gross aberrations in fetal liver hematopoiesis, a total block of T-cell differentiation, and a retarded or missing lower jaw area (Pandolfi *et al.,* 1995; Lim *et al.,* 2000). Abnormalities of parathyroid development were not reported. These Gata3 −/− mice had an anatomically normal sympathetic nervous system, yet the sympathetic ganglia lacked tyrosine hydroxylase and dopamine beta-hydroxylase, which are key enzymes that convert tyrosine to L-DOPA and dopamine to noradrenaline, respectively, in the catecholamine synthesis pathway. Thus, the Gata −/− mice lacked noradrenaline in the sympathetic neurons, and this was contributing to the early embryonic lethality (Lim *et al.,* 2000). Feeding of catecholamine intermediates to the pregnant dams helped to partially rescue the Gata −/− embryos to 12.5 to 16.5 dpc. These older, pharmacologically rescued Gata −/− embryos showed abnormalities that could not be detected in the untreated mice (Lim *et al.,* 2000). These late embryonic defects included thymic hypoplasia, a thin-walled ventricular septum, a poorly developed mandible, other developmental defects in structures derived from the cephalic neural crest cells, renal hypoplasia, a failure to form the metanephros, and an aberrant elongation of the nephric duct along the anteroposterior axis of the embryo (Lim *et al.,* 2000; Grote *et al.,* 2005). The defect of the nephric duct, which consisted of an abnormal morphogenesis and guidance in the developing kidney, was characterized by the loss of Ret expression that is an essential component of the glial-derived-nerve-factor (GDNF) signaling pathway involved in ureteric bud formation and nephric duct guidance (Grote *et al.,* 2005). Parathyroid development was not studied in the catecholamine rescued Gata3 −/− mice. Thus, Gata3 has a role in the differentiation of multiple cell lineages during embryogenesis as well as being a key regulator of nephric duct morphogenesis and guidance of the nephric duct in its caudal extension in the pro/mesonephric kidney (Lim *et al.,* 2000; Grote *et al.,* 2005).

Role of GATA3 in Developmental Pathogenesis

The mechanisms whereby GATA3 haploinsufficiency leads to the phenotypic features of the HDR syndrome remain to be elucidated. Important clues have been obtained from *in vitro* studies and from *in vivo* studies of the mouse knockout. The *in vitro* studies have shown that the HDR-associated GATA3 mutations do result in impaired binding to the target DNA motif, and this in turn will alter the transcription role of GATA3. However, the genes that are under the transcription regulation of GATA3 in the different organs remain largely unknown with the exceptions of the T-cell antigen receptor subunits, interleukin 5 (IL5) and Ret (Marine et al., 1991; Zheng *et al.*, 1997; Zhang *et al.*,1997; Grote *et al.,* 2005). Despite the essential role of GATA3 in determining T-cell lineage (Zhang *et al.,* 1997), it is important to note GATA3 haploinsufficiency in the HDR patients is not associated with immunodeficiency (van Esch *et al.,* 2000; Lichtner *et al.,* 2000), indicating either that reduced amounts of GATA3 are sufficient for T-cell development, or that GATA1 and GATA2 may be able to compensate for the loss of GATA3. The regulation of Ret expression by GATA3 is of importance in the development of the kidney and nephric duct (Grote *et al.,* 2005). Moreover, Gata3 and Ret form part of an important transcriptional cascade, whereby Pax proteins (see earlier discussion)—Pax2 and Pax8—participate upstream to activate Gata3 (Grote *et al.,* 2005). However, it is important to note that the altered renal morphogenesis is observed only in the Gata3 −/− mice and not in the Gata3 +/− mice, which unlike the HDR patients who are also heterozygous for the GATA3 mutation, have normal kidneys (Pandolfi *et al.,* 1995). Thus, there are important phenotypic differences between Gata3 +/− mice and HDR patients, who are heterozygous for GATA3 mutations, and the mechanisms underlying these interspecies differences and the tissue-specific differences that conference susceptibility to GATA3 haploinsufficiency remain to be elucidated. In contrast to these renal differences between HDR patients and Gata +/− mice, there are marked similarities in the hearing loss (Bilous *et al.,* 1992; Lichtner *et al.,* 2000; van der Wees *et al.,* 2004; van Looij *et al.,* 2005). It has not been possible to perform detailed functional and histological studies on the auditory system of HDR patients, but such studies in the Gata3 +/− mice have revealed that the hearing loss is due to degeneration and loss of the outer hair cells which progressively involves the other types of hair cells and nerve fibers in the cochlea (van der Wees *et al.,* 2004, van Looij *et al.,* 2005). The genes under the transcriptional regulator of GATA3 in the cochlea remain to be identified. The morphological changes and genetic pathways involved in the parathyroids of HDR patients and Gata3 knockout also remain unknown. Thus, although the HDR phenotype is consistent with the expression pattern of GATA3 during human and mouse embryogenesis in the developing kidney (ureteric bud, collecting duct system, and mesangial cells), otic vesicle, and parathyroids, much remains unknown regarding the underlying transcription pathways and the basis of the interspecies differences between the Gata3 +/− mice and the HDR patients.

Kenney-Caffey and Sanjad-Sakati Syndromes

Hypoparathyroidism has been reported to occur in over 50% of patients with the Kenny-Caffey syndrome, which is associated with short stature, osteosclerosis and cortical thickening of the long bones, delayed closure of the anterior fontanel, basal ganglia calcification, nanophthalmos, and hyperopia (Fanconi *et al.,* 1986; Bergada *et al.,* 1988; Franceschini *et al.,* 1992). Parathyroid tissue could not be found in a detailed postmortem examination of one patient (Boynton *et al.,* 1979), and this suggests that hypoparathyroidism may be due to an embryological defect of parathyroid development. In the Sanjad-Sakati syndrome,

hypoparathyroidism is associated with severe growth failure and dysmorphic features, and this has been reported in 12 patients from Saudi Arabia (Sanjad *et al.,* 1991). Consanguinity was noted in 11 of the 12 patients' families, the majority of which originated from the western province of Saudi Arabia. This syndrome, which is inherited as an autosomal recessive disorder, has also been identified in families of Bedouin origin, and homozygosity and linkage disequilibrium studies mapped this gene to chromosome 1q42–q43 (Parvari *et al.,* 1998). Molecular genetic investigations have identified that mutations of the tubulin-specific chaperone (TBCE) are associated with the Kenny-Caffey and Sanjad-Sakati syndromes (Parvari *et al.,* 2002). TBCE encodes one of several chaperone proteins required for the proper folding of α-tubulin subunits and the formation of α-β tubulin heterodimers (Parvari *et al.,* 2002).

Additional Familial Syndromes

Single familial syndromes in which hypoparathyroidism is a component have been reported (see Table I). The inheritance of the disorder in some instances has been established, and molecular genetic analysis of the PTH gene has revealed no abnormalities. Thus, an association of hypoparathyroidism, renal insufficiency, and developmental delay has been reported in one Asian family in whom autosomal recessive inheritance of the disorder was established (Parkinson *et al.,* 1993). An analysis of the PTH gene in this family revealed no abnormalities (Parkinson *et al.,* 1993). The occurrence of hypoparathyroidism, nerve deafness, and a steroid-resistant nephrosis leading to renal failure, which has been referred to as the *Barakat syndrome* (Barakat *et al.,* 1977), has been reported in four brothers from one family, and an association of hypoparathyroidism with congenital lymphedema, nephropathy, mitral valve prolapse, and brachytelephalangy has been observed in two brothers from another family (Dahlberg *et al.,* 1983). Molecular genetic studies have not been reported from these two families.

Mitochondrial Disorders Associated with Hypoparathyroidism

Hypoparathyroidism has been reported to occur in three disorders associated with mitochondrial dysfunction: the Kearns-Sayre syndrome (KSS), the MELAS syndrome, and a mitochondrial trifunctional protein deficiency syndrome (MTPDS). KSS is characterized by progressive external ophthalmoplegia and pigmentary retinopathy before the age of 20 years and is often associated with heart block or cardiomyopathy. The MELAS syndrome consists of a childhood onset of mitochondrial encephalopathy, lactic acidosis, and strokelike episodes. In addition, varying degrees of proximal myopathy can be seen in both conditions. Both the KSS and MELAS syndromes have been reported to occur with insulin-dependent diabetes mellitus and hypoparathyroidism (Moraes *et al.*, 1989; Zupanc *et al.*, 1991). A point mutation in the mitochondrial gene tRNA leucine (UUR) has been reported in one patient with the MELAS syndrome who also suffered from hypoparathyroidism and diabetes mellitus (Morten *et al.*, 1993). Large deletions, consisting of 6741 and 6903 bp and involving more than 38% of the mitochondrial genome, have been reported in other patients who suffered from KSS, hypoparathyroidism, and sensorineural deafness (Zupanc *et al.*, 1991; Isotani *et al.*, 1996). Rearrangements (Wilichowski *et al.*, 1997) and duplication (Abramowicz *et al.*, 1996) of mitochondrial DNA have also been reported in KSS. Mitochondrial trifunctional protein deficiency is a disorder of fatty-acid oxidation that is associated with peripheral neuropathy, pigmentary retinopathy, and acute fatty liver degeneration in pregnant women who carry an affected fetus. Hypoparathyroidism has been observed in one patient with trifunctional protein deficiency (Dionisi-Via *et al.*, 1996). The role of these mitochondrial mutations in the etiology of hypoparathyroidism remains to be further elucidated.

Pluriglandular Autoimmune Hypoparathyroidism

Hypoparathyroidism may occur in association with candidiasis and autoimmune Addison's disease, and the disorder has been referred to as either the autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED) syndrome or the autoimmune polyglandular syndrome (APS1) type 1 (Ahonen *et al.,* 1990). This disorder has a high incidence in Finland, and a genetic analysis of Finnish families indicated autosomal recessive inheritance of the disorder (Ahonen *et al.,* 1985). In addition, the disorder has been reported to have a high incidence among Iranian Jews, although the occurrence of candidiasis was less common in this population (Zlotogora *et al.,* 1992). Linkage studies of Finnish families mapped the APECED gene to chromosome 21q22.3 (Aaltonen *et al.,* 1994). Further positional cloning approaches led to the isolation of a novel gene from chromosome 21q22.3. This gene, referred to as AIRE1 (autoimmune regulator type 1), encodes a 545-amino-acid protein that contains motifs suggestive of a transcriptional factor and includes two zinc-finger motifs, a proline-rich region, and three LXXLL motifs (Nagamine *et al.,* 1997; Finnish-German APECED Consortium 1997). Four AIRE1 mutations are commonly found in APECED families, and these are Arg257Stop in Finnish, German, Swiss, British and Northern Italian families; Arg139Stop in Sardinian families; Tyr85Cys in Iranian Jewish families; and a 13-bp deletion in exon 8 in British, Dutch, German, and Finnish families (Nagamine *et al.,* 1997; Finnish-German APECED

Consortium 1997; Pearce *et al.*, 1998; Scott *et al.*, 1998; Rosatelli *et al.*, 1998; Bjorses *et al.*, 2000). AIRE1 has been shown to regulate the elimination of organ-specific T cells in the thymus, and thus APECED is likely to be caused by a failure of this specialized mechanism for deleting forbidden T cell and establishing immunologic tolerance (Liston *et al.*, 2003).

ISOLATED HYPOPARATHYROIDISM

Isolated hypoparathyroidism may be inherited either as an autosomal-dominant (Barr *et al.*, 1971; Ahn *et al.*, 1986), autosomal-recessive (Bronsky *et al.*, 1968; Parkinson and Thakker, 1992), or X-linked recessive (Peden, 1960; Whyte and Weldon, 1981; Thakker *et al.*, 1990) disorder. Some autosomal forms of hypoparathyroidism have been shown to be due to abnormalities of the PTH and Gcm2 genes.

PTH Gene Abnormalities

PTH Gene Structure and Function

The PTH gene is located on chromosome 11p15 and consists of three exons, which are separated by two introns (Naylor *et al.*, 1983). Exon 1 of the PTH gene is 85 bp in length and is untranslated (Fig. 1), whereas exons 2 and 3 encode the 115-amino-acid prepro-PTH peptide. Exon 2 is 90 bp in length and encodes the initiation (ATG) codon, the prehormone sequence, and part of the prohormone sequence. Exon 3 is 612 bp in size and encodes the remainder of the prohormone sequence, the mature PTH peptide, and the 3′ untranslated region (Vasicek *et al.*, 1983). The 5′ regulatory sequence of the human PTH gene contains a vitamin D response element 125 bp upstream of the transcription start site, which downregulates PTH mRNA transcription in response to vitamin D receptor binding (Okazaki *et al.*, 1988; Demay *et al.*, 1992). PTH gene transcription (as well as PTH peptide secretion) is also dependent on the extracellular concentrations of calcium and phosphate (Naveh-Many *et al.*, 1995; Slatopolsky *et al.*, 1996; Almaden *et al.*, 1996), although the presence of specific upstream "calcium or phosphate response element(s)" has not yet been demonstrated (Russell *et al.*, 1983; Naveh-Many *et al.*, 1989). The mature PTH peptide is secreted from the parathyroid chief cell as an 84-amino-acid peptide, and this is regulated through a G protein-coupled calcium-sensing receptor (CaSR) which is also expressed in renal tubules. However, when the PTH mRNA is first translated it is as a prepro-PTH peptide. The "pre" sequence consists of a 25-amino-acid signal peptide (leader sequence) that is responsible for directing the nascent peptide into the endoplasmic reticulum to be packaged for secretion from the cell (Kemper *et al.*, 1974). The "pro" sequence is six amino acids in length and, although its function is less well defined than that of the "pre" sequence, it is also essential for correct PTH processing and secretion (Kemper *et al.*, 1974). After the 84-amino-acid mature PTH peptide is secreted from the parathyroid cell, it is cleared from the circulation with a short half-life of about 2 minutes, via nonsaturable hepatic uptake and renal excretion. PTH shares a receptor with PTH-related peptide (PTHrP, also known as PTHrH, PTH-related hormone; Jüppner *et al.*, 1991), and this receptor is a member

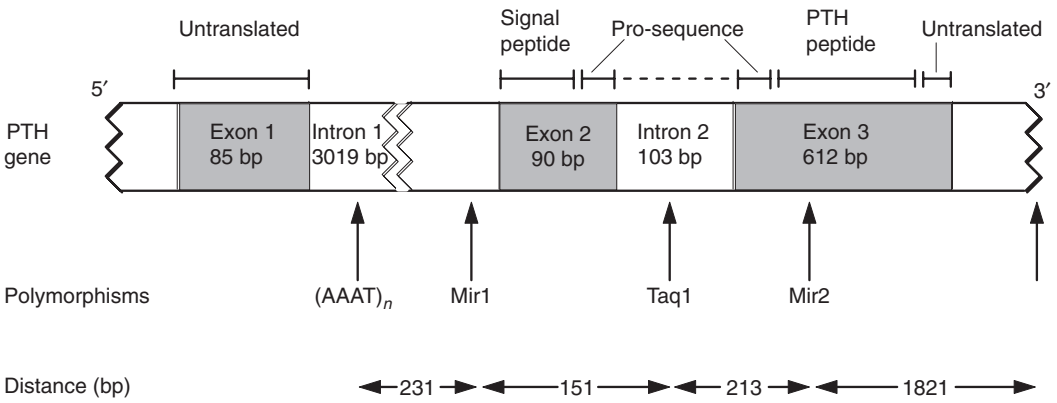

FIGURE 1 Schematic representation of the PTH gene. The PTH gene consists of three exons and two introns; the peptide is encoded by exons 2 and 3. The PTH peptide is synthesized as a precursor that contains a pre- and a prosequence. The mature PTH peptide, which contains 84 amino acids, and larger carboxy-terminal PTH fragments are secreted from the parathyroid cell. The polymorphic sites associated with the PTH gene are indicated. Two restriction fragment length polymorphisms (RFLPs) are associated with the PTH gene: The *Taq*I polymorphic site is within intron 2, and the P*st*I polymorphic site is 1.7 kbp downstream in the 3′ direction of the gene (Schmidtke *et al.*, 1984). Two other polymorphisms (Miric and Levine, 1992) of the PTH gene designated Mir1 and Mir2 are located in intron 1 and exon 3, respectively, and the tetranucleotide $(AAAT)_n$ polymorphism is in intron 1 (Parkinson *et al.*, 1993). The distance between the tetranucleotide $(AAAT)_n$ polymorphism and the Mir1 polymorphism is 231 base pairs (bp), that between the Mir1 polymorphism and the *Taq*1 RFLP is 152 bp, that between the *Taq*I RFLP site and the Mir2 polymorphism is 212 bp, and that between the Mir2 polymorphism and the P*st*I RFLP is 1821 bp. Linkage disequilibrium between the $(AAAT)_n$, T*aq*I, and P*st*I polymorphic sites has been established (Parkinson *et al.*, 1993). Adapted from Parkinson and Thakker (1992).

of a subgroup of G protein-coupled receptors. The PTH/PTHrP receptor gene is located on chromosome 3p21–p24 (Gelbert *et al.*, 1994) and is highly expressed in kidney and bone, where PTH is its predominant agonist (Abou-Samra *et al.*, 1992). However, the most abundant expression of the PTH/PTHrP receptor occurs in chondrocytes of the metaphyseal growth plate where it mediates predominantly the autocrine/paracrine actions of PTHrP (Segré, 1996; Potts and Jüppner, 1997). Five polymorphisms of the PTH gene have been reported and two of these are associated with restriction fragment length polymorphisms (RFLPs; Schmidtke *et al.*, 1984), another two are the result of single base changes that are not associated with RFLPs (Miric and Levine, 1992), and one is due to a variation in the length of a microsatellite repetitive sequence in intron 1 (Parkinson *et al.*, 1993). These polymorphisms are inherited in a Mendelian manner and are thus useful as genetic markers in family studies. Mutations involving the PTH gene affect the regulation of calcium homeostasis and are associated with hypoparathyroidism (see Table I).

Autosomal Dominant Hypoparathyroidism

DNA sequence analysis of the PTH gene (see Fig. 1) from one patient with autosomal dominant isolated hypoparathyroidism has revealed a single base substitution (T→C) in codon 18 of exon 2 (Arnold *et al.*, 1990), which resulted in the substitution of arginine (CGT) for the normal cysteine (TGT) in the signal peptide. The presence of this charged amino acid in the midst of the hydrophobic core of the signal peptide impeded the processing of the mutant prepro-PTH, as demonstrated by *in vitro* studies. These revealed that the mutation impaired the interaction with the nascent protein and the translocation machinery, and that cleavage of the mutant signal sequence by solubilized signal peptidase was ineffective (Arnold *et al.*, 1990; Karaplis *et al.*, 1995). Ineffective cleavage of the prepro PTH sequence results in a molecule that does not proceed successfully through the subsequent intracellular steps required for ultimate delivery of PTH to secretary granules. The parathyroid cell, therefore, cannot respond to hypocalcemia with the secretion of native, biologically active PTH.

Autosomal Recessive Hypoparathyroidism

Autosomal recessive hypoparathyroidism has usually arisen in families with consanguineous marriages (Parkinson and Thakker, 1992; Parkinson *et al.*, 1993). Abnormalities in the PTH gene have been sought (Parkinson *et al.*, 1993) and mutations identified in two unrelated families (Parkinson and Thakker, 1992; Sunthornepvarakul *et al.*, 1999). In one such family a donor splice site at the exon 2-intron 2 boundary has been identified (Parkinson and Thakker, 1992). This mutation involved a single base transition (**g→c**) at position 1 of intron 2, and the effects of this alteration in the invariant **gt** dinucleotide of the 5′ donor splice site consensus on mRNA processing were assessed by an analysis of the non-tissue-specific transcription of the normal and mutant PTH genes. This non-tissue-specific expression of genes has been estimated to be at the rate of one molecule of correctly spliced mRNA per 1000 cells (von Heijne, 1983; Chelly *et al.*, 1989). Although the physiological relevance of this low level of non-tissue-specific or illegitimate transcription is not known, it is of clinical importance. Easily accessible peripheral blood lymphocytes can be used to detect abnormalities in mRNA processing, thereby avoiding the requirement for tissue that may only be obtainable by biopsy. Use of these methods revealed that the donor splice site mutation resulted in exon skipping, in which exon 2 of the PTH gene was lost and exon 1 was spliced to exon 3. The lack of exon 2 would lead to a loss of the initiation codon (ATG) and the signal peptide sequence, which are required, respectively, for the commencement of PTH mRNA translation and for the translocation of the PTH peptide. Thus, the patients' parathyroid cells would not contain any translated PTH products. In the other family a single base substitution (**T→C**) involving codon 23 of exon 2 was detected. This resulted in the substitution of proline (CCG) for the normal serine (TCG) in the signal peptide (Sunthornepvarakul *et al.*, 1999). This mutation alters the −3 position of the prepro-PTH protein cleavage site (von Heijne, 1983). Indeed, amino acid residues at the −3 and −1 positions of the signal peptidase recognition site have to conform to certain criteria for correct processing through the rough endoplasmic reticulum (RER), and one of these is an absence of proline in the region −3 and +1 of the site (von Heijne, 1983). Thus, the presence of a proline, which is a strong helix-breaking residue, at the −3 position is likely to disrupt cleavage of the mutant prepro-PTH that would be subsequently degraded in the RER, and PTH would not be available (Sunthornepvarakul *et al.*, 1999).

GCMB Gene Abnormalities

GCMB (glial cells missing B), which is the human homologue of the *Drosophila* gene Gcm and of the mouse gcm2 gene, is expressed exclusively in the parathyroid glands, suggesting that it may be a specific regulator of parathyroid gland development (Günther *et al.*, 2000; Kim *et al.*, 1998). In order to investigate this, mice deleted for Gcm2 were generated by the method of homologous recombination using embryonic stem cells. Mice that were heterozygous (+/−) for the deletion were normal, whereas mice that were homozygous (−/−) for the deletion lacked parathyroid glands and developed the hypocalcemia and hyperphosphatemia observed in hypoparathyroidism (Günther *et al.*, 2000). However, despite their lack of parathyroid glands, Gcm2-deficient (−/−) mice did not have undetectable serum PTH levels, but instead had PTH levels identical

to those of normal (+/+ , wild-type) mice. This endogenous level of PTH in the Gcm2-deficient (−/−) mice was too low to correct the hypocalcemia, but exogenous continuous PTH infusion could correct the hypocalcemia (Günther *et al.*, 2000). Interestingly, there were no compensatory increases in PTHrP or $1,25(OH)_2$ vitamin D_3. These findings indicate that Gcm2 mice have a normal response (and not resistance) to PTH and that the PTH in the serum of Gcm2-deficient mice was active. The auxiliary source of PTH was determined by combined expression and ablation studies (Günther *et al.*, 2000). These revealed a cluster of PTH-expressing cells under the thymic capsule in both the Gcm2-deficient (−/−) and wild-type (+/+) mice. These thymic PTH-producing cells also expressed the calcium-sensing receptor (CaSR), and long-term treatment of the Gcm2-deficient mice with $1,25(OH)_2$ vitamin D_3 restored the serum calcium concentrations to normal and reduced the serum PTH levels, thereby indicating that the thymic production of PTH can be downregulated (Günther *et al.*, 2000). However, it appears that this thymic production of PTH cannot be upregulated, because serum PTH levels are not high despite the hypocalcemia in the Gcm2-deficient mice. This absence of upregulation would be consistent with the very small size of the thymic PTH-producing cell cluster, when compared to the size of normal parathyroid glands. The development of the thymic PTH-producing cells likely involves Gcm1, which is the other mouse homologue of *Drosophila* Gcm (Kim *et al.*, 1998). Gcm1 expression, which could not be detected in parathyroid glands, colocalized with PTH expression in the thymus (Günther *et al.*, 2000). The specific role of Gcm2 in the development of the parathyroids from the third pharyngeal pouch has been further investigated by studying the expression of the Hoxa3-Pax1/9-Eya1 transcription factor and Sonic hedgehog–Bone morphogenetic protein 4 (Shh-Bmp4) signaling networks (Liu *et al.*, 2007). These studies have revealed that Gcm2 (−/−) embryos that are 12 dpc have a parathyroid-specific domain, but that this parathyroid domain undergoes coordinated programmed cell death (apoptosis) by 12.5 dpc in the Gcm2-null mouse embryos (Liu *et al.*, 2007). Moreover, the expression of the transcription factors Hoxa3 (see earlier discussion), Pax 1, Pax 9, Eya1, and Tbx1 and of Shh and Bmp4 was normal in the third pharyngeal pouch of these Gcm2-null mouse embryos. These findings indicate that the Hoxa3-Pax1/9-Eya transcription factor cascade, the transcription factor Tbx1, and the Shh-Bmp4 signaling network all act upstream of Gcm2 (Liu *et al.*, 2007). Moreover, these studies have revealed that Gcm2 has a role in promoting differentiation and survival of parathyroid cells in the developing embryo (Liu *et al.*, 2007).

Gcm genes have similar roles in human parathyroid development, as homozygous GCMB mutations have been identified in patients with autosomal recessive hypoparathyroidism (Ding *et al.*, 2001), whereas in another family a homozygous missense mutation (Arg47Leu) of the DNA binding domain was identified (Baumber *et al.*, 2005). Functional analysis, using electrophoretic mobility shift assays (EMSAs), of this Arg47Leu GCMB mutation revealed that is resulted in a loss of DNA binding to the GCM DNA binding site (Baumber *et al.*, 2005). More recently, heterozygous GCMB mutations, which consist of single nucleotide deletions (c1389deT and c1399delC) that introduce frame shifts and premature truncations, have been identified in two unrelated families with autosomal dominant hypoparathyroidism (Mannstadt *et al.*, 2007). Both of these mutations were shown, by using a GCMB-associated luciferase reporter, to inhibit the action of the wild-type transcription factor, thereby indicating that these GCMB mutants have dominant-negative properties (Mannstadt *et al.*, 2007).

X-LINKED RECESSIVE HYPOPARATHYROIDISM

Hypoparathyroidism with an X-linked recessive transmission pattern has been reported in two multigenerational kindreds (Peden, 1960; Whyte and Weldon, 1981). Only males were affected, and they suffered from infantile epilepsy and hypocalcemia. The hypoparathyroidism is due to a defect in parathyroid gland development (Whyte *et al.*, 1986). Linkage studies utilizing X-linked RFLPs in these two families assigned the mutant gene to chromosome Xq26–q27 (Thakker *et al.*, 1990). An approach utilizing mitochondrial DNA analysis established a common ancestry in these two X-linked hypoparathyroid kindreds (Mumm *et al.*, 1997). A common ancestry for these two kindreds from eastern Missouri had been suspected, but it could not be established despite five generations of extensive genealogical records (Whyte and Weldon, 1981). The mitochondrial genes are transmitted through the maternal line exclusively. If relatedness among the two kindreds involved the maternal lines, analysis of mitochondrial genetic markers would reveal common features. The DNA sequence of the mitochondrial (mt) D-loop was compared among individuals in both kindreds. The mt DNA sequence was identical among affected males and their maternal lineage for individuals in both kindreds, but differed at three to six positions when compared with the mitochondrial DNA of the fathers. These results demonstrated that the two kindreds with X-linked recessive hypoparathyroidism are indeed related and that an identical gene defect is likely to be responsible for the disease. Additional studies refined the location of this gene to be between the locus for diffuse B cell lymphoma (DBL) and DXS984; a 906kb region in Xq27.1 (Trump *et al.*, 1998, Nesbit *et al.*, 2004b). Furthermore, DNA sequence analyses of the coding regions of the three genes—adenosine triphosphatase 11C (ATP11C), U7snRNA homologue, and Sry-box3 (SOX3)—that are contained within this 906-kb interval did not reveal any abnormalities (Nesbit *et al.*, 2004b). These findings together with the reported absence of

hypocalcemia in a boy with hemophilia B and mental retardation who had a chromosomal deletion that encompassed the entire 906-kb interval containing ATP11C, U7snRNA, and SOX3 genes (Stevanovic *et al.,* 1993) suggested that other genomic abnormalities such as molecular duplications for translocations, which could cause altered gene function may underlie the etiology of X-linked recessive hyperparathyroidism (Bowl *et al.,* 2005). Indeed, this proved to be the case, and a complex interstitial deletion-insertion involving chromosomes 2p25.3 and Xq27.1, near SOX3, was shown to cosegregate with X-linked recessive hypoparathyroidism (Bowl *et al.,* 2005). This deletion-insertion was located approximately 67 kb downstream of SOX3, and hence it was likely to exert a position effect on SOX3 expression. Moreover, SOX3 was shown to be expressed in the developing parathyroids of mouse embryos, and this indicates a likely role for SOX3 in the embryonic development of the parathyroid glands (Bowl *et al.,* 2005).

SOX3 belongs to a family of genes encoding high-mobility group (HMG) box transcription factors and is related to SRY, the sex-determining gene on the Y chromosome. The mouse homologue is expressed in the prestreak embryo and subsequently in the developing central nervous system (CNS), which includes the region of the ventral diencephalon that induces development of the anterior pituitary and gives rise to the hypothalamus, olfactory placodes, and parathyroids (Solomon *et al.,* 2004; Rizzoti *et al.,* 2004; Collignon *et al.,* 1996; Bowl *et al.,* 2005). Patients with X-linked hypopituitarism have been reported to have duplications involving a 686-kb to 13-Mb region, that contains SOX3 (Solomon *et al.,* 2002, -2004; Woods *et al.,* 2005), and overexpression of SOX3 has been reported to inhibit Wnt signaling, which has an important role in pituitary development (Zorn *et al.,* 1999). Furthermore, increased levels of SOX3 have been shown to cause developmental hypoplasia of tissues, such as the lens and otic placodes in fish embryos (Koster *et al.,* 2000). Reduced levels of SOX3 expression also result in hypopituitarism. Thus, SOX3-null mice have abnormal pituitary development associated with hypopituitarism, craniofacial abnormalities, and midline CNS defects (Rizzoti *et al.,* 2004). These phenotypic features are similar to those observed in patients with X-linked hypopituitarism, and with X-linked mental retardation and growth hormone deficiency, who have in-frame duplications of 21 bp or 33 bp encoding for seven or 11 alanines, respectively, in a polyalanine tract of the SOX3 gene (Woods *et al.,* 2005; Laumonnier *et al.,* 2002). The polyalanine tract expansion resulted in a reduction of SOX3 transcriptional activity that was associated with an impaired nuclear localization of the mutant protein (Woods *et al.,* 2005). These findings demonstrate that pituitary development is sensitive to SOX3 dosage, and that both loss- and gain-of-function mutations can result in X-linked hypopituitarism (Solomon *et al.,* 2002, 2004; Laumonnier *et al.,* 2002; Rizzoti *et al.,* 2004).

Patients with X-linked hypopituitarism have not been reported to suffer from hypoparathyroidism (Solomon *et al.,* 2002, 2004; Woods *et al.,* 2005; Laumonnier *et al.,* 2002), and conversely, the patients affected with X-linked recessive hypoparathyroidism do not suffer from hypopituitarism (Peden, 1960; Whyte and Weldon, 1981). These clinical differences may be due to the differences in the temporal expression patterns of SOX3 in the pituitary and parathyroids, or to interactions with different tissue-specific enhancers or repressors. Alternatively, they may be due to differences in the locations of the associated SOX3 genomic abnormalities, and it is important to note that X-linked hypopituitarism is associated either with duplications of the entire SOX3 coding region or with an intragenic expansion of a polyalanine tract (Solomon *et al.,* 2002, 2004; Woods *et al.,* 2005; Laumonnier *et al.,* 2007), whereas X-linked recessive hypoparathyroidism is associated with a deletion that is approximately 67 kb downstream from the SOX3 coding region. This situation may be analogous to that reported to occur in disorders associated with abnormalities of the sonic hedgehog (SHH) gene (Kleinjan and van Heyningen, 2005). SHH is a secreted protein that provides key inductive signals for the patterning of ventral neural tube, the anterior posterior limb axis, and the ventral somites. SHH gene abnormalities lead to holoprosencephaly type 3 (HPE3) and preaxial polydactyly (PPD) in man. HPE3 is caused by deletions or point mutations that involve the coding region and result in haploinsufficiency of SHH, whereas PPD is caused by breakpoints or point mutations within a limb regulatory element that is 1 Mb upstream of SHH (Kleinjan and van Heyningen, 2005). These findings illustrate that phenotypes caused by mutations in regulatory elements can be very different from those caused by mutations of coding regions, and that point mutations in regulatory elements at a distance as far as 1 Mb from the gene promoter can have a detrimental affect on embryonic development (Kleinjan and van Heyningen, 2005). Thus, it seems likely that the differences between X-linked recessive hypoparathyroidism and hypopituitarism occur because the hypoparathyroidism deletion-insertion, which is about 67 kb downstream of SOX3, involves disruption of regulatory elements, whereas the abnormalities resulting in hypopituitarism involve alterations of the SOX3 coding region. It is also important to note that the disruption in the regulatory region could also lead to upregulation or misregulation of the gene, thereby resulting in phenotypes due to gain-of-function (i.e., hypermorphic or neomorphic).

The location of the deletion-insertion about 67 kb downstream of SOX3 in X-linked recessive hypoparathyroid patients is likely to result in altered SOX3 expression, because SOX3 expression has been reported to be sensitive to position effects caused by X-chromosome abnormalities (Kleinjan and van Heyningen, 2005). Indeed, reporter-construct studies of the mouse Sox3 gene have demonstrated the presence of both 5′ and 3′ regulatory elements (Brunelli *et al.,* 2003), and thus it is possible that the deletion-insertion

in the X-linked recessive hypoparathyroid patients may have a position effect on SOX3 expression and parathyroid development from the pharyngeal pouches. Indeed, such position effects on SOX genes, which may be exerted over large distances, have been reported. For example, the very closely related Sox2 gene has been shown to have regulatory regions spread over a long distance, both 5′ and 3′ to the coding region (Uchikawa *et al.,* 2003), and disruption of sequences at some distance 3′ has been reported to lead to loss of expression in the developing inner ear and absence of sensory cells, whereas expression in other sites is unaffected (Kiernan *et al.,* 2005). Similarly, for the SRY gene, which probably originated from SOX3 (Stevanovic *et al.,* 1993), both 5′ and 3′ deletions result in abnormalities of sexual development, and translocation break points over 1 Mb upstream of the SOX9 gene have been reported to result in camptomelic dysplasia due to removal of elements that regulate SOX9 expression (Kleinjan and van Heyningen, 2005). The molecular deletion-insertion identified in X-linked recessive hypoparathyroidism may similarly cause position effects on SOX3 expression, and this points to a potential role for the SOX3 gene in the embryological development of the parathyroid glands from the pharyngeal pouches.

CONCLUSIONS

Application of the methods of molecular genetics to the study of the hypoparathyroid disorders has resulted in considerable advances that have identified some genes and their encoded proteins that are involved in the embryological development of the parathyroids, mediating its actions in different target issues. In addition, the identification of mutations has helped to provide molecular explanations and insights into a variety of familial and sporadic forms of hypopara thyroidism. Moreover, investigation of mouse models has helped to increase our understanding of the molecular regulation of pharyngeal pouch development. However, many challenges remain in this complex field, and in particular to resolving the issues of phenotypic variance and interspecies differences.

ACKNOWLEDGMENTS

I am grateful to the Medical Research Council (UK) for support, and to Mrs. Tracey Walker for typing the manuscript and expert secretarial assistance.

INTRODUCTION

The PTH/PTHrP receptor (also referred to as type I PTH/PTHrP receptor or PTH1R) mediates the actions of two ligands, parathyroid hormone (PTH) and parathyroid hormone-related peptide (PTHrP) and stimulates at least two distinct second messenger pathways, cAMP/PKA and IP_3/Ca^{2+}/PKC (Jüppner *et al.,* 1991; Abou-Samra *et al.,* 1992; Schipani *et al.,* 1993). This receptor is most abundantly expressed in kidney, bone, and growth plates, and at lower levels in a large variety of other tissues (Tian *et al.,* 1993; Urena *et al.,* 1993). The PTH-dependent endocrine actions that are mediated through the PTH/PTHrP receptor, i.e., the regulation of mineral ion homeostasis, had been explored through studies in intact and parathyroidectomized animals. The role of the PTH/PTHrP receptor in mediating the PTHrP-dependent autocrine/paracrine regulation of chondrocyte growth and differentiation became apparent only through the analysis of genetically manipulated mice. For example, animals that are "null" for PTHrP or the PTH/PTHrP receptor die *in utero* or shortly thereafter and show a profound acceleration of growth plate mineralization. In contrast, mice overexpressing PTHrP under the control of a growth plate-specific promoter are viable, but showed a severe delay in chondrocyte maturation, which leads to impaired bone growth and elongation (Karaplis *et al.,* 1994; Amizuka *et al.,* 1994; Weir *et al.,* 1996; Lanske *et al.,* 1996; Vortkamp *et al.,* 1996). These studies in mice thus provided important clues regarding the phenotypic abnormalities that were to be expected in humans with PTH/PTHrP receptor mutations and consequently led to the identification of different activating and inactivating PTH/PTHrP receptor mutations in several genetic disorders. Because the biological consequences of these PTH/PTHrP receptor mutations require a detailed understanding of the PTH- and PTHrP-dependent actions that are mediated through this G protein-coupled receptor, we will first review the physiological roles of these two peptide hormones.

PARATHYROID HORMONE (PTH)

Besides $1,25(OH)_2$ vitamin D_3 ($1,25(OH)_2D_3$), PTH is the most important endocrine regulator of extracellular calcium homeostasis in mammals (Kronenberg *et al.,* 1993, Jüppner *et al.,* 2005). PTH is predominantly expressed in the parathyroid glands. However, lower protein and mRNA levels were identified in the hypothalamus and the thymus of *glial cells missing 2* (*gcm2*)-ablated mice (Günther *et al.,* 2000). These findings confirmed earlier studies in rats (Nutley *et al.,* 1995), but it remains unlikely that PTH derived from tissues other than the parathyroid glands is involved in the regulation of mineral ion homeostasis. Its synthesis and secretion by the parathyroid glands are dependent predominantly on the extracellular concentration of calcium (Brown, 1983; Silver and Kronenberg, 1996), which is monitored by a calcium-sensing receptor (Brown *et al.,* 1993, 1999), and to a lesser extend by $1,25(OH)_2D_3$ and phosphate (Silver and Kronenberg, 1996; Almaden *et al.,* 1996; Slatopolsky *et al.,* 1996; Moallem *et al.,* 1998).

PTH acts primarily on kidney and bone, where it binds to cells expressing the PTH/PTHrP receptor and thereby initiates a series of processes that serve to maintain blood calcium and phosphate concentrations within narrow limits (Fig. 1). In kidney, the mRNA encoding the PTH/PTHrP receptor is expressed primarily in the convoluted and

Principles of Bone Biology, 3rd Edition

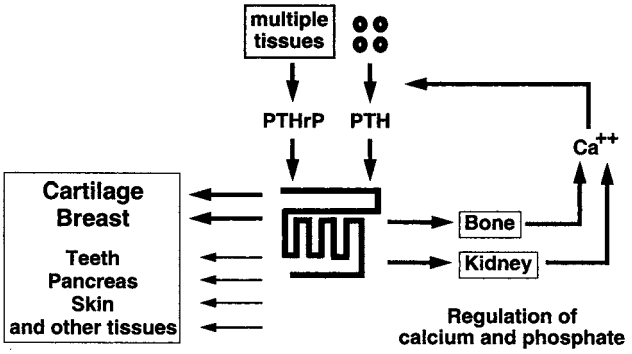

FIGURE 1 The PTH/PTHrP receptor is abundantly expressed in kidney and bone, where it mediates the PTH-dependent regulation of calcium and phosphate homeostasis. It is also expressed in numerous other tissues, particularly in the growth plate chondrocytes, where it mediates the regulation of cellular proliferation and differentiation during development.

straight proximal tubules, the cortical portion of the thick ascending limb, and the distal convoluted renal tubules (Riccardi *et al.,* 1996; Lee *et al.,* 1996; Yang *et al.,* 1997), i.e., in those renal segments that respond to PTH with an increase in cAMP accumulation (Chabardes *et al.,* 1975, 1980; Morel *et al.,* 1981).

The most important PTH-mediated actions in the kidney affect the synthesis of $1,25(OH)_2D_3$ from its precursor $25OHD_3$, the excretion of phosphate, and the reabsorption of calcium. The stimulation of 1α-hydroxylase activity, an action that appears to be at least partially cAMP-dependent (Garabedian *et al.,* 1972; Fraser and Kodicek, 1973; Horiuchi *et al.,* 1977; Kong *et al.,* 1999a; Fu *et al.,* 1997; Takeyama *et al.,* 1999), is largely restricted to the proximal convoluted tubule. The resulting increase in $1,25(OH)_2D_3$ production enhances the absorption of calcium and phosphate from the intestine. The PTH-dependent inhibition of renal tubular phosphate reabsorption has been extensively documented in a variety of *in vivo* and *in vitro* studies (for reviews, see Stewart and Broadus, 1987; Amiel *et al.,* 1998; Murer *et al.,* 1999; Silve and Friedlander, 2000). Thus, to increase renal phosphate excretion, PTH reduces the abundance of two type II sodium-phosphate cotransporters (Npt-2a and Npt-2c, also referred to as NaPi-IIa and NaPi-IIc) on the apical surface of proximal tubules; Npt-2a is expressed in the segments S1–S3, whereas Npt-2c is expressed only in the S1 segment (Segawa *et al.,* 2007). This effect of PTH is mediated by both cAMP-dependent and -independent mechanisms and is associated with an increased internalization and subsequent lysosomal degradation of Npt-2a, and similar mechanisms appear to apply to the regulation of Npt-2c (Segawa *et al.,* 2007; Bell *et al.,* 1972; Goldfarb *et al.,* 1978; Pfister *et al.,* 1998, 1999; Lotscher *et al.,* 1999; for review, see Muere *et al.,* 2000). PTH/PTHrP receptor protein expression has been demonstrated by immunohistochemical and immunoelectron microscopic analysis, and by functional studies, on both basolateral and luminal membranes in proximal tubular cells *in vitro* and in intact proximal tubules (Reshkin *et al.,* 1991; Kaufmann *et al.,* 1994; Amizuka *et al.,* 1997; Traebert *et al.,* 2000). Apical receptors may be preferentially coupled to cAMP-independent signaling pathway, whereas basolateral receptor activation initiates both cAMP-dependent and -independent effects. Recently, megalin, a multifunctional clearance receptor expressed on the apical surface of proximal tubular cells, has been shown to regulate the renal catabolism of PTH and to potentially antagonize PTH/PTHrP receptor activity (Hilpert *et al.,* 1999). In the distal convoluted tubule, PTH stimulates, possibly through second messengers other than cAMP, the reabsorption of calcium (Friedman *et al.,* 1996, 1999), which is associated with an increased expression of the calcium channel TRPV5 (Mensenkamp *et al.,* 2007). PTH also decreases the glomerular filtration, inhibits the proximal reabsorption of bicarbonate and of amino acids, and stimulates gluconeogenesis (Amiel *et al.,* 1998; Jaeger *et al.,* 1987). Consistent with the findings regarding the second messenger systems that mediate the proximal and distal actions of PTH, recently established clonal cell lines derived from proximal segments of rat renal tubules showed a PTH-dependent accumulation of cAMP accumulation and a rapid increase in intracellular free calcium. In contrast to the characteristics of these "proximal" tubular cells, where PTH stimulation led to a rapid release of intracellular calcium from intracellular stores, the increase in this second messenger in the "distal" tubular cells was dependent largely on extracellular calcium (Friedman *et al.,* 1996, 1999). These findings indicated that distinct portions of the nephron respond differently to challenge with PTH.

Similar to its renal tubular effects, the PTH-dependent actions on bone are complex and often difficult to study. As outlined later in more detail, the hormone can influence, either directly or indirectly, the proliferation and differentiation of several bone cell precursors. Furthermore, the effects resulting from PTH stimulation of mature osteoblasts appear to be different depending on the intensity and duration of the stimulus, the type of bone (trabecular versus cortical), and the hormonal millieu of bone. As a result, the hormonal effects observed *in vitro* often fail to reflect the conditions *in vivo*. For example, PTH stimulates both bone formation and osteoclastic bone resorption, however the continuous administration of PTH *in vivo* is thought to favor bone resorption over bone formation, whereas intermittent doses of the hormone results in net anabolic effects (Tam *et al.,* 1982; Lane *et al.,* 1998; Neer *et al.,* 2001; Finkelstein *et al.,* 2003; Horwitz *et al.,* 2005).

The initial, PTH-dependent effect on bone is a rapid release of calcium from areas of the matrix that allow rapid exchange with the extracellular fluid (ECF). These events are followed, after a delay of several hours, by PTH-induced changes in bone cell metabolism. After stimulating osteoblast activity and thus bone formation (Silve

et al., 1982), activated osteoblasts increase the activity of already present osteoclasts as well as the differentiation of osteoclast precursors into mature bone-resorbing cells. The coupling between bone-forming osteoblasts and bone-resorbing osteoclasts is thought to depend, at least in part, on the ability of PTH to induce changes in the synthesis and/or activity of several different osteoblast-specific proteins, including insulin-like growth factor 1 (IGF1; Canalis *et al.,* 1989). However, the most important of these "coupling" factors is RANKL (also referred to as osteoclast-differentiation factor (ODF), TRANCE, or osteoprotegerin ligand), a TNF-related protein that is anchored on the surface of osteoblasts. RANKL interacts with the receptor RANK, which is expressed on preosteoclasts and mature osteoclasts and facilitates the differentiation of precursor cells into osteoclasts and stimulates the activity of these bone-resorbing cells (Quinn *et al.,* 1998; Yasuda *et al.,* 1998; Simonet *et al.,* 1997; Kong *et al.,* 1999b). PTH thus acts on two distinct tissues, kidney and bone, to increase through different mechanisms the blood concentration of calcium and to thereby prevent significant hypocalcemia.

PARATHYROID HORMONE-RELATED PEPTIDE (PTHrP)

PTHrP was first discovered as the major cause of the humoral hypercalcemia of malignancy syndrome (Stewart *et al.,* 1980; Mosely *et al.,* 1987; Suva *et al.,* 1987; Strewler *et al.,* 1987; Mangin 1988). Within its amino-terminal portion, PTHrP shares partial amino acid sequence homology with PTH, and as a result of these limited structural similarities, amino-terminal fragments of both peptides have largely indistinguishable biological properties, at least with regard to the regulation of mineral ion homeostasis (Kemp *et al.,* 1987; Horiuchi *et al.,* 1987; Fraher *et al.,* 1992; Everhart-Caye *et al.,* 1996). Shortly after its initial isolation from several different tumors, PTHrP and its mRNA were found in a large variety of fetal and adult tissues, suggesting that this peptide has an important biological role throughout life (Ikeda *et al.,* 1988; Broadus and Stewart, 1994; Yang and Stewart, 1996). However, it was not until the generation of genetically manipulated mice that the major physiological roles of PTHrP became apparent. These roles include the regulation of chondrocyte proliferation and differentiation during the process of endochondral bone formation (Karaplis *et al.,* 1994; Amizuka *et al.,* 1994; Weir *et al.,* 1996; Lanske *et al.,* 1996; Vortkamp *et al.,* 1997; Kronenberg, 2003) and epithelial-mesenchymal interactions during organogenesis of certain epithelial organs, including skin, mammary gland, and teeth (Wysolmerski *et al.,* 1994, 1996, 1998; Philbrick *et al.,* 1998; Calvi *et al.,* 2004; Strewler, 2000). During fetal development, the expression of mRNA transcripts encoding PTHrP or the PTH/PTHrP receptor is closely linked, both spatially and temporally, implying that the ligand and its receptor are involved in paracrine/autocrine signaling events at these sites (Karaplis *et al.,* 1994; Kronenberg, 2003; Wysolmerski *et al.,* 1998; Philbrick *et al.,* 1998; Lee *et al.,* 1995). These observations are furthermore consistent with the hypothesis that the PTH/PTHrP receptor mediates most of the actions of PTHrP.

Other PTHrP-dependent effects are likely to involve mid-/carboxyl-terminal peptide fragments that are generated through alternative splicing and/or post-translational processing and involve distinct, only incompletely characterized cell surface receptors and/or direct interactions with the nucleus (Wu *et al.,* 1996; Kovacs *et al.,* 1996; Lanske *et al.,* 1999; Henderson *et al.,* 1995; Nguyen and Karaplis, 1998; Massfelder *et al.,* 1997; de Miguel *et al.,* 2001; Fiaschi-Taesch *et al.,* 2006). Although these non-amino-terminal PTHrP fragments are unlikely to be of biological importance for adult mineral ion metabolism, recent evidence suggests that large carboxyl-terminal fragments of PTH such as PTH(7–84) act, directly or indirectly, as antagonists of the calcemic actions of PTH(1–84) (Slatopolsky *et al.,* 2000; Nguyen-Yamamoto *et al.,* 2001; D'Amour *et al.,* 2005). Through yet undefined mechanisms, carboxyl-terminal fragments of PTH may thus contribute to the regulation of calcium homeostasis.

THE PTH/PTHrP RECEPTOR: A RECEPTOR FOR TWO DISTINCT LIGANDS

The isolation of cDNAs encoding the PTH/PTHrP receptor from several different species, including humans, and subsequent expression of these cDNAs in various mammalian cell lines has confirmed and extended three key observations: (1) the recombinant PTH/PTHrP receptor binds amino-terminal fragments of PTH and PTHrP with similar or indistinguishable affinity; (2) both ligands stimulate with similar potency the formation of at least two second messengers, cAMP and inositol phosphate; and (3) identical receptors are expressed in renal tubular cells and in osteoblasts (Jüppner *et al.,* 1991; Abou-Samra *et al.,* 1992; Schipani *et al.,* 1993). Furthermore, similar to the widely expressed PTHrP, the mRNA encoding the PTH/PTHrP receptor is found in a large variety of fetal and adult tissues (Tian *et al.,* 1993; Urena *et al.,* 1993; Riccardi *et al.,* 1996; Lee *et al.,* 1994, 1995,1996) and at particularly abundant concentrations in proximal tubular cells, in osteoblasts, and in prehypertrophic chondrocytes of metaphyseal growth plate (Karaplis *et al.,* 1994; Weir *et al.,* 1996; Lanske *et al.,* 1996; Vortkamp *et al.,* 1996).

PTH/PTHrP receptor belongs to the class B family of heptahelical G protein-coupled receptors (GPCR), which also comprises the receptors for secretin, calcitonin, glucagon, and several other peptide hormones (Jüppner *et al.,* 2005; Gardella *et al.,* 2002; Gensure *et al.,* 2005). These

hormone receptors share no homology with other G protein-coupled receptors, for example the members of the class A and class C family of receptors, and the organization of genes encoding the latter receptors are distinctly different from encoding the class B receptors. All class B receptors are characterized by an amino-terminal, extracellular domain that comprises approximately 150 amino acids and by eight conserved extracellular cysteine residues, as well as several other conserved amino acids that are dispersed throughout the amino-terminal domain, the membrane-spanning helices, and the connecting loops.

The organization of the PTH/PTHrP receptor gene, which comprises in mammals 14 coding exons, appears to be similar in all vertebrates (Kong *et al.,* 1994; McCuaig *et al.,* 1994). The approximately 2.5-kb transcript encoding the full-length PTH/PTHrP receptor is the predominant mRNA species in most tissues (Tian *et al.,* 1993; Urena *et al.,* 1993), but several larger and smaller transcripts have also been detected, suggesting the presence of splice variants of the PTH/PTHrP receptor. In contrast to alternatively spliced mRNAs that encode functional calcitonin and CRF receptors lacking portions of the seventh membrane-spanning helix (Shyu *et al.,* 1996; Grammatopoulos *et al.,* 1999), no alternatively spliced, functionally active PTH/PTHrP receptors have yet been identified (Jobert *et al.,* 1996; Joun *et al.,* 1997).

Transcripts encoding identical PTH/PTHrP receptors are derived from at least three different promoters that are located upstream of one of three different untranslated exons (Kong *et al.,* 1994; McCuaig *et al.,* 1994; Bettoun *et al.,* 1997; Manen *et al.,* 1998). Little is known about the factors that control the activity of these promoters, some of which appear to be species- and tissue-specific (Amizuka *et al.,* 1997; Bettoun *et al.,* 1998), and their activity may be different throughout development and adult life (Bettoun *et al.,* 1998; Amizuka *et al.,* 1999). Transcripts derived from the P1 and the P2 promoter have been observed in rodents and humans (McCuaig *et al.,* 1994, 1995; Joun *et al.,* 1997). P1-derived transcripts are found mainly, at least in rodents, in vascular smooth muscles and in peritubular endothelial cells of the adult kidney (Amizuka *et al.,* 1997). In contrast, transcripts derived from ubiquitous P2 promoter can be detected in numerous fetal and adult tissues, including cartilage and bone (Amizuka *et al.,* 1999). The P2 promoter activity is equivalent in humans and mice, whereas the activity of the P1 promoter is prominent only in rodents and appears to be weak or absent in humans. A third promoter, P3, has been identified thus far only in humans, where it is thought to control PTH/PTHrP receptor expression in several different tissues, including kidney and bone (Manen *et al.,* 1998; Bettoun *et al.,* 1998). Methylation appears to play a role in controlling human PTH/PTHrP receptor gene promoter activity (Bettoun *et al.,* 2000). A differential regulation of P2 activity in osteoblasts and chondrocytes following vitamin D_3 administration has been demonstrated in rodents (Amizuka *et al.,* 1999).

A second PTH-receptor, termed type 2 PTH receptor or PTH2-receptor, which belongs to the same family of G protein-coupled receptors as the PTH/PTHrP receptor, is less broadly expressed, with little if any expression in kidney and bone (Usdin *et al.,* 1996, 1999). The human PTH2-receptor is efficiently activated by PTH, but not by PTHrP (Usdin *et al.,* 1995; Gardella *et al.,* 1996; Behar *et al.,* 1996), whereas the rat receptor homologue is not activated by either of these two ligands (Hoare *et al.,* 1999). Instead, both PTH2-receptor isoforms are efficiently and equally activated by TIP39, a recently identified hypothalamic peptide, which shows limited amino acid sequence homology with PTH and PTHrP. It is therefore likely that TIP39 represents the primary agonist for the PTH2-receptor (Usdin *et al.,* 1999; Usdin, 1997). Although TIP39 does not activate the PTH/PTHrP receptor, the full-length peptide as well as several fragments that are truncated at the amino-terminus can bind to the latter receptor and furthermore inhibit PTH- and PTHrP-stimulated cAMP accumulation (Hoare *et al.,* 2000a, 2000b; Jonsson *et al.,* 2001). It appears unlikely, however, that TIP39 has a role in the regulation of mineral ion homeostasis.

Role of PTHrP and the PTH/PTHrP Receptor in Endochondral Bone Formation

PTHrP was initially discovered as the cause of the humoral hypercalcemia of malignancy syndrome. However, its most prominent physiological role was revealed only through the homologous ablation of its gene in mice and through the development of transgenic animals that express PTHrP under the control of a growth plate-specific promoter (Karaplis *et al.,* 1994; Weir *et al.,* 1996; Kronenberg, 2003).

Homozygous PTHrP gene-ablated animals die during the perinatal period and show striking skeletal changes, which include domed skulls, short snouts and mandibles, and disproportionately short extremities, yet no obvious developmental defects in other organs (Fig. 2). These skeletal changes are caused by a dramatic acceleration of chondrocyte differentiation that lead to premature growth plate mineralization (Karaplis *et al.*, 1994; Fig. 3). Heterozygous animals, lacking only one copy of the PTHrP gene, show normal growth and development and are fertile, but develop, despite apparently normal calcium and phosphorus homeostasis, mild osteopenia later in life (Amizuka *et al.,* 1996). Growth plate abnormalities that are, in many aspects, the opposite of those found in PTHrP-ablated mice are observed in animals that overexpress PTHrP under the control of the α1(II) collagen promoter (Weir *et al.,* 1996). Throughout life these animals are smaller in size than their wild-type litter mates and show a disproportionate

foreshortening of limbs and tail, which is most likely due to a severe delay in chondrocyte differentiation and endochondral ossification. Thus, too little or too much PTHrP expression in the growth plate leads to short-limbed dwarfism, although through entirely different mechanisms.

From these and other studies, it is now well established that PTHrP facilitates the continuous proliferation of chondrocytes in the growth plate, and that it postpones their programmed differentiation into hypertrophic chondrocytes. Consistent with this role of PTHrP in endochondral bone formation, earlier *in vitro* studies had shown that PTH (used in these studies instead of PTHrP) affects chondrocyte maturation and activity (Lebovitz and Eisenbarth, 1975; Smith *et al.,* 1976). More recent studies confirmed these findings by showing that PTH and PTHrP stimulate, presumably through cAMP-dependent mechanisms (Jikko *et al.,* 1996), the proliferation of fetal growth plate chondrocytes, inhibit the differentiation of these cells into hypertrophic chondrocytes, and stimulate the accumulation of cartilage-specific proteoglycans that are thought to act as inhibitors of mineralization (Takano *et al.,* 1985; Koike *et al.,* 1990; Iwamoto *et al.,* 1994). In the absence of these cartilage-specific PTHrP effects, growth plates of homozygous PTHrP gene-ablated mice have a thinner layer of proliferating chondrocytes, whereas the layer of hypertrophic chondrocytes is relatively normal in thickness, but somewhat disorganized. Taken together, these findings suggested that the lack of PTHrP accelerates the normal differentiation process of growth plate chondrocytes, i.e., resting and proliferating chondrocytes undergo fewer cycles of cell division and differentiate prematurely into hypertrophic cells, which then undergo apoptosis before being replaced by invading osteoblasts.

The phenotypic changes in mice that are "null" for either PTHrP or the PTH/PTHrP receptor are similar, and current evidence indicates that the autocrine/paracrine

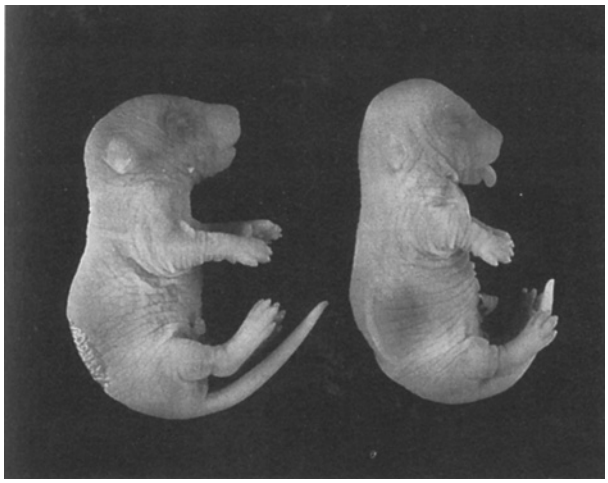

FIGURE 2 Phenotype of a homozygous PTHrP-ablated mouse (day 18.5 of embryonic development). Note the chondrodysplasia characterized by a domed skull, short snout and mandible, protruding tongue, narrow thorax, and disproportionately short limbs, From Karaplis *et al.* (1996), with permission.

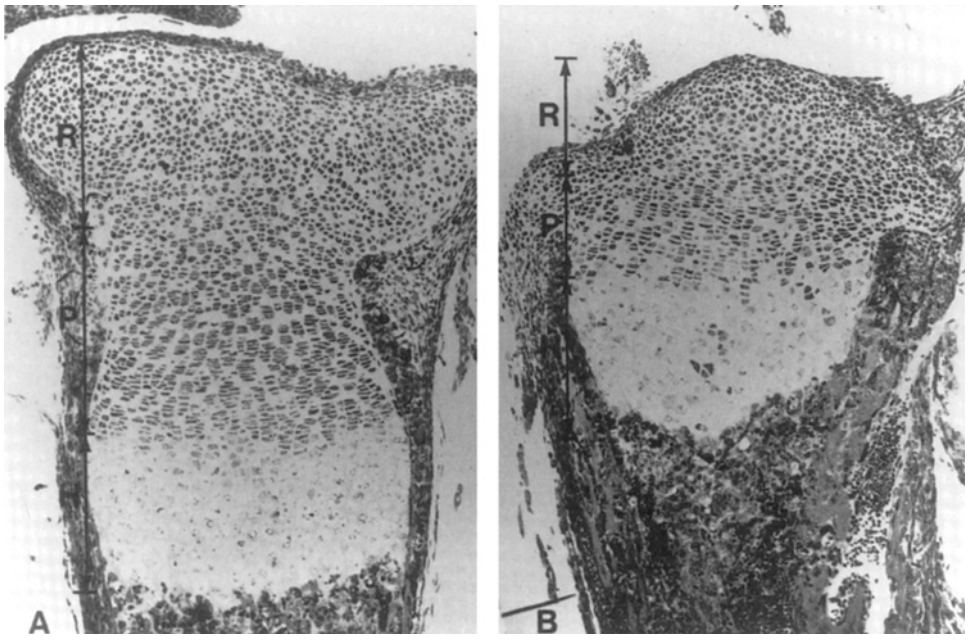

FIGURE 3 Low-magnification photomicrographs of the proximal tibiae of a wild-type mouse (**A**) and a homozygous PTHrP-ablated mouse (**B**) (E 18.5). Note that the tibial epiphysis of the PTHrP ablated mouse is shortened and the zones of reserve and proliferative chondrocytes are markedly reduced. From Amizuka *et al.* (1994), with permission.

actions of PTHrP within the growth plate are mediated through the PTH/PTHrP receptor (Karaplis *et al.,* 1994; Lanske *et al.,* 1996; Chung *et al.,* 1998). Furthermore, mice missing either PTHrP or its receptor are resistant to the actions of *Indian Hedgehog* (*Ihh*), a developmentally important protein that is most abundantly expressed in growth plate chondrocytes which are about to differentiate into hypertrophic cells. *Ihh* binds directly to *patched,* a membrane receptor, which interacts with *smoothened* and thereby suppresses the constitutive activity of the latter protein (Stone *et al.,* 1996; Marigo *et al.,* 1996). The ectopic expression of *Ihh* in the chicken wing cartilage stimulates the production of PTHrP and thereby blocks the normal chondrocyte differentiation program (Vortkamp *et al.,* 1996); whether PTHrP represses, as part of a feedback loop, the expression of *Ihh* remains to be established. PTHrP and *Ihh* are thus critically important components of normal bone growth and elongation (Lanske *et al.,* 1996; Vortkamp *et al.,* 1996). However, not all actions of PTHrP appear to be mediated through the PTH/PTHrP receptor, because the ablation of the PTHrP gene or the PTH/PTHrP receptor gene leads to subtle, but distinctly different, abnormalities in early bone development (Lanske *et al.,* 1999). This suggests that some actions of PTHrP in bone involve either distinct receptors or the peptide's direct nuclear actions (Henderson *et al.,* 1995; Nguyen and Karaplis, 1998; Massfelder *et al.,* 1997; de Miguel *et al.,* 2001; Fiaschi-Taesch *et al.,* 2006).

ROLE OF PTHrP IN REGULATING EPITHELIAL-MESENCHYMAL INTERACTIONS

Studies with transgenic mice, in which PTHrP expression is targeted through a human keratinocyte-specific promoter (K14) to the developing epidermis and mammary gland, demonstrated that PTHrP plays also a critical role in hair follicle development and branching morphogenesis of the mammary gland (Wysolmerski *et al.,* 1994, 1996). These conclusions were further supported by findings in PTHrP-null mice that had been rescued from neonatal death by targeting PTHrP expression to chondrocytes through the α1(II) collagen promoter (Weir *et al.,* 1996). These rescued mice lack mammary epithelial ducts, because of a failure of the initial round of branching growth that is required for transforming the mammary bud into the primary duct system; ablation of both copies of the PTH/PTHrP receptor gene recapitulated the phenotype of PTHrP-ablated animals (Wysolmerski *et al.,* 1998).

Using similar approaches, it was furthermore demonstrated that PTHrP is required for normal tooth eruption. Teeth appeared to develop normally in rescued PTHrP knockout mice, but became trapped by the surrounding bone and underwent progressive impaction (Philbrick *et al.,* 1998). In these tissues, PTHrP mRNA was identified by *in situ* hybridization in epithelial cells, whereas the PTH/PTHrP receptor mRNA was found on mesenchymal or stromal cells. These observations led to the concept that the communication between epithelium and mesenchyme involves the PTH/PTHrP receptor, and that PTHrP signaling is essential for normal development of these tissues (Wysolmerski and Stewart, 1998).

JANSEN'S METAPHYSEAL CHONDRODYSPLASIA

JMC, first described in 1934 (Jansen, 1934), is a rare autosomal-dominant form of short-limbed dwarfism associated with laboratory abnormalities that are typically observed only in patients with either primary hyperparathyroidism or with the humoral hypercalcemia of malignancy syndrome (reviewed in Jüppner, 1996, and Parfitt *et al.,* 1996). These biochemical changes, i.e., hypercalcemia, renal phosphate wasting, and increased urinary cAMP excretion, occur despite low or undetectable concentrations of PTH in the circulation and PTHrP concentrations that are not elevated (Frame and Poznanski, 1980; Holt, 1969; Kessel *et al.,* 1992; Rao *et al.,* 1979; Silverthorn *et al.,* 1983; Schipani *et al.,* 1999; Kruse and Schütz, 1993). Severe hypercalcemia, which is often asymptomatic, and hypophosphatemia had been noted in Jansen's first patient (De Haas *et al.,* 1969) and in a subsequently described child with the same disorder (Cameron *et al.,* 1954). It was not until the description of a third patient, however, that the association between the abnormalities in endochondral bone formation and in mineral ion homeostasis was formally considered (Gram *et al.,* 1959). At that time the biochemical abnormalities could not be readily distinguished from those observed in primary hyperparathyroidism, but the surgical exploration of the patient revealed no obvious abnormalities of the parathyroid glands. It was therefore concluded that the changes in mineral metabolism were either "secondary to the underlying bone defect" or "related to an undefined metabolic disorder that gave rise to both metaphyseal and biochemical changes" (Gram *et al.,* 1959). Most reported cases of JMC are sporadic, but the description of two unrelated affected females that gave birth to affected daughters (Lenz, 1969; Holthusen *et al.,* 1975; Charrow and Poznanski, 1984) suggested an autosomal dominant mode of inheritance; this conclusion was subsequently confirmed for two families at the molecular level (Schipani *et al.,* 1996; Bastepe *et al.,* 2004).

At birth some patients with JMC have dysmorphic features, which can include high skull vault, flattening of the of the nose and forehead, low-set ears, hypertelorism, high-arched palate, and micro- or retrognathia (for a review, see Jüppner, 1996). Although body length is within normal limits at birth, growth becomes increasingly abnormal, eventually

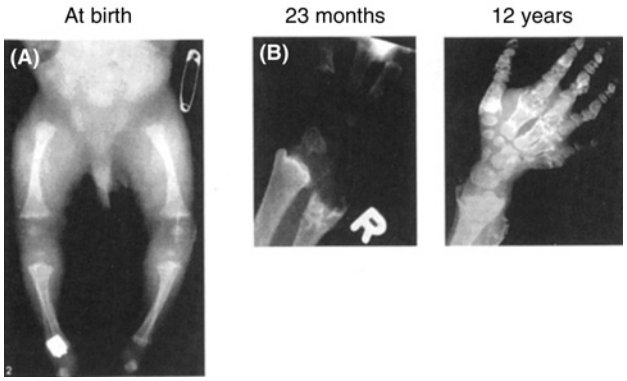

FIGURE 4 A patient with Jansen's disease and his radiological findings at different ages; at birth, 23 months, and 12 years of age. From Silverthorn *et al.* (1983), with permission.

leading to the development of short stature. Additional signs may include kyphoscoliosis with a bell-shaped thorax and widened costochondral junctions, metaphyseal enlargement of the joints, waddling gait, prominent supraorbital ridges, and frontonasal hyperplasia. The legs are usually bowed and short, whereas the arms are relatively long.

Radiological studies have shown considerable, age-dependent differences in the osseous manifestations of JMC. In younger patients, severe metaphyseal changes, especially of the long bones, are present (Fig. 4). The metaphyses are enlarged and expanded, giving a clublike appearance to the ends of the long bones with a wide zone of irregular calcifications. Patches of partially calcified cartilage that protrude into the diaphyses are also present and appear relatively radiolucent. These findings, which are characteristically observed throughout early childhood, are similar to the lesions observed in rickets. However, distinct from the findings in rickets, metacarpal and metatarsal bones are also involved.

Later in childhood, the changes are no longer reminiscent of rickets. Until the onset of puberty, almost all tubular bones show irregular patches of partially calcified cartilage that protrude into the diaphyses; the spine and vertebral bodies show no obvious abnormalities (Frame and Poznanski, 1980; Kessel *et al.,* 1992; Rao *et al.,* 1979; Silverthorn *et al.,* 1983; Schipani *et al.,* 1999; Kruse and Schütz, 1993; Cameron *et al.,* 1954; Charrow and Poznanski, 1984). After adolescence, the cartilaginous tissue in the metaphyses gradually disappears and turns into bone, leading to bulbous deformities (see Fig. 4). The ends of most tubular bones remain expanded, deformed and radiolucent, but a more normal trabecular pattern gradually emerges (Frame and Poznanski, 1980; Kessel *et al.,* 1992; Rao *et al.,* 1979; Silverthorn *et al.,* 1983; Scvhipani *et al.,* 1999; Kruse and Schütz, 1993; Cameron *et al.,* 1954; Charrow and Poznanski, 1984).

In addition, sclerosis and thickening of the base of the skull and of the calvaria is noted in most cases. The former changes are thought to be the cause of cranial auditory and optical nerve compression, which has been observed later in life in some affected individuals. Loss of the normal cortical outline, areas of subperiosteal bone resorption, and generalized osteopenia are reminiscent of the changes seen in hyperparathyroidism. Furthermore, there is an increased in trabecular bone volume and a thinning of cortical bone (Parfitt *et al.,* 1996). The two only reports that investigated the histological changes in the growth plates, described a severe delay in endochondral ossification of the metaphyses, including a lack of the regular columnar arrangement of the maturing cartilage cells, a lack of excess osteoid (which is usually indicative of active rickets or osteomalacia), little or no vascularization of cartilage, and no evidence for osteitis fibrosa (Cameron *et al.,* 1954; Jaffe, 1972).

One female patient with JMC was reported to be unable to breast-feed and to have, similar to her affected daughter, a dry and scaly skin (Schipani *et al.,* 1996). As discussed earlier, PTHrP and the PTH/PTHrP receptor are expressed in breast and skin, and this ligand/receptor system appears to have an important role in these two tissues. Tooth development and enamel formation appear normal in patients with JMC. Intelligence appears to be normal in all reported cases.

Most laboratory findings in JMC are reminiscent of those observed in patients with primary hyperparathyroidism or with the syndrome of humoral hypercalcemia of malignancy. In the newborn, blood phosphorus levels are typically at the lower end of the normal range, whereas alkaline phosphatase activity is almost invariably elevated. Hypercalcemia is usually absent at birth, but develops during the first months of life; it persists throughout life but is more pronounced during infancy and childhood. Hypercalciuria is usually present and can be associated with an increased incidence of nephrocalcinosis (Kessel *et al.,* 1992). $1,25(OH)_2D_3$ levels have been reported to be normal or at the upper end of the normal range. Serum alkaline phosphatase activity and osteocalcin concentration are elevated throughout life, indicating that osteoblast activity is increased; compatible with an increased osteoclastic activity, urinary hydroxyproline excretion is elevated (Schipani *et al.,* 1999; Kruse and Schütz, 1993).

JANSEN'S DISEASE IS CAUSED BY ACTIVATING PTH/PTHrP RECEPTOR MUTATIONS

Because of the findings in the various genetically manipulated mice described earlier, and because of the abundant expression of the PTH/PTHrP receptor in the three organs that are most obviously affected in JMC, i.e., kidney, bone, and metaphyseal growth plates, activating receptor mutations were considered as a cause of this rare disease. Indeed, in several unrelated patients with this disorder, a heterozygous nucleotide exchange, which changes a histidine at position 223 to arginine, was identified in exon M2 of the PTH/PTHrP

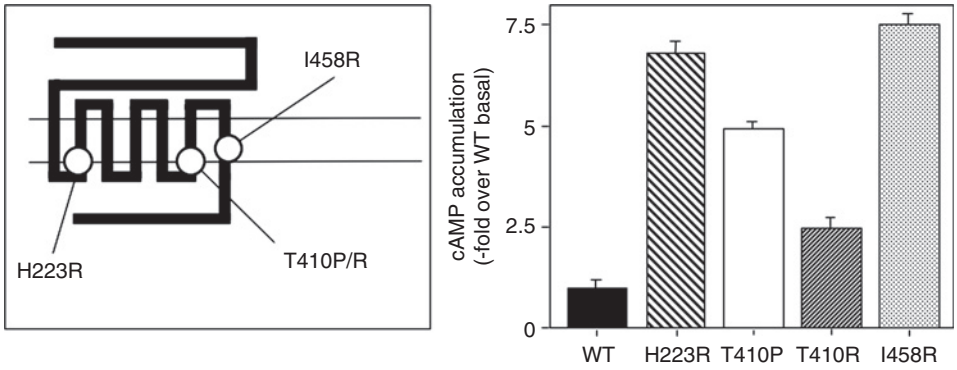

FIGURE 5 Schematic representation of the PTH/PTHrP receptor and basal, agonist-indepenent cAMP accumulation of wild-type and mutant receptors. The approximate location of the three different missense mutations that were identified in patients with Jansen's disease are indicated (*left*). Basal cAMP accumulation of COS-7 cells expressing wild-type and mutant PTH/PTHrP receptors (H223R, ; T410P, ; T410R, ; I458R, ; (*right*). Modified from Schipani *et al*. (1996, 1999).

receptor gene (Schipani *et al.,* 1995, 1996, 1999; Minagawa *et al.,* 1997). In other patients, two additional heterozygous nucleotide exchanges were identified that change either a threonine at position 410 to proline (exon M5), or isoleucine at position 458 to arginine (exon M7; Schipani *et al.,* 1996, 1999; Fig. 5; also see Table I). The three mutated residues are predicted to be located at or close to the intracellular surface of the cell membrane and are strictly conserved in all mammalian members of this receptor family (Jüppner *et al.,* 2005; Gardella *et al.,* 2002; Gensure *et al.,* 2005), suggesting an important functional role for these three residues. With the exception of one family where a mother-to-daughter transmission of the H223R mutation was documented (Schipani *et al.,* 1996), each of the three mutations was excluded in the healthy parents and siblings, and in genomic DNA from a significant number of unrelated healthy individuals. This suggests that JMC is usually caused by *de novo* mutations. To date, the T410P and the I458R mutation have been found in one patient each, whereas the H223R mutation has been identified in eight patients and is thus the most frequent PTH/PTHrP receptor mutation in JMC.

To test *in vitro* the functional consequences of the identified missense mutations in JMC, each of the three different nucleotide exchanges was introduced into the cDNA encoding the wild-type human PTH/PTHrP receptor (Schipani *et al.,* 1995, 1996, 1999; Minagawa *et al.,* 1997). COS-7 cells transiently expressing PTH/PTHrP receptors with either the H223R, the T410P, or the I458R mutation showed significantly higher basal accumulation of cAMP than did cells expressing the wild-type PTH/PTHrP receptor (see Fig. 5). Cells expressing PTH/PTHrP receptors with either of the three point mutations showed no evidence for increased basal accumulation of IP3, indicating that this signaling pathway is not constitutively activated (Schipani *et al.,* 1995, 1996, 1999). Interestingly, the D578H mutation in the luteinizing hormone receptor, which is at a position equivalent to the T410P mutation in the PTH/PTHrP receptor, led to constitutive activity of both signaling pathways, cAMP and IP3 (Liu *et al.,* 1999). It is therefore plausible that the lack of constitutive IP3 generation by three activating mutations in the PTH/PTHrP receptor could be related to insufficient sensitivity of the methods that were used to explore this second-messenger system.

When challenged with increasing concentrations of either PTH or PTHrP, cells expressing the mutant H223R and T410P receptors showed, in comparison to cells expressing the wild-type PTH/PTHrP receptor, reduced maximal cAMP accumulation. In contrast, cells expressing the I458R mutant showed the same maximal cAMP accumulation as cells transfected with the wild-type receptor (Schipani *et al.,* 1999). Agonist-dependent IP accumulation was observed with COS-7 cells expressing the I458R and the T410P mutant, but not with cells expressing the H223R mutant. Despite the differences in the *in vitro* response to PTH or PTHrP, patients with either of the three PTH/PTHrP receptor mutations showed no obvious differences in their clinical and/or biochemical presentation.

More recently, a novel T410R mutation was identified in a less severe form of Jansen disease (Bastepe *et al.,* 2004; see Table I). Patients carrying this mutation show mild skeletal dysplasia with relatively normal stature, and serum calcium levels that are within the normal range. When tested *in vitro,* the degree of constitutive activity of the T410R mutant was significantly lower, when compared with the H223R, T410P, and I458R mutants, respectively. This finding provided the first evidence of an obvious correlation between severity of phenotypical features and degree of constitutive activity in Jansen disease.

Activating mutations in other G protein-coupled receptors have been implicated in several other human diseases, but none of these involve members of the class B receptor family. These disorders include rare forms of retinitis pigmentosa or congenital stationary blindness (activating mutations in rhodopsin; Robinson *et al.,* 1992; Dryja *et al.,* 1993), thyroid adenomas or non-autoimmune hyperthyroidism (activating TSH receptor mutations; Parma

TABLE I Mutations in the PTH/PTHrP receptor gene associated with different human disorders. The description of the sequence variant is based on the nomenclature described in the last updated version (June 2007) of den Dunnen JT and Antonarakis SE (211). LOF: loss of function; GOF: gain of function.

et al., 1993; Duprez *et al.*, 1994; Paschke *et al.*, 1994; Kopp *et al.*, 1995; Tonacchera *et al.*, 1996; Grüters *et al.*, 1998; Khoo *et al.*, 1999; Nogueira *et al.*, 1999; Russo *et al.*, 1999; Trultzsch *et al.*, 1999), gonadotropin-independent male precocious puberty (Shenker *et al.*, 1993; Latronico *et al.*, 1995; Kraaij *et al.*, 1995; Shenker, 1998), Leydig-cell tumors (activating mutations in the luteinizing hormone receptor; Liu *et al.*, 1999), and autosomal dominant forms of familial hypocalcemia (activating calcium-sensing receptor mutations; Pollak *et al.*, 1994; Pearce *et al.*, 1995, 1997; Pearce and Brown, 1996; Baron *et al.*, 1996; Brown *et al.*, 1998; Watanabe *et al.*, 1998; Okazaki *et al.*, 1999). Cell membrane receptors exhibiting constitutive signaling have also been described in the pathogenesis of Kaposi's sarcoma and primary effusion lymphomas (constitutive signaling of the Kaposi's sarcoma herpesvirus-G protein-coupled receptor (KSHV-GPCR) via activation of phosphoinositide-specific phospholipase; Burger *et al.*, 1999a, 1999b).

To prove that the growth plate abnormalities in Jansen's disease are indeed caused by constitutively active PTH/PTHrP receptors, transgenic mice were generated that express the H223R mutant under the control of the rat α1(II) collagen promoter, thereby targeting receptor expression to proliferating chondrocytes (Schipani *et al.*, 1997). Two transgenic mouse lines were established, both of which showed delayed mineralization and decelerated differentiation of proliferative chondrocytes into hypertrophic chondrocytes, a delay in vascular invasion, and a prolonged presence of hypertrophic chondrocytes (Fig. 6). In one of these mouse lines, the defect in endochondral bone formation was only apparent at the microscopic level,

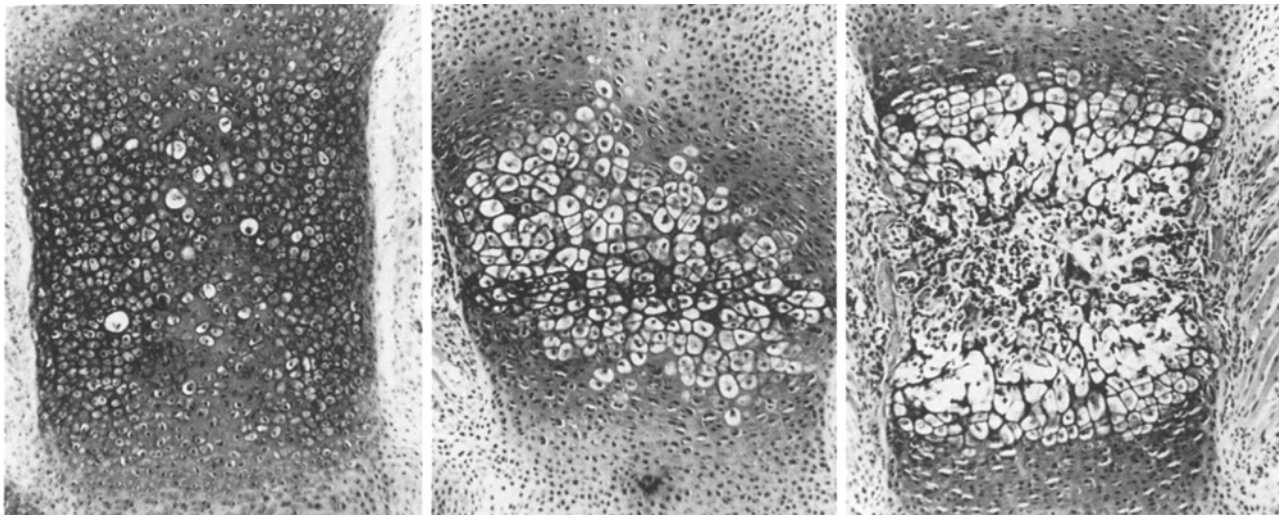

FIGURE 6 Histological sections, stained with hematoxylin and eosin, of decalcified sternum from a newborn wild-type mouse (*left*), and transgenic littermates that were heterozygous (*middle*) or homozygous (*right*) for expression of a constitutively active PTH/PTHrP receptor under the control of the type II collagen promoter. From Schipani *et al.* (1997).

whereas the second line showed shortened and deformed limbs that are reminiscent of the findings in patients with Jansen's disease. Based on these results in transgenic mice, it appears likely that the growth abnormalities in JMC are caused by the expression of mutant, constitutively active PTH/PTHrP receptor in growth-plate chondrocytes.

In an attempt to better understand how the PTH/PTHrP receptor can modulate bone development and turnover, transgenic mice were recently generated in which the human PTH/PTHrP receptor with the H223R mutation is expressed under the control of the type I collagen promoter. Constitutive activity of this receptor was thus targeted to mature osteoblasts and osteoblast precursors. When compared to control littermates, long bones of transgenic mice were reduced in length. The histological analysis of these bones revealed findings that are reminiscent of the skeletal abnormalities in patients with hyperparathyroidism and with Jansen's disease (Parfitt *et al.,* 1996), i.e., a thinner and more porous cortex in the diaphysis, an increased trabeculation of the metaphysis, and a reduction in bone marrow space (Fig. 7). Besides increased osteoblast function in trabecular bone and at the endosteal surface of cortical bone, osteoblastic activity in the periosteum was inhibited. Furthermore, mature osteoblasts as well as a heterogeneous population of pre-osteoblasts were increased in the trabecular compartment by a mechanism of increased proliferation and decreased apoptosis, and expression of the constitutively active PTH/PTHrP receptor in osteoblasts resulted in a dramatic increase in osteoclast number. The net effect of these actions was a substantial increase in trabecular bone volume and a decrease in cortical bone mass. These studies identified the PTH/PTHrP receptor as an important mediator of both bone-forming and bone-resorbing actions of PTH, and they point out the complexity and heterogeneity of the osteoblast population and/or their regulatory microenvironment (Calvi *et al.,* 2001).

Moreover, expression of a constitutively active PTH/PTHrP receptor in cells of the osteoblast lineage in the Cl2 mice led to a significant expansion of the hematopoietic stem cell (HSC) population, which very likely occurred through up-regulation of Notch-1 (Calvi *et al.,* 2003). These findings were confirmed in wild-type mice treated intermittent injection of PTH (Weber *et al.,* 2006; Adams *et al.,* 2007). PTH was also shown to promote mobilization of HCSs into circulation and to protect them from repeated exposure to chemotherapeutic agents (Adams *et al.,* 2007). Collectively, these data indicate that cells of the osteoblast lineage are critical components of the HSC niche in the bone marrow, and that activation of the PTH/PTHrP receptor can be an important pharmacological target for stem cell-based therapies.

BLOMSTRAND'S LETHAL CHONDRODYSPLASIA

Blomstrand's lethal chondrodysplasia is a recessive human disorder characterized by early lethality, advanced bone maturation and accelerated chondrocyte differentiation, and most likely severe abnormalities in mineral ion homeostasis. The first patient was described by Blomstrand and colleagues in 1985; descriptions of several other patients followed (Young *et al.,* 1993; Leroy *et al.,* 1996; Loshkajian *et al.,* 1997; den Hollander *et al.,* 1997; Oostra *et al.,* 1998, 2000; Galera *et al.,* 1999; Karperien *et al.,* 1999). The disorder was shown to occur in families of different ethnic backgrounds and appears to affect males and females equally. Most affected infants are born to consanguineous parents (only in one instance were unrelated parents reported to have two offspring that are both affected by Blomstrand's disease; Loshkajian *et al.,* 1997), suggesting that BLC is an autosomal recessive disease. Infants with

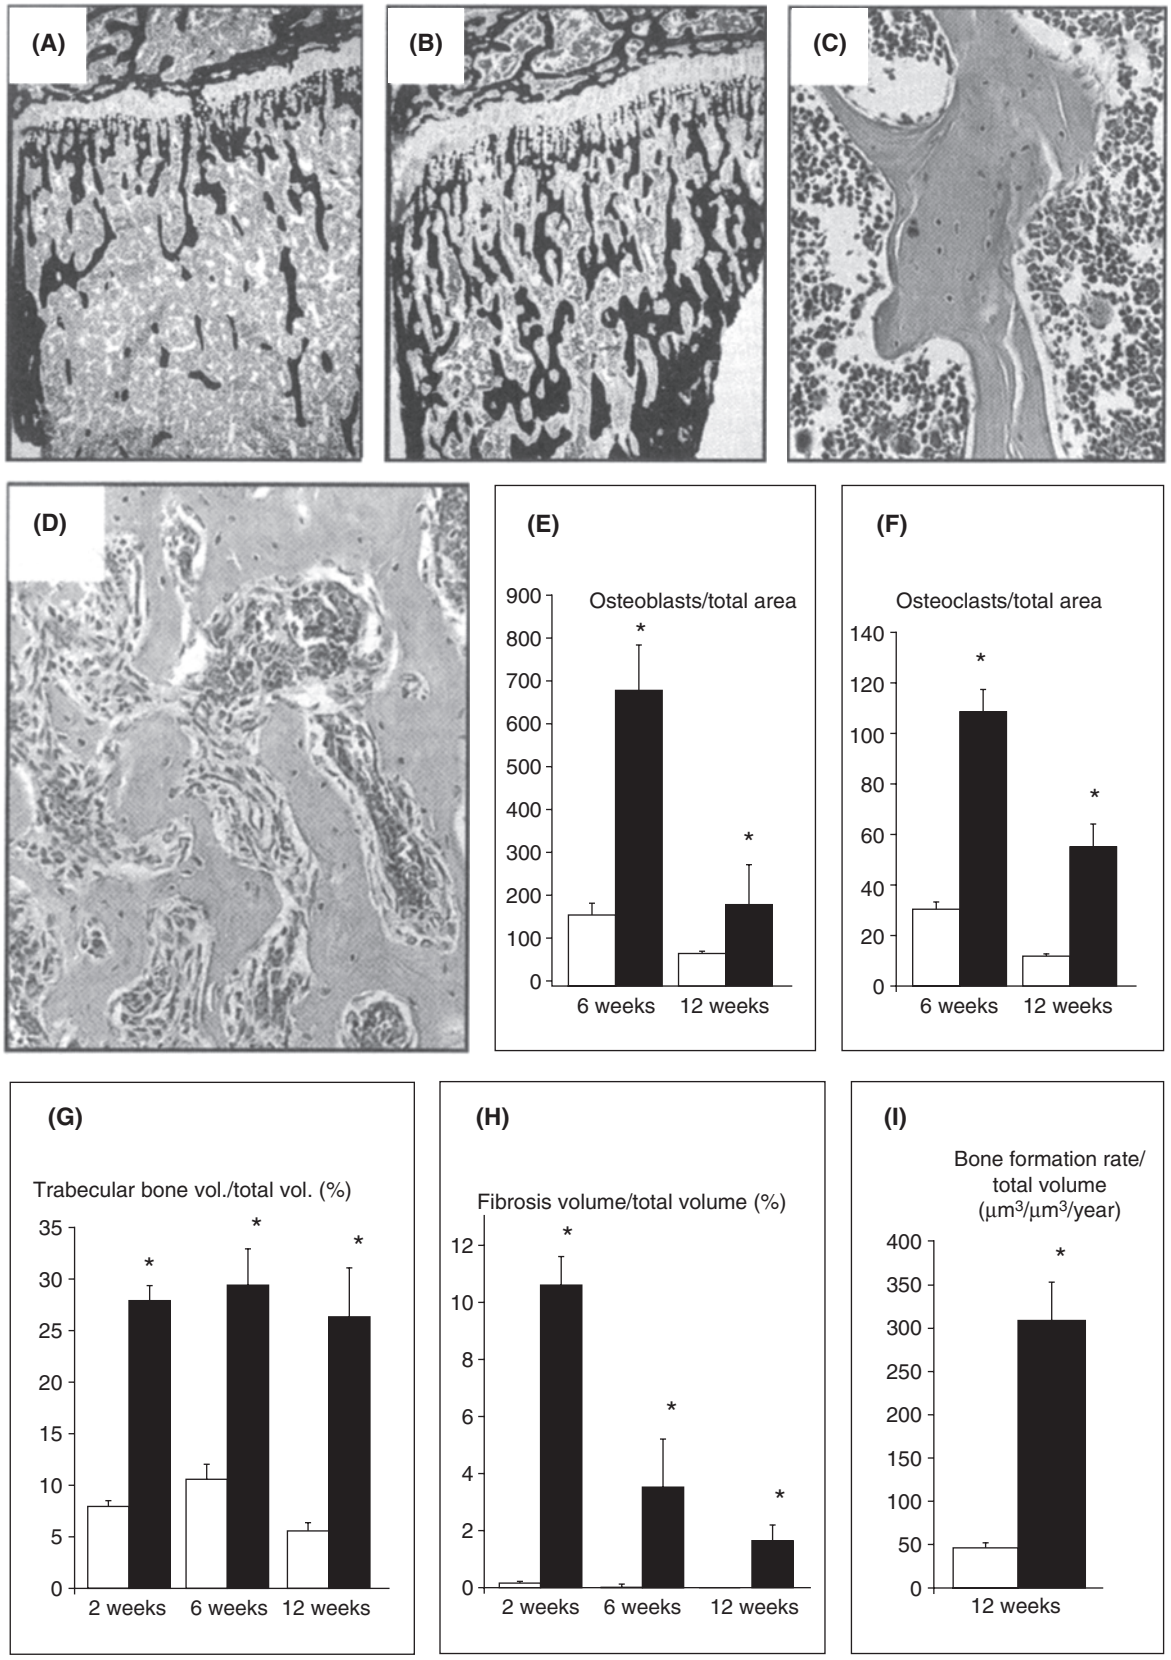

FIGURE 7 Histology and histomorphometric analysis of trabecular bone from wild-type and CL2 transgenic mice. Histologic sections of tibiae, stained by the method of von Kossa, from 12-week-old wild-type mice (**A**) and CL2 transgenic littermates (**B**). High-power light microscopy of decalcified sections, stained with hematoxylin and eosin, of the metaphyseal area from the proximal tibia of 12-week old wild-type (**C**) and CL2 transgenic littermates (**D**). Histomorphometric analysis performed in wild-type (white bars) and CL1 transgenic littermates (black bars) (E–I). Ages of animals are indicated on the *x*-axis; asterisks indicate a statistically significant difference between two groups of mice ($p < 0.05$); error bars represent the SEM. Modified from Calvi *et al.* (2001).

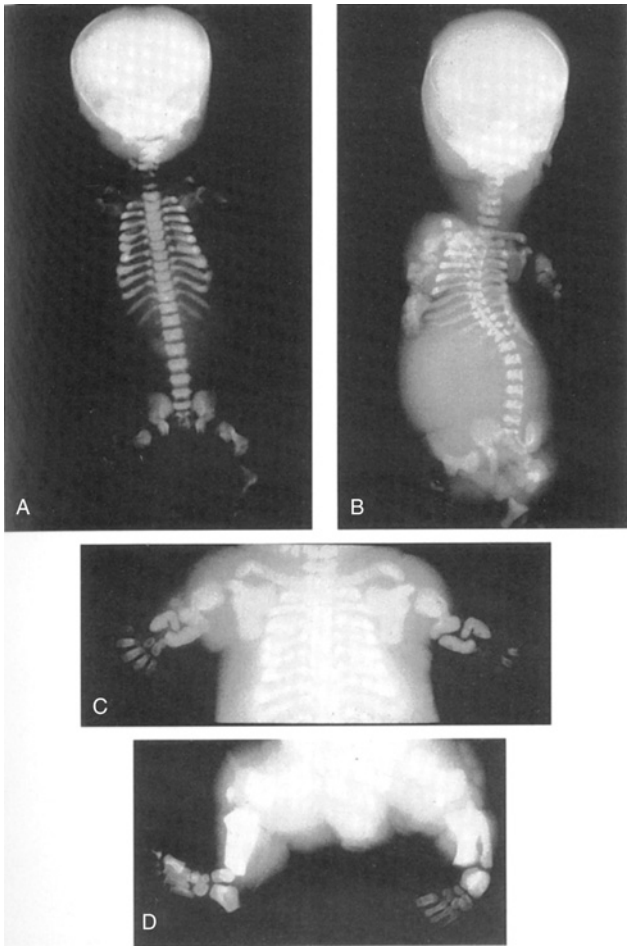

FIGURE 8 Radiological findings in two fetuses with Blomstrand's lethal chondrodysplasia (BLC). Anteroposterior (**A**) and lateral (**B**) views of a male fetus at 26 weeks of gestation; upper (**C**) and lower (**D**) limbs of a female fetus with BLC at 33 weeks of gestation. Particularly striking is the dramatic acceleration of endochondral bone formation of all skeletal elements. No secondary ossification centers of ossification are seen in the long bones. The limbs are coarsely shaped and extremely short, whereas carpal and tarsal bones have a comparatively normal shape and size. Note also that the clavicles are relatively long, but show abnormal bending. From Loshkajian *et al*. (1997), with permission.

BLC are typically born prematurely and die shortly after birth. Birth weight, when corrected for gestational age, appears to be normal, but may be overestimated because most infants are hydroptic; also, the placenta can be immature and edematous. Nasal, mandibular, and facial bones are hypoplastic; the base of the skull is short and narrow; the ears are low set; the thoracic cage is hypoplastic and narrow with short thick ribs and hypoplastic vertebrae. In contrast, the clavicles are relatively long and often abnormally shaped, the limbs are extremely short, and only the hands and feet are of relatively normal size and shape. Internal organs show no apparent structural or histological anomalies, but preductal aortic coarctation was observed in most published cases. The lungs are hypoplastic and the protruding eyes typically show cataracts. Defects in mammary gland and tooth development, previously overlooked, were demonstrated in two recently studied fetuses with BLC. In these fetuses, nipples were absent, and no subcutaneous ductal tissue could be identified by histochemical analysis. Tooth buds were present, but developing teeth were severely impacted within the surrounding alveolar bone, leading to distortions in their architecture and orientation (Wysolmerski *et al.,* 2001).

Radiological studies of patients with BLC reveal pronounced hyperdensity of the entire skeleton and markedly advanced ossification (Fig. 8). As mentioned earlier, the long bones are extremely short and poorly modeled, show markedly increased density, and lack metaphyseal growth plates. Endochondral bone formation is dramatically advanced and is associated with a major reduction in epiphyseal resting cartilage preventing the development of epiphyseal ossification centers (Fig. 9). The zones of chondrocyte proliferation and of column formation are lacking, and the zone that normally comprises the layer of hypertrophic chondrocytes is poorly defined, narrow and irregular (Oostra *et al.,* 2000). Cortical bone is thickened, and bone trabeculae are coarse with reduced diaphyseal marrow spaces. Capillary ingrowth, bone resorption, and bone formation are reported by some authors as being unaltered (Leroy *et al.,* 1996), whereas

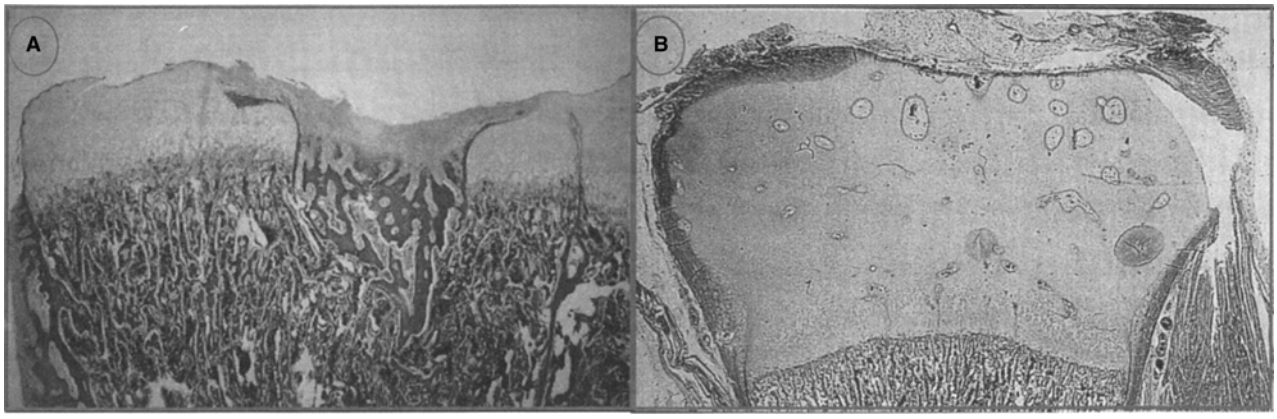

FIGURE 9 Section of the upper tibia end from a patient with BLC (**A**) and an age-matched control. Note the severely reduced size of the growth plate, the irregular boundary between the growth plate and the primary spongiosa, and the increased cortical bone thickness. From Loshkajian *et al*. (1997), with permission, and Anne-Lise Delezoide, personal collection.

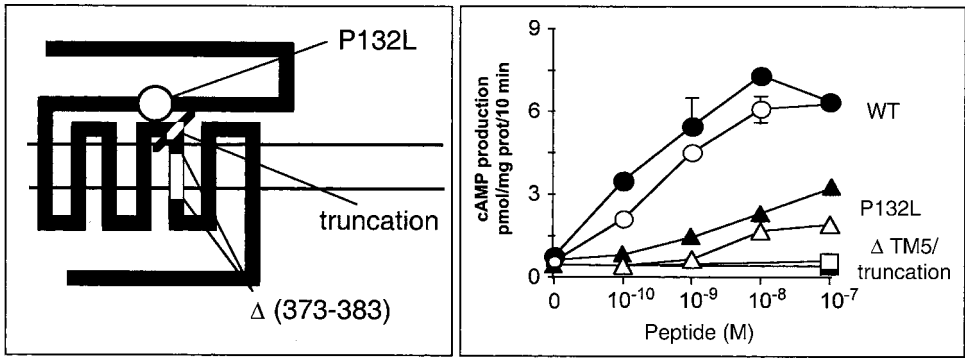

FIGURE 10 Schematic representation of the PTH/PTHrP receptor and functional evaluation of the wild-type and mutant receptors in COS-7 cells. Approximate location of loss-of-function mutation identified in patients with Blomstrand's disease (*left*) and cAMP accumulation in response to PTH (*right*, closed symbols) or PTHrP (open symbols) by wild-type and mutant PTH/PTHrP receptors. Modified from Karperien *et al.* (1999) and Zhang *et al.* (1998).

others describe these bone remodeling events as deficient (Loshkajian *et al.,* 1997).

BLOMSTRAND'S DISEASE IS CAUSED BY INACTIVATING PTH/PTHrP RECEPTOR MUTATIONS

Different defects in the PTH/PTHrP receptor gene have been described in genomic DNA from patients affected by BLC (see Table I). The first reported case, a product of nonconsanguineous parents, was shown to have two distinct abnormalities in the PTH/PTHrP receptor gene (Jobert *et al.,* 1998). Through a nucleotide exchange in exon M5 of the maternal PTH/PTHrP receptor allele, a novel splice acceptor site was introduced that led to a mutant mRNA encoding an abnormal receptor that lacks a portion of the fifth membrane-spanning domain (amino acids 373 to 383; Δ373–383). This receptor mutant fails, despite seemingly normal cell surface expression, to respond to PTH or PTHrP with an accumulation of cAMP (Fig. 10) and inositol phosphate (data not shown). For yet unknown reasons, the paternal PTH/PTHrP receptor allele from this patient is very poorly expressed, suggesting an unidentified mutation in one of the different promoter regions or in a putative enhancer element.

A second patient with BLC, the product of a consanguineous marriage, was shown to have a nucleotide exchange that leads to a proline to leucine mutation at position 132 (P132L; Zhang *et al.,* 1998; Karaplis *et al.,* 1998). This residue in the amino-terminal, extracellular domain of the PTH/PTHrP receptor is invariant in all mammalian members of this family of G protein-coupled receptors, indicating that the identified mutation is likely to have significant functional consequences. Indeed, COS-7 cells expressing this mutant PTH/PTHrP receptor showed, despite apparently normal cell surface expression, dramatically impaired binding of radiolabeled PTH and PTHrP analogues and greatly reduced agonist-stimulated cAMP accumulation (see Fig. 10), and the cells showed no measurable inositol phosphate response. It is important to note, however, that cells expressing the P132L mutant receptor showed some agonist-induced second-messenger response and showed little, but detectable, specific binding of radiolabeled PTHrP. To date the P132L mutation has been identified in two additional patients affected with BLC (Hoogendam *et al.,* 2007). Although not definitive, haplotype analysis performed on the genomic DNA of these patients with the P132L mutation is consistent with an ancient founder effect (Hoogendam *et al.,* 2007).

A homozygous deletion of G at position 1093 (from A of the ATG-translation initiation codon; exon EL2) was identified in a third case of BLC (Karperien *et al.,* 1999). This mutation led to a shift in the open reading frame, which resulted in a truncated protein that completely diverged from the wild-type receptor sequence after amino acid 364, and thus lacked transmembrane domains 5, 6, and 7, the connecting intra- and extracellular loops, and the cytoplasmic tail (Δ365–593). Functional analysis of the Δ365–593 recombinant mutant receptor in COS-7 cells demonstrated a total absence of PTH-stimulated accumulation of intracellular cAMP, which was confirmed in studies performed with the patient's dermal fibroblasts (see Fig. 10).

As for the other cases of BLC, these findings provided a plausible explanation for the severe abnormalities in endochondral bone formation. The abnormalities in mammary gland and tooth development furthermore support the conclusion that the PTH/PTHrP receptor has in humans and mice identical roles in the development of these organs. Compatible with the role of PTH/PTHrP receptor and PTHrP in organogenesis, both were demonstrated to be expressed in the developing breast and tooth of human control fetuses (Wysolmerski *et al.,* 2001). It is also worth noting that abnormalities in skeletal development in the fetuses carrying the P132L mutation, which inactivates the PTH/PTHrP receptor incompletely, are less severe than those observed in most cases, particularly with

regard to the bones of the lower limbs (Young *et al.,* 1993; Karperien *et al.,* 1999; Oostra *et al.,* 2000). This led to the proposal that two forms of BLC can be distinguished clinically and on the basis of the *in vitro* characteristics of the mutant PTH/PTHrP receptors (Oostra *et al.,* 2000).

More recently, two additional homozygous mutations in the PTH/PTHrP receptor have been identified in fetuses affected BLC that further document the molecular basis for the two forms of BLC Hoogendam *et al.,* 2007; see Table I). A homozygous point mutation causing a premature stop codon at position 104 (R104X) and therefore resulting in a truncated completely inactive protein has been identified in a case affected with the severe (type I) form. A homozygous nucleotide change (intron M4 + 27C > T) creating a novel splice site has been identified in a case affected with the less severe form (type II). This novel splice site, which results in an aberrant transcript with a premature stop codon, was shown to be preferentially used in dermal fibroblasts, but the wild-type transcript remained expressed, albeit at low levels. Taken together the findings in patients with BLC suggested that this rare human disease is the equivalent of the mouse PTH/PTHrP receptor "knockout" (Lanske *et al.,* 1996).

Inactivating mutations have been described in several other G protein-coupled receptors (reviewed in Spiegel and Weinstein, 2004, and Tao, 2006). For example, genetic forms of growth hormone deficiency were shown to be caused by mutations in the growth hormone-releasing hormone receptor (Wajnrajch *et al.,* 1996; Godfrey *et al.,* 1993), mutations in the thyrotropin receptor are the cause of inherited hypothyroidism (Sunthornthepvarakui *et al.,* 1995), and mutations in the calcium-sensing receptor have been associated with familial hypocalciuric hypercalcemia and neonatal severe primary hyperparathyroidism (reviewed in Jüppner and Thakker, 2007).

PTH/PTHrP RECEPTOR MUTATIONS IN EIKEN FAMILIAL SKELETAL DYSPLASIA AND ENCHONDROMATOSIS (OLLIER'S DISEASE)

In addition to BLC and JMC, PTH/PTHrP receptor gene mutations have been associated to two other diseases, Eiken familial skeletal dysplasia (Duchatelet *et al.,* 2004) and enchondromatosis (Ollier's disease; Hopyan *et al.,* 2002).

