unlikely to explain the suppression of bone turnover with feeding, and suggested that the hypoglycemia-induced decrease in bone resorption may be related to changes in PTH or other hormones (Clowes *et al.*, 2002b).

Attempts to explain the postprandial decrease in bone resorption subsequently focused on the gastrointestinal hormones, glucose-dependent insulinotropic peptide (GIP), glucagon-like peptide-1 (GLP-1), and GLP-2. Of these, only GLP-2 appeared to play a direct role in bone remodeling, as evidenced by measurements of biochemical markers after intravenous or subcutaneous injections of these peptides (Henriksen *et al.*, 2003). There was an acute, dose-dependent decrease in bone resorption after GLP-2 administration, suggesting that part of the circadian variation in resorption may be owing to the nutrient-induced release of this hormone during the nonfasting period of the day. GLP-2 injections in postmenopausal women given at 10 PM reduced the nocturnal rise in bone resorption and increased bone formation markers (Henriksen *et al.*, 2004), and an extended study confirmed these findings (Henriksen *et al.*, 2007). The gastric hormone, grehlin, is increased during fasting, paralleling the changes in bone resorption, suggesting that this peptide might also mediate the effect. An observed normal postprandial decrease in bone resorption in patients with gastrectomy (Holst *et al.*, 2007) argues against this suggestion, however, and other studies have confirmed the lack of acute effects (Huda *et al.*, 2007).

RELEASE OF CROSS-LINKED COMPONENTS FROM BONE *IN VITRO*

The use of osteoclastic cells cultured on dentine slices or with bone particles has given information on the mechanisms and extent of collagen degradation in bone. Cross-linked N-telopeptide fragments (NTX) were shown to be released into medium from human bone, whereas no free pyridinium cross-links could be detected by HPLC (Apone *et al.*, 1997). Confocal microscopy of labeled bone surfaces has revealed the intracellular pathway of proteins, including degraded collagen type I, through osteoclasts (Nesbitt and Horton, 1997), and other studies indicate that cathepsin K co-localized with the degrading collagen (Nesbitt and Horton, 2003). These types of study, combining immunolocalization of collagen fragments with the response to enzyme inhibitors, provide a powerful technique to address the cellular mechanism of bone collagen resorption. Cathepsin K was shown to solubilize demineralized bone *in vitro* through cleavage at sites in both the telopeptides and within the collagen helix (Garnero *et al.*, 1998a).

Collagen Metabolites as Markers of Bone Metabolism

N- and C-Terminal Propeptides as Formation Markers

Procollagen type I, the initially synthesized product, is about 50% larger than the collagen molecule in fibrils,

having large extension peptides at both N- and C-terminal ends. These propeptides are removed *en bloc* by separate proteases at or near the cell surface during secretion of the molecule. The intact C-terminal propeptide (PICP) containing intermolecular disulfide bonds can be detected in the blood as a 100-kDa component (Melkko *et al.*, 1990) and several commercial assays are now available. The assay has been used successfully to assess growth (Trivedi *et al.*, 1991), but its sensitivity to relatively small changes in bone formation, such as those accompanying menopause, has been rather limited.

Immunoassays for the N-terminal propeptide of procollagen I (PINP) have received renewed interest as this molecular domain appears to have more favorable degradative metabolism and clearance characteristics. In serum, there are components related to the N-propeptide having apparent molecular masses of about 100 and 30 kDa and, despite initial uncertainties (Orum *et al.*, 1996; Melkko *et al.*, 1996), immunoassays that measure both molecular species (Jensen *et al.*, 1998) are now accepted as good markers of bone formation. PINP assays, which are now available on automated clinical analyzers, have proved to be particular useful in monitoring bone metastases (Luftner *et al.*, 2005; Pollmann *et al.*, 2007). Animal models are important particularly for drug development research and methods to monitor PINP in rat serum have been described using immunoassay (Rissanen *et al.*, 2007) and mass spectrometry (Han *et al.*, 2007).

Cross-links and Peptide Fragments as Bone Resorption Markers

Many of the bone resorption markers currently in use are based on components or fragments of collagen type I. Such assays, comprising predominantly those for pyridinium cross-links and the N- and C-telopeptides, have generally replaced urinary hydroxyproline and urinary hydroxylysine glycosides, assays for which were both technically demanding and prone to major inaccuracies. For urinary hydroxyproline, these problems stemmed primarily from the lack of specificity for bone, extensive metabolism of the marker in liver, and the major contribution of hydroxyproline from dietary sources. Hydroxylysine glycoside markers are less prone to dietary interference and HPLC assays have developed for urine (Moro *et al.*, 1984; Yoshihara *et al.*, 1993) and serum (Al-Dehaimi *et al.*, 1999). Although an immunoassay has been described for Gal-Hyl (Leigh *et al.*, 1998) most studies of this and the disaccharide marker for soft tissue, Glc-Gal-Hyl, have used HPLC assays (Rauch *et al.*, 2002).

Pyridinium Cross-Links

As discussed previously, pyridinium cross-links are maturation products of lysyl oxidase-mediated cross-linking and their concentrations in urine; therefore, they reflect only the degradation of insoluble collagen fibers and not of any precursors. The ratio PYD:DPD in urine is similar to the ratio of these two cross-links in bone, suggesting that both of the cross-links are likely to be derived predominantly from bone. Because of its more restricted tissue distribution, generally to mineralized tissues (Eyre *et al.*, 1984; Seibel *et al.*, 1992), DPD is often described as a more bone-specific marker: this notion was reinforced by the close correlation between DPD excretion and an independent, stable isotope method for determining bone turnover rate (Eastell *et al.*, 1997). Initially, the assays for pyridinium cross-links were HPLC methods with a hydrolysis and prefractionation step (Black *et al.*, 1988); despite later automation of the procedure (Pratt *et al.*, 1992), these procedures are time-consuming. The observation that the ratio of free to peptide-bound cross-links was similar in urine from healthy individuals and from patients with a range of metabolic bone disorders (Robins *et al.*, 1990; Abbiati *et al.*, 1993) opened the way for direct analysis of urine samples without the need for the hydrolysis step. This in turn led to the development of specific immunoassays for DPD (Robins *et al.*, 1994) or for both pyridinium cross-links (Gomez *et al.*, 1996), and some of these immunoassays are now more widely available on multiple clinical analyzers. The excretion of pyridinium cross-links has been shown to be independent of dietary ingestion of these compounds (Colwell *et al.*, 1993). Changes in the metabolism of the pyridinium components can, however, give rise to problems, particularly where this leads to alterations in the proportions of free to bound cross-links. Treatment with amino-bisphosphonates appears to give particular problems in this respect, as discussed later.

Peptide Assays

Instead of using cross-links themselves as markers, several groups have developed assays based on specific antibodies raised against isolated collagen peptides containing the cross-links. The NTX and ICTP assays exemplify this type of development.

NTX Assay. The antigen for the cross-linked N-telopeptide assay was isolated from the urine of a patient with Paget disease of bone, and an immunoassay based on a monoclonal antibody was developed (Hanson *et al.*, 1992). This assay showed detectable reaction with urine from normal individuals, as well as large increases associated with elevated turnover. Although the antibody recognizes components in urine containing pyridinium cross-links (Hanson *et al.*, 1992), this type of cross-link is not essential and peptides containing pyrrolic cross-links may also be detected (Hanson and Eyre, 1996). Some form of cross-link must, however, be present for antibody recognition, thus ensuring that only degradation products of mature tissue are detected.

ICTP Assay. This assay detects fragments from the C-telopeptide region of collagen type I. The antigen was a partially purified, cross-linked peptide from a bacterial collagenase digest of human bone collagen (Risteli *et al.*, 1993). Again, the isolated peptide contained pyridinium cross-links, but this type of bond was not essential for reactivity with the rabbit antiserum used in the assay. ICTP is a serum assay and metabolism of the analyte has proved to be an important factor limiting its application. The observation that cathepsin K cleaves within the epitope for the ICTP antibody (Sassi *et al.*, 2000) appears to explain why this assay is relatively insensitive to changes in bone remodeling mediated by normal osteoclastic activity. In contrast, pathological increases in bone degradation, such as those occurring in myeloma (Elomaa *et al.*, 1992), metastatic bone disease (Aruga *et al.*, 1997), or rheumatoid arthritis (Sassi *et al.*, 2003), are well detected by the assay, as other enzyme systems, probably including MMPs, seem to be involved.

CTX Assay. Developments of the CTX assay have been discussed in connection with the occurrence of α- and β-aspartyl residues within the C-terminal portion of collagen. These forms of assay, applicable to both urine and serum and also available on multiple clinical analyzers, now represent some of the most widely used assays for monitoring bone resorption.

DISTURBANCES OF DEGRADATIVE METABOLISM

As discussed previously, treatment with aminobisphosphonates represents a major area of uncertainty in the application of bone resorption markers. Because the proportion of free pyridinium cross-links is increased by the treatment, the apparent decrease in bone resorption indicated by these markers is less than the true value. This change is measurable and has been well documented. The pools of peptides undergoing further degradation to give free cross-links are, however, those being measured by the NTX and CTX assays. Consequently, the changes in degradative metabolism caused by bisphosphonates will result in decreased concentrations of these peptides larger than those warranted by the decrease in true bone resorption: the extent of these overestimates of bone resorption rate cannot be ascertained easily. In practical terms, these considerations have a limited impact on the applications of these markers to monitor treatment. Where more precise indications of the true changes in bone resorption rate are required, however, the use of total (hydrolyzed) pyridinium cross-links gives results less susceptible to changes in degradative metabolism.

CONCLUDING COMMENTS

In the past decade, major advances have been made in understanding the structure and metabolism of bone collagen. In terms of cross-linking, most of the structural components have been identified, although immunochemical studies have suggested that a significant proportion of mature, trifunctional cross-links within the C-terminal region of bone collagen have yet to be identified (Eriksen *et al.*, 2004). More information is needed on the functional significance of the different cross-links, and intriguing suggestions have been put forward on associations between the relative proportions of pyrrole and pyridinium cross-links and the structural organization and properties of bone trabeculae (Banse *et al.*, 2002a; Banse *et al.*, 2002b).

With the realization that BMD measurements lacked specificity in predicting fracture risk, particularly in patients treated with bisphosphonates, the concept of bone quality has attracted much attention. Although this property of bone is difficult to define precisely, many of the collagen maturation and aging changes discussed in this chapter are undoubtedly relevant to assessments of bone quality. In particular, maturation of cross-links is likely to have a profound effect on bone and the newer methods of FTIR and Raman spectroscopy now used to monitor such changes in spatially defined regions of bone may have important applications in this area of research. The isomerization and racemization of telopeptide aspartyl residues represent an additional area of research relevant to questions of bone quality and changes in the biomechanical properties of the tissue. Although the presence of such amino acid residues in bone collagen telopeptides may not contribute directly to changes in properties, these indices of age-related changes are likely to contribute to a panel of markers for bone quality, which will be the focus of future research.

Chapter 17

Noncollagenous Bone Matrix Proteins

Pamela Gehron Robey*

Craniofacial and Skeletal Diseases Branch, National Institute of Dental and Craniofacial Research, National Institutes of Health, Department of Health and Human Services, Bethesda, Maryland

INTRODUCTION

Although the organic matrix of bone is composed primarily of collagen(s) (as reviewed in a previous chapter), the existence of other noncollagenous components was first postulated by Herring and coworkers in the 1960s (Herring and Ashton, 1974). By using degradative techniques, a variety of carbohydrate-containing moieties were extracted and partially characterized. The major breakthrough in the chemical isolation and characterization of noncollagenous bone matrix proteins came with the development of techniques whereby proteins could be extracted in an intact form (Termine *et al.*, 1980, 1981). Although these procedures were suitable for the isolation of the more abundant bone matrix proteins, the advent of osteoblastic cultures that faithfully retain phenotypic traits of cells in this lineage allowed for the discovery of other proteins that are sequestered in the matrix. Although they are not as abundant as the so-called structural elements, their importance in bone physiology cannot be underestimated. This has been underscored by the identification of mutations in a number of these proteins that result in abnormal bone. Many of these low-abundance proteins are discussed in subsequent chapters.

Collagen(s) is by far and away the major organic constituent of bone matrix (Table I). However, collagen most likely is not the direct nucleator of hydroxyapatite deposition. Physicochemical studies based on predictions of the surface topography of the hydroxyapatite unit cell predict that such a nucleator would have a β-pleated sheet structure, a feature that is not found in the predicted structure of the collagen molecule (Addadi and Weiner, 1985). In addition, collagen is not present in the extracellular environment in an unbound form. There are a large number of matrix proteins that have been found to bind to collagen, thereby regulating fibril formation, and it is probable that collagen serves as scaffolding on which nucleators are oriented. Consequently, the nucleators of hydroxyapatite deposition are most likely members of the noncollagenous components of the organic bone matrix. This chapter discusses the major structural proteins (proteoglycans, glycoproteins, and γ-glutamic acid-containing proteins) found in bone matrix. These proteins have been reviewed extensively elsewhere (Zu *et al.*, 2007). This is an area that is expanding rapidly owing to the generation of better tools, such as antibodies, cDNA probes, and genomic constructs. These reagents have been quite useful in determining the pattern and regulation of expression. Furthermore, the development of transgenic animals that either overexpress or are deficient in these proteins has also provided insight into their potential function.

PROTEOGLYCANS

This class of molecules is characterized by the covalent attachment of long-chain polysaccharides (glycosaminoglycans, GAGs) to core protein molecules. GAGs are composed of repeating disaccharide units that are sulfated to varying degrees and include chondroitin sulfate (CS), dermatan sulfate (DS), keratan sulfate (KS), and heparan sulfate (HS). Hyaluronic acid (HA) is also a GAG found in bone, but is not attached to a core protein. Different subclasses of proteoglycans are generally characterized by the structure of the core protein and by the nature of the GAG (Table II). Although other types of molecules can be sulfated, proteoglycans bear greater than 95% of the sulfate groups within any organic matrix (Lamoureux *et al.*, 2007).