Eiken Familial Skeletal Dysplasia

Eiken familial skeletal dysplasia has been described in a single consanguineous family (Eiken *et al.,* 1984). The disease is characterized by multiple epiphyseal dysplasia, with extremely retarded ossification, as well as by abnormal modeling of the bones in hands and feet, abnormal persistence of cartilage in the pelvis, and mild growth retardation. Serum calcium and phosphate levels have been normal in all the examined patients; serum PTH level was measured in only one patient and was found to be slightly elevated with a normal 1,25-$(OH)_2$ vitamin D level. A homozygous mutation in the PTH/PTHrP receptor, R485X, which leads to the truncation of the last 108 amino-acids of the PTH/PTHrP receptor, was identified in all affected patients, but it was not found in DNA from healthy controls (Duchatelet *et al.,* 2004; see Table I). The functional properties of the mutant PTH/PTHrP receptor have not been characterized *in vitro*. However, based on the properties of a receptor mutant with deletion after amino acid 480 (Iida-Klein *et al.,* 1995; Castro *et al.,* 2002), it appears plausible that the truncated receptor has an unbalance between the different signaling pathways that are activated by PTH. Why the deletion of the carboxy-terminal tail of the PTHR1 results in a bone phenotype, but no obvious abnormality in the regulation of mineral ion homeostasis, remains unclear.

Enchondromatosis (Ollier's Disease)

Enchondromatosis is usually a nonfamilial disorder characterized by the presence of multiple enchondromas. It is characterized by an asymmetric distribution of the cartilaginous lesions, which can be extremely variable (in terms of size, number, location, evolution of enchondromas, age of onset and of diagnosis, and requirement for surgery). Clinical problems caused by enchondromas include skeletal deformities, limb-length discrepancy, and the potential risk for malignant change to chondrosarcoma. The condition in which multiple enchondromatosis is associated with soft-tissue hemangiomas is also referred to as Maffucci's syndrome. The irregular distribution of the lesions in Ollier's disease strongly suggests that it is a disorder of endochondral bone formation that occurs due to a postzygotic somatic mutation that results in mosaicism. A mutant PTHR1 (R150C) was found to be expressed in the enchondromas from two of six unrelated patients with enchondromatosis (Hopyan *et al.,* 2002; see Table I). The mutation was found on one parental allele in one patient and his father, who presented with atypical mild skeletal dysplasia, but not with enchondromatosis. Neither the R150C mutation (26 tumors) nor any other mutation in the *PTHR1* gene (11 patients) could be identified in a subsequent study, suggesting heterogeneity of the molecular defect(s) leading to enchondromatosis (Rozeman *et al.,* 2005). Consistent with a role of the PTH/PTHrP receptor in some forms of Ollier's disease, novel heterozygous PTHR1 mutations were recently identified in several additional patients (Couvineau *et al*., 2008).

The mutant PTHR1 (R150C) seems to constitutively activate the PTHrP-dependent pathway, thus decreasing chondrocyte differentiation, thereby leading to the formation of

enchondromas (Hopyan *et al.,* 2002). Consistent with this conclusion, transgenic mice expressing the mutant PTHR1, but not the wild-type receptor, under the control of the collagen type II promoter develop tumors that are similar to those observed in human enchondromatosis. Because regulation of Ihh by PTHrP was found to be lost in these enchondromas, additional transgenic mice were generated that overexpress the Hedgehog (Hh) transcriptional regulator, Gli2. These mice develop ectopic cartilaginous islands similar to those observed in the mice expressing the mutant PTHR1. Thus, Ihh signaling seems to play a crucial role in the formation of enchondromas.

CONCLUSIONS

The findings in PTHrP- and PTH/PTHrP receptor-ablated mice, and in transgenic animals overexpressing PTHrP in the growth plate, predicted that human disorders caused by mutations in either of these two proteins would be associated with severe abnormalities in endochondral bone formation and in the regulation of mineral ion homeostasis. These insights from genetically manipulated animals led to the identification of activating and inactivating PTH/PTHrP receptor mutations in two rare genetic disorders, Jansen's and Blomstrand's disease, respectively. More recently, mutations in the PTH/PTHrP receptor gene were found in two other diseases, namely Eiken familial skeletal dysplasia and Ollier's disease. In addition to resolving the pathogenesis of puzzling human disorders, these naturally occurring PTH/PTHrP receptor mutations have provided important new insights into the importance of this G protein-coupled receptor in mammalian development. The availability of mutant, constitutively active PTH/PTHrP receptors has furthermore provided novel tools to study bone and cartilage development independent of PTH and PTHrP.

Chapter 67

Diseases Resulting from Defects in the G Protein $G_s\alpha$

Lee S. Weinstein*
Metabolic Diseases Branch, National Institute of Diabetes, Digestive, and Kidney Diseases, National Institutes of Health, Bethesda, Maryland

Michael T. Collins
Craniofacial and Skeletal Diseases Branch, National Institute for Dental and Craniofacial Research, National Institutes of Health, Bethesda, Maryland

OVERVIEW

$G_s\alpha$ is a ubiquitously expressed heterotrimeric G protein α-subunit that couples cell surface receptors for hormones and other extracellular ligands to adenylyl cyclase and mediates receptor-stimulated intracellular cyclic adenosine monophosphate (cAMP) generation. Upon ligand binding, receptors promote the release of GDP and binding of GTP to $G_s\alpha$, leading to its activation. The "turn-off" mechanism is an intrinsic GTPase activity of $G_s\alpha$ that hydrolyzes bound GTP to GDP. Genetic defects involving $G_s\alpha$ are associated with a wide variety of human disorders, which are summarized in Table I. Heterozygous inactivating $G_s\alpha$ mutations in the germline usually lead to Albright hereditary osteodystrophy (AHO) and, less often, to progressive osseous heteroplasia (POH). Paternal transmission of these mutations leads to the AHO phenotype alone (pseudopseudohypoparathyroidism, PPHP), whereas maternal transmission leads to AHO plus obesity and multihormone resistance (pseudohypoparathyroidism type IA, PHPIA). The clinical differences between PHPIA and PPHP result from the fact that $G_s\alpha$ is imprinted in a tissue-specific manner, being primarily expressed from the maternal allele in specific hormone target tissues. $G_s\alpha$ is encoded by a complex imprinted gene (*GNAS*), which encodes other gene products other than $G_s\alpha$. Patients with isolated renal PTH resistance without AHO (pseudohypoparathyroidism type IB, PHPIB) have a *GNAS*-imprinting defect that presumably leads to tissue-specific $G_s\alpha$ deficiency. Endocrine tumors, fibrous dysplasia of bone (FD), and the McCune–Albright syndrome (MAS) result from somatic $G_s\alpha$ mutations that are constitutively activating because of loss of GTPase activity.

$G_s\alpha$ STRUCTURE AND FUNCTION

Like all heterotrimeric G proteins, G_s is composed of a specific α-subunit ($G_s\alpha$) associated with tightly but noncovalently bound $\beta\gamma$ dimers. These heterotrimeric complexes reside in the inner leaflet of the plasma membrane as well as in intracellular membranes. $G_s\alpha$ is ubiquitously expressed and couples a wide variety of seven-transmembrane receptors, including those for glycoprotein and peptide hormones, biogenic amines, and neurotransmitters, to the stimulation of adenylyl cyclase and generation of the intracellular second messenger cAMP (Weinstein *et al.*, 2001, 2004). cAMP mediates many of its downstream effects by activating cAMP-dependent protein kinase (protein kinase A [PKA]), a serine/threonine protein kinase that phosphorylates many substrates, including enzymes involved in intermediary metabolism, and transcription factors such as the cAMP response element binding protein CREB (Montminy, 1997). cAMP also binds to and modulates the activity of other molecules (Richards, 2001), including ion channels (Sudlow *et al.*, 1993; Wainger *et al.*, 2001) and guanine nucleotide exchange factors for the small guanine nucleotide-binding protein Rap1 (cAMP-GEFs) (de Rooij *et al.*, 1998; Kawasaki *et al.*, 1998). Whereas in many tissues cAMP is antimitogenic, in many neuroendocrine cell types it is mitogenic through activation of Rap1, which stimulates various mitogenic pathways

TABLE I Human Diseases Associated with GNAS Gene Defects

GNAS gene defect	Disease
$G_s\alpha$ null mutations (maternal)	PHPIA (AHO + multihormone resistance and obesity PHPIA + POH)
$G_s\alpha$ null mutations (paternal)	PPHP (AHO alone) POH
$G_s\alpha$ A366S mutation (maternal)	PHPIA + testotoxicosis
Loss of exon 1A maternal imprinting (sporadic or associated with *STX16* or NESP55 deletion) Paternal UPD of chrom 20q $G_s\alpha$ ΔI382 mutation (maternal)	PHPIB
$G_s\alpha$ activating mutations (somatic)	GH-secreting pituitary tumors Thyroid adenomas, carcinomas Leydig cell tumors Pheochromocytoma Parathyroid adenoma ACTH-secreting pituitary tumor McCune–Albright syndrome Fibrous dysplasia Skeletal muscle myxomas Premature thelarche

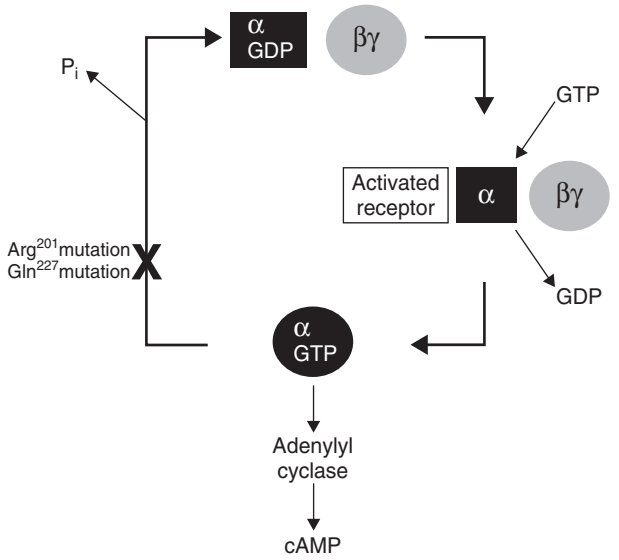

FIGURE 1 The Gs GTPase cycle. In the basal state GDP-bound $G_s\alpha$ associates with βγ to form a heterotrimer. Activated (ligand-bound) receptors promote the exchange of GTP for GDP on $G_s\alpha$, which allows $G_s\alpha$ to attain an active conformation and dissociate from βγ. GTP-bound $G_s\alpha$ directly activates adenylyl cyclase to generate cAMP. $G_s\alpha$ is deactivated through an intrinsic GTPase activity that hydrolyzes bound GTP to GDP, allowing $G_s\alpha$ to reassociate with βγ. Mutation of Arg^{201} or Gln^{227} leads to constitutive activation by disruption of the GTPase activity.

including B-raf/mitogen-activated protein kinase, p70S6 kinase, and Akt (Cass and Meinkoth, 1998; Mei *et al.*, 2002; Miller, M. J. *et al.*, 1997; Vossler *et al.*, 1997; Wang *et al.*, 2006).

$G_s\alpha$ may also be activated by tyrosine kinase (growth factor) receptors through tyrosine phosphorylation (Krieger-Brauer *et al.*, 2000; Poppleton *et al.*, 1996; Sun *et al.*, 1997) and may activate other effectors, including cardiac Ca^{2+} channels (Mattera *et al.*, 1989; Yatani *et al.*, 1988) and Src tyrosine kinases (Ma *et al.*, 2000). In addition to its role as a signal transducer at the plasma membrane, $G_s\alpha$ may also play a role in the control of intracellular membrane and vesicle trafficking (Bomsel and Mostov, 1992; Zheng *et al.*, 2001).

Like all G proteins, G_s undergoes activation and deactivation through a "GTPase" cycle (Fig. 1). In the inactive state GDP is bound to $G_s\alpha$, which is localized to the inner leaflet of the plasma membrane associated with βγ. Ligand-bound receptors promote GDP release and binding of ambient GTP, allowing $G_s\alpha$ to attain an active conformation and to dissociate from βγ. Dissociation from βγ as well as depalmitoylation results in $G_s\alpha$ being released from the plasma membrane upon activation (Allen *et al.*, 2005; Huang *et al.*, 1999; Wedegaertner *et al.*, 1996; Yu, J. Z. and Rasenick, 2002). GTP-bound $G_s\alpha$ directly activates its effectors including adenylyl cyclase. The turn-off mechanism is an intrinsic GTPase activity that hydrolyzes bound GTP to GDP, allowing $G_s\alpha$ to reassociate with βγ. An RGS (regulator of G protein signaling) protein that stimulates the GTPase activity of $G_s\alpha$ has been recently identified (Zheng *et al.*, 2001). Crystal structures have identified two highly conserved residues (Arg201 and Gln227 in the long form of $G_s\alpha$) that are critical for catalyzing the GTPase reaction (Coleman *et al.*, 1994; Graziano and Gilman, 1989; Landis *et al.*, 1989; Sondek *et al.*, 1994), and mutation or post-translational modifications of these residues leads to constitutive activation and human disease (see below).

Like all Gα's, $G_s\alpha$ contains two structural domains, a Ras-like GTPase domain, which includes the sites for guanine nucleotide binding and effector interaction, and a helical domain (Sunahara *et al.*, 1997; Tesmer *et al.*, 1997). Alternative splicing leads to two long and two short forms of $G_s\alpha$ with helical domains of slightly differing length (Bray *et al.*, 1986; Kozasa *et al.*, 1988), which have only subtle biochemical differences between them (Jones *et al.*, 1990; Seifert *et al.*, 1998). Contacts between the helical and GTPase domains may be important for maintaining the binding of guanine nucleotide, which sits within a cleft between the two domains. (Mixon *et al.*, 1995; Warner *et al.*, 1998). GTP binding leads to an active conformation by altering the positions of three regions (named switches

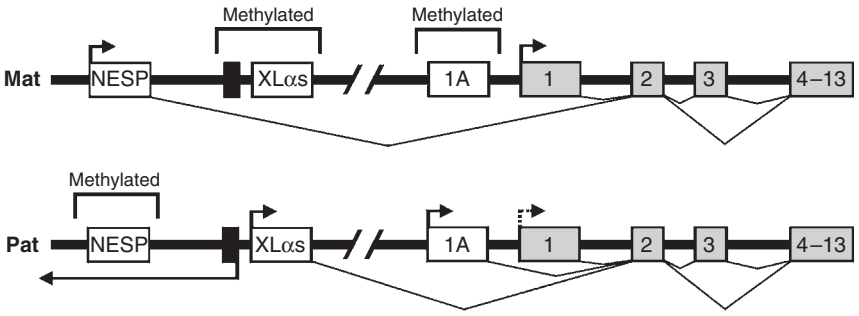

FIGURE 2 Organization and imprinting of *GNAS*. The maternal allele is shown above and paternal allele below (not to scale) indicating regions of DNA methylation, active promoters (arrows), and exon splicing. $G_s\alpha$ coding exons are depicted as gray boxes with exons 4–13 shown as a single box. Three other alternative first exons are shown as white boxes and the first exon of the antisense transcript is shown as a black box. The striped arrow for the paternal $G_s\alpha$ promoter indicates that the promoter is silenced in a tissue-specific manner. Long and short forms of $G_s\alpha$ result from alternative splicing of exon 3. (Reproduced from Weinstein (2004) "Molecular Basis of Inborn Errors of Development," Oxford University Press).

1, 2, and 3) within the GTPase domain (Lambright *et al.*, 1994; Noel *et al.*, 1993). In particular, switches 2 and 3 move toward each other and the active conformation is stabilized through mutual interactions between acidic and basic residues within these regions (Iiri *et al.*, 1997; Li and Cerione, 1997; Warner *et al.*, 1999). Interactions between switch 3 and helical domain residues may also be important for receptor-mediated activation (Grishina and Berlot, 1998; Marsh *et al.*, 1998; Warner *et al.*, 1998; Warner and Weinstein, 1999). The carboxyl terminus is the major site of interaction with receptors (Conklin *et al.*, 1996; Grishina and Berlot, 2000; Mazzoni *et al.*, 2000; Schwindinger *et al.*, 1994; Simonds *et al.*, 1989; Sullivan *et al.*, 1987).

THE $G_s\alpha$ GENE *GNAS*

GNAS, the gene encoding $G_s\alpha$, is located at 20q13.2–13.3 (Gejman *et al.*, 1991; Levine *et al.*, 1991; Rao, V.V. *et al.*, 1991). *GNAS* generates several gene products in addition to $G_s\alpha$ through the use of alternative promoters and first exons that splice onto a common exon (exon 2) (Fig. 2). In addition, *GNAS* is affected by genomic imprinting, an epigenetic phenomenon that leads to partial or complete suppression of gene expression from one parental allele (Reik and Walter, 2001). Allele-specific differences in gene expression are most likely the result allele-specific differences in DNA methylation, which are observed in all imprinted genes. Primary imprinting centers are regions of differential methylation in which DNA methylation is erased in primordial germ cells, reestablished in either male or female gametes, and maintained in all tissues throughout development. Differential gene expression may result from differential methylation of gene promoters (with the silenced allele methylated) or may result from more indirect mechanisms.

$G_s\alpha$ mRNA transcripts are generated from the most downstream *GNAS* promoter and span 13 exons (Kozasa *et al.*, 1988). Biologically active long and short forms of $G_s\alpha$ are generated by alternative splicing of exon 3, which encodes 15 amino acids within the helical domain (Bray *et al.*, 1986; Kozasa *et al.*, 1988). $G_s\alpha$ is imprinted in a tissue-specific manner, being primarily from the maternal allele in a few tissues (e.g., the pituitary, thyroid, and renal proximal tubules) and biallelically expressed in most tissues (Campbell *et al.*, 1994; Davies and Hughes, 1993; Germain-Lee *et al.*, 2002; Hayward *et al.*, 2001; Liu *et al.*, 2003; Mantovani *et al.*, 2002; Weinstein *et al.*, 2001; Yu, S. *et al.*, 1998). This imprinting is not associated with methylation of its promoter (Hayward *et al.*, 1998a; Kozasa *et al.*, 1988; Liu *et al.*, 2000b; Peters *et al.*, 1999). Rather, $G_s\alpha$ imprinting is controlled by a primary imprinting center located ~2 kb upstream of its promoter, which is methylated on the maternal allele (Liu *et al.*, 2000b, 2005a; Williamson *et al.*, 2004). This region contains a promoter and first exon (exon 1A or A/B) that splices to exon 2 to generate untranslated mRNA transcripts from the paternal allele (see Fig. 67.2) (Ishikawa *et al.*, 1990; Liu *et al.*, 2000a, 2000b). Maternal imprinting (methylation) of the exon 1A region is absent in PHPIB patients, as discussed in greater detail later.

Alternative promoters and first exons located 46 and 35 kb upstream of the $G_s\alpha$ promoter generate transcripts that encode the chromogranin-like protein NESP55 and the alternative $G_s\alpha$ isoform XLαs, respectively (Hayward *et al.*, 1998a, 1998b; Kelsey *et al.*, 1999; Peters *et al.*, 1999) (see Fig. 67.2). The NESP55 and XLαs promoter regions are oppositely imprinted: NESP55 is only expressed from the maternal allele and its promoter is methylated on the paternal allele, whereas XLαs is only expressed from the paternal allele and its promoter is methylated on the maternal allele. Both NESP55 and XLαs are expressed primarily in neuroendocrine tissues. NESP55 is unrelated to the Gα family and its coding sequence is restricted to its specific upstream exon. Its biological function is unknown and studies in mouse and humans suggest that loss of its expression leads to minimal phenotypic consequences (Liu *et al.*, 2000a;

Plagge *et al.*, 2005). Imprinting of NESP55 is not established until after implantation and depends on a primary imprinting center located within the promoter region of a paternally expressed antisense transcript that traverses the NESP55 promoter from the opposite direction (Liu *et al.*, 2000b; Williamson *et al.*, 2006). XLαs is a $G_s\alpha$ isoform in which the first 47 amino acids of $G_s\alpha$ are replaced with a long amino-terminal extension encoded by its specific first exon (Kehlenbach *et al.*, 1994; Pasolli *et al.*, 2000). XLαs is capable of signal transduction and activation of adenylyl cyclase (Bastepe *et al.*, 2002; Klemke *et al.*, 2000). Although XLαs is critical for postnatal feeding and metabolic regulation in mice (Plagge *et al.*, 2004; Xie *et al.*, 2006), its role in humans is less clear.

ALBRIGHT HEREDITARY OSTEODYSTROPHY (AHO)

Clinical Presentation

Patients with AHO may present with one or more of the following clinical features: short stature, round face, broad body habitus, brachydactyly, subcutaneous ossifications, depressed nasal bridge, hypertelorism, and mental deficits or developmental delay (Fig. 3) (Ringel *et al.*, 1996; Spiegel and Weinstein, 2001; Weinstein, 1998; Weinstein *et al.*, 2001). None of these features are completely specific for this disorder, but the presence of subcutaneous ossifications is a fairly specific sign for AHO. The severity of the phenotype varies greatly, and some patients who carry the genetic trait present with few or no clinical manifestations (Farfel and Friedman, 1986; Miric *et al.*, 1993; Shore *et al.*, 2002; Weinstein *et al.*, 1990). Although obesity has in the past been considered a general feature of AHO, a recent study shows that it is selectively present only in PHPIA patients, as discussed later (Long *et al.*, 2007).

Ectopic ossifications in AHO (osteoma or calcinosis cutis) are often one of the earliest features of the disease (Gelfand *et al.*, 2006; Poomthavorn and Zacharin, 2006) and can occur in any location. They present as punctate hard nodules or as subcutaneous calcifications on radiographs located within the dermis and subcutaneous tissue (Eyre and Reed, 1971; Goeteyn *et al.*, 1999; Prendiville *et al.*, 1992; Sethuraman *et al.*, 2006) which occasionally enlarge to form more plate-like lesions but do not invade into deeper tissues. These lesions result from intramembranous, as opposed

FIGURE 3 Albright hereditary osteodystrophy (AHO). (*Left*) AHO patient with short stature, obesity, and rounded face with depressed nasal bridge. (*Right*) Photograph (above) and radiograph (below) of hand with severe brachydactyly of the first, fourth, and fifth metacarpals. (Reproduced from Weinstein (2004) "Molecular Basis of Inborn Errors of Development," Oxford University Press).

to endochondral, ossification, and may be surrounded by inflammation (Riepe *et al.*, 2005). These lesions result from a primary cellular defect, rather than a defect in mineral metabolism, because they are absent in patients with primary hypoparathyroidism and are present in PPHP patients, who are normocalcemic and have no evidence for parathyroid hormone (PTH) resistance.

Brachydactyly refers to shortening and widening of long bones in the hands and feet. Patients with AHO have a relatively specific pattern, which most often involves the distal thumb and third, fourth, and fifth metacarpals and is often asymmetric (de Sanctis, L., *et al.*, 2004; Graudal *et al.*, 1986; Poznanski *et al.*, 1977; Steinbach and Young, 1966). Brachydactyly is generally not observed in early childhood but becomes apparent later in the first decade of life because of premature growth plate closure with coning of the epiphysis (Gelfand *et al.*, 2006). Spinal cord compression occurs rarely, either from calcifications of longitudinal spinal ligaments (Chen, H. *et al.*, 2005a; Mak and Mok, 2005; Yamamoto, Y. *et al.*, 1997) or spinal canal narrowing (Goadsby *et al.*, 1991; Okada *et al.*, 1994).

Neurobehavioral abnormalities are also common in AHO patients, occurring in up to 50% of cases (Farfel and Friedman, 1986). There is no distinct neurocognitive syndrome associated with AHO, although psychomotor delay and mental retardation are relatively common. Psychiatric conditions and juvenile dementia have also been described in AHO patients (Maeda *et al.*, 2005). In rare cases, basal ganglia calcification resulting from the hypoparathyroid biochemical state may lead to Parkinsonian symptoms.

In addition to the physical features described earlier, AHO patients who inherit the disease from their mother (or have a *de novo* $G_s\alpha$ mutation on the maternal allele) also develop obesity and multihormone resistance, a condition known as PHPIA (Davies and Hughes, 1993; Long *et al.*, 2007; Weinstein *et al.*, 2001). In patients who inherit AHO from their father (or have a *de novo* mutation on the paternal allele) obesity and multihormone resistance is absent. This condition, in which patients present with only AHO, is also known as PPHP. Both PHPIA and PPHP often occur in the same kindred with the presentation of each case determined by parental inheritance. The multihormone resistance in PHPIA primarily involves PTH, thyroid-stimulating hormone (TSH), growth hormone-releasing hormone (GHRH), and the gonadotropins, all of which activate G_s pathways in their target tissues. There is no resistance, at least based on clinical parameters, to other hormones that also activate G_s, such as glucagon (Brickman *et al.*, 1986; Levine *et al.*, 1983), adrenocorticotropic hormone (ACTH) (Faull *et al.*, 1991; Levine *et al.*, 1983), isoproterenol (Carlson and Brickman, 1983), and vasopressin (Faull *et al.*, 1991; Moses *et al.*, 1986).

PHPIA patients develop renal PTH resistance during early childhood but may initially present with acute symptoms of hypocalcemia (seizures, tetany, numbness) at any time of life, often during early adolescence. In general, there is no evidence for PTH resistance at birth or even in the first year of life, but soon thereafter PTH levels rise followed by the development of hyperphosphatemia and finally hypocalcemia (Barr *et al.*, 1994; Gelfand *et al.*, 2006; Riepe *et al.*, 2005; Tsang *et al.*, 1984; Werder *et al.*, 1978; Yu, D. *et al.*, 1999). Over time patients develop chronic features of biochemical hypoparathyroidism, including basal ganglia calcifications, cataracts, and calcifications at other sites, and on rare occasions may develop rickets. Some PHPIA patients have elevated PTH levels but remain eucalcemic (Balachandar *et al.*, 1975; Breslau *et al.*, 1980; Drezner and Haussler, 1979). The PTH signaling defect is primarily localized to the renal proximal tubule, and this results in hyperphosphatemia owing to increased phosphate reabsorption and low or inappropriate normal serum 1,25 dihydroxyvitamin D [$1,25(OH)_2D$] levels (Braun *et al.*, 1981; Breslau and Weinstock, 1988; Lambert *et al.*, 1980; Miura *et al.*, 1990). Because the defect is limited to the proximal tubules, the ability of the distal tubules to reabsorb calcium in response to PTH remains intact, and therefore, PHP patients do not tend to develop hypercalciuria upon treatment as do patients with primary hypoparathyroidism. Consistent with the presence of a G_s defect, the acute PTH-stimulated urinary cAMP response is markedly blunted in PHPIA patients with PHPIA, whereas it is normal in PPHP patients (Chase *et al.*, 1969; Levine *et al.*, 1986). Although one bone sample from a PHPIA patient showed no defect in PTH-$G_s\alpha$ signaling (Ish-Shalom *et al.*, 1996), the occurrence of secondary skeletal effects of chronically elevated PTH is lower in PHPIA than in PHPIB, perhaps because of partial $G_s\alpha$ deficiency in osteoblasts from these patients.

TSH resistance is present in virtually all PHPIA patients and is often the first observed manifestation as TSH levels are generally elevated in neonatal screening (Gelfand *et al.*, 2006; Levine *et al.*, 1985; Weisman *et al.*, 1985; Yokoro *et al.*, 1990; Yu, D. *et al.*, 1999). TSH levels may normalize for several months before once again becoming elevated (Yu, D. *et al.*, 1999). Once TSH resistance is established, TSH levels are mildly or moderately elevated and thyroid hormone levels are normal or slightly low. Because the defect is at the level of TSH signaling, which also stimulates thyroid growth, goiter is usually absent. Antithyroid antibodies are usually absent.

Female PHPIA patients often present with signs of clinical hypogonadism, including delayed or incomplete sexual maturation, oligomenorrhea, or infertility, associated with mildly low estrogen levels (de Sanctis, C. *et al.*, 2003; Levine *et al.*, 1983; Namnoum *et al.*, 1998; Shapiro *et al.*, 1980; Shima *et al.*, 1988; Wolfsdorf *et al.*, 1978). Although it is assumed that these patients are resistant to gonadotropins, studies have not consistently demonstrated that they have elevated gonadotropin levels. It has been proposed that PHPIA patients may have a more subtle

form of gonadotropin resistance that leads to an ovulatory defect owing to a poor ovulatory response to the midcycle luteinizing hormone surge (Namnoum *et al.*, 1998). Some PHPIA patients also have prolactin deficiency (Brickman *et al.*, 1981; Carlson *et al.*, 1977; Faull *et al.*, 1991; Kruse *et al.*, 1981; Levine *et al.*, 1983; Schuster *et al.*, 1993).

Many, although not all, PHPIA patients have growth hormone (GH) deficiency, presumably secondary to pituitary resistance to GHRH (de Sanctis, L. *et al.*, 2007; Faull *et al.*, 1991; Germain-Lee *et al.*, 2003; Mantovani *et al.*, 2003; Shima *et al.*, 1988). However, short stature in PHPIA does not correlate with GH deficiency and appears to result from a primary skeletal growth plate defect leading to premature maturation and closure. In fact, prior to puberty, PHPIA patients often are tall for their biological age and have advanced bone ages. Olfactory defects have also been described in PHPIA (but not PPHP) patients, although it is unclear whether this reflects a true sensory defect or a central neurological defect (Doty *et al.*, 1997; Henkin, 1968; Ikeda *et al.*, 1988; Weinstock *et al.*, 1986).

Molecular Genetics

AHO was initially shown to be associated with a G_s signaling defect by biochemical and cellular assays performed on membrane samples from various tissues. (Bourne *et al.*, 1981; Downs *et al.*, 1983; Farfel and Bourne, 1980; Farfel *et al.*, 1980, 1981, 1982; Heinsimer *et al.*, 1984; Levine *et al.*, 1980, 1986; Mallet *et al.*, 1982; Ong *et al.*, 1996; Spiegel *et al.*, 1982). In these assays G_s signaling activity was similarly reduced by ~50% in tissues from both PHPIA and PPHP patients, suggesting that these patients have similar genetic G_s defects resulting from a genetic defect in one parental allele. Consistent with these findings, these patients were shown to have similar reductions in $G_s\alpha$ mRNA (Carter *et al.*, 1987; Levine *et al.*, 1988) and protein (Patten and Levine, 1990), and to have heterozygous $G_s\alpha$ loss-of-function mutations (Ahmed *et al.*, 1998; Ahrens *et al.*, 2001; Aldred *et al.*, 2000; Aldred and Trembath, 2000; de Sanctis, C. *et al.*, 2003; Linglart *et al.*, 2002; Miric *et al.*, 1993; Oude Luttikhuis *et al.*, 1994; Patten *et al.*, 1990; Rickard and Wilson, 2003; Shapira *et al.*, 1996; Spiegel and Weinstein, 2001; Thiele *et al.*, 2007; Weinstein *et al.*, 1990; Weinstein, 2004). All AHO patients within the same kindred (both those with PHPIA and PPHP) have identical mutations, confirming that AHO is an autosomal dominant disorder (Fischer *et al.*, 1998; Mantovani *et al.*, 2000; Nakamoto *et al.*, 1998; Walden *et al.*, 1999; Weinstein *et al.*, 1990; Wilson *et al.*, 1994; Yu, D. *et al.*, 1999). Whether an individual has PHPIA or PPHP is determined by parental inheritance, as discussed in the section on pathogenesis.

$G_s\alpha$ mutations in AHO are spread throughout the coding exons and in the majority of cases are unique to each kindred, although some identical mutations or mutations affecting the same amino acid have been identified in more than one kindred (Ahmed *et al.*, 1998; Ahrens *et al.*, 2001; Aldred and Trembath, 2000; Farfel *et al.*, 1996; Iiri *et al.*, 1994; Miric *et al.*, 1993). One 4-bp deletion in exon 7 has been identified in many families (Ahrens *et al.*, 2001; Aldred and Trembath, 2000; de Sanctis, C. *et al.*, 2003; Linglart *et al.*, 2002; Mantovani *et al.*, 2000; Shore *et al.*, 2002; Yu, S. *et al.*, 1995) as this site appears prone to *de novo* mutation owing to pausing of DNA polymerase and slipped strand mispairing (Yu, S. *et al.*, 1995). In most cases, there is no genotype–phenotype correlation as the mutations completely disrupt $G_s\alpha$ mRNA expression (frame shift, nonsense, or splice junction mutations) or $G_s\alpha$ protein stability (Warner *et al.*, 1997, 1998, 1999).

Several missense mutations have specific effects on $G_s\alpha$ function. For example, mutations at the carboxyl terminus uncouple $G_s\alpha$ from receptors (Linglart *et al.*, 2002, 2006; Schwindinger *et al.*, 1994; Wu, W.I. *et al.*, 2001). Mutation of the either Arg^{231} within the switch 2 region or Glu^{259} within the switch 3 region lead to a receptor activation defect by destabilizing interactions between the two switch regions that are necessary to maintain the active conformation (Iiri *et al.*, 1997; Warner *et al.*, 1999). The Arg^{258}Trp mutation results in decreased GDP binding in the basal state as well as a receptor-activation defect owing to increased GTPase activity (Warner *et al.*, 1998; Warner and Weinstein, 1999). The Ala^{366}Ser mutation results in PHPIA plus male gonadotropin-independent precocious puberty (testotoxicosis) (Iiri *et al.*, 1994). This mutation leads to increased GDP release in a temperature-sensitive manner. At core body temperature, the mutant protein has thermolability owing to an inability to maintain GDP binding, which results in PHPIA. At the lower testicular temperature, the GDP-binding defect is more subtle, allowing the protein to remain stable. However, testotoxicosis results from constitutive activation of $G_s\alpha$ owing to increased GDP/GTP exchange in the absence of receptor stimulation. but resulting in constitutive activation owing to GDP/GTP exchange independent of activation by receptor.

Diagnosis and Management

Although PTH stimulation of urinary cAMP (Ellsworth–Howard test) is the classical test for confirming the presence of PTH resistance (Chase *et al.*, 1969), the PTH analogue is no longer clinically available and with modern PTH assays the diagnosis can usually be made based on baseline hormonal measures once nutritional vitamin D deficiency and renal dysfunction are ruled out. Patients with a blunted urinary cAMP response to PTH are classified as having PHPI. PHPI is further subclassified as PHPIA or PHPIB based on the presence or absence of AHO and multihormone resistance, respectively. Rarely, patients have the PHPIA phenotype without evidence for a $G_s\alpha$ defect, and are classified as PHPIC. Patients who have

a normal urinary cAMP response but a defective phosphaturic response to PTH are classified as PHP type II (Rao, D.S. *et al.*, 1985).

Because many of the features of AHO (brachydactyly, obesity, neurobehavioral abnormalities) are nonspecific, the diagnosis should not be made based on the presence of these features alone, especially in the absence of family history, multihormone resistance, or subcutaneous ossifications, which is a more specific feature of AHO. These features are also present in other known genetic syndromes (e.g., Prader–Willi, brachydactyly syndromes, Turner's syndrome, Rubinstein–Taybi syndrome) and have also been found in association with chromosomal deletion of 2q37 (Phelan *et al.*, 1995; Wilson *et al.*, 1995). Therefore, in order to confirm the diagnosis of PHPIA or PPHP, one must confirm the presence of a $G_s\alpha$ defect by biochemical or genetic studies.

The most direct way to confirm the presence of a $G_s\alpha$ defect is by *GNAS* mutation, which is commercially available but only has a sensitivity of ~70%. Alternatively one can assay for G_s signaling activity in erythrocyte membrane sample, but this is only available in a few research laboratories and is more technically difficult. In at least some cases patients have been diagnosed as having PHPIC because a nonhydrolyzable GTP analogue was used to stimulate G_s in the biochemical assay. Because this bypasses the necessity for receptor stimulation, it will give a normal result even when the mutation produces a specific defect in receptor-stimulated signaling (Iiri *et al.*, 1997; Linglart *et al.*, 2002, 2006). For this reason, biochemical assays should be performed using a receptor ligand (e.g., isoproterenol) so that these $G_s\alpha$ biochemical defects are not missed.

There is no specific therapy for the physical and neurocognitive manifestations of AHO. The subcutaneous ossifications rarely require surgical excision to relieve discomfort or disfigurement. PTH resistance in PHPIA (and PHPIB) patients should be aggressively managed with oral calcium and vitamin D (either 50 to 100,000 IU/day of ergocalciferol or cholecalciferol or 0.5 to 2 μg/day of calcitriol). The goal is to try to normalize calcium and PTH, if possible, in order to prevent the skeletal effects of chronically elevated PTH and the development of autonomous (tertiary) hyperparathyroidism. Treatment should be initiated when patients develop high PTH levels even if normocalcemic. If autonomous parathyroid tumors develop, surgical excision may be required to reverse hypercalcemia, but management of the underlying PTH resistance will still be required postoperatively. PHP patients generally do not develop hypercalciuria upon treatment because the PTH defect is localized to the renal proximal tubule and the distal tubules can still increase calcium reabsorption in response to circulating PTH (Mizunashi *et al.*, 1990; Stone *et al.*, 1993). However, patients still need to be periodically monitored for hypercalciuria while on therapy.

Levothyroxine should be prescribed to normalize TSH levels and hypogonadism can be managed with oral contraceptives in females and testosterone in males. GH testing should be performed in children with PHPIA and GH therapy may be instituted if GH deficiency is diagnosed (de Sanctis, L. *et al.*, 2007; Germain-Lee *et al.*, 2003; Mantovani *et al.*, 2003). The more general use of GH in AHO patients to maximize height is under investigation.

Pathogenesis

The first clue that *GNAS* imprinting may be important for the clinical variability of AHO (PHPIA vs. PPHP) came from that observation that maternal inheritance produces offspring with PHPIA whereas paternal inheritance produces offspring with PPHP (Davies and Hughes, 1993; Nakamoto *et al.*, 1998; Wilson *et al.*, 1994). Molecular studies in mice and humans have confirmed that $G_s\alpha$ is imprinted in a tissue-specific manner, being expressed primarily from the maternal allele in pituitary, thyroid, gonads, and renal proximal tubules (Germain-Lee *et al.*, 2002; Hayward *et al.*, 2001; Liu *et al.*, 2003; Mantovani *et al.*, 2002; Yu, S. *et al.*, 1998). In these tissues mutation of the active maternal allele will result in $G_s\alpha$ deficiency and impaired hormone signaling, whereas mutation of the inactive paternal allele would have little effect on $G_s\alpha$ expression or hormone action (Fig. 4). Therefore, $G_s\alpha$ imprinting in renal proximal tubules would account for the fact that PTH-stimulated urinary cAMP is markedly reduced in PHPIA but is normal in PPHP (Chase *et al.*, 1969; Levine *et al.*, 1986). In most other nonendocrine tissues $G_s\alpha$ is biallelically expressed (Campbell *et al.*, 1994; Hayward *et al.*, 1998a, 1998b), which accounts for a similar ~50% reduction in $G_s\alpha$ expression observed in erythrocytes and other tissues in both PHPIA and PPHP patients (Levine *et al.*, 1986).

In renal proximal tubules PTH normally stimulates G_s/cAMP signaling pathways, which leads to decreased phosphate reabsorption and increased $1,25(OH)_2D$ production by induction of the 1α-hydroxylase gene. Therefore $G_s\alpha$ deficiency in PHPIA (and PHPIB) leads to decreased $1,25(OH)_2D$ production and hyperphosphatemia owing to low urinary phosphate excretion. Hyperphosphatemia also acts to inhibit $1,25(OH)_2D$ production. Hypocalcemia results from the combined effects of hyperphosphatemia and low $1,25(OH)_2D$ levels, because the latter results in decreased intestinal calcium absorption and skeletal calcium mobilization (Drezner *et al.*, 1976; Drezner and Haussler, 1979; Epstein *et al.*, 1983). Hypocalcemia, hyperphosphatemia, and low $1,25(OH)_2D$ levels all contribute to secondary hyperparathyroidism. Likewise, hypothyroidism, hypogonadism, and GH deficiency in PHPIA likely results from resistance to TSH, gonadotropins, and GHRH in their respective target tissues (thyroid, gonads, pituitary). (Germain-Lee *et al.*, 2003; Mallet *et al.*, 1982;

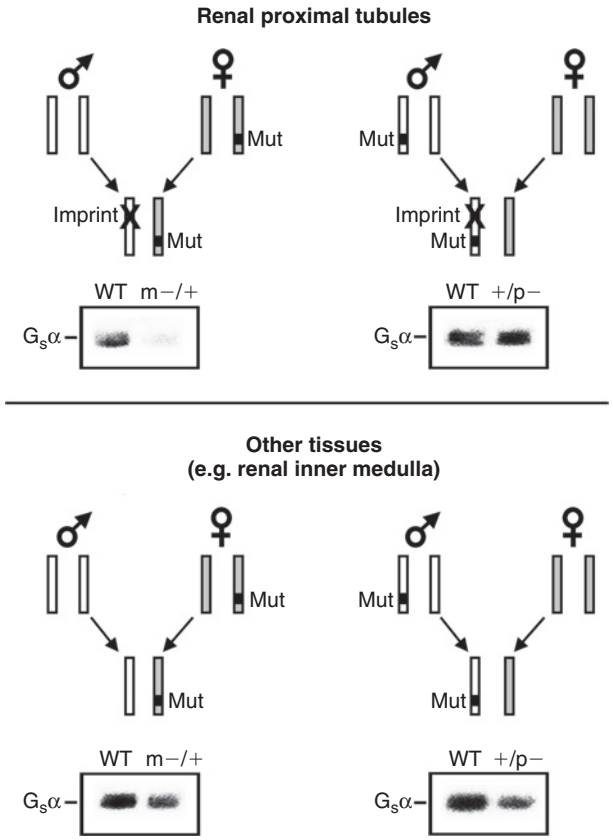

FIGURE 4 The role of tissue-specific $G_s\alpha$ imprinting in the pathogenesis of PHPIA and PPHP. (*Top*) $G_s\alpha$ is paternally imprinted (denoted with an X) in renal proximal tubules and therefore mutation (Mut) of the active maternal allele (gray) results in loss of $G_s\alpha$ expression and PTH resistance (*left*), whereas mutations in the inactive paternal allele (white) do not effect $G_s\alpha$ expression or hormone signaling (*right*), as shown below in immunoblots of renal cortical membranes from wild-type (WT) mice and mice with a $G_s\alpha$ mutation on the maternal or paternal allele (m −/+ or +/p−, respectively) using a $G_s\alpha$-specific antibody (Yu *et al.*, 1998). (*Bottom*) In other tissues $G_s\alpha$ is not imprinted and therefore maternal and paternal $G_s\alpha$ mutations both lead to ~50% loss of $G_s\alpha$ expression, as shown below in immunoblots of renal inner medullary membranes from the same mice (Yu *et al.*, 1998). (Reproduced from Weinstein (2004) "Molecular Basis of Inborn Errors of Development," Oxford University Press).

Mantovani *et al.*, 2003; Namnoum *et al.*, 1998). In all of these tissues $G_s\alpha$ has been shown to be imprinted, and therefore, maternal $G_s\alpha$ mutation leads to severe $G_s\alpha$ deficiency.

A likely explanation for why PHPIA patients do not show clinical resistance to other hormones that also activate $G_s\alpha$ in their target tissues (e.g., ACTH or vasopressin) is that $G_s\alpha$ is not imprinted in these target tissues and therefore $G_s\alpha$ expression is only reduced to ~50% in these tissues (Weinstein *et al.*, 2000). This partial $G_s\alpha$ deficiency may be insufficient to produce clinical hormone resistance, either because $G_s\alpha$ is not rate limiting for generating the cAMP second messenger, or because the cAMP levels, although reduced, are still sufficient to elicit a normal physiological response (Brickman *et al.*, 1986; Carlson *et al.*, 1985; Weinstein *et al.*, 2000). This would also explain why PTH resistance is evident in the renal proximal tubule, but not in the distal tubule or in the skeleton (Ish-Shalom *et al.*, 1996; Stone *et al.*, 1993).

Obesity is also a feature specific for PHPIA and therefore is also a consequence of severe $G_s\alpha$ deficiency in a tissue in which $G_s\alpha$ expression is normally affected by imprinting (Long *et al.*, 2007). This is confirmed by mouse studies showing that germline disruption of $G_s\alpha$ expression on the maternal allele leads to severe obesity and insulin resistance, whereas disruption of the paternal allele leads to a much less severe metabolic phenotype (Chen, M. *et al.*, 2005b). One potential mechanism for the pathogenesis of obesity in PHPIA would be $G_s\alpha$ deficiency in adipocytes leading a decreased ability of the sympathetic nervous system activity and hormones to stimulate lipolysis in these cells of these cells, which has been documented in these patients (Carel *et al.*, 1999; Kaartinen *et al.*, 1994). Moreover, genetic manipulations in mice that increase or decrease cAMP or its downstream effectors can lead to a lean or obese phenotype, respectively (Cummings *et al.*, 1996; Martinez-Botas *et al.*, 2000; Valet *et al.*, 2000). However $G_s\alpha$ has been shown not to be imprinted in adipose tissue (Mantovani *et al.*, 2004a) and mice with adipose tissue-specific $G_s\alpha$ deficiency do not develop obesity (Min Chen, L. Weinstein, unpublished results). Rather, the primary defect is probably in the central nervous system as norepinephrine levels, which reflect sympathetic nervous system activity are low in both PHPIA patients (Carel *et al.*, 1999) and mice with disruption of the $G_s\alpha$ maternal allele (Yu, S. *et al.*, 2000). This is confirmed by results showing that disruption of the $G_s\alpha$ maternal (but not paternal) allele in the central nervous system leads to severe obesity in mice (Min Chen, L. Weinstein, unpublished results). Presumably $G_s\alpha$ is imprinted in one or more sites in the central nervous system that are critical for energy balance. One potential site is the hypothalamus, because this is a site where α-melanocyte-stimulating hormone is known to act through $G_s\alpha$ pathways to decrease food intake and increase sympathetic active and energy expenditure. Recent studies have shown that odorant receptor/$G_s\alpha$/cAMP pathways may be important for axon guidance of odorant neurons, but whether this can explain the olfactory defect observed in PHPIA is at present unknown (Imai *et al.*, 2006).

The other AHO features that are present in both PHPIA and PPHP patients are also most likely to be caused by $G_s\alpha$ deficiency rather than NESP55 or XLαs deficiency, because these gene products would only be disrupted by maternal or paternal mutations, respectively, and AHO is absent in PHPIB patients in whom NESP55 is not expressed because of biallelic methylation of its promoter (Liu *et al.*, 2000a). Brachydactyly is likely the result of $G_s\alpha$ deficiency in

growth plate chondrocytes, which normally mediates the paracrine effects of PTH-related peptide (PTHrP) to inhibit hypertrophic differentiation of chondrocytes (Kronenberg, 2003; Vortkamp *et al.*, 1996). Mice with disruption of the gene encoding PTHrP (Karaplis *et al.*, 1994) or its receptor (Jobert *et al.*, 1998; Lanske *et al.*, 1996) develop severe skeletal dysplasia with stunted long bone growth resulting from accelerated chondrocyte differentiation. Other studies in mice have confirmed that $G_s\alpha$ deficiency in growth plate chondrocytes leads to a similar cellular and whole animal phenotype (Bastepe *et al.*, 2004; Sakamoto *et al.*, 2005). Osteoma cutis appears to result from the fact that $G_s\alpha$ deficiency in mesenchymal cells promotes osteoblast differentiation, as discussed in more detail in the sections on POH and MAS/FD. The exact mechanisms by which some AHO patients develop mental deficits are not clear, but may also be related to $G_s\alpha$ deficiency, as cAMP and PKA are known to be important for learning and memory (Abel *et al.*, 1997; Levin *et al.*, 1992; Rotenberg *et al.*, 2000; Wu, Z.L. *et al.*, 1995) and for neurite outgrowth and differentiation (Jessen *et al.*, 2001; Vossler *et al.*, 1997).

PROGRESSIVE OSSEOUS HETEROPLASIA

Clinical Features

POH is a more severe form of the ectopic ossification observed in AHO in which dermal and subcutaneous ossifications coalesce to form large plaques and invade deep connective tissues and skeletal muscle, leading to joint stiffness and bone deformity (Kaplan and Shore, 2000). Its onset is generally in early childhood, although one case of adult-onset POH has been reported in which a $G_s\alpha$ mutation was not identified (Seror *et al.*, 2007). POH may occur sporadically or in a familial manner. In many cases there are no other features of AHO, although POH has been reported to coexist with other features of AHO or multihormone resistance (Eddy *et al.*, 2000; Gelfand *et al.*, 2007). There is no specific therapy for the ossifications. A report of one case suggested that intravenous pamidronate may have slowed the progression of new lesions, although it did not affect the lesions that already had developed (Hou, 2006).

Genetics

In most cases POH is associated with heterozygous germline $G_s\alpha$ loss-of-function mutations that are similar, and in some cases identical, to those observed in patients with PHPIA and PPHP (Ahmed *et al.*, 2002; Eddy *et al.*, 2000; Gelfand *et al.*, 2007; Shore *et al.*, 2002; Yeh *et al.*, 2000). Although it has been reported that POH only occurs with paternal inheritance of *GNAS* mutations (Shore *et al.*, 2002), POH has been shown to occur upon maternal transmission of mutations in two cases, one of which also had features of PHPIA (Ahmed *et al.*, 2002; Eddy *et al.*, 2000). In one of these cases, the proband had POH whereas his affected sister presented with PHPIA without POH (Ahmed *et al.*, 2002). Moreover, another case showed features consistent with POH, AHO, and multihormone resistance (PHPIA) (Gelfand *et al.*, 2007). Although neither parent had the mutation, the presence of hormone resistance in the proband strongly suggests that the mutation was on the maternal allele. In one family, paternal transmission of a $G_s\alpha$ mutation resulted in five cases of POH in one generation, but maternal transmission of the mutation resulted in AHO (PHPIA vs. PPHP not determined) in the next generation (Shore *et al.*, 2002).

Pathogenesis

As in AHO, the ectopic ossifications in POH form by intramembranous ossification. Given that AHO and POH patients have similar mutations that completely disrupt $G_s\alpha$ expression, the severity of ectopic ossification in an individual patient is most likely determined by other factors, including differences in genetic background. Other genes that may modify the severity of ossification include those that may affect $G_s\alpha$ expression from the unaffected allele or those that encode other proteins involved in $G_s\alpha$ signaling or bone formation. It remains unclear why many POH patients do not also have other features of AHO. Although it has been reported that POH is only associated with mutation on the paternal allele (Shore *et al.*, 2002), several reports have contradicted this conclusion (Ahmed *et al.*, 2002; Eddy *et al.*, 2000; Gelfand *et al.*, 2007).

Although activation of $G_s\alpha$ mutations appears to inhibit osteoblast differentiation in FD, as discussed later, decreased $G_s\alpha$ expression promotes osteoblast differentiation in cultured cells with increased expression of the osteogenic transcription factor Cbfa1/RUNX2 and other osteoblast-specific genes (Lietman *et al.*, 2005). The effect of reduced cAMP on cellular levels of Cbfa1/RUNX2 protein may be, in part, the result of reduced degradation (Tintut *et al.*, 1999). This regulation may be bidirectional, because one study showed that Cbfa1/RUNX2 suppresses the expression of $G_s\alpha$ in a cultured osteoblastic cell line (Bertaux *et al.*, 2006). $G_s\alpha$ deficiency in mesenchymal precursor cells may promote osteoblast differentiation, leading to ectopic ossification in AHO and POH. Consistent with this, Cbfa1/RUNX2 mRNA was shown to be expressed in dermal fibroblasts from a POH patient (Yeh *et al.*, 2000).

PSEUDOHYPOPARATHYROIDISM TYPE IB

Clinical Features

PHPIB patients present with renal PTH resistance in much the same way as PHPIA patients, with diminished urinary

cAMP response to administered PTH or its analogues, but do not exhibit the AHO phenotype or resistance to most other hormones (Levine *et al.*, 1983). Consistent with the absence of AHO, G_s bioactivity is unaffected in erythrocyte membranes derived from PHPIB patients (Levine *et al.*, 1983; Silve *et al.*, 1986). About half of the patients show evidence of borderline TSH resistance, with slightly elevated TSH levels that in some cases may be intermittent (Bastepe *et al.*, 2001a; Foppiani *et al.*, 2006; Liu *et al.*, 2003). Some PHPIB patients present with elevated serum alkaline phosphatase, cortical bone resorption, osteitis fibrosa cystica, or slipped capital femoral epiphysis, presumably owing to the skeletal effects of chronically elevated PTH levels (Agarwal *et al.*, 2006; Costello and Dent, 1963; Kolb and Steinbach, 1962) and can rarely present with a rachitic picture. These complications seem to be relatively specific for PHPIB, as this is not a feature of PHPIA. Management of the PTH and TSH resistance is similar to that discussed for PHPIA, except that normalization of PTH levels may be more critical to prevent skeletal manifestations of elevated PTH levels and the development of autonomous (tertiary) hyperparathyroidism. In one kindred PHPIB was associated with increased uric acid excretion and hypouricemia (Laspa *et al.*, 2004), whereas in another kindred the affected patients initially presented with paroxysmal dyskinesia (Mahmud *et al.*, 2005).

Genetics

Most cases of PHPIB are sporadic, but some are familial. In familial cases the PTH resistance only occurs upon maternal transmission of the trait, similar to the inheritance pattern in PHPIA (Juppner *et al.*, 1998). Those who inherit the trait paternally are asymptomatic carriers. Although mapping studies linked familial PHPIB to the vicinity of *GNAS* on 20q13 (Juppner *et al.*, 1998), the presence of normal erythrocyte G_s function in PHPIB patients ruled out the possibility that the disease is caused by mutations that directly disrupt the $G_s\alpha$-coding exons (Levine *et al.*, 1983; Silve *et al.*, 1986). Rather, PHPIB is associated with a *GNAS*-imprinting defect in which maternal-specific imprinting (methylation) of the exon 1A-imprinting control region is absent in virtually all cases, resulting in a paternal-specific imprinting pattern (unmethylated) on both parental alleles (Bastepe *et al.*, 2001b; Jan de Beur *et al.*, 2003; Liu *et al.*, 2000a, 2005b). In sporadic cases the upstream NESP55, XLαs, and antisense promoters may also be abnormally imprinted, although imprinting of these upstream regions is unaffected in most familial cases (Liu *et al.*, 2005b). PTH resistance specifically correlates with loss of exon 1A maternal imprinting, and there is no phenotypic correlation with the imprinting status of NESP55, XLαs, or the antisense promoter. Paternal UPD of chromosome 20 has been reported in one patient with PTH and TSH resistance associated with other abnormalities (Bastepe *et al.*, 2001a).

Familial PHPIB in almost all cases is associated with a deletion within the linked STX16 gene (Bastepe *et al.*, 2003 ; Linglart *et al.*, 2005; Liu *et al.*, 2005b). Upon maternal transmission the deletion results in loss of maternal exon 1A methylation and PHPIB, but paternal transmission has no effect on exon 1A imprinting because the region is normally unmethylated on this allele and does not produce a phenotype. Although this region is presumed to have one or more *cis*-acting elements required for the establishment or maintenance of exon 1A methylation, deletion of the orthologous region in mice did not result in the exon 1A methylation defect or PTH resistance (Frohlich *et al.*, 2007). In two kindreds PHPIB was associated with maternal deletion of the NESP55 region and loss of maternal imprinting throughout the rest of the *GNAS* locus (Bastepe *et al.*, 2005). In another kindred PHPIB resulted from maternal, but not paternal, inheritance of a 3-bp deletion that removes the carboxyl-terminal residue Ile^{382} in $G_s\alpha$ (Wu, W.I. *et al.*, 2001). The original report showed evidence that this mutation resulted in selective uncoupling of the G protein from the PTH/PTHrP receptor, but a subsequent study showed evidence that the mutation leads to uncoupling from other receptors as well (Linglart *et al.*, 2006).

Pathogenesis

Loss of exon 1A imprinting in PHPIB strongly suggests that this region, which is a primary imprinting control center (Liu *et al.*, 2000b), is required for tissue-specific imprinting of $G_s\alpha$. A model has been proposed in which the exon 1A region contains one or more *cis*-acting regulatory elements that inhibit the activity of the $G_s\alpha$ promoter in a methylation-sensitive and tissue-specific manner (Weinstein *et al.*, 2001). In the model shown in Fig. 5, the exon 1A region contains a silencer element that binds a *trans*-acting repressor protein that is only expressed in specific tissues such as renal proximal tubules. Normally the repressor binds to the paternal allele and inhibits the paternal $G_s\alpha$ promoter but is unable to bind to the maternal allele because of methylation, allowing the maternal $G_s\alpha$ promoter to remain active. In PHPIB both parental alleles are unmethylated and therefore the repressor can bind to and suppress $G_s\alpha$ expression from both alleles, resulting in renal PTH resistance. In most other tissues the repressor is not expressed and therefore $G_s\alpha$ is expressed from both parental alleles. Moreover, the absence of the repressor would predict that loss of maternal exon 1A methylation in PHPIB patients would have no effect on $G_s\alpha$ expression, which is consistent with the fact that $G_s\alpha$ is unaffected in erythrocyte membranes from these patients. The absence of the AHO phenotype in PHPIB patients presumably is due

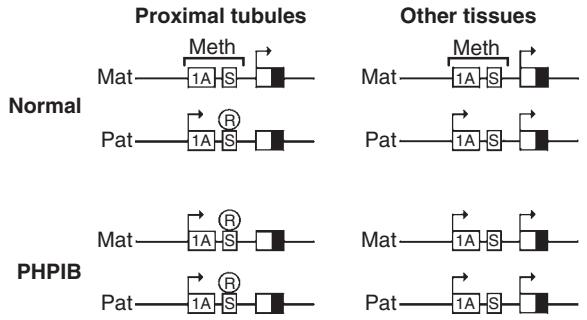

FIGURE 5 Model for tissue-specific $G_s\alpha$ imprinting and the pathogenesis of PHPIB. The model shown predicts that the exon 1A differentially methylated region has a *cis*-acting silencer element (S) that inhibits the paternal $G_s\alpha$ promoter (shown as half-filled box) in a tissue-specific manner by binding a repressor (R) that is expressed in a tissue-specific manner. In renal proximal tubules (*left*) the repressor can bind to and silence $G_s\alpha$ on the paternal allele but is unable to bind to or silence $G_s\alpha$ on the maternal allele because the binding site is methylated. In most other tissues (*right*) the repressor is not expressed and therefore $G_s\alpha$ is biallelically expressed. In PHPIB, methylation of the maternal allele is absent, allowing the repressor to bind to and silence $G_s\alpha$ from both alleles in renal proximal tubules, leading to $G_s\alpha$ deficiency and renal PTH resistance. In most other tissues $G_s\alpha$ expression is unaffected because the repressor is not expressed. This would explain why PHPIB patients have normal $G_s\alpha$ expression in erythrocytes and why they do not develop AHO. (Adapted from Weinstein (2004) "Molecular Basis of Inborn Errors of Development," Oxford University Press).

to the fact that $G_s\alpha$ expression levels are unaffected in the vast majority of tissues where $G_s\alpha$ is normally expressed equally from both parental alleles. Because $G_s\alpha$ is not imprinted in bone, this tissue would be expected to have normal $G_s\alpha$ levels and PTH responsiveness, and therefore be prone to the adverse effects of chronically elevated PTH levels (Murray *et al.*, 1993).

This model is supported by the observation that deletion of the exon 1A region from the paternal allele in mice leads to loss of tissue-specific $G_s\alpha$ imprinting (Liu *et al.*, 2005a; Williamson *et al.*, 2004). In fact, these mice have markedly reduced circulating PTH levels, presumably because of increased PTH sensitivity in renal proximal tubules owing to $G_s\alpha$ overexpression. Borderline TSH resistance in PHPIB results from the fact that $G_s\alpha$ expression from the paternal allele is normally only partially suppressed (Liu *et al.*, 2003).

FIBROUS DYSPLASIA OF BONE AND THE MCCUNE–ALBRIGHT SYNDROME

Clinical Features

Fibrous dysplasia of bone (FD) is a benign skeletal disorder with a broad spectrum of severity. It may involve a single bone (monostotic fibrous dysplasia, MFD), multiple bones (polyostotic fibrous dysplasia, PFD), or in rare

FIGURE 6 (A typical café-au-lait spot in a patient with McCune–Albright syndrome. Note the relationship of the skin lesions to the midline, the jagged (coast of Maine) borders, and the relationship to the developmental lines of Blashko. The linear patch at the nape of the neck is seen quite commonly, either in isolation or in association with the larger skin lesions.

circumstances, the entire skeleton (panostotic fibrous dysplasia) (Bianco *et al.*, 2003; Collins and Bianco, 2006; Collins, 2006; Lichtenstein and Jaffe, 1942). In a minority of cases FD (usually PFD) is found in association with characteristic skin spots and hyperfunctioning endocrinopathies, and this triad is known as the McCune–Albright syndrome (MAS) (Albright *et al.*, 1937; McCune, 1936). The skin lesions (café-au-lait spots) have a characteristic appearance of jagged borders (resembling the cartographic appearance of the coast of Maine), and tend to follow the developmental lines of Blaschko (Fig. 6). The hyperfunctioning endocrinopathies, in order of decreasing prevalence, include gonadotropin-independent precocious puberty, thyroid nodules with hyperthyroidism, growth hormone excess (acromegaly/gigantism), and/or adrenal hyperplasia with glucocorticoid excess (Cushing's syndrome) (Collins and Shenker, 1999; Danon and Crawford, 1987; Ringel *et al.*, 1996). In each case the associated pituitary trophic hormones (gonadotropins, thyrotropin, ACTH) are undetectable, indicating a primary defect in each endocrine gland. Parathyroid gland involvement has been reported to be part of the syndrome, but it is questionable if this is really a feature of the disease. In the one reported case of hyperparathyroidism associated with FD/MAS in which a mutation in the hyperplastic gland was sought, it was not present. Some of the suspected cases may in fact be affected with hyperparathyroidism jaw tumor syndrome (HJTS), in which fibro-osseous lesions (somewhat reminiscent of FD at the clinical, radiographic, and histopathological level) arise in the gnathic bones in association with hyperparathyroidism (Carpten *et al.*, 2002). The misdiagnosis of HJTS (a familial disease) as FD has led to some cases reported as "familial FD/MAS"(Osundwa *et al.*, 2001).

FD was originally described by Donovan McCune and Fuller Albright in association with café-au-lait spots and

endocrine hyperfunction, with Albright labeling the disease as osteitis fibrosa dessiminata (Albright *et al.*, 1937; McCune, 1936). This name was assigned because of the resemblance, especially at the histopathological level, to the bone disease of hyperparathyroidism, osteitis fibrosa cystica. In the original cases Albright described, the patients had extensive (disseminated) PFD, thus dessiminata. It was Lichtenstein who labeled the disease FD (Lichtenstein, 1938), and Lichtenstein and Jaffe were the first to report extensively on the spectrum, radiographic appearance, and histopathology of FD (Lichtenstein and Jaffe, 1942). FD in the long bones usually presents in childhood as a limp, pain, or pathological fracture (DiCaprio and Enneking, 2005; Leet and Collins, 2007). FD in the skull may first appear as subtle facial asymmetry, or a "lump," and is sometimes associated with pain (Riminucci *et al.*, 2002). Fractures (especially low trauma, pathological fractures) are more common in childhood, but can persist into adulthood (Leet *et al.*, 2004a). Pain, sometimes severe, even in the absence of fractures or trauma is a common feature of FD, particularly in adults (Kelly *et al.*, 2007a). The extent of the disease (skeletal disease burden score) can be quantified with the use of nuclear medicine bone scans (Collins, *et al.*, 2005), and the skeletal disease burden score directly correlates with fracture rate and number, but surprisingly not with the extent of pain. The skeletal disease burden score also has a direct correlation with the extent to which FD has a deleterious effect on the health-related quality of life (Kelly *et al.*, 2005), with the predominant factor affecting quality of life being the extent to which the skeletal disease burden impacts on the ability to ambulate without assistance. Renal phosphate wasting leading to hypophosphatemia, rickets, and osteomalacia is also seen in cases of FD or MAS with extensive skeletal involvement (Collins, *et al.*, 2001; Riminucci *et al.*, 2003a).

FD affects the spine commonly and can be associated with scoliosis (Leet *et al.*, 2004b) (Fig. 7). The FD-associated scoliosis usually appears in childhood and can progress rapidly, even into adulthood, and rarely can be lethal. An uncommon finding in association with FD can be intramuscular myxomas, known as Mazabraud's syndrome (Mazabraud and Girard, 1957). Isolated intramuscular myxomas, in the absence of FD, are also caused by the same $G_s\alpha$ mutations (Okamoto *et al.*, 2000). Rarely (<1% of cases), FD can undergo malignant transformation. Cancer will usually present as the rapid expansion of a preexisting FD lesion in association with pain. On imaging studies there will be a disruption of the cortex in association with a soft-tissue mass. Bone cancers have been reported in 123 cases in two large case series (Ruggieri, M. *et al.*, 1999; Schwartz and Alpert, 1964) and in two large reviews (Lopez-Ben *et al.*, 1999; Yabut *et al.*, 1988), wherein it was found that approximately half of the cases of cancer arose in MFD and half in PFD. When one considers that MFD is more common, cancer is more likely to occur in PFD. The region/bones most commonly involved are the craniofacial bones, the femur, and the tibia. In these series, the most commonly seen histological types were osteosarcoma, fibrosarcoma, and chondrosarcoma. There are reports suggesting that malignant transformation may be more common in patients with Mazabraud's syndrome (Jhala *et al.*, 2003; Lopez-Ben *et al.*, 1999). However, this is likely not the case, but rather represents an ascertainment bias, as the actual prevalence of intramuscular myxomas in association with FD may be more common than expected because most intramuscular myxomas are asymptomatic and go undetected.

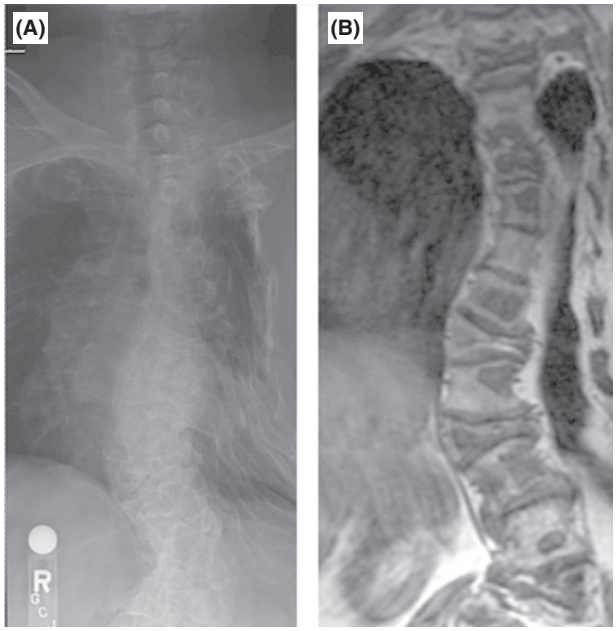

FIGURE 7 *Scoliosis in FD.* Scoliosis of the spine is demonstrated in an x-ray (**A**) and MRI of the spine (**B**) in a 54-year-old woman with FD. The extent of the involvement of the vertebral columns with FD is demonstrated in the MRI where large parts of the vertebrae are shown to be replaced with FD. Surprisingly, and typically, the woman had neither pain nor any evidence of neurological compromise, despite extensive disease and multiple compression fractures.

Genetics

FD/MAS is the result of activating mutations in $G_s\alpha$ (Schwindinger *et al.*, 1992; Weinstein *et al.*, 1991). The vast majority of the mutations (>95% in our series, unpublished data, and 100% in a large published series [Lumbroso *et al.*, 2004]) occur at Arg^{201}, and are divided roughly equally between either Arg^{201} to His or Arg^{201} to Cys. However, a recent report from a large series of patients with FD has found three cases (5%) in which the patients had Gln^{227} to Leu mutations (Idowu *et al.*, 2007). The lack of vertical transmission of FD or MAS, the fact that the skin lesions appear to roughly follow the developmental lines of

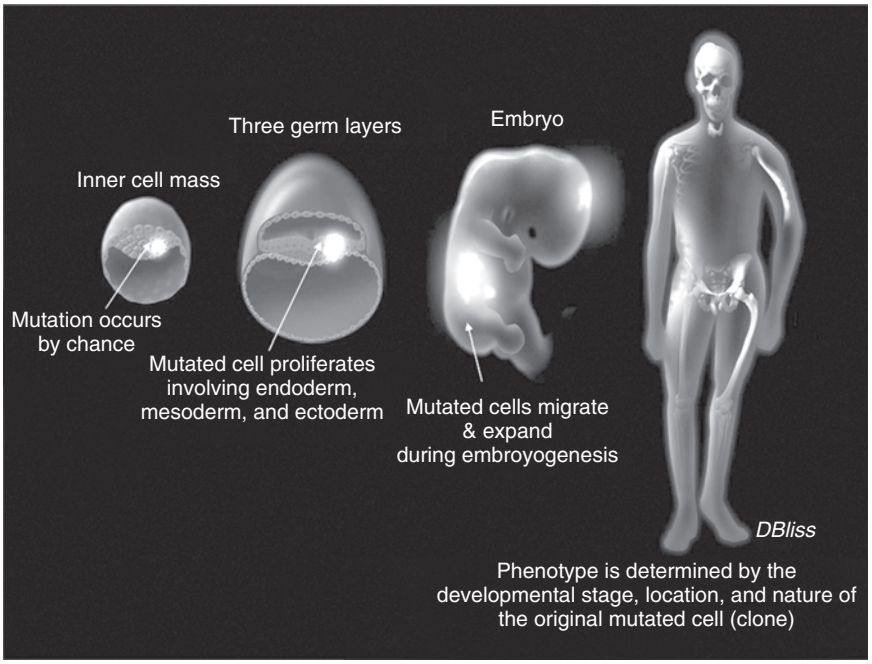

FIGURE 8 Developmental explanation for FD and MAS. For involvement of tissues that derive from all three germ layers (skin, bone, and thyroid, for example), the mutation must have occurred in the inner cell mass at the blastocyst stage. The clone in which the mutation occurs is propagated into the three germ layers and the cells migrate and proliferate, leading to the final phenotype.

Blaschko, and the fact that the skeletal lesions often tend to affect one side of the body has led to the widely held concept that FD and MAS are the manifestation of somatically acquired *GNAS* mutations and that patients are mosaics. The concept, first proposed by Happle (1986), is that if germline, the *GNAS* mutations that cause FD and MAS, were lethal, the mutation would only "survive" because the somatic, mosaic nature of the mutation. The implication of this line of reasoning is that, for a patient with MAS whose disease is manifested by, for example, café-au-lait skin spots (a tissue of ectodermal origin), FD of the long bones (a tissue of mesodermal origin), and hyperthyroidism (a tissue of endodermal origin), the mutation must have occurred very early in development at the inner cell mass stage, prior to the development of the three germ layers (Fig. 8). Although the clinical data appear to support this model, it has yet to have been proven experimentally. Because $G_s\alpha$ is imprinted in a tissue-specific manner, the clinical presentation of individuals may also be affected by the parental allele that harbors the mutation, particularly with respect to the presence or absence of acromegaly (Mantovani *et al.*, 2004b).

Pathogenesis

FD is the result of $G_s\alpha$ activating mutations in bone marrow stromal cells, which are the skeletal stem cell that gives rise to osteogenic cells, including chondrocytes, osteoblasts, and osteocytes, as well as bone marrow adipocytes and hematopoietic supportive stromal cells (Bianco and Robey, 1999). Lichtenstein was the first to speculate that FD is the result of the "perverted activity of the specific bone-forming mesenchyme" (Lichtenstein, 1938) and Bianco and colleagues were the first to prove that FD results specifically from bone marrow stromal cells harboring the activating $G_s\alpha$ mutations (Bianco *et al.*, 1998; Bianco and Robey, 1999; Riminucci *et al.*, 1997). In addition, it has been shown that the ability of cells harboring the $G_s\alpha$ mutation to produce an FD lesion depends on the presence of both mutated and nonmutated cells (Bianco *et al.*, 1998). It is the fate of the original clone in which the mutation occurs that dictates the phenotype of an individual patient (see Fig. 8). If the mutation occurs very early in development in a clone in the inner cell mass there will be widespread tissue involvement, perhaps involving all bones and multiple endocrine glands as well. If it occurs later in development, perhaps lateral to the midline, there may be only skeletal tissue on one side of the body involved. The "map" of affected tissue is established early in life, with the majority of FD lesions established by the age of 5 years and with virtually no new lesions occurring after the age of 15 (Hart *et al.*, 2007). Developmentally, the skeleton forms normally, in that all bones are present in the appropriate anatomical location and relative size, growth plates form normally, and the cortex of bones is intact and normal (at least initially). FD first appears in the bone marrow space of an anatomically normal bone. The fibroosseous tissue that makes up FD replaces the normal bone marrow. It can, and often does expand within the bone

marrow space, increasing the relative size of the bone marrow compartment, deforming the segment of the involved bone in an expansile fashion and thinning the bone cortices. Although entire bones, or even the entire skeleton, can be involved, the disease only involves the bone marrow compartment. Because of the fibrous nature of the tissue and the thinning of the cortex, the weight-bearing bones, especially the femurs, will often bow, giving rise to the "shepherd's crook" deformity of the proximal femur and the "windswept" deformity of the lower extremities (Fig. 9).

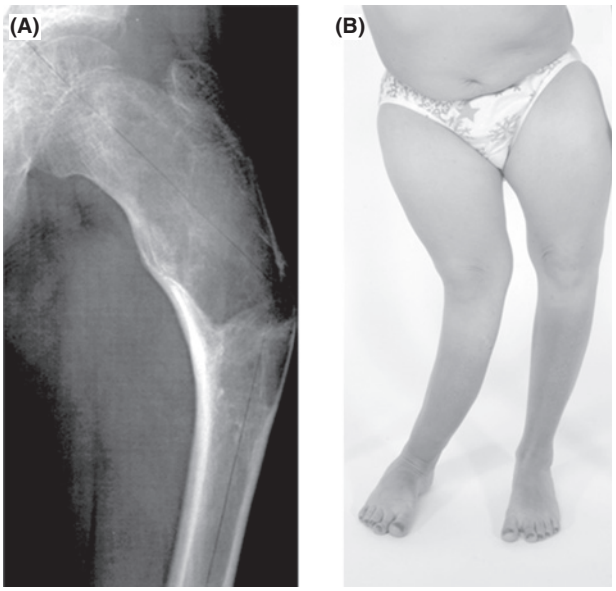

FIGURE 9 Classic deformities associated with FD. The shepherd's crook deformity (**A**) of the proximal femur and, the "windswept" deformity often seen in severe bilateral lower extremity disease (**B**) are shown.

The genesis of a FD lesion, from a nascent, virtually undetectable collection of bone marrow stromal cells harboring the $G_s\alpha$ mutation and residing in the marrow of an as yet clinically unaffected young child, to the full blown, clinically significant lesion giving rise to the shepherd's crook or windswept deformity involves a complex process that involves all steps in bone development and maintenance, including modeling, bone deposition, mineralization, and remodeling (Riminucci *et al.*, 2007). These processes give rise to a fibroosseous bone disease with a distinct and unique histopathology (Fig. 10). The details of the histopathology are complex and are detailed elsewhere (Bianco *et al.*, 1998; Bianco and Robey, 1999; Bianco *et al.*, 2000; Riminucci *et al.*, 1997, 1999., 2003b, 2006, 2007), but the essentials include a bone marrow space that is replaced with a "fibrous" tissue that is composed of cells that express markers of osteogenic cells. The islands of bone within the fibrous tissue are abnormal in that this tissue is immature, woven bone and has increased numbers of osteocytes. In some cases the lesions may also include islands of chondrocytic cells. There are two hallmarks of FD histopathology: one is the presence of retracted, stellate-shaped osteoblastic cells, which is because of the effect of excess cAMP (Miller, S.S. *et al.*, 1976; Riminucci *et al.*, 1997); and the second is the arrays of collagen bundles running perpendicular to the trabecular surface, known as Sharpey fibers (Riminucci *et al.*, 1997), which are a normal feature at sites of tendon and ligament insertion into bone. In addition, FD, which is created by the intrinsic genetic defect in the bone marrow stromal cell, is further impacted by the abnormal extrinsic hormonal milieu that can exist as part of the McCune–Albright syndrome.

It was an understanding of the signaling pathways in the endocrine tissues affected in MAS patients that led to the discovery of the molecular defect underlying FD. The

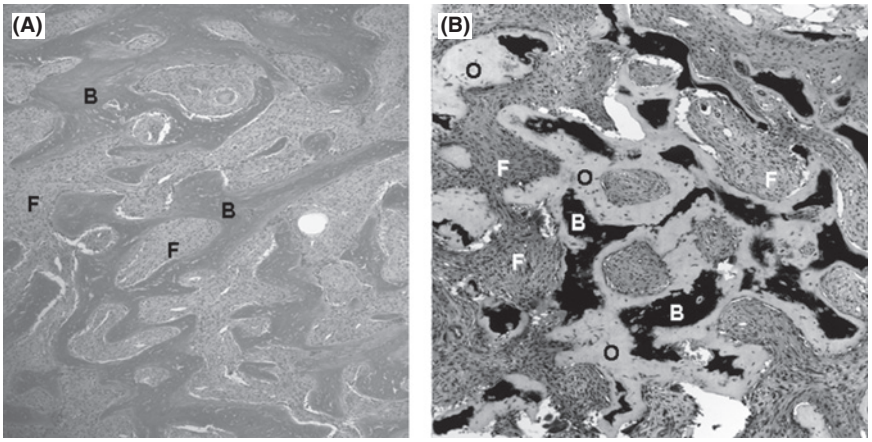

FIGURE 10 Histopathological appearance of FD. (**A**) H&E staining of a demineralized section of FD showing the classic "Chinese characters" made of trabeculae bone (labeled **B**) with fibrous tissue interwoven between (labeled F). (**B**) Von Kossa stain of an undemineralized, plastic-embedded section of bone, useful for inspecting the degree of mineralization, shows that the trabeculae of bone are composed of bone (black, labeled B) as well as osteoid (labeled O). The fibrous tissue is labeled (F). The presence of the unmineralized bone confirms the osteomalacic nature of the lesions.

realization that in each endocrine tissue growth and hormonal hypersecretion occurs in the absence of pituitary trophic hormones suggested that the defect was downstream of the cell surface receptors for these hormones and may involve the G proteins that are coupled to cell surface receptors in the generation of downstream signaling (Schwindinger, *et al.*, 1992; Weinstein *et al.*, 1991). The activating mutations in $G_s\alpha$ that give rise to FD lead to ligand-independent generation of intracellular cAMP by inhibiting its intrinsic GTPase activity, leading to activation of downstream signaling pathways (Fig. 11) (Spiegel and Weinstein, 2004). In osteogenic cells increased stimulation of protein kinase A by cAMP leads to phosphorylation of the cAMP-response element-binding protein (CREB) and the related cAMP-response element modulator proteins (CREM). CREB phosphorylation induces the c-*fos* gene, leading to increased expression of Fos protein, a component of the activator protein 1 (AP1) transcription complex (Gaiddon *et al.*, 1994; Sassone-Corsi, 1995). AP1 is more abundant in proliferating osteogenic precursors and its expression markedly decreases upon the onset of differentiation (Stein and Lian, 1993). Fos is overexpressed in FD lesions (Candeliere *et al.*, 1995) and Fos overexpression in osteogenic cells leads to lesions reminiscent of FD in mice (Rüther *et al.*, 1987). Consistent with this, cells in FD lesions have an increased proliferative rate and only express early markers of osteoblast differentiation (Marie *et al.*, 1997; Riminucci *et al.*, 1997). Phosphorylated CREB and AP1 also lead to induction of the interleukin 6 (IL6) gene, and increased IL6 production leads to osteoclast recruitment and cortical bone resorption, allowing concentric expansion of the FD lesion (Motomura *et al.*, 1998; Yamamoto, T. *et al.*, 1996).

Another metabolic syndrome that is commonly seen in association with FD is renal phosphate wasting (Collins *et al.*, 2001). Whereas it was originally thought that the phosphaturia, with resultant hypophosphatemia, was the result of the presence of the $G_s\alpha$ mutation in the kidney (Zung *et al.*, 1995), it has more recently been shown that phosphaturia is caused by oversecretion of the recently described phosphaturic hormone fibroblast growth factor 23 (FGF-23) by FD bone cells (Riminucci *et al.*, 2003a). As such, the degree of renal phosphate wasting is directly correlated with the extent of the FD skeletal disease burden (Collins *et al.*, 2005). Of the associated extrinsic endocrine/metabolic syndromes associated with FD, it is hypophosphatemia that probably has the most profound effect on FD. Hypophosphatemia will exacerbate the intrinsic

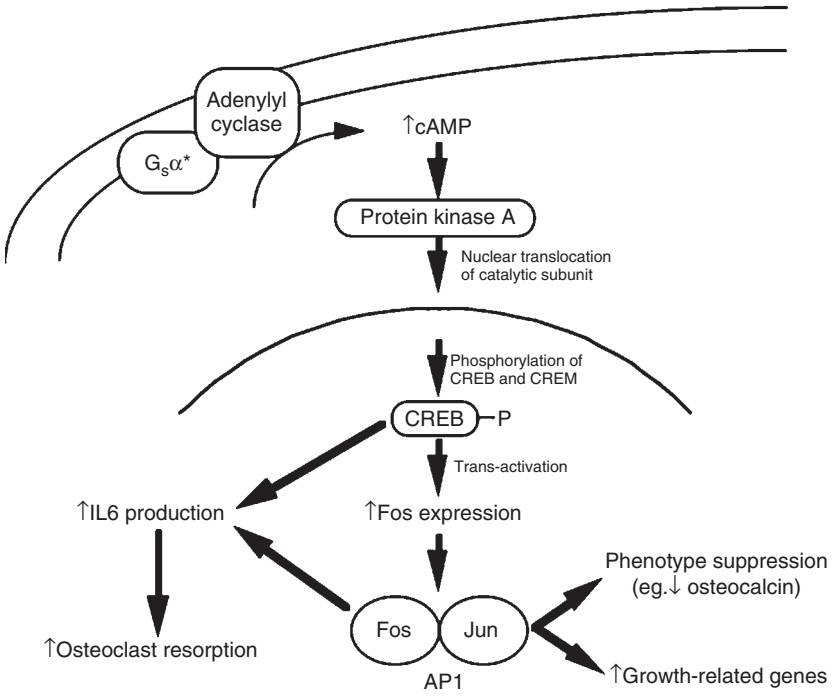

FIGURE 11 Possible mechanisms by which activated G_s in osteogenic cells may lead to FD. G_s activation increases the activity of the effector adenylyl cyclase, leading to increased intracellular cAMP levels. Binding of cAMP to the regulatory subunits of cAMP-dependent protein kinase (protein kinase A) allows release of its catalytic subunits, which translocate to the nucleus and phosphorylate proteins such as CREB and CREM. Phosphorylated CREB binds to promoters of cAMP-responsive immediate-early genes (e.g., c-*fos*) and increases their expression. Fos, the product of c-*fos*, binds with Jun to form AP-1. AP-1 is a transcription factor that increases the expression of growth-related genes and decreases the expression of osteoblast-specific genes, such as osteocalcin (phenotype suppression). Phosphorylated CREB and AP-1 also stimulate the transcription of the IL-6 gene. IL-6 may be important in recruiting osteoclasts and stimulating osteoclastic bone resorption.

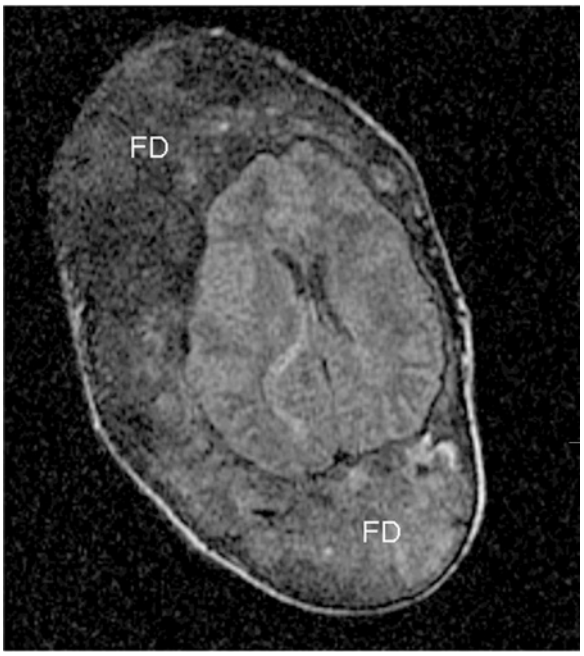

FIGURE 12 Craniofacial FD complicated by growth hormone excess. Areas of FD that have undergone massive expansion under the stimulation of excess GH/IGF-1 in a patient with McCune–Albright syndrome are shown. The craniofacial bones are the only bones to undergo such expansion in patients with FD and GH excess.

hypomineralization that exists in FD lesions (Bianco *et al.*, 2000; Corsi *et al.*, 2003) and is associated with greater degree of deformity and an increased number of fractures that occur at a younger age (Leet *et al.*, 2004a). Growth hormone excess worsens craniofacial fibrous dysplasia and may lead to bone overgrowth that can be dramatic (Lee *et al.*, 2002; Uwaifo *et al.*, 2001) (Fig. 12) and lead to vision and hearing loss owing to nerve compression (Cutler *et al.*, 2006).

Diagnosis and Management

Clinically significant disease is usually diagnosed in childhood—the more significant, the earlier the presentation. The initial presentation of disease in the long bones is usually a limp, pain, or fracture through an FD lesion. Disease in the craniofacial region usually presents as a "lump," which in recollection by the parents is often felt to have occurred as the result of minor, everyday trauma of childhood, but which never resolved. X-rays usually have a characteristic "ground glass" appearance (Fig. 13A). However, this classic ground glass appearance is, to an extent, age-dependent. In fact, in very young children, FD is not even apparent on x-rays and is only detected on a nuclear medicine bone, and when it does appear on an x-ray it has an inhomogeneous "streaked" appearance, rather then the ground glass appearance (see Fig. 13B). This streaked appearance is sometimes mistaken for the "dripping candle wax" appearance of Ollier's disease. In older patients, sclerosis can appear at the edges of FD lesions, representing the reaction of the adjacent normal bone to the FD, and indicating less active disease (see Fig. 13C). The same is true of FD in the craniofacial region. By CT scanning, the modality of choice for imaging craniofacial FD, the appearance is homogeneous and ground glass in young children (see Fig. 13D). With time, the lesions develop a mottled appearance, in which the lesions are an admixture of typical fibroosseous tissue with islands of what is essentially soft tissue (see Fig. 12E). This appearance is often referred to as "cystic," which is a useful descriptor, but it must not be mistaken for true, fluid-filled cysts, which occur uncommonly in FD. Fluid-filled cysts, with pathognomonic fluid levels, which are best seen on MRI scans, occur in fewer than 5% of the cases of FD. These truly cystic lesions often behave aggressively, rapidly expanding into adjacent tissue, destroying cortex, and when they are adjacent to vital structures, especially in the skull, can have significant morbidity. These lesions require immediate surgical attention. Fluid-filled cysts in the craniofacial region can be distinguished from soft tissue "cystic" lesions on CT scanning by measuring the Houndsfield units; fluid-filled lesions will be = 10 HU, while cystic lesions will be more than 10 HU (Collins and Bianco, 2006).

When FD lesions occur in the setting of either typical café-au-lait spots or hyperfunctioning endocrinopathies, the diagnosis is straightforward. However, if there is confusion, a biopsy demonstrating the typical histopathological changes cited earlier can aid in the diagnosis. Finally, if confusion still exists, mutation analysis on affected tissue can confirm the diagnosis if positive for a $G_s\alpha$ mutation. Another factor that can aid in the diagnosis is consideration of the bones involved and/or the distribution of the disease. FD most commonly involves the proximal femur and skull base, and in polyostotic disease at least one of these two areas will always be involved. When multiple bones are involved, asymmetry is the rule, and the presence of bilateral, symmetric disease is suggestive of another process. A nuclear medicine bone scan is a useful tool for assessing the extent of disease and distribution. In addition, measurement of skeletal disease burden by bone scan can quantify the extent of the disease and aid in prognostication in terms of potential future morbidity (Collins *et al.*, 2005).

In evaluating and caring for patients with FD, it is important to screen for and treat associated endocrinopathies. There often is not a direct correlation between the extent of the skeletal disease and the extent of endocrine involvement, so one cannot assume that minimal skeletal disease automatically excludes the presence of significant endocrine disease. A careful history, physical examination, evaluation of the growth chart, and focused laboratory testing is necessary. The evaluation should assess for precocious puberty, hyperthyroidism, hypophosphatemia (with a low serum $1,25(OH)_2$-vitamin D and renal phosphate

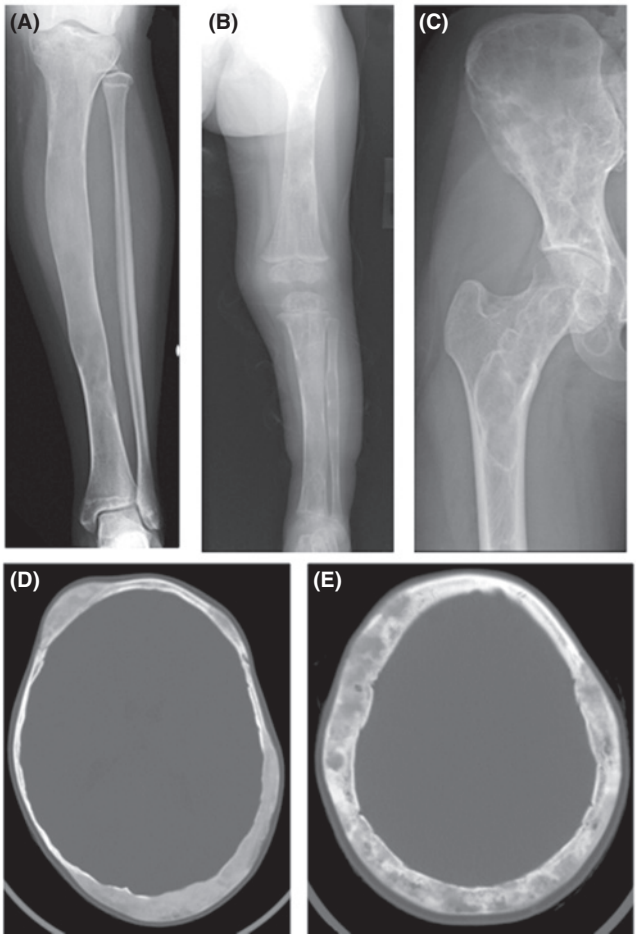

FIGURE 13 Radiographic appearance of FD. The classic description of the radiographic appearance of FD is "ground glass," which is depicted in the tibia (**A**). In very young children, the appearance has more of a streaked appearance (**B**), and in older patients with less active disease there is often a sclerotic rim around FD lesions (**C**). On CT scanning in young children the appearance is, again, homogeneous and ground glass (**D**), but with age, the appearance is inhomogeneous and mottled, and is sometimes reported to be "cystic" (**E**).

wasting), and growth hormone excess. Glucocorticoid excess can also occur, usually in the neonatal period. The altered phosphate and vitamin D metabolism is caused by overproduction of the phosphaturic factor FGF-23 by FD bone, so measurement of serum FGF-23 (which is not currently commercially available) can aid in the diagnosis (Collins *et al.*, 2001; Riminucci *et al.*, 2003a). There is a direct correlation between the risk for hypophosphatemia and the FD skeletal burden, so FGF-23-mediated renal phosphate wasting is only seen in cases of fairly extensive FD.

Surgery remains the mainstay of treatment for FD of the appendicular skeleton. Yet, there is no consensus to date as to the timing or indications and which techniques are best for which indication and at which age. There is an emerging consensus that, when their use is possible, intramedullary rods are better than side plates and screws.(Ippolito *et al.*, 2003; Leet and Collins, 2007; Stanton, 2006). Although bone grafting (filling FD lesions with grafting material— often bone bank, cadaveric bone) was at one time considered useful, a consensus is emerging, especially considering children, that this is not the best practice.

The skull base, through which the optic nerves pass, is the most common site for FD involvement, and it was believed that optic nerve encasement was progressive and visual impairment the rule if left untreated (Chen, Y. R. *et al.*, 1997; Moore *et al.*, 1985). For this reason, prophylactic decompression of the optic nerves was recommended. However, recent evidence has shown that this not the case (Lee *et al.*, 2002). In fact, the vast majority of patients with skull base FD, despite extensive disease, will have normal vision throughout their lives. It has been further shown that the one group of patients who do suffer functional morbidity owing to craniofacial FD (blindness and deafness) are the subgroup of patients with growth hormone excess (Cutler *et al.*, 2006). This point emphasizes the importance for screening and treatment of growth hormone excess in patients with craniofacial FD.

Another aspect of the disease that needs to be noted because of the possibility of significant morbidity, and even mortality, is that of scoliosis associated with FD of the vertebral column. FD in the spine was thought to be an uncommon occurrence, probably because it is difficult to detect on plain radiographs. However, it has been shown recently that when the sensitive detection technique of ^{99}Tc-MDP bone scanning is used, FD in the spine can be seen in up to 63% of the patients with FD, and that in 64% of the patients who had FD in the spine there was associated scoliosis (Leet *et al.*, 2004b). Importantly, although scoliosis can be progressive and associated with significant morbidity and mortality, it is also amenable to surgical correction, and the surgical correction is effective and lasting— more lasting than most other surgical interventions in FD.

Bisphosphonates are a useful adjuvant in the treatment of FD. Early reports contained great enthusiasm for the use of bisphosphonates in having a significant effect on the natural history of the disease (Chapurlat *et al.*, 1997; Liens *et al.*, 1994; Parisi *et al.*, 2001; Zacharin and O'Sullivan, 2000). However, subsequent studies and longer follow-up have not substantiated this benefit (Chan and Zacharin, 2006; Plotkin *et al.*, 2003). Yet, it is clear that bisphosphonates are quite effective in the relief of pain associated with FD (Chapurlat, 2006; Lala *et al.*, 2006; Plotkin *et al.*, 2003). Pain is one of the most significant causes of disease-related loss of quality of life in FD (Kelly *et al.*, 2005, 2007b). The pain can often be debilitating and require the use of narcotic analgesics. Quite often this pain can be controlled with the use of high-dose intravenous bisphosphonates. However, it has been our experience that the pain of craniofacial FD is often less amendable to treatment with bisphosphonates. Other medical treatments have been tried, including calcitonin (Bell *et al.*, 1970), glucocorticoids(Di Figlia, 1951), and external beam radiation (Tanner *et al.*, 1961), but with no benefit. In fact, it has been demonstrated that external beam radiation is probably associated with an increased rate of sarcomatous transformation (Ruggieri, P. *et al.*, 1994).

In summary, FD is a complicated disease that results from somatic mutations in *GNAS* that occur early in embryogenesis and lead to a specific mosaic pattern of involved bones that is established early in development. The intrinsic genetic defect can be impacted by associated endocrine dysfunction that can occur as part of MAS, and highlights the need for screening for and treatment of the associated endocrine diseases. Although a consensus on surgical treatment is lacking, progress has been made. To date medical treatment appears to be palliative, with bisphosphonates offering significant benefit in terms of pain control. Improvement in both medical and surgical care is needed, and given the relative rarity of the disease, will only come from multicenter, international cooperative studies.

Chapter 68

Renal Osteodystrophy

Pathogenic Mechanisms and Therapeutic Options

William G. Goodman*

Nephrology Therapeutic Area, Amgen Inc., Thousand Oaks, CA

INTRODUCTION

Renal osteodystrophy has been considered traditionally to encompass all of the disorders of mineral metabolism that occur among persons with chronic kidney disease (CKD) (Coburn and Slatopolsky, 1990; Goodman *et al.*, 2003a; Lentz *et al.*, 1978; Malluche and Faugere, 1990). These include most prominently disturbances in calcium, phosphorus, and magnesium metabolism, in vitamin D metabolism, and in parathyroid gland function (Cozzolino *et al.*, 2005; Llach and Massry, 1985; Mawer *et al.*, 1973; Slatopolsky and Bricker, 1973). Each is affected adversely to a degree that varies when the excretory and metabolic functions of the kidney become impaired as renal function declines. Either alone or together, these abnormalities lead to discrete types of metabolic bone disease that are described collectively as the renal bone diseases (Coburn and Slatopolsky, 1990; Goodman *et al.*, 2003a; Lentz *et al.*, 1978; Malluche and Faugere, 1990).

Apart from untreated patients with CKD, certain therapeutic interventions such as the use of vitamin D sterols to treat secondary hyperparathyroidism (HPT) and the use of phosphate-binding agents to manage phosphorus retention influence bone metabolism both directly and indirectly through effects on mineral homeostasis systemically (Goodman *et al.*, 1994; Indridason and Quarles, 2000). They too contribute to skeletal abnormalities in some patients with CKD whether or not treatment with dialysis is required (Hernandez *et al.*, 1994).

Information is now available that provides a better understanding about the relationships among the renal bone diseases, the abnormalities in mineral metabolism associated with them, and the occurrence of soft-tissue and vascular calcification among patients with CKD (Blacher *et al.*, 2001; Goodman *et al.*, 2004; London *et al.*, 2002). Vascular calcification, specifically arterial calcification, is common in CKD (Kramer *et al.*, 2005). This has been known for many years, but recent evidence indicates that vascular calcification has substantial and specific adverse consequences on the cardiovascular system (Blacher *et al.*, 2001; London *et al.*, 2002). It may contribute to the very high rates of morbidity and mortality from cardiovascular causes among patients with CKD (Blacher *et al.*, 2003; London *et al.*, 2003; London, 2003).

Vascular calcification has long been considered to be one consequence of the broader problem of soft-tissue calcification that occurs among patients with CKD (Kuzela *et al.*, 1977; Parfitt, 1969). The disorder was thought to arise primarily from the passive, dystrophic deposition of mineral in soft tissues owing largely to alterations in calcium and phosphorus metabolism. A growing body of evidence indicates, however, that arterial calcification in CKD is a regulated process that is affected, at least in part, by certain genes and proteins that are normally involved in the regulation of bone metabolism (Giachelli, 2004; Shanahan *et al.*, 1999; Shanahan, 2005). Similar relationships have been documented in the calcification of atherosclerotic plaques and cardiac valves among persons from the general population (Bostrom *et al.*, 1993; Levy *et al.*, 1983; Shanahan *et al.*, 1994).

Because bone disease has been implicated as a contributor to cardiovascular calcification among patients with CKD, it has been suggested that vascular calcification be included as an integral component of renal osteodystrophy as understood traditionally (Moe *et al.*, 2006). In this context, renal bone disease is considered to be only one part of a broader disease entity or syndrome that encompasses the various clinical, biochemical, and radiographic consequences of abnormal mineral metabolism among patients with CKD that includes alterations in bone mass and/or bone density. Soft-tissue and cardiovascular calcification

Principles of Bone Biology, 3rd Edition

TABLE I A Suggested Framework for the Classification of the Syndrome of Chronic Kidney Disease-Mineral and Bone Disorder (CKD-MBD)[a]

Type	Laboratory abnormalities (L)[b]	Bone disease (B)[c]	Vascular or soft-tissue calcification (C)[d]
L	Present	Absent	Absent
LB	Present	Present	Absent
LC	Present	Absent	Present
LBC	Present	Present	Present

[a] *Adapted from Moe et al., 2006.*

[b] L, *abnormal values for serum or plasma concentrations of for calcium, phosphorus,* PTH, *alkaline phosphatase, or metabolites of vitamin* D.

[c] B, *bone disease as documented by abnormalities in of bone turnover* (T), *mineralization* (M), *or volume* (V) *using bone histomorphometry, reductions in linear growth, or evidence of reductions in bone strength.*

[d] C, *calcification in vascular or other soft tissues.*

represent important components of this newly defined clinical syndrome (Moe *et al.*, 2006).

The term Chronic Kidney Disease-Mineral and Bone Disorder, or CKD-MBD, has recently been introduced to displace the traditional definition of renal osteodystrophy as summarized in a position statement from the Kidney Disease Improving Global Outcomes (KDIGO) initiative (Moe *et al.*, 2006). A framework for classifying patients with CKD-MBD has also been proposed based on the presence or absence of three key elements of this newly defined clinical syndrome (Table I). These elements are biochemical abnormalities as measured by selected laboratory parameters of mineral metabolism, bone disease as determined by bone morphometry, and evidence of vascular and/or soft-tissue calcification.

Within the context of the syndrome of CKD-MBD, the term renal osteodystrophy is now defined more narrowly to refer solely to the bone pathology that affects patients with CKD (Moe *et al.*, 2006). Renal bone disease thus represents but one aspect of CKD-MBD. It is judged by laboratory assessments of bone morphology using bone histomorphometry to characterize three key components of skeletal health, specifically bone turnover (T), bone mineralization (M), and bone volume (V) (Fig. 1).

In quantitative terms, bone turnover can be normal, reduced, or elevated, whereas mineralization may be either normal or impaired (Table II). The assessment of each parameter requires measurements obtained in bone biopsy samples evaluated using the technique of double-tetracycline labeling. Bone volume is determined separately, and values may be normal, diminished, or elevated as judged by static measures of bone morphology, which provide information about the volume of bone per unit volume of skeletal tissue (see Table II). Such findings are crucial to understanding

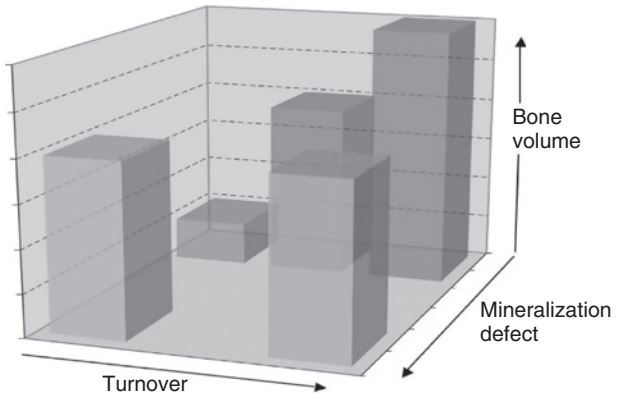

FIGURE 1 The classification of renal osteodystrophy based upon measurements of bone turnover (T), mineralization (M), and bone volume (V) as measured by bone histomorphometry. (From reference (Moe *et al.*, 2006)).

the impact of the renal bone diseases on bone mass, the relationship between various types of renal osteodystrophy and osteoporosis as defined traditionally, and their aggregate effects on the structural integrity of bone and on the risk of skeletal fracture among patients with CKD (Martin *et al.*, 2004; Moe *et al.*, 2006).

OVERVIEW OF THE RENAL BONE DISEASES

From one perspective, the renal bone diseases represent a set of discrete pathological entities when assessed by bone histomorphometry in biopsy specimens obtained from patients with CKD (see Fig. 1). This categorical method has been used for many years, and it serves to highlight

TABLE II A System for Classifying Renal Osteodystrophy, or Renal Bone Disease, Based on Measurements of Bone Turnover (T), Mineralization (M), and Volume (V) Using Bone Histomorphometry

Turnover	Mineralization	Volume
High		High
Normal	Normal	Normal
Low	Abnormal	Low

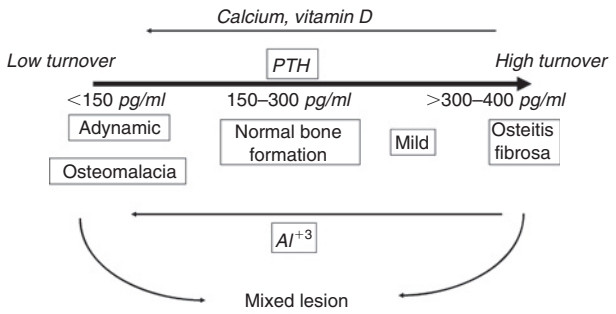

FIGURE 2 The spectrum of renal osteodystrophy. (From reference (Salusky and Goodman, 1995)).

the importance of certain pathogenic factors for some skeletal lesions (Malluche and Faugere, 1990; Sherrard *et al.*, 1993). The approach may understate, however, the role of other key elements such as variations in parathyroid gland function that account for the development and progression of several of the renal bone diseases and the importance of common pathogenic mechanisms among them. An integrated view of renal osteodystrophy thus places somewhat greater emphasis on mechanisms that account for transitions among various skeletal lesions over time (Fig. 2). Both approaches are informative and they share central common elements (Goodman *et al.*, 2003a; Salusky and Goodman, 1995).

Hyperparathyroidism

Histological manifestations of hyperparathyroidism in bone occur in most patients with CKD who have persistently elevated plasma parathyroid hormone (PTH) levels (Quarles *et al.*, 1992; Salusky *et al.*, 1988; Sherrard, 1986; Sherrard *et al.*, 1993; Wang *et al.*, 1995). The extent and severity of such changes correspond generally to the magnitude of the increase in plasma PTH. The skeletal response to PTH differs substantially, however, between patients classified as stage 5 CKD, who require treatment with dialysis, and those with less advanced CKD, that is, CKD stages 1 to 4 (Table III). Plasma PTH levels that are four to five times higher than the upper limit of the normal reference range are required before the skeletal features of hyperparathyroidism develop among patients undergoing dialysis (Qi *et al.*, 1995; Quarles *et al.*, 1992; Salusky *et al.*, 1988; Sherrard, 1986; Sherrard *et al.*, 1993; Wang *et al.*, 1995). In contrast, the skeletal changes owing to hyperparathyroidism are evident when plasma PTH values exceed only modestly the upper limit of normal among patients with stage 3 or stage 4 CKD (Kanis *et al.*, 1979). Tissue resistance to the biological actions of PTH probably accounts for this difference, but the mechanisms responsible are not understood fully (Massry *et al.*, 1973, 1979).

Apart from biochemical assessments of the severity of secondary HPT as judged by plasma PTH measurements, bone histology is useful for differentiating subjects with less advanced skeletal lesions, or mild secondary hyperparathyroidism, from those with overt disease, or osteitis fibrosa cystica (Table IV) (Salusky *et al.*, 1988). Measurements of the rates of bone formation and bone remodeling using the technique of double-tetracycline labeling are often required to discriminate adequately between the two disorders and to distinguish patients with mild lesions of secondary HPT from normal (Goodman *et al.*, 1994; Salusky *et al.*, 1988, 1998; Sanchez *et al.*, 1998).

Bone formation and turnover rates in most patients with secondary HPT exceed those of persons with normal renal and parathyroid gland function (Quarles *et al.*, 1992; Salusky *et al.*, 1988; Sherrard, 1986; Sherrard *et al.*, 1993; Wang *et al.*, 1995). By using the suggested classification scheme for renal osteodystrophy as defined recently in the context of CKD-MBD, bone turnover (T) is high in hyperparathyroidism owing to CKD, whereas mineralization (M) is normal (see Table IV) (Moe *et al.*, 2006). Assessments of bone volume (V) may differ, however, according to the skeletal site chosen and the method of measurement. Bone volume may be normal or high in cancellous bone when evaluated by histomorphometry, but values are normal

TABLE IV Histological Features of High-Turnover Renal Osteodystrophy

	Mild lesion of secondary HPT	Osteitis fibrosa
Bone volume		
Trabecular bone volume	Normal	Normal or high
Bone formation		
Osteoid volume	Normal or high	Normal or high
Osteoid seam thickness	Normal or high	Normal or high
Osteoid surface	Normal	Normal or high
Number of osteoblasts	High	Very high
Bone formation rate	High	Very high
Mineralization lag time	Normal	Normal
Bone resorption		
Eroded surface	High	Very high
Number of osteoclasts	High	Very high
Marrow fibrosis	Absent	Present

TABLE V Histological Features of Low-Turnover Renal Osteodystrophy

	Adynamic	Osteomalacia
Bone volume		
Trabecular bone volume	Normal or low	Variable Low, normal, or high
Bone formation		
Osteoid volume	Normal or low	High or very high
Osteoid seam thickness	Normal or low	High or very high
Osteoid surface	Normal or low	High
Number of of osteoblasts	Low	Low
Bone formation rate	Low or immeasurable	Low or immeasurable
Mineralization lag time	Normal*	Prolonged
Bone resorption		
Eroded surface	Normal or low	Low
Number of osteoclasts	Low	Low or normal, but may be high
Marrow fibrosis	Absent	Absent

**As measured by conventional histomorphometric methods, the mineralization lag time (Mlt), which reflects the average value for all osteoid seams, may be prolonged in adynamic renal osteodystrophy. In contrast, the osteoid maturation time (O.mt), which represents values for osteoid seams that are undergoing active mineralization as judged by the uptake of tetracycline into bone, is normal in the adynamic lesion. The disparity between values for Mlt and O.mt is attributable to the lower proportion of osteoid seams undergoing active mineralization at any given point in time.*

or low when measurements are obtained in cortical bone either by histomorphometry or by radiographic imaging methods (Parfitt, 2003; Schober *et al.*, 1998).

Hypoparathyroidism and Adynamic Bone

Dialysis patients who have plasma PTH levels substantially lower than those seen typically in cases of established secondary HPT often display histological features in bone that are more characteristic of persons with hypoparathyroidism, a disorder known as adynamic renal osteodystrophy (Hercz *et al.*, 1993; Salusky *et al.*, 1988; Sherrard, 1986). Unlike hyperparathyroidism, bone turnover (T) is reduced, and this is a cardinal feature of the adynamic lesion. Mineralization (M) is normal, and bone volume (V) is usually maintained (Table V). Bone volume is reduced, however, if osteoporosis is the underlying cause. Decreases in cancellous bone volume may also occur in adynamic bone owing to aluminum toxicity (Faugere *et al.*, 1986; Faugere and Malluche, 1986).

Adynamic bone can arise from a variety of causes (Table VI). In many but not all, parathyroid gland function is impaired and plasma PTH levels are uncharacteristically low, particularly among patients with stage 5 CKD, but this aspect of the disorder has not been assessed fully (Hercz *et al.*, 1993; Pei *et al.*, 1993; Sanchez *et al.*, 1995). Causal factors for adynamic bone include diabetes, aluminum-related bone disease, steroid-induced osteoporosis, immobilization, and sustained reductions in plasma PTH levels owing to treatment with vitamin D sterols and/or calcium-containing compounds or after parathyroidectomy (Hercz *et al.*, 1989, 1993; Pei *et al.*, 1993; Salusky and Goodman, 2001; Wang *et al.*, 1995). Some causes of adynamic bone can be corrected, whereas others can not. Racial and gender differences in bone turnover may also account for adynamic renal osteodystrophy in some patients with CKD (Garabedian *et al.*, 1981; Parfitt *et al.*, 1997; Sawaya *et al.*, 2003).

Unfortunately, the prevalence of these various factors, and their importance as causes of adynamic renal osteodystrophy in the current dialysis population, has not been studied systematically. Even less is known about such relationships among patients with less advanced CKD. Certain causes of adynamic bone are unique to patients

TABLE VI Causes of Adynamic Bone

Sustained	Reversible
Hypoparathyroidism	Vitamin D therapy
After parathyroidectomy	Exogenous calcium loading • Oral/dietary • Ca-based phosphate binders • Dialysate
Steroid-induced osteoporosis	Immobilization
Osteoporosis • Estrogen deficiency • Aging	Bone aluminum toxicity
Diabetes	

with stage 5 CKD who require treatment with dialysis (see later) (see Table VI).

The histological features of adynamic renal osteodystrophy do not differ substantially from those of postmenopausal or age-related osteoporosis (Goodman *et al.*, 2003a; Sherrard, 1986; Sherrard *et al.*, 1996). It is thus difficult to distinguish between adynamic bone that arises solely from factors unique to CKD and adynamic bone owing to osteoporosis among older women, or even older men, who are treated with dialysis regularly. Histomorphometric assessments of bone volume per unit volume of bone tissue and tetracycline-based measurements of bone turnover may be informative in this regard, but they are often not definitive. Bone volume is low in osteoporosis, but values are often normal in adynamic bone from other causes (Goodman *et al.*, 2003a; Sherrard, 1986; Sherrard *et al.*, 1996).

Additional information is needed to better understand the role of age-related factors such as osteoporosis that are distinct from the renal bone diseases *per se* as contributors to the very high rates of skeletal fracture, not only among patients undergoing dialysis, but also among those with less advanced CKD (Danese *et al.*, 2006; Leinau and Perazella, 2006; Stehman-Breen *et al.*, 2000). The observation that more than half of the current dialysis population in the United States are 65 years of age or older only further highlights the importance of this issue (United States Renal Data System: Annual Data Report, 2005).

Osteomalacia

Osteomalacia is a skeletal disorder characterized by the inadequate mineralization of newly formed bone collagen, or osteoid, that leads to the accumulation of excess amounts of unmineralized osteoid within cortical and cancellous bone (Eastwood *et al.*, 1977; Frame and Parfitt, 1978; Malluche *et al.*, 1979). Such changes compromise the structural integrity of bone and increase the risk of skeletal fracture (Pierides, 1978). Skeletal mineralization (M) is impaired and bone turnover (T) is reduced (see Table V). Bone volume (V), which includes both mineralized tissue and unmineralized osteoid, may be normal, but values are often elevated in trabecular bone when assessed by histomorphometry (Coburn *et al.*, 1980; Llach *et al.*, 1984).

Osteomalacia is classically associated with nutritional vitamin D deficiency, but other causes may be found among patients with CKD (Frame and Parfitt, 1978; Llach *et al.*, 1984; Ott *et al.*, 1983). Sustained reductions in serum calcium and/or phosphorus concentrations overextended periods to levels that are insufficient to adequately support skeletal mineralization account for osteomalacia in some cases of CKD (Baker *et al.*, 1974; Eastwood *et al.*, 1976; Frame and Parfitt, 1978; Sherrard *et al.*, 1974). Others are unique to patients managed by dialysis. Specific examples include the accumulation in bone of excess amounts of metals such as aluminum, iron, and strontium that directly and adversely affect skeletal mineralization (D′Haese *et al.*, 2000; Hodsman *et al.*, 1981, 1982).

Mixed Renal Osteodystrophy

Assessments of bone histology in some patients with CKD demonstrate changes of both hyperparathyroidism and osteomalacia (Malluche *et al.*, 1976; Ritz *et al.*, 1978; Sherrard *et al.*, 1974). The disorder is best described as the mixed lesion of renal osteodystrophy, and it represents the combined result of two distinct pathogenic processes (Sherrard *et al.*, 1974). Patients typically have biochemical evidence of secondary HPT with elevated plasma PTH levels, changes that account for the histological manifestations of hyperparathyroidism in bone. Other disturbances, however, are responsible for the concurrent defect in skeletal mineralization. The same pathogenic factors discussed previously as causes of osteomalacia are usually responsible for impaired mineralization in mixed renal osteodystrophy.

Bone turnover (T) in the mixed lesion reflects the integrated result of hyperparathyroidism, which promotes skeletal remodeling, and osteomalacia, which diminishes it. Turnover is elevated if hyperparathyroidism is the dominant component, whereas turnover will be low if osteomalacia predominates. Mineralization (M) is suboptimal, leading to osteoid accumulation both in cortical and in cancellous bone. Bone volume (V) may be normal, but values are elevated if the mineralization defect is pronounced and the accumulation of osteoid is extensive (Schultz *et al.*, 1984; Sherrard *et al.*, 1974).

Renal Bone Disease as a Dynamic Disorder

Results from studies that have used bone histomorphometry to assess biopsy samples obtained sequentially provide evidence that the histological features of renal bone

osteodystrophy do not remain static but rather evolve over time (Goodman and Salusky, 1991; Hercz *et al.*, 1988; Hercz *et al.*, 1994; Salusky *et al.*, 1998; Sanchez *et al.*, 1998). The skeletal changes of secondary HPT thus diminish or revert toward normal as plasma PTH levels decrease during successful medical management (Keeting *et al.*, 1992). Adynamic bone can develop, however, if plasma PTH levels are lowered excessively or if values remain suppressed for sustained periods during treatment with vitamin D sterols or after surgical parathyroidectomy (Goodman *et al.*, 1994). Conversely, the histological changes of secondary HPT worsen as plasma PTH rise progressively in untreated patients or in those who do not respond adequately to medical therapy (Goodman and Salusky, 1991; Salusky *et al.*, 1998).

In this regard, the skeletal lesions of secondary HPT and adynamic bone can be considered to represent different portions of a spectrum of disorders determined largely by differences in parathyroid gland function among patients with CKD (see Fig. 2) (Goodman *et al.*, 2003a; Salusky and Goodman, 1995). Transitions from one skeletal lesion to another along this continuum are determined largely by interval changes in plasma PTH levels. Because PTH is such an important determinant of bone formation and skeletal remodeling among patients with CKD, the presence or absence of secondary HPT, and its severity, is a pivotal mediator of the development, progression, and resolution of certain types of renal bone disease, specifically hyperparathyroidism and adynamic bone (Salusky and Goodman, 1995).

Apart from PTH, other factors influence bone formation and skeletal remodeling more directly, and these can account for the development and resolution of renal bone disease by PTH-independent mechanisms. Corticosteroid therapy, bone aluminum toxicity, and osteoporosis all affect bone metabolism adversely, diminish bone formation, and can account for adynamic skeletal lesions (Avioli, 1984; Coburn *et al.*, 1986; Freundlich *et al.*, 2004; Kim *et al.*, 2006; Schot and Schuurs, 1990; Taal *et al.*, 1999). Vitamin D deficiency and bone aluminum deposition disrupt skeletal mineralization and lead to osteomalacia (Coburn *et al.*, 1986; Frame and Parfitt, 1978). These skeletal disorders are largely unrelated to alterations in parathyroid gland function, and different strategies are required to address them therapeutically.

PATHOGENIC MECHANISMS IN RENAL BONE DISEASE

Hyperparathyroidism: High-Turnover Renal Bone Disease

A detailed discussion of the pathogenesis of secondary HPT owing to CKD is beyond the scope of the current chapter. The matter has been considered elsewhere in this

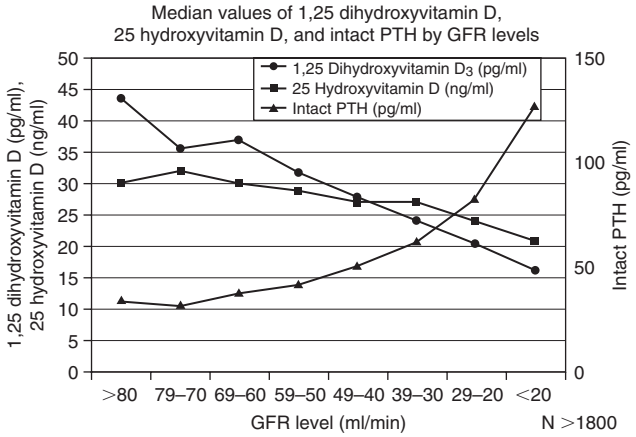

FIGURE 3 The serum levels of 1,25-dihydroxyvitamin D and parathyroid hormone (PTH) according to estimated glomerular filtration rate among patients with chronic kidney disease. (From reference (Levin *et al.*, 2007)).

volume and it has been reviewed comprehensively by several authors (Goodman and Quarles, 2007; Silver *et al.*, 2002; Slatopolsky and Delmez, 1994). Several points, however, deserve comment. Secondary HPT develops early during the course of progressive CKD as an adaptive response to maintain serum calcium concentrations and to preserve calcium homeostasis systemically. It arises primarily because of reductions in the synthesis of calcitriol, or 1,25-dihydroxyvitamin D, by the diseased kidney, and it can be aggravated by inadequate dietary calcium intake.

Calcitriol is produced normally in cells of the proximal nephron (Nykjaer *et al.*, 1999). It is then released into the blood where it circulates in plasma bound to vitamin D-binding protein, or DBP, and interacts with its receptor, the vitamin D receptor, or VDR, in various tissues (Holick, 2006, 2007). Calcitriol functions systemically as a calcium-regulating hormone, and it serves as a key determinant of intestinal calcium absorption by regulating the expression of several proteins that mediate calcium transport in epithelial cells (Hoenderop *et al.*, 2005).

Serum calcitriol levels fall gradually as CKD progresses owing largely to a loss of renal parenchyma (Fig. 3) (De Boer *et al.*, 2002). Subtle changes in phosphorus metabolism and increases in the circulating levels of fibroblast growth factor 23 (FGF23), an important phosphate-regulating hormone, may further impede renal calcitriol production (Gutierrez *et al.*, 2005). Low levels of calcitriol in the circulation adversely affect vitamin D-dependent intestinal calcium transport and are largely responsible for impaired intestinal calcium absorption in CKD (Brickman *et al.*, 1975; Coburn *et al.*, 1973b). Such changes also explain the hypocalciuria that is a cardinal feature of untreated patients with mild to moderate CKD (Coburn *et al.*, 1973a, 2004).

As in other forms of secondary HPT where intestinal calcium absorption is impaired, such as that owing to mild to moderate vitamin D deficiency, increases in PTH

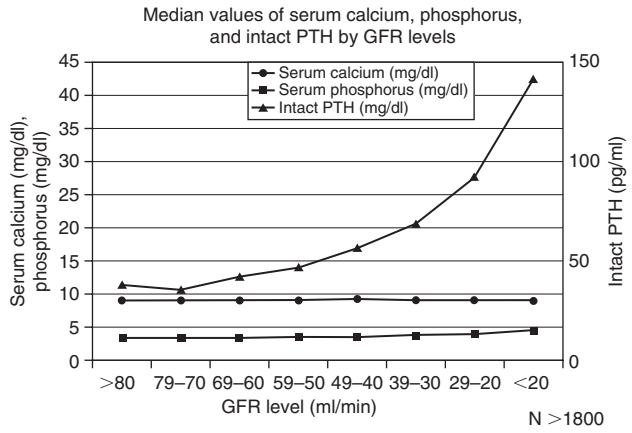

FIGURE 4 The serum concentrations of calcium and phosphorus and plasma parathyroid hormone (PTH) levels according to estimated glomerular filtration rate among patients with chronic kidney disease. (From reference (Levin *et al.*, 2007)).

synthesis and secretion by the parathyroid glands represent an appropriate physiological response to maintain serum calcium levels. Plasma PTH levels thus rise progressively when serum calcitriol levels and intestinal calcium absorption decline as renal function deteriorates, and values exceed the upper limit of normal in the majority of those with an estimated glomerular filtration rate below 30 to 40 mL/min (see Fig. 3) (De Boer *et al.*, 2002). This adaptive response is sufficient to prevent measurable decreases in serum calcium concentration in most patients (Fig. 4) (Goodman and Quarles, 2007). Overt hypocalcemia develops only when these compensatory responses no longer prove adequate. As such, correcting disturbances in calcium and vitamin D metabolism that arise owing to CKD represent important therapeutic measures for the treatment and prevention of secondary HPT.

Phosphorus retention owing to decreases in phosphorus excretion in the urine leads ultimately to the development of hyperphosphatemia among patients with advanced CKD, and serum phosphorus levels are elevated in nearly all patients undergoing dialysis regularly (Levin *et al.*, 2007). Hyperphosphatemia aggravates secondary HPT by contributing to parathyroid gland hyperplasia (Dusso *et al.*, 2001). It also renders treatment of the disorder quite challenging because vitamin D sterols cannot be used safely to lower plasma PTH levels when serum phosphorus concentrations are elevated because of the risks of soft-tissue and vascular calcification (Coburn *et al.*, 1991).

Separately, secondary HPT *per se* can worsen hyperphosphatemia among dialysis patients who have little or no residual renal function. Serum phosphorus levels decrease consistently when plasma PTH levels are lowered in such patients during treatment with calcimimetic agents, compounds that do not promote intestinal phosphorus transport (Goodman *et al.*, 2000a, 2002a). In contrast, serum phosphorus levels remain elevated or increase further when vitamin D sterols are used to lower plasma PTH levels because these agents enhance intestinal phosphorus absorption (Andress *et al.*, 1989; Frazao *et al.*, 2000; Martin *et al.*, 1998). Ongoing PTH-mediated phosphorus release from bone thus contributes materially to the persistent hyperphosphatemia that affects many dialysis patients with secondary HPT.

Once established, secondary HPT is a progressive disorder that increases in severity as a function of the duration of CKD and/or the number years of treatment with dialysis (Chertow *et al.*, 2000; Kestenbaum *et al.*, 2004; Malberti *et al.*, 2001). The likelihood of surgical parathyroidectomy also rises progressively as the duration of renal replacement therapy increases (Foley *et al.*, 2005; Malberti *et al.*, 2001). Parathyroid gland hyperplasia is a key determinant not only of disease severity but also of disease progression. Monoclonal proliferation of subpopulations of parathyroid cells can be demonstrated in more than half of parathyroid glands removed surgically from patients with secondary HPT occurring in both the diffuse and nodular forms of parathyroid gland hyperplasia (Arnold *et al.*, 1995). There is little evidence that the hyperplastic process can be reversed or that the size of enlarged parathyroid glands diminishes with medical treatment or after successful kidney transplantation.

The manifestations of secondary HPT in bone reflect the known biological actions of PTH on skeletal tissue (Parisien *et al.*, 1990a, 1990b). The disorder is characterized by increases in the number of sites of active bone remodeling by basic multicellular units, or BMUs, both in cancellous and in cortical bone (Parfitt, 1976). Bone reabsorption by osteoclasts and bone formation by osteoblasts are both abnormally high, and the proportion of skeletal tissue undergoing remodeling at any given point in time is greater than normal. Such changes lead ultimately to bone loss and to reductions in bone mass because the amounts of mineral removed during the reabsorption phase slightly exceed the amounts replaced during the formation phase with each remodeling cycle (Parfitt, 1983).

Parathyroid hormone enhances bone reabsorption by promoting the differentiation of precursor cells of the monocyte-macrophage lineage into mature osteoclasts (Boyle *et al.*, 2003; Teitelbaum, 2000). The receptor activator of nuclear factor kappa B (RANK), its ligand (RANK-L), and the soluble decoy receptor osteoprotegerin (OPG) serve as key regulators of this process. Both PTH and 1,25-dihydroxyvitamin D enhance the recruitment and differentiation of osteoclasts via this pathway.

Various cytokines and growth factors also affect osteoclastic maturation in an autocrine/paracrine fashion within bone and the adjacent bone marrow (Hruska and Teitelbaum, 1995). They serve indirectly to mediate some of the actions of PTH on osteoclastic bone reabsorption. In this regard, the type 1 PTH receptor, or PTH1R, is expressed exclusively in osteoblasts and osteocytes but

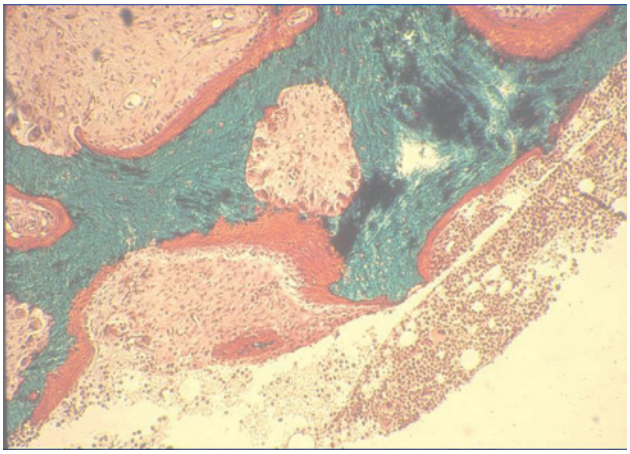

FIGURE 5 A Goldner stained section of undecalcified bone from a hemodialysis patient with osteitis fibrosa; magnification, 50×. Mineralized bone appears green and osteoid appears red. Fibrous tissue has accumulated within the marrow space immediately adjacent to bone, and the serrated margins along the bone surface represent sites of osteoclastic bone resorption. (See plate section)

not in osteoclasts (Jüppner *et al.*, 1991; Kronenberg *et al.*, 1998).

Both the number and size of osteoclasts is greater than normal in hyperparathyroidism, and the fraction of cancellous bone surfaces undergoing reabsorption is increased when assessed by bone histomorphometry (see Table IV). Fibrous tissue often accumulates immediately adjacent to individual bony trabeculae, a change described as peritrabecular fibrosis. More extensive deposits of fibrous tissue may be found throughout the marrow space, and partial or complete fibrous replacement of trabecular structures can occur in advanced cases (Fig. 5).

As noted previously, bone formation rates are elevated in hyperparathyroidism owing to increases in the number of active remodeling sites both in cortical and in cancellous bone. Static histological indices of bone formation such as the fraction of trabecular bone surfaces covered by osteoid seams, the volume of osteoid per unit volume of bone, and the number of osteoblasts along trabecular bone surfaces are thus greater than normal.

The maturation of newly formed bone matrix may be disrupted in overt secondary HPT owing in part to high rates of synthesis of type I collagen by osteoblasts and to the rapid deposition of collagen fibrils as new bone matrix in the extracellular space (Malluche *et al.*, 1976, 1979; Sherrard *et al.*, 1983). Under these circumstances, collagen molecules that are normally arranged tightly and aligned closely in parallel become spatially less well organized. The newly formed osteoid and the subsequently mineralized bone thus have a coarse, hatched appearance microscopically that is described as woven osteoid or woven bone, respectively. The pattern is similar to that of a straw basket. The disordered arrangement of collagen fibrils within bone alters its material properties and adversely affects its structural integrity.

The histological changes of hyperparathyroidism in bone in secondary HPT owing to CKD are generally more pronounced and they are often much more severe than in primary HPT (Goodman *et al.*, 2003a). Among patients receiving dialysis, such differences are most likely caused by the very high plasma PTH levels that characterize these individuals. In contrast, overt histological manifestations of HPT are common among patients with stage 3 or stage 4 CKD who have plasma PTH levels that are substantially lower than those typical of dialysis patients with secondary HPT and not markedly different from those seen in primary HPT (Hamdy *et al.*, 1995). Lesser increases in plasma PTH levels are thus required to invoke the skeletal changes of hyperparathyroidism in persons with mild to moderate CKD compared with those with advanced CKD who require treatment with dialysis.

The reasons for this disparity are not understood. Differences in serum calcitriol levels and variations in the levels of expression of the PTH1R, vitamin D receptor (VDR), and calcium-sensing receptor (CaR) in osteoblasts and other bone cells may be involved (Korkor, 1987; Ureña *et al.*, 1994). Peptide fragments of PTH(1–84) that interact with a putative carboxyl-terminal PTH receptor (C-PTH receptor), distinct from the PTH1R, could also play a role (D′Amour *et al.*, 2005; Divieti *et al.*, 2002, 2005; Nguyen-Yamamoto *et al.*, 2001). There is evidence to support such a mechanism, but its importance will remain uncertain until the receptor is identified and cloned and the signal transduction pathways associated with it are characterized adequately.

Patients with CKD who have less pronounced histopathological changes of hyperparathyroidism in bone are categorized as mild lesions of secondary HPT (see Table IV) (Salusky *et al.*, 1988; Sherrard *et al.*, 1983). Plasma PTH levels are elevated, but values are generally not as high as in patients with overt secondary HPT (Salusky *et al.*, 1994; Sherrard *et al.*, 1993). Tetracycline-based measurements of bone formation and other histomorphometric criteria are needed to distinguish patients with mild skeletal lesions of hyperparathyroidism from those with normal bone histology and bone turnover and from others with adynamic skeletal lesions (see Table IV) (Salusky *et al.*, 1988; Sherrard *et al.*, 1983).

Among patients with CKD that progresses over several or many years before dialysis becomes necessary, secondary HPT represents an important and potentially preventable cause of bone loss (Rix *et al.*, 1999). Bone mass is reduced when renal replacement therapy is begun in a substantial proportion of patients with CKD, in particular, when measurements are obtained at skeletal sites in the appendicular skeleton that are composed mainly of cortical bone (Parfitt, 1998, 2003). Two factors account for this finding.

First, the presence of a large number of bone-remodeling sites, or Haversian systems, within cortical bone increases its porosity among patients with hyperparathyroidism. Additionally, the mineral content of newly completed osteons is less than that of fully mature osteons in older quiescent bone. Both changes diminish the volumetric density of cortical bone as a tissue and lower its mineral content. Second, bone is lost disproportionately from the endosteal surface of long bones in hyperparathyroidism owing to subcortical tunneling by osteoclasts. As a result, cortical bone along endosteal surfaces is transformed structurally to become partially trabecular in nature, thus contributing to reductions in cortical thickness, a common radiographic finding among patients with secondary HPT owing to CKD (Parfitt, 2003).

The Low-Turnover Skeletal Lesions of Relative or Absolute Hypoparathyroidism: Adynamic Bone

The histological features of adynamic renal osteodystrophy differ markedly from those of hyperparathyroidism (Goodman *et al.*, 2003a; Sherrard *et al.*, 1983, 1993). Indeed, they are more consistent with the skeletal changes of hypoparathyroidism from a variety of causes. The volume of osteoid and the width of osteoid seams are either normal or reduced, resorption surfaces are diminished, and few osteoblasts or osteoclasts are seen (Fig. 6). Peritrabecular and marrow fibrosis are distinctly absent. Static and dynamic indices of bone formation are subnormal, and the rate of bone formation often cannot be measured using the technique of double-tetracycline labeling (see Table V) (Andress *et al.*, 1986; Salusky *et al.*, 1988; Sherrard *et al.*, 1983).

Adynamic bone was first described as a discrete entity in dialysis patients with bone aluminum toxicity (Table VI) (Andress *et al.*, 1986). In the past, aluminum-related bone disease owing to aluminum retention was common among patients managed with dialysis (Coburn *et al.*, 1986). Key sources of aluminum exposure included aluminum-based phosphate-binding agents and dialysis solutions that contained aluminum. The use of aluminum-free compounds to manage phosphorus retention and the widespread application of effective methods of water purification in dialysis facilities has markedly diminished these risks. Aluminum-related bone disease is now an infrequent cause of either adynamic bone or osteomalacia (see later) among patients managed with dialysis.

The adynamic lesion arising from bone aluminum toxicity may represent a histological forerunner of overt aluminum-related osteomalacia (Goodman, 1984, 1985). Bone aluminum levels are thus not as high among patients with adynamic bone as in those with osteomalacia when aluminum retention is the cause (Hodsman *et al.*, 1982). The adverse effects of aluminum on osteoblasts are mediated, at least in part, by the uptake of transferrin-bound aluminum by osteoblasts via the transferrin receptor (Kasai *et al.*, 1990, 1991). Several metals such as aluminum, gallium, and iron itself adversely affect the proliferation rate and differentiated function of cells when excess amounts enter the cytoplasm via this pathway.

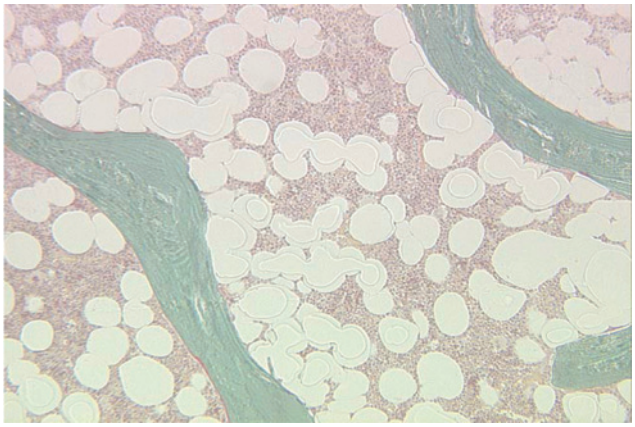

FIGURE 6 A Goldner stained section of undecalcified bone from a hemodialysis patients with adynamic renal osteodystrophy, magnification 50×. Mineralized bone appears green and osteoid appears red. The total amount of osteoid is less than normal, osteoid seams are thin, the fraction of the trabecular bone surface that is covered with osteoid is diminished, and there are no eroded surfaces. (See plate section)

Although aluminum-related bone disease is now uncommon, adynamic lesions still account for 10% to 40% of cases of renal bone disease in the current dialysis population. The overall prevalence of adynamic renal osteodystrophy is even higher now than in the past. Other causes of the disorder probably account for this finding, most notably diabetes and ageing (see Table VI). In this regard, the increased prevalence of adynamic bone in the current dialysis population in the United States corresponds temporally to the progressive rise in the proportion of diabetic patients and persons older than 65 years undergoing renal replacement therapy (United States Renal Data System: Annual Data Report, 2005).

Nearly half of patients receiving dialysis regularly in the United States have diabetes. Reductions in bone formation and turnover, which are key features of adynamic bone, are common among diabetic subjects. Such changes may reflect either insulin resistance or insulin deficiency at the level of bone as a tissue, but subtle alterations in parathyroid gland function consistent with hypoparathyroidism may also contribute (Goodman and Hori, 1984; Hough *et al.*, 1981).

The average age of the dialysis population in the United States, and elsewhere around the world, continues to rise. More than half of patients currently receiving dialysis in the United States are 65 years of age or older (United States Renal Data System: Annual Data Report, 2005). Postmenopausal osteoporosis and age-related osteoporosis both represent potential causes of adynamic bone among older women with CKD (Cunningham *et al.*, 2004).

Estrogen deficiency may also explain the occurrence of adynamic lesions among younger women receiving dialysis because partial or complete amenorrhea is common in such individuals.

Little is known about the role of aging as a contributor to bone disease among older men with CKD. Male osteoporosis is likely to occur, however, in men who require treatment with dialysis just as it does in the general population (Jackson and Kleerekoper, 1990). Men with advanced CKD often have biochemical evidence of gonadal insufficiency as judged by reductions in serum testosterone levels. Whether such changes adversely affect bone remodeling and/or bone mass or account for the development of adynamic bone in male dialysis recipients has not been determined (Khosla *et al.*, 2005).

Additional causes of adynamic renal osteodystrophy among patients with CKD include previous parathyroidectomy and the use of large intermittent doses of vitamin D sterols to manage secondary HPT either alone or together with large oral doses of calcium-containing, phosphate-binding agents (see Table VI) (Andress *et al.*, 1985, 1989; Charhon *et al.*, 1985; Goodman *et al.*, 1994). Treatment-induced decreases in plasma PTH levels, often to values that are quite low, are largely responsible (Goodman *et al.*, 1994). Intermittent, or pulse, calcitriol therapy has been reported to diminish bone formation markedly even when plasma PTH levels remain elevated, a change that may reflect direct inhibitory effects of calcitriol on osteoblasts or on other bone cells (Goodman *et al.*, 1994). Whether similar changes occur with the use of new vitamin D analogues such as paricalcitol or doxercalciferol is not known. The combined use of large intravenous doses of vitamin D sterols and large oral doses of calcium to manage secondary HPT among patients undergoing hemodialysis may thus account for the high prevalence of adynamic bone in the current dialysis population (Pei *et al.*, 1992).

The long-term consequences of adynamic renal osteodystrophy remain uncertain. If bone aluminum toxicity is the cause, bone pain and fractures are prominent features (Coburn *et al.*, 1986). The risk of skeletal fracture has been reported to be greater among dialysis patients with low plasma PTH than those with higher values, but the results available are not conclusive (Atsumi *et al.*, 1999; Coco and Rush, 2000). The prevalence and extent of vascular calcification was found to be greater among hemodialysis patients with low-turnover skeletal lesions as documented by bone biopsy regardless of the cause, which included previous parathyroidectomy, aluminum-related bone disease, and exogenous calcium loading from oral medications (London *et al.*, 2004). Additional work is required to determine whether these findings are attributable to alterations in the regulation of mineral metabolism systemically or to tissue-specific mechanisms that have yet to be characterized. Reductions in linear growth have been described by some but not by others in prepubertal children with adynamic renal osteodystrophy (Kuizon *et al.*, 1998; Schmitt *et al.*, 2003).

Patients with certain glomerular diseases and others with systemic vasculitis, such as systemic lupus erythematosus, are often treated with corticosteroids. These compounds are recognized widely to adversely affect bone metabolism. They not only diminish bone formation markedly, in part, by increasing apoptosis in osteoblasts, but also enhance bone reabsorption (Kim *et al.*, 2006; Weinstein *et al.*, 1998). Together such changes can lead to marked reductions in bone mass. Steroid-induced osteoporosis thus represents another important cause of adynamic renal osteodystrophy.

Osteomalacia: The Other Major Type of Low-Turnover Renal Bone Disease

Osteomalacia was a common type of renal bone disease in the past, but the disorder is seen less often in the current dialysis population. As noted previously, the cardinal feature of osteomalacia is the accumulation of excess amounts osteoid in bone owing to a primary defect in skeletal mineralization (Goodman *et al.*, 2003a). Osteoid seams along trabecular bone surfaces and within cortical Haversian systems are thickened, and they have multiple lamellae. The fraction of trabecular bone surfaces covered with osteoid is increased, often markedly (see Table V). Few cells with features that characterize active osteoblasts are seen adjacent to osteoid seams and most have the flattened, spindle-like profile of resting or inactive osteoblasts. Bone formation rates are subnormal, and measurements often cannot be obtained (see Table V). Although the rates of deposition of new bone matrix and its subsequent mineralization are both reduced, mineralization lags behind matrix formation. The disparity causes osteoid seams to widen and osteoid to accumulate (Goodman *et al.*, 2003a).

Before calcitriol became available for use clinically, hypocalcemia was a common biochemical finding among patients with CKD and in those receiving dialysis (Sherrard *et al.*, 1983). It still occurs in some who are not receiving oral calcium supplements or treatment with vitamin D sterols. Persistently low serum calcium concentrations compromise the mineralization of bone and account for the development of osteomalacia in some patients with CKD (Sherrard *et al.*, 1983; Stauffer *et al.*, 1973). Longstanding hypophosphatemia, although uncommon, can also adversely affect skeletal mineralization (Abrams *et al.*, 1974). Available evidence indicates that the primary physiological role of calcitriol, or 1,25-dihydroxyvitamin D, is to maintain sufficient levels of calcium and phosphorus in serum to adequately support skeletal mineralization (Li *et al.*, 1998). The widespread use of calcium-containing compounds and vitamin D sterols to manage patients with CKD probably explains the relatively low prevalence of osteomalacia in the current dialysis population.

Nutritional vitamin D deficiency is common among patients with CKD as judged by measurements of serum 25-hydroxyvitamin D levels (Eastwood *et al.*, 1976; Thomas *et al.*, 1998). The disorder may aggravate secondary HPT among persons with mild to moderate CKD, and it can cause osteomalacia among those with overt hypocalcemia (Ghazali *et al.*, 1999). Losses of vitamin D-binding protein (DBP) in the urine may further compromise vitamin D nutrition among patients with proteinuria owing to diabetes, amyloidosis, or various types of glomerulonephritis (Malluche *et al.*, 1979). Long-term treatment with phenytoin and/or phenobarbital have been implicated as causes of osteomalacia in persons with normal renal function, and a higher incidence of symptomatic bone disease was reported among dialysis patients receiving these agents (Pierides *et al.*, 1976a).

Nutritional vitamin D deficiency is often overlooked or not considered as a cause of osteomalacia among patients with CKD because of the widespread use of polar metabolites of vitamin D such as calcitriol or paricalcitol to treat secondary HPT, in particular, in those receiving dialysis. Such compounds do not, however, satisfy the nutritional requirements for vitamin D, and they may not support the localized needs for calcitriol in bone and other tissues (Holick, 2006, 2007; Vieth *et al.*, 2007). These agents are not substrates for the 1α-hydroxlase enzymes in extrarenal tissues that regulate calcitriol synthesis locally to fulfill autocrine and paracrine functions. The pleiotropic actions of vitamin D on cell-mediated immunity, inflammation, and other processes in tissues that express the 1α-hydroxlase enzyme are probably mediated through this mechanism (Holick, 2006, 2007). Localized tissue-specific effects of 1,25-dihydroxyvitamin D on cell proliferation and differentiation may also account for the lower incidence of certain cancers, such as breast, prostate, and colon among others, in populations where the prevalence of nutritional vitamin D deficiency is less common than those where it is higher (Holick, 2006, 2007; Vieth *et al.*, 2007).

In the past, bone aluminum toxicity was a frequent cause not only of adynamic bone but also of osteomalacia among patients treated with dialysis (Coburn *et al.*, 1986). Unlike other forms of osteomalacia, hypercalcemia is seen often when aluminum is the cause. The mechanisms responsible for the development of osteomalacia owing to bone aluminum accumulation include adverse effects of aluminum on the recruitment of fully differentiated osteoblasts, inhibition of differentiated osteoblastic functions, and disturbances in the physical-chemical processes of crystal deposition and crystal growth by aluminum ions during skeletal mineralization (Blumenthal and Posner, 1984; Goodman *et al.*, 1984; Posner *et al.*, 1986; Sedman *et al.*, 1987).

Risk factors for aluminum-related osteomalacia included previous parathyroidectomy, a history of renal transplantation and graft failure, bilateral nephrectomy, and diabetes mellitus (Coburn *et al.*, 1986). The ingestion of citrate can markedly enhance intestinal aluminum absorption, and such compounds should not be given to patients with CKD who are taking medications that contain aluminum (Froment *et al.*, 1989; Molitoris *et al.*, 1989). Elevated plasma PTH levels owing to persistent secondary HPT appear to offset the adverse effects of aluminum on bone, which may explain the higher prevalence of aluminum-related bone disease among diabetic patients and those with a history of parathyroidectomy (de Vernejoul *et al.*, 1985; Felsenfeld *et al.*, 1982).

Mixed Lesion of Renal Osteodystrophy

Apart from uncomplicated osteomalacia from any cause, mixed lesions of renal osteodystrophy occur when a mineralization defect develops in individuals with preexisting skeletal manifestations of hyperparathyroidism. Persistent hypocalcemia and/or hypophosphatemia, either alone or arising from nutritional vitamin D deficiency, is responsible in some patients (Sherrard *et al.*, 1974). Impaired skeletal mineralization oiwng to bone aluminum toxicity may occur in others.

Historically, mixed lesions of renal osteodystrophy developed as bone aluminum deposition worsened among patients with previously uncomplicated secondary HPT hyperparathyroidism owing to CKD (Sherrard, 1986). In contrast, osseous changes of hyperparathyroidism could emerge as secondary HPT progressed among patients with established osteomalacia from any cause. Under these circumstances, the histological features of hyperparathyroidism became superimposed on those of osteomalacia, resulting in a mixed histological picture. This occurred in some patients with aluminum-related osteomalacia who responded favorably to treatment with the chelating agent deferoxamine (Sherrard, 1986). Mixed renal osteodystrophy can thus represent a transitional state between the high-turnover skeletal lesions of mild hyperparathyroidism or osteitis fibrosa cystica and the low-turnover lesions of osteomalacia or adynamic bone (Goodman and Leite Duarte, 1991).

Amyloid Deposition in Bone

Localized deposits of amyloid within bone develop in some patients with CKD who are treated with dialysis for 7 to 10 years or longer (Bardin *et al.*, 1985; Cary, 1985). Such deposits are composed of a unique fibril of amyloid derived from β_2-microglobulin (β_2M), a normal plasma constituent (Gejyo *et al.*, 1985; Morita *et al.*, 1985). These occur typically as cystic lesions at the ends of long bones near tendon insertions either in isolation or as multiple cysts (Kleinman and Coburn, 1989). Radiographs are useful

for identifying such lesions in the femoral head, femoral neck, and proximal humerus. Pathological fractures can occur at these sites, particularly at the hip. Amyloid cysts are found not infrequently in metacarpal and carpal bones.

Amyloid deposition also occurs in the soft tissues surrounding joints, particularly the shoulder, and it is an important cause of a painful scapulo-humeral arthritis (Kleinman and Coburn, 1989). Extensive deposits of amyloid within or adjacent to cervical vertebrae can lead to destructive spondyloarthropathy, and displacement fractures of the cervical spine can result in spinal cord compression and paralysis (Bai *et al.*, 2004; Kessler *et al.*, 1990). Amyloid deposition is a common cause of medial nerve compression and the carpal tunnel syndrome among long-term hemodialysis patients (Bardin *et al.*, 1985; Bazzi *et al.*, 1995; Kleinman and Coburn, 1989; Koch, 1992).

Symptoms of bone and joint pain and complaints of joint stiffness owing to the localized accumulation of β_2M are difficult to distinguish from those arising from other types of renal bone disease. Key clinical features of dialysis-related amyloidosis include generalized arthritis, erosive arthritis, and joint effusions (Kleinman and Coburn, 1989). These are not manifestations of a generalized metabolic bone disorder but represent the consequences of local amyloid deposition in bone and/or periarticular tissues. Clinical manifestations of dialysis-related amyloidosis appear rarely among patients who have been treated with dialysis for less than five years. The disorder is more common among those undergoing renal replacement therapy for extended periods or who begin dialysis after the age of 50 years (van Ypersele de Strihou *et al.*, 1991).

The fraction of patients afflicted with amyloidosis increases progressively as a function of the number of years of treatment with dialysis (Bazzi et al., 1995; Zingraff and Drüeke, 1991). Clinical management is often unsatisfactory, but interventions are often needed to control pain arising from bone and joint involvement. The carpal tunnel syndrome improves after surgical intervention, but it can reoccur. Successful renal transplantation may provide symptomatic improvement, but there is little evidence that amyloid deposits in bone or in soft tissue resolve after kidney transplantation (Jadoul *et al.*, 1989).

THERAPEUTIC OPTIONS

Hyperparathyroidism: High-Turnover Renal Bone Disease

Effective strategies for managing secondary HPT among patients with CKD address the key pathogenic factors that account for the development and progression of the disorder. These include alterations in calcium and phosphorus metabolism and in vitamin D metabolism and nutrition (Goodman, 2001). Interventions that address each of these disturbances are an integral component of the general clinical management of any patient with CKD whether or not dialysis is required. They are often however, insufficient to fully control secondary HPT among patients with CKD, and more definitive measures may be required (Goodman, 2001).

Treatment with vitamin D sterols and/or with calcimimetic agents is necessary to effectively modify parathyroid gland function, to control plasma PTH levels, and to manage the bone disease of secondary HPT in many patients with CKD (Goodman, 2001). The approach differs substantially, however, between patients with mild to moderate CKD, who have significant residual renal function, and those with little or no residual renal function, who require dialysis. Modest calcium supplementation is often necessary and beneficial among patients with stage 3 or stage 4 CKD, but the use of large doses of calcium may lead to calcium retention and aggravate vascular calcification in those undergoing dialysis (Goodman *et al.*, 2000b). Vitamin D sterols and calcimimetic agents can be used either alone or together to control plasma PTH levels among dialysis patients with secondary HPT (Block *et al.*, 2004b; Goodman, 2002). In contrast, vitamin D sterols represent the only definitive pharmacological intervention for the disorder among patients with less advanced CKD (Coburn and Elangovan, 1998). Calcimimetic compounds are not approved for use in such patients.

Secondary HPT in CKD, Stages 1 to 4

Diet and nutrition

Among patients with CKD who do not require treatment with dialysis, inadequate dietary calcium intake, marginal vitamin D nutrition, and overt vitamin D deficiency can adversely affect calcium metabolism and provide an ongoing stimulus for PTH synthesis and secretion by the parathyroid glands (Coburn *et al.*, 1973a). In more advanced cases of CKD, phosphorus retention and hyperphosphatemia may develop, which can further aggravate secondary HPT (Slatopolsky and Delmez, 1994). Specific interventions are required to address these issues.

Dietary calcium intake is suboptimal in many patients with CKD, particularly in those who adhere to phosphorus-restricted diets that contain few dairy products (Slatopolsky and Delmez, 1994). Such diets are used commonly among patients with stage 3 or stage 4 CKD, but they typically provide only 500 to 600 mg of elemental calcium per day. Hypocalcemia thus occurs in some patients, whereas hypocalciuria is observed consistently among patients with stage 3 or stage 4 CKD who are not receiving oral calcium supplements or vitamin D sterols, results documented repeatedly in recent clinical trials (Charytan *et al.*, 2005; Coburn *et al.*, 2004; Coyne *et al.*, 2006).

Under circumstances where calcium intake is inadequate or intestinal calcium absorption is compromised,

increases in PTH secretion owing to secondary HPT diminish calcium excretion in the urine and mobilize calcium from bone (Goodman, 2005b, 2005c). These adaptive responses serve to attenuate reductions in serum calcium concentration. They can be offset by providing additional amounts of calcium in the diet or by giving oral calcium supplements that enhance intestinal calcium transport, reduce PTH secretion, and lower plasma PTH levels (Rudnicki *et al.*, 1993). Dietary calcium supplementation is often required among patients with CKD to maintain a daily calcium intake of 1000 to 1200 mg as recommended currently.

The use of calcium-containing, phosphate-binding agents such as calcium carbonate or calcium acetate can support calcium nutrition among patients with CKD, stages 2 to 4, but these compounds are often not prescribed because serum phosphorus levels remain normal in most cases. If they are given, some of the additional calcium will be absorbed from the intestine predominantly by passive, vitamin D-independent mechanisms (Sheikh *et al.*, 1989). This serves to correct hypocalcemia and lower plasma PTH levels. Calcium excretion in the urine should be monitored regularly and the doses of calcium-based compounds adjusted appropriately to avoid hypercalciuria.

Apart from the need to avoid dietary calcium deprivation, current guidelines suggest that the total intake of elemental calcium both from dietary and medicinal sources not exceed 2000 mg/day among patients with CKD (Eknoyan *et al.*, 2003). The recommendation is based largely on concerns about the use of very large oral does of calcium-containing compounds as phosphate-binding agents among patients undergoing dialysis and the reported association between this therapeutic strategy and the occurrence of soft-tissue and/or vascular calcification (Blacher *et al.*, 2001; Goodman *et al.*, 2000b; Guérin *et al.*, 2000). The risks of calcium retention and/or calcium loading are much lower, however, among patients with less advanced CKD where both urine output and the capacity to excrete calcium in the urine are preserved. Concerns about calcium retention among patients with mild to moderate CKD should not preclude the judicious use of oral calcium supplements to maintain calcium nutrition and to prevent or attenuate the development of secondary HPT.

Dietary phosphorus restriction and phosphate-binding agents are the first interventions recommended traditionally to control secondary HPT owing to CKD even when serum phosphorus concentrations remain within the normal range as summarized in current treatment guidelines (Eknoyan *et al.*, 2003). To be effective, phosphate-binding compounds should be given with meals to sequester phosphorus within the intestinal lumen and thus diminish its absorption. The effect of calcium-containing compounds to lower plasma PTH levels when given to control serum phosphorus levels in this context is caused in part by improvements in calcium nutrition and by increases in net intestinal calcium absorption as already discussed (Bleyer *et al.*, 1999; Emmett, 2004; Pflanz *et al.*, 1994). Calcium-free, phosphate-binding agents may also promote intestinal calcium transport by diminishing the amounts of phosphorus available to form insoluble complexes with calcium in the lumen of the gut, thus leaving more free calcium ions to be absorbed across the intestinal epithelium (Chertow *et al.*, 1999a). Decreases in intestinal phosphorus absorption during treatment with phosphate-binding agents alter phosphorus metabolism systemically and promote renal calcitriol synthesis by enhancing renal 1α-hydroxylase activity, thereby increasing vitamin D-dependent intestinal calcium transport (Portale *et al.*, 1984, 1986, 1989). Reductions in the serum levels of FGF23 may also enhance renal calcitriol production (Llach and Massry, 1985; Moallem *et al.*, 1998; Portale *et al.*, 1984). As such, phosphate-binding agents lower plasma PTH levels primarily by indirect mechanisms.

As noted previously, inadequate vitamin D nutrition and overt vitamin D deficiency are common among patients with CKD (Coburn *et al.*, 2004). Vitamin D nutrition is assessed by measuring the serum level of 25-hydroxyvitamin D, the predominant circulating metabolite of vitamin D. Values less than 30 ng/mL are considered to be inadequate and provide biochemical evidence of vitamin D deficiency. Repletion with generic vitamin D is recommended to maintain serum 25-hydroxyvitamin D levels above this biochemical threshold. Current guidelines suggest that this be done among patients with CKD, stages 1 to 4, but, for reasons that are unclear, the recommendation has not been extended to patients undergoing dialysis (Eknoyan *et al.*, 2003).

Either ergocalciferol, vitamin D_2, or cholecalciferol, vitamin D_3, can be used to restore vitamin D nutrition among patients with CKD. Larger doses are recommended for patients with overt vitamin D deficiency and very low serum 25-hydroxyvitamin D levels compared with those with vitamin D insufficiency and lesser reductions in serum 25-hydroxyvitamin D (Eknoyan *et al.*, 2003). Specific information about the dosing of ergocalciferol is provided in certain practice guidelines because this compound is more widely available for use clinically (Eknoyan *et al.*, 2003). The guidance is based, however, on results obtained in persons with normal renal function, not in those with CKD.

Some authorities suggest that serum 25-hydroxyvitamin D levels much greater than 30 ng/mL are required to fully satisfy the nutritional requirements for vitamin D (Dawson-Hughes *et al.*, 2005; Norman *et al.*, 2007; Vieth *et al.*, 2007). The issue is the focus of ongoing discussions and further research. The biochemical definition of adequate vitamin D nutrition may thus be revised in the future not only for persons with normal renal function but also for those with CKD.

Plasma PTH levels decrease modestly after vitamin D nutrition is restored following treatment with ergocalciferol

in some patients with secondary HPT owing to CKD. Greater reductions are seen in stage 3 than in stage 4 CKD, but plasma PTH levels remain elevated in many patients (Zisman *et al.*, 2007). Treatment with ergocalciferol is thus alone insufficient to control secondary HPT in a substantial proportion of patients with stage 3 or stage 4 CKD, but this is not the primary reason for providing either ergocalciferol or cholecalciferol to such individuals. Rather, the goal is to maintain adequate vitamin D nutrition among patients known to be at risk for vitamin D deficiency. Studies to compare the efficacy of ergocalciferol to that of cholecalciferol for correcting vitamin D deficiency or for lowering plasma PTH levels among patients with CKD have not been reported.

Pharmacological interventions

Vitamin* D *sterols Apart from dietary and nutritional considerations, treatment with vitamin D sterols is required to adequately control plasma PTH levels in many patients with CKD. The primary therapeutic objective is to reduce plasma PTH levels and to manage the bone disease of secondary HPT. Unfortunately, bone biopsy and bone histology are not readily available to most clinicians, and less invasive biochemical tests are typically used to guide clinical management.

Plasma PTH levels have served traditionally as the most reliable biochemical index of the severity of secondary HPT and its skeletal consequences. The results are used widely for clinical diagnosis and for monitoring disease progression (Eknoyan *et al.*, 2003; Goodman *et al.*, 2002b, 2003b). Available guidelines recommend that treatment for secondary HPT be initiated either when plasma PTH levels exceed 70 pg/mL for patients with stage 3 CKD or when values exceed 110 pg/mL for those with stage 4 CKD (Eknoyan *et al.*, 2003). Values above these thresholds are usually associated with histological evidence of hyperparathyroidism in bone (Hamdy *et al.*, 1995).

A number of PTH assays are available commercially (Boudou *et al.*, 2005). The results obtained with many of them differ, sometimes substantially, from those provided by the method used in published reports that serve as the basis for current practice guidelines (Souberbielle *et al.*, 2006). Such differences must be recognized and their potential impact on the interpretation of PTH values should be considered when results obtained with any particular assay are used for diagnostic purposes. Most immunometric assays detect not only full-length PTH, which is comprised of 84 amino acids, but also one or more amino-terminally truncated peptide fragments of PTH (Goodman, 2003b; Goodman *et al.*, 2003b). Variations in the extent of cross-reactivity with these peptide fragments largely explain disparities among results using different PTH assays (Souberbielle *et al.*, 2006).

Several polar metabolites of vitamin D can be used to treat secondary HPT among patients with CKD. Calcitriol became available for this purpose in the late 1970s (Brickman *et al.*, 1972). It was the first vitamin D analogue shown to be consistently effective for correcting hypocalcemia and for reducing plasma PTH levels among patients with secondary HPT owing to CKD, including those receiving dialysis (Brickman *et al.*, 1974a, 1974b).

Treatment with daily oral doses of calcitriol reduces plasma PTH levels by raising serum calcium concentrations, which activates the calcium-sensing receptor (CaSR) in parathyroid tissue and inhibits PTH secretion (Brickman *et al.*, 1974a, 1974b; Llach *et al.*, 1977). Calcitriol also downregulates pre-pro-PTH gene transcription and diminishes PTH mRNA expression (Cantley *et al.*, 1985; Russell *et al.*, 1984; Silver *et al.*, 1985). Successful treatment with oral doses of calcitriol diminishes the histological severity of secondary HPT in bone and may attenuate bone loss from the appendicular skeleton among patients with CKD (Bianchi *et al.*, 1994; Coen *et al.*, 1986). Increases in bone mass, as measured by dual energy x-ray absorptiometry (DXA), have also been reported (Przedlacki *et al.*, 1995; Ruedin *et al.*, 1994). Similar results have been achieved during treatment with daily oral doses of alfacalcidol, or 1α-hydroxyvitamin D_3, which undergoes 25-hydroxylation in the liver to form calcitriol (Hamdy *et al.*, 1995; Kanis *et al.*, 1977; Pierides *et al.*, 1976b; Rix *et al.*, 1999). Alfacalcidol is used widely in Europe, but it is not available for use clinically in the United States.

Because calcitriol and alfacalcidol enhance intestinal calcium absorption, both compounds are useful for correcting hypocalcemia among patients with CKD. Increases in serum calcium concentration are responsible, at least in part, for the effect of these agents to lower plasma PTH levels. Treatment is started with small doses initially, usually 0.125 to 0.25 μg/day of calcitriol or 0.25 to 0.5 μg/day of alfacalcidol. Doses are subsequently adjusted upward, as needed, either to correct hypocalcemia or to control plasma PTH levels if serum calcium and phosphorus levels do not become elevated (Coburn and Elangovan, 1998).

Serum calcium concentrations should be monitored regularly during treatment with either calcitriol or alfacalcidol because the development of hypercalcemia and/or hypercalciuria can adversely affect renal function, cause nephrolithiasis, or lead to nephrocalcinosis (Coburn and Elangovan, 1998; Goodman and Coburn, 1992; Sanchez *et al.*, 1999). These events are uncommon in adults with stage 3 or stage 4 CKD when the daily doses of calcitriol and alfacalcidol do not exceed 0.5 μg and 0.9 μg, respectively (Bianchi *et al.*, 1994; Goodman and Coburn, 1992; Nordal and Dahl, 1988). Caution is warranted, however, when higher doses are used.

Treatment with daily oral doses of 0.125 μg of calcitriol was more effective than placebo in preventing increases in plasma PTH levels during 12 months of follow-up among

patients with CKD, stages 3 and 4 (Ritz *et al.*, 1995). Similarly, plasma PTH levels remained controlled for 24 months and the histological changes of hyperparathyroidism in bone improved after 12 months of treatment with daily oral doses of alfacalcidol among adult patients with creatinine clearance values between 15 and 50 mL/min (Hamdy *et al.*, 1995).

Two other analogues of vitamin D are now available for treating secondary HPT among patients with CKD who do not require dialysis (Coburn *et al.*, 2004; Coyne *et al.*, 2006). Doxercalciferol and paricalcitol are both vitamin D_2 derivatives, and they are available currently as oral preparations in the United States. Doxercalciferol, or 1α-hydroxyvitamin D_2, is the vitamin D_2 equivalent of alfacalcidol. In practical terms, it is a prohormone that is converted into the biologically more potent metabolite 1,25-dihydroxyvitamin D_2 after undergoing 25-hydroxylation in the liver. A unique structural modification to the A ring of the secosteroid characterizes paricalcitol, which is 19-nor-1,25-dihydroxyvitamin D_2.

Clinical studies in humans and work in experimental animals suggest that vitamin D_2 analogues are less potent than their vitamin D_3 counterparts in promoting intestinal calcium and phosphorus absorption and in raising serum calcium and phosphorus concentrations (Finch *et al.*, 1999; Gallagher *et al.*, 1994; Takahashi *et al.*, 1997; Weber *et al.*, 2001). They may thus offer a more favorable safety profile than calcitriol and other metabolites of vitamin D_3 when used to treat secondary HPT among patients with mild to moderate CKD in whom episodes of hypercalcemia and/or hyperphosphatemia can adversely affect kidney function. Unfortunately, only limited information is available from controlled clinical trials to support this contention (Sprague *et al.*, 2003), and no controlled clinical trials have been done in patients with stage 3 or stage 4 CKD.

Both doxercalciferol and paricalcitol effectively lower plasma PTH levels when used to treat secondary HPT among patients with CKD, stages 3 and 4 (Fig. 7 and Fig. 8) (Coburn *et al.*, 2004; Coyne *et al.*, 2006). They do so without substantially raising serum calcium or phosphorus concentrations, probably by diminishing pre-pro-PTH gene transcription. In clinical trials lasting 24 weeks, the frequency of episodes of hypercalcemia and/or hyperphosphatemia was no greater among patients treated with daily oral doses of either doxercalciferol or paricalcitol compared with placebo (Coburn *et al.*, 2004; Coyne *et al.*, 2006). Calcium excretion in the urine increased modestly during treatment with both agents, but overt hypercalciuria did not occur. Kidney function did not change from baseline values during treatment with either compound (Coburn *et al.*, 2004; Coyne *et al.*, 2006). Doxercalciferol and paricalcitol are thus generally safe and effective for lowering plasma PTH levels among patients with secondary HPT owing to CKD, stages 3 and 4.

Long-term safety and efficacy data have yet to be reported with either agent among patients with CKD. The role of either compound in modifying the progression of secondary HPT has not been determined. Similarly, studies to evaluate the impact of treatment with either doxercalciferol or paricalcitol on bone histology or on bone mass have not been done among patients with mild to moderate CKD.

Current guidelines suggest that plasma PTH levels be maintained between 35 and 70 pg/mL among patients with stage 3 CKD and between 70 and 110 pg/mL among those with stage 4 CKD (Eknoyan *et al.*, 2003). Periodic adjustments to the doses of calcitriol or alfacalcidol may be required to achieve these biochemical objectives, but the issue has been evaluated critically in clinical trials. Virtually all studies to date have used prespecified percentage reductions in plasma PTH levels or a plasma PTH level below a predetermined value to assess therapeutic efficacy.

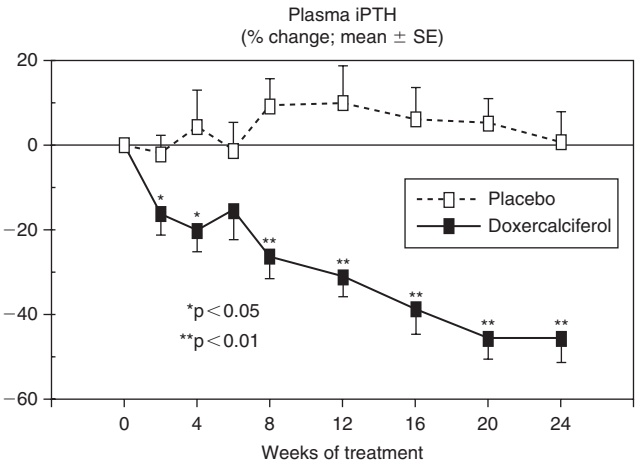

FIGURE 7 The percentage change in plasma PTH levels during 24 weeks of treatment with daily oral doses of either doxercalciferol (solid symbols) or placebo (open symbols) among patients with stage 3 or stage 4 CKD. (From reference (Coburn *et al.*, 2004)).

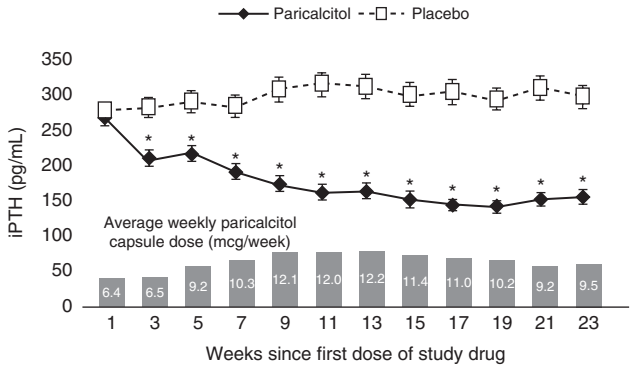

FIGURE 8 Plasma PTH levels during 24 weeks of treatment with daily oral doses of either paricalcitol (solid symbols) or placebo (open symbols) among patients with stage 3 or stage 4 CKD. The results are combined data from three separate randomized, placebo-controlled clinical trials. Paricalcitol was given orally three times per week in two of the studies, whereas daily oral doses were used in the third. Bars depict the average weekly dose of paricalcitol. (From reference (Coyne *et al.*, 2006)).

None have been done using plasma PTH values that fall within a specified therapeutic target range to judge biochemical outcomes or to assess drug efficacy.

To limit the risks of soft-tissue and vascular calcification, the dose of any vitamin D sterol should be reduced or treatment withheld temporarily if hypercalcemia or hyperphosphatemia develop (Eknoyan *et al.*, 2003). Treatment should also be withdrawn when plasma PTH levels fall below the lower limit of the therapeutic target range because adynamic renal osteodystrophy can occur when values remain low for sustained periods (Goodman *et al.*, 1994). If plasma PTH levels rise substantially after vitamin D therapy is withdrawn, treatment should be restarted by using smaller doses.

Secondary HPT in CKD, stage 5

Diet and nutrition

As discussed previously for patients with less advanced CKD, measures to support adequate calcium and vitamin D nutrition are also required in many with stage 5 CKD who are treated with dialysis. Nearly all have hyperphosphatemia and most receive phosphorus-restricted diets that contain only limited amounts of elemental calcium. As such, dietary calcium intake is usually inadequate as judged by conventional criteria. Intestinal calcium absorption is suboptimal because endogenous renal calcitriol production is impaired and serum calcitriol levels are reduced, often substantially.

The defect in intestinal calcium transport among patients with stage 5 CKD can be offset partially either by raising the dietary calcium content or by prescribing oral calcium supplements (Indridason and Quarles, 2000). A portion of the additional calcium provided will be absorbed by vitamin D-independent mechanisms (Sheikh *et al.*, 1988, 1989). Unfortunately, the amounts of calcium required to maintain adequate calcium nutrition among patients undergoing dialysis have not been established, and current guidance is based on limited information.

Because the capacity to excrete calcium in the urine is reduced markedly among patients with advanced CKD, it is recommended that the daily intake of elemental calcium not exceed 1500 to 2000 mg/day among those treated with dialysis (Eknoyan *et al.*, 2003). This includes both dietary and medicinal sources. The objective is to limit the risk of calcium retention and to avoid circumstances where total body calcium balance remains positive for extended periods. The use of large oral doses of calcium as a phosphate-binding agent has been associated with soft-tissue and vascular calcification among patients receiving dialysis, and arterial calcification may progress more rapidly among hemodialysis patients managed with calcium-containing compounds compared with those receiving calcium-free compounds (Chertow *et al.*, 2002; Goodman *et al.*, 2000b; Guérin *et al.*, 2000; Spiegel *et al.*, 2007).

When calcium-containing compounds are used exclusively as part of a phosphate-binding strategy, the doses of elemental calcium required to control hyperphosphatemia often far exceed 1500 to 2000 mg/day (Goodman *et al.*, 2000b; Slatopolsky *et al.*, 1986). Such amounts can raise serum calcium concentrations among patients undergoing dialysis regularly, and they can cause episodes of hypercalcemia even in those who are not receiving treatment with vitamin D sterols (Bleyer *et al.*, 1999; Fournier *et al.*, 1986; Moriniere *et al.*, 1989). Calcium-free agents such as sevelamer and lanthanum carbonate are thus often required to manage hyperphosphatemia when the total daily intake of calcium is constrained as recommended in current practice guidelines. Although aluminum-containing, phosphate-binding agents represent another alternative, they should generally be avoided to limit the risks of aluminum retention and toxicity (Coburn *et al.*, 1986).

Sevelamer hydrochloride, or hydrogel of cross-linked poly-allylamine hydrochloride, is an ion exchange polymer that binds phosphorus in the intestinal lumen and diminishes its absorption (Chertow *et al.*, 1997). Sevelamer does not contain calcium or aluminum. It is as effective as calcium acetate for controlling serum phosphorus levels among patients undergoing dialysis, but episodes of hypercalcemia occur less often among those given sevelamer (Chertow *et al.*, 1999b). Daily doses averaging 5 to 6 g are needed to maintain serum phosphorus levels in the range of 5.8 to 6.0 mg/dL, or 1.8 to 2.0 mM, among patients undergoing thrice-weekly hemodialysis, but larger doses are required in many patients (Chertow *et al.*, 1999a). Symptoms arising from the upper gastrointestinal tract such as nausea and vomiting are not uncommon, and some patients complain of bloating or abdominal fullness. The relationship between these side effects and the doses of sevelamer remain uncertain, but they may limit the total amount of sevelamer that can be given to control serum phosphorus levels.

Serum total cholesterol and LDL cholesterol levels decrease by 20% to 30% during treatment with sevelamer, whereas HDL cholesterol levels rise, changes probably attributable to the binding of cholesterol and bile acids within the intestinal lumen (Chertow *et al.*, 1997, 1999a; Wilkes *et al.*, 1998). Serum carbon dioxide levels also decline in some patients, reflecting modest decreases in plasma bicarbonate and mild academia (De Santo *et al.*, 2006). Bicarbonate levels before hemodialysis may thus be lower among patients treated with sevelamer compared with those receiving calcium carbonate. The release of protons from the resin in exchange for inorganic phosphate accounts for this biochemical change. A new formulation of sevelamer that contains carbonate rather than chloride as the exchange anion has been developed to circumvent this problem (Delmez *et al.*, 2007).

Lanthanum carbonate represents another calcium-free, phosphate-binding agent (Hutchison, 1999). Its capacity to

bind phosphorus is equivalent to that of aluminum hydroxide, which has long been considered to be among the most potent phosphate-binding agents. The phosphate-binding capacity of lanthanum carbonate exceeds that of calcium acetate, calcium carbonate, and sevelamer (Hutchison, 1999). Unlike calcium-based compounds, the binding of phosphorus by lanthanum is unaffected by pH (Joy and Finn, 2003). Clinical trials using amounts as high as 3000 mg/day, given in divided doses with meals, confirm its efficacy for lowering serum phosphorus levels among patients undergoing dialysis (Al Baaj *et al.*, 2005; Finn and Joy, 2005; Hutchison *et al.*, 2005, 2006). Gastrointestinal symptoms are not uncommon, however, among patients treated with lanthanum carbonate.

A very small fraction of lanthanum is absorbed from the gastrointestinal tract. It can thus be detected in serum and in several tissues, including liver and bone. The implications of these findings remain uncertain. Histomorphometric assessments of bone biopsy samples obtained after several years of treatment with lanthanum carbonate among patients undergoing hemodialysis reveal no adverse effects on skeletal mineralization or on bone remodeling (D′Haese *et al.*, 2003). Safety and efficacy have been documented among patients treated for as long as three years (Hutchison *et al.*, 2006), but additional studies are required to determine whether lanthanum accumulates in bone or other tissues with long-term therapy (D′Haese *et al.*, 2003).

Pharmacological interventions

Use of oral vitamin D sterols For many years, treatment with small daily oral doses of either calcitriol or alfacalcidol was the only definitive therapeutic intervention for secondary HPT among patients undergoing dialysis regularly (Coburn and Elangovan, 1998; Salusky *et al.*, 1987). The doses employed typically ranged from 0.125 to 1.0 μg/day for calcitriol and were approximately twofold higher for alfacalcidol. Both were effective in lowering plasma PTH levels among patients receiving either hemodialysis or peritoneal dialysis (Quarles *et al.*, 1988; Salusky *et al.*, 1987; Salusky and Goodman, 1996). They also raised serum calcium concentrations and were useful for correcting hypocalcemia, a common consequence of CKD during the 1970s and 1980s when aluminum-containing rather than calcium-containing compounds were used widely as phosphate-binding agents.

Episodes of hypercalcemia and/or hyperphosphatemia are frequent dose-limiting side effects of treatment with oral doses of calcitriol or alfacalcidol. Hypercalcemia is not uncommon in adult patients when the dose of calcitriol exceeds 0.50 μg/day. Hypercalcemia develops more often among patients receiving calcium-containing, phosphate-binding compounds, in those with adynamic renal osteodystrophy, and after plasma PTH and serum alkaline phosphatase levels have decreased and approach normal values during treatment (Coburn *et al.*, 1977; Goodman *et al.*, 2003a).

Intermittent oral doses of calcitriol, given twice or thrice weekly, have also been used to manage secondary HPT both in patients receiving hemodialysis and in those undergoing peritoneal dialysis (Kwan *et al.*, 1992; Martin *et al.*, 1992; Moe *et al.*, 1998). Although, larger cumulative weekly doses of calcitriol can be achieved by using an intermittent dosing strategy, there is little evidence that this approach is more effective than daily oral calcitriol therapy for controlling secondary HPT (Bacchini *et al.*, 1997; Caravaca *et al.*, 1995; Liou *et al.*, 1994; Monier-Faugere and Malluche, 1994; Muramoto *et al.*, 1991).

Use of parenteral vitamin D sterols Treatment with intermittent intravenous doses of vitamin D sterols is the most widespread approach for treating secondary HPT among persons undergoing hemodialysis, at least in the United States. The use of oral doses of calcitriol or other vitamin D sterols is now uncommon. In contrast, oral vitamin D therapy continues to be used widely in Europe and elsewhere.

Calcitriol was the first vitamin D sterol to be given intravenously during thrice-weekly hemodialysis sessions to control plasma PTH levels among patients with secondary HPT (Slatopolsky *et al.*, 1984). Potential advantages of the intravenous route of administration included assured patient compliance and the ability to deliver larger cumulative weekly doses of calcitriol in an effort to lower plasma PTH levels. It was also suggested that the high serum levels of calcitriol achieved after bolus intravenous injections were more effective in suppressing pre-pro-PTH gene transcription and in reducing plasma PTH levels, but evidence to support this contention is limited (Fischer and Harris, 1993; Slatopolsky *et al.*, 1984).

In short-term studies of adult hemodialysis patients with mild to moderate secondary HPT, plasma PTH levels decreased promptly within two weeks during treatment with thrice-weekly intravenous doses of calcitriol (Fig. 9)

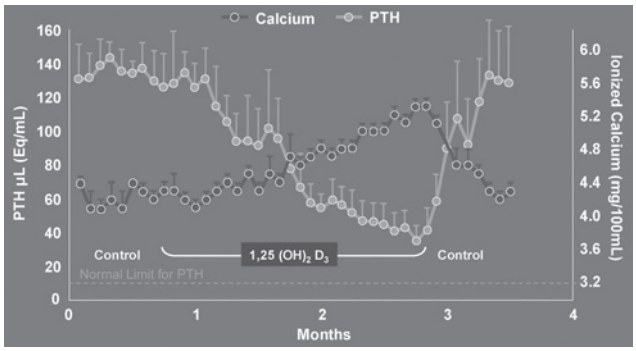

FIGURE 9 Plasma PTH and blood ionized calcium concentrations during two weeks of treatment with thrice-weekly intravenous doses of calcitriol. Plasma PTH levels were measured using a single-antibody mid-region immunoassay for PTH. (From reference (Slatopolsky *et al.*, 1984)).

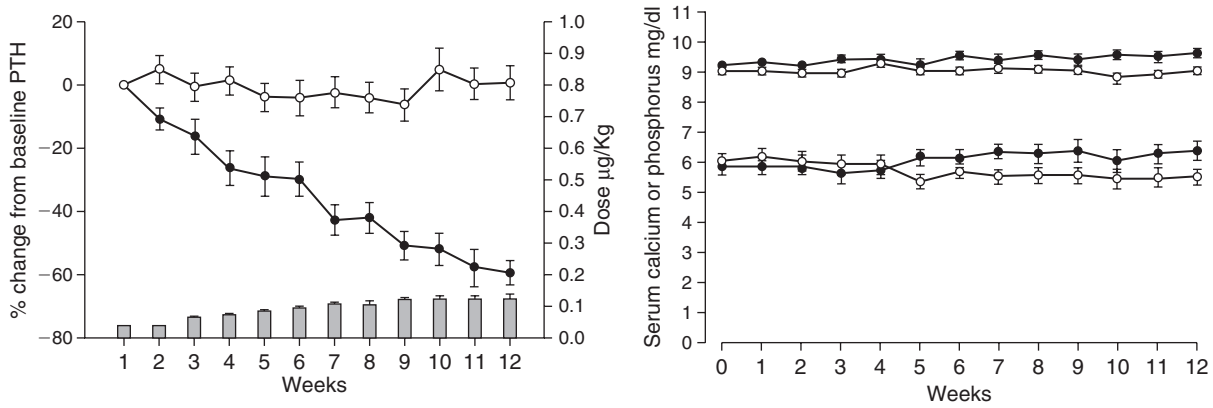

FIGURE 10 The percentage reduction in plasma PTH levels from pre-treatment values during 12 weeks of treatment with thrice-weekly intravenous doses of paricalcitol among hemodialysis patients with secondary hyperparathyroidism (left panel). Bars indicate the average weekly dose of paricalcitol in µg per kilogram of body weight. Serum calcium and phosphorus concentrations at each study visit are also presented (right panel). (From reference (Martin *et al.,* 1998)).

(Slatopolsky *et al.*, 1984). In a separate study of patients undergoing hemodialysis regularly, plasma PTH levels fell by 52% after 12 months and by 71% after 24 months of treatment using doses of calcitriol that ranged from 0.5 µg to 2.25 µg three times weekly (Sprague and Moe, 1992). Greater reductions in plasma PTH levels can be achieved with higher thrice-weekly doses, but values may fall below the target range currently recommended (Dressler *et al.*, 1995). Patients with marked parathyroid gland enlargement are less likely to respond favorably to treatment (Malberti *et al.*, 1996).

Little information has been provided about the efficacy of intravenous calcitriol therapy for controlling plasma PTH levels and for managing secondary HPT beyond two years of follow-up. Data on other important clinical outcomes is also unavailable. These include the impact of treatment on bone mass, on the need for surgical parathyroidectomy, and on skeletal fracture rates (Foley *et al.*, 2005).

As with oral calcitriol therapy, the doses of calcitriol that can be given intravenously to manage secondary HPT are limited by increases in serum calcium and phosphorus concentrations (Slatopolsky *et al.*, 1984; Sprague and Moe, 1992). Such changes can aggravate vascular and soft-tissue calcification. Recurrent episodes of hypercalcemia occur more often among patients ingesting large doses of calcium as a phosphate-binding agent, an approach that remains quite common. Because of these concerns, treatment with intravenous doses of new vitamin D sterols such as paricalcitol and doxercalciferol has largely replaced intravenous calcitriol therapy in the management of secondary HPT among patients undergoing hemodialysis. Other compounds such as 22-oxacalcitriol, or maxacalcitol, have been developed, but they are not available for use clinically in the United States (Brown, 1998).

In a placebo-controlled clinical trial, treatment for 12 weeks with thrice-weekly intravenous doses of paricalcitol lowered plasma PTH levels by an average of 60% from baseline values among patients with moderately severe secondary HPT (Fig. 10) (Martin *et al.*, 1998). Initial doses of 2 to 3 µg were titrated upward to a mean dose of approximately 8 µg thrice weekly to reduce plasma PTH levels. Serum calcium and phosphorus concentrations rose modestly compared with placebo. Episodes of hypercalcemia were more frequent in subjects treated with paricalcitol but often occurred after plasma PTH levels had decreased substantially (Martin *et al.*, 1998). Sustained reductions in plasma PTH levels were achieved among patients treated with thrice-weekly intravenous doses of paricalcitol for 12 months, but greater increases in serum calcium and phosphorus levels were observed during long-term follow-up (Lindberg *et al.*, 2001). The frequency of persistent elevations in serum calcium and/or phosphorus concentrations was modestly lower among hemodialysis patients managed with paricalcitol compared with calcitriol in one prospective clinical trial (Sprague *et al.*, 2003).

In short-term studies, thrice-weekly doses of doxercalciferol, given orally or intravenously, also effectively lowered plasma PTH levels among hemodialysis patients with moderately severe secondary HPT. Values decreased by approximately 60% from pretreatment levels after 16 weeks using oral doses ranging from 2.5 to 10 µg three times weekly (Fig. 11) (Frazao *et al.*, 2000). Similar reductions in plasma PTH levels were observed over the same interval of follow-up during treatment with thrice-weekly intravenous doses of doxercalciferol ranging from 1 to 4 µg (Fig. 12) (Tan *et al.*, 1997). Serum calcium concentrations rose modestly during treatment with oral or intravenous doses, but the number of episodes of hypercalcemia and hyperphosphatemia was greater among patients given doxercalciferol compared with placebo regardless of the route of drug administration. Hypercalcemia and hyperphosphatemia occur less frequently, however, among subjects

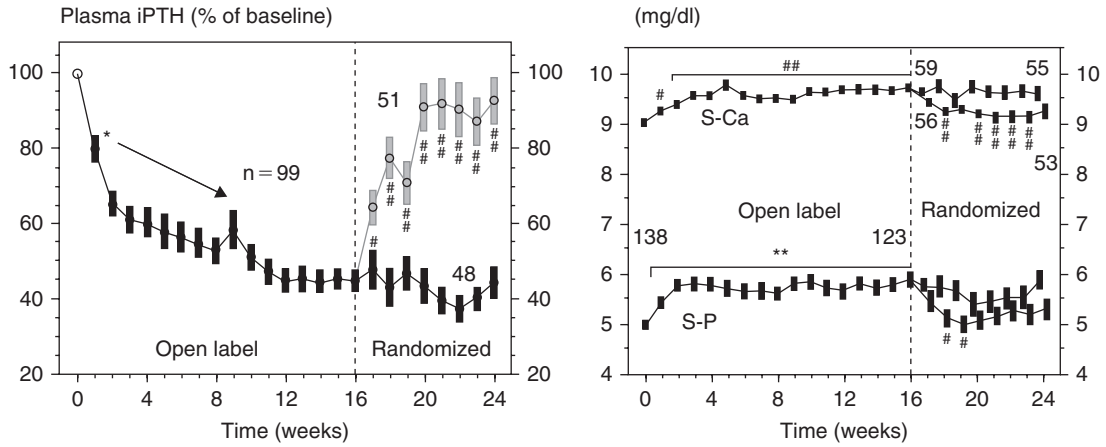

FIGURE 11 The percentage change in plasma PTH levels from pre-treatment values during treatment with thrice-weekly oral doses of doxercalciferol among hemodialysis patients with secondary hyperparathyroidism (left panel). All patients were initially given doxercalciferol for 16 weeks. Subjects were then assigned randomly to receive either doxercalciferol or placebo for another eight weeks. Mean serum calcium and phosphorus concentrations during the study are also shown (right panel). (From reference (Frazao *et al.,* 2000)).

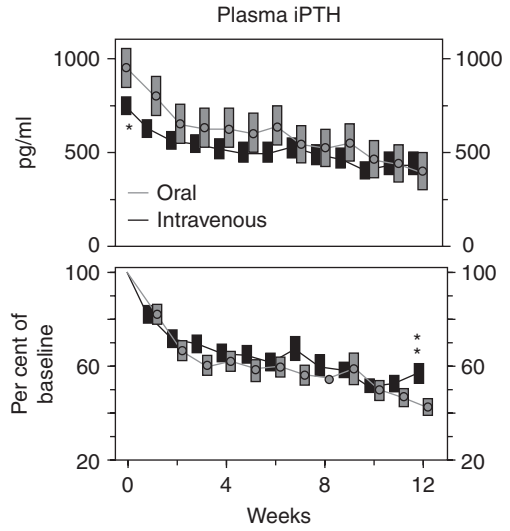

FIGURE 12 Plasma PTH levels (top panel) and the percentage change in plasma PTH (bottom panel) during treatment with thrice-weekly doses of doxercalciferol given orally or intravenously among hemodialysis patients with secondary hyperparathyroidism. Oral doses of doxercalciferol ranged from 2.5 μg to10.0 μg whereas intravenous doses ranged from 1.0 μg to 4.0 μg with each hemodialysis session. (From reference Maung *et al.,* 2001)).

managed with intravenous doses than with oral doses of doxercalciferol (Maung *et al.*, 2001). Episodes of hypercalcemia or hyperphosphatemia usually resolve within three to seven days after treatment is withdrawn (Tan *et al.*, 1997). The use of intravenous rather than oral doses of doxercalciferol may thus provide a better alternative for managing secondary HPT when serum calcium and phosphorus levels are not controlled optimally or when episodes of hypercalcemia and/or hyperphosphatemia have occurred previously (Frazao *et al.*, 2000).

Additional studies are needed to determine whether the frequency of episodes of hypercalcemia and hyperphosphatemia is less during treatment with doxercalciferol than with calcitriol or other vitamin D sterols. Clinical trials to compare the safety and efficacy of paricalcitol with that of doxercalciferol have not been done. The value of paricalcitol and doxercalciferol for achieving and maintaining biochemical control of secondary HPT after several years of follow-up has not been assessed. Similarly, information about the impact of treatment with either paricalcitol or doxercalciferol on bone mass and on skeletal fracture rates among patients undergoing dialysis has not been reported.

The effect of vitamin D sterols to downregulate pre-pro-PTH gene transcription and to lower plasma PTH levels is limited in duration, and ongoing treatment is required to sustain these responses (Goodman, 2001). Plasma PTH levels thus often rise substantially within weeks after treatment is withdrawn among patients who have responded previously to vitamin D therapy (Frazao *et al.*, 2000). As such, the impact of periodic adjustments to the doses of vitamin D sterols must be considered when evaluating interval changes in plasma PTH levels during clinical management.

Plasma PTH levels should be monitored regularly during treatment with intermittent doses of vitamin D sterols, whether given orally or intravenously. Doses should be reduced when plasma PTH levels approach values that are four to five times the upper limit of normal to diminish the risk of inducing adynamic bone, which can develop after intermittent calcitriol therapy (Goodman *et al.*, 1994; Salusky and Goodman, 1996, 2001). Whether treatment with paricalcitol or doxercalciferol produces similar reductions in bone formation and turnover is not known. Data on bone histology after the treatment of secondary HPT with these vitamin D sterols have not been reported among patients managed with dialysis.

Calcimimetics The calcimimetic agent cinacalcet hydrochloride first became available in 2004 for use clinically to manage secondary HPT among patients undergoing dialysis. Cinacalcet acts as an allosteric activator of the calcium-sensing receptor (CaSR), lowering the threshold for receptor activation by extracellular calcium ions and thereby inhibiting PTH secretion (Hammerland *et al.*, 1998). It thus reduces plasma PTH levels by a mechanism distinct from that of the vitamin D sterols and provides a second pharmacological intervention for secondary HPT among persons with CKD (Goodman, 2003a, 2005a).

Cinacalcet is available only as tablets for oral administration. A formulation for intravenous use among patients receiving thrice-weekly hemodialysis is not available owing largely to the hydrophobic nature of the compound. Nevertheless, cinacalcet is absorbed rapidly after oral administration (Harris *et al.*, 2004). Peak plasma levels are achieved within 60 to 90 minutes and depend largely on the doses given (Antonsen *et al.*, 1998; Harris *et al.*, 2004; Silverberg *et al.*, 1997). Plasma PTH levels decrease abruptly after single oral doses reaching a nadir after two to four hours, but values rise subsequently toward predose levels during the remainder of the day (Goodman *et al.*, 2002a; Harris *et al.*, 2004). The immediate effects of cinacalcet to inhibit PTH secretion and to lower plasma PTH do not differ substantially between patients with mild or advanced secondary HPT, and they do not diminish with ongoing therapy (Moe *et al.*, 2005b).

Treatment with cinacalcet is initiated by using single daily oral doses of 30 mg. Doses are titrated sequentially upward at two- to four-week intervals to 60 mg, 90 mg, 120 mg, or to the maximum daily dose of 180 mg to control plasma PTH levels (Block *et al.*, 2004b). As expected, serum calcium concentrations decrease as plasma PTH levels decline. Serum calcium levels should thus be monitored regularly during cinacalcet therapy. The largest reductions occur during the first week, and serum calcium levels should be measured one week after treatment is started to assess this biochemical change. Smaller decrements in serum calcium are seen with subsequent dosage adjustments. Symptomatic hypocalcemia has not been reported among dialysis patients treated by using a dose titration scheme (Block *et al.*, 2004b).

Serum phosphorus levels also often decline during treatment with cinacalcet (Goodman *et al.*, 2002a). Reductions in the mobilization of phosphorus to form bone are largely responsible. Elevated serum calcium and phosphorus values are common among hemodialysis patients who are frequently treated with calcium-containing compounds and/or vitamin D sterols. These biochemical disturbances have been associated in observational studies with adverse outcomes including cardiovascular events and mortality (Block *et al.*, 2004a). Additional work is required, however, to determine whether improvements in the control of serum calcium and phosphorus levels during the treatment of secondary HPT with cinacalcet modifies important clinical outcomes. Unlike the vitamin D sterols, neither hypercalcemia nor hyperphosphatemia preclude the use of cinacalcet for lowering plasma PTH levels in patients with overt secondary HPT.

Among patients with inadequately controlled secondary HPT despite previous treatment with vitamin D sterols and phosphate-binding agents, plasma PTH levels declined progressively during 26 weeks of treatment with cinacalcet (see Fig. 12) (Block *et al.*, 2004b). The proportion of patients who achieved a plasma PTH level less than 250 pg/mL rose progressively over time, and 41% of subjects reached this therapeutic endpoint (Fig. 13) (Block *et al.*, 2004b). Serum calcium and phosphorus levels decreased modestly despite the continued use of vitamin D sterols in two-thirds of patients.

Treatment with cinacalcet is similarly effective for controlling plasma PTH levels when used together with smaller doses of vitamin D sterols or without concurrent vitamin D therapy. Serum calcium and phosphorus concentrations can be maintained more often within the ranges recommended by current practice guidelines among patients treated with cinacalcet than with conventional therapies (Moe *et al.*, 2005a), but prospective clinical trials to address this issue have yet to be reported.

The efficacy of cinacalcet does not differ according to disease severity as judged by baseline PTH values (see Fig. 13) (Block *et al.*, 2004b; Martin *et al.*, 2005). Cinacalcet thus appears to be similarly effective for lowering plasma PTH levels among patients with mild, moderate, or severe secondary HPT (Fig. 14). Although CaSR expression is diminished in hyperplastic parathyroid tissue, such changes do not substantially modify the biochemical response to treatment (Chen and Goodman, 2004).

The use of daily oral doses of cinacalcet induces an oscillating hormone concentration profile during the day (Lindberg *et al.*, 2003; Seidel *et al.*, 1993). These short-term variations must be considered when interpreting PTH results during clinical management (Goodman, 2005a). Values will be affected by the length of the interval between oral drug administration and the time at which blood samples are collected (Goodman, 2005a). Plasma PTH levels obtained 24 hours after preceding doses of cinacalcet have been used in all published clinical trials to assess therapeutic efficacy and to guide dosage adjustments, and a similar approach is recommended in clinical practice (Block *et al.*, 2004b; Goodman, 2005a; Lindberg *et al.*, 2003; Quarles *et al.*, 2003). Measurements done 12 to 24 hours after daily doses of cinacalcet thus provide biochemical information similar to that reported in clinical trials to inform therapeutic decisions (Block *et al.*, 2004b; Goodman, 2005a; Lindberg *et al.*, 2003; Quarles *et al.*, 2003).

In all published clinical trials, single daily oral doses of cinacalcet have been used to manage secondary HPT among patients undergoing dialysis. Information about the safety and efficacy of cinacalcet using alternative dosing strategies in such patients is not available.

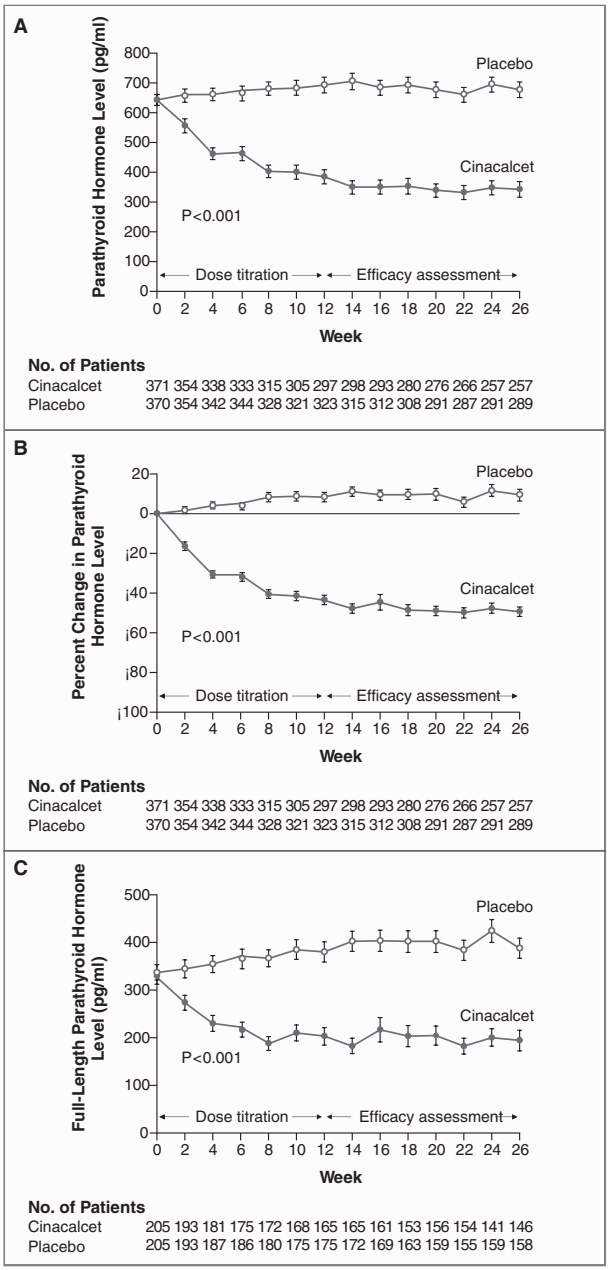

FIGURE 13 The percentage of patients treated for 26 weeks with cinacalcet or placebo who achieved a mean plasma PTH level ≤250 pg/mL or a decrease in plasma PTH equal to or greater than 30% (top panel). The proportion who achieved a plasma PTH level ≤250 pg/mL increased progressively during the study (middle panel), and the fraction of cinacalcet-treated patients that experienced a 30% or greater decrease in plasma PTH levels from pre-treatment values did not differ according to disease severity as judged by baseline, or pre-treatment, plasma PTH determination (bottom panel). (From reference (Block *et al.*, 2004b)).

Parathyroidectomy Some patients undergoing dialysis and others with less advanced CKD fail to respond adequately to treatment with vitamin D sterols or cinacalcet, and plasma PTH levels cannot be controlled adequately. Such patients generally have advanced secondary HPT that requires surgery to control the disorder. Plasma PTH levels are markedly elevated, and attempts to lower them during treatment with vitamin D sterols are frequently constrained by recurrent episodes of hypercalcemia and/or hyperphosphatemia that limit the doses that can be given safely.

For patients with hypercalcemia and a history of exposure to of aluminum-containing medications, the possibility of bone aluminum toxicity should be considered and the diagnosis excluded by using bone biopsy and bone histomorphometry, if necessary, before proceeding with surgery. Aluminum-related bone disease can worsen and overt osteomalacia can develop during the weeks or months immediately after parathyroidectomy among patients with bone aluminum toxicity (Coburn and Slatopolsky, 1990). Additional causes of hypercalcemia, such as sarcoidosis, other granulomatous disorders, malignancy, and treatment with large doses of calcium or vitamin D analogues, should be considered and excluded.

Apart from hypercalcemia, hyperphosphatemia that persists or reoccurs frequently during treatment with vitamin D sterols or despite ongoing management with dietary phosphorus restriction and phosphate-binding represents another reason to consider parathyroidectomy. Additional indications include persistent bone pain, skeletal fractures, intractable pruritus that does not respond to intensive dialysis or to other medical interventions, evidence of progressive extraskeletal calcification, and calciphylaxis among patients with markedly elevated plasma PTH levels (Llach, 1990).

Either subtotal or total parathyroidectomy is done most often among patients treated with dialysis (Kaye *et al.*, 1989; Kaye, 1989). Hyperparathyroidism reoccurs in 15% to 30% of those who have had a previous successful subtotal parathyroidectomy, a finding likely owing to ongoing hyperplasia in the residual parathyroid tissue. For patients who are candidates for renal transplantation, subtotal parathyroidectomy is preferred because the remaining tissue serves to maintain calcium homeostasis after renal function is restored.

An alternative surgical approach is total parathyroidectomy followed by the implantation of parathyroid gland fragments into subcutaneous tissues in the forearm or elsewhere to preserve some glandular function postoperatively. Caution is warranted, however, regarding this approach, and several limitations must be acknowledged. The implanted tissue can enlarge and develop autonomous secretory behavior. As such, hyperparathyroidism may recur. The implanted fragments can also spread locally into surrounding tissues, rendering surgical resection difficult.

Adynamic Bone

The appropriate management of patients with adynamic renal osteodystrophy depends largely on whether the cause

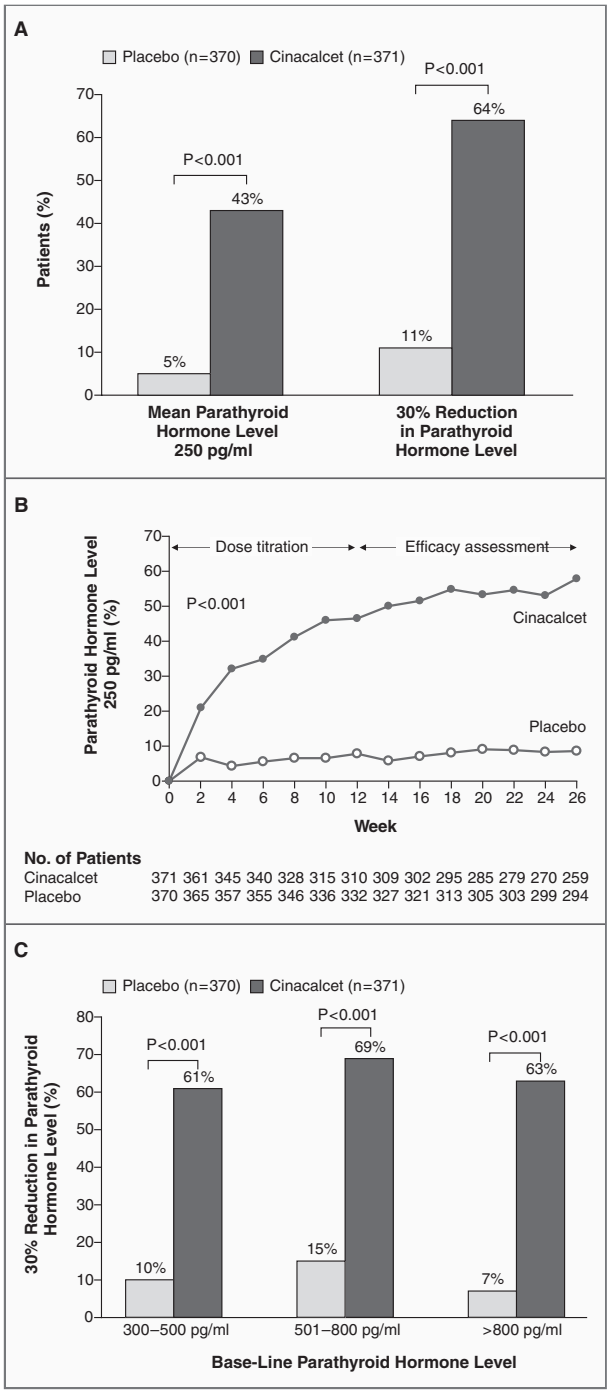

FIGURE 14 The percentage of patients treated for 26 weeks with cinacalcet or placebo who achieved a mean plasma PTH level ≤250 pg/m or a decrease in plasma PTH equal to or greater than 30% from pretreatment values (top panel). The proportion who reached a plasma PTH level ≤250 pg/m increased progressively during treatment with cinacalcet (middle panel), and the proportion who had a 30% or greater decrease in plasma PTH levels from pretreatment values did not differ according to disease severity as judged by baseline, or pre-treatment, plasma PTH determination (bottom panel). (From reference (Block *et al.*, 2004b)).

can be identified definitively. Among patients receiving large doses of calcium-containing, phosphate-binding agents, the amounts utilized should be reduced to avoid ongoing parathyroid gland suppression. Treatment with vitamin D sterols should be withdrawn when plasma PTH levels have been lowered excessively, in particular, when accompanied by recurrent episodes of hypercalcemia. If bone aluminum deposition is the underlying cause, eliminating the source of ongoing aluminum loading may be sufficient to reverse the adynamic lesion. Bone formation increases substantially in many patients after treatment with aluminum-containing compounds is withdrawn (Hercz *et al.*, 1988).

Although relative hypoparathyroidism is thought to be a factor in the pathogenesis of adynamic renal osteodystrophy, the use of exogenous doses of PTH or teriparatide has not been evaluated as a therapeutic strategy. Little is known about the impact of treatments for other causes of adynamic bone such as diabetes or postmenopausal osteoporosis among patients receiving dialysis. Nevertheless, the use of bisphosphonates is not recommended. These compounds are normally eliminated from the body by excretion in the urine. The renal clearance of bisphosphonates is markedly diminished among patients with advanced CKD, and these agents are not removed effectively by dialysis. As such, extensive sequestration in bone may occur with potentially adverse consequences.

Osteomalacia

The treatment of osteomalacia should be directed toward the specific cause identified. Overt vitamin D deficiency or marginal vitamin D nutrition should be corrected by the administration of either ergocalciferol or cholecalciferol over several months. The efficacy of treatment is assessed by follow-up measurements of serum 25-hydroxyvitamin D levels. Values should be maintained above 30 ng/mL. Ongoing therapy may be required to achieve this objective, but the matter has not been studied in detail among patients undergoing dialysis regularly. Other factors that adversely affect skeletal mineralization, such as hypocalcemia or hypophosphatemia that cannot be explained by vitamin D deficiency, must also be identified and eliminated.

Among patients with bone aluminum toxicity, the source of aluminum exposure should be identified and suitable corrective measures undertaken to avoid further aluminum loading. Oral medications and dialysis solutions that contain aluminum are implicated most often. Therapeutic interventions that preclude further aluminum exposure are often sufficient to effectively manage aluminum-related osteomalacia in subjects who do not have severe bone pain and/or recurrent skeletal fractures. Others, however, are markedly incapacitated, and more definitive interventions are required.

Deferoxamine (DFO) effectively mobilizes aluminum from bone and other tissues and enhances its removal during hemodialysis and peritoneal dialysis procedures (Malluche *et al.*, 1984; Ott *et al.*, 1986). Doses can be given either intravenously or subcutaneously, but low-dose subcutaneous therapy is recommended (Hercz *et al.*, 1986; Milliner *et al.*, 1986). Bone pain and other musculoskeletal symptoms attributable to bone aluminum toxicity generally improve after four to ten months of treatment in severely affected cases (Coburn *et al.*, 1986; Ott *et al.*, 1986).

Serum calcium levels decrease modestly and episodes of hypercalcemia become less frequent or resolve altogether during the successful treatment of aluminum-related osteomalacia with DFO. Serum alkaline phosphatase levels often rise, suggesting improvements in skeletal mineralization and osteoblastic activity (Coburn *et al.*, 1986). Plasma PTH levels also increase modestly, and this biochemical change may contribute to increases in bone formation and remodeling as bone aluminum levels decline (Ott *et al.*, 1986). The amount of surface-stainable aluminum in bone decreases in most patients who are treated with DFO, but those who have undergone previous parathyroidectomy respond less well or not at all (Ott *et al.*, 1986).

Serious and often lethal infections with *Rhizipus* and *Yersinia* can develop during DFO therapy among patients undergoing dialysis (Boelaert *et al.*, 1985; Gallant *et al.*, 1986; Hoen *et al.*, 1988; Segal *et al.*, 1988; Windus *et al.*, 1987). The chelation of plasma iron by DFO enhances its delivery into the cytoplasm of certain organisms thus increasing their pathogenic potential (Abe *et al.*, 1990; Robins-Browne and Prpic, 1985; Van Cutsem and Boelaert, 1989). As such, DFO must be used judiciously in the management of aluminum-related bone disease, and treatment should be confined only to those severely affected. In asymptomatic patients with aluminum deposition in bone, bone histology and bone formation improves solely by withdrawing aluminum-containing medications and replacing them with calcium-containing compounds to control serum phosphorus levels (Hercz *et al.*, 1988).

Evidence of bone toxicity owing to aluminum deposition should be documented fully by using bone biopsy and bone histomorphometry before DFO therapy is initiated. Doses should not exceed 0.5 to 1.0 g/week, and plasma aluminum levels should be measured regularly. Subcutaneous rather than intravenous DFO therapy is recommended. Subcutaneous doses do not produce the high serum levels of ferrioxamine that occur after intravenous doses, a factor thought to enhance iron uptake by pathogenic organisms, thereby increasing the risk of opportunistic infection.

Mixed Renal Osteodystrophy

A definitive diagnosis of mixed renal osteodystrophy requires bone biopsy and histomorphometric assessments, procedures not done commonly in clinical practice. Certain laboratory findings such as persistent hypocalcemia, low serum 25-hydroxvitamin D levels, or elevated serum aluminum levels suggest the presence of an underlying defect in skeletal mineralization, but they are by no means conclusive. Similarly, histological changes of hyperparathyroidism in bone would be expected if plasma PTH were persistently elevated, but such findings do little to distinguish patients with mixed lesions of renal osteodystrophy from those with uncomplicated secondary HPT. If confirmed by bone biopsy, therapeutic measures to control secondary HPT and to eliminate causes of inadequate skeletal mineralization are required among patients with mixed renal osteodystrophy.

Chapter 69

Osteogenesis Imperfecta

David W. Rowe, MD
Department of Genetics and Developmental Biology, University of Connecticut Health Center, Farmington, CT

INTRODUCTION

Osteogenesis imperfecta (OI) is a highly variable heritable disease of bone characterized by recurring bone fractures. It is the most common single gene defect causing bone disease and its typical clinical presentation and the natural history have been well chronicled in many review articles and book chapters. The disease has received attention from basic scientists because it has become the paradigm for mutations affecting a well-defined extracellular matrix protein. The results of these biochemical and molecular studies have provided the foundation for understanding the broad spectrum of heritable diseases of connective tissue, and OI will continue to be the disease that provides the breakthroughs for this class of heritable diseases. The purpose of this chapter is to provide an update to the well-described clinical classifications and point out recent advances in the diagnosis and therapy of the disease. Most of the chapter will review the consequences of mutations of type 1 collagen on the structure of the collagen fibers, the biology of the osteoblast, and the pathophysiology of the resulting bone disease. It will emphasize how this information influences our understanding of osteoporosis and other heritable diseases of connective tissue. In addition, outstanding problems requiring further research attention, particularly relating to cell and somatic gene therapy, will be presented.

CLINICAL CLASSIFICATIONS AND VARIANTS OF OI

The most widely used clinical classification for OI continues to be the one developed by Sillence that is based on disease severity (Sillence, 1988). For purposes of correlating clinical phenotype with the underlying genetic and pathophysiological basis of the disease, grouping the classes into deforming and nondeforming bone disease can be helpful even though this too is an arbitrary distinction. Three degrees of deforming OI – types II, III, and IV – are associated with decreasing severity of growth retardation and limb deformity and all result from a mutation affecting the structure of the type 1 collagen molecule (Table. I). The consequences of this mutation on the structure of the extracellular matrix and the biology of bone cell are very similar, varying only in their degree of severity. In contrast, most cases of nondeforming OI, type I, are the result of mutations affecting the production of an otherwise normal type I collagen molecule.