Aggrecan and Versican (PG-100)

There are two large chondroitin sulfate proteoglycans associated with skeletal tissue that are characterized by core proteins with globular domains at the amino and carboxy termini and by binding to hyaluronan to form large

TABLE I Characteristics of Collagen-Related Genes and Proteins Found in Bone Matrix

Collagens	Gene	Protein	Function
Type I	COL1A1 17q21.3-22 18 kb, 51 exons, 7.2 and 5.9 kb mRNA	$[\alpha l(I)_2\alpha 2(I)]$ $[\alpha 1(I)_3]$	Most abundant protein in bone matrix (90% of organic matrix), serves as scaffolding, binds and orients other proteins that nucleate hydroxyapatite deposition
	COL1A2 7q21.3-22 35 kb, 52 exons, 6.5 and 5.5 kb mRNA		
Type X	COL10A1	$[\alpha 1(x)_3]$	Present in hypertrophic cartilage but does not appear to regulate matrix mineralization
Others Type III Type V FACITS ?	COL3A1 2q24.3-q31 COL5A1 9q34.2 COL5A2 2q14 COL5A319p13.2	$[\alpha 1(III)]_3$ $[\alpha 1(V)_2\alpha 2(V)]$ $[\alpha 1(V)\alpha 2(V)\alpha 3(V)]$	Present in bone in trace amounts, may regulate collagen fibril diameter; their paucity in bone may explain the large diameter size of bone collagen fibrils

TABLE II Gene and Protein Characteristics of Proteoglycans, Leucine-Rich Repeat Proteins, and Glycosaminoglycans in Bone Matrix

	Gene	Protein	Function
Versican (PG-100)	5q 12-14 90 kb, 15 exons one splice variant 10, 9, 8 kb mRNAs	1×10^6 intact protein, ~360 kDa core, ~12 CS chains of 45 kDa, G1 and G3 globular domains with hyaluronan-binding sites, EGF- and CRP-like sequences	May "capture" space that is destined to become bone
Decorin	12q21-23 > 45 kb, 9 exons alternative promoters, 1.6 and 1.9 kb mRNA	~130 kDa intact protein, ~38–45 kDa core with 10 leucine-rich repeat sequences, 1 CS chain of 40 kDa	Binds to collagen and may regulate fibril diameter, binds to TGF-β and may modulate activity, inhibits cell attachment to fibronectin
Biglycan	Xq27 7 kb, 8 exons 2.1 and 2.6 kb mRNA	~270 kDa intact protein, ~38–45 kDa core protein with 12 leucine-rich repeat sequences, exons, 2 CS chains of 40 kDa	May bind to collagen, may bind to TGF-β, pericellular environment, a genetic determinant of peak bone mass
Fibromodulin	1q32 8.5 kb, 3 exons	59 kDa intact protein, 42 kDa core protein with leucine-rich repeat sequences, one N-linked KS chain	Binds to collagen, may regulate fibril formation, binds to TGF-β
Osteoglycin (Mimecan)	9q21,3-22 33 kb, 8 exons 3.7 kb mRNA	299 aa precursor, 105 aa mature protein leucine-rich repeat sequences	Binds to TGF-β, no GAG in bone, keratan sulfate in other tissues
Osteoadherin	9q21.3-22 4.5 kb mRNA	85 kDa intact protein, 47 kDa core protein, 11 leucine-rich repeat sequences, RGD sequence	May mediate cell attachment
Perlican	1p36.1	~660 kDa intact protein, 450 kDA core protein,3 70-100 kDA HS GAGs	Interacts with matrix components, regulates cell signaling
Glypican	Xq26	Lipid linked HSPG, 66 kDa core, 2 HS GAGs	Regulates BMP-SMAD signaling, regulates development.
Hyaluronan	Multigene complex	Multiple proteins associated outside of the cell, structure unknown	May work with versican-like molecule to capture space destined to become bone

aggregates. Aggrecan is virtually cartilage specific, but mRNA levels have been detected in developing bone (Wong *et al.*, 1992). In the nanomelic chick, there is a mutation in the aggrecan core protein such that it is not expressed in cartilage (Primorac et al., 1999). However, there is a slight effect on bones that form via the intramembranous pathway, an unexpected finding because these bones would not be expected to be affected by abnormal cartilage development. Mutation in the aggrecan gene results in a form of spondyloepiphyseal dysplasia in humans leading to premature osteoarthritis (Gleghorn *et al.*, 2005), and in mice, a mutation leading to a null allele results in cartilage matrix deficiency (cdm mice) (Watanabe *et al.*, 1994).

Closely related, but not identical, is a soft connective tissue-enriched proteoglycan termed versican, which is most localized to loose, interstitial mesenchyme in developing bone. It has been hypothesized that it captures space that will ultimately become bone (Fisher and Termine, 1985). It is this proteoglycan that is destroyed as osteogenesis progresses. It is noteworthy that the core protein of versican contains EGF-like sequences (Wight, 2002), and release of these sequences may influence the metabolism of cells in the osteoblastic lineage. As osteogenesis progresses, versican is replaced by two members of another class of proteoglycans that contain core proteins of a different chemical nature [decorin and biglycan (Fisher and Termine, 1985)]. In the *hdf* (heart defect) mouse, the versican gene is disrupted and the protein is not expressed. The mutation is embryonic lethal, and *in vitro* studies have shown defective chondrogenesis by limb mesenchyme (Williams *et al.*, 2005).

Decorin (PG-II) and Biglycan (PG-I)

The two small proteoglycans that are heavily enriched in bone matrix are decorin and biglycan, both of which contain chondroitin sulfate chains in bone, but bear dermatan sulfate in soft connective tissues. They are characterized by core proteins that contain a leucine-rich repeat (LRR) sequence, a property shared with proteins that are associated with morphogenesis such as *Drosophila* toll protein and chaoptin, the leucine-rich protein of serum and adenylyl cyclase (Fisher *et al.*, 1989). The three-dimensional structure of another protein containing this repeat sequence, ribonuclease inhibitor protein, has been determined by physicochemical methods, and the structure predicts a highly interactive surface for protein binding (Kobe and Deisenhofer, 1995). More recently, the crystal structure of decorin has been determined, and based on this analysis, it appears that the small leucine-rich repeat-containing proteoglycans (SLRPs) are not as curved as ribonuclease, and predicts that they may dimerize (McEwan *et al.*, 2006).

Although decorin and biglycan share many properties owing to the high degree of homology of their core proteins, they are also quite distinct, as best demonstrated by their pattern of expression (Bianco *et al.*, 1990). In cartilage, decorin is found in the interterritorial matrix away from the chondrocytes, whereas biglycan is in the intraterritorial matrix. In keeping with this pattern, during endochondral bone formation, decorin is widely distributed in a pattern that is virtually indistinguishable from that of type I collagen. It first appears in preosteoblasts, is maintained in fully mature osteoblasts, and is subsequently downregulated as cells become buried in the extracellular matrix to become osteocytes. However, biglycan exhibits a much more distinctive pattern of distribution. It is found in a pericellular location in unique areas undergoing morphological delineation. It is upregulated in osteoblasts and, interestingly, its expression is maintained in osteocytes and is localized to lacunae and canaliculi. It is speculated that osteocytes act as mechanoreceptors within the bone matrix (Bonewald, 2006), and that proteoglycans, possibly biglycan or cell surface-associated molecules (such as heparan sulfate proteoglycans), may act as transducers of sheer forces within canaliculi.

Transgenic mice that are deficient in decorin have primarily thin skin (Danielson *et al.*, 1997), whereas mice deficient in biglycan fail to achieve peak bone mass and develop osteopenia (Xu *et al.*, 1998). Animals that are double deficient for decorin and biglycan exhibit a phenotype reminiscent of the progeriod form of Ehlers–Danlos syndrome, whereby collagen fibrils are highly disrupted in both the dermis and in bone (Corsi *et al.*, 2002).

Although decorin and biglycan are found in soft connective tissues that do not mineralize, their presence in osteoid makes them potential candidates as nucleators of hydroxyapatite precipitation. Decorin does not appear to be a direct nucleator, because it has no effect on hydroxyapatite precipitation or crystal growth in solution assays, and it has a low affinity for calcium. In similar assays, biglycan has varying effects depending on concentration. Biglycan has a low affinity for calcium, and at low concentrations it facilitates hydroxyapatite precipitation, but inhibits precipitation at high concentrations. However, it is thought that sulfate-containing molecules must be removed prior to matrix mineralization and that they may mask sites that will ultimately act as nucleators. Consequently, it is unlikely that decorin or biglycan are initiators of matrix mineralization (reviewed in Zu *et al.*, 2007).

Both decorin and biglycan have been found to bind to transforming growth factor (TGF)-β and to regulate its availability and activity (Schonherr and Hausser, 2000). Decorin binds to collagen (decorating collagen fibrils), as does biglycan. Another activity has been demonstrated by *in vitro* cell attachment assays where decorin and biglycan were both found to inhibit bone cell attachment, presumably by binding to fibronectin and inhibiting its cell-matrix-binding capabilities (Grzesik and Robey, 1994). It is not clear how this *in vitro* phenomenon relates to normal

bone cell physiology, but it points to a role for these proteoglycans in modulating cell–matrix interactions.

Other Leucine-Rich Repeat Sequence Proteins and Proteoglycans

Interestingly, there are at least 60 proteins that have been found to contain LLRs, and many of them are also proteoglycan, SLRPs (Matsushima *et al*., 2000). One LRR found in bone is osteoglycin, previously termed osteoinductive factor and later found to be a protein bound to TGF-β (Ujita *et al*., 1995). This molecule is similar but not identical to the proteoglycan, PG-Lb, which has now been found to be epiphycan, localized primarily in epiphyseal cartilage. More recently, another LRR, asporin, has been localized to developing bone. Unlike other LRRs, it has an aspartic acid-rich amino sequence (Henry *et al*., 2001; Lorenzo *et al*., 2001). Other members of the SLRP family found in bone include fibromodulin, which contains keratan sulfate and binds to collagen fibrils in regions distinctly different from those of decorin (Hedbom and Heinegard, 1993), osteoadherin, which also contains the cell attachment sequence, RGD (Sommarin *et al*., 1998), and lumican, which may regulate collagen fibril formation. Although SLRPs appear to be "born to bind," definitive functions are not known. A mouse deficient for both biglycan and fibromodulin exhibits initial joint laxity, followed by development of extra sesmoid bones in many tendons and development of an osteoarthritis-like condition (Ameye *et al*., 2002), the lumican/fibromodulin knockout mouse resembles a variant of Ehlers–Danlos syndrome (OMIM 130000) and has ectopic calcification (Chakravarti *et al*., 2003). Other proteoglycans have been isolated from a variety of animal species by using varying techniques such as HAPGIII (so named for its ability to bind to hydroxyapatite) and PG-100, which has been shown subsequently to be homologous to versican as reviewed previously (Zu *et al*., 2007).

Although not generally found in the extracellular matrix, heparan sulfate proteoglycans found associated with, or intercalated into, cell membranes may be very influential in regulating bone cell metabolism. Receptors for several growth factors (TGF-β and FGF-2, to name two) have been found to associate with heparan sulfate (either bound covalently to core proteins or as free glycosaminoglycans). Intercalated heparan sulfate proteoglycans (the syndecan family) have been postulated to regulate cell growth, perhaps through modulation of growth factor and receptor activity (Schonherr and Hausser, 2000). Perlecan has been found to interact with matrix components and to regulate cell signaling. Knockout mice have a phenotype that resembles thanatophoric dysplasia type I (OMIM 187600), and mutations in humans are associated with Schwartz–Jample syndrome (OMIM 142461). Another class of heparan sulfate proteoglycans is linked to cell membranes by phosphoinositol linkages that are cleavable by phospholipase C (glypicans). Consequently, their activity may be in the pericellular environment or in the extracellular matrix. Mutations in glypican 3 give rise to Simpson–Golabi–Behmel Syndrome (OMIM 300037), and the knockout mouse has delayed endochondral bone formation and impaired osteoclastic development. The complete cast of heparan sulfate proteoglycans present in the cellular and pericellular environment in bone is not yet complete [see Zu *et al*. (2007) for a review].

HYALURONAN

This unsulfated glycosaminoglycan is not attached to a protein core and is synthesized by a completely different pathway (see Table II). Whereas other glycosaminoglycans are formed by the transfer of growing glycosaminoglycan chains from a lipid carrier (dolichol phosphate) to a protein carrier, hyaluronan is synthesized in the extracellular environment by a group of enzymes that are localized on the outer cell membrane. Large amounts of hyaluronan are synthesized during early stages of bone formation and may associate with versican to form high molecular weight aggregates, although this association has not been demonstrated to occur in developing bone. Very little is known about the potential function of hyaluronan in bone formation, but in other tissues it is speculated to participate in cell migration and differentiation (Fedarko *et al*., 1992).

GLYCOPROTEINS

Virtually all of the bone matrix proteins are modified post-translationally to contain either N- or O-linked oligosaccharides, many of which can be modified further by the addition of phosphate and/or sulfate (Table III). In general, compared with their soft connective tissue counterparts, bone matrix proteins are modified more extensively and in a different pattern. In some cases, differences in post-translational modifications result from differential splicing of heterogeneous nuclear RNA, but, in general, they result from differences in the activities of enzymes located along the intracellular pathway of secretion. The pattern of post-translational modifications may be cell type specific and consequently may be of use in distinguishing protein metabolism from one tissue type versus another. The development of probes and antibodies against these types of tissue-specific determinants may be of great diagnostic value.

The number of glycoproteins that have been identified in bone matrix grows by leaps and bounds every year. This, in part, is because of the explosion of sequence information from cDNA libraries, where one has the ability to pick up even the scarcest of clones. What follows next is a brief description of the more abundant bone matrix glycoproteins that most likely play major structural as well as metabolic roles. Other glycoprotein species have

TABLE III Gene and Protein Characteristics of Glycoproteins in Bone Matrix

	Gene	Protein	Function
Alkaline phosphatase	12p13.1 15 kb, 12 exons alternative promoters, one RFLP 2.5, 4.1, 4.7 kb mRNA	Two identical subunits of ~80 kDa, disulfide-bonded, tissue-specific post-translational modifications	Potential Ca^{2+} carrier, hydrolyzes inhibitors of mineral deposition such as pyrophosphates
Osteonectin	5q31-33 20 kb, 10 exons, one RFLP, 2.2, 3.0 kb mRNA	~35–45 kDa, intramolecular disulfide bonds, α-helical amino terminus with multiple low-affinity Ca^{2+} binding sites, two EF hand high-affinity Ca^{2+} sites, ovomucoid homology, glycosylated, phosphorylated, tissue-specific modifications	May mediate deposition of hydroxyapatite, binds to growth factors, may influence cell cycle, positive regulator of bone formation
Tetranectin	3p22 12 kb, 3 exons 1 kb mRNA	21 kDa protein composed of four identical subunits of 5.8 kDa, sequence homologies with asialoprotein receptor and G3 domain of aggrecan	Binds to plasminogen, may regulate matrix mineralization

been identified primarily as growth factors, produced both endogenously and exogenously, and will be covered in more detail elsewhere in this volume.