Deforming OI

The criteria for identifying individuals as OI type II, III, or IV are somewhat arbitrary. Although this classification helps to stratify patients according to their disease severity, the typing does not necessarily predict the natural history of the disease or the type of underlying genetic mutation. Furthermore, with the implementation of bisphosphonate in children, disease severity and natural history are being greatly improved and eventually may force a revaluation of this classification system.

Most infants who succumb to OI in the perinatal period are considered OI type II. The hallmarks of type II include shortened and deformed limbs in the presence of normal birth weight and length. The cranium is unusually soft and molded and may be fractured at birth. Intracranial bleeding may have occurred. The sclerae are deep blue. The limbs are deformed and short, raising the consideration of hypophosphatasia, achondrogenesis, and thanatophoric dwarfism in the diagnosis. Multiple fractures are seen on x-ray and the extremities appear broad and crumpled. The critical problem is neonatal pulmonary insufficiency that may lead to death in the first postnatal week (Shapiro, 1989). Faulty thoracic musculoskeletal development also limits respiratory function in the majority of cases. However, prolonged survival has been documented in occasional type II cases.

Infants born with fractures and deformity who survive the perinatal period are grouped as OI type III. The natural history of type III includes the presence of multiple

Principles of Bone Biology, 3rd Edition

TABLE I An All-Inclusive Clinical and Molecular Classification of Osteogenesis Imperfecta

Molecular Classification	Clinical Classification	Clinical Severity	Molecular Mechanism
Dominant Negative OI	Type II	Perinatal lethal	Glycine substitutions preferentially located in C terminal helical domain of either collagen chain
	Type III	Progressive Deforming	Glycine substitutions preferentially located in midhelical domain of either collagen chain
	Type IV	Moderately Deforming	Glycine substitutions preferentially located in midhelical domain of the a2 collagen chain
	Type V	Moderately Deforming	Non-type I collagen gene mutation
	Type VI	Moderately Deforming	Non-type I collagen gene mutation
	Type VII	Perinatal lethal	Mutation in the 3-prolyl hydrolase protein complex
	Type I	Nondeforming	Glycine substitutions preferentially located in N terminal helical domain of either collagen chain
	Sp1-associated osteoporosis	Osteoporosis-associated risk factor	Excessive alpha 1 chain production may lead to accumulation of alpha 1(I) trimer molecules with the bone matrix
	Noncollagen mutations	Mutation of proteins that interact with the collagen microfibril	Murine knockout studies suggest that noncollagenous proteins of bone may contribute to formation of a stable bone matrix. The osteoporosis of Marfan's may be an example
Haploid Insufficiency	Type I	Classical mild OI	Complete nonfunctional Col1A1 allele usually due to premature stop codon
	Osteoporosis	Associated risk factor for osteoporosis	Partial inactivation of a Col1A1 allele either due to a mutation affecting processing of the transcript or the activity of the promoter

fractures, significant molding of the calvarium, and deformity of the extremities at birth. Fractures may continue to occur in infancy and childhood precluding a normal pattern of ambulation. Deformity of the thoracic cage (pectus carinatum, pectus excavatum) may be present in early childhood and may advance as the scoliosis and vertebral compression increase. Type III OI subjects develop scoliosis at an early age. Vertebral compression, most commonly of the central or "codfish" type, begins shortly after birth and progresses relentlessly prior to puberty (Engelbert, 2003). The volume of the thoracic cage decreases with age and eventually cardiorespiratory insufficiency, including right-sided cardiac failure, may occur (Vitale, 2007). As adults, these individuals are very short, frequently less than 4 feet in height. Skeletal involvement is associated with a severe defect in remodeling so that the appendicular bones are usually very narrow although in some cases, a "broad bone" x-ray appearance is seen. In either event, the epiphyseal zone is markedly dysplastic, which effectively limits endochondral and therefore somatic bone growth. Because of severe limb deformity and a marked degree of osteopenia at an early age, type III subjects are wheelchair bound. Because of molding of the base of the skull, type III subjects are at risk for the development of basilar invagination that may cause brainstem compression with both respiratory and neurologic complications and sudden death (Janus, 2003; Kovero, 2006). Charnas reported communicating hydrocephalus in 17 out of 76 subjects with OI (Charnas, 1993). Seizure disorders were observed in 5 out of 76 cases. Brainstem compression requiring surgical decompression or reinforcement of the craniocervical junction is extremely complex, requiring mechanical support, trans-oral clivectomy, and decompression of the posterior fossa where respiratory center function is compromised (Bhangoo and Crockard, 1999; Sawin and Menezes, 1997).

Infants who appear normal at birth but develop deformity upon ambulation generally fall into the OI type IV group, although this form can merge into features seen in Moderate short stature is common, but ambulation is generally possible with the aid of rods and braces. Radiologically, the extent of skeletal dysplasia in type IV disease is more severe than found in type I cases, but less than in type III OI. There is more severe osteoporosis with significant cortical and trabecular bone loss. Cystic changes may appear in the long bones. Vertebral compression fractures occur frequently. In addition to more severe

scoliosis, there is moderate deformity of the pelvis and lower extremities that limits ambulation without support. Dentinogenesis imperfecta (DI) is most frequent in OI types III and IV, and overall, affects about 15% of OI patients among the different phenotypes (Lund, Jensen *et al.*, 1998; Petersen and Wetzel, 1998; Rios, 2005). It appears as a bluish-brown translucent discoloration. Deciduous teeth tend to be more severely affected than permanent teeth. These teeth are soft because of a defect in underlying dentin (type I collagen) so that the enamel layer is lost, which leads to extreme dental erosion even in children. Expert dental care is essential in affected children. Hearing loss, present in all OI phenotypes (Garretsen, 1997) has its onset in children (Kuurila *et al.,* 2000) or during second or third decade (Kuurila, 2002). Conductive, mixed, and sensorineural hearing loss have been documented in OI (Shapiro *et al.*, 1982). The lesions are a combination of bony trauma (i.e., fractures of the stapes crura and footplate) and damage to vestibular structures in the inner ear (Kuurila, 2003). These lesions are not identical to those of otosclerosis.

Until recently there were no examples of OI resulting from mutations in genes other than type 1 collagen. As a result of forming an integrated research, diagnostic, and treatment team with the opportunity to examine the broad spectrum of patients with deforming OI, Glorieux has identified at least three additional OI-like diseases (OI type V–VII) that are not a result of a mutation in the type I collagen genes. Type V OI has radiologic features of type IV OI with subtle differences including calcification of the interosseous membrane and a metaphyseal band adjacent to the growth plate. Hyperplastic callus formation is frequently found in this form of OI (Ramirez, 2003 ; Cheung, 2007) and can be confused with osteosarcoma (Vieira, 2006). The disease is inherited as an autosomal dominant and no mutations with the type I collagen genes have been found (Glorieux *et al.,* 2000). OI type VI is similar in severity to type IV OI but has high levels of serum alkaline phosphatase and a mineralization defect but no radiological features of rickets (Glorieux, 2002). In both cases, linkage studies have been possible and have excluded type 1 collagen genes. The importance of these new clinical phenotypes is that they demonstrate that molecules other than type 1 collagen are essential for formation of a stable bone matrix and will eventually lead to a discovery of the role that these gene products play in bone biology.

Murine models have also led to the discovery of genes that modify type I collagen as another mechanism for severe OI. Type VII OI, a severe recessively inherited form resembling type II OI that does not map to collagen loci (Ward, 2002), has been shown to be a mutation in either prolyl 3-hydroxylase (Cabral, 2007) or cartilage-associated protein (CTRAP), which is a binding partner of the 3-hydroxylase complex (Morello, 2006). In either case, there is defective hydroxylation of the single prolyl 3-hydroxylase site within the alpha 1(I) chain with excessive lysyl hydroxylation suggesting that the 3-hydroxy site is essential for collagen assembly. Another murine model resembling OI is the fro/fro mouse, which has been shown to be a defect in sphingomyelin phosphodiesterase 3 (Smpd3) (Aubin, 2005). Although a human form of OI has yet to be mapped to this locus, the mouse points an aspect of lipid metabolism important for bone formation that is likely to have a clinical homologue.

Another unifying feature of most of the deforming forms of OI is the strong dominant negative properties of the mutation. In those cases where affected individuals choose to have children, the disease is passed on in an autosomal dominant manner. However, in most cases the disease results from a random and isolated mutation in the germ cell of a parent. Usually this event is a one-time occurrence and the likelihood of another affected individual is extremely small. However, in 5 to 10 percent of cases one of the parents sustained a somatic mutation during his or her embryonic development such that a proportion of their somatic and germ cells have an OI mutation (Cole and Dalgleish, 1995 ; Lund *et al.*, 1997). The mosaic parent does not have features of OI despite having a significant number of mutant cells (Cabral, 2004)and most of their children have normal bones. However, if the child is conceived with a germ cell carrying the OI mutation, then full-blown OI results. As a result of this possibility for recurrence, families with one child with OI who wish to have more children are advised to undergo prenatal testing (Byers, 2006) or sensitive ultrasound analysis with the possibility that a subsequent child might be affected (Parilla, 2003; Ruano, 2004). With the recognition of type VII OI as a recessive disorder with a defined molecular defect, it will be important to identify mutations other noncollagen genes that modify type I collagen to distinguish germinal mosaicism from a true recessive disorder.

MILD NONDEFORMING OI

Although this class of OI patients is relative common, it is not unusual to be unappreciated by the family or their physician. In cases with blue sclera (Sillence *et al.,*1993), mild short stature, ligamentous laxity, mild scoliosis, and a strong family history of recurring fractures and osteoporosis, the diagnosis is not difficult. Radiographs are not diagnostic and fractures usually heal without deformity. In many cases, there is not a high degree of morbidity and once puberty is attained, fractures are rare. Perhaps the most important reason for identifying these individuals is to initiate anti-osteoporosis therapy as soon as menopausal symptoms have developed because these individuals are particularly susceptible to accelerated bone loss when sex steroids are lost (Bischoff *et al.,* 1999). Other patients who fit into this category can have symptoms that overlap with mild Ehlers-Danlos syndrome (EDS). The overlap appears to be related to where the mutation is placed within the collagen molecule, making this type of mutation

of interest to the structural biologist (Feshchenko *et al.,* 1998; Raff *et al.,* 2000) (Cabral, 2005 ; Makareeva, 2006). More recently, mutations affecting processing of the C-terminal propeptide of the COL1A1 gene (Symoens, 2004) and even point mutation in the Y position of the collagen helix (Cabral, 2007) have been shown to have an OI/EDS overlap syndrome. The importance to the clinician is to recognize that the two genetic phenotypes can coexist so that measures to strengthen the skeleton are initiated when appropriate.

Probably the most difficult situation that arises within this class of patients is child abuse. Although OI is frequently invoked as a potential explanation for the infants and young child with multiple fractures, it is rare that any of the clinical features that are characteristic of OI are present (Steiner *et al.,* 1996; Byers, 2006) and instead there usually is no family history of recurring fractures, short stature, or abnormal radiographs. Because OI can result from a new mutation within the type I collagen genes and potentially other extracellular matrix genes, lack of a family history does not exclude the diagnosis. Genetic testing based on protein electrophoresis may lack the sensitivity for mild forms of OI, necessitating DNA sequencing of the collagen genes (Cabral, 2006). Recently the term *temporary brittle bone disease* has been invoked to explain certain forms of multiple fractures in a setting without an obvious perpetrator (Paterson *et al.,* 1993) but the concept has not gained acceptance (Ablin and Sane, 1997; Chapman and Hall, 1997). A recent report finds that infants and children with this diagnosis have reduced bone mass by radiographic absorptiometry or computed tomography (Miller and Hangartner, 1999) and a mechanism of prenatal bone unloading has been proposed (Miller, 2003). Progress is being made in developing standards for DEXA evaluation of infants (Koo, 2004, 2006) so there is hope that a more objective measure of bone (radiological and rapid DNA sequencing) may replace the diagnostic decisions that are based on emotion and opinion frequently in an antagonistic environment. This topic is probably best addressed in literature prepared by the Osteogenesis Imperfecta Foundation on their website (http://www.oif.org).

The relationship of mutations within the type I collagen genes and osteoporosis has been difficult to establish. In families where OI mutations and osteoporosis have been identified, careful clinical scrutiny usually identifies features of the disease (Shapiro *et al.,* 1992; Spotila *et al.,* 1991). Nonglycine substitutions in the helical domain have been found in a few instances, but the significance of these findings is difficult to interpret (Spotila *et al.,* 1994). Quantitative trait linkage (QTL) studies of populations of individuals with osteoporosis have failed to demonstrate linkage to either type I collagen gene (Niu *et al.,* 1999; Cardon *et al.,* 2000). However, an Sp1 polymorphism was shown a statistical association to individuals with osteoporosis (Grant *et al.,* 1996) and this linkage has been examined by numerous investigators with varying outcomes (Mann, 2003). The most recent and comprehensive study does demonstrate an effect on bone mass and increase in vertebral fracture but the effect is small requiring a large study to achieve statistical significance (Ralston, 2006).

NEEDED ADVANCES IN CLINICAL DIAGNOSIS AND MANAGEMENT

In most cases, the diagnosis of OI can be made on clinical grounds alone. Unfortunately radiographs are generally insensitive to the diminished bone mass associated with type 1 OI. DEXA has been shown to be effective in detecting the diminished bone mass associated with type 1 OI in adults although its application to children and particularly infants has not been adequately developed. Such standards would be particularly helpful in evaluating individuals with suspected abuse. pQCT might be more sensitive in young children to discriminate individuals with normal or diminished bone mass (Fredericks *et al.,* 1990; Keen *et al.,* 1999). Other clinical tests that may be helpful in the diagnosis OI are serum level of procollagen propeptide fragments reflecting the rate of type I collagen formation (Kauppila *et al.,* 1998; Lund, Jensen *et al*., 1998) and the generation of collagen-derived cross-links reflecting removal (Bank *et al.,* 2000). Here again standards need to be developed for age and sex, degree of sexual maturation, or menopause to make these tests of bone turnover useful in OI.

In many instances, it is advantageous to know the underlying molecular abnormalities for purposes of genetic counseling and in some cases for predicting natural history. Frequently molecular testing is also used to help in the evaluation of children with recurring fractures. The OIF website has a comprehensive listing of the molecular diagnostic services available (http://www.oif.org/site/PageServer?pagename=Testing). The analysis can begin as a screening test on fibroblasts derived from an affected individual for biochemical abnormalities of the collagen molecules followed by confirmation at the genetic level by DNA sequencing or it can go directly to DNA sequencing of the collagen loci. Both approaches have an excellent track record for finding mutations although not all the patients with OI yield an identified mutation. With increasing power and reduced cost of DNA sequencing, this is likely to become the method of choice. For clinicians not familiar with interpretation of genetic testing, it is suggested that services that directly communicate with the requestor regarding test results is preferable to those who refer the requestor to a genetic counselor.

Given the complexity in the clinical management of OI, a multidisciplinary clinical team approach to treatment is of greatest value for both the patient and the field. Not only are there significant orthopedic and medical issues, but problems of daily living are pervasive. Proper

handling during infancy, mainstreaming within schools, driving an automobile, attending college, scoliosis and pulmonary insufficiency, neurological symptoms, pregnancy and genetic risk, and acceleration of bone disease after menopause are complex problems that are difficult for an individual clinician to manage and require an experienced and broad-based treatment team. Many of these issues are covered on the OIF website (http://www.oif.org) and in their literature. Because OI is a relatively rare and highly variable disorder, no single clinician or clinic can perform phenotype/genotype or clinical intervention studies with the power that multi-site studies achieve in areas such as pediatric oncology. The OIF is working to develop this concept as linked clinical research centers where patients are recruited for common protocols. The first step in the process is the establishment of a patient registry with the intent to identify patients who have an interest in participating in clinical research protocols http://www.osteogenesisimperfecta.org/oir/. The progress of this exciting initiative can be viewed at http://www.oif.org/site/PageServer?pagename=RegistryLCRCs.

ANIMAL MODELS OF OI

Naturally arising forms of OI have been described in cows (Agerholm *et al.,* 1994) and dogs (Campbell, 2001; Seeliger, 2003). Although these animal models have value for evaluating orthopedic strategies, the maintenance of large animal models is extremely expensive so they are not useful for the initial development of new medical or genetic strategies. However, once an intervention has the possibility of a clinical trial then a larger animal model will probably be a requirement for FDA approval.

To date, the mouse has contributed the most to our understanding of the disease and is the initial platform for evaluating new therapies. Lethal OI has been produced experimentally by insertion of a collagen transgene containing a glycine point mutation (Stacey *et al.,* 1988) or an internal deletion within the helical domain of the molecule (Khillan *et al.,* 1991). Whereas transgene insertions are relatively easy to produce, there is significant variability in the clinical severity even within the same pedigree (Pereira *et al.,* 1994), reducing their value as a experimental model. OI mutations within the endogenous collagen gene yield a more reproducible phenotype. The oim/oim mouse arose from a spontaneous mutation within the Col1A2 gene. Because the mutation produces a nonfunctional alpha-2(I) chain, the disease results from an accumulation of alpha 1(I) trimer molecules (Chipman *et al.,* 1993). It has been widely used even though this is a recessive form of OI that is quite unlike the more common dominantly inherited forms of OI. In addition, a patient with a lack of Col1A2 chain production resulting in a mild form of EDS not OI (Malfait, 2006) was recently identified indicating that the phenotypic consequences of COL1A2 deficiency is more complex than is currently appreciated. A cysteine (G349C) substitution has been knocked into the Col1A1 gene to produce a moderately severe form of OI (Brit IV mouse) that has a stable phenotype and is very representative of the common forms of OI (Forlino *et al.,* 1999; Kozloff, 2004; Kuznetsova, 2004). The only murine model of type I OI is the heterozygous Mov 13 mouse in which one of the two Col1A1 genes is nonfunctional due to a retroviral insertion within the first intron. The heterozygous mouse was initially thought to have normal bone and was used for generating a double knockout of the Col1A1 gene, which has an embryonic lethal phenotype (Lohler *et al.,* 1984). However, more sensitive testing did demonstrate diminished bone mass and underproduction of type 1 collagen (Bonadio *et al.,* 1990). Unfortunately, the mice succumb to leukemia in their early adulthood limiting their value to basic bone research. A viable model for OI type 1 needs to be produced by genetic knock in.

The fro/fro mouse has a bone fragility phenotype that is not associated with a defect in collagen (Sillence, Ritchie *et al.,* 1993). Linkage studies followed by direct gene analysis uncovered the unanticipated locus to be sphingomyelin phosphodiesterase 3 (Smpd3) (Aubin, 2005). The biochemical and physiological consequences of this gene mutation await elucidation.

MOLECULAR BASIS OF OI

A comprehensive listing of the mutations within type I collagen genes resulting in OI is now maintained in the OI mutation database at http://www.oiprogram.nichd.nih.gov/consortium.html/ (Marini, 2007). They can be broadly correlated with clinical severity with the deforming forms of OI being associated with mutations that interrupt the helical stability of the collagen molecule or its interaction with noncollagenous protein of the collagen fibril whereas most forms of type I OI are associated with underproduction of an otherwise normal type I collagen.

Deforming OI

Essentially all of these mutations act in a dominant negative manner, i.e., it is the presence of the abnormal gene product that causes the disease. Because of this mechanism, the disease either develops as a sporadic new mutation or is inherited in an autosomal dominant manner. Those cases in which recurrence is observed represent germinal mosaicism in one parent and not recessive inheritance. The only known exception to this statement is a null mutation within the Col1A2 gene (see later discussion).

The three-dimensional structure of the collagen fibril can be altered by a substitution for glycine in the collagen (gly-x-y) triplet, inframe deletion, an inframe insertion, or

by exon skipping. Depending on the helical location of a mutation, these produce a variety of clinical pictures that range from lethal (OI type II) to severely deforming (OI type III) to mildly deforming (OI type IV). Glycine substitution in the helical domain of the collagen alpha 1(I) chain is the most common defect. Glycine, the smallest amino acid, is a critical component that must fit in a sterically restricted space where the three chains of the triple helix come together. Substitutions usually occur in the first base of the genetic code for glycine (GGN) and do not alter the length of the chain but disrupt helical stability. The eight potential amino acid substitutions are cysteine, alanine, arginine, aspartic acid, cysteine, glutamic acid, serine, valine, and tryptophan. How the substitution affects the conformation of the collagen helix is still not well understood and current biochemical analysis does not always predict clinical severity. Because the helix assembles from the C-terminal propeptide, a mutation in the C terminal helical and propeptide region results in greater instability and more severe disease while mutations located in the midhelical domain tend to be less severe. However, mutations within the midhelical domain can have a severe phenotype suggesting that subdomains within the helix are critical for function beyond just contributing to an intact helical structure such as ligand-binding domains for various noncollagenous components of the collagen matrix (Marini, 2007). Mutations located at the N-terminal domain of either chain can be extremely mild and fall into the category of type I OI.

Because the exons that encode the helical domain maintain the reading frame, mutations in the consensus donor or acceptor site can lead to exon skipping, producing a shortened helix that has the same effect on helical stability as a glycine substitution (Byers *et al.,* 1983). Much less common are mutations that delete a portion of the gene and along with it a number of inframe exons (Mundlos *et al.,* 1996) or mutations that insert a segment of intron that remains inframe with the entire transcript. In the latter case, a nonhelical segment is inserted within the helical domain disrupting the structure of the collagen helix (Wang *et al.*, 1996).

The one exception to the statement that severe disease results from a dominant negative mutation in either type I collagen gene is a null mutation of the Col1A2 gene. Formation of the heterotrimeric collagen molecule requires that the alpha 2(I) chain account for 50% of the available chains at the time the procollagen molecule is assembled. When this requirement is not met, either because of underproduction of the alpha 2(I) chain or overproduction of the alpha 1(I) chain, then homotrimeric molecules are formed. Severity of disease depends on the balance between homotrimeric and heterotrimeric molecules within the bone matrix. This may explain why there is a spectrum of disease severity from OI type III when both Col1A2 alleles are affected, to measurable osteopenia and fragility in the heterozygous state (McBride *et al.,* 1998; Saban *et al.,* 1996), to an association with osteoporosis due to the sp1 polymorphic alteration in the Col1A1 gene. This variation in disease severity acts in a recessive manner or as quantitative trait in which gene dosage contributes to the severity of bone disease.

NONDEFORMING OI

The most common mutation causing type I OI reduces the output of otherwise normal type I collagen. Because of the 2:1 requirement for formation of heterotrimeric collagen, the level of Col1A1 production directly influences the accumulation of normal type I collagen molecules. Reduced output from a single Col1A1 allele reduces the production of heterotrimeric collagen and the unincorporated alpha 2(I) chains are degraded intracellularly (Gotkin, 2004). The genetic mechanism for a clinical phenotype resulting from complete inactivation of one allele is referred to as haploid insufficiency. In fact, a spectrum of disease severity related to gene dosage is observed in the Mov 13 mouse. The homozygous Mov 13 is an embryonic lethal that does not reach the stage of skeletal development (Lohler *et al.,* 1984), whereas the heterozygous Mov 13 is a model for OI type I (Bonadio *et al.,* 1990). Similarly, the severity of osteopenia in type I OI is probably related to the degree that one of the Col1A1 alleles underperforms. It would not be surprising to find that a more subtle underproduction from a Col1A1 allele could be a contributing quantitative trait to the development of osteoporosis.

Mutations introducing a premature stop codon are the most frequent cause for a null Col1A1 allele (Redford-Badwal *et al.,* 1996; Slayton *et al.,* 2000; Willing *et al.,* 1994). Premature stop codons arising in all but the terminal exon of a gene usually lead to rapid destruction of the transcript rather than producing a truncated protein. The process is called nonsense mediated RNA decay and it appears to mediated by a nuclear protein complex that is able to recognize a premature stop codon and to target an RNA with this feature for rapid destruction (Medghalchi *et al.,* 2001). This appears to be an important mechanism for preventing a truncated protein from expression thus saving the cell from proteins with unintended function (Isken, 2007). Mutations of these surveillance genes are incompatible with development (Medghalchi *et al.,* 2001) in mice and can result in mental retardation in humans (Tarpey, 2007). Demonstrating that a truncated alpha 1(I) chain is produced from a Col1A1 transcript *in vitro* serves as the basis for uncovering the presence and location of the stop codon (Bateman *et al.,* 1999). Otherwise, finding the mutation by a molecular approach is laborious and can be missed.

A second mechanism for producing a null Col1A1 allele is retention of an intron within the mature transcript. Intron retention instead of exon skipping can result when a mutation of a splice donor site is located in a small intron such

that the combination of the intron and the flanking upstream and downstream exon is regarded as an acceptable exon (Stover *et al.,* 1993). However, the presence of the mutant donor site retains the transcript within the splicing apparatus of the nucleus (S35 domain) and it is eventually destroyed (Johnson *et al.,* 2000). Although this is an uncommon cause of a null allele, it has provided insight into the normal pathway for splicing a complex transcript such as collagen and demonstrated that splicing of otherwise normal but small collagen introns is relatively slow. Because approximately 25% of the Col1A1 introns are small and thus are candidates to be affected in this mechanism, it would not be surprising to find polymorphic changes within the gene that contribute to the rate of splicing which in turn could be associated with mild osteoporosis.

Finally, a nonfunctional collagen gene can result from synthesis of a procollagen chain, which is unable to incorporate within the triple helical molecule. Frameshift mutations within the terminal exon of either collagen gene have been identified that lead to synthesis of full-sized procollagen chain, which is rapidly degraded intracellularly when it fails to incorporate into the collagen molecule (Willing *et al.,* 1993). In the case of the Col1A1 product, mild OI is observed, but when it occurs in the Col1A2 product, homotrimeric molecules are formed causing a more severe bone phenotype (see earlier discussion).

CONSEQUENCES OF OI-PRODUCING MUTATIONS

Formation on the Extracellular Matrix and Osteoid Mineralization

Many approaches have been employed to characterize the triple helical structure and intramolecular organization of collagen fibrils in normal and OI subjects. X-ray diffraction analysis of collagen-like peptides show the destabilizing effect of a glycine point mutation (Beck *et al.,* 2000) and studies using NMR and circular dichroism lead to a similar conclusion (Baum and Brodsky, 1999; Liu *et al.,* 1998; Melacini *et al.,* 2000). At the intramolecular level, x-ray diffraction has shown small fibers with less well-defined lateral growth and more fiber disorganization in tissue obtained from OI subjects (McBride *et al.,* 1997). At the biochemical level, mutations that interrupt the helix decrease the thermal stability of procollagen molecules and render the molecule more susceptible to proteolytic attack by tissue proteases (Bachinger *et al.,* 1993). This may explain the observation that mutant collagen molecules are not uniformly distributed through matrix but are found on the surface of bone (Bank *et al.,* 2000). Because 25% of the collagen produced by cells containing a Col1A1 mutation are normal and 50% of the collagen produced by cells containing a Col1A2 mutation are normal, tissue proteases probably select against the mutant molecules (Bateman and Golub, 1994) allowing for a substrata of relatively normal collagen fibers to accumulate.

Transmission and scanning EM have shown that the periodicity of OI fibrils is normal but the fibrils are disorganized and have wide variation in fiber diameter (Eyden and Tzaphlidou, 2001). Fibril formation can be studied *in vitro* from components synthesized by cultured cells (Hashizume *et al.,* 1999; Holmes *et al.,* 2001). The importance of other proteins that modify the size and organization of otherwise normal type I collagen fibrils has been revealed by EM studies. These changes can affect the mechanical properties of the collagen fibers formed *in vitro* (Christiansen *et al.,* 2000; Ottani *et al.,* 2001). For example, the co-polymerization of type V collagen within the type I collagen fibril influences the size and structure of the type I collagen fibril (Kypreos *et al.,* 2000; Mizuno *et al.,* 2001). Another modifier of the collagen fiber size is the incorporation of unprocessed type I procollagen producing another form of EDS that can overlap with features of type I OI. The EDS–OI-like symptoms appear to result from impairing cleavage of the procollagen propeptide secondary to glycine substitution disruption in the N-terminal helical domain. A similar problem might be expected with a mutation affecting cleavage of the C terminal propeptide (Holmes *et al.,* 1996). Induced mutations in certain noncollagenous proteins such as decorin (Danielson *et al.,* 1997), fibromodulin (Ezura *et al.,* 2000), and microfibrillin (Kielty *et al.,* 1998) can affect the structure or organization of type I collagen fibers indicating that physical interaction between the two components play an important role in this process. It would not be surprising that OI mutations may affect some of these binding interactions, adding to the complexity of the bone phenotype.

The interaction of the mineralizing phase of new bone formation with the matrix has been studied by high-voltage electron microscopy (Landis, 1996a, 1996b), Fourier transform infrared microspectroscopic analysis (Cassella *et al.,* 2000; Camacho, 2003), and small angle x-ray scattering (Fratzl *et al.,* 1996). These methods demonstrate that although the absolute amount and composition of hydroxyapatite within an OI bone is probably not abnormal, the crystal structure is deformed and probably contributes to the overall weakened nature of the bone (Camacho *et al.,* 1999). Thus while the primary defect is in helix formation, the ultimate determination of bone strength reflects how the helix influences the interaction of noncollagenous proteins and minerals and at this point the critical features of the molecule that control these interactive events are not fully understood.

INTRINSIC PROPERTIES OF THE OI OSTEOBLAST

The presence of intracellular mutant procollagen molecules and the physiological response to the abnormal extracellular

osteoid combine to have a profound impact on the biology of the osteoblast that further influences the severity and natural history of disease. It has been appreciated for some time that the rough endoplasmic reticulum of OI fibroblasts are grossly dilated (Lamande *et al.,* 1995) and the secretion of fully formed procollagen is impaired (Fitzgerald *et al.,* 1999; Lamande and Bateman, 1999). The role that hsp47 chaperone protein has in determining the trafficking of normal and mutant molecules within these cells is likely to be an important determinant for the biology of the affected osteoblast (Kojima *et al.,* 1998). In fact, gene knockout of the hsp47 protein is an embryonic lethal in which type I procollagen is produced that is susceptible to protease digestion (Nagai *et al.,* 2000; Nagata, 2003 ; Kubota, 2004), suggesting that this chaperone protein plays an essential role in normal triple helix formation, secretion, and fibril assembly (Ishida, 2006). Specific Y position amino acids with the collagen triplets are required for hsp47 to collagen (Koide, 2006) and many of the abnormalities in collagen production may result from loss of this interaction. The central role of chaperone proteins in explaining the disease severity in the Brit IV mouse has been demonstrated (Forlino, 2007). The retention of the mutant procollagen molecule also leads to post-translational overmodification of the lysine residues in the helical domain that may further affect the quality of fibril formation.

The inherent ability of an OI fibroblast or bone cell to produce collagen and proliferate *in vitro* is impaired and probably a consequence of the retained procollagen molecules with the distended rough ER. *In vitro* studies of osteoblasts derived from OI humans (Fedarko *et al.,* 1995; Fedarko *et al.,* 1996) or OI mice (Balk *et al.,* 1997) show diminished markers of osteoblastic differentiation as well as reduced rate of cell proliferation. However, the cells can be driven into osteoblastic differentiation when given exogenous bone morphogenic protein (BMPs). The explanation for this observation is not clear but may reflect the quality or quantity of the extracellular matrix that is made by the preosteoblastic cell that is necessary for osteoblast differentiation *in vitro*. Possibly the high rate of bone turnover that is characteristic of this disease (see next section), may lead to exhaustion and/or premature senescence of stem cells capable of generating vigorous osteoblastic cells *in vitro*. If stem cell exhaustion is also present in intact bone, then an additional factor of osteoblast number will contribute to the severity of the bone disease.

PHYSIOLOGICAL DEMANDS ON THE OI OSTEOBLAST

Intact bone, probably through the osteocyte, is able to sense its mechanical environment and initiate a new round of bone formation when the load on the region exceeds its ability to carry it. This fundamental principle of bone biology is continuously called upon in OI because the matrix that is produced is never able to support the load placed on the skeleton. This situation is illustrated in the histology of OI bone that shows a state of high turnover characterized by increased numbers of osteoblasts and osteocytes (Jones *et al.,* 1999) and an increased number of osteoclasts. Dynamic labeling shows that increased number of double labeled surfaces of normal thickness (Rauch *et al.,* 2000). Biochemical markers for bone formation and resorption in growing children and adults do reflect the histological findings although the measurements are variable because of differences in growth rate and the underlying mutation (Lund, Hansen *et al.,* 1998;Braga, 2004). Some of these variables can be overcome in murine models in which there is uniformity of the genetic defect and sufficient numbers of mice of similar age and sex.

Analysis of murine models is particularly instructive in appreciating the pathophysiology of the OI mutation (Kalajzic, 2002). Because net total bone formation in OI bone is low and its intrinsic properties for matrix production in culture are impaired, the OI osteoblast or its lineage is viewed as underproductive. This view can lead to the conclusion that stimulation to increase its rate of matrix formation should be beneficial to the disease. However, the OI osteoblast lineage is under constant stimulation to proliferate to build up sufficient numbers of precursor cells to progress to full osteoblast differentiation and produce the matrix that was resorbed by the activated osteoclasts. The activated osteoblastic lineage can be demonstrated by measuring the content of col1a1 mRNA in OI bone or the activity of a type I collagen promoter transgene that is sensitive to osteoblastic activity. In both cases, a high level of transcriptional activity for type I collagen can be demonstrated relative to normal bone. The net effect is an uncoupling between the signals transmitted from the bone matrix to be bone lineage in which the bone cells do respond at the gene level but cannot deliver at the protein level. The lineage is already maximally stimulated in response to the activated osteoclastic pathways but the new matrix that is produced does not improve the mechanical properties of the bone.

Studies on the oim mouse model illustrates that it is the balance between matrix formation and resorption that determines bone strength in OI (Fig. 1). During periods of rapid linear growth, the deficit between formation and resorption is maximal because at this time bone turnover is enhanced even beyond the level that is responsive to mechanical forces. Although normal bone has the reserve within the bone lineage to increase its rate of matrix formation, the OI bone lineage is already maximally stimulated so that it is during the period of linear growth that the deficit in net bone formation is most severe. This may explain why growth retardation and fractures are so severe in the rapidly growing child. With the completion of puberty and cessation of linear growth, bone remodeling slows and a balance between formation and resorption becomes more favorable. Thus, puberty does not improve bone strength

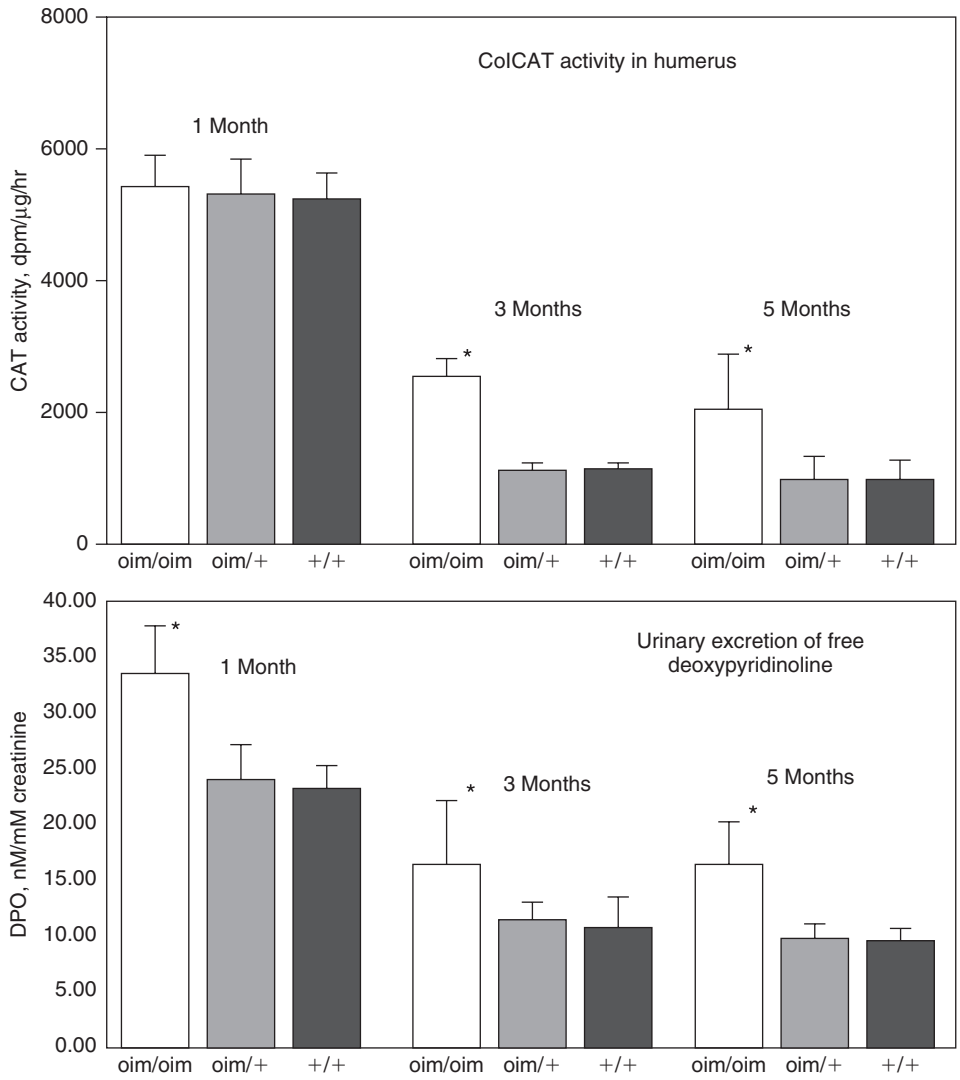

FIGURE 1 Relative balance of bone formation and resorption in OIM mice during the period of rapid somatic growth (1 month), adulthood (3 months), and older age (5 months). During somatic growth, the activity of the oim/oim osteoblast population does not exceed that of normal animals whereas bone resorption of the 1-month-old animal is greater than normal. Thus, it is during the period of rapid bone growth that the deficit between bone formation and resorption is maximal. With stabilization of the skeleton, the continuous demand for new bone formation in the oim/oim mouse become evident and during this time the deficit between bone formation and resorption is less severe.

by stimulating the lineage but instead it stabilizes the skeleton and reduces the need for bone remodeling. When menopause reinstates a state of high bone resorption, the balance between formation and resorption again becomes unfavorable and fractures can return. In effect, the pathophysiology of OI can be view as a consequence of the activated osteoclast lineage and this probably explains the success of bisphosphonate treatment in OI.

Nondeforming OI secondary to an expressed collagen mutation probably represents a mild variant of deforming OI discussed earlier. However, OI type 1 resulting from haploid insufficiency of a COL1A1 chain may have subtle differences. Analysis of the heterozygous Mov 13 mice show diminished bone volume and half-normal levels of col1a1 mRNA. This is consistent with human OI in which low levels of procollagen propeptide in blood reflect the null mutation in type I collagen-producing cells (Minisola *et al.,* 1994). Histomorphometry does show increased osteoblast cellularity and bone forming units and dynamic histomorphometry suggest a decrease in osteoid seams (McCarthy *et al.,* 1997). Excessive osteoclastic activity does not appear to be present. In both mouse and man with type I OI, significant skeletal remodeling becomes apparent upon sexual maturation so that the mechanical properties of the bone approach normal (Bonadio *et al.,* 1993; Jepsen *et al.,* 1997). Although further analysis of a murine model that is healthy into adulthood is necessary, it would appear that the deficit between bone formation and resorption in type I OI is much less than in deforming forms of OI, particularly after the adult skeleton is established.

Thus, it is during adulthood that a relatively normal bone matrix is accumulated and fractures are uncommon. It is only during growth and in menopause that this relationship is unfavorable, again underscoring the value of bisphosphonates for improving bone strength during these periods.

THERAPY OF OI

Anti-Resorptive Agents

Bisphosphonate therapy in infants or young children with OI has changed the natural history of the disease. When administrated properly, it can reduce fracture frequency, increase bone mineral content, and improve the radiographic assessment of the bone shape in growing children (Astrom and Soderhall, 1998; Glorieux *et al.,* 1998). The positive effects are most dramatic in infants from ages 1 to 3 in which the severity of the classification of the disease can be improved (Plotkin *et al.,* 2000) (Astrom, 2007). In infants and young children, remarkable improvement is seen in the quality of life, which includes motor function and muscle strength (Montpetit, 2003 ; Land, 2006). Infants begin to ambulate and children participate in more strenuous physical activities. Bone pain and diaphoresis, which is a major complaint often overlooked by physicians as well as families, is greatly diminished by the treatment. Linear growth is not impaired and in fact augmentation of final stature in the most severely affected subjects can exceed their predicted outcome (Zeitlin, 2003). Fractures heal at their expected rate. The major effects on bone mineral density (BMD) occur during the first 2 years of treatment, but continued treatment for at least 4 years does result in continued improvements in BMD and fracture rate (Rauch, 2003; Rauch, 2007). Less dramatic increases in bone density are being observed in adults with mild OI although the effect on fracture frequency has not been apparent (Shapiro, 2003; Chevrel, 2006). Bisphosphonate treatment appears to be effective in OI type V (Fleming, 2005; Zeitlin, 2006) and type VI (Land, 2007) and it can be anticipated that it should be effective in OI type VII.

Initial studies have used cyclical intravenous administration of pamidronate and currently prospective studies using oral forms of bisphosphonates are ongoing (Glorieux, 2000). Other published studies using agents that are active orally or require less frequent intravenous dosing appear to be equally effective (Sakkers, 2004; Seikaly, 2005; Gatti, 2005; DiMeglio, 2006). Other studies are currently ongoing so it is difficult to say which form is most optimal for any subset of affected individuals.

The success of bisphosphonate appears to be related to the unremitting osteoclastic activity (Rauch, 2002). The effect of the drug can be monitored by measuring the level of collagen-derived cross-links in blood or urine. Clinical symptoms of bone pain and diaphoresis also correlate with the inhibitory effect of the drug on osteoclastic activity suggesting that it is the process of high bone turnover and associated high blood flow, not unlike a pagetic lesion, that underlie these symptoms. Even though the matrix it now accumulates still contains the mutant collagen molecules, the balance between formation and degradation is improved and the accumulation of matrix improves bone strength relative to a bone without matrix. The experience in children indicates that linear growth and repair of fractures is not compromised by the use of the bisphosphonate. Murine studies show less bowing and a diminished fractured frequency, even though bone strength by direct mechanical testing cannot be demonstrated. Further work is needed using animal models to confirm that the drug is acting primarily at the level of the osteoclast and does not have other actions that contribute to clinical improvement. For example, if the bisphosphonate acts to reduce the level of bone turnover it might have the additional benefit of extending the longevity of the osteoblast lineage or allowing the resident osteoblast to achieve full differentiation and time to remodel the existing matrix from a woven to lamellar bone.

ANABOLIC AGENTS

Growth hormone, IGF1, and PTH have the potential to increase bone mass. Except for a treatment protocol with growth hormone in children with deforming OI, most of the experience with these agents has been anecdotal. Like all children who are initially started on growth hormone, OI children do experience an initial acceleration of growth rate and increase in BMD (Marini, 2003). Because the treatment duration has been limited, a bone mass increase in excess to the increase in body size has not been reported, although stable (42)Ca isotopic studies demonstrate an improvement in mineral incorporation while on treatment (Vieira *et al.,* 2000; Vieira *et al.,* 1999). Given the underlying physiological basis of OI, it would be surprising that an agent that stimulates more bone turnover as part of its anabolic action would have a long-term beneficial effect (Wright, 2000). The osteoblast lineage is already maximally stimulated and the addition of agents that enhance osteoclastic activity will only contribute to the deficit between formation and degradation. Perhaps the milder forms of OI that lack the inherent high rate of bone resorption will be more responsive to an anabolic agent (Antoniazzi *et al.,* 1996) as suggested by the murine studies of the heterozygous OIM mouse (King, 2005). Potentially the combination of growth hormone and bisphosphonate might provide a compromise that is acceptable and studies of this combination are underway. PTH is also being evaluated for OI. Although the molecular and cellular mechanism of PTH enhancement of bone formation is still controversial, its known action to enhance

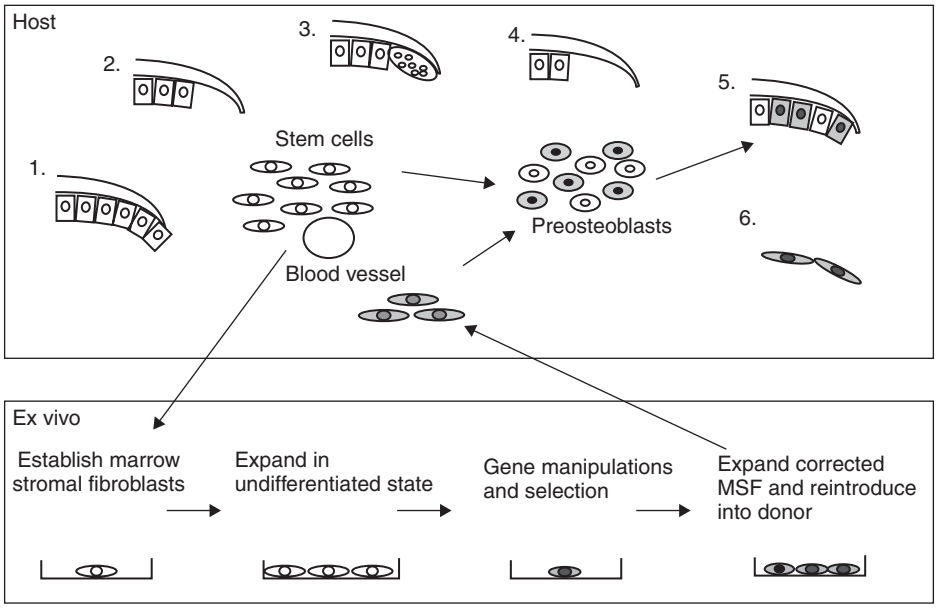

FIGURE 2 Strategy for somatic gene therapy for OI. The host bone is undergoing rapid and continuous bone turnover in which activated osteoblasts (1) start a cycle of bone remodeling; (2) Osteoclasts remove damaged bone matrix; (3) followed by a new wave of bone formation (4 and 5). Cells that contribute to the new round of bone formation are captured, probably by bone marrow aspiration, and grown in a culture dish under nondifferentiating conditions. Genetic manipulations include elimination and replacement of the mutant gene followed by expansion of the population of corrected cells. These cells are reintroduced into the host (darkened cells) and they begin to participate in the cycle of new bone formation. Over time the corrected cells outpopulate the endogenous cells and the quality of the bone matrix improves (5 and 6).

commitment of progenitor cells to bone as opposed to fat (Rickard, 2006), and its anti-apoptotic effect on mature osteoblasts (Bringhurst, 2002) should favorably promote bone formation by osteoblasts in the individual with OI.

CELL AND GENE THERAPY

Because bisphosphonates do not correct the primary cause for OI and their long-term use and its long-term effectiveness are still uncertain, steps to correct underlying genetic mutation are being evaluated in both humans and mice. The possibility that gene therapy is a feasible strategy in OI came from the analysis of individuals who are somatic mosaic for an OI mutation that constitute up to 40% of mutant cell within bone but do not have evidence of bone disease (Cabral, 2004). Those studies suggest that the deleterious effect of OI cells can be neutralized by the presence of normal cells so that if it were possible to introduce normal cells into an individual with OI, the severity of bone disease would be reduced (Figure 2). Furthermore, because bone turnover is high and the endogenous osteoblast lineage is activated in OI, introduction of normal cells into this environment would rapidly populate the bone with cells having a normal proliferative rate and making a normal matrix that would outproduce the effort from the resident OI cells. This treatment strategy requires the ability to introduce cells from the osteoblast lineage into OI subjects. Ideally, autologous bone progenitor cells could be engineered to replace the OI collagen gene activity or the progenitors could be derived from a tissue-matched normal individual. The latter choice was the rationale for non-autologous bone marrow transplant procedures in a limited number of children with severe OI (Horwitz *et al.,* 1999; Horwitz *et al.,* 2001). The long-term success of these initial studies has been difficult to assess and even the basic rationale of this approach is being questioned based on animal experimental data. Thus, there are two primary questions that need to be answered before cell therapy can be considered an alternative. First, is there a source of tissue-matched bone progenitor cells available for transplantation, and second, is it possible to deliver progenitor cells to bone that can affect an improvement in bone quality?

The immune compatible progenitor problem has been approached using a wide variety of genetic engineering techniques. The goal is to reduce the relative output of mutant collagen chain production relative to the normal allele. Numerous RNA suppression techniques such as hammerhead (Smicun, 2003; Peace, 2005) and hairpin (Lian *et al.,* 1999) ribozymes, U1snRNA (Beckley *et al.,* 2001; Liu, 2002), RNA transplicing (Mansfield *et al.,* 2000), RNase P (Kawa *et al.,* 1998) and RNAi (Millington-Ward, 2004) have achieved partial suppression in cultured cells but have not been evaluated in murine models of OI. Overexpression of the normal allele (Pochampally, 2005) is another approach that may achieve a more favorable

output of bone matrix. Complete inactivation of the mutant allele has been achieved by specific integrations of a fragment of DNA containing a transcription stop sequence from an adeno-associated viral vector (Chamberlain, 2004). Because the integration event targets both the normal and mutant allele with equal affinity as well as integrating other sites randomly, a selection technique for the correctly targeted cell is necessary. Although the resulting cells now have a type I OI phenotype, it is clearly an improvement over the parental cells. Another strategy, yet to be employed in OI, are RNA/DNA oligonucleotides that utilize host gene repair mechanism to correct a point mutation (Ino, 2004; Bertoni, 2005; Tagalakis, 2005). The potential to correct, not just inactivate a mutation, is a particularly attractive aspect of this approach but the efficiency is quite variable and a strategy to identify correctly targeted cells from a large mutant background have not been developed.

Despite the genetic engineering problems, the most severe hurdle for somatic gene therapy for OI is the reintroduction into a host of cells that are capable of homing to bone and participating in new bone formation. Although there is no question regarding the ability of marrow stromal cells to differentiate into mature osteoblasts *in vitro* or in subcutaneous implant (Dennis *et al.,* 1999; Bilic-Curcic, 2005), demonstration that this is possible when administered systemically is still unconvincing. The plasticity of this cell source has been cited for adult stem cell from bone marrow or fetal cord blood (Chang, 2006) after systemic injection for numerous nonskeletal tissues. However, the interpretation of experiments have come under increasing scrutiny (Wagers, 2002, 2004) to suggest that the apparent success may be due to donor-host cell fusion (Sherwood, 2004; Quintana-Bustamante, 2006), engraftment of donor-derived myeloid cells (Balsam, 2004) or excessive optimism (Theise, 2005). Most studies in man and mouse can demonstrate a low degree (1–5%) of engraftment of bone or bone marrow stroma as assessed by a nonspecific, donor-derived transgenic or unique endogenous genetic marker (Ding *et al.,* 1999; Onyia *et al.,* 1998; Pereira *et al.,* 1998; Nilsson *et al.,* 1999; Dominici, 2004). These experiments were repeated using a differentiation-restricted transgenic visual marker gene (Kalajzic, 2002) to identify the donor cells that achieved systemic distribution and that lined the surface of bone and other tissues. In bone, many donor-derived cells had markers of an osteoclast (Wang, 2005; Boban, 2006) whereas in lung they had markers of macrophages (Boban, 2007). Bone cell differentiation from donor-derived marrow stromal cells can be demonstrated in this transplantation model, but the donor cells with osteogenic properties remain at the site of intramarrow injection and do not circulate (Wang, 2005). These data do not support the strategy that genetically modified cells can be used to repopulate bone via a systemic route.

The underlying genetic abnormality also determines the success of stromal cell transplantation. When the disease is non-cell autonomous, (i.e., the transplanted cells are engineered to secrete a deficient soluble factor), an improvement in the disease phenotype occurs irrespective of where the cells established residence. This is most obvious when the transplanted cells express a cytokine (Brouard *et al.,* 1998) or clotting factor (Chuah *et al.,* 2000). This mechanism may explain the recent success of bone fragment transplantation for infantile hypophosphatasia (Cahill, 2007; Whyte, 2003). Clinical improvement of a disease that is cell autonomous, such as OI, requires that the cells populate the affected bone, proliferate, differentiate, and participate in bone turnover. This is a standard that has not yet been met in any murine studies. The one exception is when the transplanted cells have undergone prolonged expansion *ex vivo* (Dahir *et al.,* 2000; (Oyama *et al.,* 1999; Niyibizi, 2004; Wang, 2006). For mouse, this type of treatment rapidly leads to cell immortalization, making interpretation of a transplantation experiment difficult.

As new pharmacologic or genetic therapies are developed, it will be increasingly necessary to establish a set of criteria that is used to judge its success relative to current therapies. Although bisphosphonates still need further evaluation to appreciate fully their most effective use in different age and disease classifications, they do represent a significant advance in the treatment of OI and probably have to be regarded as the threshold that a new therapy has to exceed. Particularly as it relates to somatic gene therapy for OI, to develop criteria that (a) demonstrate successful engraftment and (b) document improvements in bone health that are equivalent to or exceed medical therapy (Table II, column A). Whether the transplanted individual is mouse or man, it must be demonstrated that the transplanted cells populate the bone, expand in number over time, participate in the new bone formation, and provide a continuous source of new bone cells over the life of the transplanted subject. These studies are easier to perform in the mouse when the transplanted cells are engineered to contain visual transgenes driven by bone-specific promoters. Not only does the transgenic marker identify the source of the cell, it can reflect its level of participation in new bone formation. Moreover, this approach can be used to determine whether donor stem cells removed from the transplanted bone are still able to generate differentiated osteoblastic cells *in vitro*. If the transplanted cells are participating in new bone formation, the quality and quantity of the bone should improve over time. Radiographs should show remodeled bones with improved architecture and bone density measurements at well-defined sites will be increased in humans. QCT scanning can be used to assess bone mass and architecture in mice. Bone histomorphometry and dynamic labeling studies should confirm these clinical measures of bone health. Particularly in the mouse, it should be possible to demonstrate improved mechanical properties of the bone after the intervention. Biochemical studies can also contribute to the impression of success by demonstrating that markers of new

TABLE II Criteria for Successful Therapy of OI. Assessment of Current Trials of Bisphosphonate and Cell Transplantation in Man and Mouse.

	A. Drug Therapy		B. Cell Therapy	
Criteria	Man	Mouse	Man	Mouse
Cellular evaluation				
Cell engraftment	–	–	+	+
New bone formation	+++	+++	NR	NR
Increasing cell number; graft persistence	+++	+++	NR	NR
Bone evaluation				
BMD, QCT	+++	+++	+	NR
X-ray	++	+	NR	NR
Bone histology	+++	+++	+	+
Structural properties	NA	+++	NA	NR
Biochemical	+	++	NR	NR
Clinical criteria				
Quality of life	+++	+	NR	NR
Growth, weight gain	+++	+	++	+
Muscle strength	++	++	NR	NR
Fracture rate	+	+	+	NR

NR – *not reported*; NA – *not ascertainable*.
+ *Present*.
- *Absent*.

bone formation remain elevated while the level of markers reflecting bone degradation gradually subside.

The clinical evaluation of transplanted individuals is equally important to the assessment of success. Bone pain and diaphoresis are major symptoms that are daily facts of life for many patients with OI. Muscle weakness can be profound and in growing children greatly delay acquisition of motor milestones. Successful interruption of the pathophysiological cycle of OI appears to reduce greatly these symptoms. Bone pain diminishes, diaphoresis is greatly reduced, and muscle tone improves. Children begin to ambulate and adults find that their activities of daily living are easier to perform. Because the symptoms are so profound for individuals with OI, they need to be recorded in a prospective manner as clinical outcome measure. These types of measurements are difficult to record in the mouse although cage activity can be quantitated and probably would be informative. Certainly fracture frequency, linear growth, and weight gain are important to record although they can be influenced by many other factors unrelated to the intervention.

Even disregarding the molecular steps necessary to correct the genetic abnormalities in OI stromal cells, the success of transplantation of normal cells into a normal or OI host is relatively ineffective at this time (Table II, column B). Given the experimental difficulties of performing these studies in a controlled and quantitative manner in humans, greater emphasis must be placed on studies in experimental animals in which the problems inherent to the procedure can be identified and solved. Ultimately, these problems will be solved and this will open a new era of therapeutic opportunities for OI and other osteopenic bone diseases.

ACKNOWLEDGMENT

The author receives grant support for OI-related research from the Public Health Department, National Institute of Health, National Institute of Arthritis, and Musculoskeletal Disease (AR30426 and AR44545) and from the Children's Brittle Bone Foundation.

Chapter 70

Hereditary Deficiencies in Vitamin D Action

Uri A. Liberman*

Department of Physiology and Pharmacology and the Felsenstein Medical Research Center, Sackler Faculty of Medicine, Tel Aviv University, Tel-Aviv, Israel

INTRODUCTION

Hereditary deficiencies in vitamin D action can be caused by disturbances in the synthesis of the hormonal form of the vitamin, 1,25-dihydroxyvitamin D (1,25$(OH)_2$Dcalcitriol), or defects in the interaction of calcitriol and its target tissues.

Vitamin D derived from endogenous production in the skin or absorbed from the gut is transformed into its active form by two successive steps: hydroxylation in the liver to 25-hydroxyvitamin D [25(OH)D], followed by 1α-hydroxylation in the renal proximal tubule to 1,25$(OH)_2$D. Some other cells exhibit 1α-hydroxylase activity: placental decidual cells, keratinocytes, macrophages of various origins, and some tumor cells. The role of the extrarenal production of 1,25$(OH)_2$D is unknown, and under normal conditions it does not significantly contribute to the circulating levels of the hormone. Hydroxylation at carbon 24, to produce 24, 25-dihydroxyvitamin D [24,25$(OH)_2$D] or 1,24,25-trihydroxyvitamin D, is performed in a wide range of normal tissues and is believed to be important in the removal of vitamin D metabolites. All these enzymes are mitochondrial mixed-function oxidases containing cytochrome P450 and having ferredoxin- and heme-binding domains. Cloning of cDNA for porcine 25-hydroxylase and the mouse, rat, and human 24- and 1-hydroxylase, as well as the genes for the later two enzymes, has been reported (Akeno *et al.*, 1997; Fu *et al.*, 1997a; Jehan *et al.*, 1998; Jones *et al.*, 1999; Monkawa *et al.*, 1997; Murayama *et al.*, 1999; Ohyama *et al.*, 1993; Shinki *et al.*, 1997; Takeyama *et al.*, 1997). Hereditary defects along the cascade of 1,25$(OH)_2$D synthesis lead to a deficiency in the vitamin D hormonal form.

*Corresponding author: Uri A. Liberman, Department of Physiology and Pharmacology and the Felsenstein Medical Research Center, Sackler Faculty of Medicine, Tel Aviv University, Tel-Aviv, Israel, Tel: + 972-3-6417827, Fax: +972-3-6419506, E-mail: uliberm@post.tau.ac.il

Isolated deficiency of 25(OH)D is a very rare autosomal recessive disorder, attributed to, but not proven to be caused by deficiency in the hepatic vitamin D-25 hydroxylase activity (Gill *et al.*, 2000).

This discussion will therefore concentrate on hereditary defects in the renal 25-hydroxyvitamin D-1α-hydroxylase activity. Regarding interaction with the target tissue, as detailed elsewhere in this book, calcitriol effects are mediated via a high-affinity intracellular receptor: the vitamin D receptor (VDR). VDR acts as a ligand-modulated transcription factor that belongs to the steroid, thyroid, and retinoic acid receptors gene family (Baker *et al.*, 1988; Burmester *et al.*, 1988; Evans, 1988; Ozur *et al.*, 1991). Thus, hereditary defects in the interaction of calcitriol and its target tissues could evolve from defects in hormone binding to VDR, defects in the heterodimerization with RXR or the interaction of the receptor complexes with DNA, or defects in the transcription modulation function.

Though VDRs were demonstrated in most, if not all, tissues, leading to the increased recognition of multiple target organs and actions of the hormone, it seems that most, if not all, clinical signs and symptoms associated with deficient vitamin D actions are caused by perturbations in mineral metabolism.

1,25$(OH)_2$D is the most powerful physiological agent that stimulates active transport of calcium, and to a lesser degree phosphorus and magnesium, across the small intestine (DeLuca, 1984; Mayer *et al.*, 1984). Thus, deficiencies in vitamin D action will lead to a decrease in the net flux of mineral to the extracellular compartment, causing hypocalcemia and secondary hyperparathyroidism. Hypophosphatemia will ensue as a result of both reduced absorption of phosphorus owing to deficient calcitriol action on the gut and increased renal phosphate clearance owing to secondary hyperparathyroidism. Low concentrations of calcium and phosphorus in the extracellular

Principles of Bone Biology, 3rd Edition

fluid will lead to defective mineralization of organic bone matrix. Defective bone matrix mineralization of the newly formed bone and growth plate cartilage will produce the characteristic morphological and clinical signs of rickets, whereas at sites of bone remodeling, it will cause osteomalacia. Deficiencies in vitamin D action may impair the differentiation of osteoblasts and thus their functional capacity to mineralize bone matrix; this may be an additional mechanism leading to rickets and osteomalacia (Owen *et al.*, 1991; Reichel *et al.*, 1989).

Because all hereditary deficiencies in vitamin D action will lead to the same clinical, radiological, histological, and most of the biochemical aberrations, those common features will be discussed first.

CLINICAL FEATURES OF RICKETS AND OSTEOMALACIA

Children with hereditary deficiencies in vitamin D action will appear normal at birth and usually develop the characteristic features of rickets within the first 2 years of life. Defects in bone mineralization are particularly evident in regions of rapid bone growth, including, during the first year of life, the cranium, wrist, and ribs. Rickets at this time will lead to widened cranial sutures, frontal bossing, posterior flattening of the skull (craniotabes), bulging of costochondral junction (rachitic rosary), indentation of the ribs at the diaphragmatic insertion (Harrison's groove), and widening of the wrists. After the first year of life with the acquisition of erect posture and rapid linear growth, the deformities are most severe in the legs. Bow legs (genu varum) or knock-knee (genu valgum) deformities of varying severity develop as well as widening of the ends of long bones. If not treated, rickets may cause severe lasting deformities, compromise adult height, and increase susceptibility to pathological fractures.

The specific radiographic features of rickets reflect the failure of cartilage calcification and endochondral ossification and therefore are best seen in the metaphysis of rapidly growing bones. The metaphyses are widened, uneven, concave, or cupped, and because of the delay in or absence of calcification, the metaphyses could become partially or totally invisible (Fig. 1). In more severe forms or in patients untreated for prolonged periods, rarefaction and thinning of the cortex of the entire shaft, as well as bone deformities and greenstick fractures, will become evident.

The clinical features of osteomalacia are subtle and could be manifested as bone pain or low-back pain of varying severity in some cases. The first clinical presentation could be an acute fracture of the long bones, public ramii, ribs, or spine. The radiographic manifestations could be mild, e.g., generalized, nonspecific osteopenia or more specific, such as pseudofractures, commonly seen at the medial edges of long bones shaft.

FIGURE 1 Radiographs of wrists and hands of a patient with VDDR. Note the signs of severe rickets and demineralization.

In hypocalcemic rickets and/or osteomalacia, as is the case in deficiencies in vitamin D action, radiographic features of secondary hyperparathyroidism such as subperiosteal resorption and cysts of the long bones may exist.

The characteristic histological feature of rickets and osteomalacia is deficiency or lack of mineralization of the organic matrix of bone. Because in clinical practice a bone specimen can be obtained only from the iliac crest, the histological picture is osteomalacia. Osteomalacia is defined as excess osteoid (hyperosteoidosis) and a quantitative dynamic proof of defective bone matrix mineralization obtained by analysis of time-spaced tetracycline labeling (Parfitt, 1983; Teitelbaum and Bollough, 1979).

The biochemical parameters characterizing deficiencies in vitamin D action can be divided into those associated with vitamin D status, the primary disturbance in mineral homeostasis and the respective compensatory mechanisms, and changes in bone metabolism. Changes in mineral and bone metabolism will be similar in all states of deficient vitamin D action, whereas serum levels of vitamin D metabolites will characterize each of the two classes delineated in the introduction (Table I).

As previously discussed, deficiencies in vitamin D action will lead to hypocalcemia and secondary hyperparathyroidism. Thus, the characteristic biochemical features are low to low-normal concentrations of serum calcium

TABLE I Biochemical Features of Vitamin D-Dependent Rickets (VDDR) Types I and II

	Serum concentrations						
	Calcium	Phosphorus	Alkaline phosphatase	iPTH	25OHD	$1,25(OH)_2D$	$24,25(OH)_2D$
VDRR-I	↓	↓	↑	↑	N–↑	↓	↑
VDRR-II	↓	↓	↑	↑	N–↑	↑	↓

(depending on compensatory parathyroid activity), low urinary calcium excretion, hypophosphatemia, increased serum immunoreactive parathyroid hormone (iPTH) levels, increased urinary cyclic AMP excretion, and decreased tubular reabsorption of phosphate (the last two measures reflecting the biological activity of elevated iPTH). Biochemical markers associated with increased osteoid production, such as bone-specific alkaline phosphatase and osteocalcin, will be elevated in states of rickets and osteomalacia (Cole *et al.*, 1985). However, as $1,25(OH)_2D$ stimulates osteocalcin synthesis *in vivo* and *in vitro*, serum levels of this biochemical bone marker are unreliable measures in hereditary vitamin D-deficient states.

HEREDITARY DEFICIENCY IN $1,25(OH)_2D$ PRODUCTION (VITAMIN D-DEPENDENT RICKETS TYPE I)

Prader *et al.* (1961) were the first to describe two young children who showed all the usual clinical features of vitamin D deficiency despite adequate intake of the vitamin, thus coining the name "pseudovitamin D deficiency." Complete remission depended on continuous therapy with high doses of vitamin D; thus the term "vitamin D-dependent rickets" (VDDR). However, remission of the disease could be achieved by continuous therapy with physiological (microgram) doses of 1α-hydroxylated vitamin D metabolites (Delvin *et al.*, 1981; Fraser *et al.*, 1973).

Family studies have revealed that it is an autosomal recessive disease. Linkage analysis in a subset of French-Canadian families assigned the gene responsible for the disease to chromosome 12q13 (De Brackeleer and Larochell, 1991; Labuda *et al.*, 1990). The gene encoding the 1α-hydroxylase of mouse kidney, human keratinocyte, and peripheral mononuclear cells was localized on chromosome 12*q*13.1-*q*13.3, which maps to the disease locus of VDDR-I (Fu *et al.*, 1997b; Kitanaka *et al.*, 1998; Smith *et al.*, 1999; St. Arnaud *et al.*, 1997, Wang *et al.*, 1998; Yoshida *et al.*, 1998). There are no direct measures of the renal enzyme proving defective 1α-hydroxylase activity. This is virtually impossible to obtain, because of both the difficulty in obtaining tissue and the low level of expression. There are, however, several indirect observations to support this etiology. First, circulating levels of 25-hydroxyvitamin D (25(OH)D) are normal or elevated, depending on previous vitamin D treatment. Second, serum concentrations of $1,25(OH)_2D$ are very low (see Table I). Third, although massive doses (100 to 300 times the daily recommended dose) of vitamin D or 25(OH)D are required to maintain remission of rickets, physiological replacement doses of calcitriol are sufficient to achieve the same effect. Fourth, it was reported that cells isolated from the placenta of two women with this disease had deficient activity of the decidual enzyme 25(OH)D-1α-hydroxylase (Glorieux *et al.*, 1995). It is noteworthy that human decidual cells do produce $1,25(OH)_2D$ and that this enzyme was regulated by feedback mechanisms (Delvin and Arabian, 1987; Diaz *et al.*, 2000; Weisman *et al.*, 1979). Finally, the 1α-hydroxylase gene from more than 25 families with VDDR-I and some of their first-degree healthy relatives were analyzed by direct sequencing, site-directed mutagenesis, and cDNA expression in transfected cells (Fu *et al.*, 1997; Kitanaka *et al.*, 1998–1999; Smith *et al.*, 1999; St. Arnaud *et al.*, 1997; Wang *et al.*, 1998; Yoshida *et al.*, 1998). All patients had homozygous mutations, whereas parents or other healthy siblings were heterozygous for the mutation. Most patients of French-Canadian origin had the same mutation causing a frameshift and a premature stop codon in the putative heme-binding domain. The same mutation was observed in additional families of diverse origins (Smith *et al.*, 1999). All other patients had either a base-pair deletion causing premature termination codon upstream from the putative ferredoxin and heme-binding domains, or missense mutations (Fu *et al.*, 1997b; Kitanaka *et al.*, 1999; Smith *et al.*, 1998; Wang *et al.*, 1998; Yoshida *et al.*, 1998). No 1α-hydroxylase activity was detected when the mutant enzyme was expressed in various cells. The sequence of the human 1α-hydroxylase gene from keratinocytes and peripheral blood mononuclear cells has been shown to be identical with the renal gene (Fu *et al.*, 1997b; Kitanaka *et al.*, 1999; Smith *et al.*, 1999; Wang *et al.*, 1998; Yoshida *et al.*, 1998), thus supporting the use of these accessible cells as a proxy to study the renal tubular enzymatic defect. Taken together, these observations support the notion that the etiology of this hereditary disease

TABLE II Response to Treatment of Patients with Vitamin D-Dependent Rickets (VDDR) Types I and II

	Vitamin D or 25(OH)D		1α-Hydroxylated vitamin D metabolites	
	Physiological	Pharmacological	Physiological	Pharmacological
VDDR-I	−	+	+	Toxic
VDDR-II	−	− or +	−	− or +

Note. Physiological doses are those recommended or being used as replacement therapy. Pharmacological doses are 100 times and more of the physiological doses (see details in text).

is a defect in the renal tubular 25(OH)D-1α-hydroxylase activity.

The beneficial therapeutic effect of high serum concentrations of 25(OH)D in patients treated with massive doses of vitamin D, while $1,25(OH)_2D$ levels remain low, may have several possible explanations. First, high levels of 25-(OH)D may activate the VDR whose affinity for this metabolite is approximately two orders of magnitude lower than for $1,25(OH)_2D$. Second, a metabolite of 25(OH)D may act directly on target tissues, and finally, high levels of 25(OH)D may drive the local production of $1,25(OH)_2D$ via a paracrine–autocrine pathway, assuming that the tissue enzyme is controlled differently than the renal and decidual enzyme.

The differential diagnosis of VDDR-I from other hereditary forms of hypocalcemic rickets and especially the one associated with defects in the vitamin D receptor–effector system is based on serum concentrations of calcitriol and the response to treatment with 1α-hydroxylated vitamin D metabolites (see Table I and Table II).

A similar syndrome has been described and studied in a mutant strain of pigs where the mode of inheritance as well as the clinical and biochemical features is similar to the human disease (Fox *et al.*, 1985; Harmeyer *et al.*, 1982). Piglets affected by the disease have rickets, elevated 25(OH)D with low or undetectable $1,25(OH)_2D$ serum concentrations, normal specific tissue-binding sites for tritiated $1,25(OH)_2D$, and no detectable activity of 25(OH)D-1α-hydroxylase in renal cortical homogenates. Thus, there is strong evidence that the disease state in the pig is caused solely by an inherited defect in the renal enzyme.

HEREDITARY DEFECTS IN THE VITAMIN D RECEPTOR–EFFECTOR SYSTEM (VITAMIN D-DEPENDENT RICKETS TYPE II)

Introduction

This is a rare disorder and only ~60 patients have been reported (Balsan *et al.*, 1983; Bear *et al.*, 1981; Brooks *et al.*, 1978; Castells *et al.*, 1986; Chen *et al.*, 1984; Clemens *et al.*, 1983; Cockerill *et al.*, 1997; Eil *et al.*, 1981; Feldman *et al.*, 1982; Fraher *et al.*, 1986; Fujita *et al.*, 1980; Griffin and Zerwekh, 1983; Hawa *et al.*, 1996; Hewison *et al.*, 1993; Hirst *et al.*, 1985; Hochberg *et al.*, 1984; Liberman *et al.*, 1980, 1983b; Lin and Uttley, 1993; Lin *et al.*, 1996; Malloy *et al.*, 1997, 1999, 2001, 2002, 2002a, 2004; Marx *et al.*, 1978, 1984; Mechica *et al.*, 1997; Nguyen *et al.*, 2002, 2006; Rosen *et al.*, 1979; Saijo *et al.*, 1991; Simonin *et al.*, 1992; Sockalosky *et al.*, 1980; Takeda *et al.*, 1986, 1987, 1989; Tauchiya *et al.*, 1980; Yagi *et al.*, 1993; Whitfield *et al.*, 1996; Zhu *et al.*, 1998 ; and personal communications).

Brooks *et al.* (1978) described an adult patient with hypocalcemic osteomalacia and elevated serum concentration of $1,25(OH)_2D$. Treatment with vitamin D, causing a further increase in serum calcitriol levels, cured the patient. The term vitamin D-dependent rickets type II (VDDR-II) was suggested to describe this disorder. However, reports on additional patients, about half of whom did not respond to vitamin D therapy, as well as *in vivo* and *in vitro* studies to be discussed later, seem to prove that vitamin D dependency is a misnomer. The term hereditary defects in the vitamin D receptor–effector system (the abbreviation HDVDR is suggested) or end-organ resistance to $1,25(OH)_2D$ action is therefore more appropriate to describe the etiology and pathogenesis of this syndrome. However, owing to convention and convenience, the term VDDR-II will be retained in this chapter.

Clinical and Biochemical Features

General Features

The clinical, radiological, histological, and biochemical features (except serum levels of vitamin D metabolites) are typical of hypocalcemic rickets and/or osteomalacia as previously discussed. Notable exceptions are two unrelated patients with hyperphosphatemia, despite elevated serum levels of iPTH (Liberman *et al.*, 1980; Yagi *et al.*, 1993), which can be the end result of long-standing and severe hypocalcemia that paradoxically inhibits the phosphaturic response to PTH or represents an additional hereditary renal tubular defect.

In VDDR-II there is no history of vitamin D deficiency and no clinical or biochemical response to physiological doses of vitamin D or its 1α-hydroxylated active metabolites. Serum levels of 25(OH)D are normal or elevated (depending on preceding vitamin D therapy); $1,25(OH)_2D$ concentrations are markedly elevated before or during therapy with vitamin D preparations; and 24,25-dihydroxyvitamin D ($24,25(OH)_2D$) circulating levels are inappropriately low (see Table I).

The disease manifests itself as an active metabolic bone disease in early childhood. However, late onset at adolescence and adulthood was documented in several sporadic cases including the first report by Brooks *et al.* (1978) and Fujita *et al.* (1980). These patients represented the mildest form of the disease and had a complete remission when treated with vitamin D or its active metabolites. It is unclear if the adult-onset patients belonged to the same hereditary entity, because no further studies on their VDR status have been published.

Ectodermal Anomalies

A peculiar clinical feature of VDDR-II patients, appearing in approximately half of the subjects, is total alopecia or sparse hair (Fig. 2). Alopecia usually appears during the first year of life and in one patient, at least, has been associated with additional ectodermal anomalies (Liberman *et al.*, 1980). It seems that alopecia is a marker of a more severe form of the disease as judged by the earlier onset, the severity of the clinical features, the proportion of patients who do not respond to treatment with high doses of vitamin D or its active metabolites, and the extremely elevated levels of serum $1,25(OH)_2D$ recorded during therapy (Marx *et al.*, 1984, 1986). Though some patients with alopecia could achieve clinical and biochemical remission of their bone disease, none have shown hair growth. The notion that total alopecia is probably a consequence of a defective vitamin D receptor–effector system is supported by the following: alopecia has only been associated with hereditary defects in the VDR system, i.e., with end-organ resistance to the action of the hormone, and has not been recorded with hereditary deficiency in $1,25(OH)_2D$ synthesis, i.e., low circulating levels of the hormone; alopecia is present in kindreds with different defects in the VDRs; high-affinity uptake of tritiated $1,25(OH)_2D_3$ in the nucleus of the outer root sheath of the hair follicle of rodents has been demonstrated by autoradiography (Strumpf *et al.*, 1979); and the epidermis and hair follicle contain a calcium-binding protein that is partially vitamin D-dependent (Marx *et al.*, 1984). Finally, alopecia develops in homozygote VDR knockout mice (Li *et al.*, 1997; Yoshizawa *et al.*, 1997). Taken together, it could be hypothesized that an intact VDR–effector system is important for the differentiation of the hair follicle in the fetus, which is unrelated to mineral homeostasis.

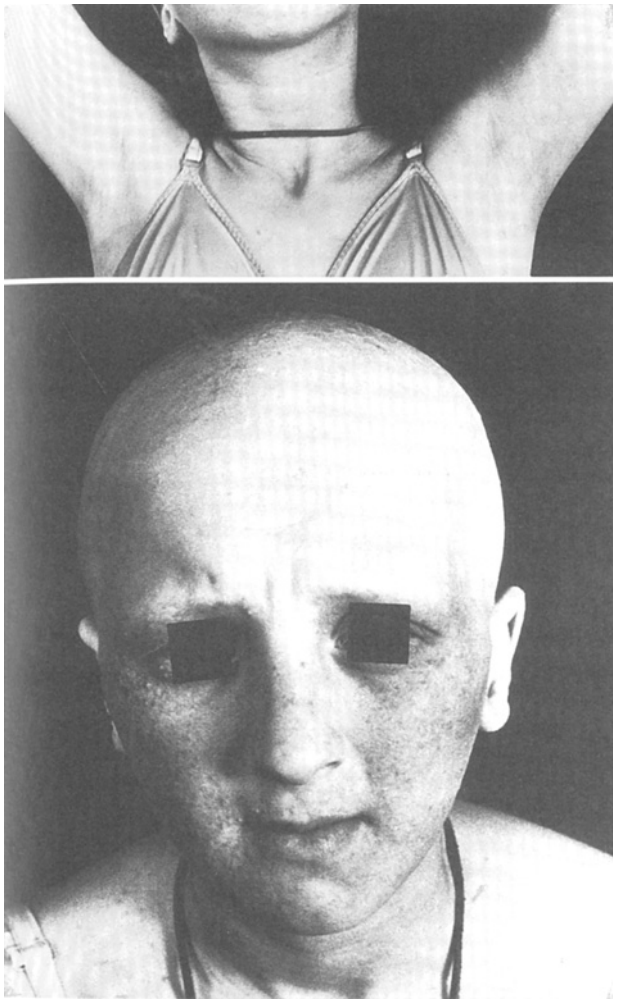

FIGURE 2 A patient with VDDR-II with total alopecia. Note: no scalp or axilla hair and no eyebrows or eyelashes.

Vitamin D Metabolism

Serum concentrations of $1,25(OH)_2D$ range from upper normal to markedly elevated values before therapy, but on vitamin D treatment may reach the highest levels found in any living system (100 times and more than the upper normal range) (Marx *et al.*, 1986). These values may represent the end results of four different mechanisms acting synergistically to stimulate strongly the renal 25(OH)D-1α-hydroxylase. Three of the mechanisms are hypocalcemia, secondary hyperparathyroidism, and hypophosphatemia. The fourth mechanism may be a failure of the negative feedback loop by which the hormone inhibits the renal enzyme activity caused by the basic defect in the VDR–effector system. This was demonstrated in two patients with VDDR-II in remission (normal serum levels of calcium, phosphorus, and PTH) in whom a load of $25(OH)D_3$ had caused a marked increase in serum $1,25(OH)_2D_3$ concentration (Balsan *et al.*, 1983; Marx *et al.*, 1984; Nguyen

et al., 2006). It was reported that the 1α-hydroxylase gene expression was not suppressed by $1,25(OH)_2D_3$ in renal tubular cells from VDR knockout mice whereas it was suppressed in cells with normal VDR or heterozygote for the null mutation (Murayama *et al.*, 1999; Takeyama *et al.*, 1997).

$1,25(OH)_2D$ is a potent inducer of the enzyme 25(OH)D-24-hydroxylase *in vivo* and *in vitro*. Serum levels of $24,25(OH)_2D$ have been very low or inappropriately low in the face of the elevated concentrations of the hormone in patients with VDDR-II (Castells *et al.*, 1986; Fraher *et al.*, 1986; Liberman *et al.*, 1980; Marx *et al.*, 1984). This probably reflects defective stimulation of $24,25(OH)_2D$ production owing to the basic deficiency in VDR activity. This assumption is supported by the observation that in mutant mice lacking the VDR, expression of 24(OH)-hydroxylase was reduced to undetectable levels and the normal induction of the enzyme by $1,25(OH)_2D_3$ was not obtained (Takeyama *et al.*, 1997).

Mode of Inheritance

In approximately half of the reported kindreds, parental consanguinity and multiple siblings with the same defect suggest an autosomal recessive mode of inheritance (Marx *et al.*, 1984). Parents of patients who are expected to be obligate heterozygotes have been reported to be normal, i.e., no bone disease or alopecia and normal blood biochemistry. However, studies on cells (cultured dermal fibroblasts, Epstein–Barr transformed lymphoblasts, and mitogen-stimulated lymphocytes) obtained from parents of affected children revealed decreased bioresponses, decreased normal VDR protein and its mRNA, and a heterozygote genotype exhibiting both normal and mutant DNA alleles (Malloy *et al.*, 1989, 1990, 1999, 2002; Nguyen *et al.*, 2006; Ritchie *et al.*, 1989; Takeda *et al.*, 1990). There is a striking clustering of patients around the Mediterranean, including patients reported from Europe and America who originated from the same area. A notable exception is a cluster of some kindred from Japan (Fujita *et al.*, 1980; Tauchiya *et al.*, 1980, 1986, 1987, 1989; Yagi *et al.*, 1993).

Cellular and Molecular Defects

Methods

The near ubiquity of a similar if not identical VDR–effector system among various cell types, including cells originating from tissues easily accessible for sampling, made feasible studies on the nature of the intracellular and molecular defects in patients with VDDR-II. The cells used were mainly fibroblasts derived from skin biopsies (Balsan *et al.*, 1983; Castells *et al.*, 1986; Chen *et al.*, 1984; Clemens *et al.*, 1983; Eil *et al.*, 1981; Feldman *et al.*, 1982; Fraher *et al.*, 1986; Griffin and Zerwekh, 1983; Hirst *et al.*, 1985; Hughes *et al.*, 1988; Liberman *et al.*, 1983b; Malloy *et al.*, 1989, 1990, 1994, 1999, 2002, 2004; Marx *et al.*, 1984; Nguyen *et al.*, 2002, 2006; Ritchie *et al.*, 1989; Takeda *et al.*, 1989) and peripheral blood mononuclear (PBM) cells (Koren *et al.*, 1985; Ritchie *et al.*, 1989; Takeda *et al.*, 1986, 1990; Yagi *et al.*, 1993). PBM cells contain high-affinity receptors for $1,25(OH)_2D_3$ that are expressed constitutively in monocytes and are induced in mitogen-stimulated T lymphocytes and Epstein–Barr (EB)-transformed lymphoblasts. All cells have been used to assess most of the steps in $1,25(OH)_2D_3$ action from cellular and subcellular uptake of the hormone to bioresponse as well as to elucidate the molecular aberrations in the VDR protein, RNA, and DNA levels.

The hormone–receptor interaction has been analyzed by several methods including the binding characteristics of $[^3H]1,25(OH)_2D_3$ to intact cells, nuclei or high-salt cellular soluble extracts, so-called cytosol (Balsan *et al.*, 1983; Castells *et al.*, 1986; Chen *et al.*, 1984; Clemens *et al.*, 1983; Eil *et al.*, 1981; Feldman *et al.*, 1982; Fraher *et al.*, 1986; Hirst *et al.*, 1985; Hochberg *et al.*, 1984; Hughes *et al.*, 1988; Koren *et al.*, 1985; Liberman *et al.*, 1983a,b; Malloy *et al.*, 1989, 1990; Marx *et al.*, 1984; Ritchie *et al.*, 1989; Sone *et al.*, 1990; Takeda *et al.*, 1985; Yagi *et al.*, 1993), measurements of VDR protein content by monoclonal antibodies with radiological immunoassay or Western blot analysis (Malloy *et al.*, 1990; Ritchie *et al.*, 1989), immunocytochemical methods in whole cells (Barsony *et al.*, 1990), and characterization of the hormone–receptor complex on continuous sucrose gradient and nonspecific DNA-cellulose columns (Balsan *et al.*, 1983; Chen *et al.*, 1984; Clemens *et al.*, 1983; Eil *et al.*, 1981; Feldman *et al.*, 1982; Hirst *et al.*, 1985; Hochberg *et al.*, 1984; Hughes *et al.*, 1988; Liberman *et al.*, 1983a,b; Malloy *et al.*, 1989; Marx *et al.*, 1984; Sone *et al.*, 1990).

The cloning and nucleotide sequencing of the human VDR gene made it feasible to study the molecular defects in patients with VDRR-II. The methods used included, among others, isolation of genomic DNA that encodes the structural portion of the human VDR, PCR amplification, screening, and sequencing of the amplified DNA fragments (Hughes *et al.*, 1988; Kristjansson *et al.*, 1993; Malloy *et al.*, 1990; Ritchie *et al.*, 1989; Sone *et al.*, 1990; Yagi *et al.*, 1993); cloning and sequencing of the VDR cDNA produced from isolated fibroblasts total RNA by reverse transcription and PCR amplification (Rut *et al.*, 1994; Saijo *et al.*, 1991; Weise *et al.*, 1993); re-creation of the mutant receptor *in vitro* by introducing the appropriate base change in normal VDR cDNA by site-directed mutagenesis that was transfected into cells that do not express endogenous VDR. Post-transcriptional action of $1,25(OH)_2D$ was tested in cells originating from patients or in cells cotransfected with VDR (either mutant or wild type fused to a promotor containing vitamin D response element,

VDRE) (Hewison *et al.*, 1993; Hughes *et al.*, 1988; Malloy *et al.*, 1990, 1999, 2002, 2004; Nguyen *et al.*, 2002, 2006; Ritchie *et al.*, 1989; Sone *et al.*, 1990; Yagi *et al.*, 1993).

Types of Defects

Studies with the above-mentioned methods in cells originating from a variety of patients with VDDR-II revealed heterogeneity of the cellular and molecular defects in the VDR–effector system. Based on the known functional properties of the VDR, different classes of defects could be identified.

Defects in the Hormone-Binding Region (Including Heterodimerization)

Deficient Hormone Binding

There are three subgroups in this class.

(i) No Hormone Binding. This is the most common abnormality observed and is characterized by unmeasurable specific binding of [^{3}H]1,25(OH)$_2$D$_3$ to either intact cells, nuclei, or cell extracts (Balsan *et al.*, 1983; Chen *et al.*, 1984; Cockeril *et al.*, 1997; Feldman *et al.*, 1982; Fraher *et al.*, 1986; Hawa *et al.*, 1996; Koren *et al.*, 1985; Kristjansson *et al.*, 1993; Liberman *et al.*, 1983a,b; Malloy *et al.*, 1990, 2001; Marx *et al.*, 1984; Mechica *et al.*, 1997; Nguyen *et al.*, 2002; Ritchie *et al.*, 1989; Sone *et al.*, 1989). Studies in several kindreds with this defect (including an extended kindred with eight patients studied) revealed undetectable levels of VDR by immunoblots on an immunoradiometric assay in most kindreds (Kristjansson *et al.*, 1993; Malloy *et al.*, 1990; Nguyen *et al.*, 2002; Ritchie *et al.*, 1989; Weise *et al.*, 1993). DNA from these affected subjects exhibited a single base mutation in each kindred resulting in (1) conversion of a normal amino acid codon into a premature termination codon in the coding sequence of the VDR protein and (2) a frameshift in translation resulting in a premature stop codon. The truncated VDRs produced lacked hormone binding or both hormone- and DNA-binding domains (Fig. 3) (Cockeril *et al.*, 1997; Hawa *et al.*, 1996; Mechica *et al.*, 1997; Weise *et al.*, 1993). The recreated mutant VDR cDNA was expressed in mammalian cells, and the resulting mutant VDR was demonstrated to be the truncated protein that exhibited no specific hormone binding. Steady-state VDR mRNA levels were decreased or undetectable in patients' cells from one kindred (Malloy *et al.*, 1990; Ritchie *et al.*, 1989). An immunoradiometric assay for VDR did not detect the 148- and 291-amino-acid-long mutant VDR, though this portion of the receptor included both epitopes required for recognition (Weise *et al.*, 1993). These observations may indicate an unstable transcript and/or increased turnover. In cells cultured from parents of some patients, expected to be obligate heterozygotes, binding of [^{3}H]1,25(OH)$_2$D$_3$, VDR protein, and mRNA content of cells ranged from the lower limit of normal to about half the normal level.

In one patient representing a kindred with no hormone binding, a missense mutation resulted in the substitution of the hydrophobic basic arginine-274 by the hydrophilic

nonpolar leucine in the hormone-binding region (Kristjansson *et al.*, 1993) (see Fig. 3). In this patient, normal transcription in a transfection assay could be elicited by 1000-fold higher concentrations of calcitriol than needed for the wild-type receptor. However, no *in vivo* or *in vitro* stimulation of 25(OH)D-24-hydroxylase could be obtained by high concentrations of $1,25(OH)_2D_3$.

Two siblings without alopecia and no response to any dose of $1,25(OH)_2D$ *in vivo* and *in vitro* had a missense mutation that caused a substitution of tryptophan by arginine at amino acid 286 of the VDR (see Fig. 3) (Nguyen *et al.*, 2002). This substitution in a normal size VDR abolished completely the binding of $1,25(OH)_2D$ to its receptor. The tryptophan in this position is critical for the positioning of calcitriol in the VDR as was unveiled by the three-dimensional arrangement of the VDR and its ligand based on its crystal structure (Rochel *et al.*, 2000).

(ii) Defective Hormone Binding Capacity. In a patient representing one kindred, the number of binding sites in nuclei and high-salt soluble cell extracts was 10% of control, with an apparent normal affinity (Balsan *et al.*, 1983; Liberman *et al.*, 1983a,b; Sone *et al.*, 1989).

Recently, a boy with total alopecia, severe rickets, and growth retardation was found to have two heterozygote different molecular defects in the ligand-binding domain (Nguyen *et al.*, 2006). The patient VDR had a low hormone-binding capacity, 10% to 30% of controls, with normal affinity and a marked deficient stimulation of $25(OH)D_3$-24-hydroxylase. The recreated mutations, each one tested separately *in vitro*, also showed deficient heterodimerization as well as different transactivation of two gene promotors. This patient, similar to another one described more than 20 years ago, could be completely cured by very high doses of 25(OH) vitamin D, 250 μg/day initially, followed by 100 μg/day and then 75 μg/day as a maintenance dose continuing for years, plus modest calcium supplementation. In both patients, it could be shown that during remission (normocalcemia, normophosphatemia, normal iPTH), $1,25(OH)_2D$ production is driven by the substrate, i.e., 25(OH) vitamin D concentrations.

(iii) Defective Hormone Binding Affinity. Binding affinity of tritiated calcitriol was reduced 20- to 30-fold, with normal capacity, in high-salt soluble dermal fibroblast extracts from one kindred (Castells *et al.*, 1986). An additional patient, representing a different kindred, had a modest decrease of VDR affinity when measured at 0°C (Malloy *et al.*, 1997).

No studies on the molecular defect were performed in patients with the last two defects.

Deficient Nuclear Uptake

The following features characterize the hormone–receptor–nuclear interaction in this defect: normal or near-normal binding capacity and affinity of $[^3H]1,25(OH)2D3$ to high-salt soluble cell extracts with low to unmeasurable hormone uptake into nuclei of intact cells (Eil *et al.*, 1981; Hewison *et al.*, 1993; Liberman *et al.*, 1983b; Takeda *et al.*, 1989; Whitfield *et al.*, 1996). These features were demonstrated in skin-derived fibroblasts in all kindreds, in cells cultured from a bone biopsy of one patient (Liberman *et al.*, 1983b), and in EB-transformed lymphoblasts of one patient (Hewison *et al.*, 1993). Occupied VDR obtained from high-salt fibroblast extracts of two kindreds demonstrated normal binding to nonspecific DNA cellulose (Liberman *et al.*, 1986). Immunocytological studies in fibroblasts of a patient with this defect showed that, immediately after 1,25(OH)2D3 treatment, VDR accumulated along the nuclear membrane with no nuclear translocation (Barsony *et al.*, 1990). Patients with this defect included a kindred with normal hair and several kindreds with total alopecia. Finally, almost all patients responded with a complete clinical remission to high doses of vitamin D and its active 1α-hydroxylated metabolites.

Attempts to characterize the molecular defect were carried in six kindreds. In three of them, no mutation in the coding region of the VDR gene was observed (Hewison *et al.*, 1993; personal communication). Studies in two kindreds revealed a normal molecular mass and quantitative expression of the VDR as judged by immunoblotting (Whitfield *et al.*, 1996). Complete sequencing of the VDR-coding region revealed a different single-nucleotide mutation in each kindred: ATC to AGC for isoleucine-314 to serine in one kindred, CGC to TCG altering arginine-391 to cysteine in the second kindred, and CAG to CCG altering glutamine-259 to proline in the third kindred (see Fig. 3) (Cockeril *et al.*, 1997; Whitfield *et al.*, 1996), This region is considered to play a role in heterodimerization of VDR with RXR, and thus it has been suggested that these patients' receptors have defects that compromise RXR heterodimerization, which is essential for nuclear localization and probably for recognition of the vitamin D-responsive element as well. The fact that no mutation in the VDR-coding region was observed in three additional kindreds with the same phenotypical defect may suggest that the genetic defect affects another component of the receptor–effector system that is essential for the VDR function as a nuclear transcription factor. It has been shown that coactivation complexes are essential for the ligand-induced transactivation of VDR (Freedman, 1999). It is worthwhile to note that in one kindred originally described with this defect (Takeda *et al.*, 1989) a missense mutation at position 140 in exon 3, encoding the DNA-binding domain, was observed (Saijo *et al.*, 1991).

Deficient coactivators of the calcitriol–VDR complex. A patient with VDDR-II without alopecia was described (Malloy *et al.*, 1999). Sequencing of the VDR-DNA revealed a missense mutation in the ligand-binding domain that caused a substitution of glutamic acid to lysine at amino acid 120 (see Fig. 3). This receptor exhibits many normal properties including calcitriol binding, dimerization,

and binding to vitamin D response elements in the DNA, but a marked impairment in binding coactivators that are essential for the transactivation of the hormone–receptor complex and the initiation of the physiological response.

Defects in DNA-Binding Region

Deficient Binding to DNA. Cell preparations derived from patients with this defect demonstrate normal or near-normal binding capacity and affinity for [^{3}H]1,25(OH)$_2$D$_3$ to nuclei of intact cells and to high-salt soluble cell extracts, as well as the normal molecular size VDR of 48 to 50 kDa, as analyzed by immunoblot. Hormone–receptor complexes, however, have decreased affinity to nonspecific DNA (peak elution from DNA-cellulose columns at 0.1 *M* KCl compared with 0.2 *M* in normals) (Hirst *et al.*, 1985; Hughes *et al.*, 1988; Liberman *et al.*, 1986; Saijo *et al.*, 1991; Yagi *et al.*, 1993). A single-nucleotide missense mutation within exon 2 or 3, encoding the DNA-binding domain of the VDR, was demonstrated in genomic DNA isolated from dermal fibroblasts and/or EB-transformed lymphoblasts from 10 unrelated kindreds (Hughes *et al.*, 1988; Lin *et al.*, 1996; Malloy *et al.*, 1989, 1994; Mechica *et al.*, 1997; Rut *et al.*, 1994; Sone *et al.*, 1990; Saijo *et al.*, 1991; Yagi *et al.*, 1993). Eight different single-nucleotide mutations were found in the ten kindreds (see Fig. 3). Two apparently unrelated kindreds share the same mutation (Saijo *et al.*, 1991; Sone *et al.*, 1990).

All point mutations caused a single substitution of an amino acid that resides in the region of the two zinc fingers of the VDR protein that are essential for the functional interaction of the hormone–receptor complex with DNA. Interestingly, all these altered amino acids are highly conserved in the steroid receptor superfamily and seem to concentrate in three regions: the tip of the first zinc fingers (three mutations), the "knuckle" region, just C-terminal of the first zinc fingers (three mutations), and the C-terminal side of the second zinc fingers (two mutations). All of these single-amino-acid residue substitutions are associated with charge changes and thus affect hydrogen bonding. These aberrations, as well as changes in hydrophobicity, will have a deleterious effect on the interaction of the hormone–receptor complex with DNA.

Each of the mutants was recreated by introducing the appropriate base change into the normal VDR cDNA and then transfecting the mutated cDNA into mammalian cells. The functional properties of the resultant VDR expression product were indistinguishable from mutant DNA, i.e., normal hormone binding and deficient binding to nuclear extracts and nonspecific DNA (Hughes *et al.*, 1988; Saijo *et al.*, 1991; Sone *et al.*, 1990). Studies on cells obtained from parents of some of these patients revealed, as expected, a heterozygous state, i.e., expression of both normal and defective forms of VDR as well as normal and mutant gene sequences (Hughes *et al.*, 1988; Malloy *et al.*, 1989), but without any clinical or biochemical abnormalities.

In vitro Post-transcriptional and Transcriptional Effect of 1,25(OH)$_2$D$_3$

In vitro bioeffects of the hormone on various cells in patients with VDDR-II have been assayed mainly by two procedures: induction of 25(OH)D-24-hydroxylase and inhibition of mitogen-stimulated PBM cells.

1,25(OH)$_2$D$_3$ induces 25(OH)D-24-hydroxylase activity in skin-derived fibroblasts (Balsan *et al.*, 1983; Castells *et al.*, 1986; Chen *et al.*, 1984; Clemens *et al.*, 1983; Feldman *et al.*, 1982; Fraher *et al.*, 1986; Gamblin *et al.*, 1985; Griffin *et al.*, 1983; Hewison *et al.*, 1993; Hirst *et al.*, 1985; Hughes *et al.*, 1988; Liberman *et al.*, 1983b; Malloy *et al.*, 1990; Ritchie *et al.*, 1989; Rut *et al.*, 1994; Sone *et al.*, 1990; Yagi *et al.*, 1993), mitogen-stimulated lymphocytes (Takeda *et al.*, 1990), and cells originating from bone (Balsan *et al.*, 1986) in a dose-dependent manner. In cells from normal subjects, maximal and half-maximal induction of the enzyme was achieved by 10^{-8} and 10^{-9} *M* concentrations of 1,25(OH)$_2$D$_3$, respectively. Dermal fibroblast or PBM cells from VDDR-II patients with no calcemic response to maximal doses of vitamin D or its metabolites *in vivo* did not show any 25(OH)D-24-hydroxylase response to very high concentrations of 1,25(OH)$_2$D$_3$ *in vitro*, whereas dermal fibroblasts from patients with a calcemic response to high doses of vitamin D or its metabolites *in vivo* showed inducible 24-hydroxylase with supraphysiological concentrations of 1,25(OH)$_2$D$_3$, i.e., a shift to the right, *in vitro*. Physiological concentrations of 1,25(OH)$_2$D$_3$ partially inhibit mitogen-induced DNA synthesis in peripheral lymphocytes with a half-maximal inhibition achieved at 10^{-10} *M* hormone (Koren *et al.*, 1985; Takeda *et al.*, 1986). Mitogen-stimulated lymphocytes from several kindreds with defects characterized as no hormone binding or deficient binding to DNA, with no calcemic response to high doses of vitamin D and its metabolites *in vivo*, showed no inhibition of lymphocyte proliferation *in vitro*, with concentrations of up to 10^{-6} *M* 1,25(OH)$_2$D$_3$ (Fig. 4). Additional methods for measuring bioeffects of 1,25(OH)$_2$D$_3$ on various cells *in vitro* were carried out only in few patients and included inhibition of dermal fibroblast proliferation (Clemens *et al.*, 1983), induction of osteocalcin synthesis in cells derived from bone (Balsan *et al.*, 1986), a mitogenic effect on dermal fibroblasts (Barsony *et al.*, 1989), and stimulation of cGMP production in cultured skin fibroblasts (Barsony and Marx, 1988). It is noteworthy that in all assays mentioned, and without exception, each patient's cells showed severely deficient responses.

With the elucidation of the molecular defects in VDDR-II, the transactivation abilities of naturally occurring mutant or recreated mutant VDRs were evaluated in a transcriptional

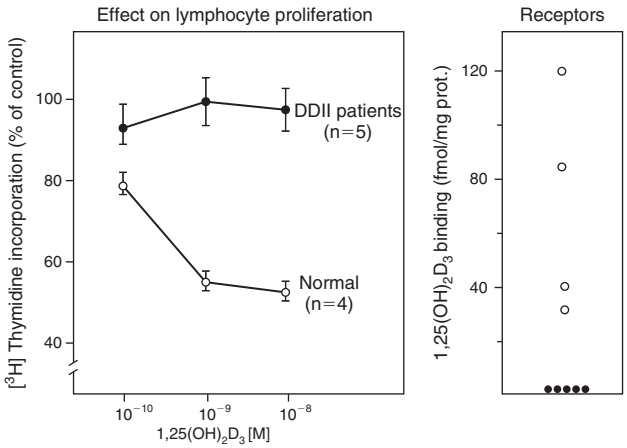

FIGURE 4 Effect of increasing concentrations of $1,25(OH)_2D_3$ on mitogen-induced lymphocyte proliferation from patients with VDDR-II (DD-II) and normal controls. The numbers of specific $[^3H]1,25(OH)_2D_3$-binding sites are depicted (*right*) in the same cell populations. VDRR-II patients tested here are with the defect characterized as no hormone binding.

activation assay. The human osteocalcin gene promoter fused to chloramphenicol acetyltransferase (CAT) gene reporter plasmid was transfected into the patients or into normal fibroblasts (Hewison *et al.*, 1993; Hughes *et al.*, 1988; Malloy *et al.*, 1990; Ritchie *et al.*, 1989; Saijo *et al.*, 1991; Sone *et al.*, 1989; Yagi *et al.*, 1993). Treating normal transfected cells with $1,25(OH)_2D_3$, caused a concentration-dependent induction of transcription, measured by increased CAT activity. No induction of transcription was observed in cells originating from patients with defects characterized as no hormone binding (Kristjansson *et al.*, 1993; Malloy *et al.*, 1990; Ritchie *et al.*, 1989) or deficient binding to DNA (Hughes *et al.*, 1988; Saijo *et al.*, 1991; Sone *et al.*, 1990; Yagi *et al.*, 1993). Moreover, in a cotransfection assay, the addition of a normal human VDR cDNA expression vector to the transfected plasmid that directed synthesis of a normal VDR restored the hormone responsiveness of resistant cells. Finally, in a patient characterized as having a deficient nuclear uptake defect no mutation was identified within the coding region of the VDR gene; no induction of 25(OH)D-24-hydroxylase activity by up to 10^{-6} *M* $1,25(OH)_2D_3$ was observed in cultured skin fibroblasts, but there was normal transactivation by $1,25(OH)_2D_3$ in the transcriptional activation assay (Hewison *et al.*, 1993).

Cellular Defects and Clinical Features

Normal hair was described with most phenotypes of the cellular defects, the exception being patients with deficient hormone-binding capacity and affinity, but this could be because only very few kindreds were described per subgroup. Normal hair is usually associated with a milder form of the disease, as judged by the age of onset, severity of the clinical features, and usually the complete clinical and biochemical remission on high doses of vitamin D or its metabolites. Notable exceptions are two patients, from two separate kindreds, with normal hair that displayed resistance both *in vivo* (no clinical remission on circulating calcitriol level up to 100 times the mean normal adult values) and *in vitro* (no induction of 25(OH)D-24-hydroxylase activity in dermal fibroblasts by up to 10^{-8} *M* $1,25(OH)_2D_3$ (Fraher *et al.*, 1986; Mally *et al.*, 2002). Only approximately half of the patients with alopecia have shown satisfactory clinical and biochemical remission to high doses of vitamin D or its active 1α-hydroxylated metabolites, but the dose requirement is ~10-fold higher than in patients with normal hair (Marx *et al.*, 1986).

It seems that patient defects characterized as deficient hormone-binding affinity and deficient nuclear uptake achieve complete clinical and biochemical remission on high doses of vitamin D or its active 1α-hydroxylated metabolites. Most of the patients with other types of defects could not be cured with high doses of vitamin D or its metabolites. However, it should be emphasized that not all of the patients received treatment for a long enough period of time and with sufficiently high doses (see "Treatment").

Diagnosis

Clinical features of early-onset rickets with no history of vitamin D deficiency, total alopecia, parental consanguinity, additional siblings with the same disease, serum biochemistry of hypocalcemic rickets, elevated circulating levels of $1,25(OH)_2D$, and normal to high levels of 25(OH)D (see Table I) support the diagnosis of VDDR-II. The issue becomes more complicated when the clinical features are atypical, i.e., late onset of the disease, sporadic cases, and normal hair. Failure of a therapeutic trial with calcium and/or physiological replacement doses of vitamin D or its metabolites may support the diagnosis, but the final direct proof requires the demonstration of a cellular, molecular, and functional defect in the VDR–effector system.

Based on the clinical and biochemical features, the following additional disease states should be considered: (1) extreme calcium deficiency: a seemingly rare situation, described in a group of children from a rural community in South Africa, who consumed an exceptionally low-calcium diet of 125 mg/day (Pettifor *et al.*, 1981). All had severe bone disease with histologically proven osteomalacia, biochemical features of hypocalcemic rickets with elevated serum levels of 1,25(OH)2D, and sufficient vitamin D. Calcium repletion caused complete clinical and biochemical remission. Nutritional history and the response to calcium supplementation support this diagnosis. (2) Severe vitamin D

deficiency: during initial stages of vitamin D therapy in children with severe vitamin D-deficient rickets, the biochemical picture may resemble VDDR-II, i.e., hypocalcemic rickets with elevated serum calcitriol levels. This may represent a "hungry bone syndrome," i.e., high calcium demands of the abundant osteoid tissue becoming mineralized. This is a transient condition that may be differentiated from VDDR-II by a history of vitamin D deficiency and the final therapeutic response to replacement doses of vitamin D.

Treatment

In about half of the kindreds with VDDR-II, the bioeffects of $1,25(OH)_2D_3$ were measured *in vitro* (see earlier). An invariable correlation (with one exception) was documented between the *in vitro* effect and the therapeutic response *in vivo*; i.e., patients with no calcemic response to high levels of serum calcitriol showed no effects of $1,25(OH)_2D_3$ on their cells *in vitro* (either induction of 25(OH)D-24-hydroxylase or inhibition of lymphocyte proliferation) and vice versa. If the predictive therapeutic value of the *in vitro* cellular response to $1,25(OH)_2D_3$ could be substantiated convincingly, it may eliminate the need for time-consuming and expensive therapeutic trials with massive doses of vitamin D or its active metabolites. In the meantime, it is mandatory to treat every patient with VDDR-II irrespective of the type of receptor defect.

An adequate therapeutic trial must include vitamin D at a dose that is sufficient to maintain high-serum concentrations of $1,25(OH)_2D_3$, as the patients can produce high hormone levels if supplied with enough substrate (Brooks *et al.*, 1978; Marx *et al.*, 1978). If high serum calcitriol levels are not achieved, it is advisable to treat with 1α-hydroxylated vitamin D metabolites in daily doses of up to 6 μg/kg or a total of 30 to 60 μg and calcium supplementation of up to 3 g of elemental calcium daily; therapy must be maintained for a period sufficient to mineralize the abundant osteoid (usually 3 to 5 months). Therapy may be considered a failure if no change in the clinical, radiological, or biochemical parameters occurs during continuous and frequent follow-up while serum $1,25(OH)_2D$ concentrations are maintained at ~100 times the mean normal range.

In some patients with no response to adequate therapeutic trials with vitamin D or its metabolites, a remarkable clinical and biochemical remission of their bone disease, including catch-up growth, was obtained by treatment with large amounts of calcium. This was achieved by long-term (months) intracaval infusions of up to 1000 mg of calcium daily (Balsan *et al.*, 1986; Bliziotes *et al.*, 1988; Weisman *et al.*, 1987). Another way to increase calcium input into the extracellular compartment is to increase net gut absorption, independent of vitamin D, by increasing calcium intake (Sakati *et al.*, 1986). This approach is limited by dose and patient tolerability and was actually used successfully in very few patients.

Several patients have shown unexplained fluctuations in response to therapy or in presentation of the disease. One patient, after a prolonged remission, became completely unresponsive to much higher doses of active 1α-hydroxylated vitamin D metabolites (Balsan *et al.*, 1983), and another patient seemed to show amelioration of resistance to $1,25(OH)_2D_3$ after a brief therapeutic trial with $24,25(OH)_2D_3$ (Liberman *et al.*, 1980). In several patients, spontaneous healing occurred in their teens (Hochberg *et al.*, 1984) or rickets did not recur for 14 years after cessation of therapy (Takeda *et al.*, 1989).

Animals Models

Some New World primates (marmoset and tamarins) that develop osteomalacia in captivity are known to have high nutritional requirements for vitamin D and maintain high serum levels of $1,25(OH)_2D$, thus exhibiting a form of end-organ resistance to $1,25(OH)_2D$ (Adams and Gacad, 1988; Liberman *et al.*, 1985; Shinki *et al.*, 1983; Takahashi *et al.*, 1985). Cultured dermal fibroblasts and EB-virus-transformed lymphoblasts have shown deficient hormone-binding capacity and affinity (Adams and Gacad, 1988; Liberman *et al.*, 1985). It has been observed that marmoset lymphoblasts contain a soluble protein of 50 to 60 kDa that binds $1,25(OH)_2D_3$ with a low affinity but high capacity and thus may serve as a sink that interferes with the hormone binding and its cognate receptor (Gacad and Adams, 1993). The same group described another protein present in the nuclear extract of these cells capable of inhibiting normal VDR-RXR binding to the vitamin D response element (Arbelle *et al.*, 1996).

It is of interest that these New World primates also exhibit a compensated hereditary end-organ resistance to the true steroid hormones including glucocorticoids, estrogens, and progestins (Lipsett *et al.*, 1985). This, of course, raises the interesting possibility that the defect in the hormone–receptor–effector system involves an element shared by all the members of this superfamily of ligand-modulated transcription factors.

VDR knockout mice have been created by targeted ablation of the first or second zinc finger (Li *et al.*, 1997; Yoshizawa *et al.*, 1997). Only the homozygotic mice were affected. Though phenotypically normal at birth, after weaning, they become hypocalcemic, develop secondary hyperparathyroidism, rickets, osteomalacia, and progressive alopecia. The female mice with ablation of the first zinc finger are infertile and show uterine hypoplasia and impaired folliculogenesis. Otherwise, both VDR cell mutant mice show clinical, radiological, histological, and biochemical features that are identical to the human disease VDRR-II. Supplementation with a calcium-enriched diet can prevent or treat most of the disturbances in mineral and bone metabolism in these animal models except alopecia (Delling and Demay, 1998). It is of interest that

targeting expression of human VDR to keratinocytes of VDR null mice prevented alopecia (Chen *et al.*, 2001).

CONCLUDING REMARKS

Hereditary deficiencies in vitamin D action are rare disorders. The importance of studying these diseases stems from the fact that they represent a naturally occurring experimental model that helps to elucidate the function and importance of vitamin D and the VDR–effector system in humans *in vivo*.

VDRs are abundant and widely distributed among most tissues studied and multiple effects of calcitriol are observed on various cell functions *in vitro*. Yet, the clinical and biochemical features in patients with VDDR-I and -II seem to demonstrate that the only disturbances of clinical relevance are perturbations in mineral and bone metabolism. This demonstrates the pivotal role of $1,25(OH)_2D$ in transepithelial net calcium fluxes. Moreover, the fact that, in patients with extreme end-organ resistance to calcitriol, calcium infusions correct the disturbances in mineral homeostasis and cure the bone disease may support the notion that defective bone matrix mineralization in VDRR-I and -II is secondary to disturbances in mineral homeostasis. Characterization of the molecular, cellular, and functional defects of the different natural mutants of the human VDR in VDDR-II demonstrates the essentiality of the VDR as the mediator of calcitriol action and the importance and function of its different domains. Furthermore, to function biologically, the VDR must associate with additional partners, i.e., $1,25(OH)_2D$, an RXR isoform, a specifically defined DNA region, as well as coactivators and corepressor complexes. This notion has been based primarily on *in vitro*-created point mutations and *in vitro* functional assays. However, the acid test for the relevance of the structure–function relationship is the demonstration of *in vivo* effects, in general, and deficient function under pathological conditions, in particular. Thus, studies in patients with hereditary deficiencies in vitamin D action are the essential link between molecular defects and physiological relevant effects.

Chapter 71

Tumor-Induced Osteomalacia

Jennifer Mammen and Suzanne M. Jan de Beur*

Department of Medicine, Division of Endocrinology and Metabolism, The Johns Hopkins University School of Medicine, 5200 Eastern Avenue, Mason F. Lord Building, Suite 4300, Baltimore, Maryland

INTRODUCTION

Tumor-induced osteomalacia (TIO) is a rare, paraneoplastic disease that can be difficult to distinguish from genetic forms of hypophosphatemia and severe osteomalacia. The hallmark of TIO, and its genetic phenocopies, is renal phosphate wasting and abnormal vitamin D metabolism; specifically, lack of compensatory increase in 1,25-dihydroxyvitamin D ($1,25(OH)_2D_3$) in response to hypophosphatemia. Ultimately, unchecked renal phosphorus excretion and relative $1,25(OH)_2D_3$ deficiency leads to osteomalacia, a metabolic bone disease characterized by a failure of mineralization and resultant weak, painful bones. Osteomalacia itself has myriad causes, many of which display low serum phosphate levels (Parfitt, 1990). Vitamin D ($25(OH)D_3$) deficiency is the most common cause of osteomalacia in adults and rickets in children. Osteomalacia that was resistant to vitamin D therapy led to the recognition of other causes, including TIO and genetic disorders such as X-linked hypophosphatemic rickets (XLH). McCance first described TIO in 1947, when a patient with vitamin D-resistant osteomalacia was cured by surgical resection of a bone tumor (McCance, 1947). Subsequent research into the humoral factors that are responsible for TIO, and the genetic factors responsible for inherited forms of hypophosphatemic rickets, has converged to elucidate novel phosphate homeostatic pathways.

INITIAL CLINICAL EVALUATION OF SUSPECTED OSTEOMALACIA

Osteomalacia is usually suspected clinically or found on x-rays, for example, after a fracture. Patients with osteomalacia complain of diffuse bone pain, muscle weakness, fractures, and fatigue. The pain is most often in the axial skeleton and long bones of the lower extremities. The vitamin D receptor (VDR) is also present in muscle and a myopathy may be present along with the bone symptoms, especially in the proximal muscles. Studies of adults with vitamin deficiency have noted gait instability and more frequent falls among vitamin D-deficient elderly adults compared with controls (Bischoff-Ferrari *et al.*, 2005; Burleigh *et al.*, 2007; Jackson *et al.*, 2007). In TIO, the myopathy can be very severe and may be related to the phosphorus deficiency.

Physical examination often reveals bone pain, especially with palpation of the anterior tibia and sternum. In children, long bone deformity, lower extremity bowing, and chest wall deformity is observed. If TIO is suspected, an extensive examination for masses or nodules is warranted, concentrating on soft tissues adjacent to long bones, distal extremities, the oral cavity and jaw, and the groin.

Both fractures and pseudofractures are visualized on plain films. Pseudofractures are radiolucent lines, called Looser zones, around nutrient canals that have enlarged from the failure of mineralization. Pseudofractures are generally perpendicular to the cortex of the bone. Generalized osteopenia and coarse trabeculae may be appreciated on x-ray. In children, rickets is characterized by widening of the epiphyseal growth plate and bowing the long bones, particularly the lower extremities, which can be very dramatic on x-ray.

Histological examination of the bone confirms the diagnosis of osteomalacia when clinical and radiographic evaluation is nondiagnostic. In this disorder, the organic bone matrix, osteoid, continues to be deposited at sites of remodeling at a reduced rate, whereas mineralization with hydroxyapatite is significantly inhibited (Drezner, 1999; Kumar, 2000). This leads to characteristic findings on biopsy of a widened osteoid seam (Fig. 1). The degree of matrix synthesis can be assessed with two pulses of tetracycline, taken orally for three days, separated by ten days prior to biopsy. Tetracycline is incorporated into newly synthesized matrix, and thus the space between the lines created with each pulse measures the rate of active bone deposition.

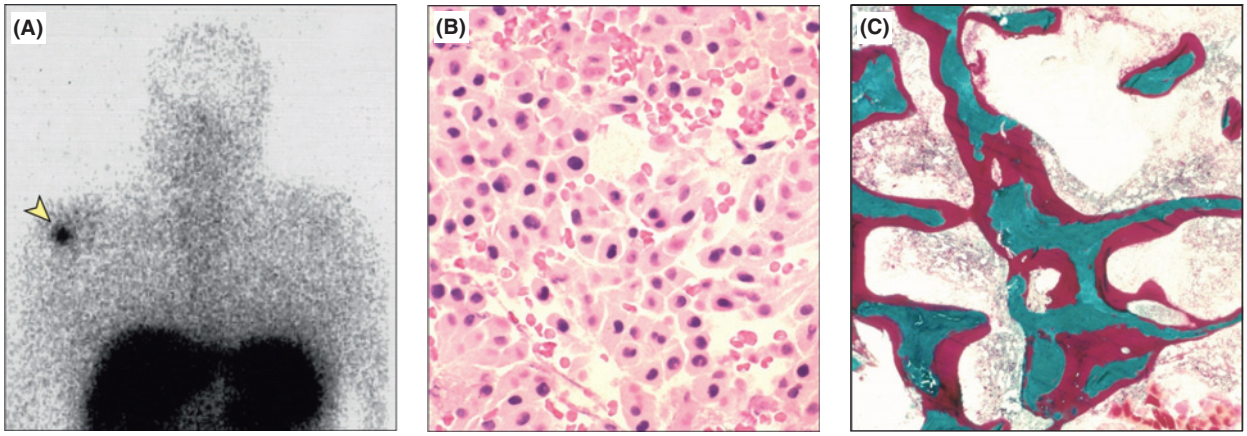

FIGURE 1 Radiographic and histological features in TIO. (**A**) Octreotide scan showing small mesenchymal tumor in the head of the humerus. (**B**) Hemiangiopericytoma with numerous pericytes and vascular channels (H&E strain). (**C**) Bone biopsy with Goldner stain. Excessive osteoid or unmineralized bone matrix composed mainly of collagen stains pink. Minerlized bone stains blue. This bone biopsy shows severe osteomalacia. (See plate section)

Rickets is characterized by the presence of similar findings at the growth plate. Although bone biopsy will confirm osteomalacia, it cannot distinguish the underlying cause.

The differential diagnosis of osteomalacia is dominated by vitamin D deficiency (Table I). With the increased use of sunscreens, decreased time spent out-of-doors, and the lack of dietary sources, vitamin D deficiency has become increasingly prevalent, especially in the elderly (Holick, 2007). If vitamin D deficiency is identified, an underlying cause of the deficiency, such as celiac sprue or other malabsorptive state, must be sought. The proliferation of gastric bypass surgery will contribute significantly to this population in the future. In rare circumstances, a patient may have primary nutritional deficiencies that lead to low serum phosphorus or calcium, for example, with alcoholism or anorexia nervosa. Genetic defects in vitamin D synthetic enzymes or in the vitamin D receptor (VDR) result in functional vitamin D deficiency. End-stage renal disease leads to a deficiency of $1,25(OH)_2D_3$ from loss of kidney-dependent 1α-hydroxylation; this paired with secondary hyperparathyroidism results in renal osteodystrophy, a variant of osteomalacia with a mixed picture of mineralization defect and parathyroid bone disease. Acquired and genetic renal phosphate wasting syndromes, the focus of the remainder of the chapter, are a major cause of osteomalacia. These disorders include tumor-induced osteomalacia (TIO), X-linked hypophosphatemic rickets (XLH), autosomal dominant hypophosphatemic rickets (ADHR), autosomal recessive hypophosphatemic rickets (ARHR), hereditary hypophosphatemic rickets with hypercalciuria (HHRH), and Fanconi's syndrome.

In general, an astute physician armed with a comprehensive history, directed physical examination, and specific laboratory tests can distinguish between the most common forms of osteomalacia. The causes of osteomalacia can generally be distinguished biochemically (Table 1) and (Fig. 2). When osteomalacia is suspected, the initial laboratory investigation should include serum levels of $25(OH)D_3$, calcium, fasting phosphorus, PTH, creatinine, alkaline phosphatase, and 24-hour urine calcium measurements. If serum phosphorus is known to be low, a $1,25(OH_2)D_3$ level and a 24-hour urine phosphorus collection should also be obtained [in order to

TABLE I Differential Diagnosis of Rickets and Osteomalacia

Vitamin D deficiency
Nutritional deficiency: low sunshine exposure, low dietary intake
Malabsorption: celiac disease, Crohn's disease, gastrectomy, bowel resection, pancreatitis, gastric bypass
Chronic liver disease: impaired 25-hydroxylation
Chronic renal disease: renal osteodystrophy (impaired 1α-hydroxylation and secondary hyperparathyroidism); nephrotic syndrome (renal loss of binding proteins)
Increased catabolism: anticonvulsant therapy
Vitamin D receptor defects: Vitamin D-dependent rickets type 2
Vitamin D synthetic defects: 1α-hydroxylase (CYP27B1): Vitamin D-dependent rickets type 1 25-hydroxylase (CYP27A1)
Hypophosphatemia
Nutritional deficiency: alcoholism, anorexia, starvation
Renal phosphate wasting X-linked Hypophosphatemic Rickets Autosomal Dominant Hypophosphatemic Rickets Autosomal Recessive Hypophosphatemic Rickets Hereditary Hypophophatemic Rickets with Hypercalciuria Tumor-Induced Osteomalacia Fanconi Syndrome Dent's Disease
Isolated hypocalcemia
Nutritional calcium deficiency (rare)

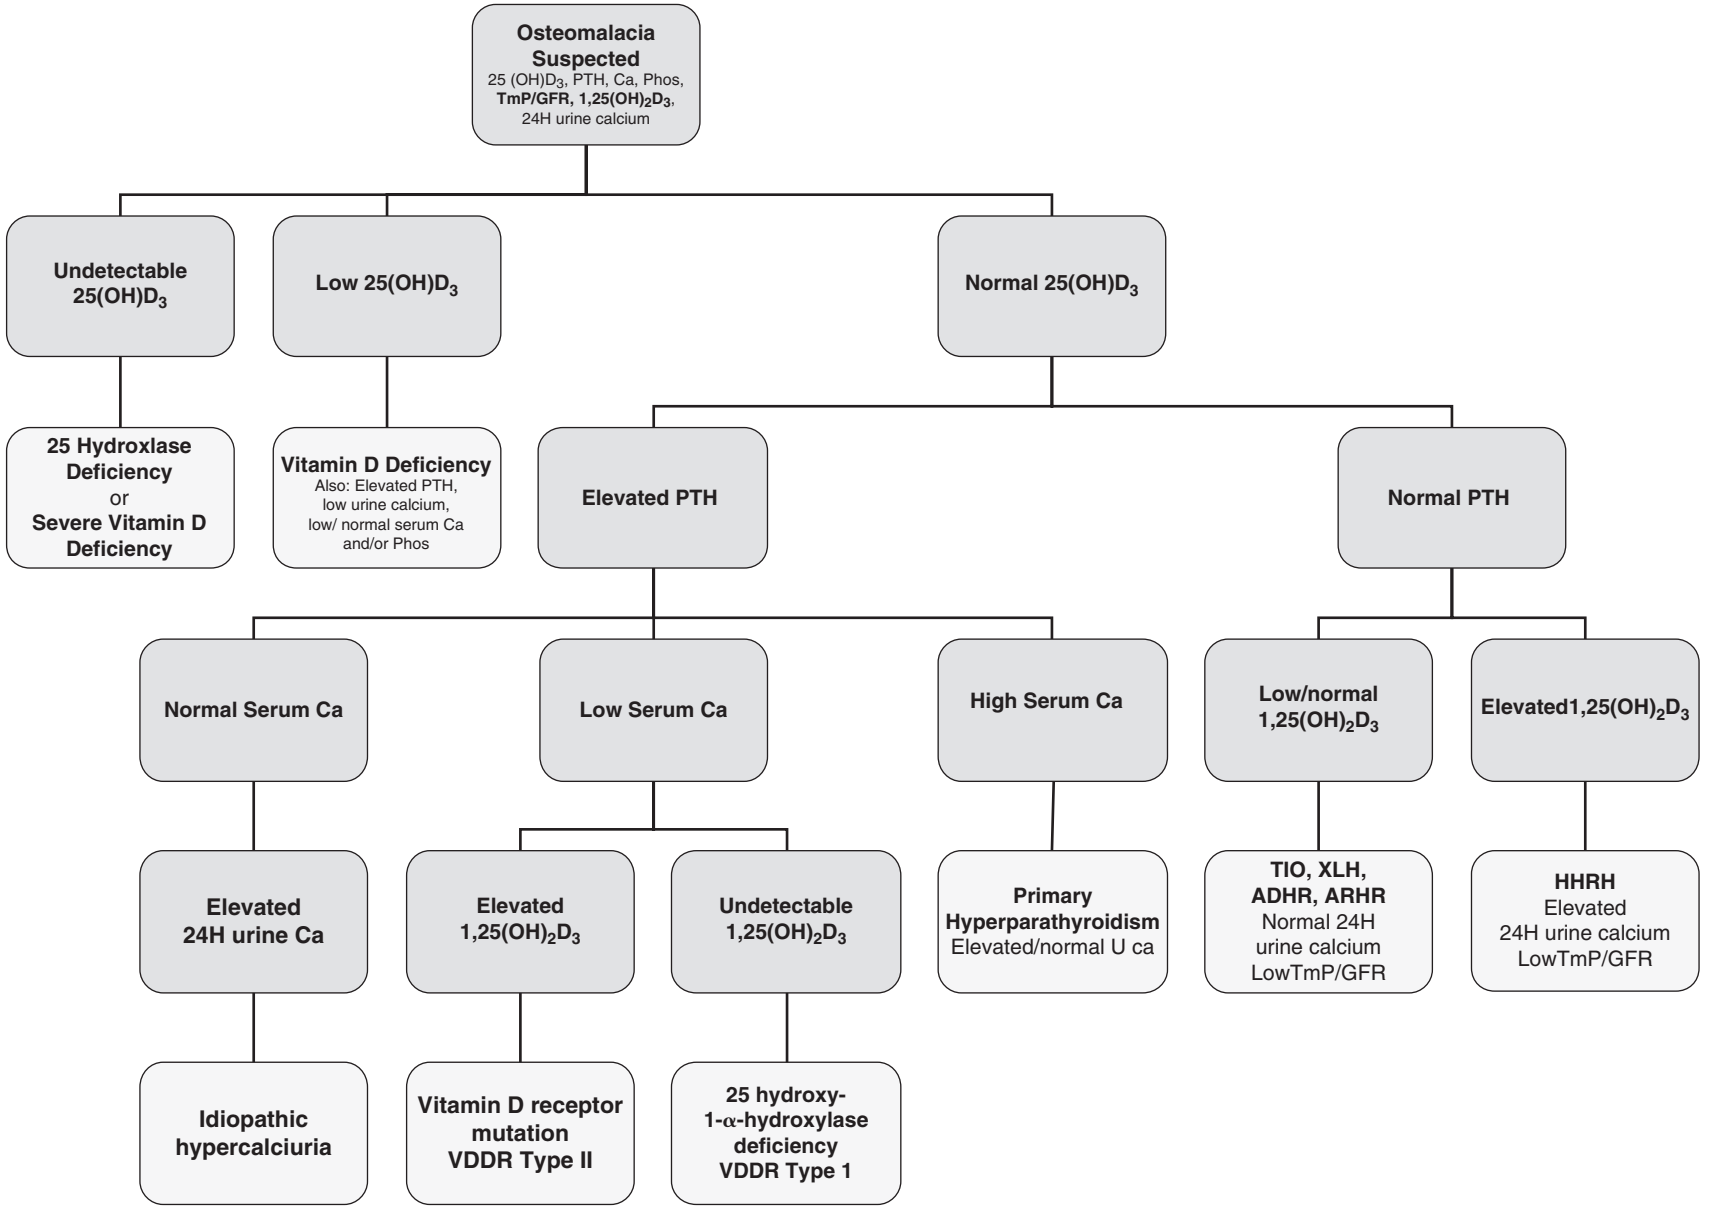

FIGURE 2 Evaluation of suspected osteomalacia.

calculate the tubular reabsorption of phosphate, transmembrane potential (TmP)/glomerular filtration rate (GFR)].

Vitamin D deficiency leads to poor absorption of minerals from the gastrointestinal tract, requiring compensatory changes to mobilize calcium and phosphorus from bone, which is mediated by PTH. In the presence of normal renal function, vitamin D deficiency is characterized by low-normal serum calcium and phosphorus as well as elevated serum PTH and alkaline phosphatase. Low urine calcium is characteristic of vitamin D deficiency because the filtered load of calcium is diminished and excess PTH results in avid reabsorption of calcium in the proximal renal tubule. Nutritional deficiencies of calcium and phosphate from severe dietary restriction and alcoholism can present with similar biochemical findings and are often exacerbating factors in the right host.

Mutations in the 25-hydroxy-1α-hydroxylase enzyme and the VDR (vitamin D-resistant rickets type I and II, respectively) are manifest with similar calcium, phosphorus, and PTH changes associated with vitamin D deficiency; however, $25(OH)D_3$ levels are normal. As implied by the name, neither disorder is responsive to vitamin D supplementation. In these cases, measuring the serum $1,25(OH)_2D_3$ is helpful, because it will be low in the absence of 1α-hydroxylase activity and elevated in the face of impaired VDR signaling.

Marked hypophosphatemia and renal phosphate wasting characterize TIO and the related genetic disorders. The serum phosphate levels should be measured fasting and the degree of hypophosphatemia can be profound. Serum calcium, $25(OH)D_3$, and PTH levels are normal; however, $1,25(OH)_2D_3$ level is generally lower than expected for the degree of hypophosphatemia, although it may be within the normal range. This failure to induce $1,25(OH)_2D_3$ synthesis in response to hypophosphatemia contributes to the pathophysiology of these disorders. PTH is not generally elevated, with a few exceptions reported (Cheng *et al.*, 1989; Shenker and Grekin, 1984). Increased bone turnover typically elevates alkaline phosphatase. Elevated urine phosphate excretion uniquely identifies this group of disorders. Renal loss of phosphate is measured by calculating the maximal tubular resorption of phosphate normalized to the GFR, the TmP/GFR, according to a nomogram with a 24-hour urine collection for phosphorus and creatinine (Walton and Bijvoet, 1975), and can be estimated with spot urine collections (Walton and Bijvoet, 1977). With the increased renal losses in these disorders, the TmP/GFR is reduced, and can be less than 50% of normal in TIO. Urine glucose and amino acids levels should also be measured as a more generalized defect in tubular function can be seem with some tumors (Leehey *et al.*, 1985) and with Faconi's syndrome.

Although, in general, osteomalacia secondary to vitamin D deficiency can be distinguished on the basis of elevated serum PTH levels and lower serum calcium levels (in more severe cases), some patients have small changes that are indeterminate. Because urine phosphorus excretion can be elevated in vitamin D deficiency owing to secondary hyperparathyroidism, in some cases $25(OH)D_3$ must be replaced and the patient reassessed for evidence of continued hypophosphatemia and hyperphosphaturia before further investigation is warranted.

DIFFERENTIAL DIAGNOSIS OF RENAL PHOSPHATE WASTING

Hypophosphatemia secondary to renal phosphate wasting has a wide differential diagnosis (Table II). These disorders can result from primary renal defects, overproduction of the phosphaturic hormone, FGF23, from normal or dysplastic bone and ectopic production of FGF23 or other phosphaturic proteins from tumors.

Fanconi's syndrome is the result of a generalized proximal tubular defect, which can result from genetic causes such as Wilson's disease and galactosemia, or acquired damage from heavy metals, connective tissue disorders, hematological malignancies (Clarke *et al.*, 1995) or medications (Colson and De Broe, 2005; Earle *et al.*, 2004; Izzedine *et al.*, 2003). Dent disease is an X-linked renal tubulopathy caused by mutations in the chloride channel, CLCN5, and is characterized by nephrolithiasis, renal failure, and Fanconi's syndrome with variable degrees of rickets and osteomalacia. The renal phosphate wasting observed in Dent's disease results from reduced membrane expression of NaPiIIc, a sodium-phosphate cotransporter (Piwon *et al.*, 2000). In addition to renal phosphate wasting, a more generalized proximal tubular defect in membrane trafficking leads to urinary losses of glucose, amino acids, and bicarbonate.

Hereditary hypophosphatemic rickets with hypercalciuria (HHRH) is a rare genetic form of hypophosphatemic rickets characterized by hypophosphatemia, renal phosphate wasting, and preserved responsiveness of $1,25(OH_2)D_3$ to hypophosphatemia (Tieder *et al.*, 1985). This appropriate increase in $1,25(OH_2)D_3$ leads to increased calcium absorption from the gastrointestinal tract and thus to hypercalciuria and nephrolithiasis. The genetic defect in HHRH is loss-of-function mutations in gene that endcodes NaPiIIc, one of three subtypes of the type II sodium phosphate cotransporters (Bergwitz *et al.*, 2006; Ichikawa *et al.*, 2006; Lorenz-Depiereux *et al.*, 2006b). HHRH is clinically similar to TIO with bone pain, osteomalacia, and muscle weakness as prominent features, yet the distinction is easily made with biochemical testing. Both syndromes are characterized by hypophosphatemia owing to decreased renal phosphorus reabsorption; however, patients with HHRH exhibit elevated levels of calcitriol and hypercalciuria that distinguish it from TIO, XLH, and ADHR.

TABLE II Characteristics of Renal Phosphate Wasting Syndromes

Acquired Disease	Defect	Biochemical features	Pathogenesis
TIO	Mesenchymal tumor	• Renal phosphate wasting Low Phos, low TmP/GFR • Inappriopriately low $1,25(OH)_2D$ Low or low-normal • Absence of hypercalcemia or hyperparathyroidism Normal calcium, PRH, normal urine calcium	Ectopic, unregulated production of FGF23 and other phosphatonins sFRP-4, MEPE, FGF7
Fanconi's	Renal proximal tubular defect that alters absorption of Pi, glucose, amino acids, bicarbonate	Similar to TIO with additional features of glocosuria, amino aciduria, and bicarbonate wasting	Proximal renal tubular damage owing to multiple myeloma, lymphoma, amyloidosis, light-chain disease, nephrotic syndrome, drugs, heavy metals, and heritable metabolic and renal disorders
Fibrous dysplasia	GNAS Gain of function	Biochemically indistinguishable from TIO	Increased FGF23 production from fibrous dysplastic bone; correlated with extent of bone disease
XLH	PHEX gene Loss of function	Biochemically indistinguishable from TIO	Increased FGF23 synthesis from bone
ADHR	FGF23 gene Gain of function	Biochemically indistinguishable from TIO	Increase circulating intact FGF23 owing to mutations that render it resistant to cleavage
ARHR	DMP1 gene Loss of function	Biochemically indistinguishable from TIO	Loss of DMP1 causes impaired osteocyte differentiation and increased production of FGF23
HHRN	SLC34A3 (NaPillc) Loss of function	• Renal phosphate wasting Low Phos, low TmP/GFR • Appropriately elevated $1,25(OH)_2D$ Elevated urine calcium and high-normal serum calcium • PRH is normal or suppressed	Defective renal sodium-dependent phosphate transport owing to loss-of-function mutations in NaPillc results in renal phosphate wasting without defect in $1,25(OH)_2D$ synthesis. Hypophosphatemia stimulated $1,25(OH)_2D$ production with high-normal serum calcium and elevated urine calcium.
OGD	FHFR1 Gain of function	Biochemically indistinguishable from TIO	Increased production of FGF23 by dyplastic bone

Heterozygous, dominant-negative mutations in the renal NaPiIIa gene (*NPT-2*) were identified in two patients with hypophosphatemia secondary to renal phosphate wasting and osteopenia or nephrolithiasis. The prominent symptoms of bone pain and muscle weakness seen in TIO are absent in those with *NPT-2* mutations. Furthermore, the presence of hypercalciuria and elevated calcitriol make these patients easily distinguishable from patients with TIO (Prie *et al.*, 2002). Therefore, either through mutations of the sodium-phosphate transporters themselves as in HHRH, through damage to the proximal renal tubule as in Fanconi's syndrome, or through aberrant regulation via FGF23, decreased expression or function of the renal sodium-phosphate cotransporters likely represent the common pathway in renal phosphate wasting observed in these syndromes (Shimada *et al.*, 2004b; Sitara *et al.*, 2004; Tenenhouse and Sabbagh, 2002).

FGF23, a circulating fibroblast growth factor produced by osteocytes and osteoblasts, has two currently known physiological functions: first, FGF23 promotes

internalization of NaPiIIa and NaPiIIc from the brush-border membrane and thus reduces reabsorption of urinary phosphorus resulting in hypophosphatemia; second, it diminishes mRNA expression of the 25-hydroxy-1α-hydroxylase enzyme that converts vitamin D to its active form, $1,25(OH_2)D_3$, and disrupts the compensatory increase in $1,25(OH_2)D_3$ triggered by hypophosphatemia. In several disorders that result in expansion of abnormal bone, FGF23 is overproduced and results in renal phosphate wasting and hypophosphatemia. Fibrous dysplasia, bone lesions that replace medullary bone with fibrous tissue, are associated with disorders such as McCune–Albright Syndrome, a somatic gene defect that leads to hormone-independent activation of G protein (Gsα) coupled signaling, and a rare form of dwarfism called osteoglophonic dysplasia, owing to activating mutations in FGF receptor 1 (FGFR1) (White *et al.*, 2005). In patients with a high burden of these nonossifying lesions, phosphate wasting and lower-than-expected $1,25(OH)_2D_3$ levels have been observed. FGF23 produced by the abnormal bone is likely responsible, because the degree of fibrous dysplasia is correlated with FGF levels as well as the degree of phosphate wasting (Riminucci *et al.*, 2003; White *et al.*, 2005).

FGF23 excess is central to the pathophysiology of TIO and three genetic disorders of renal phosphate wasting, XLH, ADHR, and ARHR. Biochemically, these disorders are indistinguishable from TIO and one another; it is only through careful assessment of the family history, inheritance pattern, and physical examination that clues to the specific disorders can be garnered. Family history and a thorough chart review to determine the onset of hypophosphatemia help to make the diagnosis, because a prior normal phosphate level decreases the likelihood of a genetic disease, whereas similarly affected family members suggest a genetic cause. Physical findings of rickets, such as lower extremity deformity, suggest the disorder has been present since childhood. A word of caution is in order because the genetic forms of hypophosphatemic rickets have highly variable penetrance and sometimes individuals may not manifest the disorder until adulthood. Furthermore, many times the affected individual represents a *de novo* mutation and there is not family history of hypophophatemic rickets. In general, however, age of onset can be helpful in distinguishing TIO from inherited forms of hypophosphatemic rickets. Most cases of TIO are diagnosed in adults in the sixth decade of life. Another important historical feature is the rate of onset, because rapid onset of symptoms is more characteristic of an acquired disorder such as TIO. However, symptoms of TIO can be present for many years before a diagnosis is made. In fact, the average time to diagnosis is 2.5 years from the onset of symptoms. At the onset of TIO, the symptoms are often vague and ill-defined but over time they crescendo into a severe syndrome of pain, fractures, and myopathy that are typically more extreme than those observed in patients with inherited forms of hypophosphatemic rickets. In cases where it is difficult to distinguish between TIO and inherited forms of hypophosphatemic rickets, genetic testing is available. Single-gene defects have been identified for XLH [PHEX (HYP Consortium, 1995)], ADHR [FGF23 (ADHR Consortium, 2000)], and ARHR [DMP1 (Lorenz-Depiereux *et al.*, 2006a)], and gene tests are commercially available (Table II).

TUMOR IDENTIFICATION

Most tumors responsible for TIO are of mesenchymal origin, and are found in bone or soft tissue (Folpe *et al.*, 2004; Jan de Beur *et al.*, 2002) (see Fig. 1). The most common sites are in the long bones and extremities, but nasopharynx, sinuses, and groin are other locations, which deserve careful scrutiny. They are generally benign and slow growing, but even quite small lesions are capable of causing profound biochemical changes. A helpful classification system divides these tumors into four categories (Weidner and Santa Cruz, 1987), the most common of which is the phosphaturic mesenchymal tumor: mixed connective tissue type (PMTMCT). The others are osteoblastoma-like tumors and ossifying and nonossifying fibrous-like tumors. PMTMCT accounts for up to 80% of the tumors (Weidner and Santa Cruz, 1987). This tumor contains a variety of cells, including spindle cells, which comprise a primitive stroma, and osteoclast-like cells, with prominent blood vessels and a cartilaginous matrix.

Because these mesenchymal tumors are typically small, localization can prove challenging. Plain films and radionuclide bone scanning are generally consistent with osteomalacia, but rarely localize the causative tumor. Whole-body CT or MRI scanning has a low yield but is often the first step. Based on the presence of somatostatin receptors in mesenchymal tumors (Reubi *et al.*, 1996), ^{111}Indium pentreotide, a radio-labeled somatostatin analogue (octreotide scanning), has been used successfully in many patients to localize tumors (Jan de Beur *et al.*, 2002; Seufert *et al.*, 2001) (see Fig. 1). Because a nonfunctional mesenchymal tumor may be identified on such a scan, definitive biochemical evidence for TIO is required before embarking on imaging studies (Jan de Beur and Levine, 2002). Other modalities that have been used successfully to locate tumors in individual patients include MRI (Avila *et al.*, 1996) and 18F fluorodeoxyglucose PET scan (Dupond *et al.*, 2005a, 2005b; Roarke and Nguyen, 2007; Vandergheynst *et al.*, 2006). One group has reported using venous sampling of FGF23 preoperatively to confirm the causal nature of the tumor identified with standard imaging modalities (Takeuchi *et al.*, 2004).

Various malignant neoplasms have also been associated with TIO. These include carcinoma of the prostate (Hosking *et al.*, 1975; Nakahama *et al.*, 1995), breast, lung (Robin *et al.*, 1994;, van Heyningen *et al.*, 1994), as well

as multiple myeloma (Maldonado *et al.*, 1975; Pope and Belchetz, 1993), sarcomas (Cheng *et al.*, 1989; Linovitz *et al.*, 1976), malignant fibrous histiocytoma, and malignant neurinoma (Hauge, 1956). Although these tumors are endodermal and epidermal in origin, many produce fibrous tissue proliferation and osteoblastic lesions, which may be the source of the paraneoplastic syndrome. Interestingly, epidermal nevi and neurofibromatosis can be associated with a pattern of phosphate wasting and aberrant synthesis of $1,25(OH_2)D_3$, perhaps also through changes in the differentiation and behavior of the surrounding stroma (Aschinberg *et al.*, 1977; Goldblum and Headington, 1993; Konishi *et al.*, 1991; Saville *et al.*, 1955).

PATHOPHYSIOLOGY

Tumors causing TIO do so through the secretion of factors that decrease the renal resorption of phosphorus and inhibit the conversion of $25(OH)D_3$ to $1,25(OH)_2D_3$. The presence of humoral mediators, later coined "phophatonin," was suggested initially by the rapid reversal of the syndrome by surgical resection of the associated tumor (McCance, 1947). Subsequent studies demonstrated that transplantation of tumor cells into animals could recapitulate the syndrome (Aschinberg *et al.*, 1977; Miyauchi *et al.*, 1988; Nitzan *et al.*, 1989). Furthermore, media derived from the cultured tumor inhibited phosphate transport in a renal cell line (Cai *et al.*, 1994), but the phosphatonin was not able to be isolated biochemically.

A genetic approach employing differential gene expression profiling of the TIO tumors identified several candidates for "phosphatonin," among them FGF23 (De Beur *et al.*, 2002; Rowe, 2000; Shimada *et al.*, 2001). Contemporaneously, mutations in FGF23 were identified in families with ADHR, an inherited form of hypophosphatemic rickets biochemically similar to TIO (ADHR Consortium, 2000). In ADHR, mutations at arginine residues 176 or 179 that reside in a subtilisin-like proprotein convertase recognition site render FGF23 resistant to cleavage and degradation, thus prolonging its biological activity (Bai *et al.*, 2003; Shimada *et al.*, 2002; White *et al.*, 2001a).

That FGF23 excess is a powerful mediator of TIO, and perhaps the predominant one, is supported by abundant evidence. When injected into mice, FGF23 reduces serum phosphate and increases fractional excretion of phosphorus (Shimada *et al.*, 2001, 2002). Mice chronically exposed to FGF23-transfected Chinese hamster ovary (CHO) cell xenografts become hypophosphatemic with increased renal phosphate clearance, show reduced bone mineralization, and have reduced expression of renal 25-hydroxyvitaminD-1α-hydroxylase with decreased circulating levels of calcitriol (Shimada *et al.*, 2001). The biochemical and skeletal abnormalities of transgenic mice that overexpress FGF23 mimic human TIO (Larsson *et al.*, 2004; Shimada *et al.*, 2004b). This suggests that FGF23 is an upstream regulator of phosphate homeostasis, able to control both renal and $1,25(OH)_2D_3$ activity to decrease phosphorus levels. In humans, FGF23 is highly expressed in many tumors associated with TIO by both mRNA and immunohistochemical evaluation (Bowe *et al.*, 2001; De Beur *et al.*, 2002; Shimada *et al.*, 2001; White *et al.*, 2001b). FGF23 is measurable in serum and is elevated in most patients with TIO (Jonsson *et al.*, 2003; Yamazaki *et al.*, 2002). Furthermore, circulating FGF23 plummets after successful surgical removal of the causative tumor.

FGF23 excess results in renal phosphate wasting in several disorders associated with dysplastic bone and fibrous cells. In patients with fibrous dysplasia, FGF23 levels correlate with the degree of phosphate wasting and the response of the dysplasia to bisphosphonate therapy was correlated with a reduction in the FGF23 levels (Riminucci *et al.*, 2003). In a study of osteoglophonic dysplasia (OD), where the underlying defect is an activating mutation of the FGFR1, one patient had normal phosphate homeostasis, normal FGF23 levels, and a low burden of cystic bone lesions. In contrast, another patient with OD and a large burden of nonossifying bone lesions exhibited phosphate wasting and an elevated serum FGF23 (White *et al.*, 2005). Thus, overproduction of FGF23 by dysplastic bone or fibrous cells appears to be a critical step in a common pathway for many of the acquired forms of renal phosphate wasting.

Genetic disorders that cause FGF23 deficiency present with an opposite phenotype to TIO. Mice lacking *Ffg23* develop hyperphosphatemia and elevated $1,25(OH)_2D_3$ (Shimada *et al.*, 2004a) and appear similar to humans with familial tumoral calcinosis. Familial tumoral calcinosis (FTC) is a human disorder associated with hyperphosphatemia, elevated $1,25(OH)_2D_3$, hypercalcemia, and ectopic calcification. Initially, loss-of-function mutations in the gene that encodes GALNT3, a protein involved in O-linked glycosylation, were identified in several families with tumoral calcinosis (Campagnoli *et al.*, 2006; Ichikawa *et al.*, 2005; Specktor *et al.*, 2006; Topaz *et al.*, 2004). This was puzzling as inactivating mutations in *FGF23* were hypothesized to be the molecular defect in FTC. Subsequently, families with loss-of-function mutations in *FGF23* itself were recognized (Araya *et al.*, 2005; Benet-Pages *et al.*, 2005; Chefetz *et al.*, 2005; Larsson *et al.*, 2005). Further investigation revealed that GALNT3 glycosylates threonine 178 in FGF23. This residue resides in the region that is cleaved to inactivate FGF23 (and the site of activating mutations in ADHR). Glycosylation protects FGF23 from degradation and defective or absent glycosylation renders FGF23 vulnerable to cleavage and inactivation (Kato *et al.*, 2006). Similarly, a mutation in the gene encoding KLOTHO, a matrix molecule that acts as a cofactor/coreceptor for FGF23 and enhances binding to FGFR1c (Kurosu *et al.*, 2006; Urakawa *et al.*, 2006), was recently identified in a patient with tumor calcinosis (Ichikawa *et al.*, 2007). Therefore, loss of function of FGF23, either directly through inappropriate glycosylation

or loss of its signaling cofactor, results in tumoral calcinosis with its disordered phosphate and vitamin D homeostasis. Again, the centrality of FGF23 in disorders of hypo- and hyperphosphatemia make a compelling argument for FGF23 as an important physiological regulator of phosphate and vitamin D homeostasis.

Although FGF23 appears to be the predominant mediator of TIO, several other proteins are highly expressed in tumors associated with TIO. Matrix extracellular phosphoglycoprotein (MEPE) (De Beur *et al.*, 2002; Rowe *et al.*, 2000, 2004; Shimada *et al.*, 2001) is a matrix protein that contains several functional domains involved in bone mineralization, which may act opposite to each other depending on the cleavage products generated (reviewed in White *et al.*, 2006). One important domain, ASARM (acidic serine-aspartate-rich MEPE-associated motif), is released by cathepsisn C-mediated cleaveage (Guo *et al.*, 2002). Loss of this peptide in the presence of mutant enzyme is thought to cause ectopic calcification (Toomes *et al.*, 1999) and pharmacological administration can impair mineralization (Rowe *et al.*, 2004). Thus cleavage of MEPE to ASARM appears to act to inhibit matrix formation. However, in healthy humans, levels of MEPE appear to be positively correlated with bone density (Jain *et al.*, 2004). This effect may be because of a second domain of MEPE, called AC-100, which has been shown to increase bone formation (Hayashibara *et al.*, 2004).

Whether MEPE plays direct a role in the production of TIO is not clear. MEPE can inhibit phosphate resorption *in vitro* and *in vivo*; however, in these animals low serum phosphorus was associated with an appropriate increase in $1,25(OH)_2D_3$ levels (Rowe *et al.*, 2004). Furthermore, CHO cells overexpressing MEPE did not cause TIO when implanted in nude mice (Shimada *et al.*, 2001) and MEPE null mice have normal phosphate and vitamin D status (Gowen *et al.*, 2003). Thus, increased MEPE expression in TIO may be an appropriate response of bone to low serum phosphorus, inhibiting mineralization in the absence of substrate. PHEX, the enzyme that is defective in XLH, may interact with MEPE, preventing cleavage and subsequent release of the ASARM fragment (Guo *et al.*, 2002). PHEX may, therefore, promote bone mineralization by keeping both FGF23 and MEPE suppressed. However, conflicting data about the role of MEPE in XLH stem from studies in deletion of MEPE in *hyp* mice (mouse model of XLH) do not supprot rescue of the *hyp* phenotype (Liu *et al.*, 2005). These observations suggest that MEPE is not directly responsible for renal phosphate wasting or aberrant vitamin D metabolism in XLH.

Secreted frizzled related protein 4 (sFRP4) is another highly expressed protein in TIO. sFRP4 is a secreted inhibitor of Wnt signaling. Wnt signal is important in human bone formation and bone mass accrual, suggesting that modulation of Wnt signaling may be important in regulating determinants of bone mass including some aspects of mineral ion homeostasis. Several lines of evidence suggest that sFRP4 has phosphaturic properties. sFRP4 inhibits phosphate transport in cultured renal epithelial cells (Berndt *et al.*, 2003), it reduces fractional excretion of phosphorus when infused into mice and rats, and with longer-term exposure, sFRP4 produces hypophosphatemia with blunting of the compensatory increase in 25-hydroxyvitamin D-1α-hydroxylase expression induced by hypophosphatemia (Berndt *et al.*, 2003).

Similarly, FGF7 is differentially overexpressed in TIO and conditioned media from culture tumor cells inhibited phosphate reabsorption in a renal cell line (Carpenter *et al.*, 2005). Furthermore, this activity was neutralized by an FGF7 antibody. However, the effect on vitamin D metabolism in these experiments was equivocal, leaving unresolved whether FGF7 alone could mediate all aspects of TIO.

Patients with XLH exhibit the same renal phosphate wasting and abnormal vitamin D metabolism as those with TIO. Yet, the genetic defect is not in FGF23 but is caused by loss-of-function mutations in a metalloprotease PHEX (Francis *et al.*, 1997; HYP Consortium, 1995; Sabbagh *et al.*, 2003). Although PHEX does not appear to cleave FGF23 directly (Benet-Pages *et al.*, 2004; Guo *et al.*, 2001; Liu *et al.*, 2003), serum FGF23 levels are elevated in many XLH patients (Jonsson *et al.*, 2003; Weber *et al.*, 2003; Yamazaki *et al.*, 2002) and FGF23 expression is increased in the bones of *hyp* mice (Liu *et al.*, 2003). These observations suggest that PHEX is involved in downregulation and control of FGF23; however, the precise interplay between FGF23 and PHEX is not currently understood.

The genetic defect in the third form of hypophosphatemic rickets, autosomal recessive hypophosphatemic rickets (ARHR), was identified as loss-of-function mutations in Dentin Matrix Protein 1 (DMP-1), a matrix protein related to MEPE and a member of the SIBLING (small integrin-binding ligand N-linked glycoprotein) family (Feng *et al.*, 2006). Interestingly, this protein appears to have two functions, it translocates into the nucleus to regulate gene transcription early in osteocyte proliferation and then, likely in response to calcium fluxes, becomes phosphorylated and is exported to the extracellular matrix to facilitate mineralization by hydroxyapetite (Narayanan *et al.*, 2003) in a process that requires appropriate cleavage of the full-length protein (Tartaix *et al.*, 2004). Loss of DMP-1 function in ARHR leads to modestly and variably increased serum FGF23, dramatically increased expression of FGF23 in bone, defects in osteocyte maturation, and impaired skeletal mineralization (Feng *et al.*, 2003, 2006). It appears that the immature osteocytes overproduce FGF23, which then circulates and acts on the kidney to produce phosphaturia and aberrant vitamin D synthesis.

TREATMENT

TIO is only definitively treated by identification and resection of the causative tumor. Tumor removal results in rapid

reversal of the defects in phosphate homeostasis with eventual remineralization of bones. However, in many cases, either because of the difficulty in localizing the tumor or incomplete tumor resection, medical management is indicated.

Medical therapy is directed at increasing serum phosphorus levels with both direct supplementation and the increase of intestinal absorption and renal reabsorption with calcitriol ($1,25(OH)_2D_3$). Calcitriol and phosphorus may be needed in high doses to maintain fasting phosphorus in the low-normal range. Typically 2 g/day of phosphorus in divided doses with 1–3 μg of calcitriol is used, although in some patients calcitriol alone may be sufficient. Therapeutic efficacy can be monitored through resolution of symptoms, normalized serum phosphorus and alkaline phosphatase, and resolution of secondary hyperparathyroidism. Treatment can improve pain and muscle weakness and lead to healing of osteomalacia (Drezner and Feinglos, 1977).

Urine and serum calcium must be monitored to prevent the hypercalcemia, hypercalciuria, nephrolithiasis, and nephrocalcinosis that can result with calcitriol therapy (Lyles *et al.*, 1985). Autonomous parathyroid function with long-term medical therapy is common (Firth *et al.*, 1985; Olefsky *et al.*, 1972) and thus PTH and renal function should be monitored every three months.

The use of octreotide therapy in refractory cases has been reported with variable success. Because some mesenchymal tumors express somatostatin receptors, therapeutic trials with octreotide have been attempted. Of three patients treated with octreotide, one (Seufert *et al.*, 2001) showed improvement whereas two others did not after 8 weeks of therapy (Jan de Beur and Levine, 2002; Kumar, 2000).

Recently, the calcium-sensing receptor agonist, cinacalcet, has been shown to be an effective adjuvant in the treatment of TIO (Geller *et al.*, 2007). Cinacalcet acts on the calcium-sensing receptor to decrease PTH synthesis and secretion. In the absence of PTH, FGF23 is less phosphaturic. Thus, in a small series, treatment with cinacalcet resulted in increased renal phosphate reabsorption, increased serum phosphorus, and reduced oral phosphate supplementation.

Chapter 72

Osteopetrosis

L. Lyndon Key, Jr.* and William L. Ries
Department of Pediatrics, General Clinical Research Center, Medical University of South Carolina, Charleston, South Carolina

INTRODUCTION

Osteopetrosis results from a reduction in bone resorption relative to bone formation, leading to an accumulation of excessive amounts of bone. The relative decrease in resorption is a consequence of inadequate osteoclastic bone resorption. Karsdal *et al.* (2007) have demonstrated that osteoclasts, although unable to resorb bone owing to an inability to acidify the ruffled border, are still capable of stimulating osteoblastic bone formation. del Fattore *et al*. (2006) examined 49 patients with osteopetrosis. Bone formation was increased beyond a normal level. This suggested that a coupling factor was being produced, increasing osteoblastic bone formation. Although a specific coupling factor(s) has not been defined, Karsdal *et al.* proposed that IGF1, TGF-β, BMP-2, IL-7, and IL-6 could be factors that result in the excessive stimulation. These imbalances lead to a thickening of the cortical region and a decrease in the size of the medullary space in the long bones, with sclerosis of the base of the skull (Elster *et al.*, 1992a,b) and vertebral bodies. There are a number of serious consequences resulting from the excessive accumulation of bone. A reduced marrow space results in decrease in hematopoiesis, even to the point of complete bone marrow failure. Extramedullary hematopoiesis occurs but is unable to compensate for the reduction in medullary blood cell production. A decrease in the caliber of the cranial nerve and vascular canals leads to nerve compression and vascular compromise. Dense, poorly vascularized bones are subject to fracture and, being vascularized, are predisposed to necrosis and infection. An increased risk of morbidity and mortality during anesthesia is present in children with osteopetrosis. The increase risk in children with osteopetrosis is primarily related to airway and respiratory factors; however, anemia, hypocalcemia, and airway reactivity have all been noted during anesthesia for surgical procedures. Anesthesia management needs to consider the high rate of adverse events and to prepare a plan for each patient's needs (Burt *et al*., 1999).

An understanding of osteopetrosis in humans has been intertwined with the description and creation of a variety of animal mutations in osteoclastic function (Seifert *et al.*, 1993). Although the precise genetic defect in most patients remains to be established (one exception being the deficiency in carbonic anhydrase type II Fathallah *et al.*, 1994; Whyte, 1993a), the animal models have contributed substantially to the understanding of osteoclastic function and dysfunction. The osteoclast biology learned from these mutants has led to a variety of treatment strategies that have been used in patients with osteopetrosis. An understanding of the genetic basis of the animal mutations has generated a list of candidate genes that may prove to be the basis for discovering the genetic defects in humans.

CLINICAL DESCRIPTION

Classically, osteopetrosis has been divided into a fatal infantile malignant form, Albers–Schönberg disease, and a milder adult form of osteopetrosis with long-term survival (Grodum *et al.*, 1995; Key, 1987; Shapiro, 1993; Whyte, 1993b). Recently, a variety of intermediate forms have been described. Without knowledge of the genetic defect explaining the osteoclastic dysfunction, it has been difficult to delineate the mechanisms of these different forms (Table I).

Severe

A variety of presentations of osteopetrosis have been seen in infancy. In general, patients have had sporadic forms that appear to have an autosomal recessive inheritance. Although the severe, malignant form predominates, milder forms and autosomal dominant inheritance patterns have also been observed in individuals diagnosed in the neonatal period (Manusov *et al.*, 1993; Whyte, 1993b). In the absence of a known genetic defect in osteoclastic function, histomorphometric and clinical parameters have been established to describe the degree of severity.

TABLE I Genetic Defects Identified in Human and Animal Osteopetrotic Syndromes

		Genetic defects	Animal correlates	Human disease	Mechanism	Function	References
Severe	TCIRG1	T-cell immunoregulatory 1	osteosclerosis mouse	severe infantile malignant	loss of function	encodes a3 subunit of the vacuolar ATPase, proton pump	Kornak *et al.* (2001)
	ClCN-7	chloride channel 7	ClCN-7$^{-/-}$ mouse (*mi/mi* mouse) Mitf	infantile milder bone disease, but neurodegeneration	loss of function	encodes the chloride channel (ClC-7)	Li *et al.* (1999)
	OSTM1	osteopetrosis-associated transmembrane protein 1	gray lethal mouse	severe infantile malignant	loss of function	possible protein degradation decreasing protein transport	Ramirez *et al.* (2004)
Intermediate	ClCN-7	chloride channel 7		(ADO)II	loss of function	encodes the chloride channel CIC	Waguespack *et al.* (2003)
	LRP5	low-density lipoprotein receptor-related protein 5		(ADO)I	gain of function	putatively upregulates an osteoblastic gene function	Van Wesenbeeck *et al.* (2003)
	PLEKHM1	plekstrin homology domain-containing family M (with RUN domain) member 1	incisor absent rat	intermediate osteopetrosis	loss of function	trafficking acidic vesicles in osteoclasts	Van Wesenbeeck *et al.* (2007)
Mild	CA II	carbonic anyhydrase II		mild osteopetrosis with cerebral calcification and RTA	loss of function	proton production	Fathallah *et al.* (1994)

Patients with osteopetrosis presenting at birth or in early infancy are usually referred to as having the severe, malignant form. The implication is that these patients will have severe sequelae and will die during the first decade of life. This has been the justification for using treatment modalities, such as bone marrow transplantation, that carry a high risk of mortality and morbidity (Gerritsen *et al.*, 1994b; Key and Ries 1993; Schroeder *et al.*, 1992). Patients with this form are characterized by a diffusely sclerotic skeleton with little or no bone marrow space evident, even at birth (Fig. 1) (Gerritsen *et al.*, 1994a). In addition, there is evidence of a severe defect in bone resorption, leading to the presence of the "bone-in-bone" appearance on radiographs (Fig. 2) and in cartilaginous islands within mineralized bone on histology (Fig. 3).

However, some patients with this phenotype will not have a fatal outcome. Indeed, up to 30% of patients diagnosed with severe, malignant osteopetrosis are still alive at age 6 years, with rare patients surviving into the second or third decade (Gerritsen *et al.*, 1994a). Although the quality of life is reported to be poor, up to half of the surviving patients, despite a variety of skeletal and neurological impairments, have normal intelligence and are capable of attending school (Charles and Key, 1998).

A subgroup of patients has an extremely malignant form of the disease. In a group of 33 patients reported by Gerritsen *et al.*, eight patients had hematological and visual impairment before 3 months of age (Gerritsen *et al.*, 1994a). All eight of these patients died before the age of 12 months. Hematological impairment before 6 months of life is prognostic of a markedly reduced survival rate; however, visual impairment alone does not correlate with an early fatal outcome.

Cytological evidence of large osteoclasts with increased numbers of nuclei and a markedly increased amount of ruffled border membrane correlates with a poor prognosis for cure with bone marrow transplantation (Schroeder *et al.*, 1992; Shapiro *et al.*, 1988). Although there is no exact explanation for the reduced success in cure by transplantation, the defect in bone resorption in these patients could be explained if the osteoclast itself were normal but some other aspect of the bone rendered it less resorbable. Thus, histological and electron microscopic analysis of osteoclasts is recommended before a transplantation is undertaken.

Another form of osteopetrosis that has not responded to any therapeutic modality is associated with a neurodegenerative disease (Whyte, 1993b). In some patients, a

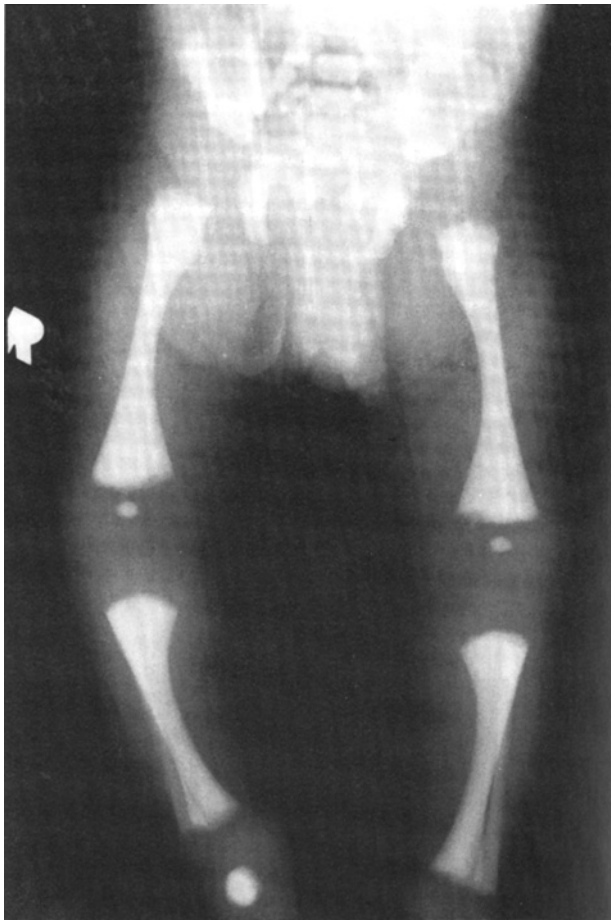

FIGURE 1 The skeleton, both the long bones and the pelvis, is shown to be sclerotic in this radiograph of a 5-day-old infant with anemia and optic nerve compression. Patients with this severe presentation have a 100% chance of death before age 1 year, if untreated. Note that no intramedullary space is seen in the long bones or the pelvis.

neuronal storage disease has been suggested by cytoplasmic inclusions. In most patients, seizures, poor neurological development, abnormalities in the cerebral cortex seen on magnetic resonance imaging, and early development of central apnea characterize this specific presentation. No therapy that has been tried in these patients (bone marrow transplantation, calcitriol, or interferon-γ) has resulted in any significant improvement of the disease. It is likely that even when the bony disease can be reversed (as has occurred by using each of the modalities), the underlying neurological disorder remains unaffected. Death usually occurs before 2 years of age.

Intermediate

The intermediate form of osteopetrosis is frequently "silent" at birth with few or no obvious clinical abnormalities (Key, 1987; Whyte, 1993b). Some cases are diagnosed in infancy, when suspected, suggesting that the defect is present at a subclinical level even from birth. Of interest, the radiographs frequently demonstrate severe manifestation of diffuse sclerotic bone in this form of the disorder, quite similar to those seen in the malignant form (Fig. 4). These patients tend to have fractures toward the end of the first decade and frequently have repetitive fractures with very minor trauma. Infections of the bone can be difficult to eradicate, especially if the mandible is involved. Most patients survive into adulthood. Although anemia and hepatosplenomegaly are rare, at least one patient developed anemia and thrombocytopenia so severe that he was transfusion dependent. His anemia and thrombocytopenia were eliminated by splenectomy.

A subgroup of patients with the intermediate form of osteopetrosis has a carbonic anhydrase II deficiency (Fathal-lah *et al.*, 1994; Whyte, 1993a). These patients have a hyperchloremic metabolic acidosis. Several different mutations have been described in the 50 cases diagnosed. Patients tend to have delayed development with a reduction in intelligence as adults, short stature, fractures, cranial nerve compression, dental malocclusion, and cerebral calcifications. Patients usually have no defects in hematological function and no increased risk of infection.

Transient

Some patients with severe radiographic abnormalities and with anemia have had severely sclerotic bone early, which resolves without specific therapy (Monaghan *et al.*, 1991; Whyte, 1993b; L. L. Key, personal observation). Although long-term follow-up is not available in these patients, no known sequelae resulted from the condition. The patients had no visual impairment, but did have anemia and thrombocytopenia. In one patient (personal experience), there was a history of acetazolamide administration. Whereas osteopetrosis has not been widely associated with acetazolamide administration, the existence of osteopetrosis with naturally occurring mutations in carbonic anhydrase suggests that the therapy may be related to the osteoclastic dysfunction. In both cases, the resolution in the bone disease was apparent early (within 1 month). In addition, patients with other milder sclerosing bony dysplasias are frequently considered to have osteopetrosis in infancy. A classic case is seen in the natural history of severe craniometaphyseal dysplasia where early radiographs are nearly indistinguishable from osteopetrosis (Fig. 5); however, there is no involvement of the vertebral bodies.

ADULT FORMS

In general, patients with the adult forms of the disease have a family history suggesting an autosomal dominant inheritance pattern (Whyte, 1993b). Anemia is not a common manifestation; however, fractures and cranial nerve dysfunction are frequently observed (Bollerslev and Mosekilde, 1993; Bollerslev *et al.*, 1994). When defects have been

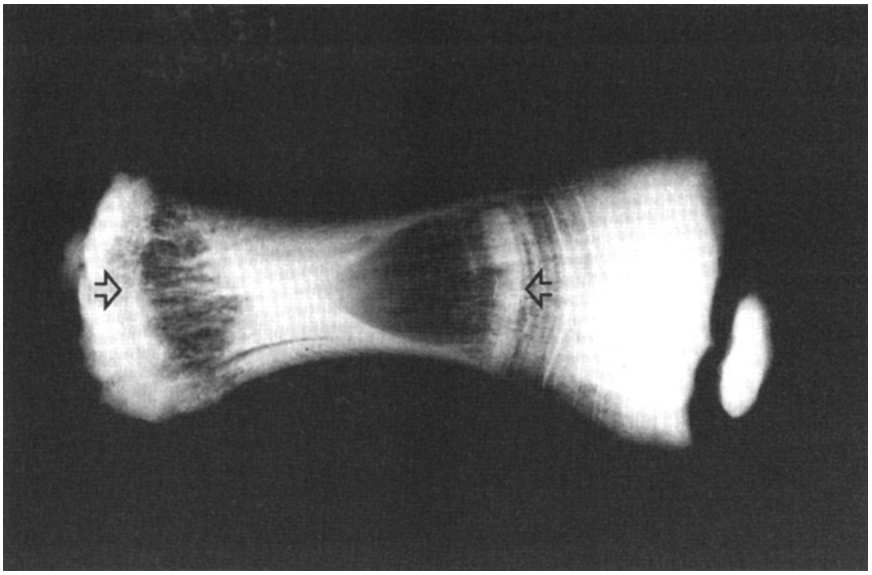

FIGURE 2 This radiograph shows a phalangeal bone, obtained at autopsy from a 7-year-old with malignant osteopetrosis treated with calcitriol. Note the presence of the original bony template (endobone, between the arrows) which was present at birth and never remodeled. The radiograph shows the presence of mineralized bone that has been laid down outside of this original bone/cartilage template without the underlying template having been resorbed.

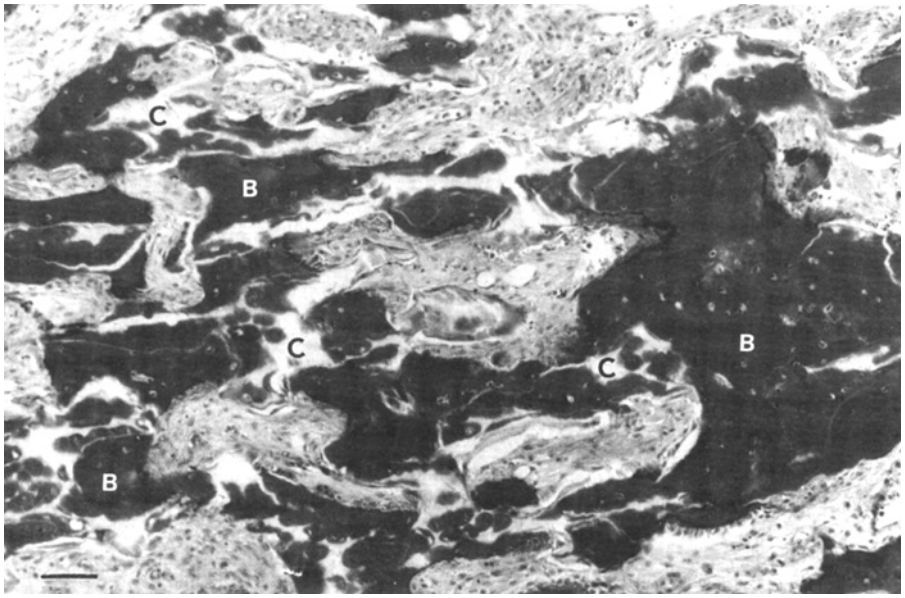

FIGURE 3 The pathognomonic feature of osteopetrosis at the histological level is the presence of unresorbed cartilage (denoted at "C"). Around the cartilage, a highly cellular, embryonic bone (designated as "B") has been laid down. This combination of nonresorbed cartilage and poorly formed bone is the microscopic feature that results in the macroscopic appearance seen in the "bone-in-bone" appearance on radiographs (see Fig. 2). The bar denotes 80.

sought for in infancy, radiographic abnormalities have been found that define the presence of the disease and portend the onset of symptoms in later life.

Severe

We have observed two patients who presented with severe neonatal disease that had a family history suggestive of the presence of an autosomal dominant disorder. In each of these cases, the children were diagnosed with the malignant form of the disease owing to anemia and cranial nerve dysfunction presenting in infancy. In one patient, there was a history of severe infections and failure to thrive. Family members in each case had survived into the fifth and sixth decade (Fig. 6). In each case, the parent transmitting the disease was unaffected.

FIGURE 4 A radiograph of the long bones of a 6-year-old with an intermediate form of osteopetrosis shows the presence of some intramedullary space (denoted as "I"). The deformities of modeling result in bowing and thickening of the shaft and metaphyseal regions of the bone. Note a fracture, which was clinically not apparent, is present in the left tibia (arrow).

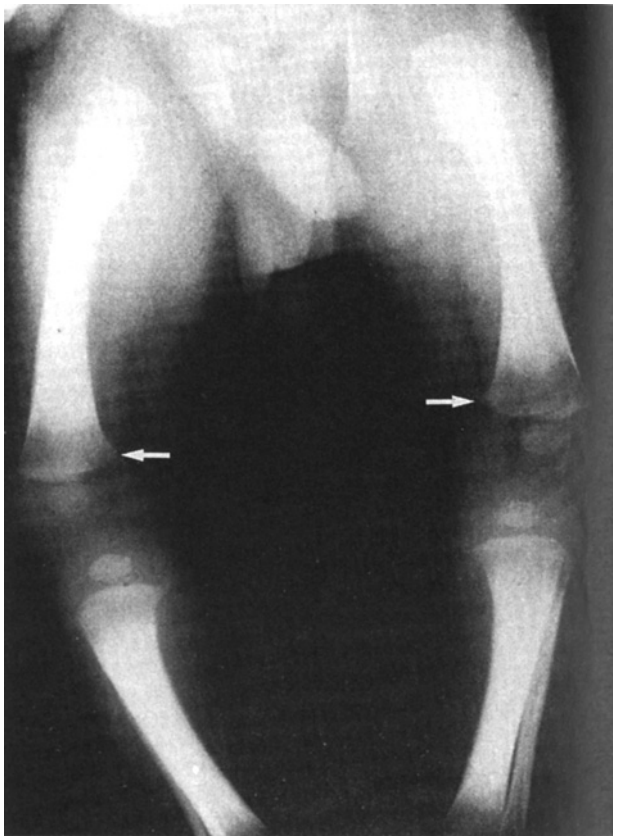

FIGURE 5 This radiograph of a 1 month old with craniometaphyseal dysplasia demonstrates sclerotic long bones with little marrow space seen in the diaphyses. It should be noted that there is already some clearing of the bone in the distal metaphyseal region of both femurs (arrows, which had been sclerotic at birth).

Mild

The "benign" adult form of osteopetrosis is frequently "silent" until later in life (Bollerslev and Mosekidle, 1993; Whyte, 1993b). Two distinct subtypes have been described based on radiographic appearance, symptoms, and biochemical characteristics. Each of these subtypes has been inherited in a variety of kindreds. Each subtype has a distinct natural history, resulting in differing symptomatic presentations. Both types have universally sclerotic bones, primarily involving the axial skeleton. Little or no modeling defects are seen in the long bones. Both types have been observed in some children in the identified families. Approximately 40% of patients with the adult form of osteopetrosis are symptom-free regardless of type. Anemia is rare in either type. Bone pain is common to both types.

Type I is characterized radiographically, by massive sclerosis of the skull with increased thickness of the cranial vault. There is diffusely sclerotic bone in the spine and pelvis. Cranial nerve compression is common in type I. There are few abnormalities seen in the remodeling of bony trabeculae. Indeed, the strength of bone in type I is increased compared with normal. Thus, pathological fractures are rarely observed.

Radiographs from patients with type II disease demonstrate massive sclerosis of the base of the skull, hypersclerotic endplates of the vertebrae resulting in the "rugger jersey" spine, and subcristal sclerotic bands diagnostic of "endobones." Bone turnover is decreased, leading to a reduction in bone tensile strength and resulting in frequent fractures. In type II, creatine phosphokinase, especially the BB isoenzyme, is increased. Histomorphometric analysis shows a defect in trabecular remodeling, resulting in bone that had not been replaced, yielding weakness.

In summary, the adult forms of osteopetrosis are usually diagnosed symptomatically in the second decade. These disorders rarely significantly alter hematopoiesis. Defects in type I disease result in cranial nerve compression, but fractures are rare. In type II disease, fractures are common, but nerve compression is rare.

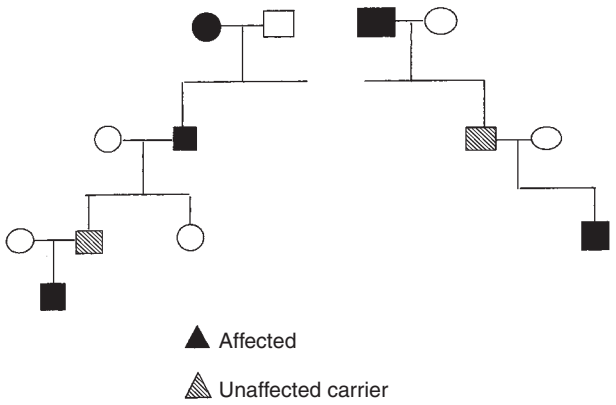

FIGURE 6 This is the family tree of two patients with adult forms of osteopetrosis. The presentation of these patients was severe enough (sclerosis of the long bones in one, anemia, sclerosis of the long bones, and blindness in the second) to result in an initial diagnosis of the severe malignant form.

PATHOPHYSIOLOGY

Osteoclast Dysfunction

Although animal models and a few patients have been found with a profoundly reduced number of osteoclasts, defective function rather than a reduction of formation appears to be the primary pathogenesis (Key and Ries, 1993). This holds true for malignant, intermediate, and benign forms. In the malignant form, there is the possibility of replacing the defective cell and curing the disease with bone marrow transplantation. However, defects in the osteoclasts' environment have also been suspected and may be the explanation for the greater-than-predicted rate of failure in bone marrow transplantation therapy in this disorder (Gerritsen *et al.*, 1994a; Key, 1987). However, to date, no patient has been definitively diagnosed with the one clear-cut stromal defect, a defect in producing macrophage colony-stimulating factor (M-CSF) seen in the *op/op* (osteopetrotic) mouse model (Key *et al.*, 1995a). One patient was reported with a decreased level of M-CSF after a failed transplantation; however, no data were available before the immunomodulation necessary for the transplantation.

A defect in white blood cell and osteoclastic superoxide production has been documented in the majority of patients with osteopetrosis (Key and Ries, 1993). Although the defect in superoxide generation in osteoclasts may represent a more generalized decrease in the ability of the osteoclast to resorb bone, therapy with interferon-γ-1b, designed to increase superoxide production, increases white blood cell superoxide production, thereby reducing infections, and increases bone resorption, enhancing hematopoiesis and enlarging cranial nerve foramina. The result is a reduction in the need for intravenous antibiotics and transfusions and in a deceleration of cranial nerve damage. The net result is an improved survival with reduced morbidity.

Genetic Defects

The search for genetic abnormalities that result in osteopetrosis has recently identified two genetic defects that are related to the osteopetrotic condition. In the first report of a gene localization based on linkage analysis, van Hul *et al.* reported an 8.5-cM region on chromosome 1*p*21 that is associated with the autosomal dominant adult form, type II (van Hul *et al.*, 1997). Although this region was chosen for study because of the presence of the *CSF-1 gene*, a precise defect has not been identified. Indeed, a survey of 20 patients with osteopetrosis found no evidence of defects in the c-*src*, c-*fos*, c-*cbl*, and MITF (human equivalent of the *mi/mi*) genes (Yang *et al.*, 1998).

Two studies have identified precise mutations in a subunit of the V-type H^+-ATPase protein, OC116 (Kornak *et al.*, 2000; Frattini *et al.*, 2000). Numerous genetic defects have been reported (see Table I). All of these patients appear to have a classic severe osteopetrosis with severe osteosclerosis, hematological failure secondary to reduced bone marrow space, and visual impairment in all but one patient. A history of consanguinity was a common theme for four patients.

Functionally, the defect causes the absence of the *a*3-subunit, OC116, of the V-type proton pump that is present along the ruffled border and responsible for acidification next to the bone surface. In the absence of this acidification, calcium cannot be removed from the surface of the bone. Of interest, a knockout animal has been described (Li *et al.*, 1999), providing the first example of an animal model predicting a human osteopetrotic genetic defect (the details of animal model are presented later). This makes the existing animal models even more exciting as a repository of defects that may potentially explain human disease.

ANIMAL MODELS

Classic

A variety of animal models for osteopetrosis have been explored. The M-CSF deficiency in the *op/op* mouse seems to be the most clearly related defect (Begg *et al.*, 1993; Lowe *et al.*, 1993; Marks *et al.*, 1992; Nilsson and Bertoncello, 1994; Philippart *et al.*, 1993; Wiktor-Jedrezejczak *et al.*, 1994); however, replacing the M-CSF with exogenous cytokine does not result in a complete remission (Sundquist *et al.*, 1995). Several possible explanations have been suggested. The timing of the administration may not be the most advantageous (Hofstetter *et al.*, 1995; Lee *et al.*, 1994; Sundquist *et al.*, 1995). Alternatively, there may be other related factors that must interact. One of the most plausible ideas is that, in addition to circulating levels of M-CSF, there is also the need for membrane-bound M-CSF (Stanley *et al.*, 1994) on the osteoblast or embedded in the bone surface (Ohtsuki *et al.*, 1995) to be

presented to the osteoclast or its precursors. A less clear-cut defect, but a role demonstrated for M-CSF therapy in improving the phenotypic abnormalities in the *tl/tl* (toothless) rat (Aharinejad *et al.*, 1995; Marks *et al.*, 1993) has suggested some involvement with the M-CSF production or the M-CSF receptor in the genesis of this mutant phenotype as well. To date the precise defect has not been reported. Thus, animals or humans with few macrophages and osteoclasts may be found to have a defect in M-CSF production or response.

In the *mi/mi* mouse (microphthalmic), there is a defect in the production of a transcription factor (Steingrímsson *et al.*, 1994). This has led to the possibility that a variety of defects, all related to the presence of a defective transcription factor, could exist in the osteoclast and/or in other cells as well. One suggested defect is a decrease in the c-*kit* receptor production, which is necessary for stimulation of tyrosine kinase activity with the stem-cell factor (Ebi *et al.*, 1992). Stem-cell factor and M-CSF activate similar receptor populations, c-*kit* and c-*fims*, which are quite similar in their binding regions. There are also data suggesting that possibly there is a defect in the ability of *mi/mi* stromal cells, failing to support osteoclastic function (Key, 1987) or possibly even inhibiting osteoclastic function *in vitro.*

Both M-CSF and/or interferon-γ have been shown to improve the defect in the *mi/mi* mouse (Key *et al.*, 1995a). Because these cytokines are not deficient in these animals, the studies suggest that these therapies circumvent the specific defects rather than reversing the defects directly. Similar effects of these cytokines have been observed in patients with osteopetrosis where defects are unknown and not directly related to deficiencies in cytokine production or response elements.

Knockout

Perhaps the greatest interest has been in the analysis of man-made knockout mutations that have been found to yield an osteopetrotic phenotype. The effects of a targeted disruption of *Atp6i*, a gene encoding a subunit of the vacuolar pump in the C57BL/6J inbred mouse strain, have been described (Li *et al.*, 1999). The mutant animals resulting from this mutation have extremely dense bones with cartilaginous islands, reduced marrow space (decreased by 80% in the long bones), absent tooth eruption, decreased growth, and severely deformed bones. The condition was lethal in all animals by the fifth week. These animals appear to be quite similar to the patients described with defects in the *TCIRG1* gene of the human vacuolar proton pump described by Frattini *et al.* (2000) and Kornak *et al.* (2000). The results of this animal mutation prove that a defect in the proton pump can cause osteopetrosis, confirming the speculation that the genetic mutations in the vacuolar pump documented in humans is responsible for the associated osteopetrotic phenotype.

The most well studied of these mutants is the c-*src* knockout mutation (Boyce *et al.*, 1993; Lowe *et al.*, 1993). In this mutation, the c-*src* tyrosine kinase is defective and yields a mutant with osteoclasts lacking ruffled borders. This appears to result from the lack of production of phosphorylated proteins necessary to allow fusion of the membrane of endosomes with the cellular membrane within the sealed attachment of the osteoclast to bone. The result is an inactive cell with none of the machinery present at the osteoclast-bone interface necessary to resorb bone. The precise mechanism is not well understood and seems to be more complex than originally thought.

In the c-*fos* knockout mutation (Jacento, 1995; Grigoriadis *et al.*, 1994; Johnson *et al.*, 1992; Wang *et al.*, 1992), there are few mature osteoclasts formed and there is a reduction in the number of osteoclasts and an increase in the number of macrophages. Thus, it appears that c-*fos* is related to the osteoclast lineage's "switch point," which determines whether the progenitor moves in the direction of the osteoclast or the macrophage (Jacento, 1995).

The knockout of PU.1 (Tondravi *et al.*, 1997), an ETS-domain transcription factor essential for the development of myeloid and B-lymphoid cells, is thought to regulate the c-*fms* receptor (receptor for CSF-1). A mutation in this gene results in a nearly complete absence of osteoclasts, resulting in severe osteopetrosis. Bone marrow transplantation with PU.1 competent stem cells rescued the animals, completely reversing the defects. No human correlate has been found. Knocking out the gene for cathepsin K generated an additional osteopetrotic mouse model (Saftig *et al.*, 1998; Gowen *et al.*, 1999). This mutant was found to have dense bones with a reduction in bone marrow space, and extramedullary hematopoiesis. Although these animals shared features of osteopetrosis, it was noted that the defective bone resorption varied from bone to bone. Recently, a similar mutation was identified in humans with pycnodysostosis, a disorder resembling osteopetrosis, but having osteoacrolysis, poor fusion of the sagittal suture, micrognathia, and a predisposition for fracture (Ho *et al.*, 1999). The osteoclastic defect appears to be an inability of the osteoclast to degrade matrix, although removal of calcium appears to be normal. Thus, it is likely that some of the knockout mutations may be genes responsible for other sclerosing bony dysplasias. It appears that mutations resulting in osteopetrosis are those that completely inactivate the osteoclastic bone resorption by either leading to a failure to generate the osteoclast itself or the failure to form the ruffled border. This suggests that there is some redundancy of function in the osteoclast's bone-resorbing process such that knocking out a single enzyme system does not completely inactivate bone resorption.

At the present time, knockout mutations have been much more important in understanding osteoclastic function than in explaining the human osteopetrotic condition. However, these studies do provide a variety of candidate

genes and are beginning to suggest genetic defects that will allow us to diagnose certain types of osteopetrosis.

Avian Osteopetrosis (Increased Osteoblastic Function)

Osteopetrosis has been described in the chicken and appears to result from infection with the avian leukosis virus. This sclerosing condition is characterized by an increase in bone formation by infected osteoblasts (Smith and Ivanyi, 1980) with normal osteoclastic function. Avian osteopetrosis, although similar to the sclerosis seen in a variety of human diseases, has not been shown to occur in humans with one possible exception. In "transient osteopetrosis," Ozsoylu and Besim have suggested that the etiology may be bony sclerosis secondary to excessive osteoblastic function (Ozsoylu and Besim, 1992).

THERAPY OF HUMAN DISEASE

Even with the marked advances in understanding the osteoclastic defects that could result in osteopetrosis, we are still left today with the need to treat somewhat blindly in trying to combat this disorder. Transplantation has been the mainstay of treatment; however, somewhat disappointing results and, at present, the lack of available donors have made it difficult to rely on transplantation as the sole therapy for this disease. Thus, a variety of other therapies have been attempted with some success. Because the mortality associated with failed transplantations is high, other treatment alternatives and/or stopgap measures remain important despite the inability of these therapies to completely cure the condition in most patients. These therapies may be the sole therapy of the patient or may result in a milder course of the disease while awaiting a definitive cure.

Transplantation

Despite the fact that, at present, transplantation is available in only ~50% of children with osteopetrosis and is successful in ~45% of patients who receive grafts; the allure of this therapy is that a successful transplantation yields a nearly complete cure (Gerritsen *et al.*, 1994b). If this cure can be obtained before there are too many physical disabilities, children with osteopetrosis tend to grow and develop normally. In transplantations where the donor graft is harvested from young siblings who have a favorable HLA match, there appears to be 70%, or slightly greater, survival. Despite the fact that not all engraftments are maintained, even the retention of a small number of donor cells seems to correct the defect significantly and stave off recurrence of symptomatic disease. However, beyond this group, the success rate is less favorable. In transplantations where the graft is obtained from HLA haploidentical (mismatched) relatives, the engraftment and survival rates for transplants are only ~15%. Given the natural history of a survival of almost 30% for the malignant form of osteopetrosis as a whole, this is considered by most transplantation experts to be an unacceptable rate of failure. However, it should be noted that in the 15% of patients where transplantations have been successful, cures have been achieved. The great hope for the future is transplants with matched unrelated donors and possibly, cord blood stem cells. (Information on cord blood transplantation in children was communicated personally by M. Klemperer, St. Petersberg, FL.) With the advent of DNA typing to ensure the adequacy of the matches, success rates of = 80% are being achieved in most diseases. However, success rates of only ~40% have been found in osteopetrosis. The exact reason for this discrepancy is not clear at this time. The possibility that cord blood or placental transplants may improve chances for engraftments is just beginning to be explored. Nonetheless, at present, in the absence of a matched sibling donor, survival can be expected to be well below 50%.

Other Therapies

Many families have found that transplantation carries an unacceptable risk, and thus, there has been a search for alternative therapies. The use of high-dose calcitriol has been tried in a large number of children with some period of stabilization, and in some instances, a cure (Key and Ries, 1993; van Lie Peters *et al.*, 1993). Nonetheless, long-term cures have been achieved in 25% of patients treated.

Interferon-γ has been used as a treatment of osteopetrosis (Key *et al.*, 1995b; Kubo *et al.*, 1993). The intent of the therapy was to enhance the production of oxygen radicals by white blood cell phagocytes as a means of fighting off life-threatening infections. In addition, therapy with interferon-γ-1b along with calcitriol increases both bone remodeling and the amount of bone marrow space in patients (Fig. 7 and Fig. 8). To determine whether interferon-γ-1b (1.5 μg/kg/dose subcutaneously, three times per week, Actimmune, Intermune Pharmaceuticals, Inc., Palo Alto, CA) plus calcitriol (1 μg/kg/day orally) or calcitriol alone is effective in delaying the time to treatment failure, 16 patients with congenital osteopetrosis were recruited from all over the world to participate in a randomized, controlled trial. Patients were randomized in a 2:1 ratio onto interferon-γ-1b plus calcitriol or calcitriol alone, respectively. The drug was administered subcutaneously to patients three times a week. The patients receiving interferon-γ-1b plus calcitriol had their first evidence of failure at a mean of 452 days compared with those on calcitriol alone, who failed at 130 days ($P = 0.016$). Only 10% of the patients treated with interferon-γ-1b experienced a serious infection compared with 67% of the patients on

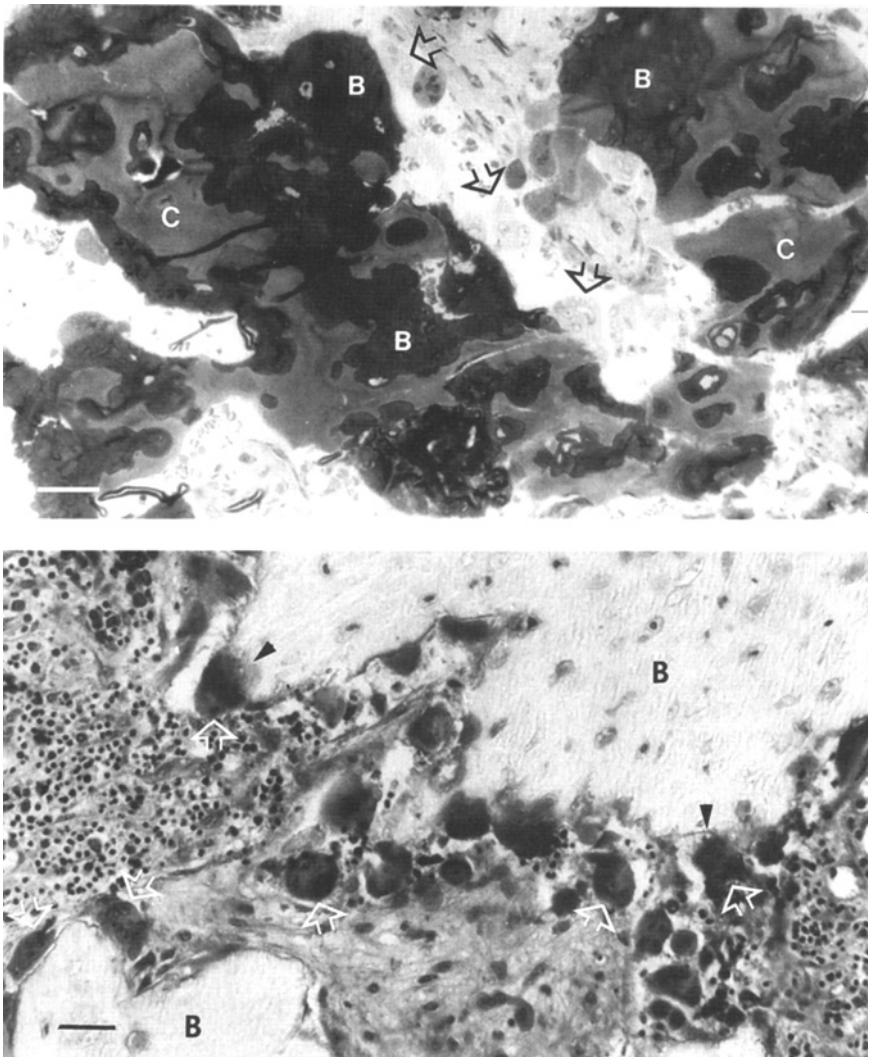

FIGURE 7 Bone biopsies from age 11 and 29 months in a patient with severe infantile osteopetrosis. (*Top*) Contains a 1-μm Epon-embedded section obtained from the patient at 11 months of age, prior to therapy with interferon-γ-1b and calcitriol. Coarse trabecular bone (denoted as "B") with cartilaginous streaks (denoted as "C") is evident. Lacunae are absent even though osteoclasts (arrows) adjoin the bone surface. Bone marrow cells are absent from this section. (*Bottom*) A 5-μm-thick methyl-methacrylate-embedded section obtained by biopsy of the same patient after 18 months of therapy. A combination of mineralized coarse trabecular bone and porous cortical bone (designated by "B") lined with numerous osteoclasts (open arrows) with brush borders and adjoining lacunae (arrowheads) is visible. Islands and streaks of cartilaginous tissue are absent. Bar = 40 μm.

calcitriol alone ($P < 0.0001$). In limited data, biopsies obtained from patients treated with interferon-γ-1b had a 50% reduction in bone mass; while no reduction was seen in one patient treated with calcitriol alone. The size of both the optic nerve foramina and auditory canals increased in subjects treated with interferon-γ-1b, but not in those treated with calcitriol only.

SUMMARY

In summary, significant progress has been made in classifying osteopetrosis. There are at least three major categories (malignant, intermediate, and mild) of the disease with a variety of subtypes. This classification allows prognostic information to be provided to the parent or patient, improving decision making concerning the appropriate therapy. The genetics of osteopetrosis has become clearer with the discovery of the etiology of the autosomal recessive disorders (severe) is related to defects in acid production and possibly, an increased bone formation. A defect in the *osteopetrosis associated transmembrane protein 1*, previously described in the grey lethal mouse (Ramirez *et al.*, 2004) and in human patients with severe infantile osteopetrosis. Additional knowledge has been gained in understanding the milder forms. ADO II, the predominant type of the "Adult" or mild osteopetrosis, appears to be related primarily to chloride channel defects (Waguespack *et al.*, 2003). Cases of intermediate severity

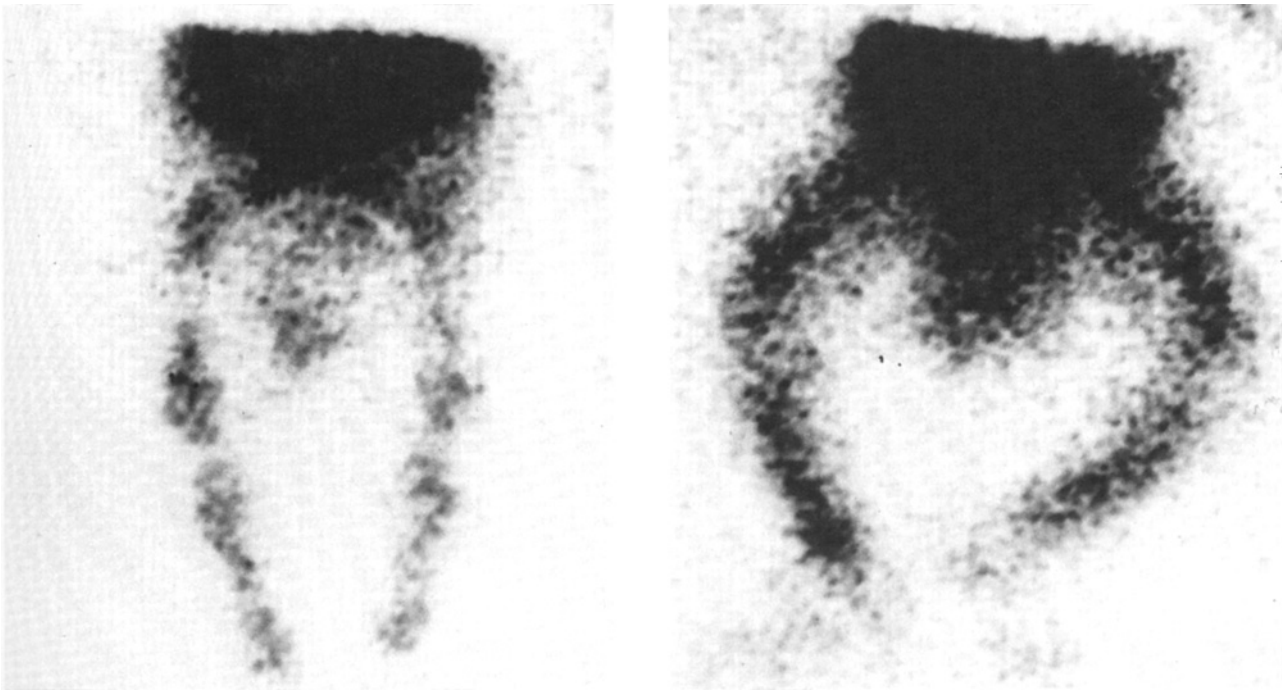

FIGURE 8 f0080^{999}Tc-labeled sulfur colloid bone marrow scans are shown from the same patient whose biopsies are shown in Fig. 7. The initial scan (*left*) shows abnormal uptake of label in the long bones of the lower extremities. Areas with little or no radionuclide are seen in the diaphyses with the uptake of the radionuclide being primarily concentrated to the subepiphyseal regions. (*Right*) After interferon γ-1b therapy, there is an increase in the amount of radionuclide labeling and there are no longer any discreet areas with reduced uptake.

also result from mutations in low-density lipoprotein receptor-related protein 5 (van Wesenbeeck *et al.*, 2003) and Plekstrin Homology Domain-containing Family M 1 (PLEKHM 1) (van Wesenbeeck *et al.*, 2007). Finally, treatment is largely still directed toward enhancing osteoclastic function in general rather than correcting specific defects. Based on the work of Karsdal *et al.* (2007) and del Fattore *et al.* (2006), we speculate that strategies for decreasing bone formation may also improve bone density and severity. Bone marrow transplantation remains the main hope for complete cure. Until now we have focused solely on osteoclastic precursors. Attention should be directed to stromal elements of marrow cells and to osteoblasts to examine the role that osteoblastic bone formation contributes to osteopetrosis. Through this route of investigation, the contribution of bone resorption in creating excessive bone formation can be explored and exploited for a more complete cure. The introduction of calcitriol, M-CSF, and interferon-γ-1b**,** along with inhibitors of bone formation may provide promise for the future survival and hopefully, the cure of osteopetrosis. In an article by Iacobini *et al.* (2001) a patient was treated with prednisone at 2mg/kg/day with apparent resolution of osteopetrosis. This may be similar to the "transient" form of osteopetrosis, but it also could be related to the inhibition of cartilage and bone formation by high-dose steroids (van der Eerden *et al.*, 2007). Thus, treatment with osteoclastic stimulators, such as high-dose calcitriol (1–1.5 μg/kg/day) and prednisone (1–2 mg/kg/day) could provide an excellent regimen. As in the past, this very interesting family of disorders continues to lead the way in developing our understanding of osteoclastic function., and now appears to be important in our understanding of formation–resorption coupling.

Chapter 73

Hypophosphatasia

Nature's Window on Alkaline Phosphatase Function in Humans

Michael P. Whyte*

Center for Metabolic Bone Disease and Molecular Research, Shriners Hospitals for Children, St. Louis, Missouri, and Division of Bone and Mineral Diseases, Washington University School of Medicine at Barnes-Jewish Hospital, St. Louis, Missouri

INTRODUCTION

Alkaline phosphatase (ALP) was discovered by Robert Robison in 1923 (Robison, 1923). From that time, he advanced the hypothesis that this enzyme functions critically in skeletal mineralization, emphasizing the liberation of inorganic phosphate (Pi) for hydroxyapatite crystal formation (Robison, 1932).

Beginning in the 1930s, physicians appreciated that significant clinical insight can come from measuring ALP activity in serum, because elevated levels (hyperphosphatasemia) usually indicate skeletal or hepatobiliary disease (Wolf, 1978). Since then, quantitation of serum ALP activity has been routine in clinical laboratories, and perhaps it is still (McComb *et al.*, 1979) the most frequently performed enzyme assay.

Although we now understand that ALP is ubiquitous throughout Nature (McComb *et al.*, 1979; Harris, 1990; Moss, 1992; Whyte, 1994), there is considerable uncertainty about the physiological function(s) of the four ALP isoenzymes in humans (Millán, 2006). Nevertheless, we have proof of Robison's hypothesis, showing that the "tissue nonspecific" isoenzyme of ALP (TNSALP) is essential for skeletal mineralization. Confirmation came from the discovery (Rathbun, 1948) and subsequent investigation of people with the inborn error of metabolism, "hypophosphatasia" (HPP) (Whyte, 1994, 2001).

As reviewed in this chapter, documentation beginning in 1988 that HPP is caused by loss-of-function mutations in *TNSALP,* the gene that encodes the TNSALP isoenzyme, confirmed Robison's hypothesis. However, the pathogenesis of the defective skeletal mineralization in HPP seems primarily to result from deficient TNSALP hydrolysis of inorganic pyrophosphate (PP_i), an inhibitor of mineralization (Weiss *et al.* 1988a; Whyte, 1994). Following a brief history of the proposed function of ALP in humans, and review of the molecular and biological chemistry of human ALPs, HPP is described in some detail in this chapter, and the insights gained from this "experiment-of-nature" are discussed. Then, refinements concerning the role of TNSALP obtained from knockout mouse studies are summarized (Millán, 2006).

HISTORY AND PROPOSED PHYSIOLOGICAL ROLE OF ALKALINE PHOSPHATASE

In 1923, Robert Robison (Fig. 1) discovered that there was considerable phosphatase activity in the bone and cartilage of growing rats and rabbits (especially those with rickets) and suggested that this new enzyme might act in skeletal mineralization by hydrolyzing hexosephosphoric esters to increase local concentrations of P_i (Robison, 1923). In 1924, with K. Soames, Robison reported that this phosphatase precipitated mineral into rachitic rat bone when monophosphate esters were the only source of P_i, and demonstrated that the enzyme had a distinctly alkaline pH optimum *in vitro* (Robison and Soames, 1924). However, Robison knew the apparent pH optimum for ALP in his laboratory was not physiological, and never referred to his discovery as "alkaline phosphatase" (Robison, 1932); the term was introduced by others (McComb *et al.*, 1979). Robison called the enzyme "bone phosphatase" (Robison, 1932). Soon after the identification and early characterization of ALP, evidence emerged that questioned Robison's hypothesis (McComb *et al.*, 1979). ALP was found to be abundant in tissues that normally do not calcify (e.g., liver, intestine, and placenta). Furthermore, extracellular fluids were supersaturated with calcium and P_i, and Robison had not isolated the enzyme's physiological substrate(s) (Neuman and Neuman, 1957). Instead, other biological purposes for ALP were proposed (see later).

TABLE I Suggested Roles for ALP in Skeletal Mineralization

Locally increase P_i levels
Destruction of inhibitors of hydroxyapatite crystal growth
Transport of P_i
Ca^{2+}-binding protein (Ca^{2+} uptake by cells)
Ca^{2+}/Mg^{2+}-ATPase
Tyrosine-specific phosphoprotein phosphatase

Reproduced with permission from M. P. Whyte (1989). In "Bone and Mineral Research" (W. A. Peck, ed.), Vol. 6, pp. 175–218. Elsevier Science Publishers BV (Biomedical Division), Amsterdam.

By the end of the 1960s, however, electron microscopy helped rejuvenate Robison's hypothesis when the earliest site of hydroxyapatite crystal deposition in the skeleton was discovered by H. C. Anderson to be unique, extracellular structures he called "matrix vesicles" (MVs) (Anderson, 1969). MVs seem to be buds of the plasma membrane of chondrocytes and osteoblasts, and are especially rich in ALP (Ali, 1986). They possess many enzyme activities [including inorganic pyrophosphatase (PP_i-ase) and ATPase], as well as phospholipids, polysaccharides, and glycolipids (Anderson, 1992). During the earliest ("primary") phase of skeletal mineralization, hydroxyapatite crystals appear and then grow within MVs. When the MV ruptures, extravesicular ("secondary") mineralization proceeds as hydroxyapatite crystal propagation continues with their eventual deposition into skeletal matrix (Ornoy *et al.*, 1985). In 1975, nucleoside phosphate (released by dying cells) was proposed as the substrate source for P_i necessary to fulfill Robison's hypothesis (Majeska and Wuthier, 1975).

Further evidence that ALP functions in skeletal mineralization emerged from studies using stereospecific inhibitors of ALP activity, such as L-tetramisole, which block calcification i*n vitro* (Fallon *et al.*, 1980). However, the noninhibitory stereoisomers were later shown to also impair mineralization (Whyte, 1994).

By the 1990s, the proposed biological roles for ALP were many (McComb *et al.*, 1979; Harris, 1990; Moss, 1992; Whyte, 1989, 1994) and included hydrolysis of P_i esters to provide the non-P_i moiety, transferase action for the synthesis of P_i esters, regulation of P_i metabolism, maintenance of steady-state levels of phosphoryl metabolites, and action as a phosphoprotein phosphatase (McComb *et al.*, 1979; Alpers *et al.*, 1990; Harris, 1990; Muller *et al.*, 1991; Simko, 1991; Moss, 1992; Whyte, 1994). At cell membranes, ALP perhaps conditioned the active transport of P_i, but also calcium, fat, protein, carbohydrate, and Na^+/K^+(Muller *et al.*, 1991; Simko, 1991). Sequence analyses of ALPs suggested they coupled to other proteins, including collagen (Wu *et al.*, 1992) (see later). In the placenta, ALP was found to bind the Fc receptor of IgG where perhaps it transcytosed this immunoglobulin (Makiya *et al.*, 1992). During embryogenesis, ALP seemed to act intracellularly (Narisawa *et al.*, 1992), although we now know that ALP functions primarily on cell surfaces (see below).

Additional proposals had emerged for an ALP role in skeletal mineralization (Table I) (Whyte, 1989, 1994). Perhaps ALP was a plasma membrane transporter for P_i (Wuthier and Register, 1985), an extracellular Ca^{2+}-binding protein that stimulates calcium-P_i precipitation and orients mineral deposition into osteoid (DeBarnard *et al.*, 1986), a Ca^{2+}/Mg^{2+}-ATPase (Birge and Gilbert, 1974), or a phosphoprotein phosphatase that conditions skeletal matrix for ossification (Lau *et al.*, 1985; Tsonis *et al.*, 1988). Furthermore, it was possible that certain structural domains enabled ALP to bind to types I, II, and X collagen in cartilage and bone (Tsonis *et al.*, 1988; Wu *et al.*, 1992). However, an early theory gained preeminence; i.e., ALP hydrolyzes an inhibitor of calcification (Neuman and Neuman, 1957; Caswell *et al.*, 1991; Moss, 1992; Whyte, 1994; Millán, 2006). The principal candidate for such inhibition was inorganic

pyrophosphate (PP_i). High concentrations of PP_i impair hydroxyapatite crystal growth, and ALP can hydrolyze PP_i (Moss *et al.*, 1967). In fact (see later), plasma and urine levels of PP_i are increased in HPP (Russell, 1965; Russell *et al.*, 1971).

Ironically, approaching almost a century after its discovery, current methods used to assay ALP activity do not capture Robison's understanding of the physiological role of this enzyme (McComb *et al.*, 1979; Harris, 1990; Moss, 1992; Whyte, 1994; Coburn *et al.*, 1998). In both clinical and research laboratories, to maximize catalytic activity, ALP continues to be measured using distinctly nonphysiological alkalinity (e.g., pH 9.2 to 10.5) and high concentrations (millimolar) of artificial substrates whose products can be detected colormetrically (e.g., *p*-nitrophenylphosphate) (McComb *et al.*, 1979). Furthermore, biological specimens for analysis are diluted into buffers without P_i, although P_i competitively inhibits ALP (Coburn *et al.*, 1998). These assays were devised especially for their utility in clinical medicine (Wolf, 1978), yet it has been known for decades that the pH optimum for ALP is considerably less alkaline for lower concentrations of potential physiological substrates, although hydrolytic rates are reduced (McComb *et al.*, 1979; Moss, 1992). Until the discovery of several natural substrates for TNSALP in studies of HPP, the significance of this observation was unknown (McComb *et al.*, 1979; Harris, 1990; Moss, 1992; Whyte, 1994).

To understand HPP and to appreciate how this disorder teaches us about ALP, it is first necessary to briefly review ALP genomic structure and protein chemistry.

GENOMIC STRUCTURE AND PROTEIN CHEMISTRY OF ALKALINE PHOSPHATASE

ALP (orthophosphoric-monoester phosphohydrolase, alkaline optimum, EC 3.1.3.1) is found throughout Nature in plants and animals (McComb *et al.*, 1979). In humans, four ALP isoenzymes are encoded by four separate genes (Millán, 1988, 2006; Harris, 1990; Moss, 1992). Three of the isoenzymes are expressed in essentially a tissue-specific distribution and are called intestinal, placental, and germ-cell (placental-like) ALP. The fourth ALP isoenzyme is ubiquitous in the body, and therefore designated tissue-nonspecific ALP (TNSALP) (Stigbrand and Fishman, 1984; Harris, 1990; Moss, 1992). Hepatic, skeletal, and renal tissue is especially rich in TNSALP. The gene mapping symbol for TNSALP is *ALPL* ("ALP-liver"), although the function of the bone, but not liver, isoform is known (see later). The distinctive physicochemical properties (e.g., heat stability, electrophoretic mobility, etc.) among the ALPs purified from human liver, bone, and kidney are lost upon exposure to glycosidases (Moss and Whitaker, 1985). In fact, the TNSALPs are a family of "secondary" isoenzymes (isoforms) with the identical polypeptide sequence encoded by the same gene, and differ only by post-translational modifications involving carbohydrates (Harris, 1980).