Osteonectin (SPARC, Culture Shock Protein, and BM40)

With the development of procedures to demineralize and extract bone matrix proteins without the use of degradative enzymes, osteonectin was one of the first proteins isolated in intact form. This molecule was so named owing to its ability to bind to Ca^{2+}, hydroxyapatite, and collagen and to nucleate hydroxyapatite deposition (Termine *et al.*, 1981). The osteonectin molecule contains several different structural features, the most notable of which is the presence of two EF hand high-affinity calcium-binding sites. These structures are usually found in intracellular proteins, such as calmodulin, that function in calcium metabolism (reviewed in Bhattacharya *et al.*, 2004).

Although osteonectin is highly enriched in bone, it is also expressed in a variety of other connective tissues at specific points during development, maturation, or repair processes *in vivo.* SPARC (secreted protein, acidic, rich in cysteine) was identified after induction by cAMP in teratocarcinoma cells and was found to be produced at very early stages of embryogenesis. Interestingly, if osteonectin is inactivated by the use of blocking antibodies during tadpole development, there is a disruption of somite formation and subsequent malformations in the head and trunk (Purcell *et al.*, 1993). Mice that are deficient of osteonectin present with severe cataracts (Bassuk *et al.*, 1999) and develop severe osteopenia characterized by decreased trabecular connectivity, decreased mineral content, but increased apatite crystal size (Delany *et al.*, 2000; Mansergh *et al.*, 2007).

Constitutive expression in the adult tissue is limited to cells associated intimately with mineralized tissues, such as hypertrophic chondrocytes, osteoblasts, and odontoblasts, and ion-transporting cells, such as mammary epithelium, distal tubule epithelium in the kidney, and salivary epithelium (cells associated with basement membrane, hence the name BM-40). Transient expression has been noted in other cell types, such as decidual cells in the uterus and in testis when cells are undergoing a maturation event. *In vitro*, expression appears to be deregulated rapidly, resulting in expression by cells that would not be expressing high levels *in situ*, hence its designation as a culture shock protein.

There have been numerous studies using both the intact molecule and peptides derived from different regions. Many of these structure–function studies have been performed in endothelial cell cultures, from which culture shock protein was originally isolated. From these studies, osteonectin has been implicated in regulating the progression of the cell through the cell cycle, cell shape, cell–matrix interactions, binding to metal ions, binding to growth factors, and modulating enzymatic activities (reviewed in Bradshaw and Sage, 2001). However, many of these activities have not been found or have not been tested in osteoblastic cultures. It should also be recognized that the activity of a peptide might not occur *in vivo* when it is taken out of context of the intact protein or naturally occurring degradative products.

Tetranectin

This tetrameric protein has been identified in woven bone and in tumors undergoing mineralization (Wewer *et al.*, 1994). This protein shares sequence homologies with globular domains of aggrecan and asialoprotein receptor. Mice deficient in tetranectin develop spinal deformities (Iba *et al.*, 2001), but the complete role that tetranectin plays ins osteogenesis is not known.

RGD-Containing Glycoproteins

Some of the major glycoproteins in bone matrix also contain the amino acid sequence Arg-Gly-Asp (RGD), which conveys the ability of the extracellular matrix protein to bind to the integrin class of cell surface receptors (reviewed in Luo *et al.*, 2007) (Table IV). This binding is the basis of many cell attachment activities that have been identified by *in vitro* analysis; however, it should be noted that it is not yet clear how this *in vitro* activity translates into *in vivo* physiology. The bone matrix contains a long list of RGD-containing glycoproteins (collagen(s), thrombospondin, fibronectin, vitronectin, fibrillins, osteoadherin, osteopontin, bone sialoprotein, dentin matrix protein 1, and proteins derived from the dentin sialophosphoprotein gene). Although this would appear to be a case of extreme redundancy, both *in vivo* and *in vitro* analysis indicates that the proteins are not equivalent in their abundance or pattern of expression during bone formation and in other tissues or in their *in vitro* activities (Grzesik and Robey, 1994).

Thrombospondins

Thrombospondins are a family of multifunctional proteins. Thrombospondin-1 was first identified as the most abundant protein in platelet α granules, but is found in many tissues during development, including bone (Robey *et al.*, 1989). Subsequently, five other members have been described, including COMP (cartilage oligomeric matrix protein) as thrombospondin-5 (reviewed in Adams and Lawler, 2004). In bone, all forms are present, synthesized by different cell types at different stages of maturation and development (Carron *et al.*, 1999). Thrombospondins have

TABLE IV Gene and Protein Characteristics of Glycoproteins in Bone Matrix - Continued RGD-Containing Glycoproteins

RGD-containing glycoproteins	Gene	Protein	Function
Thrombospondins	TSP-1 - 15q15 TSP-2 - 6q27 TSP-3 - 1q21-24 TSP-4 - 5q13 COMP - 19p13.1 4.5–16 kb, 22 exons 4.5–6.1 kb mRNA	~450 kDa molecule, three identical disulfide-linked subunits of ~150–180 kDa, homologies to fibrinogen, properdin, EGF, collagen, von Willebrand, P. *falciparum* and calmodulin, RGD at the C-terminal globular domain	Cell attachment (but usually not spreading), binds to heparin, platelets, type I and V collagens, throm fibrinogen, laminin, bin, plasminogen and plasminogen activator inhibitor, histidine-rich glycoprotein, TSP-2 is a negative regulator of bone formation
Fibronectin	2p14-16, 1q34-36 50 kb in chicken, 50 exons, multiple splice forms, 6 RFLPs,7.5 kb mRNA	~400 kDa with two nonidentical subunits of ~200 kDa, composed of type I, II, and III repeats, RGD in the 11th type III repeat 2/3 from N terminus	Binds to cells, fibrin heparin, gelatin, collagen
Vitronectin	17q ~ 70 kDa, RGD close to N 4.5 kb, 8 exons, 1.7 kb mRNA	Cell attachment protein, terminus, homology to somatomedin B, rich in cysteines, sulfated, phosphorylated	Binds to collagen, plasminogen and plasminogen activator inhibitor, and to heparin
Fibrillin	15q15-23, 5 (two different genes), 110 kb, 65 exons, 10 kb mRNA	350 kDa, EGF-like domains, RGD, cysteine motifs	May regulate elastic fiber formation
Osteopontin	4q13-21 8.2 kb, 7 exons, multiple alleles, one RFLP, one splice variant, several alleles 1.6 kb mRNA	~44–75 kDa, polyaspartyl stretches, no disulfide bonds, glycosylated, phosphorylated, RGD located 2/3 from the N terminus	Binds to cells, may regulate mineralization, may regulate proliferation, inhibits nitric oxide synthase, may regulate resistance to viral infection, a regulator of bone resorption
Bone sialoprotein	4q13-21 15 kb, 7 exons, 2.0 mRNA	~46–75 kDa, polyglutamyl stretches, no disulfide bonds, 50% carbohydrate, tyrosine-sulfated, RGD near the C terminus	Binds to cells, may initiate mineralization
BAG-75	Gene not yet isolated, mRNA not yet cloned	~75 kDa, sequence homologies to phosphophoryn, osteopontin and bone sialoprotein, 7% sialic acid, 8% phosphate	Binds to Ca^{2+}, may act as a cell attachment protein (RGD sequence not yet confirmed), may regulate bone resorption

many proposed activities, including binding to a large number of matrix proteins and cell surface proteins. *In vitro*, it mediates bone cell adhesion in an RGD-independent fashion, indicating the presence of other sequences in the molecule that are required. Furthermore, cell spreading requires the synthesis of other proteins. The thrombospondin-2-deficient mouse has been found to have increased cortical thickness compared with normal littermates, and to exhibit abnormalities in response to mechanical loading (Hankenson *et al*., 2006).

Fibronectin

Fibronectin is synthesized by virtually all connective tissue cells and is a major component of serum. There are a large number of different mRNA splice variants such that the number of potential forms is quite high. Consequently, bone matrix could contain fibronectin that originates from exogenous as well as endogenous sources (reviewed in Pankov and Yamada, 2002). The precise form that is present in cells in the osteoblastic lineage is unknown. Fibronectin is produced during early stages of bone formation and has been found to be highly upregulated in the osteoblastic cell layer. Interestingly, bone cell attachment to fibronectin *in vitro* is in an RGD-independent fashion (Grzesik and Robey, 1994). However, this correlates well with the expression of the fibronectin receptor, $\alpha_4\beta_1$, which binds to a sequence other than RGD in the fibronectin molecule and is also expressed by some osteoblastic cells. Cell–matrix interactions mediated by fibronectin-$\alpha_4\beta_1$ binding may play a role in the maturation sequence of cells in the osteoblastic lineage.

Vitronectin

This serum protein, first identified as S-protein owing to its cell-spreading activity, is found at low levels in mineralized matrix (Grzesik and Robey, 1994). Its cell surface receptor, $\alpha_v\beta_3$, is distributed broadly throughout bone tissue. There may also be endogenous synthesis of a related form (Seiffert, 1996). In addition to cell attachment activity, it also binds to and affects the activity of the plasminogen activator inhibitor (Schvartz *et al*., 1999).

Fibrillins

In addition to the RGD sequence, fibrillin-1 and fibrillin-2 are glycoproteins that also contain multiple EGF-like repeats. They are major components of microfibrils, and mutations in these genes lead to Marfan's syndrome, which exhibits abnormalities in bone growth (reviewed in Ramirez and Dietz, 2007). It is not yet known whether they are produced at a specific stage of bone formation, remodeling, or turnover; however, it is known that they associate with LTBP (latent TGF-β-binding protein) in microfibrils and regulate TGF-β bioactivity (Chaudhry *et al*., 2007).

Small Integrin-Binding Ligands with N-linked Glycosylation (SIBLINGs)

Several bone matrix proteins are characterized not only by the inclusion of RGD within their sequences, but also by the presence of relatively large amounts of sialic acid. Interestingly, they are clustered at 4q21-23 and appear to have arisen by gene duplication. For this reason, the family has been termed SIBLINGs (Fisher and Fedarko, 2003). The family includes osteopontin (OPN) and bone sialoprotein (BSP), the two best characterized proteins of the family, along with dentin matrix protein-1 (DMP-1), dentin sialoprotein (DSP), and dentin phosphoprotein (DPP), which are coded for by the same gene, now termed dentin sialophosphoprotein (DSPP), matrix extracellular glycoprotein (MEPE), and the more distantly related protein, enamelin (ENAM). Although the SIBLINGs were initially thought to be specific for mineralized tissues, it is now apparent that many of them are expressed in metabolically active epithelial cells (Ogbureke and Fisher, 2004, 2005). Interestingly, three of the family members bind to and activate specific matrix metalloproteinases (BSP–MMP-2, OPN–MMP-3, DMP1–MMP-9) (Fedarko *et al*., 2004).

Osteopontin (Spp, BSP-I)

This sialoprotein was first identified in bone matrix extracts, but it was also identified as the primary protein induced by cellular transformation. In bone, it is produced at late stages of osteoblastic maturation corresponding to stages of matrix formation just prior to mineralization. *In vitro*, it mediates the attachment of many cell types, including osteoclasts. In osteoclasts, it has also been reported to induce intracellular signaling pathways as well. In addition to the RGD sequence, it also contains stretches of polyaspartic acid and it has a fairly high affinity for Ca^{2+}; however, it does not appear to nucleate hydroxyapatite formation in several different assays. The osteopontin-deficient mouse develops normally, but has increased mineral content, although the crystals are smaller than normal. The role of osteopontin in skeletal homeostasis is covered in greater detail in another chapter in this volume, and there are numerous reviews available for its role in cancer and immune function (for example, Chakraborty *et al*., 2006; Scatena *et al*., 2007)].

Bone Sialoprotein (BSP-II)

The other major sialoprotein is bone sialoprotein, composed of 50% carbohydrate (12% is sialic acid) and stretches of polyglutamic acid (as opposed to polyaspartic acid in osteopontin). The RGD sequence is located at the carboxy terminus of the molecule, whereas it is located centrally in osteopontin. The sequence is also characterized by multiple tyrosine sulfation consensus

TABLE V Gene and Protein Characteristics of γ-Carboxy Glutamic Acid-Containing Proteins in Bone Matrix

	Gene	Protein	Function
Matrix Gla protein	12p 4 exons, 3.9 kb	~15 kDa, five Gla residues, one disulfide bridge, phosphoserine residues	May function in cartilage metabolism, a negative regulator of mineralization
Osteocalcin	4 exons, 1 1.2 kb	~5 kDa, one disulfide bridge, Gla residues located in α-helical region	May regulate activity of osteoclasts and their precursors, may mark the turning point between bone formation and resorption
Protein S	3q11.2	~75 kDa	May be made primarily in the liver, protein S deficiency may result in osteopenia

sequences found throughout the molecule, in particular, in regions flanking the RGD (Fisher *et al*., 1990). Sulfated BSP has been isolated in a number of animal species, but the levels appear to be variable.

Bone sialoprotein exhibits a more limited pattern of expression than osteopontin. In general, its expression is tightly associated to mineralization phenomena (although there are exceptions). In the skeleton, it is found at low levels in chondrocytes, in hypertrophic cartilage, in a subset of osteoblasts at the onset of matrix mineralization, and in osteoclasts (Bianco *et al*., 1991). Consequently, BSP expression marks a late stage of osteoblastic differentiation and an early stage of matrix mineralization. Outside of the skeleton, BSP is found in trophoblasts in placental membranes, which in late stages of gestation fuse and form mineralized foci. A BSP-deficient mouse has been generated, but reportedly does not exhibit a skeletal phenotype, possibly because of compensation of BSP function by other SIBLINGs.

BSP may be multifunctional in osteoblastic metabolism. It is very clear that it plays a role in matrix mineralization as supported by the timing of its appearance in relationship to the appearance of mineral and its Ca^{2+}-binding properties. BSP has a very high affinity for calcium. The polyglutamyl stretches were thought to be solely responsible for this high affinity; however, studies using recombinant peptides suggest that although the polyglutamyl stretches are required, they are not the sole determinants (Stubbs *et al*., 1997). Unlike osteopontin, BSP does nucleate hydroxyapatite deposition in a variety of assays.

It is also clear from *in vitro* assays that BSP is capable of mediating cell attachment, most likely through interaction with the somewhat ubiquitous $\alpha_v\beta_3$ (vitronectin) receptor. Bone cells attach to the intact molecule in an RGD-dependent fashion. However, when BSP is fragmented, either endogenously by cells or using commercially available enzymes, the fragment most active in cell attachment does not contain the RGD sequence (Mintz *et al*., 1993). Studies indicate that the sequence upstream from the RGD mediates attachment (in an RGD-independent fashion) and suggest that the integrin-binding site is more extended than had been envisioned previously. Sequences flanking the RGD site are often tyrosine sulfated. However, it is not known how sulfation influences BSP activity, as *in vitro*, unsulfated BSP appears to be equivalent in its activity. Once again, it is not clear if currently available *in vitro* assays are sufficiently sophisticated to determine what influence post-translational modifications, such as sulfation, have on the biological activity. In addition to sulfation, conformation of the RGD site may also influence the activity of the protein. Although the RGD region in fibronectin is found in a looped-out region that is stabilized by disulfide bonding, there are no disulfide bonds in BSP. However, the flanking sequences most likely influence the conformation of the region. The cyclic conformations also appear to have a higher affinity for cell surface receptors than linear sequences (van der Pluijm *et al*., 1996).

Dentin Matrix Protein 1 (DMP1)

Although DMP1 was originally thought to be specific to dentin, it was subsequently found to be synthesized by osteoblasts as well (D'Souza *et al*., 1997). However, its function in bone metabolism is not presently known. The DMP1-deficient mouse has craniofacial and growth plate abnormalities, along with rickets and osteomalacia owing to increased secretion of the phosphate-regulating hormone, FGF-23. The overproduction of FGF-23 is hypothesized to be caused by abnormal osteocyte function (Feng *et al*., 2006). Mutations in DMP1 have been identified in patients with dentinogenesis imperfecta (OMIM 600980) and in forms of autosomal recessive hypophosphatemic rickets (OMIM 241520).

TABLE VI Gene and Protein Characteristics of Serum Proteins Found in Bone Matrix

Serum proteins	Gene	Protein	Function
Albumin	4q11-22 17 kb, 15 exons	69 kDa, nonglycosylated, one sulfhydryl, 17 disulfide bonds, high-affinity hydrophobic binding pocket	Inhibits hydroxyapatite crystal growth
α_2HSglycoprotein	3 two RFLP 1.5 kb mRNA	Precursor protein of fetuin, cleaved to form A and B chains that are disulfide linked, Ala-Ala and Pro-Pro repeat sequences, N-linked oligosaccharides, cystatin-like domains	Promotes endocytosis, has opsonic properties, chemoattractant for monocytic cells, bovine analogue (fetuin) is a growth factor

Matrix, Extracellular, Phosphoglycoprotein (MEPE)

MEPE is expressed in bone and bone marrow, but also at high levels in the brain and low levels in the lung, kidney, and placenta. This gene is also highly expressed by tumors that induce osteomalacia, and it has been regarded as a potential phosphate-regulating hormone (Rowe *et al*., 2000). It is thought that the C-terminal portion of MEPE (ASARM), together with PHEX, regulates mineralization and renal phosphate metabolism (Rowe, 2004). Conversely, animals deficient in MEPE have significantly increased bone mass owing to increased numbers of trabeculae and increased cortical thickness (Gowen *et al*., 2003).

γ-Carboxy Glutamic Acid (GLA)-Containing Proteins

There are three proteins found in bone matrix that undergo γ-carboxylation via Vitamin K-dependent enzymes: matrix-gla-protein (MGP) (Price *et al*., 1983), osteocalcin (bone gla-protein, BGP) (Price *et al*., 1976), both of which are made by bone cells, and protein S (made primarily in the liver but also made by osteogenic cells) (Maillard *et al*., 1992) (Table V). The presence of di-carboxylic glutamyl (gla) residues confers calcium-binding properties to these proteins.

MGP is found in many connective tissues and is highly expressed in cartilage. It appears that the physiological role of MGP is to act as an inhibitor of mineral deposition. MGP-deficient mice develop calcification in extraskeletal sites such as in the aorta (Luo *et al*., 1997). Interestingly, the vascular calcification proceeds via transition of vascular smooth muscle cells into chondrocytes, which subsequently hypertrophy (El-Maadawy *et al*., 2003). In humans, mutations in MGP have been also been associated with excessive cartilage calcification (Keutel syndrome, OMIM 245150).

Whereas MGP is broadly expressed, osteocalcin is somewhat bone specific, although messenger RNA (mRNA) has been found in platelets and megakaryocytes (Thiede *et al*., 1994). Osteocalcin-deficient mice are reported to have increased bone mineral density compared with normal (Ducy *et al*., 1996). In human bone, it is concentrated in osteocytes, and its release may be a signal in the bone-turnover cascade (Kasai *et al*., 1994). Osteocalcin measurements in serum have proved valuable as a marker of bone turnover in metabolic disease states. Interestingly, it has been recently suggested that osteocalcin also acts as a hormone that influences energy metabolism by regulating insulin secretion, β-cell proliferation, and serum triglyceride (Lee *et al*., 2007).

SERUM PROTEINS

The presence of hydroxyapatite in the bone matrix accounts for the adsorption of a large number of proteins that are synthesized elsewhere and brought into the vicinity via the circulation (Delmas *et al*., 1984). Most of these proteins are synthesized in the liver and hematopoietic tissue and represent classes of immunoglobulins, carrier proteins, cytokines, chemokines, and growth factors. Interestingly, some of these proteins are also synthesized endogenously by cells in the osteoblastic lineage. It is not known if the origin of a particular factor (and hence proteins with potentially different post-translational modifications) affects biological activity or not.

Although serum proteins are not synthesized locally, they may have a significant impact on bone metabolism (Table VI). Albumin, which is synthesized by the liver, is concentrated in bone severalfold above levels found in the circulation. It is not known whether it plays a structural role in bone matrix formation but it does have an influence on hydroxyapatite formation. In *in vitro* assays, albumin inhibits hydroxyapatite growth by binding to several faces of the seed crystal (Garnett and Dieppe, 1990). In addition to this inhibitory activity, it also inhibits crystal aggregation.

Another serum protein, α_2-HS-glycoprotein, is even more highly concentrated in bone than albumin (up to 100 times more concentrated). It is known that α_2-HS-glycoprotein is the human analogue of bovine fetuin (Ohnishi *et al*., 1993). This protein is synthesized as a precursor that

contains a disulfide bond linking the amino- and carboxy-terminal regions. Subsequently, the midregion is cleaved and removed from the molecule, yielding the A and B peptides (much in the same way that insulin is processed). In rat, the midregion is not removed and the molecule consists of a single polypeptide. This protein also contains cystatin-like domains (disulfide-linked loop regions), and another member of this family has been identified in bone matrix extracts.

α_2-HS-glycoprotein has many proposed functions that may also be operative in bone cell metabolism. In other cell culture systems, it has been proposed to promote endocytosis and to have opsonic properties. It is also a chemoattractant for monocytic cells, and consequently, it may influence the influx of osteoclastic precursor cells into a particular area (Nakamura *et al*., 1999). Furthermore, it is a transforming growth factor-β type II receptor mimic and cytokine antagonist (Demetriou *et al*., 1996). Fetuin, the bovine homologue, has been found to be a major growth-promoting factor in serum, and results *in vitro* suggest that fetuin, along with transforming growth factor-β, inhibit osteogenesis (Binkert *et al*., 1999). Interestingly, deletion of the fetuin gene in mice leads to widespread ectopic calcification throughout the body (Jahnen-Dechent *et al*., 1997). Consequently, this protein may play a very important role in bone cell metabolism irrespective of whether or not it is synthesized locally.

OTHER PROTEINS

In addition to the proteins described earlier there are representatives of many other classes of proteins in the bone matrix, including proteolipids, enzymes and their inhibitors (including metalloproteinases and tissue inhibitors of metalloproteinase [TIMPs], plasminogen activator and plasminogen activator inhibitor, matrix phosphoprotein kinases, and lysosomal enzymes), morphogenetic proteins, and growth factors (Zu *et al*., 2007). Although their influence on bone cell metabolism is highly significant and they may cause significant alterations of the major structural elements of bone matrix, they are not necessarily part of the structural scaffold of bone matrix (with the possible exception of proteolipids). Important aspects of many of these classes of proteins are reviewed elsewhere.

CONTROL OF GENE EXPRESSION

In vivo and *in vitro* analysis clearly indicates that the timing and location of bone matrix protein expression are controlled by cells in the osteoblastic lineage as they progress toward maturation. The sequence of molecular events that regulate this progression is mediated by *cis*- and *trans*-acting factors present in the nucleus. *cis*-acting factors (also known as response elements) are present in the promoter region of the gene (the sequence upstream from the gene transcription start site). *cis*-acting factors can be roughly separated into two types: those that serve as binding sites for DNA polymerases (TATA, CAAT) and those that serve as binding sites for *trans*-acting (nuclear binding) factors. The interaction of *cis*-acting sequences within the promoter and *trans*-acting factors thereby modulates the activity of DNA polymerases, resulting in either activation or suppression of gene activity.

Utilizing both *in vitro* and *in vivo* analysis, virtually all of the promoters of the bone matrix protein genes have been characterized. Numerous *cis*-acting elements have been identified in all of the genes by direct sequence analysis, and their activity in serving as binding sites for *trans*-acting nuclear factors has been tested in DNA footprint and mobility assays. The most reliable information appears to be derived from studies utilizing transgenic animals that have been engineered to contain parts of the promoter, either wild type or mutated, linked to a reporter molecule, such as chloramphenicol transferase, β-galactosidase, or luciferase. This stance stems from studies of type I collagen and alkaline phosphatase gene expression whereby sequences identified as active by *in vitro* analysis were not active when placed in the animal. Transgenic animals of this sort have been generated for many of the bone matrix protein promoters and have provided a great deal of information on what factors are controlling both the timing and the location of bone matrix protein expression during bone formation. Salient features of the bone matrix protein promoters are listed in Table VII.

Although not complete, the mechanism by which the pattern of gene expression is controlled during osteogenesis is becoming clearer. This owes in large part to the identification of RUNX2/CBFA1, a transcription factor that is required for bone formation during development and for modeling and remodeling after birth (Ducy *et al*., 1997). Deletion of this gene resulted in the generation of mice that were completely devoid of bone (Komori *et al*., 1997). The promoters of bone matrix proteins expressed at late stages of osteoblastic maturation, osteopontin, bone sialoprotein, and osteocalcin, all have RUNX2/CBFA1-binding sites (Ducy *et al*., 1996), although it appears that CBFA1 represses bone sialoprotein expression (Javed *et al*., 2001). Transcriptional control of osteoblastic differentiation and of their secretory products is presented in detail elsewhere in this volume.

BONE MATRIX GLYCOPROTEINS AND ECTOPIC CALCIFICATIONS

The development of sensitive radiographic techniques, in addition to histological observations, has lead to the description of ectopic calcifications in many different pathological disorders. Although dystrophic mineralization has long been noted, it was not thought that bone matrix proteins

TABLE VII Promoter Characteristics of Bone-Related Genes

Protein	Polymerase-binding sites	*cis*-acting factors	*trans*-acting factors
Collagens			
α1(I)	TATA, CCAAT, CT rich, AG rich	SP1, VDRE, NF1	CAAT-binding protein, two silencers, VDR
α2(I)	CCAAT, CT rich	NF1	CAAT-binding protein, CTF/NF1
Proteoglycans			
Versican	TAATA, CCAAT		CAAT-binding factor
Decorin	Two promoters 1a- GC rich 1b -two TATA, one CAAT		
Biglycan	GC rich	+/− elements, XRE, SP1, CRE	
Fibromodulin	Analysis unavailable	AP1, AP5, NF-κ b, Pu/Py mirror repeat	
Glycoproteins		SP1, AP1, AP2, NF1, NF- κb	
Alkaline phosphatase	Two promoters, GC rich, TATA	3 SP1s	
Osteonectin	GA repeats, S1 sensitve	SP1, AP1, CRE, GHE, HSE, MRE, 1st intron, four CCTG repeats	VDR, RAR GGA-binding protein
Tetranectin	Analysis unavailable		
Thrombospondin	Three genes, TATA, GC rich, inverted CAAT	AP1, AP2, SP1, NFY, SRE, Egr1 Egr1	c-Jun
Fibronectin	TATA, CAAT, GC rich	CRE, SP1	ATF2
Vitronectin	Analysis not available		
Fibrillin	TATA, CCAAT, GC rich		
Osteopontin	Inverted CCAAT, TATA, GC box	+/− elements, SP1, AP, AP4, AP5, RAE, TPA, PEA3, THR, GHV, VDRE	VDR, CBFA1-binding site
Bone sialoprotein	Inverted TATA, inverted CCAAT	AP1, CRE, Homeobox, RARE, p53, GRE, VDRE, 1st intron, poly Py, poly AC, YY-1, supressor?	VDR, CBRA1-binding sites
BAG-75	Not yet cloned		
Gla-proteins			
Matrix Gla protein	TATA, CAAT	RARE, VDRE	VDR, RA
Osteocalcin	TATA, CCAAT, overlaps with other elements	OC Box, AP1, AP2, VCE, VDRE, CRE, GRE, NF1, MSX, VA	VDR, c-Fos, CBFA1-binding site
Protein S	Analysis not available		
Serum proteins			
Albumin	TATA, CCAAT	PGRBS, GRE	C/EBP, NHF1, FTF, NF1
α_2HS glycoprotein	Analysis unavailable		

played a role in generating this type of mineralization. Dystrophic mineralization (such as in traumatic muscle injury) is brought about by cell death (perhaps in the form of apoptosis) and not by the physiological pathways mediated by collagen or matrix vesicles. However, bone matrix proteins have been identified in mineralized foci in several different pathological states. Osteonectin, osteopontin, and bone sialoprotein have been found in mineralized foci in primary breast cancer (Bellahcene and Castronovo, 1997). Bone sialoprotein has also been found in other cancers, such as prostate, thyroid, and lung (Bellahcene *et al*., 1997, 1998; Waltregny *et al*., 1998). Although it is possible that, in some cases, the area mineralizes dystrophically and bone matrix proteins are adsorbed from the circulation because of their affinity to hydroxyapatite, mRNAs for the bone matrix proteins are expressed and it appears that the proteins are actually synthesized by resident cells that have been triggered (by factors that have yet to be identified).