The TNSALP gene is located near the tip of the short arm of chromosome 1 (1*p*36.1–*p*34), whereas the genes for intestinal, placental, and germ-cell ALP are at the tip of the long arm of chromosome 2 (2*q*34–*q*37) (Harris, 1990; Millán, 2006). *TNSALP* seems to represent the ancestral gene, whereas the tissue-specific ALPs were likely formed by gene duplication (Harris, 1990).

TNSALP is somewhat larger than 50 kb and contains 12 exons, 11 of which are translated to form the mature enzyme consisting of 507 amino acid residues (Weiss *et al.*, 1988b). TATA and Sp1 sequences may be regulatory elements, but basal expression seems to reflect "housekeeping" promoter effects, whereas differential expression in various tissues may be mediated by a post-transcriptional mechanism (Kiledjian and Kadesch, 1990); the 5′-untranslated region differs between bone and liver TNSALP (Nosjean *et al.*, 1997). *TNSALP* has two promoters and two corresponding 5′ noncoding exons, 1a and 1b. Expression from each promoter results in the use of either exon 1a or 1b, resulting in two different mRNAs with differing 5′-untranslated regions. Transcription from the upstream promoter (1a) is preferentially used in osteoblasts, whereas the downstream promoter (1b) is preferentially used in liver and kidney (Millán, 2006).

The tissue-specific ALP genes are smaller than *TNSALP*, primarily owing to shorter introns. Amino acid sequences deduced from their cDNAs suggest 87% positional identity between placental and intestinal ALP, but only 50% to 60% identity between the tissue-specific ALPs and TNSALP (Harris, 1990).

The cDNA sequence of TNSALP reveals five potential N-linked glycosylation sites (Weiss *et al.*, 1988). *N*-Glycosylation is necessary for catalytic activity. *O*-Glycosylation characterizes the bone, but not the liver, isoform (Nosjean *et al.*, 1997).

In 2000, the crystal structure for human placental ALP was detailed at 1.8-Å resolution (Le Due *et al.*, 2000). The active site of TNSALP would be encoded by six exons, comprising 15 amino acid residues (Zurutuza *et al.*, 1999), and feature a nucleotide sequence conserved in ALPs throughout nature (Henthorn and Whyte, 1992).

The ALPs are Zn^{2+}-metalloenzymes (McComb *et al.*, 1979). Catalytic activity requires a multimeric configuration of identical subunits with each monomer having one active site and two Zn^{2+} atoms that stabilize the tertiary structure (Kim and Wycoff, 1991).

The ALPs are generally considered homodimeric in the circulation (McComb *et al.*, 1979). TNSALP, in symmetrical dimeric form, has $\alpha\beta$ topology for each subunit with a ten-stranded β-sheet at its center (Hoylaerts and Millán, 1991). However, in tissues, ALPs are tethered (see later)

to cell surfaces, probably as homotetramers (Fedde *et al.*, 1988).

ALPs exhibit broad substrate specificities and pH optima *in vitro* depending on the type and concentration of phosphocompound undergoing catalysis (McComb *et al.*, 1979). Catalytic activity requires Mg^{2+} as a cofactor (McComb *et al.*, 1979). PP_i as well as phosphoesters can be hydrolyzed (Xu *et al.*, 1991). The reaction involves phosphorylation-dephosphorylation of a serine residue. Dissociation of the covalently linked P_i seems to be the rate-limiting step. In fact, P_i is a potent competitive inhibitor of ALP (McComb *et al.*, 1979; Kim and Wyckoff, 1991; Coburn *et al.*, 1998). However, P_i may stabilize the enzyme (Farley, 1991).

Uncertainties remain about the biosynthesis of ALP in higher organisms. Analysis of the gene sequences of the human ALP isoenzymes indicates that the nascent polypeptides have a short signal sequence of 17 to 21 amino acid residues (Harris, 1990), and a hydrophobic domain at their carboxyl terminus (Weiss *et al.*, 1988b). ALPs link to the plasma membrane surface, tethered to the polar head group of a phosphatidylinositol-glycan moiety (Whyte *et al.*, 1988; Whyte, 1994). They can be released by phosphatidylinositol-specific phospholipase (Fedde *et al.*, 1988). However, the precise interaction with phosphatidylinositol may differ among the ALP isoenzymes (Seetharam *et al.*, 1987). Intracellular degradation of ALPs can involve proteosomes (Cai *et al.*, 1998).

Lipid-free ALP is the moiety normally found in the circulation. Yet, the mechanism(s) for ALP release from cell surfaces is not known. The process could involve a phosphatidase of the C or D type, detergent action, proteolysis, membrane fractionation, or lipolysis (Alpers *et al.*, 1990).

In healthy men and women, nearly all ALP in serum or plasma consists of approximately equal amounts of the bone and liver isoforms of TNSALP (Millán *et al.*, 1980). Infants and children, and particularly newborns and adolescents, have higher circulating levels of the bone isoform (McComb *et al.*, 1979). Some individuals (with B and O blood types who are "secretors") increase intestinal ALP in the circulation after ingesting a fatty meal (Langman *et al.*, 1966; McComb *et al.*, 1979). Intestinal ALP usually contributes just a few percent to serum total ALP levels (maximum 20%) (McComb *et al.*, 1979; Mulivor *et al.*, 1985). Placental ALP is typically expressed only during the last trimester of pregnancy (Birkett *et al.*, 1966). Various cancers, however, release placental or germ-cell ("placental-like") ALP (Millán, 1988) into the blood. Clearance of circulating ALP, as for many other glycoproteins, is probably caused by uptake and degradation by the liver (Young *et al.*, 1984).

HYPOPHOSPHATASIA

Subnormal extracellular levels of calcium and P_i, or P_i alone, cause nearly all forms of rickets or osteomalacia (Whyte, 2002). HPP is a remarkably instructive exception. In HPP, circulating levels of calcium and P_i are usually normal or elevated, yet the skeleton does not mineralize properly (Whyte, 1994, 2001). HPP has been "Nature's window" for understanding the physiological role of TNSALP in humans. With the discovery, beginning in 1988 (Weiss *et al.*, 1988a), of loss-of-function mutations in TNSALP in HPP, Robison's hypothesis that ALP acts in biomineralization was confirmed. Additionally, this observation revealed that TNSALP was necessary for the development of primary teeth (Whyte, 1994). However, undisturbed function in HPP of other organs/tissues, especially the liver, questioned the biological significance for TNSALP elsewhere (Whyte, 1994, 2001).

History

John C. Rathbun (Fig. 2), a Canadian pediatrician, coined the term "hypophosphatasia" in 1948 when he reported an infant boy who died of seemingly acquired rickets complicated by epilepsy whose ALP activity in serum, bone, and other tissues was paradoxically subnormal (Rathbun, 1948). Approximately 300 cases of HPP have now been described in the medical literature (Whyte, 1994, 2001). A PubMed (http://www.ncbi.nlm.nih.gov/sites/entrez/) search from 1955 onward shows 417 articles where

FIGURE 2 John C. Rathbun, M.D. (1915–1972) who characterized hypophosphatasia in 1948.

"hypophosphatasia" is in the title, and 648 where it appears in the text.

Discussed in detail subsequently, our understanding of both the metabolic basis for HPP and the physiological function of TNSALP were advanced by the discoveries of elevated levels of three phosphocompounds in affected individuals. In 1955, in the era of paper chromatography to diagnose inborn errors of metabolism, identification of increased amounts of phosphoethanolamine (PEA) in urine provided a second biochemical marker for HPP in addition to hypophosphatasemia (Fraser *et al.*, 1955; McCance *et al.*, 1955). In 1965 and 1971, respectively, discovery of elevated levels of PP_i in the urine (Russell, 1965) and plasma (Russell *et al.*, 1971) of HPP patients would reveal the mechanism for the characteristic defective skeletal mineralization, because PP_i was increasingly documented to inhibit this process (Heinonen, 2001). In 1985, identification of high plasma concentrations of pyridoxal 5′-phosphate (PLP) in HPP, together with understanding of vitamin B_6 metabolism, revealed an ectoenzyme function for TNSALP, and explained how these three phosphocompounds could accumulate extracellularly in this "inborn-error-of-metabolism" (Whyte *et al.*, 1985).

Clinical Features

Hypophosphatasia (OMIM numbers 146300, 171760, 241500, and 241510) has been reported throughout the world and seems to affect all races (Whyte *et al.*, 2006). However, it is especially prevalent in Mennonites in Manitoba, Canada, where about 1 in 25 individuals is a carrier, and 1:2500 newborns manifests severe disease (Greenberg *et al.*, 1993). Canadian Hutterites also manifest a relatively high prevalence of HPP. In Toronto, Canada, the incidence for severe forms of HPP was estimated in 1957 to be 1 per 100,000 live births (Fraser, 1957). Conversely, HPP seems to be particularly rare in people of black ancestry in the United States (Whyte *et al.*, 2006).

Despite relatively high levels of TNSALP in bone, cartilage, liver, kidney, and adrenal tissue (and at least some TNSALP ubiquitously) in healthy individuals (McComb *et al.*, 1979), HPP seems to directly disrupt only the formation of the skeleton and dentition (Whyte, 2001). Discussed later, vitamin B_6-dependent seizures are a further metabolic consequence of severe HPP (Baumgartner-Sigl *et al.*, 2007).

One of the most remarkable features of HPP is the extraordinarily wide-ranging expressivity of the disease, spanning from death *in utero* with nearly an unmineralized skeleton to early shedding of "baby teeth" without skeletal disturbances (Fraser, 1957; Whyte, 2001). In fact, some individuals with the biochemical characteristics of HPP and one defective *TNSALP* allele, seem to escape symptoms or complications and can be considered "carriers" (Whyte *et al.*, 1982a).

Many (≈200) different deactivating mutations in *TNSALP,* usually transmitted in various combinations to compound heterozygotes by autosomal recessive inheritance (see later), have been documented in HPP (Weiss *et al.*, 1988; Henthorn *et al.*, 1992; Mornet *et al.*, 1998; Whyte, 2000; Mumm *et al.*, 2002). Understandably, therefore, a TNSALP mutation-based nosology for clinical characterization and prognostication would be extremely challenging, especially for severe instances of this rare disorder (Whyte, 2001). Furthermore, it is increasingly apparent that other genetic and nongenetic factors can significantly condition HPP expressivity. This fact is illustrated by the variable HPP severity and complications noted among siblings sharing identical TNSALP defects (Henthorn *et al.*, 1992; Whyte *et al.*, 2006; Mumm *et al.*, 2006) (Fig. 3). Accordingly, the prevailing classification scheme for patients (Whyte, 2001) remains a clinical one based on the proposals of Fraser in 1957 (Fraser, 1957).

FIGURE 3 Variable clinical expressivity of hypophosphatasia is exemplified by these sisters who are compound heterozygotes sharing the same two *TNSALP* missense mutations. The proposita (*Right*) at age 5–3/12 years survived infantile HPP featuring poor weight gain, hypercalcemia with nephrocalcinosis, and severe rickets (Barcia *et al.*, 1997) that was followed by short stature, premature loss of teeth, and craniosynostosis. Her younger sister (*Left*) at age 2–2/12 years appears well and has mild rickets despite very similar hypophosphatasemia and endogenous elevations of the TNSALP substrates.

Five principal forms of HPP are usually discussed. The age at which HPP is diagnosed because of skeletal disease distinguishes the perinatal, infantile, childhood, and adult types (Fraser, 1957; Whyte, 2001). Individuals who do not have skeletal disease, but instead manifest dental features only, are said to have "odontohypophosphatasia" (Whyte, 2001). However, this nosology does not unambiguously classify all patients, and it is better to appreciate that HPP manifests a continuum of expressivity. An extremely rare form of HPP called "pseudohypophosphatasia" resembles infantile HPP except that serum ALP activity is not subnormal, but instead normal or increased, in the clinical laboratory (see later) (Scriver and Cameron, 1969; Whyte, 2001). A "benign *in utero*" form of HPP, characterized in 1999 from fetal sonography, demonstrates that skeletal deformity *in utero* owing to HPP may not always predict a lethal outcome (Moore *et al.*, 1999; Pauli *et al.*, 1999).

The prognoses for the five major forms of HPP are determined by the severity of the skeletal disease. Typically, the earlier the skeletal signs and symptoms, the worse the outcome (Fraser, 1957; Whyte, 2001).

Perinatal Hypophosphatasia

This most severe form of HPP, defined by generalized skeletal disease obvious in a neonate, manifests *in utero* with profound hypomineralization of cartilage and bone and typically causes death at, or soon after, birth. Remarkable skeletal undermineralization results in caput membraneceum and limbs that are shortened and deformed. Some affected newborns survive a few days or weeks, but then suffer increasing respiratory compromise owing to rachitic disease of the chest and possibly lungs that are hypoplastic (Silver *et al.*, 1988). There may be vitamin B_6-dependent seizures (Baumgartner-Sigl *et al.*, 2007). Myelophthisic anemia perhaps follows encroachment on the marrow space by excessive osteoid (Terheggen and Wischermann, 1984). Extended survival is very rare.

Skeletal radiographs (Fig. 4) readily distinguish perinatal HPP from even the most severe forms of osteogenesis imperfecta or congenital dwarfism, and the findings may be considered diagnostic. Nevertheless, there is considerable patient-to-patient variability (Shohat *et al.*, 1991). In some stillborns, the bones are nearly devoid of mineral (see Fig. 4A). In others, there are severe rachitic changes (see Fig. 4B). Occasionally, individual vertebrae appear to be completely or partially missing (Shohat *et al.*, 1991). In the skull, these membranous bones may calcify only at their centers, giving the illusion that the cranial sutures are widely separated ("open"), although they may be functionally closed (see Fig. 4C). Other unusual radiographic features (Whyte, 1988) include bony protrusions (Bowdler spurs) extending from the midshafts of the ulnas and fibulas (see Fig. 4D).

Infantile Hypophosphatasia

This form of HPP was described by Rathbun (Rathbun, 1948). Skeletal disease manifests after birth, but before 6 months of age (Fraser, 1957; Whyte, 2001). Development may seem normal until there is poor feeding, hypotonia, and inadequate weight gain. At this time, the clinical manifestations of rickets appear, leading to the diagnosis. Vitamin B_6-dependent epilepsy can be the first manifestation of infantile HPP and predicts a lethal outcome (Baumgartner-Sigl *et al.*, 2007). A flail chest from rib fractures, rachitic deformity, etc., often leads to pneumonia. Hypercalcemia and hypercalciuria are common, and may explain episodes of recurrent vomiting, as well as nephrocalcinosis and renal compromise (Fraser, 1957; Whyte *et al.*, 1982b).

Although the striking radiographic features of the skeletal disease of infantile HPP are diagnostic (Fig. 5A), they are less severe than in perinatal HPP. Radiographs may suggest that cranial sutures are wide open, but this is an illusion from hypomineralization of the skull, and there can instead be "functional" craniosynostosis. Later, true, early sutural fusion can occur if the patient survives infancy, causing symptoms and complications of craniosynostosis (see Fig. 5B). In some babies, abrupt transition from relatively normal-appearing diaphyses to poorly mineralized metaphyses (see Fig. 5C) suggests that metabolic deterioration has occurred suddenly (Fraser, 1957). This observation is supported by the acquired hypercalciuria and hypercalcemia that can develop in this form of HPP. Serial radiographs may reveal not only impaired skeletal mineralization (i.e., rickets), but also gradual, generalized demineralization of osseous tissue and fractures (Whyte *et al.*, 1982b) indicating a lethal outcome (Whyte *et al.*, 2003; Cahill *et al.*, 2007) (see Fig. 5D). Alternatively, there can be spontaneous but unexplained improvement (Ish-Shalom *et al.*, 1986).

Childhood Hypophosphatasia

This form of HPP has especially variable expressivity (Fallon *et al.*, 1984; Whyte, 2001). The diagnosis is made because of bone disease discovered after 6 months of age, but before skeletal maturity. In 1953, premature loss of deciduous teeth was found to be a major clinical feature (Sobel *et al.*, 1953). Early shedding of "baby" teeth (i.e., at less than 5 years of age) results from hypoplasia or aplasia of dental cementum (Van den Bos *et al.*, 2005). Consequently, the roots are not bound sufficiently by the periodontal ligament (Lundgren *et al.*, 1991) and entire teeth come out painlessly without trauma (Fig. 6A). The incisors are typically lost first, and occasionally almost the entire primary dentition is exfoliated prematurely. We have encountered early loss of at least one deciduous tooth in 98% of our pediatric patients with HPP (Whyte *et al.*, in

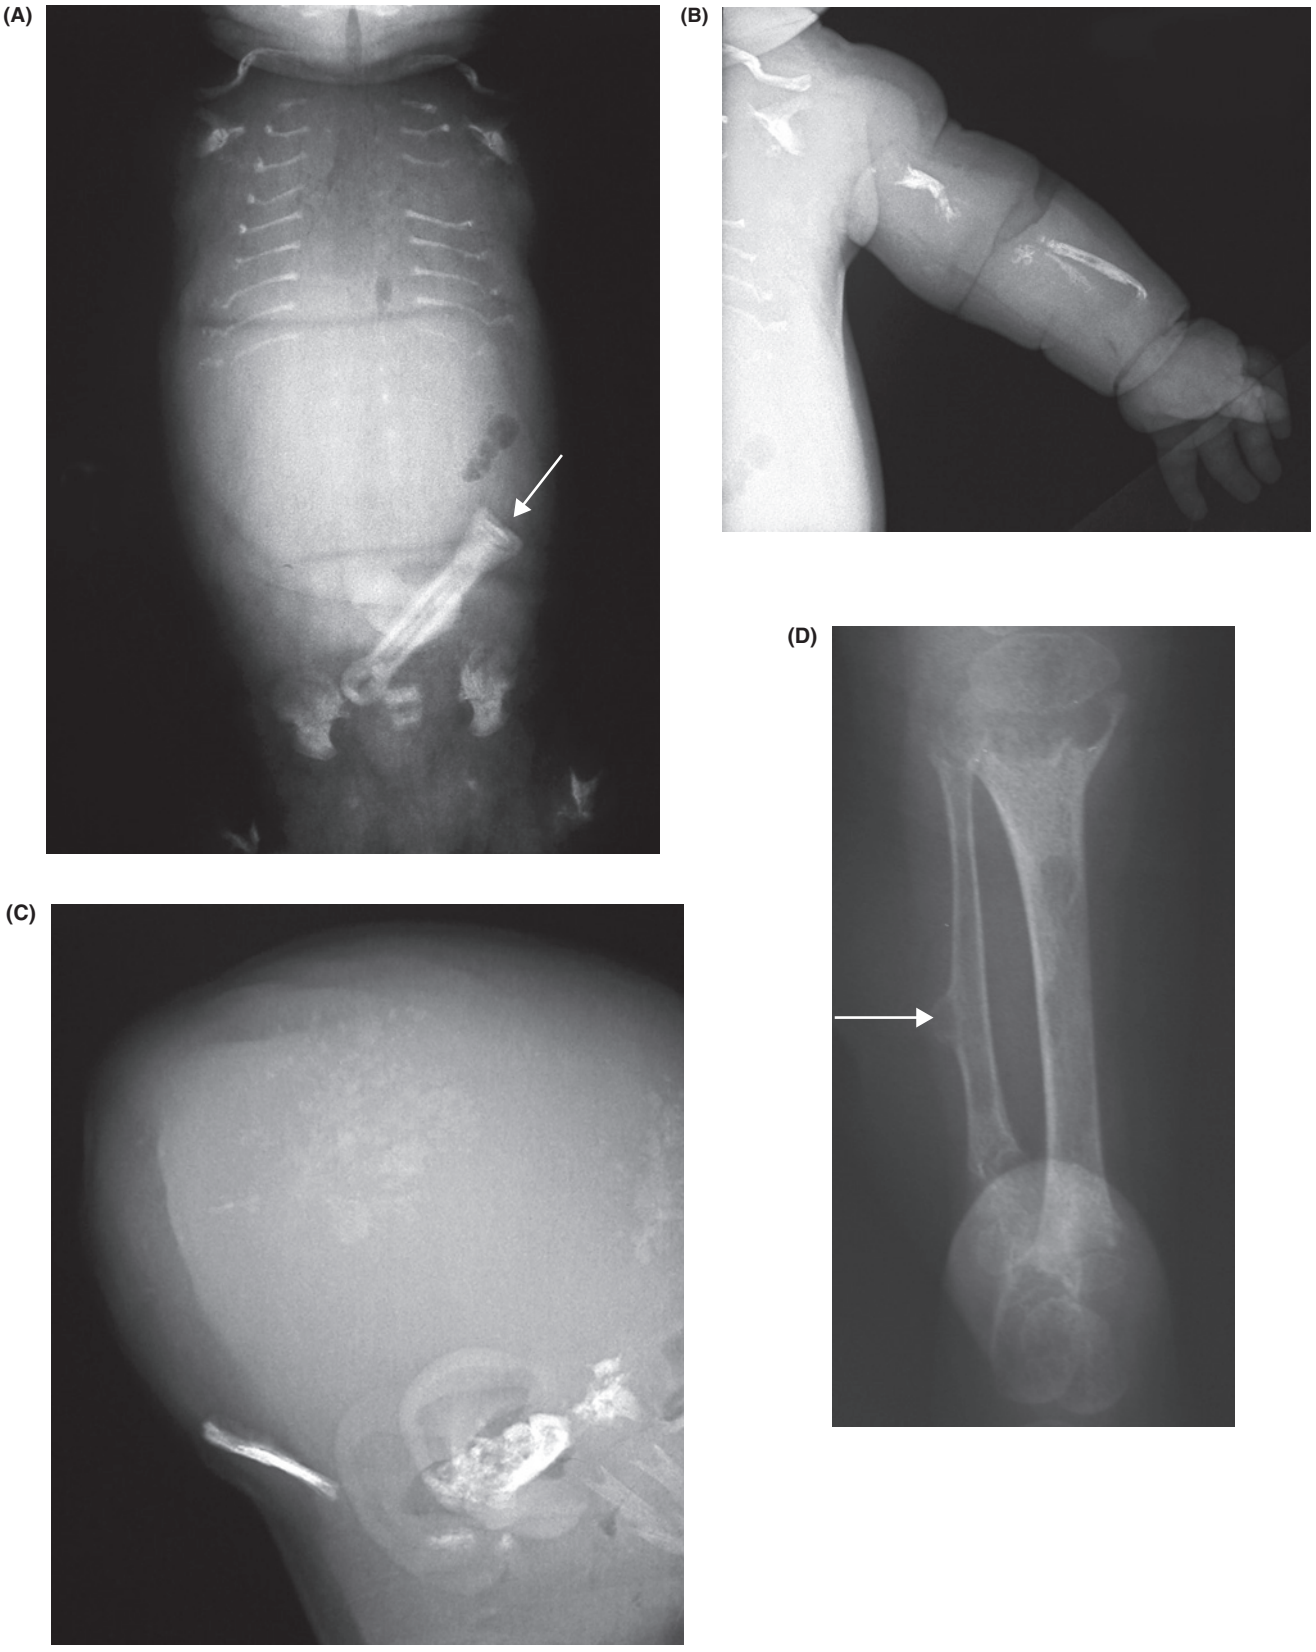

FIGURE 4 Perinatal hypophosphatasia. (**A**) Profound skeletal hypomineralization is obvious at birth (arrow points to umbilical cord clip). (**B**) The ends of the upper extremity long bones at 1 day of age show characteristic, extreme, rachitic changes. (**C**) Severe hypomineralization of the calvarium is present at 1 day of age. (**D**) A Bowdler spur (arrow) is found in some patients.

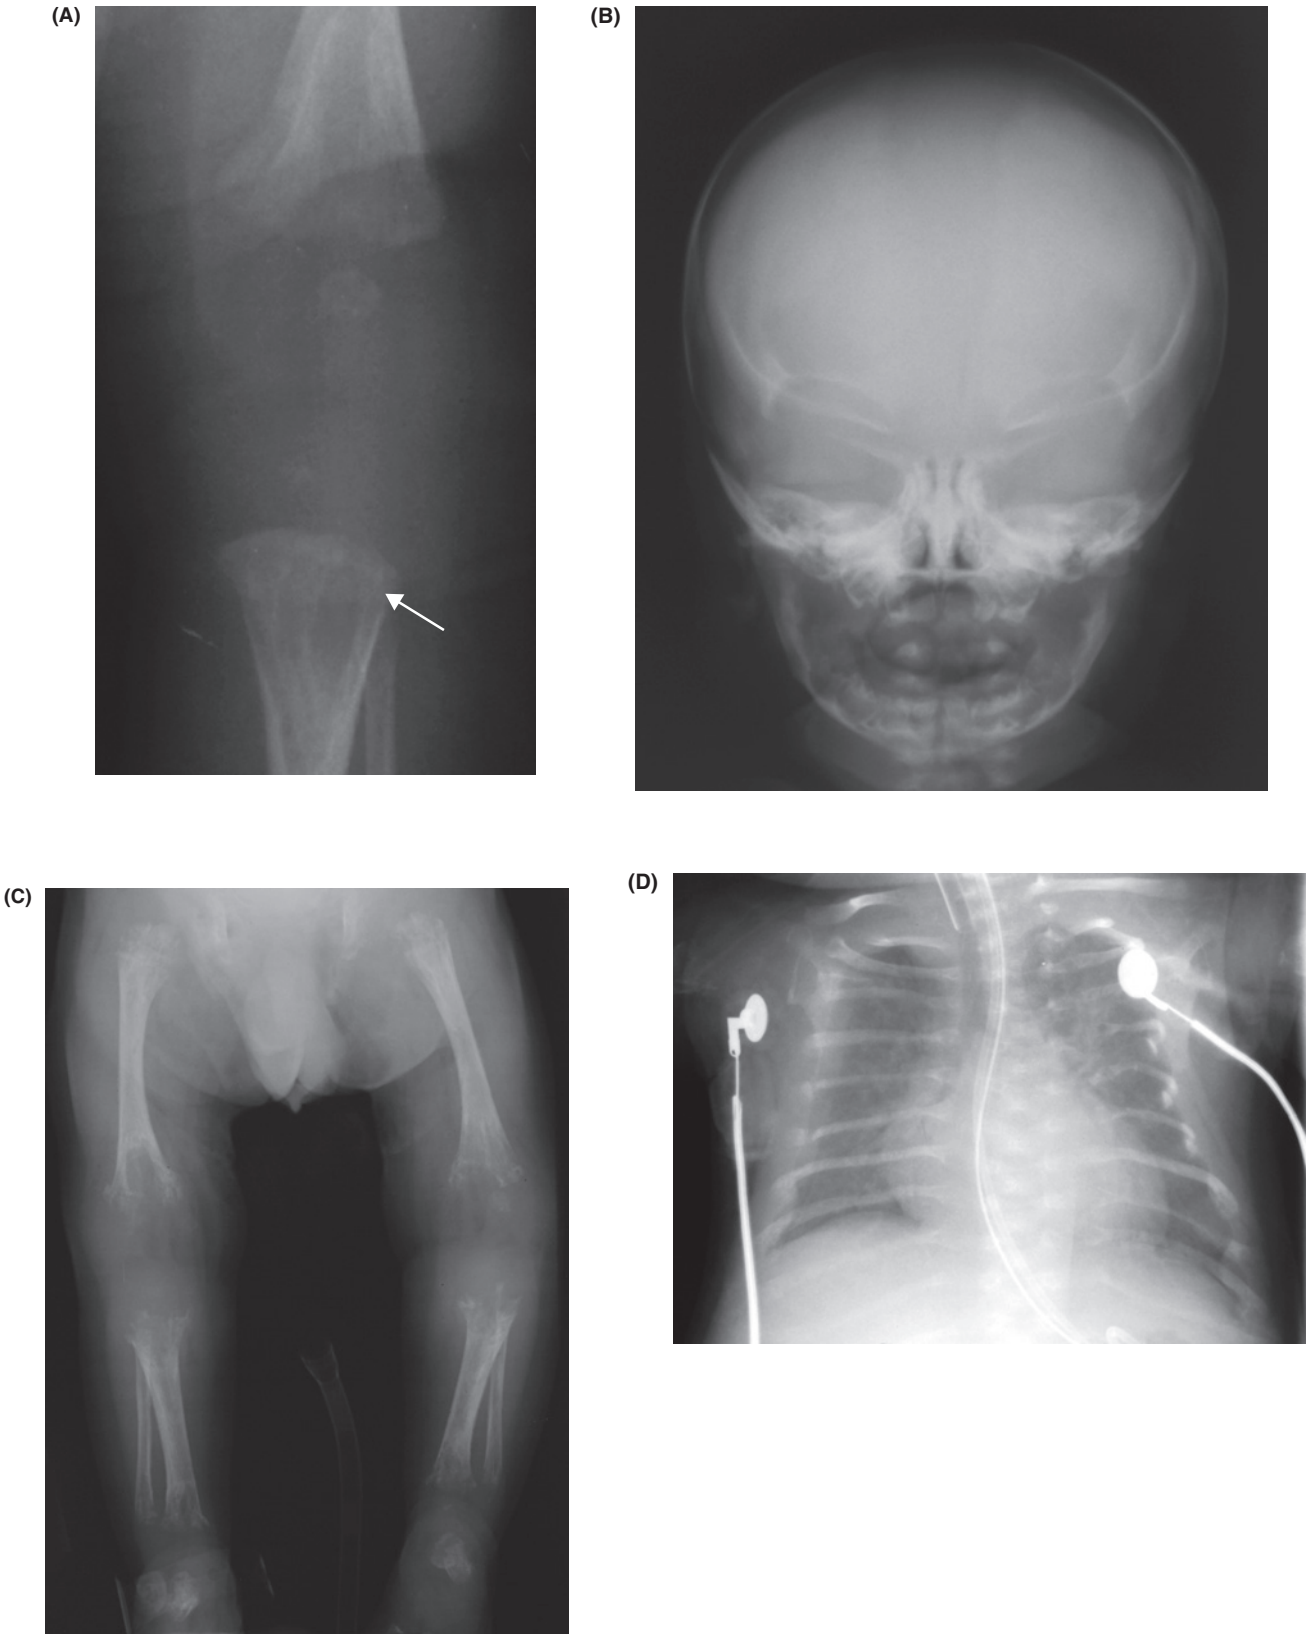

FIGURE 5 Infantile hypophosphatasia. (**A**) Characteristic tongues of radiolucency (arrow) extend from the growth plate into the metaphysis. (**B**) Cranial sutures appear widened in this hypomineralized skull at 1 month of age. (**C**) An abrupt transition seems to have occurred from well mineralized diaphyses to poorly mineralized metaphyses by age 3 months. (**D**) The "bell-shaped" configuration of the chest from a soft thorax together with rib fractures will predispose to respiratory disease at 23 months of age.

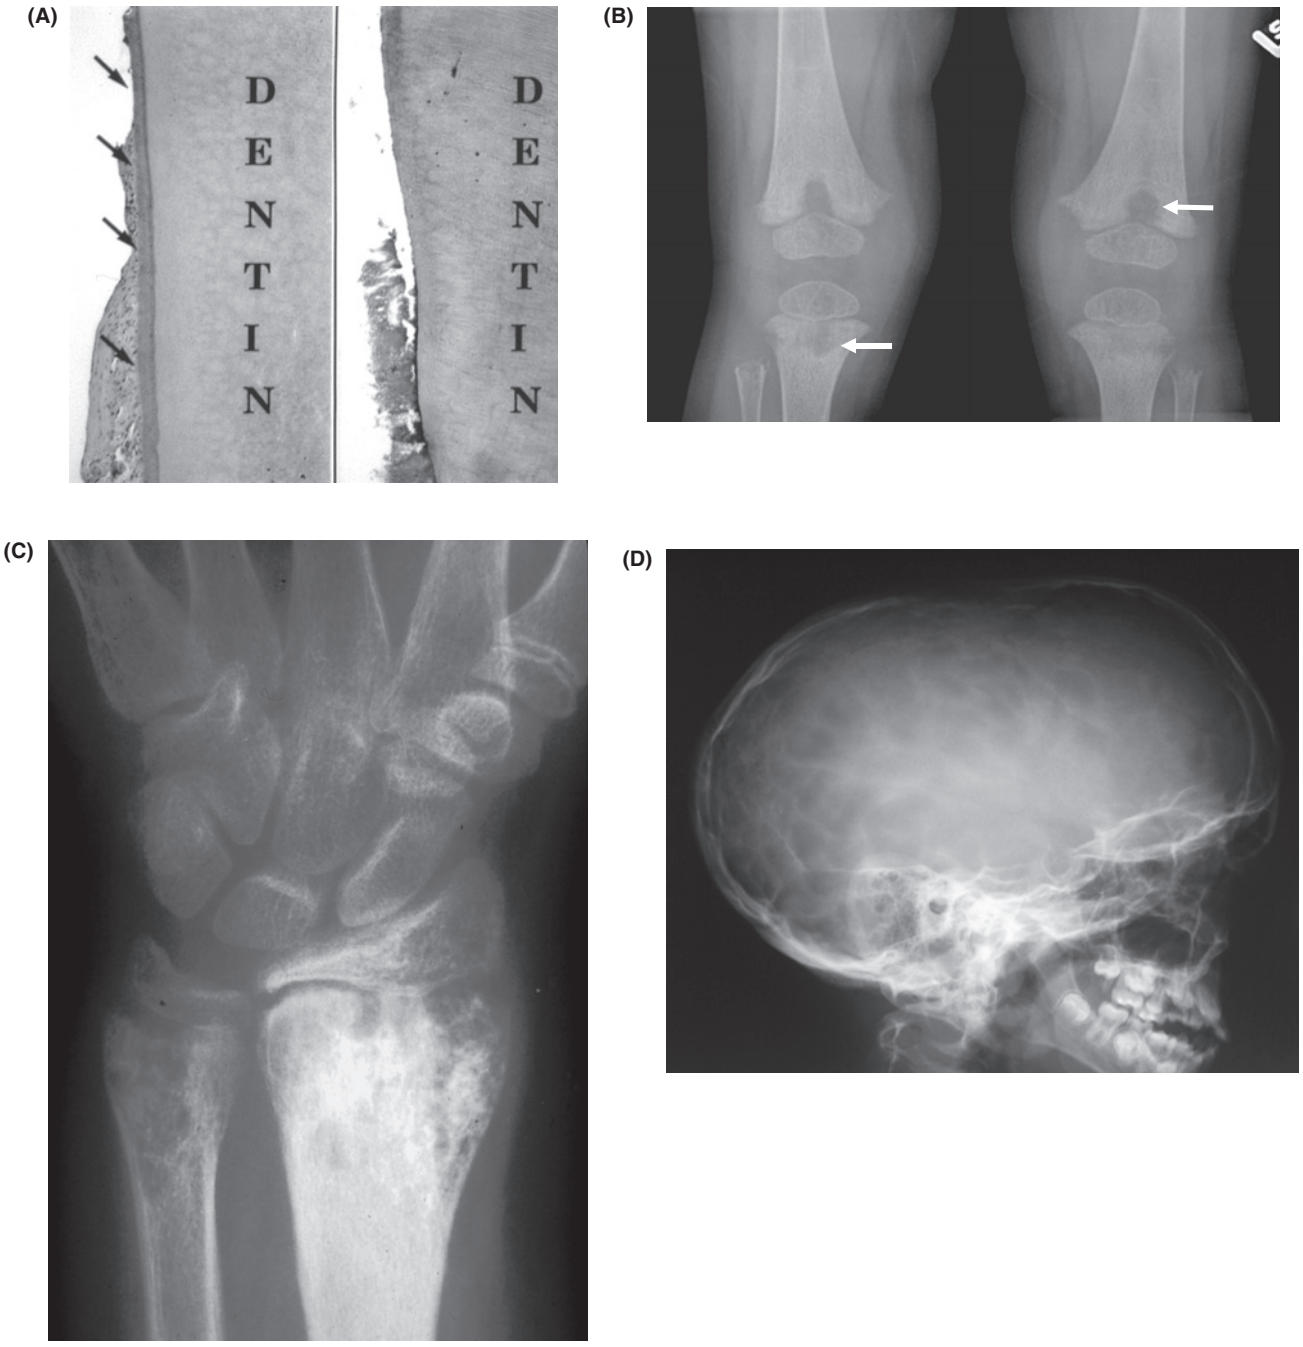

FIGURE 6 Childhood hypophosphatasia. (**A**) Dental findings. (*Left*) Decalcified section of part of the root of a maxillary incisor from a child with X-linked hypophosphatemia is essentially normal and shows primary cementum (delineated by arrows) at its surface (original magnification, ×150). (*Right*) In hypophosphatasia, cementum is absent. Original magnification, × 150. [Reproduced with permission from Whyte (2001).] (**B**) Characteristic tongues of radiolucency (arrows) project from growth plates into metaphyses at 16 months of age. (**C**) Idiopathic, patchy, metaphyseal osteosclerosis is a common finding. (**D**) A "beaten copper" appearance in the calvarium, here at age 11 years, signifies premature closure of cranial sutures (craniosynostosis) that can lead to raised intracranial pressure.

manuscript). Delayed walking and a characteristic waddling gait are also typical of childhood HPP. These problems seem to reflect the degree of skeletal disease. Patients can complain of stiffness and pain and have appendicular muscle weakness (especially in the thighs) consistent with a nonprogressive myopathy (Seshia *et al.*, 1990). There may also be delays in speech and language acquisition (Ruzicka *et al.*, in manuscript).

Radiographs usually show characteristic focal "tongues" of radiolucency that project from rachitic growth plates into the metaphysis (see Fig. 6B). There can be patchy areas of metaphyseal osteosclerosis (see Fig. 6C). True premature

bony fusion of cranial sutures may raise intracranial pressure (see Fig. 6D). Dental radiographs sometimes show enlarged pulp chambers and root canals that characterize the "shell teeth" of rickets.

Adult Hypophosphatasia

This form of HPP typically presents after middle age (Whyte, 2001; Whyte *et al.*, 1982a). Not infrequently, however, patients recall being told of rickets and/or premature loss of their deciduous teeth in childhood. Then, there is relatively good health during young adult life (Weinstein and Whyte, 1981). Some of these individuals may have been considered "carriers" of HPP until they manifested the skeletal disease.

In adult HPP, osteomalacia often presents as recurrent, painful, poorly healing, metatarsal stress fractures (Fig. 7A) (Whyte *et al.*, 2007). With more advanced disease, persistent aching or tenderness in the thighs or hips is explained by femoral pseudofractures (see Fig. 7B) that will not heal spontaneously unless they progress to complete fractures (Khandwala *et al.*, 2006). Early loss or extraction of the secondary dentition is not uncommon, although what may be wrong with the adult teeth is not well understood (Whyte *et al.*, 1982a). Calcium pyrophosphate dihydrate (CPPD) crystal deposition, occasionally with overt attacks of arthritis (pseudogout), troubles some patients and stems from increased endogenous levels of PP_i (see later) (O'Duffy, 1970; Whyte *et al.*, 1982a). Some affected individuals suffer degeneration of articular cartilage and "pyrophosphate arthropathy" (Whyte *et al.*, 1982a). Radiographs may reveal osteopenia and chondrocalcinosis (Lassere and Jones, 1990; Whyte *et al.*, 1982a). In certain families with hypophosphatasemia, calcium phosphate deposition manifests as calcific periarthritis with ossification of ligaments (syndesmophytes) resembling spinal hyperostosis (Forestier's disease) (Lassere and Jones, 1990).

Odontohypophosphatasia

This form of HPP is diagnosed when there are dental manifestations, but radiographic or histological studies reveal no evidence of rickets or osteomalacia.

Pseudohypophosphatasia

This especially rare variant of HPP has been documented convincingly in two infants (Scriver and Cameron, 1969;

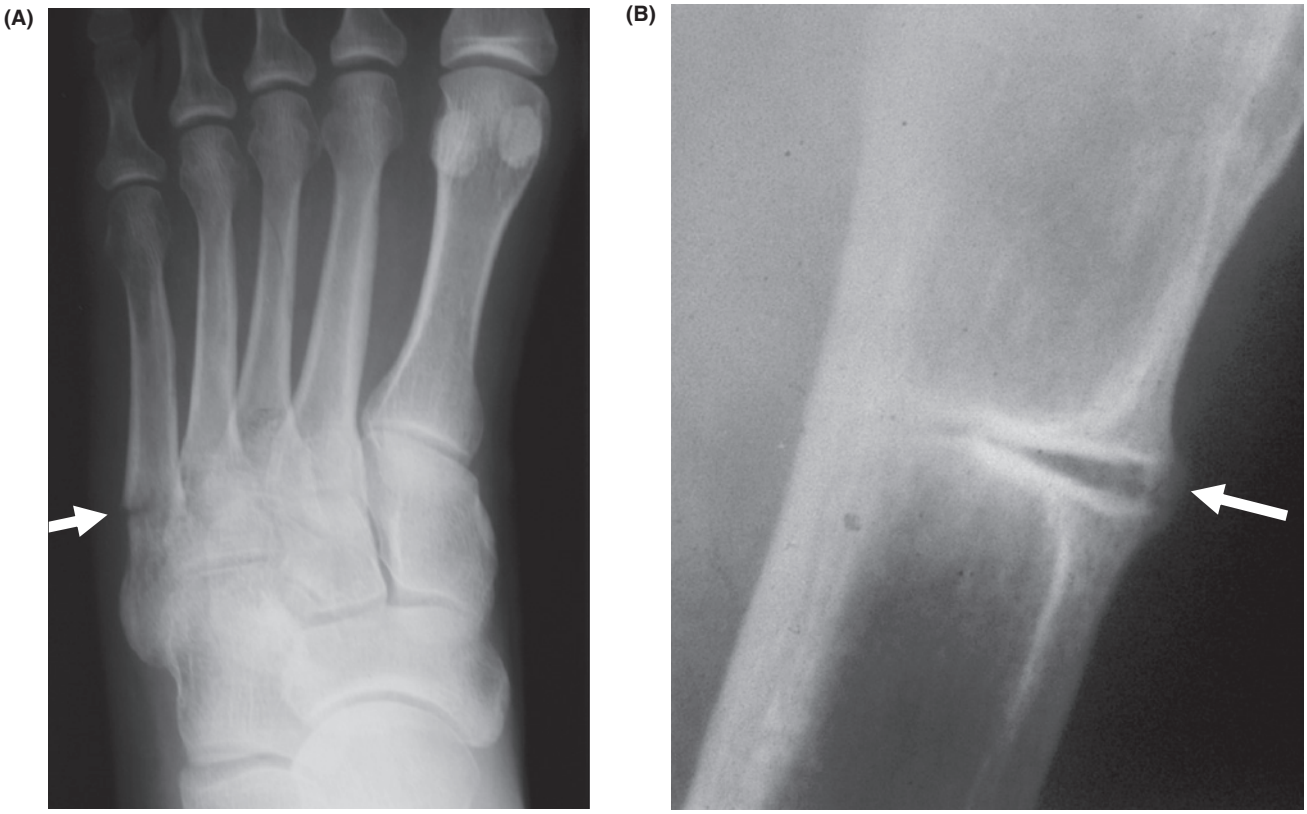

FIGURE 7 Adult hypophosphatasia. (**A**) Recurrent, poorly healing, metatarsal stress fractures (arrow) may be the most common skeletal manifestation of the adult form of hypophosphatasia. (**B**) Femoral pseudofractures (arrow) are often painful and characteristically occur on the lateral aspect proximally in adult hypophosphatasia. They do not heal spontaneously, unless a through-and-through break occurs.

Whyte, 2001). The clinical, radiographic, and biochemical findings are those of infantile HPP with one key exception—serum total ALP activity is not low, but instead consistently normal or increased (Whyte, 1994, 2001). The enzymatic defect causing pseudo-HPP involves a TNSALP with diminished hydrolysis for PEA, PP_i, and PLP endogenously, but normal or even increased catalysis for artificial substrates in the nonphysiological conditions of ALP assays used in clinical laboratories (see later) (Fedde *et al.*, 1990).

Benign *in Utero* Hypophosphatasia

Increasing use of sonography is revealing fetuses with bowing of major long bones that do not have a lethal form of HPP or skeletal dysplasia, but instead show spontaneous improvement in their deformities after birth and prove to have a relatively mild form of HPP (Moore *et al.*, 1999; Pauli *et al.*, 1999; Wenkert *et al.*, 2005)

Laboratory Diagnosis

Biochemical Findings

HPP can be diagnosed with confidence from a consistent medical history and physical findings, typical skeletal radiographic changes, and serum ALP activity that is subnormal for the patient's age (Whyte, 2001). Even individuals with odonto-HPP are distinguishable from healthy subjects by their low serum ALP activity, although values for odonto-HPP can approach the lower end of carefully established reference ranges (Fig. 8). In general, HPP severity correlates inversely with age-appropriate serum ALP activity. In perinatal and infantile HPP, hypophosphatasemia is detectable at birth in umbilical cord blood (Whyte, 2001).

Hypophosphatasemia can occur from other conditions (starvation, hypothyroidism, scurvy, severe anemia, Wilson's disease, celiac disease, multiple myeloma, hypomagnesemia, Zn^{2+} deficiency), certain drugs (glucocorticoids, clofibrate, chemotherapy, vitamin D intoxication, milk-alkali syndrome), and exposure to radioactive heavy metals or massive transfusion of blood or plasma (Macfarlane *et al.*, 1992). These clinical situations should, however, be readily recognized. Especially rare cases of lethal osteogenesis imperfecta (Royce *et al.*, 1988) and some infants with cleidocranial dysplasia (Unger *et al.*, 2002; Wycoff *et al.*, 2005) can also have hypophosphatasemia (apparently from little skeletal mass together with impaired cellular processing of bone ALP, or osteoblast hypofunction, respectively). Severe cleidocranial dysplasia is the most likely disorder to be confused with HPP (Unger *et al.*, 2002; Wycoff *et al.*, 2005).

Transient increments in serum ALP activity (probably the bone isoform of TNSALP) can occur in HPP after orthopedic surgery or significant fracture. In theory, circumstances that increase serum levels of any type of ALP (e.g., pregnancy, liver disease) could obscure the biochemical diagnosis of HPP. Thus, documenting hypophosphatasemia on more than one occasion during clinical stability seems advisable for the exceptional, confusing case. Quantitation in serum of the ALP isoenzymes (Mulivor *et al.*, 1985), isoforms of TNSALP (Whyte *et al.*, 1996), or leukocyte ALP (Iqbal *et al.*, 2000)—all available in clinical laboratories—may also be helpful.

Mineral homeostasis

Neither circulating calcium nor P_i levels are subnormal in HPP. In fact, in infantile HPP there may be hypercalcemia and hyperphosphatemia together with hypercalciuria (Fraser, 1957; Shohat *et al.*, 1991; Whyte *et al.*, 1982b). The disturbed mineral homeostasis is incompletely understood, but seems, in part, to be from impaired calcium and P_i uptake by a poorly growing skeleton, sometimes together with progressive bone demineralization. In childhood HPP, patients often manifest hypercalciuria, but usually without hypercalcemia. Serum levels of 25(OH)D,

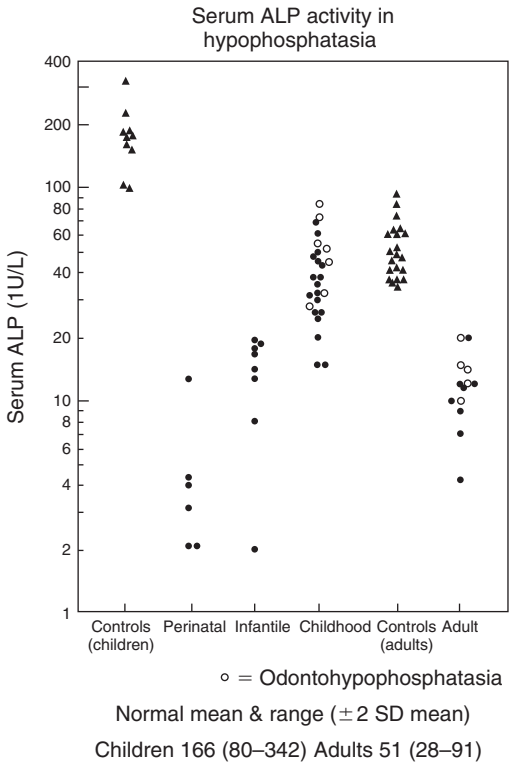

FIGURE 8 Serum ALP activity in hypophosphatasia. Serum total ALP activity in healthy children and adults and in 52 patients from 47 families with the various clinical forms of hypophosphatasia (note the logarithmic scale). All assays were performed at the Center for Metabolic Bone Disease and Molecular Research, Shriners Hospitals for Crippled Children, St. Louis, MO. [Reproduced with permission from Whyte (2001)].

$1,25(OH)_2D$, and parathyroid hormone (PTH) are typically normal (Whyte and Seino, 1982), unless altered physiologically by hypercalcemia or by renal failure (Fallon *et al.*, 1984). Several HPP patients have had elevated serum PTH levels, but impaired renal function (causing retention of immunoreactive PTH fragments) may have been the explanation (Whyte, 1994). Others had primary hyperparathyroidism for which there may be a predisposition in adult HPP (Whyte, 2001). Conversely, a low circulating level of intact PTH (likely from feedback of increased ionized calcium levels on the parathyroid glands) is not uncommon in our pediatric patients (unpublished work).

Individuals with the childhood or adult forms of HPP have serum P_i levels above average values for age-matched controls (Whyte, 2001). Indeed, ≈50% are distinctly hyperphosphatemic. Enhanced renal reclamation of P_i (increased TmP/GFR) underlies this poorly understood finding (Whyte and Rettinger, 1987). In some, but not all, instances, suppressed PTH seems contributory. Rarely, hypophosphatasemia is reported with hypophosphatemia from renal P_i wasting (Juan and Lambert, 1981).

Phosphoethanolamine

Elevated urine levels of PEA support a diagnosis of HPP (Rasmussen, 1968), but are not pathognomonic. Licata *et al.* (1978) demonstrated that phosphoethanolaminuria occurs in other conditions, including several metabolic bone diseases. Reference ranges for urine PEA vary according to age and somewhat by diet, and follow a circadian rhythm. PEA values can be unremarkable in mildly affected HPP patients. Age-adjusted normal ranges (expressed as micromoles of PEA per gram of creatinine) are: for less than 15 years, 83 to 222; for 15 to 30 years, 42 to 146; for 31 to 41 years, 38 to 155; and for more than 45 years, 48 to 93 (Licata *et al.*, 1978).

Pyridoxal 5′-phosphate

An increased plasma concentration of PLP is a sensitive marker for HPP (including pseudo-HPP) (Coburn and Whyte, 1988) (Fig. 9). Testing is available at several commercial laboratories, sometimes designated "vitamin B_6". Even patients with odonto-HPP manifest this biochemical finding (Whyte *et al.*, 1985). Vitamin supplements containing pyridoxine should not be taken, if possible, for one week before blood is obtained in order to avoid false-positive results. HPP disease severity correlates positively with the elevation in the plasma PLP concentration (Whyte, 2001). Nevertheless, values overlap between the different clinical types (see Fig. 9). Quantitation of plasma PLP after challenge with pyridoxine given orally once each day for six days seems to distinguish HPP patients especially well (Whyte, 1994), and identifies Canadian Mennonite carriers of severe HPP (Chodirker *et al.*, 1990).

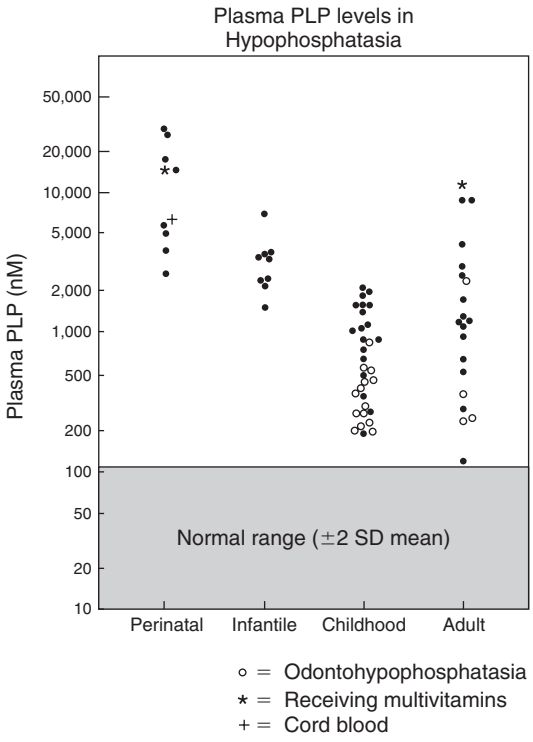

FIGURE 9 Plasma PLP levels in hypophosphatasia. PLP concentrations in plasma in various clinical forms of hypophosphatasia (hatched area is the normal range for children and adults). Note the logarithmetic scale with some overlap between the clinical forms (assays performed courtesy of Dr. Stephen P. Coburn, Fort Wayne State Developmental Center, Fort Wayne, IN). [Reproduced with permission from Whyte (2001)].

Inorganic pyrophosphate

Assay of PP_i in plasma or urine is not commercially available. Urine PP_i levels are increased in most HPP patients, but can be unremarkable in mildly affected individuals (Caswell *et al.*, 1991). Nevertheless, this test may help with carrier detection (Whyte, 2001).

Radiographic Findings

The radiographic features of HPP (see Figs. 4 to 7) have been illustrated for the principal clinical forms (see earlier).

Histopathological Findings

Histopathological disturbances in HPP that are a direct outcome of TNSALP deficiency seem to be limited to hard tissues. In severe cases, extramedullary hematopoiesis (Fallon *et al.*, 1984; Ornoy *et al.*, 1985) may derive from marrow space crowding owing to the osteomalacia. The cause for any pulmonary hypoplasia is not clear (Silver *et al.*, 1988), but perhaps involves a small thorax.

Skeleton

In all but the mildest cases of HPP (i.e., odonto-HPP), nondecalcified sections of the skeleton reveal defective mineralization (Fallon *et al.*, 1984; Ornoy *et al.*, 1985). The degree of rickets or osteomalacia generally reflects the clinical severity (Fallon *et al.*, 1984). Features of secondary hyperparathyroidism (present in rickets or osteomalacia associated with hypocalcemia) are typically absent (Fallon *et al.*, 1984; Anderson *et al.*, 1997).

In growth plates and osseous tissue, the cellular sources of the bone isoform of TNSALP (chondrocytes and osteoblasts) are present (Anderson *et al.*, 1997), but their TNSALP activity is deficient (Fallon *et al.*, 1984; Ornoy *et al.*, 1985). Other forms of rickets or osteomalacia cannot be excluded by their histopathological features unless ALP activity is assessed. In HPP, ALP activity in bone inversely reflects the degree of osteoid accumulation, and therefore the severity of the skeletal disease (Fallon *et al.*, 1984).

Electron microscopy of perinatal HPP has shown normal distribution of MVs, proteoglycan granules, and collagen fibers in the extracellular space of cartilage (Fallon *et al.*, 1984; Ali, 1986), although the MVs lacked ALP activity. Early reports described only isolated or tiny groups of hydroxyapatite crystals (calcospherites) that frequently were not associated with vesicular structures (Ali, 1986; Shohat *et al.*, 1991). Actually, HPP MVs do contain hydroxyapatite, but the crystals fail to enlarge after these structures rupture (Anderson *et al.*, 1997). Secondary, but not primary, mineralization is compromised.

Dentition

Premature exfoliation of primary teeth occurs in a few diseases, such as cyclical neutropenia and Papillon–Lefevre syndrome (Van den Bos *et al.*, 2005). In HPP, a paucity of cementum (despite presence of cells that look like cementoblasts) seems to explain this complication (see Fig. 6A) (el-Labban *et al.*, 1991; Lundgren *et al.*, 1991). Desiccated teeth can still be useful for histopathological examination. What cementum may be present appears afibrillar (el-Labban *et al.*, 1991). The severity of this defect varies from tooth to tooth, but typically reflects the degree of skeletal disease. Incisors are usually most affected, and the first to be shed.

In addition to defects in cementum, dentinogenesis seems to be impaired, as shown by big pulp chambers. Dentin tubules may be enlarged although reduced in number. The excessive width of predentin, increased amounts of interglobular dentin, and impaired calcification of cementum are analogous to the osteoidosis found in bone. The enamel is not impacted directly (Lundgren *et al.*, 1991). The histopathological changes observed in the permanent teeth are similar to those in the deciduous teeth (el-Labban *et al.*, 1991), but their prognosis is better (Lepe *et al.*, 1997).

Biochemical and Genetic Defect

TNSALP Deficiency

Early on, postmortem studies of perinatal and infantile HPP revealed the enzymatic defect defining this inborn error of metabolism, and thereby suggested its genetic basis. Profound deficiency of ALP activity was discovered in liver, bone, and kidney tissue, but not in intestine or placenta (fetal trophoblast) (Vanneuville and Leroy, 1981). This observation matched amino acid sequence analyses of ALP purified from various healthy human tissues (Stigbrand and Fishman, 1984)—arguing for selective deficiency of the enzymatic activities of all of the isoforms comprising the TNSALP family.

Postmortem studies of children or adults with HPP have not been reported, but globally diminished TNSALP activity is suggested by deficiencies in serum, bone, circulating granulocytes (Fallon *et al.*, 1984), and skin fibroblasts (Vanneuville and Leroy, 1981).

Hypophosphatasemia in HPP does not involve accelerated clearance of unaltered TNSALP from the circulation (Gorodischer *et al.*, 1976). Purified placental ALP (Whyte *et al.*, 1992), as well as the bone isoform of TNSALP contained in the plasma of patients with Paget's bone disease (Whyte *et al.*, 1982b), showed normal circulating half-lives of several days when infused intravenously into severely affected infants during attempted ALP enzyme replacement therapy (see later).

Furthermore, coincubation experiments with mixtures of serum, and coculture studies with fibroblasts from severely affected patients, provided evidence against an inhibitor or absence of an activator of TNSALP in HPP (Fraser, 1957; O'Duffy, 1970; Whyte and Vrabel, 1985). In 1985, heterokaryon studies using skin fibroblasts in culture indicated a defect at a single gene locus (Whyte and Vrabel, 1985).

ALP immunoreactivity has been studied in bone, liver, and kidney as well as in skin fibroblasts from patients with severe HPP (Fallon *et al.*, 1989; Fedde *et al.*, 1996). The preliminary report by Fallon and coworkers, using a polyclonal antibody to the liver isoform of TNSALP, described normal amounts of immunoreactive TNSALP in bone, liver, and kidney from five HPP patients (Fallon *et al.*, 1989). Others, using isoelectric focusing and enzyme inhibition studies, suggested that the low ALP activity remaining in one HPP patient was intestinal ALP (Mueller *et al.*, 1983). In fibroblasts from severely affected individuals, ALP had somewhat different physicochemical and immunological properties compared with ALP from healthy controls, but nevertheless seemed to be a form of TNSALP (Fedde *et al.*, 1996). Leukocyte ALP activity can be subnormal in any clinical type of HPP, except perhaps pseudo-HPP, and therefore likely represents an isoform of TNSALP (Fallon *et al.*, 1984). The nature of ALP in the circulation in HPP requires further study. Monoclonal antibody-based

immunoradiometric assays (IRMAs) for polymeric TNSALP demonstrated low levels of the bone and liver isoforms of TNSALP in sera from patients with all clinical types of HPP, except pseudo-HPP (Whyte *et al.*, 1996). Upon release from plasma membranes and entry into blood, TNSALP in HPP seemed to be altered in such a way that immunoreactivity was diminished and/or clearance was accelerated (Whyte *et al.*, 1996). Fedde *et al.* (1996) concluded that the precise impact of the underlying *TNSALP* mutation(s) (see later) must be understood to fully appreciate its effect on the enzyme's structure in tissues, and thereby HPP disease expression in patients. These cumulative findings have been clarified by the subsequent identification of ≈200, usually missense, mutations of *TNSALP* in HPP (see later).

Inheritance

Mutation analysis of *TNSALP* coupled with clinical studies of families has established that both autosomal dominant and autosomal recessive patterns of inheritance account for HPP. Although perinatal and infantile HPP represent autosomal recessive disease (Weiss *et al.*, 1988; Henthorn *et al.*, 1992; Mumm *et al.*, 2001; Whyte *et al.*, 2003, 2006), milder forms of HPP can result from either autosomal recessive (Henthorn *et al.*, 1992) or autosomal dominant transmission of *TNSALP* defects (Mumm *et al.*, 2006; Whyte *et al.*, 2007).

Certain *TNSALP* loss-of-function mutations seem to have dominant-negative effects (Henthorn, *et al.*, 1996; Mumm *et al.*, 2006) (see later).

Attempts to identify carriers for HPP by using conventional biochemical testing can have uncertainties. The utility of quantitating several such parameters has been discussed (Sorensen *et al.*, 1978). A comprehensive evaluation of vitamin B_6 loading has not been published.

TNSALP Gene Defects

In 1988, proof that HPP can be caused by deactivating mutation within the candidate (TNSALP) gene came with discovery by Weiss and coworkers of a homozygous *TNSALP* missense defect in a consanguineous boy with perinatal HPP (Weiss *et al.*, 1988). Transfection studies showed that the single-base transition compromised the enzyme's activity, perhaps by impairing metal ligand binding to an important arginine residue at the catalytic pocket (Weiss *et al.*, 1988). In 1992, Henthorn *et al.* reported eight further missense mutations in four additional, unrelated patients with perinatal or infantile HPP (Henthorn *et al.*, 1992). In this study, two siblings with childhood HPP and one unrelated woman with adult HPP were compound heterozygotes for identical *TNSALP* defects.

In 1993, Greenberg and coworkers found that homozygosity for a tenth *TNSALP* missense mutation accounts for the especially high prevalence of HPP in Mennonites in Canada (Greenberg, *et al.*, 1993).

Now, all clinical forms of HPP have been shown to involve loss-of-function mutations in *TNSALP* (Whyte, 2000), and all patients studied to date have carried one or two defective *TNSALP* alleles. A web site organized by E. Mornet summarizes the *TNSALP* mutations identified in HPP patients worldwide (http://www.sesep.uvsq.fr/Database.html). Currently, ≈200 specific *TNSALP* mutations are recorded, of which a considerable majority (≈80 %) are missense. Some have regional or national prevalence (Mumm *et al.*, 2006).

TNSALP Structural Defects

Many of the *TNSALP* mutations causing HPP (Taillander *et al.*, 2001; Mumm *et al.*, 2002) alter an amino acid residue that is conserved in mammalian TNSALPs (Henthorn and Whyte, 1992; Mornet *et al.*, 1998). In fact, several are conserved in bacteria (Henthorn *et al.*, 1992).

Revelation of the three-dimensional structure of *Escherichia coli* ALP (Kim and Wyckoff, 1991) and human placental ALP (Le Due *et al.*, 2000) by x-ray crystallography has greatly advanced our understanding the biochemical basis for HPP (Henthorn *et al.*, 1992; Kim and Wyckoff, 1991; Millán, 2006). Missense mutations in *TNSALP* can be examined for their impact on the catalytically active dimeric TNSALP molecule [Chemscape Chime version 1.02 by MDL Information Systems, Inc. (San Leandro, CA) at http://www.mdli.com and RasWin Molecular Graphics, Windows version 2.6 by Roger Sayle, Glaxo-Wellcome Research and Development (Stevenage, Hertfordshire, UK) at http://www.umass.edu/microbio/rasmol/index.html]. Some *TNSALP* mutations disturb the enzyme's catalytic pocket or structurally important metal ligand-binding sites; others possibly affect dimer formation (Mornet *et al.* 1998; Millán, 2006). Nevertheless, how all such *TNSALP* mutations are deleterious is not completely understood (Whyte, 2000). For example, site-directed mutagenesis with the Ala^{161}-Thr substitution, first discovered to cause HPP (Weiss *et al.*, 1988), did not compromise the catalytic activity of *E. coli* ALP (Chaidaroglou and Kantrowitz, 1993). Some mutations alter intracellular movement of TNSALP (Mornet *et al.*, 1998; Shibata *et al.*, 1998; Fukushi *et al.*, 1998). Transient transfection studies have examined the impact of specific mutations on TNSALP catalytic activity (Weiss *et al.*, 1988; Brunt-Heath, *et al.*, 2005) Clinical, radiological, and biochemical studies of heterozygous carriers of HPP may prove especially helpful for understanding the impact of particular *TNSALP* mutations on HPP disease severity (Whyte, 2000).

Prognosis

Perinatal HPP is almost always fatal. With intensive life support, affected neonates may live for a short time. Rarely, there is long-term survival.

Infantile HPP has a less certain outcome. Often there is clinical and radiographic deterioration with ≈50% of babies dying of pneumonia and respiratory compromise owing to worsening skeletal disease, particularly in the chest (Fraser, 1957; Whyte *et al.*, 2003; Cahill *et al.*, 2007). Sometimes, considerable spontaneous improvement occurs. The prognosis seems to improve if there is survival past infancy. In fact, a preliminary report from Canada (Ish-Shalom *et al.*, 1986) suggests that the stature of adult survivors of infantile HPP may be normal (I am aware of many significant exceptions in the United States) (Whyte, 2001). Childhood HPP may also spontaneously improve, but this seems to usually occur after adolescence when growth plates fuse. Unfortunately, recurrence of skeletal symptoms and complications later in adulthood is likely (Fraser, 1957; Weinstein and Whyte, 1981; Khandwala *et al.*, 2006; Whyte *et al.*, 2007).

Adult HPP causes recurrent and lingering orthopedic difficulties (Whyte *et al.*, 1982a). Worsening osteomalacia, associated with osteopenia and fractures, was not prevented in two affected women by estrogen replacement at menopause (personal observation).

Treatment

Medical

There is no established medical treatment for HPP, although several approaches have been attempted (Fraser *et al.*, 1955) including trials of ALP enzyme replacement (Whyte *et al.*, 1982b, 1984, 1992), marrow cell transplantation (Whyte *et al.*, 2003; Cahill *et al.*, 2007), and teriparatide administration (Whyte *et al.*, 2007). Cortisone given to a few pediatric patients with severe disease reportedly coincided with periods of normalization of serum ALP activity and radiographic improvement (Fraser and Laidlaw, 1956), but this has not been a consistent finding. Brief supplementation with Mg^{2+} or Zn^{2+} has also been unsuccessful (Fraser, 1957).

Choosing which patients with infantile HPP might be candidates for therapeutic trials is made difficult because some show progressive skeletal demineralization leading to a fatal outcome (Whyte *et al.*, 1982b), yet others demonstrate spontaneous, and sometimes quite significant, improvement (Ish-Shalom *et al.*, 1986; Whyte *et al.*, 1986a).

Hypercalcemia in infantile HPP can be treated by restriction of dietary calcium, but care must be taken not to exacerbate the progressive skeletal demineralization that may occur from HPP itself (Whyte *et al.*, 1982b, 1986a). If necessary, glucocorticoids may also be helpful (Whyte *et al.*, 1982b). Subcutaneous injections of salmon calcitonin could address the hypercalcemia and block skeletal demineralization in HPP (Barcia *et al.*, 1997), but experience with bisphosphonates that are derivatives of PP_i has not been reported and these antiresorptives could pose a problem for a rickets or osteomalacia (Whyte, 2001).

Hypothetically, drugs that stimulate TNSALP biosynthesis in the skeleton, such as teriparatide, could be beneficial for HPP (Whyte *et al.*, 2007). However, the hypophosphatasemia can be quite refractory. I know of hypophosphatasemia persisting despite viral hepatitis or end-stage kidney disease in affected adults (unpublished work).

Enzyme replacement therapy (EzRT) for HPP has been attempted by intravenous (i.v.) infusion of several types of ALP. In general, the results have been disappointing. In 1972, serum from a patient with Paget's bone disease, given by Macpherson and colleagues to an affected infant, was said to precede radiographic improvement (Macpherson *et al.*, 1972). In 1982, i.v. infusions weekly of fresh plasma from healthy subjects were followed by clinical and radiographic advances in one child (Albeggiani and Cataldo, 1982). However, subsequent infusions of Paget's bone disease plasma showed no significant clinical or radiographic benefit for four patients with infantile HPP that proved lethal (Whyte *et al.*, 1982b, 1984). After a brief trial of prednisone, bovine PTH 1–34, and then plasma pooled from several healthy individuals, transient correction of hypophosphatasemia and remarkable clinical, radiographic, and histological improvement occurred in a boy with infantile HPP who died soon after of pneumonia (Whyte *et al.*, 1986a). He was later found to be homozygous for a TNSALP missense mutation (Whyte *et al.*, 2006). However, subsequent trials of plasma infusions for other patients did not produce this response (Whyte *et al.*, 1988). In follow-up of a brief report in 1989 that suggested that i.v. administration of ALP purified from liver improved the histological appearance of bone and decreased urinary PEA levels (Weninger *et al.*, 1989), we gave i.v. infusions of purified placental ALP to an affected infant (Whyte *et al.*, 1992). Despite repeated doses that caused transient hyperphosphatasemia, there were only modest decrements of plasma PLP and urinary PEA concentrations with no change in urinary PP_i levels, and no clinical or radiographic improvement (Whyte *et al.*, 1992). This trial followed documentation that elevated concentrations of PLP in plasma and increased levels of PEA and PP_i in urine fell as placental ALP corrected the hypophosphatasemia of pregnant women who were carriers for HPP (Whyte *et al.*, 1995). Placental ALP seems to hydrolyze the same substrates as TNSALP. Perhaps pregnancy (with placental ALP *in situ*) might represent an "endogenous" EzRT. However, the symptoms, bone density, and so on, of affected women with HPP have not been assessed immediately before and after a pregnancy.

These discouraging cumulative observations from EzRT perhaps reflected much greater tissue needs for ALP compared with levels achieved in the circulation by such treatments. Alternatively, the findings suggested that ALP must be within the skeleton itself (and/or perhaps bound to a lipid bilayer) for physiological activity and therapeutic

efficacy (Whyte *et al.*, 1995). In fact, treatment of TNSALP knockout mice with a bone-targeted, recombinant form of human TNSALP has essentially prevented the skeletal and dental disease and vitamin B_6-dependent epilepsy (Millán *et al.*, 2008). Extreme skeletal disease in perinatal HPP despite placental ALP circulating in the mother shows that the *in utero* environment is not clearly protective (Whyte, 2001).

Indeed, there are two reports of rescue and unequivocal clinical and radiographic improvement in infantile HPP following attempts to transplant cells of mesenchymal origin hoping that sufficient numbers of TNSALP-replete osteoblasts would form. Nevertheless, these changes occurred without significant biochemical alterations, and the mechanism for the disease amelioration remains unproven (Whyte *et al.*, 1998; Cahill *et al.*, 2007).

Because patients with HPP are often hyperphosphatemic (Whyte, 2001), restriction and/or pharmacological binding of dietary P_i could potentially be therapeutic for HPP (Wenkert *et al.*, 2002). Excess extracellular P_i may be acting as a competitive inhibitor of TNSALP (McComb *et al.*, 1979; Coburn *et al.*, 1998), or suppressing TNSALP gene expression (Goseki-Sone *et al.*, 1999).

In 2007, injections of teriparatide (recombinant PTH 1–34) were associated with clinical, biochemical, and radiographic improvement in a woman with adult HPP (Whyte *et al.*, 2007). Benefits may have resulted from increased TNSALP expression in her osteoblasts and/or PTH-induced phosphaturia enhancing TNSALP catalysis as shown by increases in ALP activity and decreases in P_i levels in her serum.

Supportive

Symptoms from calcium pyrophosphate crystal deposition, or perhaps periarticular calcium phosphate precipitation ("calcific periarthritis"), may respond to nonsteroidal anti-inflammatory agents.

Intramedullary rodding of femoral fractures or pseudofractures has become a mainstay of orthopedic management (Coe *et al.*, 1986).

Prenatal Diagnosis

Perinatal HPP has been diagnosed *in utero* during the second trimester by using ultrasonography with particular attention to the shape and mineralization of the skull and major long bones (van Dongen *et al.*, 1990). However, it is now well documented that relatively mild HPP, inherited either as autosomal dominant or autosomal recessive trait, can cause *in utero* bowing of major long bones suggestive of potentially lethal HPP, yet the deformities correct spontaneously after birth followed by the phenotype of childhood HPP (Moore *et al.*, 1999; Pauli *et al.*, 1999; Wenkert *et al.*, 2007; Stevenson *et al.*, 2008). Now, *TNSALP* mutation detection is possible (Henthorn and Whyte, 1995b), and offered by several fee-for-service laboratories. The great number of specific defects in *TNSALP* complicates the search, necessitating examination of *TNSALP* exons and splice sites (Mumm *et al.*, 2002).

PHYSIOLOGICAL ROLE OF ALP EXPLORED IN HYPOPHOSPHATASIA

As reviewed earlier, several roles for TNSALP in skeletal formation have been proposed (Table I). Investigation of HPP has been a "window of opportunity" to explore a number of them in humans.

Discovery by Weiss and coworkers two decades ago that homozygosity for a deactivating mutation within *TNSALP* caused severe HPP (Weiss *et al.*, 1988) proved Robison correct; i.e., ALP functions critically in skeletal mineralization (Robison, 1923). Subsequent characterization of the dental manifestations of HPP revealed that TNSALP is also important for formation of the primary teeth.

Electron microscopy of bone and cartilage obtained at autopsy from severely affected HPP patients demonstrated that deficient activity of TNSALP causes a fundamental disturbance in skeletal mineralization. In 1985, Ornoy and coworkers reported that the process of "primary mineralization" is impaired in HPP (Ornoy *et al.*, 1985). Hydroxyapatite crystals were found near, but not within HPP MVs. Later, however, Anderson and colleagues concluded that secondary (extravesicular), not primary (vesicular), mineralization is impeded in HPP (Anderson *et al.*, 1997). There appears to be failure of hydroxyapatite crystal growth after MVs rupture.

Defects in the cementum and dentin in HPP teeth have seemed to be analogous to those in the skeleton (Lundgren *et al.*, 1991). A prominent role for TNSALP during two critical phases of dental biomineralization, initiation and completion, has been proposed (Hotton *et al.*, 1999). In 2005, Van den Bos and coworkers showed that both cellular and acellular cementum formation is impaired, but not mineralization of dentin (Van den Bos *et al.*, 2005).

Although the kidneys, liver, and adrenal glands are rich in TNSALP in health (McComb *et al.*, 1979), their functions do not seem directly impaired in HPP (see later), except that reclamation of filtered P_i by the kidney is enhanced. This disturbance does not seem to be caused always by suppression of circulating PTH levels (Whyte and Rettinger, 1987).

It has been suggested that TNSALP deficiency in HPP might impair the biosynthesis of phospholipids causing pulmonary atelectasis, but the respiratory problems of severely affected patients are likely caused by rib cage fractures and deformities, which may also account for the hypoplastic lungs (Silver *et al.*, 1988).

It is clear from studies of HPP patients that TNSALP is critically important in humans, not only for mineralization

of hard tissues, but also for the dephosphorylation of extracellular PLP (Whyte, 1994). Why patients with severe HPP experience idiopathic seizures is becoming understood. A recent case report delineates how the biosynthesis of select neurotransmitters can be impaired in severe HPP (Baumgartner-Sigl *et al.,* 2006). As discussed later, epilepsy in the murine model of infantile HPP is associated with low levels of γ-aminobutyric acid in the central nervous system (Waymire *et al.*, 1995). Pyridoxine supplementation is necessary to extend the lives of these mice (Fedde *et al.*, 1999).

TNSALP Substrates

As reviewed later, the discoveries that PEA, PLP, and PP_i accumulate endogenously in HPP were essential for elucidating the physiological role of TNSALP in humans. Each was inferred to be a natural substrate for TNSALP. However, a preliminary study using ^{31}P. Magnetic resonance spectroscopy of HPP urine indicates that there are at least several additional phosphorylated TNSALP substrates, but their identities are not known (Whyte *et al.*, 2000).

Phosphoethanolamine

The reports in 1955 by McCance and colleagues (1955) and Fraser and coworkers (1955) that PEA levels are elevated in the urine and plasma of HPP patients provided a second biochemical marker for this disorder and identified the first natural substrate for TNSALP. In 1968, Rasmussen showed that this phosphocompound appears in the urine when plasma levels are scarcely detectable; i.e., there is essentially no renal threshold for PEA excretion (Rasmussen, 1968).

Although the metabolic origin of PEA is uncertain, it is not considered to be a derivative of phosphatidylethanolamine, i.e., not from plasma membrane phospholipid breakdown. The principal source of circulating PEA has been reported to be the liver, which metabolizes PEA to ammonia, acetaldehyde, and P_i in a reaction catalyzed by *O*-phosphorylethanolamine phospholyase (Gron, 1978). Indeed, in one family with adult HPP, urine levels of PEA correlated inversely with the activity in serum of the liver (but not bone) isoform of TNSALP (Millán *et al.*, 1980). Now, PEA is understood to be a component of the phosphatidylinositol-glycan linkage apparatus (Low and Zilversmit, 1980). Hence, serum and urine PEA could be a degradation product from this tether for cell surface (ecto-) proteins (see later).

Pyridoxal 5′-Phosphate

Discovery in 1985 that plasma levels of PLP are elevated in HPP was a significant advance in our understanding of the physiological role of TNSALP (Whyte *et al.*, 1985).

As reviewed in Fig. 10, the dietary forms of vitamin B_6 (pyridoxine, pyridoxal, and pyridoxamine, and their phosphorylated derivatives) are all converted to PLP in the liver (Dolphin *et al.*, 1986). Organ ablation studies revealed that the liver is the principal source of plasma PLP in mammals. PLP is released from hepatocytes into the circulation where more than 95% is coupled to albumin (Dolphin *et al.*, 1986). Some additional PLP in plasma is bound to various enzymes; and only a small amount circulates freely.

Like many phosphorylated compounds, PLP cannot cross plasma membranes, but must be dephosphorylated to pyridoxal (PL) before it can enter tissues. Inside cells, PL is rephosphorylated to PLP or converted to pyridoxamine 5′-phosphate which then act as cofactors for many and varied enzymatic reactions. Ultimately, vitamin B_6 is degraded to 4-pyridoxic acid, primarily in the liver, which is then excreted in urine (Dolphin *et al.*, 1986; Coburn *et al.*, 2001).

In disorders featuring elevations in circulating bone and liver TNSALP activity, plasma PLP concentrations are decreased (Anderson *et al.*, 1980). The low PLP levels were once erroneously attributed to vitamin B_6 deficiency. Discovery of elevated plasma levels of PLP in HPP led to recognition of the reciprocal relationship between plasma PLP levels and serum TNSALP activity. However, such changes in circulating PLP levels are usually not physiologically important because TNSALP controls extracellular, not intracellular, dephosphorylation of PLP. Elevated

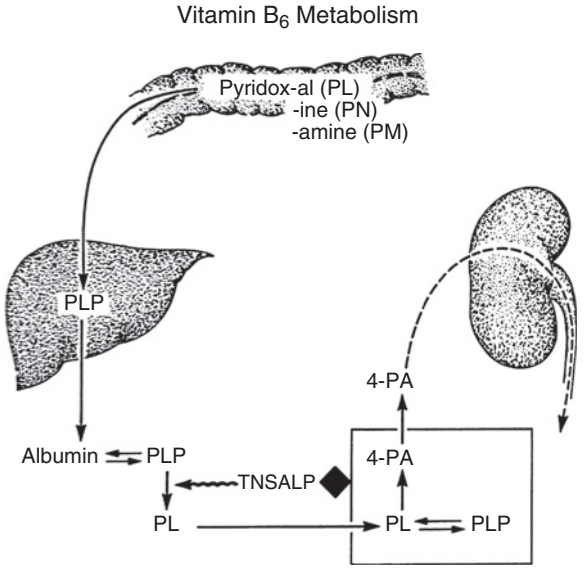

FIGURE 10 Role of TNSALP in vitamin B_6 metabolism. The various forms of vitamin B_6 are plentiful in the diet and are absorbed into the hepatic portal circulation (phosphorylated forms are first dephosphorylated in the gut). In the liver, each is converted to PLP, which is then secreted bound to albumin into the plasma. In order to enter tissues, plasma PLP must be dephosphorylated to PL which can traverse membranes. 4-Pyridoxic acid (4-PA), the major degradation product of vitamin B_6, is excreted in the urine. High plasma levels of PLP in hypophosphatasia, yet normal plasma concentrations of PL, are consistent with an ecto-enzyme role for TNSALP in the extracellular dephosphorylatin of PLP to PL. [Reproduced with permission from Whyte (2001)].

plasma PLP levels in HPP do not reflect enhanced PLP synthesis, but instead a failure of extracellular hydrolysis of PLP (Whyte *et al.*, 1985). Investigation of HPP suggested this metabolic relationship because patients typically do not have symptoms of vitamin B_6 excess such as peripheral neuropathy (Dolphin *et al.*, 1986) (see later). Similarly, in all but the most severe cases of HPP, there are no signs or symptoms of deficiency of vitamin B_6 such as stomatitis, dermatitis, peripheral neuritis, anemia, or depression (Dolphin *et al.*, 1986). Furthermore, a variety of biochemical findings indicated that intracellular levels of vitamin B_6 are unremarkable in HPP. First, urine levels of 4-pyridoxic acid are normal in patients with childhood HPP (Whyte *et al.*, 1988). Second, these children respond normally to L-tryptophan loading—a test for vitamin B_6 deficiency (Whyte and Coburn, unpublished observation). Third, in homogenates of severely TNSALP-deficient HPP fibroblasts in culture, levels of PLP and the various other forms of vitamin B_6 are normal (Whyte *et al.*, 1986b). Finally, tissues obtained at autopsy from perinatal HPP (plasma PLP concentrations 50- to 900-times elevated) contain essentially normal levels of PLP, PL, and total vitameric B_6 (Whyte *et al.*, 1988). Accordingly, TNSALP seemed to function as an ectoenzyme (Whyte *et al.*, 1985; Fedde *et al.*, 1988). This was confirmed by others in studies of membrane attachment of placental ALP (Low and Saltiel, 1988).

Because TNSALP seems to condition the dephosphorylation of PLP to PL extracellularly, plasma levels of PL could be low in HPP. However, only patients with very severe HPP have low plasma PL concentrations—other forms of HPP show normal or sometimes elevated circulating PL levels (Whyte *et al.*, 1985).

Vitamin B_6 deficiency has been associated with renal stone disease and epilepsy. Nephrocalcinosis in infants with HPP is likely caused by hypercalciuria, but oxalate excess (a consequence of vitamin B_6 deficiency) has not been looked for in HPP (Dolphin *et al.*, 1986). Epilepsy in severe HPP occurs in patients who may have cranial deformity, intracranial hemorrhage, periodic apnea, etc. Nevertheless, the convulsions also have a metabolic explanation. PEA caused seizures when given i.v. to a severely affected infant during a study of PEA metabolism (Takahashi *et al.*, 1984). Furthermore, in two patients with perinatal HPP and epilepsy, both of whom had plasma PL levels below assay sensitivity, administration of vitamin B_6 as pyridoxine did not correct the seizure disorder (personal observation), perhaps because pyridoxine was converted to PLP rather than PL. Recently, it was shown that vitamin B_6-dependent seizures can be the presenting manifestation of infantile HPP. Additionally, it was noted that all reported HPP cases with such seizures proved fatal (Baumgartner-Sigl *et al.*, 2007). In fact, the *tnsalp* knockout mouse model for infantile HPP manifests epilepsy (see later) that requires pyridoxine administration to extend the life of the animal (Waymire *et al.*, 1995; Fedde *et al.*, 1999).

The clinical and biochemical observations concerning vitamin B_6 metabolism in HPP indicated an ectoenzyme role for TNSALP (Whyte *et al.*, 1985). In 1988, Fedde and coworkers used cultivated human osteosarcoma cells (Fedde *et al.*, 1988), and then dermal fibroblasts from patients with infantile HPP (Fedde *et al.*, 1990), exposed to PLP and PEA in the medium to confirm that TNSALP is primarily a plasma membrane-associated ectoenzyme (see later). In 1980, characterization of porcine kidney ALP as membrane-bound with phosphatidylinositol (Low and Zilversmit, 1980) had suggested the attachment mechanism for TNSALP (Low and Saltiel, 1988).

Inorganic Pyrophosphate

Discovery in 1965 and 1971 that PP_i levels are increased in HPP patient urine (Russell, 1965) and plasma (Russell *et al.*, 1971) provided a plausible explanation for the defective skeletal mineralization in HPP (Caswell *et al.*, 1991) (Fig. 11). By that time, PP_i was known to be a potent inhibitor of mineralization (Heinonen, 2001). Although at low concentrations PP_i can enhance calcium and P_i precipitation from solution to form amorphous calcium phosphate, at higher concentrations PP_i prevents the growth and dissolution of hydroxyapatite crystals (Caswell *et al.*, 1991).

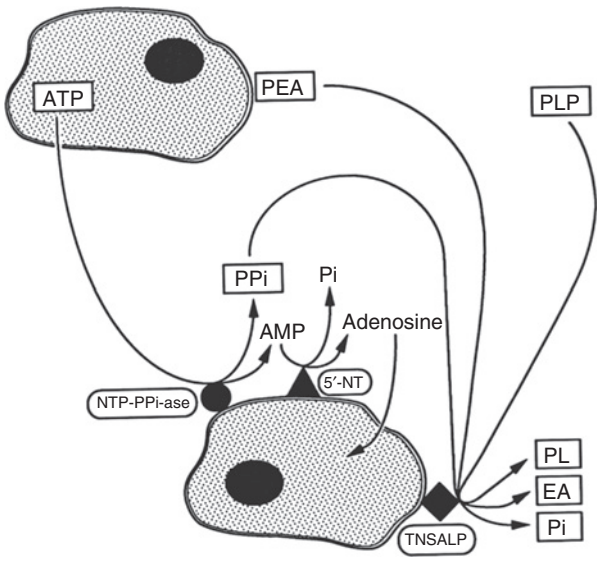

FIGURE 11 Metabolic basis for hypophosphatasia (hypothesis). Extracellular generation of PP_i, presumably by the action of nucleoside triphosphate pyrophosphatase (NTP-PP_i-ase), is normal. PP_i is also pumped extracellularly from within cells via an ANK channel (Millán, 2006). Extracellular degradation of PEA, PP_i, and PLP is diminished because of deficient ecto-TNSALP activity. Accumulation of PP_i extracellularly accounts for the CPPD precipitation and associated calcium phosphate crystal deposition. The inhibitory effect of PP_i on hydroxyapatite crystal growth accounts for the rickets/osteomalacia. [Reproduced with permission from Whyte (2001)].

Caswell and coworkers, demonstrated that nucleoside triphosphate pyrophosphatase (NTP-PP_i-ase, PC-1) activity is unremarkable in TNSALP-deficient fibroblasts from perinatal and infantile HPP patients. Generation of PP_i extracellularly from ATP by these cells is not hindered (Caswell *et al.*, 1986). Therefore, NTP-PP_i-ase seemed to be a distinctive enzyme from TNSALP. In 2000, this conclusion was supported by studies of osteoblasts from the *tnsalp* knockout mouse (see later) (Johnson *et al.*, 2000). From the studies of PLP metabolism in HPP revealing an ectoenzyme role for TNSALP, it was now understood how the clearance of $^{32}PP_i$ administered in the 1960s into the circulation of two adults with HPP was markedly delayed (R.G.G. Russell, personal communication). Endogenous accumulation of PP_i in HPP reflects defective extracellular hydrolysis of PP_i (Caswell *et al.*, 1991).

Consonant with the *in vitro* effects of PP_i, several disturbances of mineralization are observed in HPP that perhaps reflect local concentrations of PP_i together with other factors. Relatively minor excesses of PP_i may explain precipitation of amorphous calcium phosphate and the calcific periarthritis observed in some adults with HPP (Lassere and Jones, 1990). Furthermore, ALP has been shown to dissolve CPPD crystals *in vitro* (Xu *et al.*, 1991). This PP_i-ase activity seems to be unrelated to its capacity to hydrolyze phosphoesters. Thus, CPPD crystal deposition leading to chondrocalcinosis, pseudogout, and pyrophosphate arthropathy could be explained by failure of TNSALP not only to destroy PP_i, but also to hydrolyze CPPD crystals. Conversely, especially high concentrations of PP_i inhibit hydroxyapatite crystal formation and growth; hence, rickets or osteomalacia are expected characteristics of HPP. As discussed, electron microscopy of skeletal tissue from severely affected HPP patients, and in *tnsalp* knockout mice (see later), showed deficiency of secondary mineralization surrounding MVs (Anderson *et al.*, 1997).

Circulating TNSALP

Several observations suggest that ALP in the circulation is physiologically inactive. Infants with severe HPP who received i.v. infusions of plasma from patients with Paget's bone disease or purified placental ALP demonstrated no significant clinical or radiographic improvement despite transient increments in circulating ALP activity, sometimes to above normal levels. Such therapy failed to normalize urinary PEA or PP_i levels or plasma PLP concentrations (Whyte *et al.*, 1982b).

Deficiency of TNSALP activity intrinsic to the skeleton seems to account for the rickets and osteomalacia of HPP. In fact, in studies reminiscent of Robison's work (Robison, 1932), Fraser and Yendt reported in 1955 that rachitic rat cartilage would calcify in serum obtained from an infant with HPP, yet slices of the patient's costochondral junction would not mineralize in synthetic calcifying medium or in the pooled serum from healthy children (Fraser and Yendt, 1955). Subsequently, *in vitro* models showed that transfection of ALP cDNA conferred both catalysis against P_i esters and mineralization in a calcification system (Yoon *et al.*, 1989; Farley *et al.*, 1994). Nevertheless, there has been skepticism that this type of experiment reflects biomineralization, because increased P_i in metastable solutions is expected to precipitate calcium phosphate (Khouja *et al.*, 1990). However, it is probably necessary to augment ALP activity at the skeletal level to treat HPP. In fact, experience with marrow cell transplantation for two babies with infantile HPP, who then had clinical and radiographic improvement despite essentially unaltered biochemical abnormalities in blood and urine, suggests that even small increases in ALP activity within the skeleton can improve mineralization in HPP (Whyte *et al.*, 1998). Transient transfection studies of various *TNSALP* mutations causing HPP also suggested that small differences in the deficiency of ALP activity within the skeleton can account for lethal versus nonlethal patient outcomes (Mornet *et al.*, 1998).

Hypophosphatasia Fibroblast Studies

Much of our insight concerning the physiological role of TNSALP has come from investigation of people with HPP. Before the availability of *tnsalp* knockout mice for study (see later), dermal fibroblasts in culture proved useful (Fedde *et al.*, 1990; Whyte and Vrabel, 1985; Whyte *et al.*, 1986b). Fibroblasts express some TNSALP-like activity that peaks at confluence in culture (Whyte and Vrabel, 1987). Such cells obtained from severely affected HPP patients are profoundly deficient (less than 5% control) in ALP activity (Whyte *et al.*, 1983), but the residual activity seems to represent a form of TNSALP (Whyte *et al.*, 1987).

Preliminary studies using HPP fibroblasts indicated that their phospholipid composition and rates of $^{32}P_i$ accumulation were normal (Tsutsumi *et al.*, 1986; Whyte and Vrabel, 1983). In 1990, Fedde and coworkers demonstrated that TNSALP is present primarily on the surface of these cells (Fedde *et al.*, 1990). The ectophosphatase activity of TNSALP hydrolyzed extracellular PEA and PLP under physiological conditions. Although some reports suggested that ALP conditions cell growth and differentiation by influencing the phosphorylation of nucleotide pools, HPP fibroblasts proliferate at normal rates in culture (Whyte *et al.*, 1983). Furthermore, TNSALP did not seem to be a phosphoprotein phosphatase acting at the plasma membrane (Fedde *et al.*, 1993).

tnsalp Knockout Mice

Since 1995, *tnsalp* knockout mouse studies have complimented and expanded on insight gained from investigation of HPP patients concerning the pathogenesis of the skeletal, dental, and neurological disease resulting from

TNSALP deficiency (Millán, 2006). Now, *tnsalp* null mice are also being used as a preclinical model to test EzRT for HPP (Millán *et al.*, 2008). In 1995, Waymire and coworkers developed and studied a *tnsalp* null mouse that manifested the deranged vitamin B_6 metabolism of HPP causing lethal seizures from deficient γ-aminobutyric acid in the brain (Waymire *et al.*, 1995). With pyridoxal treatment, the epilepsy was controlled temporarily, and the animals survived long enough to develop dental disease. In 1997, Narisawa and colleagues developed a different *tnsalp* null mouse with vitamin B_6-dependent epilepsy that also manifested skeletal and dental disease (Narisawa *et al.*, 1997). In 1999, Fedde and coworkers demonstrated that both of these murine models recapitulate the infantile form of HPP remarkably well, including the acquired skeletal, dental, and neurological disease together with endogenous accumulation of PEA, PP_i, and PLP (Fedde *et al.*, 1999). In 2000, the mineralization defect of HPP was reproduced with osteoblasts in culture from these mice (Wennberg *et al.*, 2000). The disturbance did not seem to be related to the aberrations in vitamin B_6 metabolism (Narisawa *et al.*, 2001). Defects in secondary skeletal mineralization were also confirmed by electron microscopy (Anderson *et al.*, 2004). Subsequently, double-knockout mouse studies showed that skeletal formation is essentially normal in mice that lack both *tnsalp* and the inorganic pyrophosphate generating enzyme PC-1 (NTP-PP_i-ase), adding further support to experience with hypophosphatasia patients that PP_i accumulation owing to TNSALP deficiency causes the defective skeletal mineralization (Hessle *et al.*, 2002). Furthermore, *tnsalp* expressed under control of the APO-E promoter in the liver of *tnsalp* knockout mice prevented the skeletal disease of HPP. It is uncertain, however, if *tnsalp* in the liver itself, or liberated in especially high amounts into the circulation of these mice, explained the beneficial effects. In 2007, Hough and coworkers characterized a much milder, acquired, semidominant form of HPP in mice generated by *N*-ethyl-*N*-nitrosourea exposure. Adult mice manifested late-onset skeletal disease and arthropathy (Hough *et al.*, 2007).

SUMMARY

HPP features defective skeletal mineralization that manifests as rickets in newborns, infants, children, and adolescents, and as osteomalacia in adults. Clinical expressivity is, however, extremely variable and explained largely by autosomal dominant or autosomal recessive patterns of inheritance, and by the multitude of associated loss-of-function mutations in *TNSALP*. Perinatal HPP is apparent *in utero* and causes stillbirth from severe skeletal hypomineralization and deformity. Infantile HPP presents by age 6 months as a seemingly acquired form of rickets. Sometimes there is functional craniosynostosis and nephrocalcinosis from hypercalcemia and hypercalciuria. About 50% of these babies succumb to worsening rachitic disease compromising pulmonary function. Vitamin B_6-dependent epilepsy designates a lethal outcome. Childhood HPP features premature loss of deciduous teeth, rickets, and muscle weakness. Adult HPP causes recurrent metatarsal stress fractures, femoral pseudofractures, and occasionally arthritis from CPPD crystal deposition, and rarely calcific periarthritis from precipitation of calcium phosphate forming hydroxyapatite. Odonto-HPP refers to premature tooth loss from deficient dental cementum, but no skeletal manifestations.

Perinatal and infantile HPP are transmitted as autosomal recessive traits owing to homozygosity or compound heterozygosity involving ≈200 different loss-of-function mutations in *TNSALP*. The mutations compromise the activity and/or structure of this homodimeric or homotetrameric enzyme, and sometimes its intracellular processing. Most are missense defects. In some kindreds, relatively mild HPP is inherited as an autosomal dominant trait owing to a *TNSALP* mutation that seems to exert a dominant-negative effect. However, individuals with even the mildest forms of HPP can be compound heterozygotes for *TNSALP* mutations.

Prenatal diagnosis of HPP is possible. During the second trimester, fetal ultrasonography or radiography has proven helpful for perinatal HPP. From the first trimester, chorionic villus samples have been used successfully for *TNSALP* mutation detection. However, the considerable number and variety of *TNSALP* mutations, as well as the influence of other factors on the HPP phenotype, makes prognostication difficult.

Three phosphocompounds (PEA, PP_i, and PLP) accumulate endogenously in HPP. A variety of evidence from HPP studies shows that PLP, a cofactor form of vitamin B_6, collects extracellularly, whereas intracellular PLP levels are normal in all but the most severely affected patients. This explains the absence of symptoms of deficiency or toxicity from vitamin B_6 in HPP, and indicates that TNSALP functions as an ectoenzyme. Extracellular accumulation of PP_i at high concentrations acts as an inhibitor of hydroxyapatite crystal growth, and seems to explain the associated CPPD crystal deposition and defective mineralization of bones and teeth.

There is no established medical treatment for HPP. ALP replacement by intravenous infusion of ALP from various human tissues has been disappointing, suggesting that circulating TNSALP is physiologically inactive. Marrow cell transplantation has been followed by considerable clinical and radiographic improvement, but without significant biochemical changes, in two girls with infantile HPP. The mechanism, however, remains unproven. Teriparatide has stimulated bone ALP levels and appeared to heal fractures in adult HPP. TNSALP null mouse studies suggest that recombinant, bone-targeted TNSALP will be helpful for HPP.

CONCLUSIONS

Hypophosphatasia (HPP) is a rare but remarkably instructive inborn error of metabolism that confirms in humans a critical role for the tissue nonspecific ("liver/bone/kidney") isoenzyme of ALP (TNSALP) in skeletal mineralization and in the formation of dental cementum. Subnormal serum ALP activity (hypophosphatasemia), the biochemical hallmark of HPP, reflects a generalized deficiency of TNSALP activity. Three tissue-specific ALP isoenzymes in humans (intestinal, placental, and germ-cell ALP) are not compromised.

Insight from HPP has provided most of our understanding of the physiological role of TNSALP in humans. Discovery of increased endogenous levels of phosphoethanolamine (PEA), inorganic pyrophosphate (PP_i), and pyridoxal 5′-phosphate (PLP) in HPP demonstrated that TNSALP is catalytically active toward a variety of natural substrates; acting not only as a phosphomonoester phosphohydrolase, but also as an inorganic pyrophosphatase. Because in health these substrates occur at nanomolar or micromolar concentrations extracellularly, TNSALP acts physiologically toward them at much lower concentrations than for artificial substrates used in routine clinical assays of ALP activity. Clearly, TNSALP functions at physiological pH, and "alkaline phosphatase" is a misnomer (Whyte, 1994, 2001).

Clinical investigation of vitamin B_6 metabolism in HPP, supported by HPP fibroblast studies, confirmed that TNSALP acts as an ectoenzyme. Extracellular accumulation of PEA, PP_i, and PLP in HPP is caused by deficient ecto-TNSALP activity. Despite the increments of membrane-impermeable PLP in the plasma, normal levels of PL in plasma (and presumably in other extracellular fluids and in tissues) explain the absence of signs or symptoms of vitamin B_6 deficiency (or toxicity) in all but the most severely affected HPP patients.

The source of PLP in HPP appears to be in the liver. PEA may derive from degradation of the phosphatidylinositol-glycan moiety that anchors many proteins to cells surfaces. PP_i is formed extracellularly by cell surface NTP-PP_i-ase, and pumped from cells by a channel protein called ANK. Hyperphosphatemia owing to increased TmP/GFR in HPP suggests that TNSALP plays a direct role in renal P_i excretion.

In HPP, calcium phosphate crystal deposition rarely causes calcific periarthritis, but calcium pyrophosphate dihydrate crystal deposition frequently results in chondrocalcinosis, and sometimes in pseudogout, or PP_i arthropathy. Calcific periarthritis reflects the regional effect of PP_i at low concentrations to stimulate amorphous calcium phosphate formation. Rickets and osteomalacia in HPP reflect the effect of high extracellular concentrations of PP_i to inhibit hydroxyapatite crystal formation and growth at sites of skeletal mineralization. Trials of ALP replacement therapy for HPP suggest that TNSALP acts physiologically at the level of the skeleton, but not in the circulation.

ACKNOWLEDGMENTS

I am grateful to the staff of the Center for Metabolic Bone Disease and Molecular Research, Shriners Hospitals for Children, St. Louis, Missouri, for making this chapter possible. My colleague, Steven Mumm, Ph.D., is contributing importantly to our understanding of the molecular basis of hypophosphatasia. My associate, Deborah Wenkert, M.D., is advancing our understanding of the natural history, complications, and management of pediatric patients with hypophosphatasia. Dawn Russell photographed the illustrations. Angelia English provided expert secretarial help.

This work was supported by Shriners Hospitals for Children, The Clark And Mildred Cox Inherited Metabolic Bone Disease Research Fund, The Hypophosphatasia Research Fund, and the Barnes-Jewish Hospital Foundation.

Chapter 74

Paget's Disease of Bone

Frederick R. Singer*
John Wayne Cancer Institute, Saint John's Health Center, Santa Monica, California

G. David Roodman
Department of Medicine, Division of Hematology, University of Pittsburgh, and VA Pittsburgh Healthcare System, Pittsburgh, Pennsylvania

THE PATIENT

Paget's disease is a common disorder of the skeleton that is local in nature and extremely variable in its clinical manifestations (Singer and Krane, 1998). The majority of patients are without symptoms. When symptoms are present, skeletal deformity and pain are most common. Deformities are usually most apparent in the skull, face, and lower extremities. Pain is of several origins. Localized bone pain is surprisingly uncommon, but joint pain (hips and knees) is seen not infrequently owing to degenerative arthritis. Pain of neural or spinal origin is unusual but the most severe.

A variety of complications may first bring the patient to medical attention. The complications depend both on the affected skeletal sites and the overall extent of the disease (six bones are commonly involved). Patients with Paget's disease in the skull often develop a hearing deficit if the temporal bone is affected. Massive enlargement of the cranium is associated with basilar impression and neurological impairment. Vertebral involvement may produce compression fractures, spinal stenosis, neurological impairment, and degenerative arthritis. Paget's disease in the pelvis and femurs commonly is associated with degenerative arthritis of the hips. Involvement of the femur and tibia may lead to pathological fractures of these long bones. Nonunion of a femoral fracture is relatively common. Degenerative arthritis in the knees is also a common feature when lower extremity long bones are extensively involved by Paget's disease. The most serious complication is the development of a sarcoma that fortunately occurs in only less than 1% of patients. It always arises in a pagetic lesion and not in unaffected bone. Systemic complications of Paget's disease generally occur with more extensive disease.

*Corresponding author: Frederick R. Singer, John Wayne Cancer Institute, Saint John's Health Center, Santa Monica, CA 90404. E-mail: singerf@yahoo.com, Telephone: 310-582-7117

Hypercalcemia, preceded by hypercalcuria, usually is noted with total bed rest and is related to the accelerated bone resorption induced by immobilization. Increased cardiac output, and less commonly, congestive heart failure, is a consequence of the great vascularity of bones affected by Paget's disease. Hyperuricemia has been observed in males with extensive disease and may reflect increased purine turnover.

RADIOLOGY AND NUCLEAR MEDICINE

The diagnosis of Paget's disease is primarily accomplished by roentgenographic evaluation of the skeleton. Over the years it has become clear that the disease evolves through several stages as observed by serial roentgenograms.

The initial stage of the disease is represented by a localized area of reduced bone density often referred to as an osteolytic lesion. This is most readily detected in the skull where it is found as a discrete round or oval lesion in the frontal or occipital bones. It is called *osteoporosis circumscripta.* Paget's disease in the long bones almost always begins in the subchondral region of either epiphysis (uncommonly, both may be affected simultaneously). The osteolytic process has then been seen to advance proximally or distally at about 1 cm/year in the untreated patient. The advancing front usually has a V-shaped or arrowhead appearance.

In the most advanced stage of Paget's disease, the areas of previous osteolytic dominance now are characterized by a chaotic sclerotic appearance, a phase that is called osteoblastic or osteosclerotic. In long bones the osteolytic phase is commonly seen preceding the osteosclerotic region when much of the bone has been affected by the disease. Another feature of this phase is considerable thickening of the sclerotic bone, which can reach monumental proportions in the skull. Osteolytic activity of a secondary nature often can be observed as clefts in the thickened bone. It is

Principles of Bone Biology, 3rd Edition

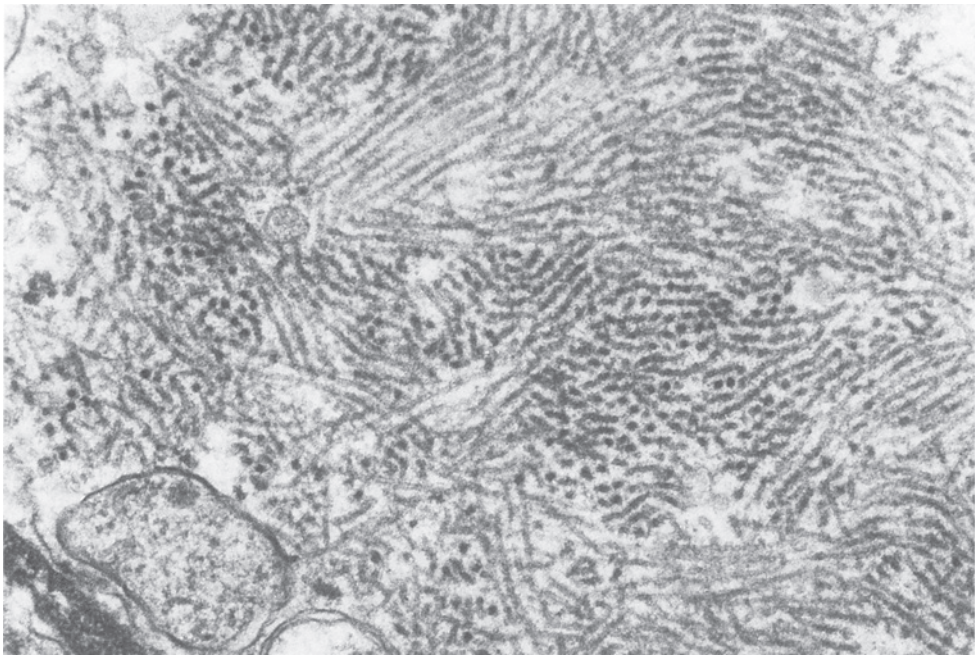

FIGURE 1 Electron micrograph of a nuclear inclusion in an osteoclast of a patient with Paget's disease. The microfilaments are seen both in longitudinal array and in paracrystalline array in cross section. Provided by Dr. Barbara G. Mills.

likely that the evolution of the disease into its most severe form occurs over much of the life span of the patient. Two other features of the disease have been noted through serial roentgenographic observations. Although the disease can slowly course through an entire bone, it does not cross a joint space to affect an adjacent bone. Also it is extremely rare for new lesions of Paget's disease to be detected at any site in the skeleton after the diagnosis and extent of the disease has been determined initially.