Given the fact that bone matrix proteins are expressed by a number of different cancers, the next question is why? The processes by which cancer cells invade the surrounding normal tissue, gain entry into the circulation, and metastasize to other tissues is complex, but recently, members of the SIBLING family have emerged as active players in tumorigenesis and metastasis. SIBLINGs and their proteolytic fragments, along with their partner MMPS (for BSP, OPN, and DMP1, at least) may modulate a tumor cell's adhesion via specific integrins, matrix degradation, and migration (reviewed in Bellahcene *et al*., 2008).

Another example of ectopic calcification is seen in atherosclerosis, again, associated with the production of bone matrix proteins (Bini , 1999). Unlike dystrophic calcification,

vascular calcification appears to form in a regulated fashion similar to what is seen in bone formation in the skeleton. As mentioned earlier in relationship to the MGP-deficient mouse, it appears that vascular smooth muscle cells are emerging as the culprit. Factors that stimulate the expression of bone matrix proteins are not yet known but may include changes in cell–cell interactions, serum lipid composition, and phosphate concentrations, and apoptosis of vascular smooth muscle cells may initiate the process (Trion and van der Laarse, 2004). It may also be that a population of stem cells exists that are normally quiescent, but then are induced to become osteogenic, again, by factors that are not known. The aorta has its own vasculature, which may harbor these stem cells. Supporting this hypothesis, pericytes from the retinal vasculature have been shown to undergo bone formation *in vitro* and *in vivo* (Canfield *et al*., 2000).

SUMMARY

Bone matrix proteoglycans and glycoproteins are proportionally the most abundant constituents of the noncollagenous proteins in bone matrix. Proteoglycans with protein cores composed of the leucine-rich repeat sequences (decorin, biglycan, fibromodulin, and osteoadherin) are the predominant form found in mineralized matrix, although hyaluronan-binding forms (in particular, versican) are present during early stages of osteogenesis. They participate in matrix organization and in regulating growth factor activity. Glycoproteins such as alkaline phosphatase, osteonectin, RGD-containing proteins (osteoadherin, thrombospondin, fibronectin, vitronectin, osteopontin, and bone sialoprotein), fibrillin, and tetranectin are produced at different stages of osteoblastic maturation. They exhibit a broad array of functions ranging from control of cell proliferation, cell–matrix interactions, and mediation of hydroxyapatite deposition. The ectopic expression of bone matrix proteins may also play a significant role in pathological states such as bone metastasis in certain forms of cancer and atherosclerosis.

Chapter 18

Osteopontin

Masaki Noda*
Department of Molecular Pharmacology, Medical Research Institute, Tokyo Medical and Dental University, Tokyo, Japan

David T. Denhardt
Department of Cell Biology and Neuroscience, Rutgers University, Piscataway, New Jersey

Osteopontin (OPN) is one of the noncollagenous proteins present in bone matrix (Mark *et al.*, 1987). Independently, it was found to be present in the plasma of patients bearing highly metastatic tumors (Brown *et al.*, 1994). Another line of study revealed that the same molecule was expressed at high levels by activated T cells (Singh *et al.*, 1990). OPN was also characterized as a molecule that regulates the calcification of urinary stones because an antibody raised against it was able to block the formation of calcium oxalate-based stones (Shiraga *et al.*, 1992). The presence of OPN in various organs, including those with and without matrix, and also in plasma, suggests that this molecule could act both as a structural molecule and as a humoral factor, or cytokine (Nanci, 1999; Rittling and Denhardt, 1999; Denhardt *et al.*, 2001). The recent accumulation of a body of new data has opened a new era of studies on OPN function. This chapter focuses on these novel features of OPN.

STRUCTURE OF OSTEOPONTIN

The amino acid sequence of OPN has been determined for a number of species (Sodek *et al.*, 2000a). The conservation of much of the sequence suggests that this molecule has had a fundamental role in biological systems during evolution. OPN consists of about 300 amino acids. Importantly, an RGDS (arginine-glycine-aspartate-serine) motif is located in the midportion of the molecule. A thrombin cleavage site is located just carboxyl-terminal to the RGDS motif (Senger *et al.*, 1994; Bautista *et al.*, 1994); the products of thrombin cleavage can be observed when serum preparations are analyzed by gel electrophoresis.

However, intact OPN is more abundant than the cleavage product in blood (Kon *et al.*, 2000). Therefore, to assay the intact OPN concentration in human blood, plasma rather than serum should be prepared to avoid the effect of thrombin, which is activated in the process of serum preparation. Consideration has been given to measuring circulating OPN levels by ELISA to identify people with high risk for diseases such as osteoporosis or to evaluate the response of patients to particular clinical treatments. However, the fact that OPN is sequestered by factor H may be a complication (Fedarko *et al.*, 2000).

Clinical measurements of OPN in the circulatory system are not restricted only to patients with involutional bone diseases; such measurements may also be relevant to the evaluation of patients with metastatic tumors, with certain kinds of immunodeficiencies, with neuronal diseases, and with urinary stones. At this point, however, it is not certain what would be the contribution of intact OPN to such a diagnosis; also the significance of the levels of its cleavage products or the function of the cleavage products in each situation is unclear.

OPN is modified post-translationally by phosphorylation, the addition of sugars, such as sialic acid, and sulfation (Nagata *et al.*, 1989; Beninati *et al.*, 1994; Sørensen *et al.*, 1995; Neame and Butler, 1996; Zhu *et al.*, 1997; Safran *et al.*, 1998). The levels of glycosylation, sulfation, and phosphorylation vary depending on the organs and the time after synthesis when OPN modification is assessed. Phosphorylation modulates osteoblastic and osteoclastic functions and has been suggested to affect the efficiency of binding to various cell types (Saavedra, 1994; Lasa *et al.*, 1997; Katayama *et al.*, 1998; Ashkar *et al.*, 2000). Sulfation can affect the formation of mineralized bone nodules in culture (Nagata, 1989). So far, these data are mostly *in vitro*, and therefore, the physiological significance of such post-translational modifications has not been elucidated. It appears that differences in the post-translational modification of OPN expressed by different cell types regulate how it impacts on target cells (Razzouk *et al.*, 2002; Gericke *et al.*, 2005; Kazanecki *et al.*, 2007). Transgenic

*Corresponding author: Masaki Noda, Deapartment of Molecular Pharmacology, Medical Research Institute, Tokyo Medical an Dental University, Tokyo, Japan

("knock-in") mice having mutations in sites of post-translational modifications may help elucidate the specific function of each of the modifications.

OPN is encoded in seven exons (Craig and Denhardt, 1991; Hijiya *et al.*, 1994; Crosby *et al.*, 1995); however, additional, or alternative, exons are sometimes expressed because more than one mRNA species has been observed in Northern analyses. In the case of human OPN, alternative splicing may produce isoforms (Young *et al.*, 1990; Crivello and Delvin, 1992; Parrish and Ramos, 1997). Functional difference among the isoforms, as well as the difference in the expression patterns in various tissues, has not yet been clearly documented. As mentioned earlier, OPN has been identified in many tissues, and in these tissues this molecule could mediate communication between cells. Thus, OPN could be regarded as a cytokine. Modification and/or splicing would allow more opportunities for this molecule to function differently under particular conditions, thus contributing to the specificity of the signaling between cells.

OPN interacts with the molecules constituting bone matrix. Proteins in the bone matrix are 90% type I collagen and 10% a variety of noncollagenous proteins. OPN is known to bind covalently to fibronectin via transglutamination, and transglutamination of OPN increases its binding to collagen (Beninati *et al.*, 1994; Kaartinen *et al.*, 1999). Other molecules, such as bone sialoprotein (BSP), also bind covalently to type I collagen. Osteocalcin suppresses trans-glutaminase-catalyzed cross-linking of OPN (Kaartinen *et al.*, 1997). Such a network and mutual regulation among matrix proteins in bone may facilitate conformational changes of the molecules and hence could add additional functions or activation/inactivation switches to the molecules depending on the sites and composition of the interaction between the molecules. So far, however, whether such covalent bonding between matrix proteins and OPN or other noncollagenous molecules plays any role in the physiological maintenance of bone during the remodeling cycle or in pathological situations such as osteoporosis or osteopenia requires further elucidation of the functional aspects of this interaction.

Another unique structural property of OPN is a run of 10–12 aspartic acid residues. This motif gives rise to a localized high negative charge that may be important for the binding of OPN to bone mineral. OPN has a strong affinity to calcified matrix, such as bone, and also to pathological calcifications, such as those seen in sclerotic glomeruli and atherosclerosis. The high affinity of OPN for calcium has been suggested to modulate the nucleation of calcium phosphate during mineralization (Boskey, 1995; Contri *et al.*, 1996; Srivatsa *et al.*, 1997; Sodek *et al.*, 2000b); however, initial studies on the OPN-deficient mouse failed to indicate the presence of any major defect in mineralization (Rittling *et al.*, 1998). Possibly, the role of OPN in bone mineralization is compensated for by other regulatory systems for mineralization.

The molecular conformation of OPN may be altered by the binding of several molecules (Jain *et al.*, 2002). In the case of calcium, it is in a manner dependent on the concentration of the Ca^{2+} ion. It has been proposed that depending on such calcium ion-dependent conformational changes, OPN may reveal binding motifs such as the RGD sequence to its cognate receptors or to any other interactive extracellular matrix protein (Singh *et al.*, 1993; Bennett *et al.*, 1997). The dependence of the structure of OPN on the calcium concentration is an attractive feature of this molecule with regard to modulation of its function, e.g., during bone resorption by osteoclasts. For instance, when osteoclasts resorb bone, there are significant changes in the calcium concentration in the secondary lysosome-like closed space underneath the resorbing osteoclast. This calcium concentration may render signals through the calcium-sensing receptor (CasR), a seven membrane-spanning type receptor (Kameda *et al.*, 1998; Kanatani *et al.*, 1999). In addition to such calcium signaling, OPN may change its conformation depending on the calcium levels, thereby affecting cell function through its binding to the receptors expressed on the surface of the osteoclasts, such as $\alpha_v\beta_3$. However, it remains to be seen whether there is any functional significance of putative calcium-dependent structural changes in the OPN molecule.

OPN was first found as a secreted protein, and consequently one of the many names that have been given to it is secreted phosphoprotein (SPP) (Denhardt and Guo, 1994). In fact, when osteoblast-like cells such as ROS17/2.8 cells were stained for OPN protein, no major signal can be observed inside the cells. However, OPN mRNA expression in these cells and protein expression in the medium were easily detectable and were regulated by calciotropic agents and cytokines (Noda *et al.*, 1990; Farrington *et al.*, 1998; Hullinger *et al.*, 2001; Shi *et al.*, 2001; Shen and Christakos, 2005). A major part of the OPN protein moves out of the cell immediately after its synthesis. However, the presence of an intracellular form of OPN has been shown (Zohar *et al.*, 1998, 2000).

Whether the intracellular form of OPN is different from other forms of OPN with regard to alternative splicing or post-translational modifications is not known. The intracellular form of OPN was co-localized with CD44 in extensions of the osteoclasts known as podosomes, but not in the perinuclear regions where BSP has been observed (Suzuki *et al.*, 2000). Therefore, CD44 and OPN as well as the co-localized $\alpha_v\beta_3$ receptors probably form a complex that facilitates osteoblast movement. As osteoblasts produce OPN and $\alpha_v\beta_3$, migration of osteoblasts may also be dependent on the intracellular form of OPN, CD44, and/or $\alpha_v\beta_3$ integrins (Suzuki *et al.*, 2000). Like CD44, OPN may promote the multinucleation of osteoclast precursors because it was observed in OPN-null mice that mononuclear cells are more abundant than multinucleated cells, similar to the situation in the CD44-deficient mouse. Migration experiments conducted *in vitro* using the Boyden

chamber system indicated that the presence of OPN is required for efficient migration through the membrane pores. Furthermore, this migration was dependent on the presence of ezrin and hyaluronan. OPN also acts after its binding to $\alpha_v\beta_3$ integrins through Rho to stimulate gelsolin-associated phosphatidylinositol 3-kinase activity, podosome assembly, stress fiber formation, osteoclast motility, and bone resorption (Chellaiah *et al.*, 2000c).

RECEPTORS FOR OPN

OPN binds to $\alpha_v\beta_1$, $\alpha_v\beta_3$, $\alpha_v\beta_5$, $\alpha_4\beta_1$, α_5, and $\alpha_9\beta_1$ integrins (Denhardt and Noda, 1998; Duong *et al.*, 2000; Zheng *et al.*, 2000; Barry *et al.*, 2000). With regard to CD44 binding to OPN, the domain in OPN that interacts with CD44 is not the glycine-arginine-aspartic acid-serine (GRGDS) motif (Katagiri *et al.*, 1999). It has been found that some melanoma cells bind in a non-RGD dependent manner to the v6/v7 isoform of CD44. During the interaction, CD44 may bind to another cell surface molecule, integrins β, and that association may in turn provide the optimal interaction for CD44 to OPN (Katagiri *et al.*, 1999). Details of the interaction of CD44 with OPN remain to be characterized. The presence of additional cell receptors, the various isoforms of CD44, and variable post-translational modifications (phosphorylation and glycosylation) of OPN and CD44 are all complicating factors.

As OPN binds to the $\alpha_v\beta_3$ integrin, this integrin is considered to be responsible for major signals in response to the binding of OPN (Miyauchi *et al.*, 1991; Zimolo *et al.*, 1994). Postreceptor signaling via the $\alpha_v\beta_3$ integrin is dependent on the cellular background (Zheng *et al.*, 2000). In addition to regulating osteoclastic activity, OPN binding to the $\alpha_v\beta_3$ integrin activates osteoprotegerin expression and protects endothelial cells from apoptosis (Malyankar *et al.*, 2000).

Studies on β_3-deficient mice are relevant to understanding at least part of the function of OPN. Cells prepared from the bone marrow of β_3 knockout mice were able to differentiate into osteoclasts with efficiencies similar to the wild type (McHugh *et al.*, 2000). This observation indicates that $\alpha_v\beta_3$ is not required for osteoclast formation. The β_3 knockout mice were relatively normal while they were young but they revealed osteosclerosis radiographically by four months, suggesting that aging is one of the factors that reveals a phenotype in these mice (again, somewhat similar to OPN-deficient mice). Also, similar to OPN-deficient mice, there was a 3.5-fold increase in osteoclast number, which would appear to compensate for the mild hypocalcemia in the mice. Osteoclasts developed from the bone marrow cells of these mice were less efficient than wild-type cells in excavating pits on dentin slices, showing some inability to resorb bone, again similar to osteoclasts derived from OPN-deficient mice. The difference appears to reside in the cytoskeleton, which is abnormal in the β_3 knockout mice, suggesting a defect in intracellular signaling compared to osteoclasts derived from OPN-deficient mice where formation of the cytoskeleton and actin rings appeared to be normal when the osteoclasts were developed by culturing in the presence of RANKL and M-CSF (McHugh *et al.*, 2000; Ihara *et al.*, 2001). Overall, these findings on β_3 knockout mice further support the notion that the OPN signaling integrin through β_3 integrin pathway is important in regulation of osteoclastic activities.

OSTEOPONTIN AND CELL ATTACHMENT

OPN promotes the attachment of fibroblasts to plastic or glass substrates or other substrate (Somerman *et al.*, 1988; Reinholt *et al.*, 1990; Helfrich *et al.*, 1992; Cheng *et al.*, 2001; Standal *et al.*, 2004; Lim *et al.*, 2005). In bone, OPN is expressed in osteoblasts and its expression is enhanced by vitamin D (Prince *et al.*, 1987). Osteoclasts also express OPN when they are vigorously resorbing bone in human osteoarthritis specimens (Merry *et al.*, 1993; Dodds *et al.*, 1995; Connor *et al.*, 1995) and adhere to osteopontin (Bernards *et al.*, 2007). Osteoclasts express $\alpha_v\beta_3$ integrin at high levels (Horton *et al.*, 1995; Duong *et al.*, 2000). Although the $\alpha_v\beta_3$ integrin is not a specific marker of osteoclasts, monoclonal antibodies raised against osteoclasts appear to specifically visualize osteoclasts in bones due to its high abundance. Therefore, $\alpha_v\beta_3$ integrin can be used as one of the markers of osteoclasts.

Immunoelectron microscopic examination using colloidal gold particles indicated that OPN was observed underneath the clear zone of osteoclasts (Reinholt *et al.*, 1990). As clear zones are involved in the attachment of osteoclasts to the bone matrix, the location of OPN appeared to fit its hypothesized function. However, later experiments indicated that OPN may bind to $\alpha_v\beta_3$ integrin expressed on the basolateral surface of the osteoclasts and this binding also generates signals to modulate osteoclastic functions (Zimolo *et al.*, 1994; Zheng *et al.*, 2000). Therefore, including the intracellular form of OPN, osteoclasts could be regulated through more than one pathway of OPN signaling. However, it is not clear whether the intracellular form of OPN is the same in terms of its post-translational modification as the form released into the extracellular environment that binds to the cells in an autocrine or paracrine manner. With regard to osteoblasts, some reports indicated the presence of the $\alpha_v\beta_3$ integrin on the surface of osteoblasts (Gronthos *et al.*, 1997) and, therefore, there could be a certain commonality in OPN function in osteoblasts and osteoclasts.

OPN is deposited along the cement line and lamina limitans after the cessation of bone resorption by osteoclasts (McKee and Nanci, 1996). This OPN may provide a signal to the osteoblasts that are attracted to the bone resorption sites to deposit bone matrix to fill the cavity. Although OPN-deficient mice do not contain OPN in the cement lines, the bone architecture by itself was not largely different from

that of wild-type mice (Rittling *et al.*, 1998; Rittling and Denhardt, 1999). Therefore, significance of the signaling by OPN deposited at the cement line or lamina limitans may be minor *in vivo*. However, when the osteoclasts were cultured individually in an *in vitro* system, the absence of OPN resulted in reduced osteoclast function, indicating a role for this molecule, at least in these cells (Chellaiah *et al.*, 2000b; Ihara *et al.*, 2001; Chellaiash *et al.*, 2003; Chellaiash and Hruska, 2003) whereas osteoclasts resorb protein-free mineral efficiently in the absence of OPN (Contractor *et al.*, 2005). In arthritis experiments, OPN's role may be related to adherion although it would depend on the model of rheumatoid arthritis (Yumoto *et al.*, 2002; Gravallese, 2003; Jacobs *et al.*, 2004; Ishii *et al.*, 2004).

OSTEOPONTIN-DEPENDENT INTRACELLULAR SIGNALING

RGD-containing molecules, such as OPN, bind to integrins on the surface of osteoclasts and induce integrin clustering (Hruska *et al.*, 1995; Rodan and Rodan, 1997; Chellaiah *et al.*, 2000a, 2000c; Duong *et al.*, 2000). This binding initiates intracellular signaling by the phosphorylation of tyrosine residues, including tyrosine 402 on PYK2. The phosphorylation of tyrosine residues leads to binding of Src via its SH2 domain, which then further increases phosphorylation of PYK2 at other sites (Duong *et al.*, 1998, 2000; Duong and Rodan, 1999). Such phosphorylation amplifies the signal, attracting other adaptor molecules to bind PYK2, thereby eliciting signals that activate cellular functions, including adhesion and cytoskeletal structure formation needed for osteoclastic actions, such as sealing zone formation and intracellular trafficking (Nakamura *et al.*, 1999). PYK2 also binds to CAS; however, this interaction is independent of tyrosine phosphorylation (on both of the two molecules).

In addition to interactions between kinases and adaptor molecules at focal adhesion sites, p21GTPase activity is also important in OPN-dependent signaling. One of the targets of rho, mDial, which appears to be involved in the formation of the actin ring, associates with gelsolin located in the podosomes of osteoclasts (Chellaiah *et al.*, 2000b). In osteoclasts isolated from OPN-deficient mice, podosome structures were similar to those in wild-type mice; however, the mDial and gelsolin association was not observed and there was a reduction in osteoclast motility in response to vitronectin (Chellaiah *et al.*, 2000b). Relative to wild-type osteoclasts, OPN-deficient osteoclasts exhibited a decrease in CD44 expression on the cell surface. This defect in the surface expression of CD44 and dissociation between mDial and gelsolin was reversed by the addition of exogenous OPN. Thus, it was suggested that OPN-deficiency induces impairment in the motility of osteoclasts by the suppression of CD44 expression on the cell surface as well as a disruption of the association between mDial and gelsolin, thereby suppressing podosome assembly. However, exogenously added OPN only stimulated the motility of osteoclasts, without correcting the depth of the pits formed on the dentin slices. Thus, the two phenomena of reduced CD44 expression and suppression of the formation of podosomes could be causing the osteoclastic cells to be hypomotile (Chellaiah *et al.*, 2000b). This may be the explanation for the inefficiency of osteoclasts in OPN-deficient mice.

PHENOTYPE OF OSTEOPONTIN-DEFICIENT MICE

Because OPN-deficient mice produced independently in two laboratories do not show any structural alterations in bones at birth and during their subsequent growth period, there does not appear to be a requirement for OPN for normal development (Rittling *et al.*, 1998; Liaw *et al.*, 1998). In these OPN-deficient mouse strains, skeletal defects were not observed, whereas altered wound healing was noted by Liaw *et al.* (1998). Several possibilities have been proposed to explain the apparent lack of major bone phenotype. The first one was that in the absence of OPN, other related molecules, such as those containing RGDS, can compensate for the missing OPN. However, in OPN/vitronectin double knockout mice, no bone abnormalities were noted (Liaw *et al.*, 1998). Another possibility could be that the T-cell-based type I immune response deficiency that results from the absence of OPN (Ashkar *et al.*, 2000) could modify the response of bone due to the alteration in the cytokine network that is involved in the maintenance of both cellular immune responses and the mineralized skeleton.

OSTEOPONTIN PLAYS A ROLE IN ESTROGEN DEPLETION-INDUCED BONE LOSS

Although compensation may account for the normal development and normal maintenance of bone in OPN-deficient mice, the difference between the absence and the presence of OPN could be overt in circumstances of accelerated bone turnover, such as osteoporosis. A mouse osteoporosis model made by the ovariectomy-induced depletion of estrogen provided clues to answer the question on the role of OPN in the regulation of bone metabolism (Yoshitake *et al.*, 1999). After ovariectomy, both wild-type mice and OPN-deficient mice exhibited a similar reduction in uterine weight within 4 weeks, suggesting that the hormonal system in OPN-deficient mice was similar to that in wild-type mice, at least in terms of the uterine response to estrogens. That the estrogen system in OPN-deficient mice is normal is suggested by the normal rate of sexual maturation and

growth, as well as the normal fertility and littermate size in OPN-deficient mice.

Micro-CT analysis indicated that trabecular bone was lost and that the porosity in the epiphyseal portion of the long bones was decreased by about 60% in ovariectomized wild-type mice (Yoshitake *et al.*, 1999). Micro-CT analysis of the epiphyseal region of the long bones in sham-operated OPN-deficient mice revealed a slight increase in the trabecular bone volume compared to sham-operated wild-type mice. Fig. 1 shows that in contrast to the clear reduction in trabecular bone volume seen in wild-type mice after ovariectomy, no major reduction is observed in OPN-deficient mice. The preservation in the levels of bone volume even after ovariectomy could be due to the increase in bone formation, decrease in bone resorption, or both. Dynamic parameters for bone formation in these mice, such as bone formation rate/bone volume (BFR/BV), were increased in ovariectomized wild-type mice as shown previously. In the case of OPN-deficient sham-operated mice, the value was similar to sham-operated wild-type mice. However, no significant increase in BFR was observed in OPN-deficient mice, indicating the absence of high turnover status in bone metabolism even after ovariectomy. Similar basal levels of BFR suggest that bone formation activity in OPN-deficient mice is basically normal.

Morphological examination also supported the suppression of ovariectomy-induced bone resorption in OPN-deficient mice. The number of osteoclasts was increased about threefold 4 weeks after ovariectomy in wild-type mice. In contrast, basal levels of osteoclast number were relatively high in OPN-deficient mice and were not increased even after depletion of estrogen. The large number of osteoclasts, together with the increased bone volume in OPN-deficient mice, appears paradoxical. However, it could be due to a feedback system in the body that maintains serum calcium levels tightly by increasing osteoclast number to compensate for the reduced efficiency of the osteoclasts to resorb calcium from bone. Even with such compensation, a defect in the ability of osteoclasts to resorb bone is suggested by the relatively large trabecular bone volume in sham-operated OPN-deficient mice (Fig. 1; Yoshitake *et al.*, 1999).

OSTEOPONTIN FACILITATES RESORPTION AND ANGIOGENESIS OF ECTOPICALLY IMPLANTED BONE DISCS

Angiogenesis is important for bone resorption because osteoclast progenitors are derived from hematopoietic precursor cells. However, it is not known whether OPN promotes bone resorption by stimulating angiogenesis or by stimulating bone resorption via signaling through the bone matrix. Studies of ectopic bone (disc-shaped pieces punched out of the calvaria) implantation revealed a relationship between OPN and bone resorption associated with vascularization (Asou *et al.*, 2001). Wild-type bone

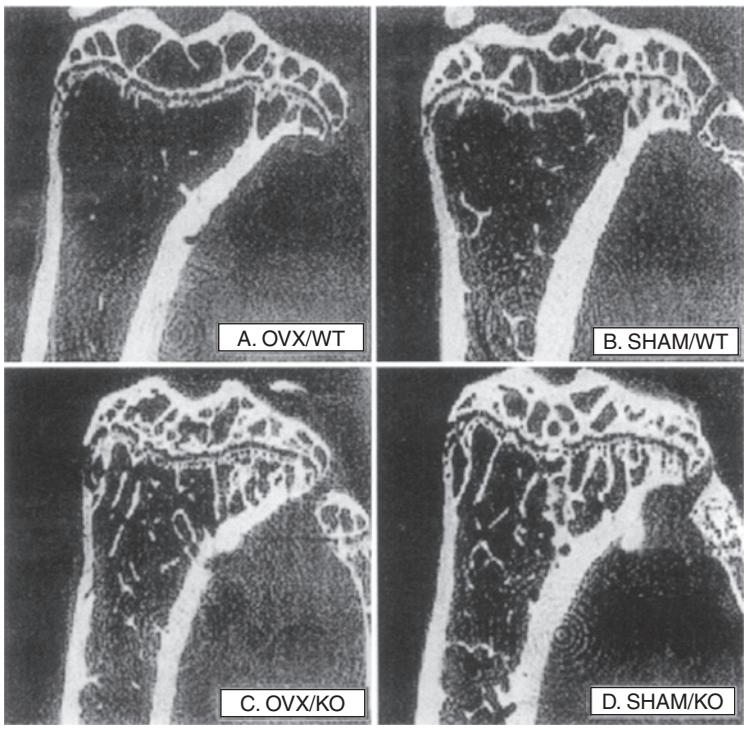

FIGURE 1 OPN deficiency suppresses ovariectomy-induced bone loss. Micro-CT images of the dissected tibia from ovariectomized and sham-operated mice, both wild-type and OPN-deficient, are shown. See Yoshitake *et al.* (1999) for further details.

implanted intramuscularly in the back of the wild-type mice was resorbed by about 25%. In contrast, bone from OPN-deficient mice implanted into OPN-deficient mice exhibited significantly less resorption (5%). Thus, about fivefold more bone was resorbed in the presence of OPN; this is illustrated in Fig. 2. The promotion of the resorption of ectopically implanted bone by OPN was associated with a larger number of osteoclasts attached to the surface of the wild-type bone than that in OPN-deficient bone. Furthermore, the number of CD31-positive vessels in the vicinity of bones implanted in OPN-deficient mice was reduced compared to the number of vessels in wild-type bones, suggesting that OPN deficiency may lead to a reduction in neovascularization of the ectopically implanted bones, and consequently a reduction in the number of osteoclasts and subsequent bone resorption efficiency. It is also possible that OPN may promote the survival of endothelial cells on the bone matrix.