Bone scans are the most sensitive means of detecting pagetic lesions. Radiolabeled bisphosphonates accumulate in regions where blood flow and bone formation are increased and can outline early lesions that are not detectable on roentgenograms. Radioactive gallium can also define areas of Paget's disease activity because of uptake of gallium by osteoclasts.

HISTOPATHOLOGY

Beginning with the observations of Schmorl in 1932, it has become appreciated that the osteoclast is the dominant cell in the pathogenesis of Paget's disease. Osteoclasts are increased in number in the Haversian canals of the cortex in the absence of other abnormalities and are in great numbers at the leading edge of the osteolytic front. The osteoclasts in Paget's disease may be far greater in size than osteoclasts in normal bone and contain as many as 100 nuclei in a cross section compared with two or three nuclei in a normal osteoclast. Osteoclasts of Paget's disease have a characteristic ultrastructural abnormality (Gherardi *et al.*, 1980; Howatson and Fornasier, 1982; Mills and Singer, 1976; Rebel *et al.*, 1974). This consists of microfilaments, sometimes grouped in a paracrystalline array, located in the nucleus and sometimes in the cytoplasm of osteoclasts (Fig. 1). These microfilaments are not seen in nonpagetic bone or bone marrow cells. These inclusions closely resemble nucleocapsids of viruses of the Paramyxoviridae family, a group of RNA viruses responsible for some of the most common childhood diseases. Despite the finding of these inclusions in the vast majority of patients studied, the budding off of an infectious virus from the osteoclasts has rarely been observed (Abe *et al.*, 1995).

Osteoblasts are another prominent feature of the cellular pathology of Paget's disease. Large numbers of osteoblasts are often found near areas of resorbed bone and may even be prominent in a lesion that appears purely osteolytic by x-ray. The osteoblasts are usually prism-shaped or polyhedral and contain abundant rough endoplasmic reticulum, mitochondria, and a well-developed Golgi zone. These signs of cellular activity are consistent with the increased bone formation in active lesions established by the use of double labeling with tetracycline.

In addition to the increased numbers of osteoclasts and osteoblasts, the marrow of pagetic lesions tends to be grossly abnormal. The normal hematopoietic elements are usually absent and replaced by mononuclear cells of indeterminate origin intermixed with highly vascular connective tissue.

The bone matrix in Paget's disease is highly abnormal in structure and arises as a consequence of disordered bone resorption and formation. The matrix consists of a "mosaic" of irregularly shaped pieces of lamellar bone

with an erratic pattern of cement lines. The matrix is interspersed with numerous foci of woven bone, which, in adults, is ordinarily found associated with fracture healing.

BIOCHEMISTRY

The biochemical findings in Paget's disease help to provide an integrated assessment of the cellular events occurring throughout the skeleton of affected patients.

Historically, the earliest index of bone matrix resorption was measurement of urinary hydroxyproline excretion while ingesting a low-gelatin diet. This index is well correlated with the extent of the disease despite the fact that hydroxyproline is a prominent component of extraskeletal connective tissue as well as skeletal collagen. Measurement of collagen cross-link degradation products in urine provides more specific measurements of skeletal matrix. Urinary N-telopeptide, C-telopeptide, pyridinoline, and deoxypyridinoline have all been reported to be more specific indices of skeletal matrix resorption and are not influenced by dietary gelatin (Alvarez *et al.*, 1995; Reid *et al.,* 2004; Shankar and Hosking, 2006).

Serum tartrate-resistant acid phosphatase, presumably released by osteoclasts, appears to be another index of bone resorption in Paget's disease but is not routinely available (Kraenzlin *et al.*, 1990).

Osteoblast activity can be assessed by measurement in the serum of total alkaline phosphatase activity, bone-specific alkaline phosphatase activity, osteocalcin concentration, and procollagen type 1 N-terminal propeptide (P1NP) concentration. The most useful of these serum markers are the total alkaline phosphatase, bone-specific alkaline phosphatase, and P1NP (Alvarez *et al.*, 1995; Reid *et al*, 2004; Shankar and Hosking, 2006). For reasons that are not understood.

TREATMENT OF PAGET'S DISEASE

Salmon calcitonin by injection and etidronate disodium by the oral route were the first effective medications introduced about 30 years ago. They generally suppress biochemical parameters of the disease by 50%. Intravenous pamidronate disodium, oral alendronate, and risedronate sodium are more recent, more potent bisphosphonates that can reduce bone turnover to normal in the majority of patients with Paget's disease (Singer and Krane, 1998). In some countries zoledronic acid has been approved for treatment of Paget's disease. A 15-minute intravenous infusion suppresses biochemical activity into the normal range even in patients with markedly elevated parameters of bone resorption and formation (Reid *et al.*, 2005). The response usually persists for at least two years (Hosking *et al*., 2007).

Surgery is sometimes necessary to treat patients with associated degenerative arthritis of the hip (total hip replacement) and of the knee (high tibial osteotomy). Orthopedic and/or neurosurgical procedures may occasionally be necessary after fractures and when skull or vertebral complications are present.

EVIDENCE FOR THE PRESENCE OF PARAMYXOVIRUSES IN PAGET'S DISEASE

In early studies, Mills and colleagues attempted to rescue an infectious virus from cells cultured from surgical specimens of Paget's disease (B. G. Mills and F. R. Singer, unpublished observations; Mills *et al.*, 1979). After trypsinization or after growing cells from explants of pagetic bones, cells were cultivated for months and then cocultivated with cell lines used to isolate Paramyxoviridae viruses. These studies failed to demonstrate an infectious virus in pagetic bone. Perhaps this is not surprising because little anatomic evidence of an infectious virus has been found in any specimen of Paget's disease, and the mononuclear cells cultured from surgical specimens have rarely been found to exhibit nuclear inclusions. Mills and colleagues (1985) also attempted to develop an animal model of Paget's disease by injecting crushed bone extracts or lysates from cells cultured from pagetic bone into the tibiae of athymic nude mice. Nothing resembling Paget's disease was induced in the mouse bone, although one cell line did produce an osteosarcoma-like lesion reproducibly.

Despite the failure to find an infectious (mature) virus in specimens of Paget's disease, abundant evidence has been generated using immunohistological and molecular biological techniques that indicate the presence of viral antigens and mRNA in Paget's disease. Initially Rebel and colleagues (1980a) used a variety of antisera directed against measles virus to demonstrate measles antigen in the osteoclasts of 20 patients with Paget's disease, but not in one patient with fluorosis and another with a healing fracture. Positive results were obtained with both indirect immunofluorescence (Fig. 2) and immunoperoxidase techniques (Rebel *et al.*, 1980b). Mills and colleagues (1980, 1981) initially reported that cell cultures from pagetic bone, as well as bone sections from 12 patients, were positive when stained with an antiserum against respiratory syncytial virus but not with antisera against measles virus, parainfluenza viruses, influenza A and B, rubella, mumps, and herpes simplex. Subsequently, Mills and colleagues (1984) did observe that measles virus nucleocapsid protein antigens were present in the osteoclasts and/or cultured bone cells of most patients with Paget's disease. Of particular interest was their finding that in serial sections of pagetic bone, both measles virus and respiratory syncytial virus nucleocapsid antigens were demonstrable in the same osteoclasts. This observation could not be explained by cross-reactivity of the measles virus monoclonal antibodies used in this study with respiratory syncytial virus

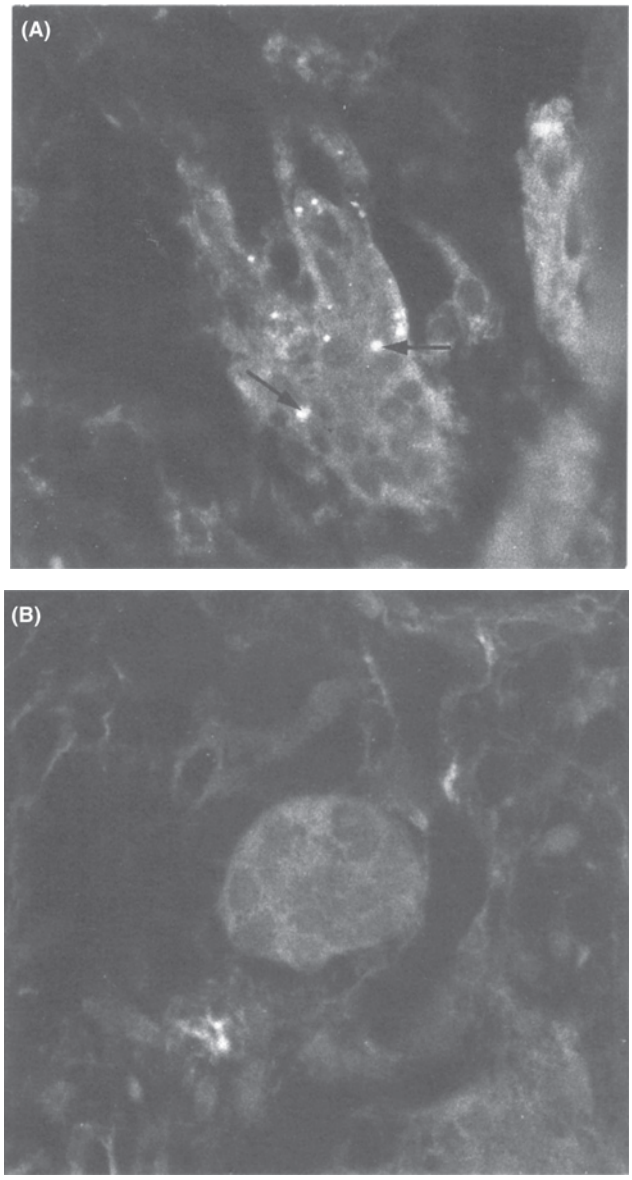

FIGURE 2 (**A**) A section of decalcified pagetic bone incubated with rabbit anti-LEC serum followed by goal antiserum coupled to fluorescein isothiocyanate. The LEC strain of measles virus was isolated from a patient with subacute sclerosing panencephalitis (SSPE). The osteoclast shows a strong positive punctate (*arrows*) fluorescent reaction. (**B**) A section of decalcified pagetic bone was treated as in **A**, except nonimmune rabbit serum was used instead of anti-LEC serum. There is no fluorescent reaction. Reproduced with permission from Rebel *et al*. (1980b).

antigens and vice versa. In other immunohistological studies, Basle and colleagues (1985) demonstrated not only measles virus antigens in 6 of 6 specimens of Paget's disease but also simian virus 5 in 6 of 6 and parainfluenza 3 in 3 of 6 specimens. No reactivity with respiratory syncytial virus, mumps virus, influenza virus, or adenovirus type 5 antibodies was found in this study. Subsequently, Basle did find a positive response with a monoclonal antibody against respiratory syncytial virus provided by Mills (personal communication). He also noted the presence of measles virus and respiratory syncytial virus antigens in the same osteoclasts on serial sections of pagetic bone. Mills and colleagues (1994) have also studied immunohistological staining of long-term cultures of marrow from patients with Paget's disease and from normal subjects with respect to viral antigens. In 12 of 12 patients, measles virus and/or respiratory syncytial virus nucleocapsid antigens were found in 40 to 50% of the mononuclear cells and/or multinucleated cells in culture. In the control subjects, less than 5% of cells were positive. Reddy and colleagues (1995) found measles virus transcripts in peripheral blood mononuclear cells in 4 of 5 patients and 0 of 10 normal subjects.

In the past 20 years, the techniques of molecular biology have increasingly been applied to the issue of the identity of the osteoclast inclusions of Paget's disease. In the first study, Basle and colleagues (1986) used *in situ* hybridization with a cloned measles virus cDNA probe specific for the nucleocapsid protein to search for measles virus RNA sequences in the bone of five patients. These sequences were detected in 80 to 90% of the osteoclasts in these specimens. Surprisingly, 30 to 40% of the mononuclear cells in these bone specimens also had detectable mRNA sequences of measles virus nucleocapsid protein. Evidence of the measles virus was found in osteoblasts, osteocytes, fibroblasts, lymphocytes, and monocytes. Negative results were obtained in three subjects who had fluorosis, fracture healing, and hyperparathyroidism, respectively.

Because an epidemiological study in England indicated that patients with Paget's disease were more likely to have had a pet dog in the past (O'Driscoll and Anderson, 1985), Gordon and colleagues (1991) used *in situ* hybridization to examine the possibility that canine distemper virus might be involved in Paget's disease. Canine distemper virus is a paramyxovirus with considerable structural homology to measles virus. Bone biopsies from 27 patients and 6 patients with other bone disorders (primary hyperparathyroidism, prostatic carcinoma, osteoporosis, osteomalacia, and fracture healing) were studied. Sense and antisense RNA probes to the nucleocapsid and fusion genes of the canine distemper virus were used as well as RNA probes to mRNA sequences of measles virus nucleocapsid protein. There was no demonstrable cross-reactivity of these probes with the heterologous virus under the experimental conditions used by the investigators. Eleven of 25 patients showed hybridization with the antisense but not the sense canine distemper virus fusion protein probe. Ten of 26 patients also showed hybridization with the antisense but not the sense probe for canine distemper virus nucleocapsid protein. The canine distemper virus probes produced hybridization in 80% of multinucleated osteoclasts, in 60% of osteoblasts, and in osteocytes as well as marrow mononuclear cells (monocytes, lymphocytes). No significant hybridization was found with the measles virus probe, and none of the control specimens reacted with any of the probes discussed earlier. In a subsequent study, Gordon

and colleagues (1992) obtained pagetic bone for RNA extraction, reverse transcribed the RNA, and specifically amplified for canine distemper virus and measles virus sequences by using the polymerase chain reaction (PCR) technique. They found that 8 of 13 patients had canine distemper virus nucleic acid sequences, and 1 of 10 patients had measles virus nucleic acid sequences in the bone specimens. One patient had both. Dideoxy sequencing of the canine distemper virus PCR products revealed 2% base pair (bp) changes in a 187-bp fragment from within position 1231–1464 of the nucleocapsid gene compared with the Onderstpoort strain of canine distemper virus. Further support of the hypothesis that canine distemper virus could be involved in the pathogenesis of Paget's disease was sought by examining the bones of dogs with distemper infections (Mee *et al.*, 1992). In 2 of 4 dogs studied, *in situ* hybridization of metaphyseal specimens revealed strong signals with sense and antisense probes for the nucleocapsid and phosphoprotein genes. The osteoclasts were strongly positive but osteoblasts, osteocytes, and bone marrow cells were also positive. Mee and colleagues (1993) also have found canine distemper virus transcripts in the bone cells of dogs with metaphyseal osteopathy. This is an acute disorder affecting young rapidly growing dogs whose signs include fever, anorexia, and painful swollen metaphyses. The histology does not resemble Paget's disease. Although the presence of canine distemper virus transcripts in dogs with distemper or metaphyseal osteopathy does not relate directly to Paget's disease, it does indicate that a paramyxovirus can infect mammalian bone cells. This has also been demonstrated *in vitro* by incubating canine distemper virus with canine bone marrow (Mee *et al.*, 1995).

Additional evidence of paramyxovirus nucleocapsid transcripts in Paget's disease has come from the studies of Reddy and colleagues. They studied bone marrow mononuclear cells obtained from aspirations of the iliac crests of six patients with radiologically demonstrable Paget's disease and from the aspirations of 10 normal subjects (Reddy *et al.*, 1995). Using the reverse transcriptase-PCR techniques, they observed that 5 of 6 patients had measles virus nucleocapsid transcripts, whereas none of the 10 normal subjects had detectable transcripts. Dideoxy sequencing of the PCR fragments revealed several mutations within the position 1360–1371 bp of the nucleocapsid gene compared with the Edmonston strain of measles virus. These mutations are in the same region as the mutations reported in the canine distemper virus nucleocapsid gene. Because granulocyte macrophage colony-forming units (CFU-GM), the most likely osteoclast precursors, circulate in the peripheral blood, Reddy and colleagues (1996) examined peripheral blood samples for the presence of measles virus nucleocapsid transcripts by reverse transcriptase-PCR in Paget's disease and control subjects. In 9 of 13 patients, measles virus transcripts were detected. They were localized to peripheral blood monocytes (whose precursor is CFU-GM) by *in situ* hybridization. Studies were negative in 10 control subjects.

Recently, Kurihara and colleagues (2006) targeted the measles virus nucleocapsid gene to cells of the osteoclast lineage in transgenic mice. Osteoclast formation in these animals was markedly increased and displayed many of the characteristics of pagetic osteoclasts. Further, 40% of these animals developed bone lesions that were localized and were very similar to bone lesions found in Paget's patients (Fig. 3). None of these findings were present in littermate controls.

Three studies from the United Kingdom, one from the United States, and one from New Zealand have produced negative results with respect to detection of Paramyxoviridae mRNA in Paget's disease. In one study, RNA extracts of 10 bone specimens failed to exhibit measles virus, canine distemper virus, respiratory syncytial virus, or parainfluenza 3 virus transcripts after reverse transcriptase-PCR evaluation (Ralston *et al.*, 1991). In a second study, both bone cells cultured from pagetic explants and bone biopsies were studied similarly by reverse transcriptase-PCR techniques for the presence of measles virus and canine distemper virus transcripts (Birch *et al.*, 1994). Completely negative results were obtained. A second U.K. study using the same primers also failed to find measles virus or canine distemper virus transcripts in long-term bone marrow cultures from lesions of Paget's disease (Ooi *et al.*, 2000). In the U.S. study, Nuovo and colleagues (1992) also could not detect measles virus-specific cDNA in pagetic specimens by using the PCR and *in situ* hybridization in combination. The New Zealand study (Matthews, *et al.*, 2008) reported no evidence of measles virus ribonucleic acid in 13 osteoblast and 13 bone marrow cell cultures. The explanation for the disparate results is unclear because these investigators demonstrated that they can detect very low levels of measles virus transcripts by PCR (Ralston *et al.*, 2007).

Several studies have addressed the levels of circulating antibodies against various paramyxoviruses in patients with Paget's disease. Antibody titers have not been found to be greater in Paget's disease than in control subjects (Basle *et al.*, 1983; Gordon *et al.*, 1993; Pringle *et al.*, 1985).

CELLULAR AND MOLECULAR BIOLOGY OF PAGET'S DISEASE

The development of *in vitro* techniques for the study of the ontogeny of human osteoclasts has made it possible to gain new insights into the pathogenesis of Paget's disease. Kukita and colleagues (1990) first established long-term cultures of marrow from involved bones from patients with Paget's disease and noted that the multinucleated cells that formed shared many of the characteristics of pagetic osteoclasts. Compared with osteoclast-like cells formed in normal marrow cultures, the pagetic osteoclast-like cells

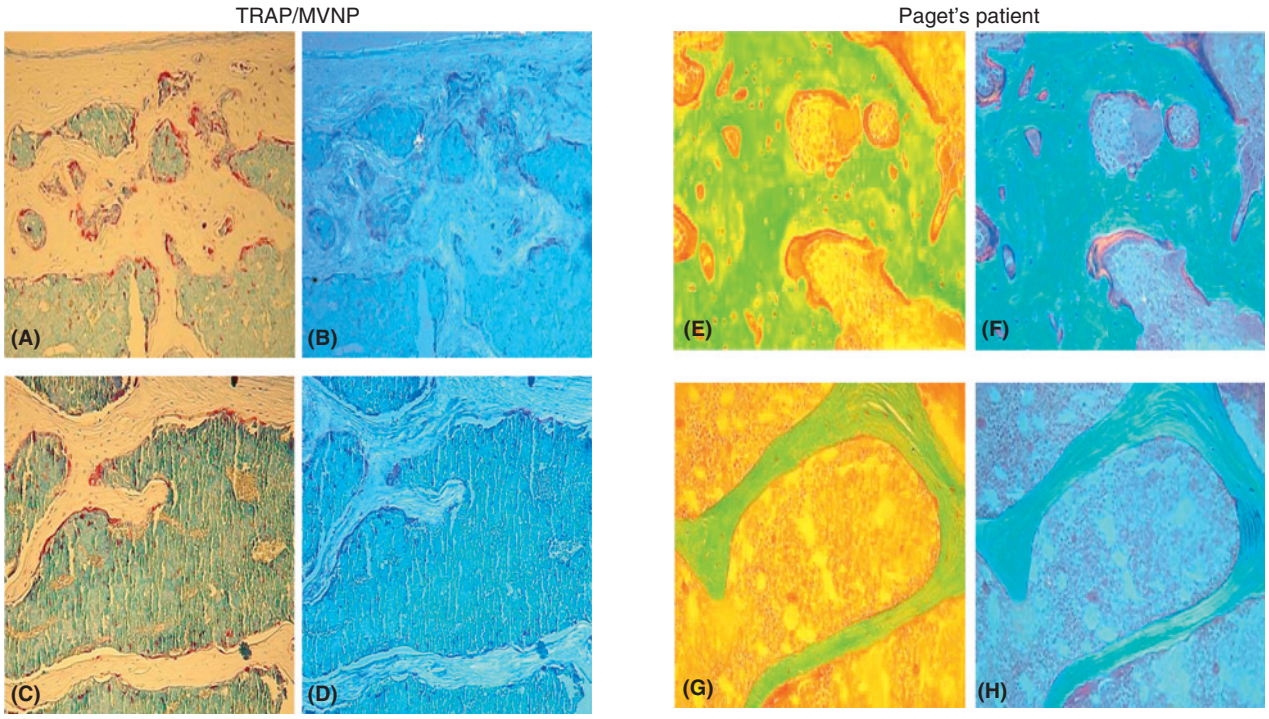

FIGURE 3 Histological features of a 12-month-old tartrate-resistant acid phosphatase/Edmonston strain measles virus nucleocapsid protein (TRACP/E-MVNP) transgenic mouse compared with wild-type (WT) controls. Histological features in a TRAPC/E-MVNP mouse (**A** and **B**) compared with a WT control (**C** and **D**) at 12 months of age. Note thickened, irregular trabeculae, increased osteoclast number (**A**), tunneling resorption, and increased amounts of woven bone in the TRAPC/E-MVNP mouse (**B**) compared with the WT control (**C** and **D**). Provided for comparison are sections from a 58-year-old woman with Paget's disease (**E** and **F**) and a 58-year-old normal subject (**G** and **H**). (**A** and **C**) TRACP stain, counterstained with methyl green-thionin. (**B** and **D**) Same sections viewed under polarized light to reveal woven bone. (**E** and **G**) Goldner's trichrome stain. (**F** and **H**) Same sections viewed under polarized light. Original magnification, ×100. From Kurihara *et al*. (2006). (See plate section)

formed more rapidly and in much greater numbers (10- to 100-fold greater), had increased numbers of nuclei, and had higher levels of tartrate-resistant acid phosphatase. Examination of these cells by electron microscopy did reveal many features of osteoclasts found in pagetic bone biopsies, but the characteristic nuclear and cytoplasmic inclusions were not observed. As mentioned previously, the antigens of measles virus and respiratory syncytial virus nucleocapsids were detectable in these cells (Mills *et al.*, 1994); apparently the nucleocapsid structures do not form in this *in vitro* setting, perhaps because the formation of nucleocapsid structures requires more than the nucleocapsid gene alone.

Because the increased numbers of osteoclasts in pagetic lesions are of obvious importance in the pathogenesis of the disease, it seemed logical to examine osteoclast precursors in the marrow aspirates to determine whether they were abnormal or whether other cells in the marrow microenvironment were participants in the pathology. Demulder and colleagues (1993) examined CFU-GM in cultures of unfractionated marrow mononuclear cells and found that CFU-GM colony formation was significantly increased compared with that of normal cells. Using an antibody that recognizes the CD34 antigen present on most hematopoietic precursors, they also isolated enriched hematopoietic precursors and found similar numbers of osteoclast precursors in pagetic and normal marrow aspirations. Subsequent coculture experiments with highly purified hematopoietic precursors ($CD34^+$ cells) and nonhematopoietic marrow accessory cells ($CD34^-$ cells) demonstrated that the growth of pagetic precursors was significantly enhanced by both normal and pagetic $CD34^-$ cells. CFU-GM colony formation was also significantly increased when normal $CD34^+$ cells were cocultured with pagetic, but not normal, $CD34^-$ cells. CFU-GM colony-derived cells from pagetic patients also formed osteoclast-like multinucleated cells with 1,25-dihydroxyvitamin D ($1,25\text{-}(OH)_2D_3$) in concentrations 1/10th of that required for normal multinucleated cell formation. Thus, these experiments suggest that osteoclast precursors are abnormal in Paget's disease and that other cells in the pagetic marrow microenvironment may stimulate the growth and differentiation of these abnormal precursors. Menaa and coworkers (2000a) have extended the original studies of Demulder *et al.* (1993) to further understand the enhanced sensitivity of osteoclast precursors from patients with Paget's disease to the marrow microenvironment and the enhanced osteoclastogenic potential of the marrow microenvironment from Paget's patients.

Menaa and coworkers (2000a) showed that pagetic osteoclast precursors are hyperresponsive to RANK ligand, a member of the tumor necrosis factor (TNF) gene family, which is absolutely required for osteoclast formation. The increased sensitivity to RANK ligand was caused by the additive effects of interleukin-6 produced by the pagetic marrow and RANK ligand on osteoclast formation. Furthermore, Menaa and coworkers showed that marrow stromal cells from patients with Paget's disease expressed higher levels of RANK ligand than normal marrow stromal cells, although, recently, Naot and colleagues (2007) did not find increased RANKL expression by osteoblasts from pagetic lesions by using gene expression profiling. Thus, in pagetic lesions the osteoclast precursors are hyperresponsive to RANK ligand, and increased amounts of RANK ligand may be expressed in the marrow microenvironment, further enhancing the osteoclastogenic potential of the pagetic lesion. In areas of bone not affected by Paget's disease, enhanced expression of RANK ligand was not detected.

As noted earlier, a strong candidate for a significant autocrine/paracrine factor involved in the increased osteoclast formation in Paget's disease is interleukin-6. Roodman and colleagues (1992) found that conditioned media from long-term pagetic marrow cultures increased multinucleated cell formation in normal marrow cultures, and antibodies to interleukin-6 blocked the stimulatory activity. Antibodies to interleukin-1, GM-CSF, and TNF-α had no effect on the stimulatory activity. *In situ* hybridization studies demonstrated that the multinucleated cells in the pagetic marrow cultures were actively transcribing interleukin-6 mRNA. In addition, bone marrow plasma samples obtained from sites of Paget's disease had increased levels of interleukin-6 in 9 of 10 patients compared with samples from normal subjects. Peripheral plasma also had elevated interleukin-6 levels in 17 of 27 patients. In another study, basal plasma interleukin-6 activity was increased in 19 of 22 patients (Schweitzer *et al.*, 1995). The concept that interleukin-6 may be an important autocrine/paracrine factor in Paget's disease is also supported by the studies of Hoyland and colleagues (1994a), who used *in situ* hybridization to localize the expression of interleukin-6, interleukin-6 receptor, and interleukin-6 transcription factor in the bone of patients with Paget's disease in comparison with those with osteoarthritis. The osteoblasts in both disorders expressed all three mRNAs, but in Paget's disease interleukin-6 and its receptor mRNA showed higher levels of expression. In the osteoclasts of both disorders, the receptor and transcription factor were expressed, but only in Paget's disease was interleukin-6 mRNA expressed in osteoclasts. Hoyland and Sharpe (1994b) also examined the expression of c-*fos* proto-oncogene in the bone of six patients with Paget's disease by *in situ* hybridization. c-*fos* has been found to be important in the regulation of osteoclasts and was markedly upregulated in pagetic osteoclasts and, to a lesser extent, in the osteoblasts. It is possible that this is a consequence of interleukin-6 action (Korholz *et al.*, 1992).

Ralston and colleagues (1994) also studied cytokine and growth factor expression in bone explants of Paget's disease and in control subjects (postmenopausal women with and without osteoporosis and young bone graft patients) and could not find differences between pagetic and nonpagetic bone. Interleukin-6 mRNA was not detected in 40% of the pagetic specimens from severely affected individuals. There is no obvious explanation for their nonconfirmatory data.

Another abnormality of pagetic osteoclast precursors is that they are hyperresponsive to 1,25-$(OH)_2D_3$. Osteoclast precursors form osteoclasts *in vitro* with concentrations of 1,25-$(OH)_2D_3$ that are 1 to 2 logs less than that required to induce osteoclast formation by normal osteoclast precursors (Kukita *et al.*, 1990). Menaa and coworkers (2000b) have shown that this increased sensitivity to 1,25-$(OH)_2D_3$ is not caused by increased numbers of vitamin D receptors in pagetic osteoclast precursors or by mutations in the vitamin D receptor. Kurihara and colleagues (2000) have used a GST-vitamin D receptor fusion protein to further examine the increased sensitivity of pagetic osteoclast precursors to 1,25-$(OH)_2D_3$. These workers found that TAFII-20, a component of the TFIID transcription complex, was increased in osteoclast precursors from patients with Paget's disease compared with normal patients. This increase in expression of TAFII-20 did not require treatment of the cells with 1,25-$(OH)_2D_3$. These data suggest that pagetic osteoclast precursors express higher levels of TAFII-20 or have increased levels of a coactivator that can bind to TAFII-20 and the vitamin D receptor in the presence of lower concentrations of 1,25-$(OH)_2D_3$ to initiate transcription of vitamin D receptor (VDR) responsive genes.

GENETIC MUTATIONS LINKED TO PAGET'S DISEASE

As noted earlier, genetic factors are an important contributor to the etiology of Paget's disease, with 15 to 40% of affected patients having a first degree relative with Paget's disease. Several susceptibility loci for Paget's disease have been recently identified including 2q36, 5q31, 5q35, 10*p*13, 18q21–22, and 18q–23 (Cody *et al.*, 1997; Good *et al.*, 2002; Haslam *et al.*, 1998; Hocking *et al.*, 2001; Laurin *et al.*, 2001; Leach *et al.*, 2001). Mutations in the RANK gene on chromosome 18q21–22 have been linked to familial expansile osteolysis, a rare bone disorder that shares many clinical features of Paget's disease, but this mutation has only been found in a Korean family with Paget's disease. Laurin and coworkers (2002a) detected a point mutation, p392L, in the sequestosome-1 gene (p62). p62 is a ubiquitin-binding protein that is involved in the IL-1, TNF, and RANKL signaling pathways. Subsequently,

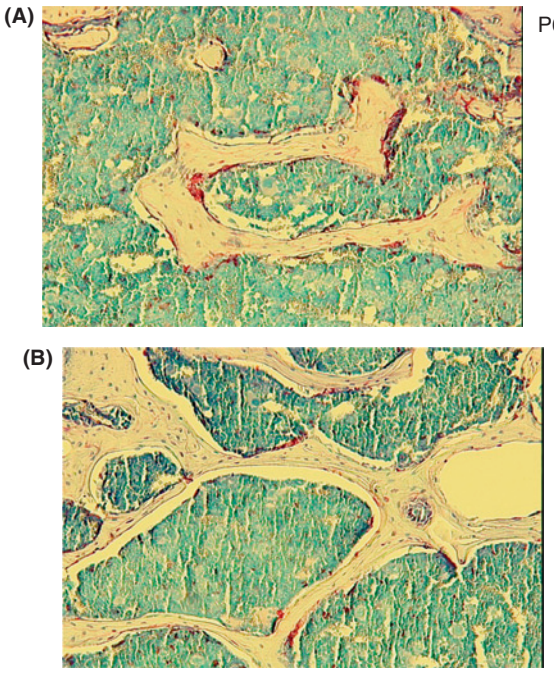

FIGURE 4 Histological studies of bone from TRAP-p62P392L mice. Vertebral cancellous bone from wild-type littermates (**A**) or TRAP-p62P392L mice (**B**). Note increased osteoclast perimeter (red stain), reduced cancellous bone volume, fewer and thinner trabeculae, and loss of trabecular connectivity in TRAP-p62P392L bone. From Kurihara *et al.* (2007). (See plate section)

other mutations in p62 have been found in both patients with familial and nonfamilial Paget's disease. However, the P392L mutation is the most frequent mutation in this gene and can be detected in up to 30% of patients with familial Paget's disease. Lucas and collegues (2008) have presented evidence that an unidentified gene on chromosome 10p13 may be present in most of the British families with Paget's disease who lack p62 mutations.

In recent studies, Kurihara and coworkers showed that transfection of normal human osteoclast precursors with a p62 construct containing the P392L mutation enhances the sensitivity of normal human osteoclast precursors for RANKL and results in increased osteoclast formation. However, these osteoclast precursors were not hyperresponsive to 1,25-$(OH)_2D_3$ nor did they contain increased numbers of nuclei per osteoclast, which are characteristics of pagetic osteoclasts (Kurihara *et al.*, 2007). Kurihara and coworkers have also targeted the P392L mutant p62 gene to cells in the osteoclast lineage in transgenic mice and found that these mice have increased osteoclast numbers but, in contrast to developing pagetic-like bone lesions, they developed severe osteopenia (Fig. 4). They also did not develop increased osteoblast activity that is characteristic of pagetic bone lesions. Osteoclasts from these transgene mice were not hypermultinucleated nor were osteoclast precursors from these animals hyperresponsive to 1,25-$(OH)_2D_3$. These *in vitro* and *in vivo* studies suggest that the P392L mutation in p62 increases osteoclast formation through increased RANK signaling.

Further, studies with families with Paget's disease linked to mutations in p62 also suggest that these mutations cannot completely account for the pathogenesis of Paget's disease, because the severity of the disease in family members carrying these mutations varies widely, and up to 83% of patients harboring the p62 mutation do not have Paget's disease (Laurin *et al.*, 2002b, Bolland *et al.*, 2007). These data suggest that additional factors may affect the pathogenesis of Paget's disease.

THE ETIOLOGY OF PAGET'S DISEASE

As reviewed earlier, Paget's disease is characterized by focal regions of highly exaggerated bone remodeling, with abnormalities in all phases of the bone remodeling process. In most affected individuals, it progresses slowly over many years without extending to new sites of involvement. The underlying pathophysiology appears to reflect a localized increase in the number of osteoclasts followed by a secondary increase in osteoblast activity. These osteoclasts have striking characteristics both by light and electron microscopy. In Paget's disease, the osteoclasts may be far greater in size than osteoclasts in normal individuals and patients with diseases in which osteoclasts are activated such as primary hyperparathyroidism. Genetic and nongenetic factors have been implicated in the pathogenesis of Paget's disease, and genetic factors are clearly an important component of the etiology of Paget's disease. However, microenvironmental factors appear to also play an important role. Two studies have shown that the prevalence of Paget's disease has decreased over the past 25 years in both the United Kingdom and New Zealand (Doyle *et al.*, 2002; van Staa *et al.*, 2002). Further, expression of the most common mutation linked to Paget's disease, the P392L and the p62, when expressed in normal osteoclast precursors or targeted to the osteoclast lineage in transgenic mice, does not induce pagetic lesions or pagetic-like osteoclasts. In contrast, expression of the measles virus nucleocapsid gene *in vitro* or *in vivo* results in formation of osteoclasts that express all the phenotypic characteristics of osteoclasts from patients with Paget's disease and form bone lesions that are very similar to those found in Paget's disease. The requirement for a nongenetic factor participating in the etiology of Paget's disease would explain why some individuals who have Paget's-associated mutations do not develop Paget's disease. One possibility is that such mutations predispose patients to Paget's disease by enhancing basal osteoclastogenesis, thereby creating a permissive environment for the development of Paget's disease. A second environmental factor, such as expression of certain viral proteins, may further alter signaling pathways or expression of specific transcription factors,

which results in development of pagetic osteoclasts. These include changes in vitamin D receptor transcription as well as changes in the NF-κB signaling pathways and other signaling pathways involved in osteoclast formation. Further, the increased numbers of osteoclasts would then secrete high levels of IL-6, which would then further expand osteoclast formation. Because osteoclast and osteoblast activity remain coupled in Paget's disease, the increased osteoclast activity would result in increased osteoblast numbers and rapid formation of new bone. In addition, in preliminary studies Hiruma and colleagues (unpublished observations) have found that marrow stromal cells expressing the P392L mutation and p62 express high levels of RANKL when treated with low concentrations of $1,25\text{-}(OH)_2D_3$. These results suggest that genetic mutations linked to Paget's disease may increase osteoclast formation both by enhancing osteoclast activity per se as well as by creating a more osteoclastogenic environment in the pagetic lesions. However, these mutations by themselves are not sufficient to induce Paget's disease in animal models or pagetic-like osteoclasts in human marrow cultures.

Thus, there has been a tremendous output of new information on the etiology and pathophysiology of Paget's disease. Identification of genes involved in osteoclastogenesis that are mutated in Paget's disease and the characterization of nongenetic factors such as measles virus that may be involved have provided important insights in the control of bone remodeling in Paget's disease as well as normal bone. Studies of abnormal bone remodeling in Paget's disease could result in identification of coupling factors produced by osteoclasts, which enhance new bone formation. Understanding the pathophysiology of Paget's disease should provide important insights into the mechanisms that control normal osteoclast differentiation and bone formation and may lead to new therapies for both patients with Paget's disease and the identification of new anabolic factors for treating patients with severe bone loss.

Chapter 75

Genetic Determinants of Bone Mass and Osteoporotic Fracture

Stuart H. Ralston*

Rheumatic Diseases Unit, Molecular Medicine Centre, Western General Hospital, Edinburgh, United Kingdom

INTRODUCTION

Genetic factors play an important role in the pathogenesis of osteoporosis. Although most interest has focused on uncovering the genetic determinants of bone mineral density (BMD), genetic factors also play a key role in regulating other phenotypes that predispose to osteoporotic fractures such as the ultrasound properties of bone, biochemical markers of bone turnover, and femoral neck geometry (Garnero *et al.,* 1996b; Bauer *et al.,* 1997; Faulkner *et al.,* 1993). In this chapter, I will review the strategies that have been used to identify and quantitate genetic influences on osteoporosis and then go on to discuss how these approaches have been applied to define candidate loci and genes that predispose to osteoporosis.

HERITABILITY OF OSTEOPOROSIS PHENOTYPES

Bone Mineral Density and Bone Loss

There is strong evidence for a genetic contribution to BMD and studies in twins and families have shown that between 50% and 85% of the variance in BMD is genetically determined depending on the skeletal site examined and characteristics of the population being studied (Christian *et al.,* 1989; Flicker *et al.,* 1995; Pocock *et al.,* 1987; Slemenda *et al.,* 1991; Smith *et al.,* 1973; Gueguen *et al.,* 1995; Krall and Dawson-Hughes, 1993). Although peak bone mass clearly has a strong genetic component, the data are conflicting with regard to the influence of genetic factors on age-related bone loss. In one study of wrist BMD in elderly male twins, no evidence for a genetic effect on bone loss was found (Christian *et al.,* 1989), whereas in another study of younger female twins, strong genetic effects on axial bone loss were observed (Kelly *et al.,* 1993). Further research is required to evaluate the role that genetic factors play in regulating bone loss.

Other Osteoporosis-Related Phenotypes

Other phenotypes such femoral neck geometry (Arden *et al.,* 1996; Flicker *et al.,* 1996), ultrasound properties of bone (Arden *et al.,* 1996; Knapp *et al.,* 2003; Hunter *et al.,* 2001b), and biochemical markers of bone turnover (Garnero *et al.,* 1996a; Hunter *et al.,* 2001a) have also been shown to have a strong heritable component. For example, heritability of biochemical markers of bone turnover has been estimated to range between 29% and 74% depending on the marker studied (Hunter *et al.,* 2001a), whereas heritability of quantitative ultrasound measurements have been reported to range between 53% and 62% (Arden *et al.,* 1996). The heritability of hip axis length and other aspects of femoral neck geometry has been estimated to range between 61% and 85% (Arden *et al.,* 1996; Koller *et al.,* 2001).

Fragility Fracture

Family history of fracture has been shown in several studies to be a risk factor for fracture independently of BMD (Cummings *et al.,* 1995; Torgerson *et al.,* 1996) and, in keeping with this, several investigators have reported that fracture has a significant heritable component. Studies of postmenopausal women and their first degree relatives from the United States showed that the heritability of wrist fracture was about 25% (Deng *et al.,* 2000), whereas similar studies in a cohort of female twins from the United Kingdom suggested that the heritability of wrist

*Corresponding author: Professor Stuart H. Ralston, Rheumatic Diseases Unit, Molecular Medicine Centre, Western General Hospital, Edinburgh EH4 2XU, UK. Phone: +44-131-1037, Fax: +44-131-1085, E-mail: stuart.ralston@ed.ac.uk

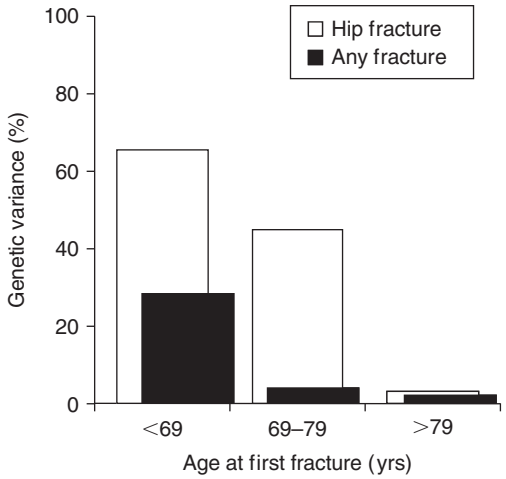

FIGURE 1 Changes in heritability of fracture with age. The genetic contribution to osteoporotic fracture (expressed as proportion of genetic variance) decreases with age. Data from Michaelsson *et al.* (2005).

fracture may be as much as 54% (Andrew *et al.,* 2005). Interestingly, the heritable component to wrist fracture in both of these studies seemed largely independent on BMD, suggesting that predisposition may have been mediated through genetic influences on bone turnover and bone geometry or nonskeletal risk factors such as cognitive function, neuromuscular control, or visual acuity. Contrasting with these observations, another heritability study of elderly twins from Finland showed little evidence to suggest that fractures were heritable (Kannus *et al.,* 1999). The largest and most comprehensive study of heritability of fracture was that of Michaelsson who elegantly demonstrated in a large study of Swedish twins that the heritability of fracture was high in those under the age of 69 years, but dropped off rapidly with age to reach a value of almost zero by the eighth decade (Michaelsson *et al.,* 2005) (Fig. 1).This illustrates that genetic factors play an important role in predisposing to fracture in younger people, but with increasing age, environmental factors come into play and eventually predominate.

PATTERNS OF INHERITANCE OF OSTEOPOROSIS

Segregation analysis in families has shown that regulation of BMD and other osteoporosis-related phenotypes is polygenic and determined by the effects of several genes each with relatively small effects rather than by a small number of genes with large effects (Gueguen *et al.,* 1995). Evidence has been presented to suggest that genes with larger effects may be involved at least in some populations (Liu *et al.,* 2004b; Deng *et al.,* 2002a). Irrespective of the contribution made by individual genetic variants, it is clear that these interact with environmental factors to regulate BMD, bone turnover, bone geometry, and susceptibility to fracture (Krall and Dawson-Hughes, 1993). Under some circumstances susceptibility to osteoporosis and fracture can be inherited in a Mendelian manner. Examples are osteogenesis imperfecta, owing to mutations in the type I collagen genes (Rowe, 1991) or the CRTAP gene (Barnes *et al.,* 2006), and osteoporosis-pseudoglioma syndrome owing to inactivating mutations in the *LRP5* gene (Gong *et al.,* 1998, 2001). Families have also been described with an inherited form of osteopetrosis linked to chromosome 11p12 where the causal gene has not been discovered (Vidal *et al.,* 2007). Osteoporosis can also form part of the phenotype in patients with inactivating mutations in the aromatase gene (Morishima *et al.,* 1995) and estrogen receptor alpha gene (Smith *et al.,* 1994). Other syndromes have been described in which affected individuals have high bone mass and are protected against osteoporotic fractures. Examples are the various autosomal dominant high-bone-mass syndromes associated with activating mutations in the *LRP5* gene (Johnson *et al.,* 1997; Van Wesenbeeck *et al.,* 2003; Little *et al.,* 2002; Boyden *et al.,* 2002) and the recessive syndromes of Sclerosteosis and Van Buchem disease that are caused by inactivating mutations in the Sclerostin (SOST) gene (Balemans *et al.,* 2001, 2002, 2005; Brunkow *et al.,* 2001). Interestingly, individuals who are heterozygous for disease-causing mutations in SOST also have high bone mass (Gardner *et al.,* 2005). In all of these examples, the consequences of the gene mutation on bone cell function are so profound as to overwhelm the effects of the many other genes that contribute to regulation of bone mass. However, even in such extreme cases, it is sometimes possible to identify polygenic effects on disease severity. The best examples of this are in osteogenesis imperfecta, where disease severity can vary markedly within and between families who have identical mutations in the collagen genes, presumably owing to the influence of other genes on bone mass and bone fragility (Willing, Cohn, and Byers, 1990).

IDENTIFYING OSTEOPOROSIS SUSCEPTIBILITY GENES

Several approaches have been used to identify the genes responsible for osteoporosis including linkage analysis in families, association studies in unrelated subjects, and animal studies (Fig. 2). Studies in experimental animals can also be of value in identifying the genes responsible for human disease, based on the assumption that key regulatory genes will be shared across species. Because these approaches are dealt with in more detail elsewhere (see Chapter 20) further discussion in this chapter will focus principally on the results of linkage and association studies of osteoporosis that have been performed in humans.

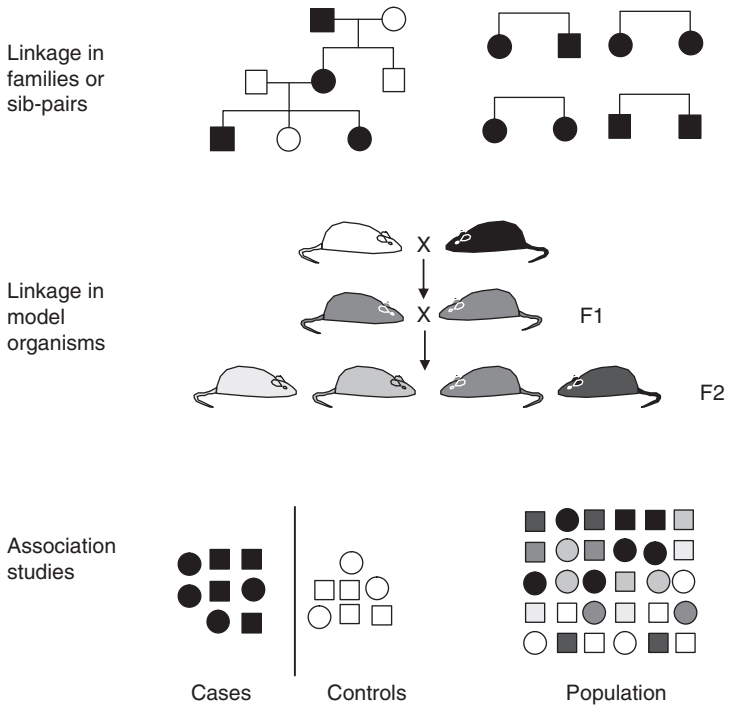

FIGURE 2 Techniques for detecting genes that predispose to osteoporosis. (**Top**) Human linkage studies are based on phenotyping members of families for the trait of interest (e.g., BMD) and relating inheritance of genetic markers in relation to inheritance of the phenotype. Phenotype can be dichotomized into affected (filled symbols) or unaffected (open symbols), or analyzed as a quantitative trait. (**Middle**) Linkage studies in animals typically involve setting up an experimental cross between two inbred mouse strains with opposing phenotypes (e.g., high and low BMD). The first generation of offspring (F_1) have intermediate BMD values owing to inheritance of high BMD alleles from one parent and low BMD alleles from the other. Brother and sister mating of the F1 generation results in a second generation of offspring (F_2) that have varying levels of BMD owing to recombination between parental chromosomes. By conducting a genome search in the F_2 generation, it is possible to relate inheritance of alleles from the parental strains to BMD levels, thereby localizing the genetic variants that regulate BMD. (**Bottom**) Association studies involve comparing frequency of alleles of candidate genes in unrelated subjects. This can either take the form of a case-control study (*bottom left*) in which patients with osteoporosis, or osteoporotic fractures (filled symbols) are compared with unaffected subjects (open symbols). Association studies can also be performed in population-based studies of individuals who have varying BMD (*bottom right*). Here, subjects are grouped according to carriage of alleles at the locus of interest and BMD values are compared in different genotype groups by analysis of variance.

LINKAGE ANALYSIS

Overview of Methodology

The classical approach for gene discovery is parametric linkage analysis that involves specifying a model of inheritance for the disease within a family (such as dominant or recessive) and looking for evidence of segregation of the disease in family members according to that model. Genotype data are then analyzed to look for evidence of segregation of alleles with the phenotype according to the specified disease model. Because the purpose of linkage analysis is to localize a disease gene, linkage studies are usually carried out on a genome-wide basis (Genome Wide Scan), which classically involves genotyping between 400 and 800 microsatellite markers spread at 5- to 10-cM intervals across the genome. In recent years however, higher-density panels of single nucleotide polymorphism (SNP) markers have also been used for genome-wide searches (Sawcer *et al.*, 2004). The related technique of nonparametric linkage uses a similar approach, but here no disease model is specified and instead the aim is to look for evidence of allele sharing in relation to sharing of the disease phenotype. For quantitative traits, variance component methods (Almasy and Blangero, 1998) or regression-based methods (Abecasis *et al.*, 2002) can be employed to estimate the proportion of genetic covariance between relatives as a function of identity by descent relationships at a marker, assuming that the marker is tightly linked to the disease-causing mutation. The results of linkage studies are typically expressed as lodscores that are defined as the logarithm of the odds that the disease locus and marker locus are linked. In parametric analysis, linkage is considered significant when the lodscore is greater than +3.3, whereas linkage is considered to be "suggestive" when the lodscore is greater than +1.9. Conversely, linkage can be excluded when the lodscore is less than −2.0. For nonparametric analysis, significant linkage is defined by a lodscore of more than about +3.6 and suggestive linkage by a lodscore greater than +2.2 (Nyholt, 2000). It is not possible to exclude linkage by nonparametric analysis.

Linkage studies in Osteoporosis

A few investigators have attempted to employ parametric linkage analysis to detect susceptibility loci for osteoporosis but so far this has not proved very fruitful (Devoto *et al.,* 1998; Spotila *et al.,* 1996; Vidal *et al.,* 2007). In view of this, most studies have been performed using non-parametric linkage analysis focusing principally on BMD as the phenotype of interest (Nui *et al.,* 1999; Devoto *et al.,* 2001; Karasik *et al.,* 2002a; Deng *et al.,* 2002b; Koller *et al.,* 2000; Ralston *et al.,* 2005; Streeten *et al.,* 2006; Kammerer *et al.,* 2003; Styrkarsdottir *et al.,* 2003; Hsu *et al.,* 2007). However the same approach has been successfully used to detect quantitative trait loci (QTL) for femoral neck geometry (Peacock *et al.,* 2005b; Koller *et al.,* 2003; Deng *et al.,* 2003; Demissie *et al.,* 2007) and ultrasound properties of bone (Wilson *et al.,* 2004; Karasik *et al.,* 2002b). Several genome-wide scans performed so far have identified QTL that meet the criteria for genome-wide significance for BMD but there has been limited replication of QTL between studies and a recent meta-analysis of nine genome-wide scans involving more than 11,842 subjects failed to detect evidence of genome-wide significance for any QTL (Ioannidis *et al.,* 2007). Some interesting findings have emerged from these studies, however. Most investigators who analyzed men and women together with adjustment for gender in the statistical model have identified different QTL than when gender-specific subgroup analysis has been performed (Ralston *et al.,* 2005; Streeten *et al.,* 2006; Karasik *et al.,* 2003; Hsu *et al.,* 2007; Kammerer *et al.,* 2003; Peacock *et al.,* 2005a; Koller *et al.,* 2000). This suggests that BMD is largely regulated in a gender-specific manner, as has been reported in mice (Orwoll *et al.,* 2001). Similar findings have been observed when data from old and young individuals has been analyzed separately rather than adjusting for age as a continuous variable in the statistical model (Karasik *et al.,* 2003; Ralston *et al.,* 2005; Kammerer *et al.,* 2003). This indicates that the genetic and environmental determinants of peak bone mass probably differ from those that regulate bone loss. Another consistent finding to emerge from genome-wide linkage studies is that the variants that regulate BMD largely do so in a site-specific manner because there has been very limited overlap between linkage peaks for BMD at different skeletal sites such as the spine and hip (Hsu *et al.,* 2007; Ralston *et al.,* 2005; Ioannidis *et al.,* 2007). This mirrors experience in other complex diseases (Altmuller *et al.,* 2001) and might reflect the fact that genes that regulate BMD differ in different populations or that genes that predispose to osteoporosis have modest effects that are difficult to detect reproducibly by conventional linkage analysis. To date, only one candidate gene for osteoporosis has been detected by genome-wide linkage scan. This is the *BMP2* gene that was discovered as the result of a positional cloning effort on a locus identified by a genome-wide scan in the population isolate of Iceland (Styrkarsdottir *et al.,* 2003). In this study, a coding variant of *BMP2* was implicated in the regulation of BMD in Icelandic and Danish subjects (Styrkarsdottir *et al.,* 2003). Nonetheless, this variant only accounted for part of the linkage signal and the association with BMD and fracture was not replicated in a study from Holland (Medici *et al.,* 2006).

There have been fewer genome-wide linkage scans for loci that regulate femoral neck geometry. Those that have been performed have detected evidence of significant linkage to some chromosomal regions, but there has been limited replication of peaks between studies (Peacock *et al.,* 2005b; Koller *et al.,* 2001; Demissie *et al.,* 2007). As in BMD, gender-specific effects in regulating bone geometry have been observed (Peacock *et al.,* 2005b). Two genome-wide scans have been carried out in relation to ultrasound properties of bone (Karasik *et al.,* 2002b; Wilson *et al.,* 2004), with differing results. Neither study detected QTL, which reached genome-wide significance, although several suggestive linkage peaks were detected.

ASSOCIATION STUDIES

Overview of Methodology

An association study typically involves studying polymorphisms in a candidate gene in a series of cases and controls and determining whether the allele distribution differs in the two groups by a chi-square test. For quantitative traits, such as BMD or ultrasound, the mean values are calculated according to genotype or allele at the chosen polymorphism and differences assessed by analysis of variance, usually with inclusion of confounding factors such as age, body weight and menopausal status in the statistical model. For many years, association studies were performed in relation to polymorphisms in candidate genes, but advances in genotyping technologies have now made it possible to perform association studies on a genome wide basis by analyzing large numbers (300,000 to 500,000) of closely spaced SNPs spread at regular intervals across the genome (Cardon and Abecasis, 2003). The rationale for this approach is that the SNP tested will be in linkage disequilibrium with causal variants in genes that predispose to the disease. Genome-wide association studies have been successfully applied to the study of many complex diseases and this approach is also now being applied to the study of osteoporosis and related phenotypes. Association studies are relatively easy to perform and can be powered to detect small effects of alleles, but they can give spurious results owing to population stratification, particularly when the sample sizes are limited and when insufficient care has been paid to matching cases and controls. These problems

have probably been overestimated in the past, but can be circumvented in part by careful study design with statistical correction for confounding factors (Hoggart *et al.,* 2003). Another problem with candidate gene association studies is that they do not provide an opportunity for identifying new genes. This is a major advantage of genome-wide association studies that are "hypothesis free" and leave open the possibility of identifying novel genes and pathways that predispose to the trait under investigation. A disadvantage of genome-wide association approaches is that they involve performing a very large number of individual tests, which means that the statistical thresholds for significance have to be extremely stringent. In practice, most investigators use an approach whereby positive hits from first-round genome-wide association studies are analyzed in replication cohorts to confirm that the results are genuine.

The transmission disequilibrium test (TDT) is a special type of association study that is performed in related individuals and often used to confirm the results obtained from population-based association studies (Spielman *et al.*, 1993). The TDT tests the hypothesis that a polymorphism or allele contributes to disease by analyzing the frequency with which affected individuals inherit the allele from a heterozygous parent. If the allele contributes to the trait or disease of interest, then the probability that an affected person has inherited the allele from a heterozygous parent should vary from the expected Mendelian ratio of 50:50. Because the transmitted allele acts as the "case" and the nontransmitted allele acts as the "control," the TDT is unaffected by confounding owing to population stratification. Although TDT is a valuable technique, one important disadvantage is that only heterozygous individuals are informative, which can reduce the effective sample size available for study and limit statistical power.

When an association has been identified and replicated, defining a causative role for any individual polymorphism is difficult. This involves an exhaustive analysis of the region surrounding the (potentially) causal polymorphism to determine whether other polymorphisms nearby might be driving the association and functional studies to explore the biological effects of putative disease-causing polymorphisms on protein function and/or gene transcription *in vitro* and *in vivo*.

CANDIDATE GENES FOR OSTEOPOROSIS SUSCEPTIBILITY

Many candidate gene associations in the osteoporosis field are based on single studies with relatively small sample sizes that have not been replicated in different populations. In view of this, the following discussion will mainly focus on candidate genes that have been studied across several populations.

COLLAGEN TYPE I ALPHA 1 (*COL1A1*)

Type I collagen is a major structural protein of bone, and the genes encoding this protein (*COL1A1* and *COL1A2*) are strong candidates for the genetic regulation of bone mass. Mutations affecting the *COL1A1* and *COL1A2* genes are responsible for the vast majority of cases of osteogenesis imperfecta, a hereditary disease characterized by premature osteoporosis and bone fragility (Rowe, 1991). Polymorphisms affecting the coding regions of the collagen type I genes are rare and do not appear to be associated with osteoporosis (Spotila *et al.,* 1994), but there is accumulating evidence that polymorphisms in the regulatory regions of *COL1A1* regulate bone mass and susceptibility to osteoporotic fracture. In 1996 a polymorphisms was identified within intron 1 of the *COL1A1* gene that affected a binding site for the transcription factor Sp1, which was more prevalent in osteoporotic vertebral fracture patients than with controls and was found to be associated with BMD (Grant *et al.,* 1996). Subsequent work showed positive associations between the *COL1A1* Sp1 polymorphism bone mass and/or osteoporotic fractures in many populations (Garnero *et al.,* 1998; Langdahl *et al.,* 1998; Uitterlinden *et al.,* 1998; Roux *et al.,* 1998; Alvarez *et al.,* 1999; Weichetova *et al.,* 2000; McGuigan *et al.,* 2000; Braga *et al.,* 2000; Keen *et al.,* 1999; Langdahl *et al.,* 1998; Liu *et al.,* 2004a; Efstathiadou *et al.,* 2001), although not all studies have yielded positive results (Pluijm *et al.,* 2004; Ashford *et al.,* 2001; Berg *et al.,* 2000; Heegaard *et al.,* 2000). Three independent meta-analyses concluded that the *COL1A1* Sp1 polymorphism was associated with osteoporotic fractures (Efstathiadou *et al.*, 2001) and bone density (Mann and Ralston, 2003; Lohmueller *et al.,* 2003). In one study the increased risk of fracture was found to be greater than expected for the allele-specific difference in BMD (Mann and Ralston, 2003). The largest individual study of the *COL1A1* Sp1 polymorphism in relation to BMD and fracture performed to date is the GENOMOS study where a participant-level meta-analysis of data was performed in 20,786 subjects. In this study *COL1A1* Sp1 alleles were found to be associated with spine and hip BMD with a recessive model of inheritance, which contrasts with the codominant model reported in other studies and meta-analyses. The Sp1 polymorphism was also associated with incident vertebral fractures in women from this study with an effect size similar to that reported in previous studies (Ralston *et al.,* 2006).

The relationship between *COL1A1* alleles and bone loss has been studied by two groups, following on from the observations made by Uitterlinden who found that genotype-related differences in BMD increased with age (Uitterlinden *et al.,* 1998). In the study by Harris and colleagues, the *COL1A1* "TT" genotype was strongly associated increased bone loss over a 5-year period in 243 elderly

men and women (Harris *et al.,* 2000), and similar findings were reported by MacDonald in a large-scale study involving more than 3000 perimenopausal women (MacDonald *et al.,* 2001). However, in another study of 133 postmenopausal women monitored for more than 18 years no association between the *COL1A1* Sp1 polymorphism and bone loss was reported (Heegaard *et al.,* 2000). The *COL1A1* Sp1 polymorphism has been studied in relation to BMD in children and adolescents but the results have been contradictory. In one study, *COL1A1* alleles were strongly related to volumetric BMD measured by quantitative computed tomography in Mexican-American girls (Sainz *et al.,*1999). In another study, an association was reported with BMD in Finnish girls during early puberty (Suuriniemi *et al.,* 2006). However, no association was found between *COL1A1* alleles and BMD as measured by DEXA in another study of prepubertal Caucasian girls (Tao *et al.,* 1999).

The *COL1A1* Sp1 polymorphism has also been associated with bone size and femoral neck geometry. In one study, the Sp1 "T" allele was associated with an increased femoral neck-shaft angle (Qureshi *et al.,* 2001), and another study showed an association with the "T" allele and reduced wrist size, although no effects on bone size were found at the hip (Long *et al.,* 2004).

The population prevalence of the *COL1A1* Sp1 polymorphism differs markedly in different populations. The osteoporosis associated "T" allele is relatively common in Caucasian populations, but is rare in the African subcontinent and seems to be virtually absent from Asian populations (Beavan *et al.,* 1998; Nakajima *et al.,* 1999; Lau *et al.,*2004). This raises the possibility that differences in population prevalence of *COL1A1* Sp1 alleles may contribute to ethnic differences in fracture risk (Beavan *et al.,* 1998).

Extensive studies have been performed on the molecular mechanism by which the Sp1 polymorphism predisposes to osteoporosis. The osteoporosis-associated *COL1A1* "T" allele has higher affinity for Sp1 protein binding than the wild-type "G" allele and the allele-specific transcription from the "T" allele has been found to be 3-fold higher than the "G" allele in heterozygotes. In keeping with this, cultured osteoblasts from subjects who are heterozygous for the G/T polymorphism produce increased amounts of collagen alpha 1 protein relative to alpha 2 *in vitro* compared with "GG" homozygotes, and also express increased amounts of *COL1A1* mRNA relative to *COL1A2* mRNA. These differences in *COL1A1* transcription are accompanied by differences in the mechanical strength of bone and bone mineralization. Biomechanical studies have shown that bone cores from G/T heterozygotes have significantly reduced bone strength *ex vivo* than those from GG homozygotes and also are less well mineralized (Stewart *et al.,* 2005; Mann *et al.,* 2001). Corresponding with this, studies *in vitro* have also shown evidence of defective mineralization in bone cores cultured from Sp1 G/T heterozygotes compared with G/G homozygotes. Overall, the data are consistent with a model whereby the "T" allele of the *COL1A1* Sp1 polymorphism increases *COL1A1* gene transcription, which leads to increased collagen alpha 1 protein production, an abnormal ratio of alpha 1 to alpha 2 protein chains, a subtle defect in bone mineralization, and reduced bone strength, leading to an increased risk of fracture (Fig. 3).

Polymorphisms have also been described in the promoter region of the *COL1A1* gene that are in linkage disequilibrium with the Sp1 polymorphism, including an insertion/deletion polymorphism in a polythymidine tract at position −1663 (−1663indelT) and a G/T polymorphism at position −1997 (−1997G/T). The −1997G/T polymorphism was found to be associated with BMD in Spanish postmenopausal women and to interact with the Sp1 polymorphism in regulating BMD (Garcia-Giralt *et al.,* 2002). Similar findings were reported in another group of women from the United States (Liu *et al.,* 2004a). The largest study of these polymorphisms is that of Stewart who reported that haplotypes defined by all three polymorphisms regulated spine and hip BMD in women from the United Kingdom with effects that were stronger than those of the individual SNP (Stewart *et al.,* 2006). There is evidence that the promoter polymorphisms are functional. The −1663indelT polymorphism is situated at a binding site for the transcription factor NMP4 and promoter-reporter assays show that different promoter haplotypes differed in their ability to regulate reporter gene expression with high levels of transcription associated with the −1997G −1663delT haplotype (Garcia-Giralt *et al.,* 2005).

In summary, current evidence suggests that common allelic variants in the 5′ flank of the *COL1A1* gene are associated with bone mass and susceptibility to osteoporotic fracture, and in particular, vertebral fractures. Three polymorphisms have been identified in the promoter at positions −1997 and −1663 and one in the intron at position +1245 affecting a Sp1 binding site. There is evidence to suggest that at least two of these polymorphisms have functional effects on DNA binding and *COL1A1* transcription, and it appears that this affects collagen protein production and bone strength. It remains unclear, however, to what extent the individual polymorphisms are responsible for the clinical associations that have been reported.

ESTROGEN RECEPTOR ALPHA (*ESR1*)

Estrogen, by interacting with its receptors in bone and other tissues, plays an important role in regulating skeletal growth and maintenance of bone mass. Knockout mice for ERα and ERβ have reduced BMD compared with wild-type controls (Windahl *et al.,* 1999; Korach, 1994) and osteoporosis has also been observed in a man with an inactivating mutation of the ERα gene (Smith *et al.,* 1994). These data indicate that the estrogen receptor genes *ESR1* and *ESR2* genes are strong candidates for genetic regulation of bone

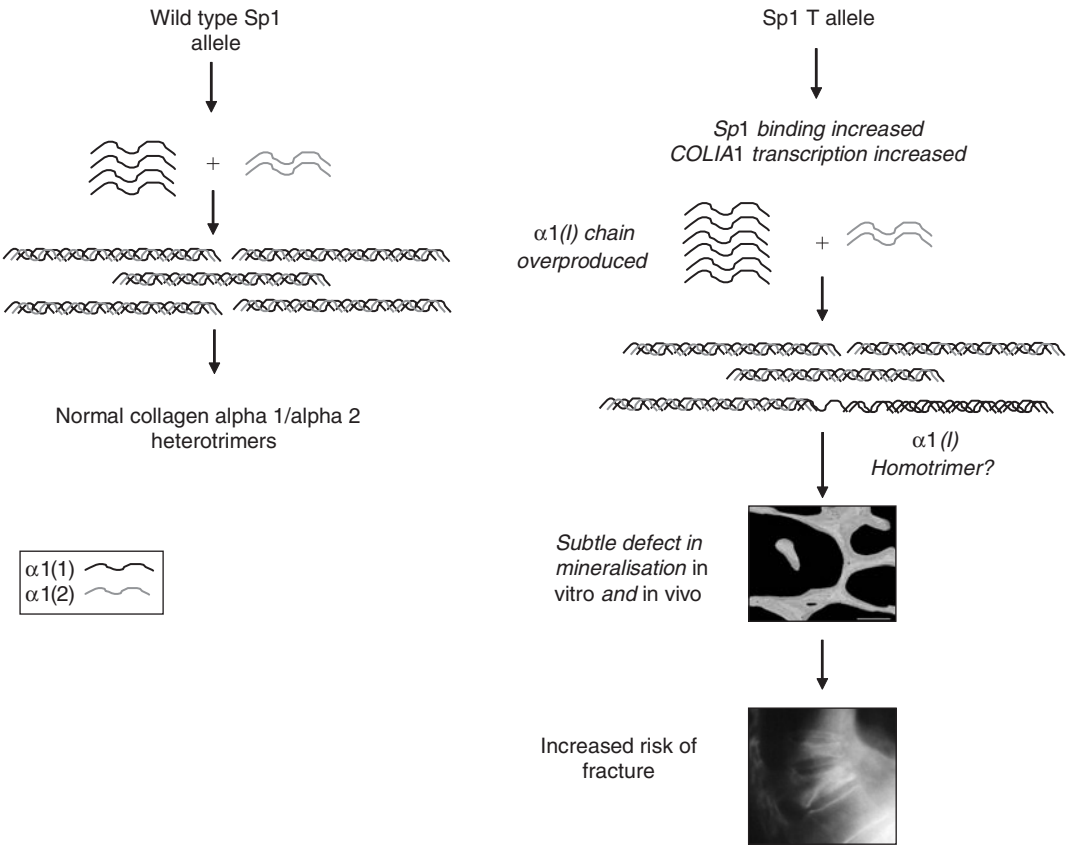

FIGURE 3 Mechanisms of osteoporosis mediated by *COL1A1* Sp1 polymorphism. The *COL1A1* Sp1 T allele has increased affinity for Sp1 binding and *COL1A1* mRNA abundance is increased in G/T heterozygotes. This causes an imbalance in the ratio of alpha 1 to alpha 2 chains, probably resulting in accumulation of collagen 1 alpha 1 homotrimer. This adversely affects mineralization, reduces bone strength, and predisposes to osteoporotic fracture.

mass. Sano *et al.* (1995) reported a positive association between a TA repeat polymorphism in the *ESR1* gene promoter and bone mass in a small Japanese study. Similar results were reported by groups in the United States and Italy (Sowers *et al.,* 1999; Becherini *et al.,* 2000). Other investigators have reported positive associations between haplotypes defined by *PvuII* and/or *XbaI* polymorphisms in the first intron of the *ESR1* gene and bone mass (Kobayashi *et al.,* 1996; Sowers *et al.,* 1999; Mizunuma *et al.,* 1997; Ongphiphadhanakul *et al.,* 1998; Albagha *et al.,* 2001b) as well as age at menopause (Weel *et al.,* 1999). In contrast, other studies in Korean (Han *et al.,* 1997), Belgian (Vandevyer *et al.,* 1999), and Italian (Gennari *et al.,*1998) women found no association between *PvuII* polymorphisms and bone mass.

Polymorphisms of *ESR1* have also been studied in relation to postmenopausal bone loss. In a longitudinal study of 322 Finnish women, increased rates of early postmenopausal bone loss were observed in women who carried the "P" allele at the *ESR1 PvuII* polymorphism (Salmen *et al.,* 2000), but this was not confirmed by another study in the United States (Willing *et al.,* 1998). In contrast, a relatively large-scale study involving 3054 women in the United Kingdom showed higher rates of bone loss in women who carried the px haplotype, lower femoral neck BMD in postmenopausal women, and reduced calcaneal broadband ultrasound attenuation (Albagha *et al.,* 2005). A meta-analysis of association studies performed up until 2002 involving 5834 participants showed no evidence of an association between BMD and fracture for the *PvuII* polymorphism but a positive association between BMD and fracture for the *XbaI* polymorphism, with a protective effect of the XX genotype (Ioannidis *et al.,* 2002). Another large-scale individual level meta-analysis from the GENOMOS study involving 18,917 individuals showed no association between the TA repeat, *PvuII*, or *XbaI* polymorphism with BMD, but a significant association between the *XbaI* polymorphism and fracture, which was independent of BMD (Ioannidis *et al.,* 2004).

The molecular mechanism by which *ESR1* polymorphisms influence osteoporosis and fracture are unclear, but there is evidence that the intron polymorphisms may affect gene transcription. For example, the *PvuII* polymorphism lies within consensus recognition sites for the AP4 and Myb transcription factors (Albagha *et al.,* 2001a; Herrington *et al.,* 2002b) and promoter-reporter assays

have shown that the *PvuII* polymorphism influences Myb-driven transcription *in vitro* (Herrington *et al.,* 2002a). Other studies have suggested that the *XbaI* and *PvuII* polymorphisms influence reporter gene transcription *in vitro* (Maruyama *et al.,* 2000). In this regard, it is of interest that the *PvuII* and *XbaI* polymorphisms are located within a region that is 70 to 80% conserved in the human, mouse, and rat genomes, whereas the TA repeat polymorphism is not conserved to any significant extent across species, suggesting that the intron plays an important role in regulating *ESR1* function.

In summary, there is evidence that the *PvuII* and *XbaI* polymorphisms within intron 1 of *ESR1* are functional variants. Effects on BMD, bone loss, and ultrasound properties of bone have been reported but the data remain conflicting. The association between the *XbaI* polymorphism and fractures noted in the GENOMOS study is an intriguing finding and raises the possibility that *ESR1* alleles may predispose to fracture by a mechanism independent of BMD.

LIPOPROTEIN RECEPTOR-RELATED PROTEIN 5 (*LRP5*)

The Lipoprotein Receptor-Related Proteins encoded by the *LRP5* and *LRP6* genes are transmembrane proteins that function as coreceptors for canonical Wnt signaling. Wnt signaling plays an important role in several key developmental processes including cell fate decisions, limb patterning, osteoblast and chondrocyte differentiation, and development of the central nervous system and of other organs (Johnson *et al.,* 2004).

The *LRP5* pathway was discovered to be a key regulator of bone mass following linkage studies in two rare human diseases: the osteoporosis-pseudoglioma syndrome (OPPS), which is a recessively inherited condition characterized by severe, early-onset osteoporosis and congenital blindness owing to vitreous opacity (Gong *et al.,* 1998), and the high-bone-mass (HBM) syndrome, which is an asymptomatic autosomal dominant disorder characterized by increased bone mineral density (Johnson *et al.,* 1997). Both of these conditions were mapped to the same region of chromosome 11*q*12 in the late 1990s and different mutations in the *LRP5* gene were identified as the cause of both disorders by positional cloning studies (Gong *et al.,* 2001; Little *et al.,* 2002; Boyden *et al.,* 2002). The high-bone-mass syndrome was found to be caused by a heterozygous missense mutation causing a substitution of valine for glycine at codon 171 (G171V) of *LRP5* within the first beta-propeller motif of the molecule (Little *et al.,* 2002). The OPPS syndrome was found to be caused by different homozygous missense, nonsense, and frameshift mutations throughout the gene (Gong *et al.,* 2001). Since these original reports, several additional missense mutations of *LRP5* have been identified as a cause of high bone mass and all of these cluster in or around the first beta-propeller motif of *LRP5* (Van Wesenbeeck *et al.,* 2003).

There is evidence that subtle variations in *LRP5* underlie variation of BMD in the general population. Several association studies and family-based studies have been performed in which various common polymorphisms of *LRP5* have been related to BMD and/or osteoporotic fracture. Most of these studies have shown evidence of associations between *LRP5* alleles and BMD, and interestingly, these associations have been particularly strong in men (Urano *et al.,* 2004; Koh *et al.,* 2004; Ferrari *et al.,* 2004; van Meurs *et al.,* 2006). Although many variants have been studied, the most likely functional candidates are an alanine to valine amino acid substitution at position 1330 (A1330V) and a valine to methionine variant at codon 667 (V667M). Evidence of an interaction between the *LRP5* A1330V variant and a coding polymorphism of LRP6 (1062V) has also been gained in the Rotterdam study, where polymorphisms of both genes were found to have an additive effect on fracture susceptibility (van Meurs *et al.,* 2006). Interactions between *LRP5* and *LRP6* as regulators of BMD have also been observed in preclinical studies where skeletal phenotyping of mice with targeted inactivation of both receptors revealed allele dose-dependent deficits in BMD and limb formation, suggesting that there is functional redundancy between these two genes in regulating bone and limb development (Holmen *et al.,* 2004).

Functional studies have shown that the mutations that cause OPPS produce a truncated or nonfunctional *LRP5* protein (Gong *et al.,* 2001) and inactivation of *LRP5* by gene targeting in mice causes a low-bone-mass phenotype, which provides a phenocopy for the human disease syndrome (Kato *et al.,* 2002). Analysis of bone histomorphometry from these mice has shown that the low bone mass is a consequence of decreased osteoblast proliferation and reduced bone matrix deposition rather than an increased bone resorption (Kato *et al.,* 2002). The G171V mutation that was associated with high bone mass in the family studied by Johnson and colleagues (Little *et al.,* 2002; Johnson *et al.,* 1997) was found to cause increased bone mass when expressed in transgenic mice (Babij *et al.,* 2003). In these studies, the mineral apposition rate was increased and the rate of osteoblast apoptosis was reduced, whereas eroded surface (reflecting bone resorption) was unaffected. The mutations of *LRP5* that cause high bone mass seem to upregulate β-catenin signaling by inhibiting interactions between LRP5 and Dkk1 an inhibitor of Wnt signaling. Studies of Boyden and colleagues (Boyden *et al.,* 2002) showed that the G171V mutation did not result in constitutive activation of *LRP5* signaling *in vitro* but instead that the mutation impaired Dkk1-mediated inhibition of Wnt-stimulated *LRP5* signaling. Another study reached the same conclusion in showing that several HBM-associated mutants (G171V, G171R, A214T, A214V, A242T, T253I, and D111Y) were resistant to Dkk1

inhibition compared with wild-type *LRP5* and had lower affinity for Dkk1 binding (Ai *et al.,* 2005). Less work has been done on the *LRP5* polymorphisms, but promoter-reporter assays have indicated that different haplotypes for the V667M and A1330V polymorphisms differ in their ability to activate reporter gene transcription, indicating that they are also functional (Kiel *et al.,* 2007).

In conclusion, the data so far indicate that genetic variation in *LRP5* and possibly *LRP6* plays an important role in regulation of bone mass and susceptibility to osteoporotic fractures in humans. Not only do rare mutations in the *LRP5* gene play a major role in regulating BMD, but more subtle polymorphisms seem also to regulate BMD in the normal population.

TRANSFORMING GROWTH FACTOR BETA 1 (*TGFB1*)

Transforming growth factor beta 1 (TGFβ1) encoded by the *TGFB1* gene is a cytokine with pleiotropic effects on cell growth and differentiation. TGFβ1 plays an important role in bone metabolism where it is thought to act as a coupling factor between bone resorption and bone formation. Mutations in *TGFB1* have been described in the syndrome of Camurati–Engelmann disease (CED), a rare disorder characterized by increased bone turnover, bone pain, and osteosclerosis, mainly affecting the diaphysis of long bones (Janssens *et al.,* 2000; Kinoshita *et al.,* 2000). The mutations that cause CED mainly cluster in the latency-associated peptide (LAP) region of TGFβ1 and prevent or inhibit binding of LAP to the mature TGFβ1 molecule (Janssens *et al.,* 2003). The effect of this is to increase levels of bioactive TGFβ1 that presumably is the cause of the increased bone turnover in the disease (McGowan *et al.,* 2003). A large number of studies have been performed on possible associations between polymorphisms in *TGFB1* and osteoporosis-related phenotypes. A rare C-deletion polymorphism in intron 4 of *TGFB1* has been associated with low BMD, increased bone turnover, and osteoporotic fracture in one study from Denmark (Langdahl *et al.,* 1997) and very similar results were recently reported in another study from Italy (Bertoldo *et al.,* 2000). Although this polymorphism is close to the splice junction, it does not affect the splice acceptor site and the functional effects on TGFβ1 function (if any) are unknown. Another polymorphism of the *TGFB1*-coding region has been described that causes a leucine-proline substitution in the signal peptide region of TGFβ1 at amino acid 10. The C allele of the codon 10 polymorphism has been associated with high BMD and a reduced frequency of osteoporotic fractures in two Japanese populations (Yamada *et al.,* 1998), with BMD in Japanese adolescents (Yamada *et al.,* 1999), and with reduced rates of bone loss and improved response to treatment with alphacalcidol, an active metabolite of vitamin D (Yamada *et al.,* 2000). This polymorphism is associated with raised circulating levels of TGFβ1 suggesting that it may influence protein secretion or stability. However, two promoter polymorphisms of TGFβ1 have been described that are also associated with circulating TGFβ1 levels (Grainger *et al.,* 1999). The largest study of *TGFB1* polymorphisms in relation to osteoporosis phenotypes was that of McGuigan who performed a comprehensive analysis of common polymorphisms in relation to BMD, bone loss, biochemical markers of bone turnover, and fracture (McGuigan *et al.,* 2007). This study showed strong linkage disequilibrium between the polymorphisms, but no convincing association between BMD, bone loss, or fracture. In view of this, the data do not support the view that common polymorphisms of *TGFB1* contribute significantly to the genetic regulation of BMD or fracture, at least in Caucasian populations.

VITAMIN D RECEPTOR (VDR)

The active metabolites of vitamin D play an important role in regulating bone cell function and maintenance of serum calcium homeostasis by binding to the vitamin D receptor and regulating the expression of a number of response genes. Polymorphisms affecting both the 3′ and 5′ regions of the VDR gene have been studied in relation to BMD and other phenotypes relevant to the pathogenesis of osteoporosis. The first study of VDR genotypes in relation to calcium metabolism were those of Morrison who found an association between polymorphisms affecting the 3′ region of the gene and circulating osteocalcin levels (Morrison *et al.,* 1992). In a subsequent study, the same group reported a significant association between *BsmI* polymorphisms in intron 8 of VDR and BMD in a twin study and a population-based study, but this association was later found to be much weaker than originally reported because of genotyping errors (Morrison *et al.,* 1997). A large number of studies have now been carried out looking at the association between BMD and other aspects of calcium metabolism in relation to *BsmI* and other polymorphisms at the VDR locus. Several studies have supported the original findings, whereas others have found no significant association and still others have reported an inverse association to those originally reported (Houston *et al.,* 1996; Uitterlinden *et al.,* 1996). Gong and colleagues reviewed the results of 75 articles and abstracts published between 1994 and 1998 that related BMD and associated skeletal phenotypes to VDR polymorphisms. The main conclusions to emerge from this study were that there was a highly significant association between VDR polymorphisms and BMD overall and that positive results were significantly more common in studies that included premenopausal rather than postmenopausal women (Gong *et al.,* 1999). Several investigators have looked for possible associations between the VDR *BsmI* alleles and fracture. In one, a positive association was found

but this was only significant in a subgroup of women aged 75 years and older (Feskanich *et al.,* 1998). Three other studies found no association between VDR 3' alleles and osteoporotic fracture (Houston *et al.,* 1996; Looney *et al.,* 1995; Ensrud *et al.,* 1999). Another common polymorphism has been described in exon 2 of the VDR gene which is a T-C transition, within exon 2 recognized by the *FokI* restriction enzyme (Arai *et al.,* 1997; Gross *et al.,* 1998a). This transition introduces an alternative translational start codon that results in a shorter isoform of the VDR gene. The *FokI* polymorphism has been associated with BMD in some studies (Harris *et al.,* 1997; Gross *et al.,* 1997; Arai *et al.,* 1997) but not in others (Eccleshall *et al.,* 1998; Langdahl *et al.,* 2000; Sowers *et al.,* 1999). The *FokI* polymorphism has also been studied in relation to osteoporotic fractures. In one study of Italian women *FokI* alleles were associated with fracture (Gennari *et al.,* 1999) but no association was found in Danish women (Langdahl *et al.,* 2000). Another common G/A polymorphism affecting a binding site for the transcription factor Cdx2 in the VDR promoter was described by Arai and found to be associated with BMD in a cohort of 261 Japanese women, with lower bone mass in carriers of the "A" allele (Arai *et al.,* 2001).

The most comprehensive single study of VDR alleles in relation to osteoporosis-related phenotypes was that of Fang and colleagues who conducted a large-scale study of haplotype tagging SNP of VDR in 6418 participants of the Rotterdam study (Fang *et al.,* 2005). As the result of this analysis, the authors identified haplotypes in the promoter and 3'-untranslated region that were associated with an increased risk of fracture. For a subgroup of individuals who carried risk alleles at both sites, the fracture risk was significantly increased by 48% when compared with control subjects. Surprisingly, the risk alleles for fracture identified in this study were not associated with differences in BMD. Although this was a large and well-conducted study, the risk estimates were modest, and if correction had been applied for all the combinations of haplotypes tested (and their interactions), the association would not have been significant. In the largest study reported to date, Uitterlinden and colleagues performed an individual level meta-analysis of common VDR polymorphisms in relation to BMD and fracture in the GENOMOS consortium. This study, which involved 26,242 subjects, found no association between VDR alleles and BMD or fracture with the exception of the Cdx2 polymorphism where subgroup analysis revealed a modest association with vertebral fracture.

Many workers have presented evidence to suggest that the relationship between VDR polymorphisms and BMD may be modified by environmental factors such as dietary calcium intake (Krall *et al.,* 1995; Ferrari *et al.,* 1995) and vitamin D status (Graafmans *et al.,* 1997). In keeping with this view, intestinal calcium absorption has been associated with the *Bsm1* VDR polymorphism in some studies (Dawson-Hughes *et al.,* 1995; Gennari *et al.,* 1997). The mechanism by which this occurs is unclear, however, and no association has been found between genotype and mucosal VDR density (Barger-Lux *et al.,* 1995; Gross *et al.,* 1998a). A positive association between the *FokI* polymorphism and intestinal calcium absorption was reported in one study (Ames *et al.,* 1999), but two other studies yielded negative results (Cauley *et al.,* 1999a; Zmuda *et al.,* 1999). The largest study of VDR alleles in relation to dietary calcium intake was that of MacDonald who, in a population study of about 3000 British women, found no association between VDR alleles and BMD. In this study no evidence of an interaction between VDR alleles, dietary calcium intake, serum 25-hydroxyvitamin D levels, and BMD was observed (MacDonald *et al.,* 2006). The only positive finding in this study was a weak association between the Cdx2 polymorphisms and bone loss, although this was not significant after correction for multiple testing.

Many investigators have conducted functional analysis of individual VDR polymorphisms and haplotypes. Reporter gene constructs prepared from the 3′ region of the VDR gene in different individuals have shown evidence of haplotype-specific differences in gene transcription, raising the possibility that polymorphisms in this region may be involved in regulating RNA stability (Morrison *et al.,* 1994). In support of this view, cell lines that were heterozygous for the TaqI polymorphism showed differences in allele-specific transcription of the VDR gene (Verbeek *et al.,* 1997). In this study, however, transcripts from the "t" allele were 30% more abundant than the "T," which is the opposite from the result expected on the basis of Morrison's results (Morrison *et al.,* 1994). In another study, evidence of differences in allele-specific transcription were observed in relation to 3′ VDR haplotypes in bone samples from male subjects in the MrOs study (Grundberg *et al.,* 2007). Specifically, carriage of haplotype 1 (baT) was associated with increased VDR mRNA abundance and this haplotype was also associated with an increased risk of fracture in men. Other *in vitro* studies have shown no differences in allele-specific transcription, mRNA stability, or ligand binding in relation to the *BsmI* polymorphism (Mocharla *et al.,* 1997; Gross *et al.,* 1998b; Durrin *et al.,* 1999). Studies *in vitro* have shown that different VDR *FokI* alleles differ in their ability to drive reporter gene expression (Arai *et al.,* 1997; Jurutka *et al.,* 2000) and the polymorphic variant lacking three amino acids ("F") has also been found to interact with human basal transcription factor IIB more efficiently than the longer isoform ("f"). Finally, peripheral blood mononuclear cells (PBMCs) from "FF" individuals were also been found to be more sensitive to the growth-inhibitory effects of calcitriol than PBMC from "Ff" and "ff" individuals (Colin *et al.,* 2000). Contrasting with these results, however, Gross and colleagues found no evidence of functional differences between *FokI* alleles in terms of ligand binding, DNA binding, or transactivation activity. There is good evidence that the Cdx2 polymorphism within the promoter of

the VDR gene is functional. Arai and colleagues noted that the G allele had reduced affinity for CDx2 protein binding and also had a 70% reduced ability to drive reporter gene expression compared with the A allele (Arai *et al.*, 2001).

In summary, the studies that have been performed to date do not support the hypothesis that allelic variation in the VDR gene plays a major role in regulating bone mass or osteoporotic fracture, although there is evidence that some of the polymorphisms described have functional effects at least *in vitro*. Some evidence has been put forward to suggest that the effects of VDR alleles may be modified by dietary calcium and vitamin D intake, but the data are conflicting and large-scale studies have failed to convincingly show such interactions.

OTHER CANDIDATE GENES

A large number of other candidate genes have been studied in relation to BMD and susceptibility to osteoporotic fracture and these are summarized in Tables I to V. Further information on the potential role of these genes in regulating susceptibility to osteoporosis can be found in recent review articles (Liu *et al.*, 2003; Albagha and Ralston, 2006).

GENE–GENE INTERACTIONS

Several investigators have studied the relationship between combinations of candidate gene polymorphisms and BMD. Willing and colleagues (1998) looked at the interaction between VDR and *ESR1* polymorphisms in predicting BMD in a series of 171 postmenopausal women and found that individuals with a combination of *ESR1* PvuII "PP" and VDR "bb" genotypes had very-high-average BMD values at all skeletal sites examined. Another study by Gennari *et al.* (1998) in a population of postmenopausal Italian women showed that the combination of VDR and *ESR1* genotypes identified subgroups of individuals with very high and very low BMD. However, Vandevyer found no significant interaction between VDR and *ESR1* genotypes in predicting BMD in Belgian postmenopausal women (Vandevyer *et al.*, 1999). The best studies of gene–gene interactions were performed in the Rotterdam study.

TABLE I Candidate genes for Osteoporosis—Hormones, Receptors, and Related Factors

Function	Protein	Gene	Reference
Converts adrenal androgens to estrogen	Aromatase	CYP19	Tofteng *et al.* (2003)
Receptor for testosterone	Androgen receptor	AR	Sowers *et al.* (1999)
Receptor for extracellular calcium	Calcium-sensing receptor	CASR	Bollerslev *et al.* (2004)
Inhibits osteoclast activity	Calcitonin	CT	Miyao *et al.* (2000)
Regulates osteoclast activity	Calcitonin receptor	CTR	Masi *et al.* (1998)
Receptor for estrogen	Estrogen receptor alpha	ESR1	Ioannidis *et al.* (2002)
Receptor for estrogen	Estrogen receptor beta	ESR2	Ogawa *et al.* (2000)
Involved in estrogen metabolism	17 alpha hydroxylase	CYP17	Somner *et al.* (2004)
Receptor for gonadotrophin-releasing hormone	Gonadotrophin-releasing hormone 1	GNRH1	Iwasaki *et al.* (2003)
Receptor for glucocorticoids	Glucocorticoid receptor	GCCR	Huizenga *et al.* (1998)
Stimulates growth	Growth hormone	GH1	Dennison *et al.* (2004)
Stimulates growth	Insulin-like growth factor 1	IGF1	Rivadeneira *et al.* (2003)
Receptor for Leptin	Leptin receptor	LEPR	Koh *et al.* (2002)
Coactivator of steroid receptor action	Nuclear receptor coactivator 3	NCOA3	Sheu *et al.* (2006)
Activates bone turnover	PTH	PTH	Hosoi *et al.* (1999)
Receptor for PTH	PTHr1	PTHR1	Scillitani *et al.* (2006)
Coactivator of steroid receptor	Retinoblastoma protein-binding zinc finger protein (RIZ)	PRDM2	Grundberg *et al.* (2004)
Transport of vitamin D	Vitamin D-binding protein	DBP	Papiha *et al.* (1999)
Receptor for vitamin D	Vitamin D receptor	VDR	Uitterlinden *et al.* (2006)

TABLE II Candidate Genes for Osteoporosis—Cytokines, Growth Factors, and Receptors

Function	Protein	Gene	Reference
Stimulates osteoblast differentiation	Bone morphogenic protein 2	BMP2	Styrkarsdottir *et al.* (2003)
Stimulates osteoblast differentiation	Bone morphogenic protein 4 Chemokine CC motif receptor 2	BMP4 CCR2	Ramesh *et al.* (2005) Yamada *et al.* (2002a)
Stimulates osteoclast activity	Interleukin-1	IL1	Knudsen *et al.* (2007)
Inhibits osteoclast activity	Interleukin 1 receptor antagonist	IL1RN	Keen *et al.* (1998)
Regulates IL-1 signaling	Interleukin-1 receptor-associated kinase	IRAK	
Osteoblast differentiation	Lipoprotein receptor-related protein 5	LRP5	van Meurs *et al.* (2006)
Osteoblast differentiation	Lipoprotein receptor-related protein 6	LRP6	van Meurs *et al.* (2006)
Inhibits osteoclast activity	Osteoprotegerin	TNFRS11B	Ueland *et al.* (2007)
Inhibits osteoclast differentiation	Osteoclast-associated receptor	OSCAR	Kim *et al.* (2005)
Regulates osteoclast differentiation	Receptor activator of nuclear factor kappa b	TNFRSF11A	Koh *et al.* (2007b)
Stimulates osteoclast differentiation and function	Receptor activator of nuclear factor kappa b ligand	TNFSF11	Xiong *et al.* (2007)
Regulates TNF and IL-1 signaling	Tumor necrosis factor receptor factor 6	TRAF6	Vidal *et al.* (2007)
Regulates TNF signaling	TRAF family member-associated NFkB activator	TANK	Ishida *et al.* (2003)
Inhibits LRP5 signaling	Sclerostin	SOST	Uitterlinden *et al.* (2004)
Regulates osteoclast and osteoblast function	Transforming growth factor beta 1	TGFB1	McGuigan *et al.* (2007)
Regulates osteoclast and osteoblast function	Tumor necrosis factor receptor 1	TNFRSF1B	Albagha *et al.* (2002)

TABLE III Candidate genes for Osteoporosis—Bone Matrix Components and Modifying enzymes

Function	Protein	Gene	Reference
Component of bone matrix	Alpha-2-HS glycoprotein	AHSG	Zmuda *et al.* (1998)
Degrades bone matrix	Cathepsin K	CATK	Giraudeau *et al.* (2004)
Component of bone matrix	Collagen type 1 alpha 1	COL1A1	Ralston *et al.* (2006)
Component of bone matrix	Collagen type 1 alpha 2	COL1A2	Suuriniemi *et al.* (2003)
Component of bone matrix	Matrix Gla protein	MGP	Tsukamoto *et al.* (2000)
Degrades collagen	Matrix metalloproteinase 1	MMP1	Yamada *et al.* (2002b)
Degrades collagen	Matrix metalloproteinase 9	MMP9	Yamada *et al.* (2004)
Component of bone matrix	Osteocalcin	BGP	Dohi *et al.* (1998)
Hydroxylates lysine residues in collagen	Procollagen-lysine, 2-oxoglutarate-5-dioxegenase	PLOD1	Tasker *et al.* (2004)

TABLE IV Candidate Genes for Osteoporosis—Lipid Metabolism and Other Metabolic Pathways

Function	Protein	Gene	Reference
Involved in lipid transport	Apolipoprotein E	APOE	Cauley *et al.* (1999b)
Transcription factor involved in adipocyte differentiation	Forkhead box C2	FOXC2	Yamada *et al.* (2006)
Transmembrane protein with multiple functions involved in phosphate and calcium metabolism	Klotho	KL	Ogata *et al.* (2002)
Lactose-metabolizing enzyme	Lactase	LCT	Obermayer-Pietsch *et al.* (2004)
Enzyme involved in homocysteine metabolism	Methionine synthase reductase	MTRR	Kim *et al.* (2006)
Enzyme involved in homocysteine metabolism	Methylene tetrahydrofolate reductase	MTHFR	Abrahamsen *et al.* (2003)
Adipocyte protein involved in lipid metabolism	Perilipin	PLIN	Yamada *et al.* (2006)
Transcription factor involved in osteoblast and adipocyte differentiation	Peroxisome proliferator-activated receptor gamma	PPARG	Ogawa *et al.* (1999)

TABLE V Candidate Genes for Osteoporosis—Miscellaneous

Function	Protein	Gene	Reference
Cell cycle regulator	Cyclin-dependent kinase inhibitor 1c	CDK1	Urano *et al.* (2000)
Osteoclast chloride channel	Chloride channel 7	CLCN7	Pettersson *et al.* (2005)
Lactose-metabolizing enzyme	Lactase	LCT	Obermayer-Pietsch *et al.* (2004)
Transcription factor expressed in bone marrow	LIM domain protein RIL	PDLIM4	Omasu *et al.* (2003)
Glycoprotein involved in immune regulation	Major histocompatibility complex, class 1 A	HLA-A	Tsuji *et al.* (1998)
Transcription factor involved in regulating osteoclast differentiation	Microphthalmia-associated transcription factor	MITF	Koh *et al.* (2007a)
Receptor for semaphorin 3A; implicated in neural control of bone remodeling	Plexin A2	PLXNA2	Hwang *et al.* (2006)
Esterases involved in metabolizing toxins and oxidized lipids	Paranoxase 1 and 2	PON1/ PNO2	Yamada *et al.* (2003)
Component of osteoclast proton pump	T-cell immune regulator 1	TCIRG1	Sobacchi *et al.* (2004)
Trancription factor that regulates osteoblast differentiation	Runt-related transcription factor 2	RUNX2	Vaughan *et al.* (2004)
Regulates monocyte / macrophage activity	Semaphorin 7A	SEMA7A	Koh *et al.* (2006)
Involved in DNA replication and genomic stability	Werner helicase	WRN	Ogata *et al.* (2001)
Regulates bone formation in mice	Brain natriuretic peptide	BNP	Kajita *et al.* (2003)

Uitterlinden and colleagues reported that VDR haplotypes and the *COL1A1* Sp1 polymorphism interacted to regulate susceptibility to fracture in 1004 women from this study. Carriers of the highest-risk alleles for both genes had a 4.4 fold increase in fracture risk compared with the reference group, raising the possibility that this approach could be used to identify patients and low and high risk of osteoporotic fractures. In another analysis of the Rotterdam population, Rivadeneira reported that alleles of *ESR1*, *ESR2,* and *IGF-1* all interacted to regulate susceptibility to osteoporotic fracture and other phenotypes including BMD and aspects of femoral neck structure in 6363 subjects (Rivadeneira *et al.,* 2006). The authors reported a significant interaction between these three genes and the phenotypes studied in women, which persisted after correction for multiple testing, although interestingly no effects were observed in men.

GENETIC DETERMINANTS OF TREATMENT RESPONSE

Uncovering the genetic determinants of response to therapeutic agents is a subject of increasing interest because it raises the prospect of being able to predict individual responses to drug treatment on the basis of genetic profiling (Roses, 2000). Several investigators have now looked at associations between candidate gene polymorphisms and the response of BMD to antiosteoporotic treatments.

Calcium and Vitamin D

Krall and colleagues (1995) studied the relationship between VDR alleles and bone loss in 229 women who had participated in a controlled trial of calcium supplements in the prevention of postmenopausal bone loss. The calcium-supplemented group showed no relationship between VDR genotype and bone loss, whereas in the placebo group, bone loss was significantly greater in the BB group when compared with the other genotype groups. Graafmans *et al.* (1997) studied the response to vitamin D supplementation in a series of 81 postmenopausal Dutch women who had taken part in a placebo-controlled trial of vitamin D supplementation on BMD and fracture incidence. These workers observed that the 2-year change of BMD values in the vitamin D group relative to the placebo group was significantly higher in the "BB" and "Bb" genotypes when compared with the "bb" genotype group. This study is of interest in relation to another study by the same group that showed that the "bb" genotype also had low BMD in a population-based study. Yamada and colleagues (2000) studied the relationship between response of BMD to one-alpha-hydroxyvitamin D in relation to a signal peptide polymorphism of the *TGFB1* gene. This study comprised 363 postmenopausal women who were treated with one-alpha-hydroxyvitamin D ($n = 117$) or with HRT ($n = 116$), or who were untreated ($n = 130$). Individuals with the high BMD-associated "CC" genotype responded significantly better to vitamin D treatment than the other genotype groups. The same trend was observed in the HRT group, but the differences were not significant.

Hormone Replacement Therapy

Some information is available on the relationship between candidate gene polymorphisms and response to HRT. Ongphiphadhanakul and colleagues (2000) studied the relationship between *ESR1* polymorphisms and the 1-year response to HRT treatment in 124 postmenopausal Thai women. Individuals with the "pp" genotype at the *ESR1* PvuII site were found to respond less well to HRT (+2.3% increase in BMD) than the other genotype groups (+6 to 7% increase in BMD). In a similar but larger study of 248 Korean women, however, Han and colleagues found no association between *XbaI* or *PvuII* polymorphisms and the 1-year response of BMD to HRT (Han *et al.,* 1999). Salmen *et al.* (2000) similarly found no association between the *ESR1* genotype and response to HRT in a study of 145 Finnish women. Taken together, these data do not support the view that *ESR1* polymorphisms consistently predict response to HRT. Other candidate genes have been also studied in relation to HRT response. They include TGFβ1 (discussed earlier) and ApoE, which was analyzed by Heikkinen and colleagues in a study of 232 women who were treated with HRT and followed-up after a 5-year period (Heikkinen *et al.,* 2000). No association was observed in this study between ApoE genotype and HRT responsiveness.

Bisphosphonates

Marc and colleagues (1999) looked at the relationship between VDR genotype and response to etidronate therapy in a small series of 24 postmenopausal women undergoing treatment with etidronate. The mean change in BMD over a 2-year period was significantly greater in the BB vs. the bb group with intermediate values in the heterozygotes. In another study, Qureshi *et al.* (2002) looked at the association between *COL1A1* genotype and the response to etidronate treatment in a series of 48 early-postmenopausal women who took part in a randomized, controlled trial of etidronate in the prevention of postmenopausal bone loss. Although no difference was observed in response of spine BMD to etidronate treatment, those with the "s" allele responded significantly less well at the femoral neck when compared with "SS" homozygotes. These preliminary data are of interest in raising the possibility that genetic markers can be used to predict therapeutic response to bisphosphonates, but further work in larger groups of patients will be required to confirm and extend these observations.

IMPLICATIONS FOR CLINICAL PRACTICE

Studies on the genetic basis of osteoporosis have potentially important implications for clinical practice. Mapping and identification of genes that regulate BMD offer the prospect of identifying novel molecules that can serve as targets for drug design in the search for new treatments for bone diseases. Already, studies on the genetics of rare bone diseases have identified several molecules and pathways such as Sclerostin and the Wnt-*LRP5* pathway that now form the focus for the design of new anti-osteoporosis drugs. In addition, genetic markers that are associated with BMD or osteoporotic fracture could be used in the identification of patients at risk for fracture. The most promising candidate genes identified so far in this respect are *COL1A1*, *ESR1,* and *LRP5* although much work is needed to explore whether these and other candidate gene polymorphisms can be successfully used along with other clinical variables such as BMD and biochemical markers to predict patients at risk of fracture.

Chapter 76

Pathophysiology of Osteoporosis

Lawrence G. Raisz[*,1], John P. Bilezikian[†] and T. John Martin[‡,1]

**New England Musculoskeletal Institute, University of Connecticut Health Center, Farmington, CT 06030; [†]Department of Medicine and Pharmacology, College of Physicians and Surgeons, Columbia University, New York, New York and; [‡]St. Vincent's Institute of Medical Research, Melbourne, Victoria, Australia*

INTRODUCTION

Osteoporosis was a relatively rare disorder until recent times when increased longevity and changes in lifestyle produced a large population of older individuals with fragile skeletons. Osteoporosis has been defined as a condition in which a low bone mass and changes in microarchitecture that compromise bone strength lead to increased fracture risk (NIH, 2001). This definition would include both primary and secondary osteoporosis. Primary osteoporosis, which has been variously termed postmenopausal, involutional, senile, and idiopathic, involves multiple pathogenetic mechanisms, many of which have not yet been adequately defined. In addition to primary osteoporosis, there are many disorders that can lead to skeletal fragility including (1) genetic disorders such as osteogenesis imperfecta and the osteoporosis-pseudoglioma syndrome; (2) endocrine disorders including Cushing syndrome, hyperparathyroidism, hyperthyroidism, and hypogonadism; and (3) inflammatory and nutritional disorders such as rheumatoid arthritis, Crohn's disease, and celiac disease. The pathogenetic mechanisms for many of these disorders are covered in other chapters. This chapter will summarize the known key elements in the pathophysiology of primary osteoporosis and describe a number of additional potential mechanisms based on our increasing understanding of the complexity of bone biology and its regulation.

BASIC PATHOPHYSIOLOGY

There are three critical factors that can lead to the development of skeletal fragility (Raisz, 2005). (1) *Failure to achieve optimal peak bone mass and strength*. This is largely determined by genetic background (Albagha *et al.*, 2006; Ralston *et al.*, 2007; Nguyen *et al.*, 2003), but can also be substantially affected by lifestyle (Lock *et al.*, 2006; Matkovic *et al.*, 1979). (2) *Accelerated bone loss owing to resorption*. This appears to be less dependent on genetic background (Pocock *et al.*, 1987; Michaelsson *et al.*, 2005). Estrogen deficiency, in particular, at the menopause, but also in older males, plays a substantial role in increasing bone loss (Amin *et al.*, 2006; Falahati-Nini *et al*, 2000). Calcium and vitamin D deficiency leading to secondary hyperparathyroidism are also important (Lips, 2001). (3) *An impaired bone formation response during remodeling*. A gradual decrease in the capacity to form adequate amounts of new bone to maintain bone mass during remodeling may begin shortly after peak bone mass has been achieved (Lips *et al.*, 1978) Its mechanisms are not clear, but changes in local and systemic growth factor production probably are important (Charatcharoenwitthaya *et al.*, 2007; Zhou *et al.*, 2006). Cytokines have been implicated in both accelerated resorption and in impaired formation.