Implantation of bone into muscle is suitable for the evaluation of bone resorption because of the higher vascularity of the tissues. However, detailed examination of the vascularization is difficult in intramuscular implantation experiments. Therefore, subcutaneous implantation was used to examine vascularization without making histological sections (Asou *et al.*, 2001). Significant vascularization was observed in both wild-type and OPN-deficient mice. Interestingly, the length of the blood vessels and the number of branch points in the vasculature on the surface of the implanted bone were both decreased in the OPN-deficient bone relative to wild-type bone. This observation further supports the notion that OPN facilitates vascularization of bone tissue. In these subcutaneous implantation experiments the absence of OPN reduced the TRAP-positive area on the bone disc. These observations indicate that OPN *in vivo* facilitates vascularization in association with osteoclast recruitment, thereby stimulating bone resorption.

Cross-mixing of the genotypes of implanted bone disc and host mouse indicated that when either the implanted bone disc or the host mouse was deficient in OPN, then bone resorption, as well as vascularization efficiency, was reduced to a value intermediate between wild-type and OPN-deficient mice. Angiogenic cytokines, such as FGF, upregulates OPN in epiphyseal growth plate (Weizmann *et al.*, 2005). Overall, data indicated the importance of OPN for vascularization during bone resorption. Because the growth plate in OPN-deficient mice is mostly normal it is intriguing to know how the mechanisms involved in vascularization and/or chondroclast accumulation in growth plate metabolism are different from those involved in bone resorption and the related vascularization.

PARATHYROID HORMONE-INDUCED BONE REGULATION AND OSTEOPONTIN

As ovariectomy experiments suggest that OPN-deficient mice are resistant to bone loss and ectopic bone implantation experiments indicate that these mice exhibit a reduced efficiency in bone resorption, it was suspected that OPN deficiency may cause a direct suppression of osteoclastic activity to resorb bone matrix. However, direct action of OPN in the process of bone resorption cannot be verified conclusively by ovariectomy experiments or ectopic bone resorption experiments per se. In this regard, bones in organ culture stimulated by parathyroid hormone have shown that OPN is directly responsible for bone resorption in the microenvironment of bone without influences from other humoral factors or vascularization (Ihara *et al.*, 2001). In these experiments, the release of $^{45}Ca^{2+}$ into the medium from $^{45}Ca^{2+}$-labeled forelimb bones excised from newborn OPN-deficient mice and cultured in the presence or absence of parathyroid hormone was measured.

The basal level of calcium release from organ cultures of forelimb bones of OPN-deficient mice was similar to that of wild-type bones. As reported previously, the presence of parathyroid hormone increased Ca^{2+} release from

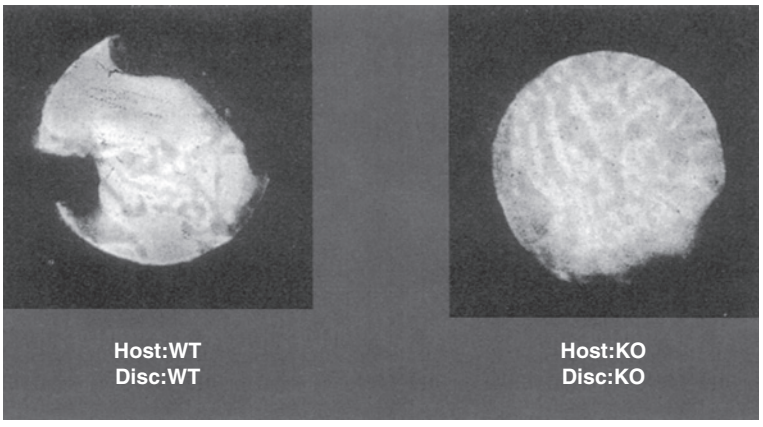

FIGURE 2 OPN is required for ectopic bone resorption. Bone discs derived from the calvaria were implanted intramuscularly as described by Asou *et al.* (2001). Four weeks after implantation, the discs were removed and examined using soft X-rays.

the cultured wild-type bones. However, as shown in Fig. 3, in the organ cultures of OPN-deficient forelimb bones, the increase in calcium release was not observed even in the presence of parathyroid hormone. Because parathyroid hormone increases osteoclast activities via stimulation of the expression of receptor activator of NFκB ligand (RANKL), soluble RANKL in combination with M-CSF was used to stimulate bone resorption. However, OPN-deficient bones failed to respond to RANKL and M-CSF, indicating that the deficiency is downstream of RANKL. Analysis of TRAP-positive cells in the cultured bones indicated that PTH treatment increased the number of these cells in wild-type bones. However, such an increase was not observed in the case of OPN-deficient bones, suggesting that the deficit resided in the inability to increase osteoclast number in the local environment of the bone rudiments. Because bone marrow cells or spleen cells taken from OPN-deficient mice were able to generate similar numbers of osteoclast-like TRAP-positive multinucleated cells with normal morphology compared to wild-type cells in culture in the presence of RANKL and M-CSF, the intrinsic ability of the progenitors to develop into osteoclasts per se is apparently not impaired in OPN-deficient mice. Actin ring formation and the distribution of Src appeared similar in osteoclasts developed in the presence of soluble RANKL and M-CSF in cultures of spleen cells regardless of the presence or absence of OPN. These observations suggest that in the absence of OPN in the microenvironment, PTH is unable to stimulate the formation of TRAP-positive cells; enabling PTH action could therefore be one mechanism by which OPN promotes bone resorption.

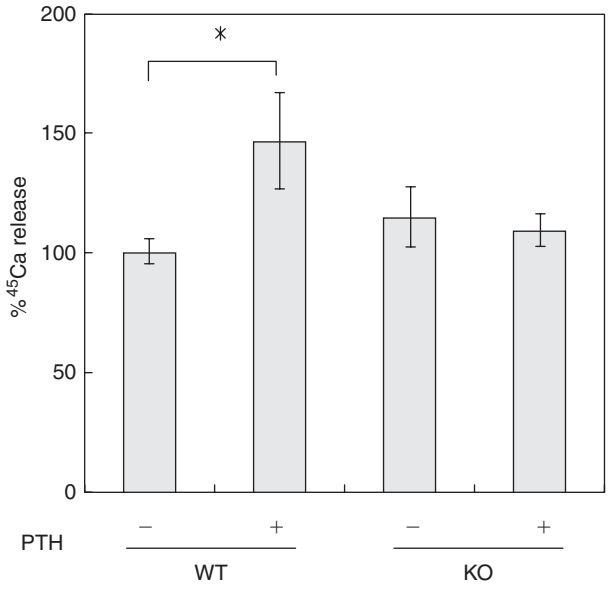

FIGURE 3 PTH fails to stimulate bone resorption in organ culture in the absence of OPN. Fetal forearm bones labeled with $45Ca^{2+}$ were incubated in the presence of 10–7 M parathyroid hormone. After 6 days the amount of $45Ca^{2+}$ in the medium was quantified. The percentage calcium released is determined relative to control cultures incubated in the absence of hormone (Ihara *et al*., 2001).

Parathyroid hormone has been used to treat severe osteoporosis patients. However, how PTH affects bones appears to be dependent on several signaling events and the full picture of the mechanism has not yet been understood. Because OPN expression is enhanced by PTH, the role of OPN in the case of PTH-induced increase in bone mass regulation was examined in the mice deficient in OPN. PTH treatment in the paradigm of intermittent administration increased bone mass levels in wild-type mice as known before. In the absence of osteopontin, however, intermittent PTH treatment further enhanced the levels of bone mass. Analysis of bone formation and bone resorption based on histomorphometry revealed that mineral apposition rate (MAR) and bone formation rate (BFR) were enhanced by PTH and this enhancement was further strengthened by the absence of OPN. Intermittent PTH treatment also enhanced the levels of osteoclast number and osteoclast surface in wild-type mice; however, the absence of OPN did not significantly alter the levels of such osteoclastic parameters in bone. Therefore, OPN acts as a negative signal to suppress the bone formation activity during PTH-induced enhancement of bone mass.

Whether such PTH-induced phenomena in the case of osteopontin deficiency were due to the PTH signal in bone or in tissues other than bone was tested by utilizing transgenic mice where constitutively active PTH/PTHrP receptor was specifically in osteoblasts using Collagen promoter. As known before, these transgenic mice exhibited high bone mass levels. When these transgenic mice were crossed with osteopontin-deficient mice, further enhancement of the increase in cancellous bone levels was observed. These data indicated that osteopontin function to suppress PTH signals was at least in part in osteoblastic compartment. Recent observations indicate that PTH signal would also be important for niche and OPN as well as osteoblasts are involved in the niche formation (Huang *et al.,* 2004; Nilsson *et al.,* 2005; Stier *et al.*, 2005).

Phosphate and mineralization-related events are also linked to OPN function as seen in *in vivo* models (Giachelli and Steitz, 2000; Steitz *et al.,* 2002; Boskey *et al.,* 2002; Harmey *et al.,* 2004; Harmey *et al.,* 2006). Osteopontin is present in bone; however, it is expressed in many other extra skeletal tissues. One of the tissues that express high levels of osteopontin is kidney. It is known that osteopontin expression in cells is enhanced by the presence of high levels of phosphate in the medium. In the body, blood phosphate levels are regulated by the function of kidney. High levels of blood phosphate could be seen in the case of chronic kidney diseases and such condition could lead to secondary hyperparathyroidism and resulting renal osteodystrophy, suggesting a link between OPN and phosphate *in vivo*. The role of osteopontin in such high phosphate-induced bone loss was tested in osteopontin-deficient mice. When the wild-type mice were fed a high phosphate diet, phosphate levels in the urine increased and high levels

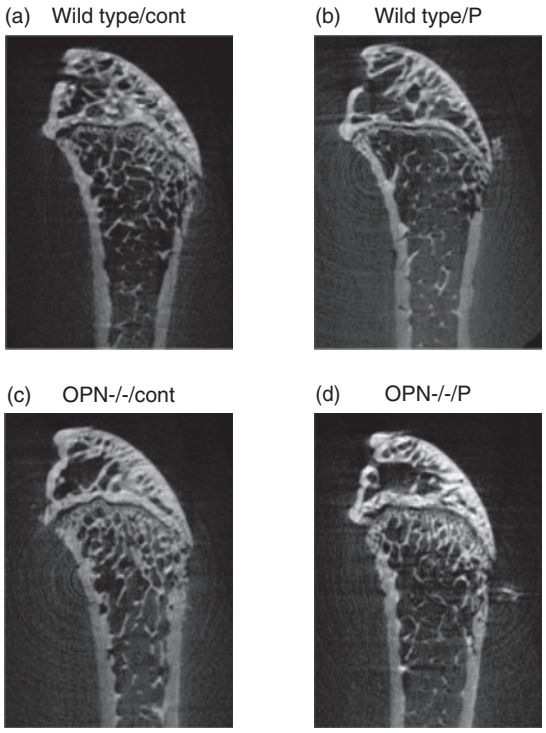

FIGURE 4 High phosphate diet-induced bone loss was prevented by osteopontin deficiency (Koyama *et al*., 2006).

of PTH were observed in association with resulting bone loss as known before. In the absence of osteopontin, however, although the levels of phosphate in the urine were high and PTH levels were also elevated, bone loss was not observed. Analysis based on histomorphometry indicated that a high phosphate diet induced an increase in the levels of osteoclast number and osteoclast surfaces were no longer observed in the absence of osteopontin. On the other hand, bone formation parameters were not significantly altered. These observations indicated that in the case of a high phosphate diet, osteopontin is highly expressed in kidney and ends up with the increase of osteoclastic activity to reduce bone due to the elevated levels of PTH. Thus, osteopontin could act as the signal to link the function of kidney to the downstream organs including bones Fig. 4; (Koyama *et al.,* 2006).

OSTEOPONTIN AND METASTATIC DISEASE

Many types of tumor cells express OPN. OPN levels in the serum of patients bearing highly metastatic tumors have been known to be high (Koeneman *et al.*, 1999; Liaw and Crawford, 1999; Carey *et al.*, 1999; Goodison *et al.*, 1999; Hotte *et al.,* 2002; Wai and Kuo, 2004; Cook *et al.,* 2006; Ramankulov *et al.,* 2007). It has been suggested that tumor cells produce OPN that could protect tumor cells themselves against the attack by macrophages by suppressing their production of nitric oxide (NO), which can kill tumor cells (Hwang *et al.*, 1994; Denhardt and Chambers, 1994; Feng *et al.*, 1995; Rollo *et al.*, 1996). Another possibility is that OPN may be a positive factor for the attachment of tumor cells and/or may promote proliferation of the tumor cells. Interestingly, in the absence of OPN, the bone loss associated with tumor growth at bone sites proceeds rapidly despite the osteoclast defects in OPN-deficient mice (Natasha *et al.,* 2006). Melanoma cells are known to be highly metastatic, and the prognosis of patients bearing those tumors is poor. Bone is one of the sites of melanoma tumor metastases. Once tumor cells metastasize to bones, the mass due to the growth of the tumor causes severe pain and eventually destroys bone tissue, resulting in debilitating fractures. Thus, elucidation of the role of OPN in the process of tumor metastasis is important.

B16 murine melanoma cells attached more effectively to a culture dish coated with recombinant OPN than with glutathione *S*-transferase (GST) control, while their proliferation was not affected by the presence of OPN (Nemoto *et al.*, 2001). The β_4 integrin and CD44 were detected in B16 melanoma cells, consistent with a previous report that these molecules may be involved in B16 cell attachment. An experimental metastasis assay based on the injection of B16 melanoma cells via an intracardiac route revealed a reduction in the number of melanoma tumors in the bones (5.4 ± 1.7) of OPN-deficient mice compared to the number in wild-type mice (11.5 ± 2.5). Injection of B16 cells into the left ventricle, which also gives rise to metastasis in nonskeletal tissues, yielded 6.5 ± 2.8 tumors in the adrenal glands of OPN-deficient mice and 17.8 ± 5.5 in wild-type animals. In the liver, the number of melanoma metastasis was 102.6 ± 53.0 for wild-type mice and 62.2 ± 32.2 for OPN-deficient mice although the difference was not statistically significant (Nemoto *et al.*, 2001).

As reported previously, a different injection route for experimental metastasis ends up with the different efficiency of metastasis to the different tissues in OPN-deficient mice. When B16 melanoma cells were injected via the femoral vein, most of the metastases were found in the lung. The number of lung metastases in OPN-deficient mice was 37.8 ± 11.4, whereas the number in wild-type mice reached up to 126.7 ± 42, again indicating suppression by the absence of OPN ($p < 0.05$). Overall, these experimental metastasis data clearly indicated that the presence of OPN promotes the metastasis of B16 melanoma cells to bone as well as to soft tissues such as lung regardless of the route of injection. In B16 cells, expression of OPN per se was very low and hardly detectable by Northern blot analyses compared to MC3T3-E1, an osteoblastic cell line that expresses high levels of OPN. Although the possibility that B16 melanoma cells still produce sufficient OPN to contribute to the metastatic process cannot be excluded, the clear difference in the number of experimental metastases seen in wild-type host animals

compared to OPN-deficient host animals indicates that at least the presence of OPN in the host makes a difference in the metastatic process (Nemoto *et al.*, 2001).

Metastasis of a tumor in an animal is a complex event initiated by the detachment of the cells from the primary tumor, followed by invasion into the vasculature (or lymphatics) and movement to other locations in the body where the tumor cells extravasate and establish themselves at a new site. Proliferation of the cells at that site and vascularization of the resulting tumor by the host animal produce an expanding tumor mass. Experimental metastasis by injection into the vascular system does not test the first steps in this process, steps that may also involve OPN. Even in the latter part of the process, how OPN functions to promote metastasis remains to be elucidated. Among vascular tissues, endothelial cells express $\alpha_v\beta_3$ integrin. Thus, vascularization may be one of the steps affected by the absence of OPN. Unfortunately, our injection model did not allow us to examine the vascularization process because the animals started to die before the tumor foci were large enough to see an effect of vascularization. Within the limit of this model, it appears that OPN can promote the metastasis of tumor cells to various skeletal and nonskeletal sites. It is known that the efficiency of metastasis can vary depending on the tumor cells and tissues. In fact, implantation of B16 cells in bone could reveal the importance of OPN (Ohyama *et al.,* 2004). The reduction of melanoma metastases in OPN-deficient mice observed in bone and lung suggests the involvement of a common mechanism operating in both tissues, for instance, possibly based on host macrophages. When tumor cells invade, host stromal cells have been suggested to produce OPN to attract macrophages, which in turn may suppress tumor formation (Crawford *et al.*, 1998). OPN also promotes migration of melanoma cells (Hayashi *et al.,* 2007). Our data suggest that OPN may be required in the initial attachment phase when the tumor cell is colonizing a new site.

ROLE OF OSTEOPONTIN IN MEDIATING MECHANICAL STRESS

OPN is expressed in cells of the osteoblastic lineage, and possibly those including osteocytes (Noble and Reeve, 2000), which are exposed to mechanical stress (Terai *et al.*, 1999). Because chondrocytes express receptors for cell attachment molecules, i.e., $\alpha_v\beta_3$ integrins, they are also candidates for the perception of mechanical stress *in vivo* (Loeser, 2000). In addition, proximal kidney tubules express OPN in response to renin–angiotensin following mechanical stimulation, such as cell stretch. When an antisense oligonucleotide was introduced to block angiotensinogen or angiotensin 2 type I receptor expression, there was a significant decrease in OPN mRNA expression compared to unstretched cells (Ricardo *et al.*, 2000).

Smooth muscle cells also express osteopontin and respond to mechanical stress. Pulsatile pressure increases the proliferation of differentiated smooth muscle cells; in contrast, cells expressing low levels of smooth muscle cell differentiation markers exhibit decreased cell growth and decreased MAPK signaling in response to the mechanical stress (Cappadona *et al.*, 1999).

Integrin-binding forces in intact cells have been measured by using atomic-force microscopy. In cells attached to hexapeptides, 32–97 pN were measured. In contrast, for larger molecules such as OPN and BSP, the experiments showed different binding affinities. Therefore, the context of the RGD sequence has considerable influence on the final binding strength of the receptor interaction (Lehenkari and Horton, 1999). OPN may affect nanomechanics in bone (Kavukcuoglu *et al.,* 2007).

In terms of tooth movement, OPN has been studied in rodent and human tissues (Lao *et al.,* 2006; Fujihara *et al.,* 2006; Wongkhantee *et al.,* 2007; Chung *et al.,* 2007; Aguiar and Arana-Chavez, 2007). Only 3.3% of the osteocytes in the interradicular septum of rats expressed OPN in the absence of the pressure. However, upon the application of pressure, the number was increased to 87.5% within 48 hours after initiation of the tooth movement. This movement was followed by a seventeen-fold increase in the number of osteoclasts on the pressure side. These responses were inhibited upon injection of an RGD peptide (Terai *et al.*, 1999). In another model of bone stress, distraction osteogenesis, chondrocyte-like cells in the osteotomized area expressed OPN, osteocalcin, and alkaline phosphatase; this region also includes many osteoblastic cells and preosteoblastic cells that are also expressing OPN at the boundary between fibrous tissue and new bone. The levels of OPN, osteonectin, bone matrix Gla protein, and osteocalcin mRNA expression were enhanced remarkably by the distraction force (0.25 mm/12 hours) (Sato *et al.*, 1998). Osteopontin has been known to be expressed in the alveolar bone and expression of osteopontin was enhanced along with the pressure application to the tooth in an experimental setting. Osteopontin levels in the bone-facing tooth are enhanced upon pressure application to the tooth. Osteopontin signal in the traction side was observed in the existing alveolar bone mainly on a cement line; however, osteopontin signal was not observed in the newly formed bone that appeared after the application of pressure to the tooth. This observation also coincided with the observation that osteopontin may play a role in suppression of bone formation. Thus, the presence and absence of osteopontin appear to be functionally related to bone remodeling in alveolar bone upon the movement of tooth (Fig. 5; Chung *et al.*, 2007).

In chondrogenic cells, induction of OPN expression by mechanical stress was found to be dependent on integrin receptors because OPN expression and the response to mechanical stimuli were blocked by the absence of

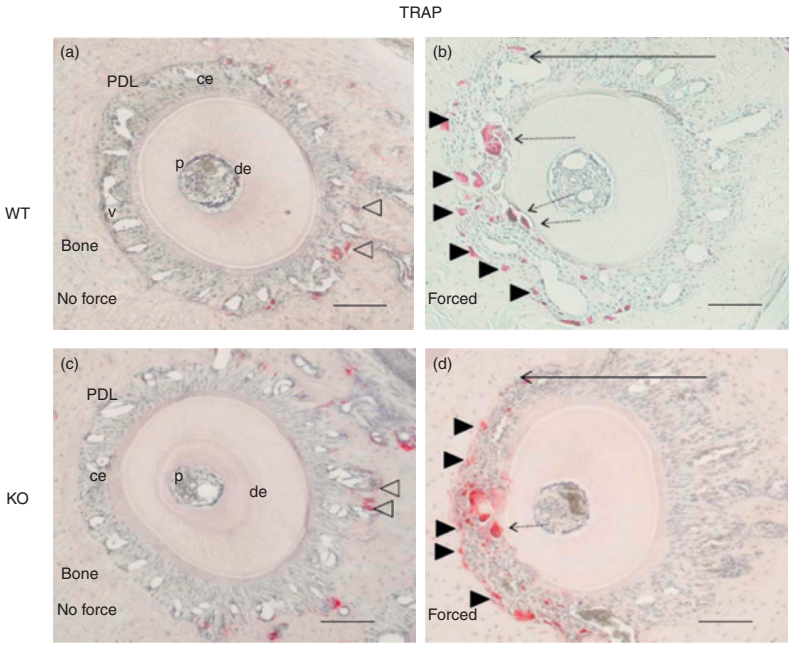

FIGURE 5 Odontoclast number, as well as tooth root resorption, were reduced in the absence of osteopontin in mouse tooth movement model. See Chung *et al.* (2007) for further details. (See plate section)

fibronectin, and by the presence of an RGD competitor (Carvalho *et al.*, 1998). These data indicate that osteopontin expression is enhanced in response to mechanical stimuli and that it is mediated by certain integrins recognizing fibronectin.

As mentioned, OPN expression is regulated by mechanical stress, whereas OPN itself is also involved in bone resorption, and possibly in bone formation. These observations suggest that OPN plays one or more roles during metabolic changes in response to mechanical loading. The question of whether OPN is involved in the mechanical stress-mediated regulation of bone metabolism was tested in a tail suspension model, which is one of the representative models to study unloading effects on bone metabolism (Vico, 1998; Vico *et al.*, 1998, 2000; Bikle and Halloran, 1999; Marie *et al.*, 2000). Unloading causes suppression of bone formation in growing rodents; however, it is not clear whether the bone resorption side is affected by tail suspension-based unloading in rodents.

To examine the role of OPN in regulation of bone loss induced by unloading, OPN-deficient mice were subjected to tail suspension. Micro-CT analysis of the metaphyseal region of the long bones indicated an increase in sparsity in wild-type mice after unloading as expected. However, no such increase in sparsity was observed in OPN-deficient mice. Quantification of the fractional trabecular bone volume indicated about 50% reduction in the wild-type animals. In contrast, no such reduction in bone volume was observed in OPN-deficient mice (Ishijima *et al.*, 2001). Biochemically, a reduction in bone volume was reflected by the increase in the bone resorption marker deoxypyridinolin, which is secreted in the urine of the mice. In wild-type mice, deoxypyridinolin secretion was increased. However, no such increase was detected in the tail-uspended OPN-deficient mice, indicating that systemic bone resorption due to tail suspension was suppressed in OPN-deficient mice.

The cellular basis for the alteration in unloading-induced bone loss in OPN-deficient mice was revealed by histomorphometric analysis. As expected, the number of osteoclasts was increased by about 150% in wild-type mice; this increase was not observed in OPN-deficient mice. In parallel to the number of osteoclasts, the osteoclast surface was also increased in wild-type but not in OPN-deficient mice. This inability of osteoclasts to respond to unloading may be due to a defect in the signaling system to support osteoclastogenesis. However, *in vitro* osteoclastogenesis experiments using RANKL and M-CSF indicated that TRAP-positive multinucleated cell formation was similar regardless of unloading or loading and/or difference in genotypes. Thus, suppression of the response to unloading in the case of osteoclastogenesis in OPN-deficient mice would be due to the signaling prior to osteoclastogenesis, as the intrinsic ability for osteoclastogenesis in the precursor cells per se does not seem to be impaired (Ihara *et al.*, 2001). Therefore, certain extracellular signaling could be lost in OPN-deficient mice. This possibility was also suggested by the analysis of the osteoblastic cells.

Osteoblasts are regarded as central players in regulating bone metabolism because they express receptors for

parathyroid hormone, prostaglandins, and vitamin D—all major humoral factors that regulate bone metabolism. In addition, they are thought to be the cells that respond to mechanical stress. Analysis of osteoblastic activity in tail-suspended mice indicated suppression of bone formation rate as well as mineral apposition rate in wild-type mice, as has been reported previously. However, a reduction in the values of these two parameters of osteoblastic bone formation did not occur when OPN-deficient mice were subjected to unloading by tail suspension (Ishijima *et al.*, 2001). Because reduction of bone formation was not affected in experiments where bisphosphonate was administered to tail-suspended animals to block bone resorption due to unloading, the two phenomena appear to be regulated independently; alternatively, the bone resorption aspect could be downstream of the bone formation aspect. However, this may not be the case as increase in bone could be observed earlier than resorption after tail suspension relative to alterations in bone formation.

The inability of osteoblasts to respond to unloading in OPN-deficient mice suggests that OPN is involved in mediating the signaling induced by tail suspension to suppress the function of osteoblastic cells. This suppression, in turn, could give another signal to increase osteoclastic activities during the loss of bone mass in tail-suspended mice. Bone resorption due to unloading occurs immediately after the exposure of animals and human to unloading conditions. However, it is not known whether such an early response of the osteoclasts to unloading is a direct or indirect phenomenon. Because osteoblastic activity, i.e., bone formation, can be detectable morphologically only after a relatively long stimulation period (a week or two) compared to bone resorption, and because the bone formation rate, though slow to change, is the most reliable marker for bone formation *in vivo*, it is possible that initial signals elicited by osteoblasts in the early period of time after exposure to loading and/or unloading have not yet been recognized by the current techniques.

To obtain further insight into the mechanism of the effects of mechanical stress, events occurring immediately after loading or unloading must be investigated by using methodology suitable to detect small changes in the metabolism or to detect signals elicited by the cells in the local environment. By such analyses it is still to be elucidated whether the absence of OPN by itself could impair sensing of the mechanical stress in the case of OPN-deficient mice directly in the osteoblasts or indirectly by prohibiting osteoblastic cells via producing other possible loading-induced signals or by delivering the molecular messenger molecules to activate osteoclasts in response to unloading. Analyses of the events that are taking place at the interface between cells and extracellular components, as well as in the intracellular signaling process resulting in modified gene expression or protein function in the early period of unloading in the case of OPN-deficient mice, may yield clues to long-standing questions regarding how bone mass is lost in response to unloading. Studies have suggested that adherent bone cells unable to synthesize OPN tended to have a defect in their ability to respond to a fluid flow stimulus or orthodontic force (Ishijima *et al.*, 2000; You *et al.*, 2001; Ishijima *et al.*, 2002; Morinobu *et al.*, 2003; Denhardt *et al.*, 2005; Ishijima *et al.*, 2006; Ishijima *et al.*, 2007). Prostaglandins induced by mechanical stress may also be important as EP4 agonist action in bone is modulated by OPN (Kato *et al.*, 2007).