In the past, osteoporosis was regarded as a disorder in which both the microarchitecture and macroarchitecture of bone were abnormal but the chemical composition was normal. However, there are genetic, environmental, and disease-related factors that could produce subtle alternations in the crystal structure and matrix composition of bone, and thus increase its fragility (Herrmann *et al.*, 2006; McLean *et al.*, 2004; Saito *et al.*, 2006; Tang *et al.*, 2007; Tinetti *et al.*, 2006; van Meurs *et al.*, 2004). Finally, a key element in the risk for nonvertebral fractures is the likelihood of falling, which may involve calcium-regulating hormones, particularly vitamin D (Nguyen *et al.*, 2007; Bischoff-Ferrari *et al.*, 2004). Although this nonskeletal feature (namely, risk of falling) is beyond the scope of this chapter, fall prevention should be a critical component of fracture prevention regimens in the elderly (Oliver *et al.*, 2007; Tinetti, 2003).

DETERMINANTS OF PEAK BONE MASS AND STRENGTH

Many genes have been identified as affecting peak bone mass and strength (Ralston, 2007). Genome-wide analyses comparing humans and animals with greater or less skeletal fragility have produced a large number of quantitative trait loci for which the genes have still not been identified. The power of genetic influences on the skeleton is strikingly illustrated by the examples of high-bone-mass phenotypes owing to activating mutations of LRP-5, a coreceptor of the Wnt signaling pathway or loss of the Wnt inhibitor sclerostin (Balemans *et al*., 2001; Little *et al*., 2002) and the severe, early-onset osteoporosis that can occur when the LRP5 gene is inactivated (Gong *et al*., 2001). Polymorphisms of the components of this pathway (Bollerslev *et al*., 2005; Grundberg *et al*., 2007; Hartikka *et al*., 2005; Xiong *et al*., 2007), as well as systemic hormones and local factors and their receptors, have been shown to affect bone mass and fracture risk (Ioannidis *et al*., 2004). In some cases, fracture risk appears to be increased independent of effects on bone density.

Nutrition and lifestyle can also determine whether or not optimal peak bone mass and strength are achieved. There is ample evidence that adequate amounts of calcium, vitamin D, and physical activity as well as good general nutrition are necessary to achieve the optimal peak bone mass that has been genetically programmed to be reached (Chevalley *et al*., 2008). Moreover, environmental effects may also influence genetically programmed acquisition of peak bone mass (Ferrari *et al*., 1999). In addition, smoking (Wong *et al*., 2007), excess alcohol intake, and a number of drugs that are used in children and young adults can adversely affect the acquisition of peak bone mass.

BONE RESORPTION

Even in individuals with relatively low peak bone mass, fragility fractures are uncommon before the age of 50. This is in part owing to the likelihood that microarchitecture has not yet begun to deteriorate. Increased bone resorption that results not only in loss of bone mass, but also in disruption of microarchitecture is critical to development of skeletal fragility. Increased bone resorption is a function of aging and accelerated by age-related events such as the menopause. Osteoclastic bone resorption is described in detail elsewhere in this book. The increase in bone resorption in osteoporosis is probably the result of many factors that affect the formation and function of osteoclasts. These effects may be mediated through the interaction of receptor activator of NFκB ligand (RANKL) from osteoblasts, and possibly other marrow cells, with its receptor RANK on osteoclast precursors (Kearns *et al.* 2007). This interaction can be blocked by the natural RANKL inhibitor, osteoprotegerin (OPG). Studies in osteoporosis are consistent with an increase in RANKL activity. RANKL can be affected by hormones (Eghbali-Fatourechi *et al.*, 2003), with increases seen in the context of estrogen deficiency and parathyroid hormone administration. Increases in RANKL are often associated with a decrease in OPG (Falahati-Nini *et al*., 2000; Huang, *et al.,* 2007; Hofbauer *et al*., 1999; Syed *et al*., 2005; Taxel *et al.*, 2007). OPG deficiency can cause osteoporosis in animals (Bucay *et al.,* 1998) but it does not appear to be critically important in the pathophysiology of primary osteoporosis in humans. In addition to the RANKL-OPG system, many cytokines have been implicated as stimulators of osteoclastic activity. In animal models, there is evidence that IL-1, TNFα, IL-6, prostaglandin E_2 (PGE_2), and IL-11 are all key regulators. The amount of bone lost is influenced when specific cytokines are deleted or inhibited against a backdrop of the ovariectomized animal. While of interest, these studies do not necessarily indicate a pathophysiological role for that specific cytokine (Ammann *et al.*, 1997; Horwitz *et al.,* 2002; Kimble *et al.*, 1995; Lorenzo *et al.,* 1998; Pacifici, 2007; Weitzmann *et al.,* 2001). There is likely to be a complex interplay between and among local factors that influence osteoclastic bone resorption. Some act in concert with, and others antagonistic of, responses that might otherwise be seen when a specific factor is studied alone (Kawaguchi, 1995). It is also important to appreciate the point that cytokine production may be regulated by oxidative damage, which has been implicated in estrogen deficiency and in age-related bone loss (Jagger *et al.,* 2005; Lean *et al.,* 2005).

The end result of excessive osteoclast activity, not compensated by a concomitant increase in osteoblast activity, is skeletal fragility. The microarchitectural deterioration probably reflects the intensity and duration of osteoclast activity as well as the number of osteoclasts formed. RANKL can prolong osteoclast survival whereas estrogen can shorten survival by increasing apoptosis (Hughes *et al.,* 1996). In addition to OPG, other naturally occurring antiresorptive factors include calcitonin and cytokines such as IL-4 (Palmqvist *et al.,* 2006; Silfversward *et al.,* 2007). TGFβ, interferon-γ, and granulocyte-macrophage colony-stimulating factor have also been shown to inhibit osteoclast formation or activity, but they have not yet been implicated in the pathophysiology of osteoporosis. Deficiency of calcitonin does not appear to be a major mechanism for bone loss in primary osteoporosis (Tiegs *et al.,* 1985), although there is little information on inhibitory cytokines.

Osteoporotic women are usually estrogen deficient. Evidence also points to the importance of estrogen in bone loss in the aging male as well. There is a graded effect of estrogen on bone in both men and women, such that the lowest levels are associated with the highest fracture risk (Cummings *et al.,* 1998; Amin *et al.,* 2006). This is consistent with the finding that low doses of estradiol, which

have little effect on the breast and uterus, can prevent bone loss (Prestwood *et al.,* 2003). Although estrogen may affect systemic hormones and also play a direct role in the activity of differentiated bone cells, there is also evidence that estrogen can affect the production or activity of local factors, including cytokines, prostaglandins, and growth factors. There are many local factors that respond to estrogen, and these factors can modulate each other, so that decreasing or increasing a single factor may not give an accurate picture of its physiological or pathological role. Data from animal models and cell and tissue cultures suggest that estrogen deficiency increases and estrogen replacement decreases the activities of IL-1, TNF-*a*, and IL-6, as well as prostaglandins (Kimble *et al.,* 1995; Manolagas and Jilka, 1995). Estrogen can increase TGFβ, leading to osteoclast apoptosis (Hughes *et al.,* 1996), and increase OPG, which would block both formation and activity of osteoclasts (Hofbauer *et al.,* 1999). Estrogen may also affect TGFβ signaling in T cells (Gao *et al.,* 2004). A significant study of the role of osteoclast regulation by estrogen is one carried out in women who were premenopausal, or postmenopausal with and without estrogen treatment (Eghbali-Fatourechi *et al.,* 2003). Serum levels of RANKL or OPG did not differ among the groups, but analyses of bone marrow mononuclear cells in these subjects showed that the production of RANKL per cell was increased up to 3-fold in untreated postmenopausal women, and furthermore correlated negatively with serum estradiol-17β levels and positively with bone resorption markers. The study draws attention to the close involvement of cells of the immune system in estrogen action on the skeleton, but without the increases in T- or B-cell numbers that occur in the mouse. Importantly, it highlights the fact that studies of cytokine-mediated processes in bone need to focus on the bone microenvironment.

Although any or all of these mechanisms have been put forward to explain the increase osteoclast production and bone resorption that follows estrogen withdrawal, there still remains the possibility that estrogen acts directly on the osteoclast. Evidence in support of this has been obtained in mice in which a direct effect of estrogen inhibiting osteoclast apoptosis via increased Fas ligand has been discovered through experiments in which the ERα was specifically deleted (Nakamura *et al.,* 2007).

Osteoclastic activation through mechanisms already described initiate the bone remodeling cycle. What limits this activity in time is not understood, but *in vitro* it is known that osteoclasts resorb bone at a single site for only a few hours before moving on to another site. *In vivo* the resorptive phase of the bone remodeling cycle probably lasts 2 weeks or less, followed by a brief reversal phase (Bonewald, 2007) and a much longer phase of bone formation that lasts several months. Because of this difference in the duration of removal and formation of bone at remodeling sites, any increase in the overall activation frequency of remodeling sites will result in at least a transient decrease in bone mass and perhaps also microarchitectural weakness.

COUPLING OF BONE RESORPTION TO FORMATION

If the acceleration of bone resorption were matched by an equal or greater increase in bone formation there might be transient bone loss, but ultimately the removed bone would be replaced by new bone. Hence, the continuous loss of bone that occurs in osteoporosis implies a defect in the coupling process. Thus, it is of great importance to determine what factors regulate coupling. The initiating of formation following resorption could be influenced by factors derived from osteoclasts (see later). The signal could also come from osteocytes that are uncovered during resorption and release matrix components or factors from the mononuclear cells that are present during the reversal phase. These factors could stimulate the migration, replication, and differentiation of osteoblast precursors. Current candidates for such a role include insulin-like growth factor (IGF), TGFβ, and the components of the Wnt signaling pathway (Krishnan *et al.,* 2006). The Wnt signaling pathway might involve release of regulators that prevent this pathway from fully expressing its anabolic potential. For example, osteocytes express sclerostin, an inhibitor of Wnt signaling. The coupling process by which bone formation follows resorptive activity could involve a reduction in sclerostin expression. Signals in this regard could be related to mechanical forces, to parathyroid hormone, and to other factors (Bellido *et al.,* 2005; Keller, 2005; Sawakami *et al.,* 2006). Estrogen deficiency may play a role in the impaired formation response during remodeling, because animals lacking ERα showed decreased formation responses to mechanical loading by a mechanism that involves the Wnt signaling pathway (Armstrong *et al.,* 2007).

BONE FORMATION

An inadequate bone formation response during remodeling is not only critical for the development of skeletal fragility, but may also be at least as important as increased resorption in some cases (Eriksen *et al.,* 1990; Parfitt *et al.,* 1995). A progressive age-related decrease in the size of the packets of new bone formed at remodeling sites (mean wall thickness) probably begins soon after peak bone mass is achieved (Khosla *et al.,* 2006; Lips *et al.,* 1978). It appears to be similar in both men and women and does not show a clear change in rate at the menopause. Many mechanisms have been implicated to account for this imbalance of bone remodeling. A progressive decrease in either production of IGF-1, its local release, or its receptor responses have been postulated. Osteoporosis in middle-aged men, without clear etiology, is associated with

decreased IGF-1 production (Rosen, 2004). Mechanical loading may enhance IGF-1 receptor signaling (Triplett *et al.,* 2007), and can also increase local prostaglandin and nitric oxide production (Kapur *et al.,* 2003; Wadhwa *et al.,* 2002). Mechanical stimulation can also decrease sclerostin expression (Robling *et al.,* 2007). Skeletal blood flow decreases with aging and this may decrease nitric oxide production (Prisby *et al.,* 2007).

A progressive change in the differentiation of marrow stromal precursor cells so that fewer progenitor cells become osteoblasts and more become adipocytes might also play a role. Increased apoptosis of osteoblasts and osteocytes has been found in response to glucocorticoids and may be an important component of this form of secondary osteoporosis (Grassi *et al.,* 2007; Jilka *et al.,* 2007). Oxidative stress could not only enhance resorption but also impair formation (Lean *et al.,* 2005). Impaired vascular supply to bone is another possibility. Finally, a number of the cytokines that have been implicated in increasing bone resorption, particularly TNFα, can also inhibit bone formation. Other growth factors including TGFβ, fibroblast growth factor (FGF), platelet-derived growth factor (PDGF), and vascular endothelial growth factor (VEGF), can all be produced by bone cells as well as adjacent hematopoietic and vascular cells in the marrow.

Although the bone formation response during remodeling may be impaired in osteoporosis, it is certainly not abrogated. In postmenopausal women with rapid rates of bone resorption, the biochemical markers for bone formation also increase. This largely reflects the increase in the number of remodeling sites. Thus, although many new formation sites may be initiated, the amount of bone formed at these sites is decreased. The so-called high-turnover state, then, is still associated with more resorption than formation, reflecting the essential imbalance in bone remodeling that characterizes the osteoporotic process.

OSTEOCLAST PRODUCTS IN THE COUPLING PROCESS

Observations made in genetically manipulated mice suggest that the osteoclast itself could also be the source of an activity that contributes to the fine control of coupling of bone formation to resorption. Generation of coupling activity was suggested by increased bone formation in $OPG^{-/-}$ mice (Nakamura *et al.,* 2007), which are severely osteoporotic because of excessive osteoclast formation presumably owing to excessive RANKL activity. In bone sections from mice obtained in this high-turnover state, active bone resorption sites commonly were seen in association with active osteoblasts nearby, suggesting that coupling activity in this high-turnover state could be caused by the osteoclasts themselves. Cytokines that signal through gp130 play an important role in intercellular communication processes in bone, with evidence indicating that they can be involved in regulating mice in which each of the two gp130-dependent signaling pathways was specifically attenuated (Sims *et al.,* 2004, 2005). Inactivation of the SHP2/ras/MAPK signaling pathway ($gp130^{Y757F/Y757F}$ mice) yielded mice with greater osteoclast numbers and bone resorption, as well as greater bone formation than wild-type mice. This increased bone remodeling resulted in less bone because the increase in resorption was relatively greater than that in formation. In other words, the coupling process was imprecise in a way that resembles the result of estrogen withdrawal, as in ovariectomy $gp130^{Y757F/Y757F}$ mice crossed with IL-6 null mice had similarly high osteoclast numbers and increased bone resorption; however, these mice showed no corresponding increase in bone formation and thus had extremely low bone mass. Thus resorption alone is insufficient to promote the coupled bone formation, but the active osteoclasts are the likely source. Furthermore, this indicated that stimulation of bone formation coupled to the high level of bone resorption in $gp130^{Y757F/Y757F}$ mice is an IL-6-dependent process, though it does not necessarily show that it is mediated by IL-6 itself (Sims *et al.,* 2004).

Some indication of an osteoclast role in coupling comes also from human genetics. In individuals with the osteopetrotic syndrome, autosomal dominant osteopetrosis II (ADOII), owing to inactivating mutations in the chloride-7 channel (ClC-7), bone resorption is deficient because of failure of the osteoclast acidification process. Bone formation in these patients is nevertheless normal, rather than diminished as might be expected because of the greatly impaired resorption (Cleiren *et al.,* 2001). Furthermore, in mice deficient in either c-*src* (Lowe *et al.,* 1993), ClC-7 (Kasper *et al.,* 2005), or tyrosine phosphatase epsilon (Aoki *et al.,* 1999), bone resorption is inhibited without inhibition of formation. In these three knockout mouse lines, osteoclast resorption is greatly reduced by the mutation, although osteoclast numbers are not reduced. Indeed, osteoclast numbers are actually increased because of reduced osteoclast apoptosis. A possibility is that these osteoclasts, although unable to resorb bone, are nevertheless capable of generating a factor (or factors) contributing to bone formation. On the other hand, mice lacking c-*fos,* which are unable to generate osteoclasts, have reduced bone formation as well as resorption (Grigoriadis *et al.,* 1994).

Current focus on the osteoclast as a contributor to bone formation within the BMU might provide information that helps in understanding how remodeling spaces are filled, a process very relevant to the pathogenesis of bone loss.

NEURAL PATHWAYS AND ENERGY METABOLISM

This new and rapidly evolving area of research is likely to shed further light on the pathogenesis of osteoporosis (Reid,

2007; Martin, 2007; Karsenty, 2006). There are three components of this topic that may act in quite different ways. (1) Effects of body weight on bone. Low body weight is clearly a risk factor for osteoporosis and increased body weight may have positive effects on bone mass, although the effects on fractures are less clear. The relative roles of lean versus fat mass in determining BMD in postmenopausal women is not clearly established, both probably play a role. One definite mechanism by which increased body mass could increase bone mass is by increased mechanical loading. Increased fat mass could also increase estrogen production because of the high levels of aromatase in adipose tissue. (2) Adipogenesis in marrow. There is a continuous increase in proportion of adipocytes in marrow with age and this appears to be exaggerated in osteoporotic patients (Moerman *et al.,* 2004). Factors that increase adipogenesis, such as thiazolidinediones (TZDs) that activate peroxizome proliferator-activated receptor (PPAR)-γ, can decrease osteoblastogenesis and cause bone loss (Lecka-Czernik *et al.,* 2006; Schwartz *et al.,* 2006). The anabolic effects of increased Wnt signaling may be caused not only by increased osteoblastogenesis, but also by inhibition of adipogenesis (Krishnan *et al.,* 2006). (3) Hormonal and neural interactions. The presence of nerve endings, particularly of sympathetic nerves, in bone has long been recognized. A number of neuropeptides have been shown to act on bone, largely by increasing resorption. However, the discovery that mice with leptin deficiency had high bone mass, despite hypogonadism, and that this depended on leptin action in the brain, pointed to a role for the central nervous system (Ducy *et al.,* 2000; Takeda *et al.,* 2002). The central action of leptin is most likely through activation of sympathetic tone that can result in decreased bone mass. Epidemiological studies suggest that blockade of the β-adrenergic pathway can increase bone mass and decrease fracture risk (Pasco *et al.,* 2004; Schlienger *et al.,* 2004; Reid *et al.,* 2005). Epidemiological studies also support a role for leptin as well as polymorphisms of the leptin receptor as determinants of bone mass and fracture risk (Fairbrother *et al.,* 2007; Lorentzon *et al.,* 2006). In addition to the β-adrenergic pathway, the cannabinoid receptor and cocaine-amphetamine-regulated transcript (Cart) and neuromedin U may play a positive role in skeletal regulation, possibly by inhibiting β-adrenergic signaling (Bab *et al.,* 2008; Elefteriou *et al.,* 2005; Ofek *et al.,* 2006).

Most recently, another potential form of crosstalk between the skeleton and energy metabolism has been described (Lee *et al.,* 2007). Mice lacking the bone-specific protein tyrosine phosphatase OST-PTP were found to be hypoglycemic with increased insulin secretion. Deletion of one allele of the osteocalcin gene corrected this metabolic phenotype. Moreover, osteocalcin could stimulate insulin and adiponectin expression in B cells. Interestingly the effect of undercarboxylated osteocalcin was greater than that of the fully carboxylated form that is active in the skeleton as a regulator of mineralization.

Because the factors discussed here may have both direct and indirect effects on skeletal tissue and may be mediated through the nervous system or through hormonal pathways, it will require much work to establish their specific roles in the maintenance of skeletal integrity as well as in the pathogenesis of osteoporosis. Nevertheless, these new findings point to new approaches that may help us to understand the enormous variation in skeletal fragility and fractures among older individuals.

SYSTEMIC FACTORS IN THE PATHOPHYSIOLOGY OF OSTEOPOROSIS

In addition to local factors that are ultimately and mechanistically of pivotal importance in the cellular pathophysiology of osteoporosis, systemic regulators of mineral metabolism are believed to play an important role. Clearly, a reduction in circulating concentrations of estrogens is the single most important reason why postmenopausal women are at greater risk for bone loss than premenopausal women (Lindsay, 1998). Observations from the Study of Osteoporotic Fractures have established further that the low "residual" estrogen levels in postmenopausal women not taking estrogens are determinants in bone mineral density and in fracture risk (Ettinger *et al.*, 1998; Cummings *et al.*, 1998). The importance of estrogen sufficiency in men also has been elucidated in two male models of estrogen deficiency involving the estrogen receptor (Smith *et al.*, 1994) and the aromatase enzyme that converts androgens to estrogens (Morishima *et al.*, 1995; Carani *et al.*, 1997; Bilezikian *et al.*, 1998; Grumbach and Auchus, 1999). Animal knockout experiments of the alpha-estrogen receptor and of the aromatase gene provide further support for the key role of estrogens in male development (Lubahn *et al.*, 1993; Couse and Korach, 1999; Windahl *et al.*, 1999; Oz *et al.*, 2000).

The importance of estrogen in male skeletal health is amplified further in epidemiological studies correlating declining estrogen levels, but not declining testosterone levels, in age-related bone loss in men (Khosla *et al.*, 2001). Falahati-Nini *et al.* (2000), Khosla and Bilezikian (2003), Fink *et al.* (2006), and Gennari and Bilezikian (2007a, 2007b) have shown recently that when men are rendered temporarily but acutely hypogonadal, estrogen is the prime regulator of the subsequent increase in markers of bone resorption.

The importance of androgens in establishing and maintaining bone mass is also well recognized (Kearns and Khosla, 2004; Mellstrom *et al,* 2006). In addition to the sex steroids, glucocorticosteroids are key systemic factors in bone metabolism. We recognize the glucocorticosteroids not so much for any major role they may play in normal mineral homeostasis but rather for their devastating impact on bone metabolism when present in excess (Canalis *et al.,* 2007a).

In Cushing's disease or when glucocorticosteroids are used therapeutically, bone loss is a major complication. Excessive thyroid hormone may also have a deleterious effect on bone metabolism (Stern and Lakatos, 1999). Elsewhere in this book, these points are considered in depth. This section deals primarily with evidence that casts a potential role for the calciotropic hormones in the pathophysiology of osteoporosis.

VITAMIN D

The potential role of vitamin D in the pathophysiology of osteoporosis should be distinguished from overt vitamin D deficiency that is associated with the clinical syndromes of rickets (children) or osteomalacia (adults). This discussion highlights, instead, the concept that subclinical vitamin D inadequacy occurring by any of the mechanisms described earlier leads to suboptimal peak bone mass or to impaired maintenance of calcium balance. The clinical endpoint, osteoporosis, is not believed to be different from any other presentation of age-related osteoporosis.

1,25-Dihydroxyvitamin D, the active metabolite of vitamin D, enhances the absorption of calcium from the gastrointestinal tract, helps to regulate calcium handling in the kidney, serves to maintain normal bone remodeling, and is an important regulator of parathyroid hormone (Deluca, 2004). Any abnormality in vitamin D formation, metabolism, or action could lead, therefore, to profound changes in calcium balance and result in bone loss. Many studies report a fall in the circulating concentration of 1,25-dihydroxyvitamin D with advancing age (Eastell *et al.*, 1991; Fujisawa *et al.*, 1998; Lanske and Razzaque, 2007). More consistently, levels of the substrate for 1,25-dihydroxyvitamin D, namely 25-hydroxyvitamin D, fall as a function of age (Blumsohn and Eastell, 1995). Reduced concentrations of these vitamin D metabolites are thus considered to be one reason why vitamin D deficiency is implicated in age-associated reductions in bone mass.

Inadequate sources of vitamin D from either diet or sunlight are the most obvious possibilities for reduced levels of vitamin D in older individuals. In the skin, ultraviolet B, at 290 to 315 nm, converts 7-dehydrocholesterol to previtamin D (Holick and Garabedian, 2006). 7-Dehydrocholesterol levels in the skin fall by about 50% between 20 and 80 years of age (McKenna, 1992). The process by which skin produces previtamin D is also a function of sunlight itself. In northern latitudes, sunlight may contribute very little to vitamin D stores during the long winter months (Bouillon *et al.*, 1987; Webb *et al.*, 1990). Even in Maine and Massachusetts, no synthesis of previtamin D occurs in the skin during the late fall and winter (Rosen *et al.*, 1994). Other factors such as avoidance of sunlight and the use of highly protective UV-blocking creams may contribute to the diminishing importance of sunlight as a source of vitamin D.

The other source of vitamin D, the diet, is also a factor contributing to the potential for inadequate stores with age. Among adult Americans, vitamin D intake is well below the recommended daily allowance of 400 to 600 IU (Holick, 2006). In addition, mechanisms associated with absorption of vitamin D from the gastrointestinal tract begin to decline with age (Barragry *et al.*, 1978).

Subclinical vitamin D deficiency has been shown in osteoporotic women (Holick *et al.*, 2005; Lips *et al.*, 2006; Holick, 2007). A number of studies indicate subclinical vitamin D deficiency among home-bound subjects or those living in extended care facilities (Chapuy *et al.*, 1992; Komar *et al.,* 1993, Gloth *et al.*, 1995; Lips, 2001).

Adequate vitamin D depends not only on sufficient sources and absorption but also on normal metabolism of the parent vitamin. Alteration of hepatic or renal hydroxylation of vitamin D or 25-hydroxyvitamin D, respectively, can lead to deficiency (Siegel and Bilezikian, 1995; Holick, 2007). The kidney becomes a pivotal organ in this discussion because it is the source of the active metabolite, 1,25-dihydroxyvitamin D. Factors that help to regulate the renal formation of 1,25-dihydroxyvitamin D are parathyroid hormone, phosphorus, calcium, and 1,25-dihydroxyvitamin D itself. A decline in the ability of the kidney to form 1,25-dihydroxyvitamin D develops with age. Older individuals respond to the stimulating effects of parathyroid hormone on 1,25-dihydroxyvitamin D production less well than young, healthy individuals (Riggs *et al.*, 1981; Tsai *et al.*, 1984). Despite attempts to demonstrate a specific defect in renal hydroxylating capacity in osteoporosis (Slovik *et al.*, 1981; Tsai *et al.*, 1984), most studies have equated the defect with declining renal function *per se* (Halloran *et al.*, 1990, 1996).

Other hypotheses related to the role of vitamin D in the pathogenesis of osteoporosis focus on reduced sensitivity of the small intestine to 1,25-dihydroxyvitamin D. Intestinal resistance to 1,25-dihydroxyvitamin D is a proposed primary alteration (Eastell *et al.*, 1991; Pattanaungkul *et al.*, 2000) owing to an acquired alteration in binding of 1,25-dihydroxyvitamin D to its receptors in the small intestine (Francis *et al.*, 1984), or to an age-related reduction in intestinal vitamin D receptor concentration (Ebeling *et al.*, 1992a; Gennari *et al.*, 1990; Horst *et al.*, 1990). An additional role may be the effect of vitamin D to reduce the risk of falls (Bischoff-Ferrari, 2004). Finally, controversial observations implicate genetic polymorphisms of the vitamin D receptor point to possible underlying genetic bases for osteoporosis. Such genetic alterations could have as a functional counterpart altered physiological action of vitamin D on calcium absorption. This subject, reviewed elsewhere, does not provide the kind of certainty that one requires to establish the vitamin D receptor in mechanisms associated with the pathophysiology of osteoporosis (Albagha *et al.*, 2006; Uitterlinden *et al.*, 2006; Williams and Spector, 2007).

PARATHYROID HORMONE

Because one of the basic pathophysiological features of osteoporosis is altered bone remodeling, a hormone that is critically important for normal bone remodeling has to be a suspect in the pathogenesis of the disease. Parathyroid hormone (PTH) is one such hormone in which its normal actions are focused at the bone-remodeling unit. Normal bone remodeling depends on normal dynamics and actions of PTH. With aging, not only is bone remodeling abnormal, but also there are changes in the synthesis, metabolism, and responsivity of parathyroid hormone. One hypothesis is that the age-associated changes in PTH are causally related to the age-associated changes in bone mass. On the other hand, some of the age-related changes in PTH may be adaptive, serving to protect the aging skeleton rather than weakening it. A contrary hypothesis would state that PTH has the potential to conserve the skeleton because it is known in specific therapeutic contexts to be anabolic for bone (Kurland *et al*., 2000; Canalis *et al*., 2007b; Girotra *et al*., 2006; Neer *et al*., 2001).

Even in primary hyperparathyroidism, a chronic state of excess PTH secretion, cancellous bone mass is often preserved not only with regard to BMD but also with regard to other structural, microarchitectural, and material properties of bone (Silverberg *et al.,* 1989a; Dempster *et al*., 2007; Roschger *et al*., 2007; Bilezikian *et al*., 2007). There are, thus, two fundamentally different views on PTH and the aging skeleton: that it contributes to bone loss and that it helps to protect from bone loss. These two concepts will be explored in this section.

Parathyroid Gland Function with Aging

The view that PTH increases with age was controversial, in part, because age-related declines in renal function lead to an expected secondary increase in circulating PTH. The compensatory increase in PTH could be caused by several factors. The aging kidney does not convert 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D efficiently because of impaired renal 1-alpha-hydroxylating ability. With reduced levels of 1,25-dihydroxyvitamin, its inhibitory effects on PTH synthesis would be reduced and PTH synthesis would be enhanced. In addition, the reduced 1,25-dihydroxyvitamin D level could be associated with reduced calcium absorption, lower levels of the serum calcium concentration (but not to an extent that it would be measurably lowered), and a further stimulus to PTH secretion. Although this concept is entirely feasible, and undoubtedly occurs when renal insufficiency ensues, it was important to establish that the species of circulating PTH, in the context of renal insufficiency, is biologically active and not owing simply to the accumulation of inactive hormone fragments. Assays for PTH that detect active hormone exclusively have helped to settle the point (Deftos, 2001). In renal insufficiency, both active and inactive fragments can accumulate. In the setting of renal insufficiency, then, one can see aspects of PTH that are deleterious to bone.

If PTH is going to be implicated as a causative agent in osteoporosis, however, the increase has to be largely independent of declining renal function, because a universal decline in renal function that would be associated with an increase in PTH (i.e., below 60 cc/min) is not characteristic of osteoporosis. Therefore, it must be shown that PTH levels rise with aging even when renal function is normal. To this point, Halloran *et al.* (1996) have shown that biologically active concentrations of PTH do increase normally with age, even in older individuals who have no apparent decline in renal function. Comparing young and elderly men with normal renal function, they showed that, despite normal serum ionized calcium activity, normal serum 1,25-dihydroxyvitamin D, and normal urinary calcium excretion, basal PTH levels were higher by 1.5-fold in older men than in younger men. The age-related increase in PTH may be associated with a similar rise in bone turnover as assessed both by bone markers (Delmas *et al*., 1983; Duda *et al*., 1988; Eastell *et al*., 1988; Vedi *et al*., 1982) and by histomorphometric indices (Kotowicz *et al*., 1990). Histomorphometric data obtained by Kotowicz *et al.* (1990) suggest that, in postmenopausal osteoporosis, for each picomole per liter rise in circulating PTH, osteoporotic women showed higher activation frequency, bone resorption rate, and cancellous bone loss.

Most studies, in addition to those of Halloran *et al*. (1996), have demonstrated increases in the serum PTH with age (Khosla *et al*., 2001). A few caveats are in order though. In studies that have shown age-related increases in PTH, the major increments appear to occur in individuals who are over 70 years old (Koh *et al*., 1997; Prince *et al*., 1995). Most studies attribute the age-related process of osteoporosis to be fully established well before the age of 70. Further, not all studies have confirmed the PTH levels rise with age (Gallagher *et al*., 1988).

If it is assumed that PTH levels rise with age, independent of declining renal function or other secondary causes, there are two fundamental hypotheses to be addressed. One links the increase in PTH to age-related bone loss; the other hypothesis links the increase in PTH to protection against age-related bone loss.

Parathyroid Hormone as a Contributing Factor to Osteoporosis

The accelerated rate of bone loss in the early postmenopausal years has been explained by the local release of bone-resorbing cytokines (Jilka *et al*., 2002). Riggs and Melton (1983) proposed that such local factors and the ensuing rapid loss of skeletal calcium could actually lead to suppression of PTH. Reduced PTH concentrations in

osteoporotic women in the face of higher bone turnover could reflect enhanced skeletal sensitivity (Ebeling *et al*., 1982; Kotowicz *et al*., 1990) to these local bone-resorbing factors. Although some studies have shown PTH suppression in the early postmenopausal years, more often, PTH concentrations have not been shown to differ from those of age-matched controls. Nevertheless, normal circulating concentrations of PTH could still induce bone loss if sensitivity is heightened in the postmenopausal state. Observations in primary hyperparathyroidism could help to advance this argument. Primary hyperparathyroidism becomes clinically apparent most often in the early postmenopausal years when estrogen deficiency has ensued. Reduced estrogen levels could enhance skeletal sensitivity to PTH. The recent observations in individuals with primary hyperparathyroidism and normal serum calcium concentrations but elevated PTH levels (normocalcemic primary hyperparathyroidism) may be an opportunity to study earlier forms of primary hyperparathyroidism with regard to estrogen loss in the early menopausal state (Silverberg *et al*., 2003; Maruani *et al*., 2003; Tordjman *et al*., 2004; Lowe *et al*., 2007; Lundgren *et al.*, 1997, 2002). Will these individuals demonstrate more clinically apparent primary hyperparathyroidism with hypercalcemia when the menopause occurs? The demonstration in certain postmenopausal women with primary hyperparathyroidism that estrogen replacement therapy is associated with a reduction in calcium levels, but no changes in the circulating PTH, adds support to this idea (Marcus, 2002). The concept implicating PTH in osteoporosis would not so much depend on increases in PTH levels, but rather on increased sensitivity to PTH, particularly in the context of estrogen deficiency.

The notion of enhanced skeletal sensitivity to PTH is not new nor is the idea that this mechanism could account for the development of postmenopausal osteoporosis (Koh *et al*., 1997; Prince *et al*., 1995; Jilka *et al*., 2002). However, enhanced sensitivity to PTH has not been universally demonstrated. Tsai *et al.* (1989) reported no difference between osteoporotic and healthy women in urinary excretion of calcium or hydroxyproline concentrations in response to bovine PTH. Ebeling *et al.* (1992) reported similar results when calcium deprivation was used to stimulate endogenous PTH secretion.

Circumstantial evidence does implicate PTH in the pathogenesis of age-related osteoporosis with regard both to estrogen deficiency, changes in bone turnover, and, to a limited extent, changes in BMD (Riggs *et al*., 1988a, 1998b; Heshmati *et al*., 1998; Khosla *et al*., 1997; McKane *et al*., 1997; Ledger *et al*., 1995). Using peripheral quantitative computed tomography to distinguish cancellous from cortical elements, Boonen *et al.* (1997*)* showed a negative correlation between cortical bone loss and rising PTH levels. Ledger *et al.* (1994) showed that elevated PTH concentrations in the elderly can be reduced to levels seen in young normals by administration of 1,25-dihydroxyvitamin D.

Although these data argue for a role for PTH in the pathogenesis of age-related osteoporosis, their indirect nature argues for caution in establishing a causal link. Moreover, our new knowledge of the salutary effects of PTH on other properties of bone such as bone size, microarchitecture, bone mineral density distribution, and collagen maturity, along with its therapeutic potential in osteoporosis, have directed attention away from the deleterious aspects of PTH on the aging skeleton, and focused instead on its positive features.

Parathyroid Hormone as a Protective influence on the Aging Skeleton

Although there is little doubt that PTH levels normally increase with aging, these observations could be interpreted to suggest that these changes are important to maintain skeletal health and that in osteoporosis this compensatory mechanism is lost. In this view, reduced responsiveness of the parathyroid glands contributes to the development of osteoporosis. Altered responsiveness could be caused by changes in PTH's circadian rhythmicity. Daily PTH secretion follows a biphasic profile with peaks at approximately hours 2 and 18 (2 AM and 6 PM) (Tohme *et al*., 1995; Calvo *et al*., 1991; Markowitz *et al.*, 1992). A larger nocturnal peak may represent compensation for mild hypocalcemia induced by night-time fasting. Calvo *et al* (1991) reported that women exhibited a blunted PTH peak relative to that of men and, subsequently, a less dramatic decline in night-time urinary calcium excretion. Night-time urinary calcium excretion declined in men by 34%, whereas, in women, it decreased by only 17%. Postmenopausal osteoporotic women showed a further blunting of their nocturnal PTH peak, with no change in nocturnal fractional excretion of calcium (Eastell *et al*., 1992). Inefficient renal calcium conservation, thus shown, could contribute to the osteoporotic process.

Another dynamic that could be abnormal in osteoporosis relates to the pulsatility, not the circadian rhymicity, of PTH. Sophisticated pulsatility studies by Prank *et al*. (1995) have shown that osteoporotic women demonstrate poorly predictable pulses and patterns of PTH. Discriminating statistic fitting could distinguish the pulsatility pattern in the osteoporotic subjects from normal subjects (Prank *et al*., 1995; Deftos *et al*., 1995). These observations were not confirmed by Samuels *et al.* (1997).

Further evidence that argues for an important protective role for PTH in osteoporosis comes from the work of Silverberg *et al.* (1986, 1989b). These studies were based on the premise that a mild hypocalcemic challenge should lead to increases in PTH concentration that differ among age groups and between normal and osteoporotic subjects. Oral phosphate was used to induce the hypocalcemic challenge. The first studies were conducted with normal subjects who differed only by age: a younger and an older

group. Neither group had osteoporosis. In each case, when administered oral phosphate, the serum phosphorus concentration rose and the serum calcium level fell to the same extent. In response to the hypocalcemic stimulus young subjects showed a 43% increase in PTH concentration over baseline values, whereas older women showed a much more exuberant response to the same hypocalcemic stimulus, with a 2.5-fold increase over baseline levels. This protocol set up two opposing stimuli with respect to 1,25-dihydroxyvitamin D: phosphorus as an inhibitor and parathyroid hormone as a stimulus. In both cases, the opposing regulators were neutralized and 1,25-dihydroxyvitamin D concentration did not change. These data were interpreted to suggest that older, normal subjects require more PTH for a given hypocalcemic challenge to maintain 1,25-dihydroxyvitamin D levels.

The same protocol was utilized in a group of postmenopausal women with osteoporosis (Silverberg *et al.*, 1989b). After phosphate administration, these women experienced the same increase in serum phosphorus concentration and the same reduction in serum calcium concentration that was observed for the young subjects and the age-matched older women. In contrast to the marked increase in PTH their age-matched counterparts, the osteoporotic women demonstrated only a modest 43% increase. Although this increase was sufficient in younger individuals to prevent the inhibitory effects of phosphorus on 1,25-dihydroxyvitamin D production, it did not suffice in these osteoporotic women, and 1,25-dihydroxyvitamin D concentrations fell by 50%. These observations are consistent with the presence of an abnormality in parathyroid secretory function in osteoporosis, at least to a hypocalcemic stimulus. It also is consistent with the hypothesis that older subjects need a more responsive parathyroid system than younger subjects.

The need for more PTH with age could be achieved by altering the calcium set point. For any given serum calcium concentration, the PTH concentration is higher in the elderly. This could account for the age-related increase in PTH without any change in the circulating calcium concentration. When Ledger *et al*. (1994) studied this point with a provocative challenge, no age-related increase in the set point for PTH secretion could be demonstrated. When postmenopausal women with osteoporosis were studied, however, differences did emerge. Cosman *et al*. (1991) used infusions of the foreshortened but fully biologically active human PTH(1–34) to test suppressability of endogenous PTH secretion. It was possible to distinguish between exogenous PTH(1–34) and endogenous PTH(1–84) by using an immunoradiometric assay that measures only PTH(1–84). The results were consistent with a higher calcium set point in osteoporotic women. Similarly, Portale *et al.* (1997*)* showed in elderly men that the set point of PTH responsiveness to calcium is "shifted" to the right. Such results are consistent with a protective effect of PTH in the pathogenesis of osteoporosis.

Parathyroid Hormone: A Positive or Negative Factor in Age-Related Bone Loss?

The data argue that PTH can be viewed as either a negative or a positive factor in preservation of the postmenopausal skeleton. The age-related increase in PTH may be adaptive or maladaptive. More information will be needed to sort out these different views. However, we already have abundant information about the skeleton in the classic condition of PTH excess in primary hyperparathyroidism. In this disorder, excess parathyroid hormone leads to relative protection against bone loss in the lumbar spine (Silverberg *et al*., 1989a). The data in primary hyperparathyroidism differ so strikingly from those in osteoporosis that one must conclude that the bone diseases of hyperparathyroidism and osteoporosis reflect completely different disorders. The protection accorded the very site that is at early risk for postmenopausal bone loss, namely the cancellous bone of the vertebral spine, suggests that the effects of PTH on the aging skeleton are best viewed as protective, not deleterious. Finally, the clear actions of PTH to improve bone strength when used as a therapeutic agent in osteoporosis further argues for its beneficial actions on the skeleton (Neer *et al*., 2001; Lindsay *et al*., 1997; Kurland *et al*., 2000; Bilezikian *et al*., 2005; Rubin *et al*., 2005).

CONCLUSION

From this review, it is apparent that the pathophysiology of osteoporosis is not only complex, but potentially quite heterogeneous. Thus, an important goal of future laboratory and translational clinical research will be to find clinical, biochemical, genetic, and other markers that can indicate which of many pathogenetic mechanisms predominate in specific subsets of patients. Achieving this goal could result in substantial advances in diagnosis and therapy.

Chapter 77

Evaluation of Risk for Osteoporotic Fracture

Stuart L. Silverman*
Cedars-Sinai/UCLA, Los Angeles, California

INTRODUCTION

Osteoporosis is a systemic disease characterized by decreased bone strength with a consequent increase in skeletal fragility and susceptibility to fracture. This decreased bone strength depends on both the quantity of bone as measured by bone mineral density (BMD) using dual x-ray absorptiometry or DXA and the quality of bone, which depends on microarchitecture, macroarchitecture, and microdamage. In addition the risk of fracture depends on the risk of falling and the ability to adapt to such falls. As clinicians we try to identify patients at risk of fracture, hopefully before the fracture occurs, so that we may treat them and reduce their risk of fracture.

In this chapter I will briefly review the diagnostic value of BMD by DXA, of clinical risk factors, and of the potential utility of combining BMD measurement and clinical risk factors using the new WHO algorithm in predicting fracture risk.

CLINICAL RISK FACTORS FOR FRACTURES

Clinical risk factors for fracture may be used in one of four ways:

1. Risk factors may be used to determine patients at intermediate to high risk of fracture who may be appropriate for BMD testing.
2. Risk factors may be used in those situations where BMD is not available to determine patients who are intermediate or high risk of fracture and in whom treatment should be considered.
3. Clinical risk factors may be used in combination with BMD to determine the probability of fracture.
4. Clinical risk factors in combination with BMD have also been used in guidelines to help us choose which patients to treat.

*Corresponding author: Stuart L. Silverman, Cedars-Sinai/UCLA, Los Angeles, CA 90048. E-mail: stuarts@Omcresearch.org, Telephone: 310-358-2234, Fax: 310 659 2841

Historically risk factors were divided into those factors that were risk factors for low BMD and those that were risk factors for fracture. Several clinical risk factors are associated with low BMD, but none is powerful enough to predict BMD level in individuals (Aloia *et al.*, 1985; Kleerekoper *et al.*, 1989; Dawson-Hughes *et al.*, 1993; Kanis *et al.*, 1994).

Clinical risk factors were further divided historically into those that were genetic or nonmodifiable versus those that were modifiable with intervention. These risk factors became long laundry lists for clinicians (Espallargues *et al.*, 2001) (Table I). However, these were not separated from risk factors that predicted fracture risk independent of BMD versus those that predicted fracture risk by predicting BMD.

TABLE I BMD-Related Risk Factors for Fracture

High Fracture Risk	Moderate Fracture Risk
Age greater than 70	Female sex
Low body weight	Current smoking
Weight loss	Low sunlight exposure
Physical activity	Family history of osteoporotic fracture
Corticosteroid use	Surgical menopause
Anticonvulsant drugs	Short fertile period of less than 30 years
Primary hyperparathyroidism	Absence of lactation
Diabetes type 1	Low calcium intake
Anorexia nervosa	Hyperparathyroidism
Gastrectomy	Hypothyroidism
Pernicious anemia	Diabetes type 2
Prior osteoporotic fracture	Rheumatoid arthritis

From Table 5 in Espallargues et al. (2001).

Principles of Bone Biology, 3rd Edition

Risk factors became important to the clinician when guidelines used them as a means of deciding which patients should get BMD testing, e.g., National Osteoporosis Foundation (NOF) website, or which patients should be treated. For example, the NOF suggests treatment for postmenopausal women with *T* scores less than −2 or less than −1.5 with clinical risk factors. However, the guidelines did not tell us how to use these risk factors when no BMD measurement was available or how to integrate them if more than one risk factor was available.

In the past few years, our focus as clinicians has switched from identifying patients with osteoporosis to identifying patients at risk of fracture. This has come from two sources: one, the recognition that many of the osteoporotic fractures in the community occur in individuals who do not have osteoporosis. The work of Siris in NORA and Wainwright in the Study of Osteoporotic Fracture (SOF) cohort, among others, has shown us that the majority of fractures are in postmenopausal women who do not have osteoporosis by *T* score. Wainwright, for example, showed that of those individuals in SOF who sustained a hip fracture, 54% had a *T* score in the hip greater than −2.5, ***% had a *T* score in lumbar spine greater than −2.5, and 42% had a *T* score in both hip and lumbar spine greater than −2.5. These data have helped us understand that BMD testing is specific but not sensitive for identification of patients at risk of fracture. Other risk factors must be playing a role. Furthermore, we recognize that globally access to BMD measurement is limited or not available, requiring that we develop means of identifying patients at risk independent of BMD.

We now separate risk factors into those which are independent of bone mineral density and those that are dependent on bone mineral density. Risk factors may also be separated further into those that impair bone strength, those that lead to excessive loads on weakened bone from falls, or in some cases ordinary activities of daily living. Risk factors that impair bone strength include such factors as bone density, age, hormonal insufficiency, nutritional deficiency, or a specific pathological process. Furthermore, bone strengthening may also be impaired by bone turnover. Risk factors related to excessive loading of the bone include falls and predisposition to falls and fall mechanics.

Some clinical risk factors predict some fractures better than others. For example, prevalent fracture and age predict risk of fracture better than smoking or alcohol use.

As Kanis *et al.* (2005a) have pointed out, there are a number of considerations in choosing risk factors for case finding. First, clinical risk factors should be easily ascertainable. For example, calcium intake is a risk factor for fracture in the elderly, but ascertaining calcium intake without use of a food frequency questionnaire, which is difficult for patients to complete. Second, clinical risk factors need to be intuitive. We recognize that dementia is associated with increased risk of fracture, yet osteoporosis and fracture risk are often not high on the health care agenda for these patients. Risk factors need to be useful in a global setting with similar predictions of fracture risk. Third, to be valuable, a risk factor needs to be amenable to therapeutic intervention. For example, falling is associated with increased fracture risk but we have no pharmacological intervention to reduce the risk of falling. Finally, risk factors should be based on evidence based medicine

HOW DO WE EXPRESS FRACTURE RISK PREDICTABILITY?

Historically predictability was expressed as increased relative risk when we compared prevalence of fracture in two cohorts, one with the risk factor and one without. With the availability of data from long-term prospective cohorts, epidemiologists have used the concept of gradient of risk, the increased relative risk of fracture per standard deviation change in a risk factor.

Use of Clinical Risk Factors for Fracture Prediction

In the absence of other risk predictors such as BMD, clinical risk factors can be used to assess fracture risk (Kanis *et al.*, 2005a). Risk factors can also be combined with BMD to improve fracture risk detection. Most clinical risk factors have effective similar magnitude, increasing the likelihood of fracture by 1.5 to 3 times more than that seen in unaffected individuals. Although there is good evidence that risk factors may increase fracture risk, it is less clear if different factors are independent of BMD, which is necessary if clinical risk factors are to be combined with BMD in predicting fractures. However, it is also important that we only include risk factors that are responsive to treatment. Although many of these risk factors are rare, they are common. A third of women with osteoporosis have at least one of them (Tannenbaum *et al.*, 2002), as do most men with osteoporosis (Orwoll, 1998).

Clinical risk factors are additive. Cummings has shown that hip fractures are 17 times greater among older women with five or more clinical risk factors, exclusive of bone density than among women with two risk factors or fewer (Cummings *et al.*, 1995). Clinical risk factors are additive to BMD in identifying women at risk; Cummings found that women with multiple risk factors were at even greater risk if their BMD was in the lowest third. Garnero *et al.* (1996) found that increased bone turnover was additive to low BMD in identifying women at high risk of fracture.

It is important to note that some risk factors, which have a devastating effect on an individual patient and

which are uncommon, may rarely appear along with independent risk factors that are identified in the population studies, for example, Cushing's syndrome.

Bone Density

BMD is a strong surrogate measure of bone strength and a strong predictor of fracture risk. A large number of clinical risk factors may exert their effects through BMD. In the 1994 WHO criteria, osteoporosis was defined as a BMD *T* score of less than −2.5 at the femoral neck (Kanis *et al*., 1994). Bone strength is determined by size of bone, shape, microarchitecture including number and connectivity of trabeculae, mineralization, and microdamage. Measurement of these other attributes is not currently available to the clinician although research is in progress.

Age

Almost all studies indicate increasing age is a strong determinant for fracture risk. Greater age is associated with lower BMD. Age predicts fracture risk independently of BMD (Kanis *et al.,* 2002). The instances of both vertebral and nonvertebral fracture rises rapidly after age 50 in women and men. The rise is most dramatic for fractures of the spine, beginning at age 50, and the hip, beginning at age 60. Part of the increased risk of aging is because of the loss of bone and quality of bone with age, part is because of increased risk of falling owing to changes in gait and loss of balance, part is because of reductions in physical activity, calcium, and/or vitamin D deficiency, as well as unmeasured risk factors (Table II). Consequently, two women who have the exact same bone density, a woman age 50 and a woman age 80, have different risks of most types of fractures. At a *T* score of −2.5 in the femoral neck, an 80-year-old woman has a 12.5% 10-year absolute risk of hip fracture, whereas a 50-year-old woman only has a risk of 2.5%. Not all fractures increase with increasing age. For example, wrist fractures rise rapidly with menopause in women but plateau and even decline after age 65, perhaps related to decreased activity and perhaps related to changes in the pattern of falls in elderly women.

Where BMD measurement is not available, body mass index (BMI) may be used. BMI predicts fracture risk similarly to BMD, except at low BMI where there is excess risk(De Laet *et al*., 2005b). Leanness increases risk, and obesity is not protective.

Nutritional Deficiencies

Deficits in calcium or vitamin D can impair peak bone mass as well as withdraw calcium from the skeleton (Heaney *et al*., 2000). Poor dietary intake may occur with aging or with younger patients with eating disorders. However, even if dietary intake is adequate, absorption of calcium from the gut may be impaired in patients with gastrectomy, gastric bypass, or pernicious anemia , all of which have been associated with increased fracture risk (von Terpitz *et al*., 2003). Calcium intake may also be reduced with inadequate vitamin D intake. Low vitamin D intake may result from low sunlight exposure, use of sunscreens, especially in institutionalized elderly, but also in ambulatory individuals with increased skin pigmentation or liberal use of sunscreens, liver disease, or use of drugs that interfere with vitamin D such as anticonvulsants (Pack *et al*., 2004).

TABLE II Intrinsic Risk Factors for Falls among the Elderly

Strong Evidence	Moderate Evidence
Older age	Arthritis
Reduced functional level	Acute illness
Cane/walker use	Anti-Parkinson's drugs
History of falls	Cardiac and antihypertension drugs
Low walking speed	Alcohol use
Reduced lower extremity strength	
Impaired postural sway	
Impaired reflexes	
Impaired vision	***
Reduced lower extremity sensory perception	
Neuromuscular diseases such as stroke	
Urinary incontinence	
Hypnotic and sedative drugs	
Antipsychotic drugs	
Cognitive impairment	
Depression and antidepressant drugs	

Hormonal Abnormalities

Estrogen deficiency is associated with rapid bone loss at menopause and also plays a role in later age-related bone loss in men and women (Riggs *et al*., 2002). Estrogen deficiency is reflected in multiple risk factors that share

decreased lifetime exposure to estrogen, such as surgical menopause, shortened time between menarche and menopause, premature ovarian failure, and athletic amenorrhea (Johnell *et al.,* 1995). Because testosterone is converted to estrogen, hypogonadism in men may also be related to low estrogen levels. Furthermore, iatrogenic hypogonadism may occur with use of gonadotropin-releasing hormone agonists in prostate cancer (Miyaji *et al.,* 2004) and of aromatase inhibitors in breast cancer (Eastell, 2007).

Diseases Associated with Structural Changes in Bone

Paget's disease is associated with fractures, most likely owing to disorganized bone (Pahlavan, 2000). Primary bone tumors such as osteosarcoma, metastases to bone from other areas, infiltration of bone by multiple myeloma that infiltrates bone marrow, or deposition diseases such as Gaucher's disease are associated with increased fracture risk (Whyte, 2003).

Prevalent Fracture

A history of prior fragility fracture indicates increased risk of future fractures regardless of bone mass (Kanis *et al.*, 2004s). In two equivalent 60-year-old women, one who had fractured her wrist and one who has no history of fracture; the woman with a history of fracture followed over time has about a 1.5% to 2% greater risk of hip and other types of fracture than a woman without any history (Cummings *et al.,* 1995). This observation is confirmed in the placebo groups of randomized controlled trials. In the Multiple Outcomes of Raloxifene (MORE) trial, if we look at the placebo group over three years, there is a fivefold increased risk of clinical vertebral fracture in those women who had prevalent fracture at baseline in the placebo group versus those who did not (Ettinger *et al.,* 1999). Similar data have been shown in the placebo group of Fracture Intervention Trial (FIT) (Black *et al.,* 2000). Prevalent fracture may be a surrogate marker of bone quality. Genant *et al.* (2007) have shown in an analysis of the MORE trial that patients with fracture had microarchitectural changes.

Family History

Family history of osteoporotic fracture, more specifically hip fracture, predicts future fracture independent of BMD (Kanis *et al.*, 2004b). Family history most likely reflects multiple genes as well as environmental influences such as behaviors or nutrition. Family history may be mediated by genetic differences in bone size, shape, or patterns of bone loss with aging or menopause.

Alcohol and Tobacco Use

Alcohol intake is a BMD-independent risk factor for fracture (Kanis *et al.*, 2005c). Smoking is an BMD-independent risk factor for fracture (Kanis *et al.*, 2005a).

Glucocorticoid Use

One of the most important complications of glucocorticoid therapy is loss of bone mass and increased risk of fracture. Glucocorticoid-induced osteoporosis is the most frequent cause of secondary osteoporosis(Devogelaer, 2006). In a recent meta-analysis of 42,000 men and women, the relative risk for osteoporotic fracture ranged from 2.63 to 1.71 and risk for hip fracture ranged from 4.42 to 2.48 from ages 50 to 85 (Kanis *et al.,* 2004a). The fracture risk was similar in men and women and was only partially explained by BMD. In a retrospective cohort of 244,325 oral glucocorticoid users compared to population controls, a relative risk of 1.61 for hip fracture and 2.6 for vertebral fracture was observed (van Staa *et al.*, 2000). The risk was related to daily dose and there was no safe low dose. All fracture risks decreased rapidly after stopping oral glucocorticoid therapy, suggesting the risk is reversible.

The pathophysiology of glucocorticoid-induced osteoporosis is not yet completely understood with several different pathophysiological mechanisms. Glucocorticoid use is associated with a dramatic decrease in bone formation and an increase in bone resorption. Bone loss is most marked in the first months of therapy and slows down thereafter (Devogelaer, 2006).

Osteoporosis Secondary to Specific Diseases

Fracture risk may be increased in individuals who have specific diseases, for instance, bone loss may be increased in patients with serious inflammatory diseases such as rheumatoid arthritis, systemic lupus erythematosus (SLE), and Crohn's, although this may be partially owing to the need for corticosteroid therapy, an important risk factor. Whether the increase in fracture risk is independent of corticosteroid use is unclear in inflammatory bowel disease, asthma, and chronic obstructive pulmonary disease.

Fracture Risk in Rheumatoid Arthritis

The first population-based study that estimated fracture risks among patients who had rheumatoid arthritis (RA) was published 20 years ago, reporting a relative risk estimate for pelvic fractures of 2.56 and for proximal femur fractures of 1.51 (Hooyman *et al.,* 1984). Ten years later, a morphometric study of spine radiographs in 76 postmenopausal women who had steroid-treated RA was compared with a sample of age-matched women. Vertebral fracture risk

was increased considerably in RA, particularly in women age 50 to 59 with an odds ratio for the whole population as high as 6.2 (Peel *et al.,* 1995). A recent study showed that patients with RA have more vertebral deformities than do population-based controls with an odds ratio of 2.0 with moderate to severe deformities and 2.6 when multiple deformities are included (Orstavik *et al.,* 2004). In a population-based control study of 300 consecutive patients with hip fracture compared with age- and sex-matched community controls, crude risk for hip fracture was approximately doubled in patients who had RA; increasing markedly with increasing functional impairment (Cooper *et al*., 1995). More recently, a study in Finland reported an age- and sex-adjusted risk of hip fracture of 3.26 in 29 patients who had RA (Huusko *et al*., 2001). It is unclear what specific factors are associated with fractures in RA. Data from recent cross-sectional studies indicate that the presence of vertebral deformity was associated independently with age, long-term corticosteroid use, history of nonvertebral fracture, and low bone mass at total hip (Orstavik, 1993). Similarly, a worsening of function measured by a one-point increase in HAQ was associated with a 70% increase in the risk of vertebral fracture in 461 cases of RA (Sinigaglia, 2000).

Systemic Lupus

Data on fractures in systemic lupus are scanty. The most extensive retrospective population-based study in a self-report of fracture of 702 women with lupus followed for almost 6000 person-years stated that the fracture risk was increased in those who had a lupus with a standardized morbidity ratio of 4.7 as compared with a control group of similar age (Ramsey-Goldman *et al*., 1999). Associated with fractures were older age, longer disease, longer corticosteroid exposure, less use of oral contraceptives, and menopause. However, in the multivariate model, only older age at time of lupus diagnosis and a longer duration of corticosteroid use were independent determinants of fractures.

Ankylosing Spondylitis

Radiographic bone loss in ankylosing spondylitis (AS) has been documented for a long time. As a consequence of osteoporosis, vertebral compression fractures are reported frequently in ankylosing spondylitis because the pain associated with them is attributed to exacerbation of spondylitis rather than to fracture. There is an early increase in fracture (Cooper *et al*., 1995), consistent with the reports of significant bone loss in early disease. Cooper *et al*. (1994), using a retrospective population-based study, showed an increase in vertebral fracture risk as great as 7.6 in comparison with expected fracture incidence in the same community. In general, vertebral fractures in patients with AS occur with increasing age and severity of disease (Donnelly *et al*., 1994; Mitra *et al.,* 2000; Cooper *et al*., 1994).

Bone Turnover as a Predictor of Fracture Risk

High levels of bone turnover markers are associated with high rates of bone loss in postmenopausal women. This relationship is stronger in a woman in the first 5 years after menopause. In older women, however, the relationship is not strong enough to be useful in an individual patient (Bauer *et al.*, 1999; Gennaro *et al*., 1999; Marcus *et al*., 1999; Rogers *et al.*, 2000). There have been several prospective studies on the relationship between bone turnover markers and fracture risks in postmenopausal women, including risks of hip, spine, and nonspine fracture. Bone resorption markers above the premenopausal reference range have been associated with a doubling in the risk of hip fracture, as shown by Garnero *et al*. (1996) and Epidos. this is Garnero 96which discussed Epidos This association is as strong as that of a one standard deviation decrease in proximal femoral neck BMD. Thus, a low BMD measurement and a high bone resorption marker put a woman at a particularly high risk of fracture. The increase in risk of fracture with high bone resorption markers is independent of bone mineral density.

Risk Factors Related to Increased Bone Loading

Although some osteoporotic fractures, such as vertebral compression fractures, may occur independent of a fall, most fractures occur in the setting of a fall. The likelihood of falling increases with aging (Winner *et al*., 1989). Most falls do not, however, result in fracture (fewer than 5%). The pathogenesis of falls is complex with causation related to extrinsic factors such as environmental barriers, i.e., loose carpets, electrical cords, and so on (Schwartz *et al.*, 2001), as well as intrinsic factors such as reduced sensory input, balance problems, impaired strength, and drug side effects. Reduced sensory input includes changes in vision such as blindness, diabetic retinopathy, cataracts, etc. Balance and gait problems include peripheral neuropathy, neuromuscular diseases, residual hemiplegia, or hemiparesis following stroke, etc. Drugs such as sedatives or psychotropic medications increase the risk of falling and fractures (Schwartz *et al*., 2001). Postural hypotension from antihypertensive medications may also be associated with increased risk of falling and fractures.

Unfortunately, it is difficult to prevent falls. Gillespie *et al*. (2004), in a recent Cochrane review, showed that meta-analysis found only a reduction in risk of falling of 14 to 27% with multidisciplinary intervention and little influence on risk of fracture.

THE NEW WHO ALGORITHM

Assessing Fracture Risk Using the New WHO Risk Factors

In an effort to identify candidate clinical risk factors that could be integrated in a clinically useful way, a WHO scientific group first reviewed the literature by using meta-analysis to identify risk factors for fracture independent of BMD. Second, a meta-analysis was done by combining data from 12 cohorts around the world, including studies in Dubbo, Australia (Jones *et al.,* 2006); Hiroshima, Japan (Fujiwara *et al*., 1997, 2003); multiple studies in Europe: such as EVOS/EPOS (Felsenberg *et al*., 2002; Oneill *et al*., 1996; Ismail *et al*., 2002), EPIDOS (Rollins *et al*., 2005), Gothenberg I (Svanborg, 1977) and II (Johannson *et al*., 1998), Rotterdam (van der Klift *et al*., 2004), Sheffield (Sheffield***)Kuopio in Finland (Honkanen *et al*., 1995); and the OFELY study in France (Albrand *et al*., 2003); as well as the CaMos in Canada (Sawka *et al*., 2005) and Rochester in the United States (Melton *et al*., 1998, 2003a).

This global cohort analysis consists of approximately 250,000 person-years, approximately 60,000 patients, and more than 5000 fractures. Using this analysis, eight candidate risk factors have been proposed (Silverman, 2006). To be chosen, each of these risk factors needed to be validated in multiple populations; adjustable for age, sex, and type of fracture; intuitive; amenable to therapeutic manipulation; and readily accessible for primary practitioners. Thus, factors such as calcium deficiency and risk of falling, which would not be easy for primary care physicians to measure were not considered (WHO Meeting on Fracture Risk, Brussels, May 5 to 6, 2004).

As listed on Table III, the eight independent risk factors that have been suggested by the WHO include age (Dawson-Hughes *et al*., 1993), prior fracture (Kanis *et al*., 2004a), BMD of the femoral neck (Johnell *et al.,* 2005) or BMI (DeLaet *et al.*, 2005a), past or present corticosteroid use (Kanis *et al.,* 2004a), family history of fracture (Kanis *et al*., 2004b), current smoking (Kanis *et al.,* 2005a), and ingestion of more than two units of alcohol per day (Kanis *et al.,* 2005c), as well as secondary osteoporosis associated

TABLE III Proposed WHO Risk Factors and Their Gradient of Risk

		Relative Risk (RR)		
Risk Factor	Reference	Any Fracture	Osteoporotic Fracture (hip, shoulder, vertebral, or forearm)	Hip Fracture
Age	Dawson-Hughes *et al.*, 1993		*T* score <–2.5; 13.9% 10-year probability at age 50 and 34.4% at age 80	*T* score <–2.5; 2.9% 10-year probability at age 50 and 23.8% at age 80
Prior fracture	Donnelly *et al.*, 1994	1.86 (95% CI = 1.75–1.98)	RR 1.86 (95% CI = 1.72–2.01)	RR 1.85 (95% CI = 1.58–2.17)
BMD femoral neck	Eastell, 2007		RR/SD decrease in BMD: 1.41 (95% CI = 1.33–1.51) in men 1.38 (95% CI = 1.28–1.48) in women	RR/SD decrease in BMD: 2.94 (95% CI = 2.02–4.27) in men 2.88 (95% CI = 2.31–3.59) in women
BMI	Espallargues *et al.*, 2001	RR per unit higher BMI 0.98 (95% CI = 0.97–0.99)	RR per unit higher BMI 0.97 (95% CI = 0.96–0.98)	RR per unit higher BMI 0.93 (95% CI = 0.91–0.94)
Ever corticosteroid use	Ettinger *et al.*, 1999	RR varies with age from 1.98 at age 50 to 1.66 at age 85	RR varies with age from 2.63 at age 50 to 1.71 at age 85	RR varies with age from 4.42 at age 50 to 2.48 at age 85
Family history of fracture	Ettinger *et al.*, 2005	RR 1.17 (95% CI = 1.07–1.28)	RR 1.18 (95% CI = 1.06–1.31)	RR 1.49 (95% CI = 1.17–1.89)
Current smoking	Felsenberg *et al.*, 2002	RR 1.13 (95% CI = 1.15–1.36)	RR 1.29 (95% CI = 1.13–1.28)	RR 1.60 (95% CI = 1.27–2.02)
Alcohol more than 2 units/day	Fujiwara *et al.*, 2003	RR 1.23 (95% CI = 1.06–1.43)	RR 1.38 (95% CI = 1.16–1.65)	RR 1.68 (95% CI = 1.19–2.36)
Secondary OP (rheumatoid arthritis)	Fujiwara *et al.*, 1997			RR 1.95 (95% CI = 1.11–3.42)

with disorders such as rheumatoid arthritis (Kanis *et al*., 2001). BMI may be used where there is limited access to DXA scanning, as BMI correlates with BMD in terms of fracture prediction. These clinical risk factors can be used to generate probabilities of fracture with or without BMD. The clinical risk factors may be added (De Laet *et al*., 2005b), but the sum would vary depending on the risk factors added because they have differing weights. These risk factors will improve the prediction of fracture risk by improving the gradient of risk. The addition of clinical risk factors to BMD may be most valuable for younger women and least valuable for those who are elderly. If information on a patient's BMD is not available, these eight risk factors can help clinicians decide which patients to treat.

In the proposed WHO model, 10-year probability of fracture is used rather than relative risk because relative risk decreases with age. For example, by age 80 the relative risk of fracture (compared with other 80-year-old women) for a woman with a *T* score of −2.5 is reduced because many women of this age are at high risk of fracture independent of BMD. Similarly, lifetime fracture risk is not used because it begins to decline at about age 70 because of the competing risk of death. Ten-year fracture probability has therefore been chosen as an intermediate point.

The risk of different clinical fractures is combined in this model. Rather than simply adding the risk of a single osteoporotic fracture, the morbidity and mortality associated with each fracture is weighed, using a utility measurement compared with the utility of a hip fracture, so-called hip fracture equivalents (Silverman, 2006). This technique will reduce fracture risks to a common currency. The model assumes that the direct cost of a fracture is proportional to the utilities measured. The proposed new WHO algorithm would predict the probability that a patient will experience a hip fracture or a clinical fracture (shoulder, hip, clinical vertebral, or forearm fracture) over the next 10 years.

Deciding on the Need for Treatment

How will this information be used to decide whom to treat? Currently, there are numerous guidelines. There is general agreement that older patients with osteoporosis need treatment (Lewiecki, 2005; Kanis *et al*., 2000), but there is no consensus about other risk groups. Most guidelines do not distinguish between risk factors that are BMD-dependent and BMD-independent. No guidelines consider the interaction between risk factors in determining who is to be treated. No current guidelines use assessment of fracture probability. Most guidelines agree that patients with *T* scores below −2.5 should be treated and those with *T* scores above −1.5 should not be treated, but the guidelines differ for the group with *T* scores between those numbers (Lewiecki, 2005).

Worldwide, there are currently two basic case-finding strategies. The International Osteoporosis Foundation (IOF) strategy is based on clinical risk factors. If the BMD femoral neck T score is less than −2.5, the patient should be treated (go to www.iofbonehealth.org). In the United States, the strategy is more liberal. The National Osteoporosis Foundation (NOF) (go to www.nof.org) recommends treatment for a postmenopausal woman with a *T* score below −2 or a *T* score below −1.5 with risk factors.

The availability of the new WHO risk platform suggests the possibility of a new, global case-finding strategy. Based on fracture probability and clinical risk factors, it should be possible to identify patients who are at low risk and should not be treated, patients at high risk who can be treated without BMD measurement, and those with intermediate risk, who will need BMD measurement before they are reassessed for risk. Those at high risk would then be treated and those with low risk would not be treated. A slightly different model may be considered in North America and Australia, where patients are initially screened for BMD and clinical risk factors are added to then determine which patients will be treated. In the United States, DXA scanning is more easily available than in the rest of the world and regulatory agencies have decided that it is medically appropriate to screen any woman above age 65 or any woman above 60 with risk factors (U.S. Preventive Systems Task Force at: www.ahrq.gov/clinic/uspstfix.htm).

To target osteoporosis treatment at those patients who will receive the greatest benefit, clinicians need to decide on an intervention threshold. There is growing consensus that an intervention threshold should be based on absolute fracture risk rather than on a diagnostic threshold (Kanis *et al*., 2002). The intervention threshold need not be consistent globally, however, as there are regional differences in the ability and willingness to pay. In the United Kingdom, treatment is cost-effective for a 50-year-old woman with a 1.1% 10-year probability of hip fracture and an 85-year-old woman with a 9% 10-year probability (Kanis *et al*., 2005c). In Sweden, treatment of a 50-year-old woman with a 1.2% 10-year probability of hip fracture is cost-effective, as is treatment of an 80-year-old woman a 7.4% probability (Kanis *et al*., 2005b). In these two societies, approximately 8% of the gross domestic product (GDP) is earmarked for health care. In the United States, which spends 13% to 14% or more of its GDP on health care, the threshold for cost-effectiveness may be lower.

How will the new osteoporosis model affect clinicians? For most patients, there will probably be little change from current clinical practice. Looking at the 10-year probability of hip fracture in patients with no prior fracture, treatment of those with *T* scores of approximately −2 is cost-effective, as is treatment of those with prior fracture and a *T* score of −1.5. This threshold closely resembles the current NOF guidelines. Clinicians will continue to treat older

women with osteoporosis or older women with fracture. The younger woman who is at relatively low risk of osteoporotic fracture may not be targeted for therapy, however. In a study by Ettinger *et al*. (2005), it was shown that physicians seeing the same clinical data but given no absolute risk data may be less likely to prescribe a bisphosphonate for younger women at low risk. It is also likely that younger patients who are told that they have only a 2% to 3% risk of fracture would not be convinced to take a medicine that would reduce their risk by half, to 1%.

CONCLUSION

Individuals at high risk of osteoporotic fracture can be identified by clinical risk factors or a combination of clinical risk factors and BMD. With the availability of a diverse but expensive menu of osteoporosis therapies, it is clear that clinicians will be unable to treat everyone. Clinicians need to treat those individuals at high risk of fracture and not treat those who are at low risk. The use of fracture risk assessment using both BMD measurement and clinical risk factors in a case-finding approach will hopefully help us target our therapies to those who need it most.

INTRODUCTION

Parathyroid hormone (PTH) is an 84-amino-acid peptide hormone released in a pulsatile fashion by the parathyroid gland *in vivo*, and regulates serum-ionized calcium levels through its actions on kidney and bone. In this chapter, PTH will either refer generically to the whole class of parathyroid hormone peptides or, more specifically in some sections, to the intact 84-amino-acid hormone [PTH(1–84)].

Until fairly recently, PTH was considered to be primarily a bone-resorbing hormone. However, it is now appreciated that PTH exerts its effects on bone primarily through the osteoblast, and its resorptive effects are only part of the PTH stimulation of bone turnover (resorption and formation). Although bone resorption is a prominent histological event seen in bone sections obtained from patients suffering from pathological secretion of PTH, osteoclasts do not present PTH receptors, and the enhanced bone resorption accompanying pathological PTH secretion appears to require the presence of osteoblasts (McSheehy and Chambers, 1986; Parfitt, 1976). Patients with primary hyperparathyroidism may be at increased risk for ongoing bone loss and fractures, together with evidence for increased bone turnover (Christiansen *et al.*, 1999; Grey *et al.*, 1994; Khosla *et al.*, Parisien *et al.*, 1995; Silverberg *et al.*, 1999).

The bone anabolic properties of exogenously injected PTH (bovine parathyroid gland extracts) were first reported in a series of serendipitous findings dating back to 1931 (Pehue *et al.*, 1931; Selye, 1932), in both human and animal situations. Some 45 years later Reeve and colleagues, citing circumstantial evidence in both clinical hyperparathyroid states and animal data, used a synthetic human (h) PTH fragment comprising the amino-terminal 34 amino acids [referred to in this text as PTH(1–34), or teriparatide], to treat a small group of elderly individuals with osteoporosis (Reeve *et al.*, 1976, 1980). They reported a dramatic histological improvement in bone turnover and structural trabecular growth.

Initially, hPTH(1–34) was obtained by solid-phase peptide synthesis, a relatively expensive process that meant the supply of drug for clinical trials remained limited. However, the small number of clinical trials evaluating the potential of exogenous PTH therapy for osteoporosis consistently demonstrated a beneficial anabolic effect. (Bradbeer *et al.*, 1992; Finkelstein *et al.*, 1994; Hesch *et al.*, 1989; Hesp *et al.*, 1981; Hodsman and Fraher, 1990; Hodsman *et al.*, 1991, 1993b, 1997; Lindsay *et al.*, 1997; Neer *et al.*, 1987, 1991; Reeve *et al.*, 1981, 1987, 1990, 1991, 1993; Slovik *et al.*, 1981, 1986; Sone *et al.*, 1995). Commercial development of PTH as an osteoporosis therapy awaited the technological advances needed for inexpensive large-scale manufacture of peptides by fermentation/recombinant DNA synthesis, and the first commercial randomized clinical trial (RCT) of recombinant hPTH(1–84) was carried out in the mid-1990s, a dose-finding placebo-controlled 12-month evaluation of the effect on bone mineral density (BMD) (Hodsman *et al.*, 2003). Shortly thereafter, a large, fracture outcome clinical trial of recombinant hPTH(1–34) was begun by Eli Lilly (Neer *et al.*, 2001).

ADVANTAGES OF ANABOLIC AGENTS FOR REVERSAL OF OSTEOPOROSIS

There are strong epidemiological associations between BMD measurements at either central (lumbar spine) or

appendicular sites (femoral neck, distal radius, os calcis) and the current or future risk for osteoporotic fractures (Cummings *et al.*, 1993; Marshall *et al.*, 1996; Ross *et al.*, 1991). There is approximately a twofold increase in the risk of fracture for every 1.0 standard deviation below average age- and sex-adjusted BMD, increasing dramatically if there is a preexisting fragility fracture in an individual with a low BMD (Marshall *et al.*, 1996; Ross *et al.*, 1991). Relatively small BMD increments reported in published placebo-controlled clinical trials translates into an incident fracture reduction of approximately 50% within 1 to 4 years of therapy. The evidence for this is best illustrated in the randomized controlled clinical trials (RCTs) of the bisphosphonates (Black *et al.*, 1996; Cummings *et al.*, 1993; Harris *et al.*, 1999; Liberman *et al.*, 1995; McClung *et al.*, 2001; Reginster *et al.*, 2000).

There are currently two therapeutic strategies to treat osteoporosis. These strategies are illustrated in Figure 1. For the purposes of this figure a fracture threshold has been indicated, but the gradient of risk is continuous (as it is for many biological variables such as blood pressure and cholesterol in ischemic vascular disease). The most important role for an anabolic agent in bone would be the rapid induction of new bone formation in the skeleton to reduce the risk of fragility fractures. It is against this background that the role of PTH therapy is discussed.

Antiresorptive Agents (Also Termed "Anticatabolic" or "Antiremodeling" agents)

This approach relies on the inhibition of osteoclastic activity during the bone mineralization unit (BMU) remodeling activity, allowing osteoblastic function to continue unimpeded. For example, the RCTs of the bisphosphonates, alendronate and risedronate, have defined the benefits of this strategy, resulting in an increased BMD and significant reductions in incident fracture risk (Black *et al.*, 1996; Cummings *et al.*, 1993; Harris *et al.*, 1999; Liberman *et al.*, 1995; McClung *et al.*, 2001; Reginster *et al.*, 2000). Evidence from observational cohort studies suggests that estrogen also reduces osteoporosis-related fractures by up to 50% (Eiken *et al.*, 1996; Kiel *et al.*, 1987; Maxim *et al.*, 1995; Naessen *et al.*, 1990); however, only one short-term RCT supported this observation (Lufkin *et al.*, 1992), until publication of the Women's Health Initiative study of postmenopausal hormone therapy (Cauley *et al.*, 2003).

The large-scale RCT with raloxifene (a selective estrogen receptor modulator) demonstrated comparable antifracture efficacy for vertebral (but not for peripheral) fractures, after a gain in vertebral BMD of less than 3% over 36 months (Ettinger *et al.*, 1999). Another antiresorption agent, calcitonin, was shown to reduce incident vertebral fractures without any significant increment in BMD (Chestnut *et al.*, 2000). These RCTs of antiresorptive therapy have called into question that increments in BMD automatically translate into a reduced fracture risk. Nonetheless, overall gains in BMD at an axial measurement site following bisphosphonate therapy (typically 4–8% at the lumbar spine over 3 years) may reduce incident fractures by approximately 40% to 50%. Detailed reports of antiresorptive therapies are reviewed in other chapters.

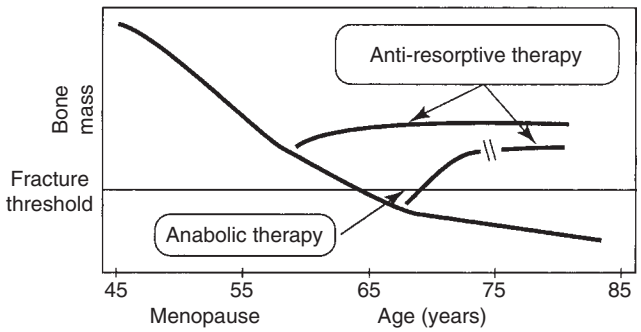

FIGURE 1 Depicts the relative efficacy of different strategies to maintain bone mass. (Upper) Antiresorptive strategy. Various agents (e.g., estrogens, bisphosphonates, and calcitonin) will arrest ongoing age-related and postmenopausal bone loss. Reductions in bone resorption and turnover are observed, and gains in skeletal bone mass may occur owing to the reduced bone resorption and perhaps to a reversal of the remodeling deficit., (Lower) Anabolic therapy. Agents such as PTH and sodium fluoride directly stimulate osteoblastic activity to increase bone mass, despite concurrent increases in bone turnover (i.e., there is an increase in both bone formation and resorption). The rapid increase in bone mass should accelerate the reduction in future fracture risk more effectively than the use of an antiresorptive agent alone.

Anabolic Agents

Two principal agents have been shown to stimulate osteoblast function within bone: sodium fluoride and analogues of PTH. Sodium fluoride and its slow-release formulations are discussed elsewhere in this publication. The landmark publication of Riggs *et al.* (1982) suggested that sodium fluoride significantly reduced vertebral fracture rates. However, although a subsequent placebo-controlled trial demonstrated a rapid and linear gain in lumbar spine BMD of 9% per year over 4 years, this study provided no evidence for a reduction in incident fractures (Kleerekoper *et al.*, 1991). Fluoride now has very limited use in osteoporosis.

Recently, strontium ranelate has been postulated to be able to combine modest effects of increasing bone formation with reduced bone resorption, resulting in steady increments in bone density, and reduction in fractures (Meunier *et al.*, 2004). The anabolic effect of this agent is somewhat confounded by the effect of a higher atomic weight strontium replacing calcium in bone mineral, and thereby amplifying the increase in BMD and the postulated anabolic effects on bone.

By whatever outcome measure used, PTH analogues have been shown to be anabolic, resulting in comparable gains in bone mass by comparison with fluoride. These

gains are considerably more rapid than those seen with antiresorptive agents. However, fluoride therapy has not supported the dictate that gains in BMD translate into lower fracture rates. Because there are as yet few controlled trials reporting incident fractures in patients treated with PTH analogues, it is necessary to evaluate the potential mechanisms by which PTH has seemingly paradoxical anabolic effects, focusing on the preclinical data in osteopenic animal models, as well as the available clinical evidence.

BONE HISTOLOGY EVIDENCE OF ANABOLIC ACTION OF PTH

Anabolic agents work by a fundamentally different cellular mechanism of action than antiresorptive agents. As noted earlier, a more appropriate term for the latter would be "antiremodeling agents" because, although their initial effect is to lower resorption, they secondarily inhibit formation. Indeed, inhibition of remodeling is the primary mechanism by which this class of drugs works. Lowering the remodeling rate has several effects that improve bone strength, including (1) a modest increase in bone density by reducing the remodeling space; (2) maintenance of cancellous bone microarchitecture; (3) a decrease in the number and size of resorption cavities, which act to concentrate stress and trigger mechanical failure; (4) an increase in the mineralization density (amount of mineral per unit volume); and (5) a decrease in cortical porosity (Chavassieux *et al.*, 1997; Dufresne *et al.*, 2003; Boivin *et al.*, 2000; Seeman and Delmas, 2006; Ettinger *et al.*, 1999; Chesnut *et al.*, 2000; Parfitt, 1991; Roschger *et al.*, 2003, Hernandez *et al.*, 2001).

By contrast, PTH treatment ultimately stimulates the bone remodeling rate and thereby stimulates net bone formation. With teriparatide treatment, the amount of bone laid down in each remodeling unit is increased, which is confirmed by an increase in osteon thickness (Bradbeer *et al.*, 1992; Hodsman *et al.*, 2000; Dempster *et al.*, 2001, Ma *et al.*, 2006). This distinguishes the effects of PTH treatment from other high-remodeling states, such as estrogen deficiency, which result in loss of bone structure and strength. The combination of an increase in the osteon thickness and an increase in the number of osteons being formed per unit time provides a mechanism for ongoing gains in the amount of bone tissue, including an increase in trabecular thickness (Bradbeer *et al.*, 1992). In addition to the stimulation of bone formation through this mechanism, referred to as "remodeling-based formation," changes in bone histology can be detected in animal experiments very early on in the course of PTH therapy. There is histomorphometric and biochemical evidence that, during the early stages of treatment, teriparatide stimulates formation directly, that is, without prior resorption (Ma *et al.*, 2006; Hodsman and Steer, 1993a; Lindsay *et al.*, 1997, 2006, 2007). Hodsman *et al.* (1993b) reported that after only 28 days of hPTH(1–34) injections, changes in both formation and resorption surfaces were increased two to five times those measured in a control panel of osteoporotic bone biopsies. Because tetracycline bone markers were given on days 14 and 28, there had not been sufficient time for a *de novo* resorption/reversal/formation cycle to be completed. This is referred to as modeling-based formation and may occur by activation of lining cells on previously quiescent bone surfaces (Jiang *et al.*, 2003), or by osteoblasts that were engaged in remodeling-based formation annexing resting bone surfaces surrounding the resorption cavity (Figs. 2 and 3) (Lindsay *et al.*, 2006, 2007).

Treatment with teriparatide or intact PTH not only leads to an increased trabecular thickness but also improves trabecular connectivity as demonstrated by microcomputed tomography of iliac crest bone biopsies (Dempster *et al.*, 2001; Jiang *et al.*, 2003; Fox *et al.*, 2005) (Fig. 4). The underlying mechanism for the improvement in trabecular

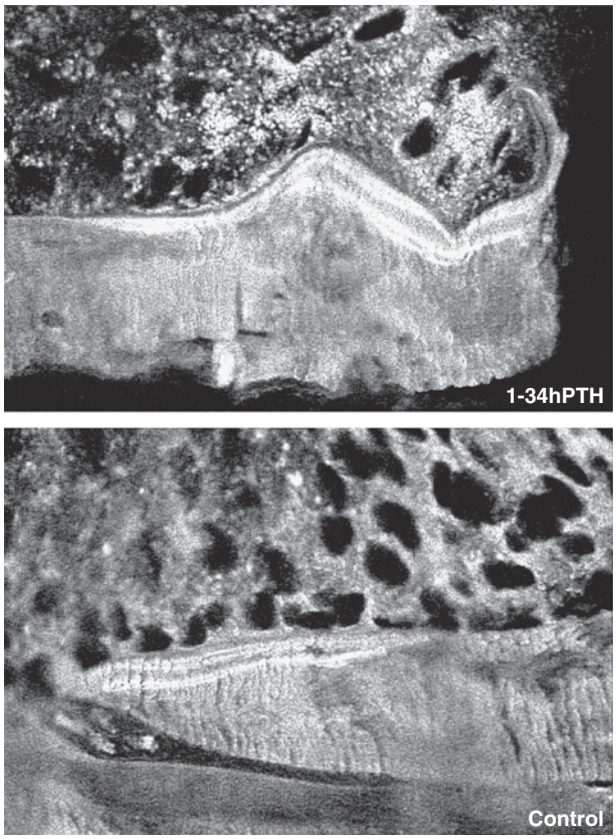

FIGURE 2 Quadruple tetracycline labels in a patient treated with teriparatide (Upper) and a control patient (Lower). Note that in the teriparatide-treated patient the second set of labels, which were incorporated during teriparatide treatment longer than the first set, which were incorporated before treatment began. This is not the case in the control subject. (Reproduced from Lindsay et al., 2006, with permission).

connectivity is still unclear but may involve thickening of trabeculae followed by intratrabecular tunneling (Jerome *et al.*, 2001; Fox *et al.*, 2007; Allen and Burr, 2006) (Fig. 5). The ability of anabolic agents to improve cancellous bone structure is in sharp distinction to antiresorptive agents, which maintain, but do not improve cancellous bone integrity (Seeman and Delmas, 2006).

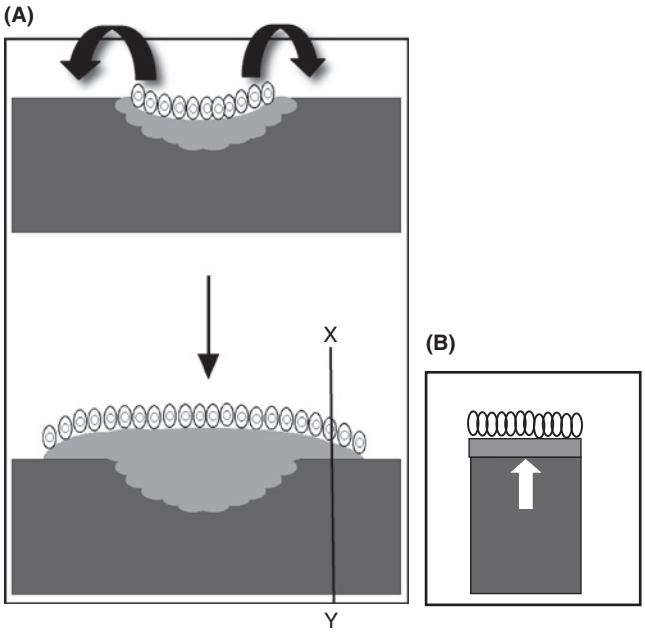

FIGURE 3 (**A**) Diagram illustrating a proposed mechanism whereby, under the influence of teriparatide treatment, bone formation is extended beyond the limits of the remodeling unit and annexes the adjacent previously unresorbed territory. (**B**) A section taken orthogonal to the plane of the paper along the line XY would display a smooth reversal line and may be erroneously interpreted as indicating that bone formation occurred on a smooth bone surface (arrow) that was temporally and spatially unrelated to a prior resorptive event. (Reproduced from Lindsay *et al.*, 2006, with permission).

There was an early concern that PTH therapy might have a negative effect on cortical bone, with the notion that gains in cancellous bone may be achieved at the expense of cortical bone (Reeve *et al.*, 1980b). This was not confirmed in animal studies, which showed that teriparatide improved cortical thickness and strength by stimulation of formation on both the endosteal and periosteal surfaces (Allen and Burr, 2006; Hirano *et al.*, 2000; Jerome *et al.*, 1999; Burr *et al.*, 2001; Mashiba *et al.*, 2001; Fox *et al.*, 2006) (see Fig. 5). Biopsy studies in humans also showed an increase in cortical thickness (see Fig. 4) and stimulation of bone formation with a decrease in eroded perimeter on the endosteal surface (Dempster *et al.*, 2001; Lindsay *et al.*, 2006, 2007; Jiang *et al.*, 2003). However, the concept that teriparatide is capable of stimulating periosteal bone formation and increasing bone diameter in humans remains controversial. Two studies, which employed different noninvasive imaging techniques on the same subjects, one cross-sectional and the other longitudinal in design, yielded conflicting results on the effects of teriparatide on bone diameter (Zanchetta *et al.*, 2003; Uusi-Rasi *et al.*, 2005). However, there is recent histomorphometric evidence for stimulation of bone formation at the periosteal surface of the ilium following teriparatide treatment (Ma *et al.*, 2006; Lindsay *et al.*, 2007) with an increase in tetracycline uptake and insulin-like growth factor expression on the periosteal surface.

The possibility that PTH may be able to increase bone size is noteworthy because the strength of a tube is dependent on the fourth power of its radius. Consequently, small increments in bone size may have disproportionately greater effects on bone strength. Bone size increases with age, which compensates for the age-related loss of bone mass (Garn, 1970; Duan *et al.*, 2001a, 2001b). PTH treatment may accelerate this natural process. Thus, the long-standing belief that intermittent PTH treatment might be harmful to cortical bone appears to be losing ground. With

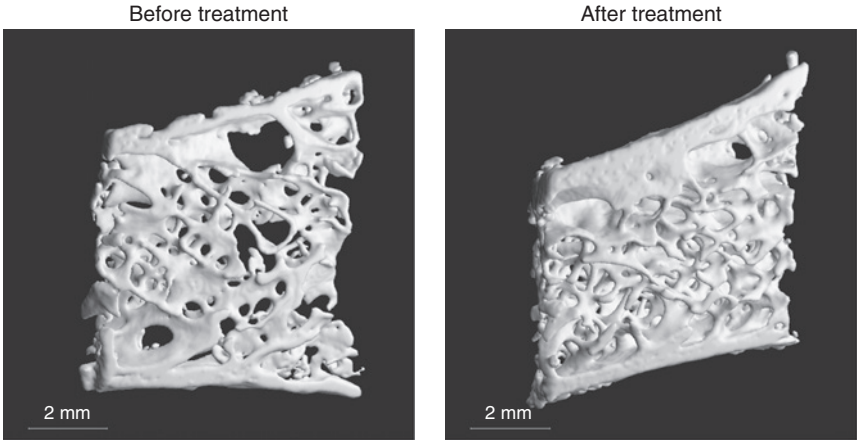

FIGURE 4 Microcomputed tomography images of paired biopsies from a 64-year-old woman before (Left) and after (Right) treatment with teriparatide. Note improvement in cancellous and cortical bone structure. (Reproduced from Dempster *et al.*, 2001, with permission).

that, however, comes the recognition that in order to assess the effects of PTH treatment in a clinical setting, we need to be careful when interpreting BMD changes, particularly areal measurements obtained by DXA. For example, a decrease in BMD owing to enhanced cortical porosity may not necessarily indicate loss of bone strength. Increased porosity under the influence of PTH treatment is limited to the inner aspect of the cortex where it has little effect on bone strength, and weakness that results may be offset by an increase in cortical thickness and bone size, as well as improvements in trabecular architecture. Another reason that areal DXA may underestimate improvement in bone mass and strength following PTH treatment is that there is more new bone matrix, which has a lower mineral content (Misof *et al.*, 2003). There is, therefore, a need to evaluate other noninvasive imaging modalities, such as those discussed in this textbook, to monitor the effects of anabolic treatment.

PHYSIOLOGICAL MECHANISMS OF ANABOLIC ACTION OF PTH

The physiological action of PTH is to maintain the ambient concentration of ionized calcium in blood (1) by influencing calcium reabsorption from the glomerular filtrate of kidney tubule cells and (2) indirectly by enhancing calcium absorption from the gut through increased activity of renal vitamin D-1-hydroxylase, which produces $1\alpha,25(OH)_2D_3$ (Bilezikian *et al.*, 1994; Brabant *et al.*, 1992). PTH also initiates a series of events that result in release of skeletal calcium by osteoclasts.

In 1931, Pehue *et al.* described the case history of an 8-year-old Parisian child who had succumbed to anemia owing to the obliteration of his marrow space by bone; he was subsequently discovered to have had hypertrophic parathyroids (Pehue *et al.*, 1931). Subsequently Selye suggested that, in contrast to the findings in primary hyperparathyroidism, PTH could have a potent anabolic effect (Selye, 1932). Selye was able to mimic this clinical situation in 30-day-old albino male rats with daily injections of 5 IU of Lilly parathyroid extract for 30 days. These low doses of parathyroid extract resulted in the production of osteopetrotic bone with no sign of osteoclastic bone resorption. In contrast to the catabolic effect of continuous infusion of PTH, as perhaps exemplified by primary hyperparathyroidism, numerous investigators have since confirmed the anabolic action of PTH (used as either the 1–84 intact hormone or various amino-terminal analogues) when administered as multiple intermittent doses. This effect has been termed "the PTH paradox" (Morley *et al.*, 1997).

The amino-terminal third of the PTH molecule appears to contain most of the biological activity in bone. Both intact PTH(1–84) and synthetic PTH(1–34) act through dual signaling pathways in target cells. In osteoblasts, the type 1 PTH/PTHRP receptor is coupled to both the adenylate cyclase activating G protein, Gs, and the phospholipase C activating Gq protein. PTH requires the first two amino acids and some part of the amino acid 25–34

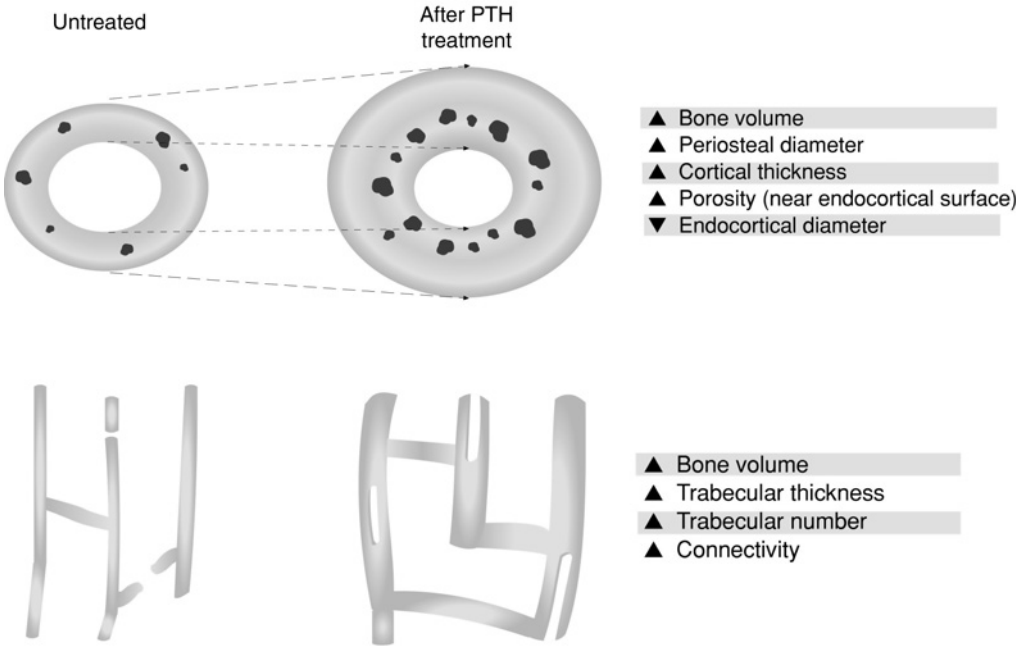

FIGURE 5 Diagram illustrating the effects of PTH treatment on cortical bone (Upper) and cancellous bone (Lower). (Reproduced from Allen and Burr, 2006, with permission).

region to activate Gs, but only the 28–32 portion to activate Gq (Whitfield *et al.*, 1998). The literature suggests that cAMP generation is positively linked to the anabolic effect of PTH. PTH fragments such as (1-desamino) hPTH(1–34), hPTH(8–84), or hPTH(28–48) that stimulate membrane-bound PKC, but not adenylate cyclase, in isolated osteoblasts do not stimulate bone formation in the oophorectomized rat model of osteoporosis (Jouishomme *et al.*, 1994; Takasu and Bringhurst, 1998). The carboxyl-terminal truncated analogue PTH (1–31) and its amide derivative (Ostabolin), are highly anabolic in the ovariectomized (OVX) rat and activate cAMP (Whitfield *et al.*, 1996, 1998; Neugebauer *et al.*, 1995; Whitfield *et al.*, 2000). Inhibition of GPCR kinase (GRK) prolongs cAMP activation and results in bone anabolism in the rat (Spurney *et al.*, 2002). In a mouse model of osteoporosis, only PTH peptides with an intact adenylyl cyclase-activating domain were anabolic to bone (Yang *et al.*, 2007), thus confirming the importance of this signaling pathway in the bone-building action of PTH.

The exact cellular mechanisms and principal mediators of the action of PTH on osteoblasts have not been fully elucidated, but it is likely to result from a combination of activating growth factors available in the immediate bone marrow environment, the recruitment of new populations of preosteoblasts from marrow stromal cells, interactions between cells in the bone microenvironment, and the recycling and trafficking of the type I PTH receptor (PTH1R). There is strong evidence that PTH stimulates both the insulin-like growth factor (IGF) and transforming growth factor beta (TGF-β) systems in bone (Watson *et al.*, 1995; McCarthy *et al.*, 1989; Canalis *et al.*, 1991; Hodsman *et al.*, 2005; Ishizuya *et al.*, 1997; Lee and Lorenzo, 1999; Wu and Kumar, 2000; Dempster *et al.*, 1993).The insulin-like growth factor regulatory system is composed of two growth factors (IGF-I and IGF-II), two receptors, six binding proteins that regulate IGF bioavailability, and IGF-binding protein-specific proteases. Following binding to the PTH receptor on osteoblasts and the generation of cAMP these cells produce more IGF-II , IGFBP-1, -4, and -5, and the IGFBP-3 and IGFBP-5 proteases (Johansson and Rosen, 1998). PTH also directly stimulates the synthesis of TGF-β by mature osteoblasts (Canalis, 1996). IGF-I, IGF-II, and TGF-β secreted by osteoblasts are bound to the collagen matrix of bone where they reside as a growth factor bank. During cycles of bone remodeling, when PTH induces osteoclastic bone resorption, these factors are released into the immediate environment where they can act on the recruitment and development of resident osteoblasts (Canalis, 1996). Intermittent (anabolic) treatment with PTH also results in the appearance of multistacked active osteoblasts (whose origin is uncertain) at sites of bone formation. They may be osteoprogenitor cells from marrow precursors, PTH-responsive postmitotic cells that have been recruited to the site by chemotaxis, or bone lining cells that have been induced to reenter proliferative cycles and pile up (Dobnig and Turner, 1995; Watson *et al.*, 1995).

Studies of the role of the osteocyte in sensing and transducing a bone anabolic response to mechanical loading have also opened the possibility of PTH modulating this response. The osteocyte-derived inhibitor of osteoblast-mediated bone formation, sclerostin, has been recently shown to be regulated by PTH (Leupin *et al.*, 2007). In UMR-106 cells, PTH downregulated expression of sclerostin via inhibiting MEF2 transcription factor activity or expression. This, in turn, would be expected to increase osteoblastic bone formation.

Mathematical modeling suggests that the ontogeny, or life span, of osteoclasts and osteoblasts is relevant to the anabolic effect of PTH. In this model, anabolic PTH treatment induces waves of remodeling where waves of short-lived osteoclasts initiate new BMUs followed by waves of much longer lived osteoblasts, resulting in a net shift of the remodeling balance toward formation (Komarova, 2005). In addition, although intermittent PTH treatment acts by enhancing formation in established remodeling units, some part of its effect owes to *de novo* bone synthesis on quiescent surfaces (Hodsman and Steer, 1993; Hodsman *et al.*, 2005; Lindsay *et al.*, 2007; Samadfam *et al.*, 2007). There are also mathematical models that suggest that intermittent PTH does not result in desensitization of the PTH1R and leaves the receptor relatively unoccupied and sensitized for new cycles of activation (Potter *et al.*, 2005).

Differences in bone cell gene expression evoked by intermittent versus continuous PTH have been documented. Onyia *et al.* (2005) utilized microarrays to explore the genes and pathways regulated by intermittent versus continuous PTH(1–34) for 1 week in 6-month-old female rats. The effect of each PTH regimen was confirmed by histomorphometry, and mRNA from metaphyseal bone was analyzed. Both PTH treatments coregulated 22 genes including collagens, osteocalcin, decorin, and osteonectin. Intermittent PTH regulated 19 additional genes, and continuous treatment regulated 173 additional genes.

Locklin *et al.* (2003), using cultured marrow cells from 6-week-old C57BL/6 mice, demonstrated that 4 days of intermittent PTH treatment (6 hours exposure every 48 hours) increased mRNA for osteoblast differentiation markers [Runx2, alkaline phosphatase (AP), and type I procollagen (COL1A1)]. IGF-I mRNA was consistently higher than after continuous treatment. In contrast, continuous treatment resulted in increased gene expression of RANK ligand (RANKL), whereas that of osteoprotegerin (OPG) was decreased, with a 25-fold increase in the RANKL/OPG ratio and production of large numbers of TRAP-positive multinucleated osteoclasts. Intermittent PTH treatment therefore appears to enhance osteoblast differentiation through an IGF-I-dependent mechanism, whereas continuous PTH treatment enhances osteoclastogenesis.

None of these studies has completely answered the question of the mechanism behind the anabolic effect of PTH, which likely results from a combination of all of these physiological effects. There are still unexplained phenomena that are likely regulated by other factors, as yet unknown, or just beginning to be unraveled. The PTH1R may be targeted to the nucleus of receptive cells (Watson *et al.*, 2000a,b). Immunoreactive PTH1R was found in both the cytoplasm and the nucleus of cultured osteoblast-like cells (Watson *et al.*, 2000b) and cells of rat kidney, gut, liver, and uterus (Watson *et al.*, 2000a), suggesting that the receptor plays a nuclear role. Nuclear translocation of the PTH1R appears to be physiologically relevant because its translocation is cell cycle dependent and is regulated by the cellular transportation machinery (Watson *et al.*, 2000b; Pickard *et al.*, 2006, 2007). The cell cycle dependence of PTH1R translocation may indicate a role in the effects of PTH on bone cell ontogeny described earlier. New aspects of cellular regulation by the nuclear PTH1R may shed further light on the anabolic action of PTH.

ANIMAL MODELS OF PTH EFFECTS ON BONE METABOLISM

Detailed investigation of the anabolic action of PTH requires a suitable animal model. The ovariectomized (OVX) mature rat rapidly develops osteopenia that is characterized by a significant decrease in both cancellous bone mineral and bone mass, and a marked increase in osteoblast and osteoclast activity typical of increased bone turnover (Frost and Jee, 1992; Kalu *et al.*, 1989; Liu *et al.*, 1991; Hori *et al.*, 1988; Hock *et al.*, 1988; Wronski *et al.*, 1989., 1991; Liu and Kalu, 1990; Kalu, 1991). The OVX rat has been widely accepted as a model for human postmenopausal osteoporosis because it closely parallels the early, rapid phase of bone loss characteristic of postmenopausal human bone loss (reviewed in Liu *et al.*, 1991; Kalu, 1991). The osteopenia of OVX rats shares many characteristics in common with the bone manifestations of perimenopausal bone loss, including increases in both bone resorption and activation frequency, with a relative deficiency in bone formation leading to a negative modeling balance (Frost and Jee, 1992; Kimmel *et al.*, 1993; Liu and Kalu, 1990; Liu *et al.*, 1991; Wronski *et al.*, 1989).

The OVX rat has been extensively used as a preclinical model for the *in vivo* anabolic action of intermittent treatment with PTH and is covered elsewhere in this book. Collectively, these studies have shown that intermittent treatment of the OVX rat with PTH or its anabolic fragments both prevents bone loss following OVX and reverses preexisting bone loss induced by OVX (Hori *et al.*, 1988; Lane *et al.*, 1996; Meng *et al.*, 1996; Lane *et al.*, 1996; Meng *et al.*, 1996; Akhter *et al.*, 2001; Kalu, 1984, 1991; Shen *et al.*, 1992; Kimmel *et al.*, 1993; Li *et al.*, 1999; Shen *et al.*, 2000; Alexander *et al.*, 2001; Fox *et al.*, 2006; Iwaniec *et al.*, 2007). Dempster and colleagues have shown that the increase in bone formation rate after intermittent therapy with PTH is primarily caused by an increase in both total mineralization surface and the mineral apposition rate that occurs in the first week after the initiation of treatment (Dempster *et al.*, 1993; Meng *et al.*, 1996). Measurement of bone mineral density (BMD) in PTH-treated rats has also shown positive increments in femur, vertebrae, and tibia confirming the histological data (Mosekilde *et al.*, 1994; Gunness-Hey and Hock, 1989; Wronski *et al.*, 1988). All of these studies show a PTH-induced increase in bone formation chiefly by the induction of osteoblast function. Thus, intermittent PTH therapy increases osteoblastic bone formation via increased activation frequency resulting in positive bone balance (Wronski *et al.*, 1993).

More recently, mouse models have been employed to study the anabolic effect of PTH and explore its mechanism of action. In brief, mouse strains are more heterogeneous than rats in both their "normal BMD" and responses to OVX or PTH treatment, but they offer a number of advantages over the rat model including economization (in terms of drugs, housing costs, etc.), the availability of strains with differing endogenous BMD (somewhat similar to various human groups), and the ability to readily analyze and manipulate their genetics (Bouxsein *et al.*, 2005a; Beamer *et al.*, 2002; Akhter *et al.*, 2004a, 2004b; Bouxsein *et al.*, 2004). In particular, the ability to produce both knockout and transgenic mice (constitutive and conditional) has already allowed for the analysis of many physiological parameters in the anabolic pathway of intermittent PTH treatment (Rosen *et al.*, 2000, 2004; Dumble *et al.*, 2004; Silva *et al.*, 2004; Pogoda *et al.*, 2005; Bodine *et al.*, 2007; Sawakami *et al.*, 2006; Hurley *et al.*, 2006; Yu *et al.*, 2006; Miao *et al.*, 2005; Bouxsein *et al.*, 2005b; Kitahara *et al.*, 2003; Demiralp *et al.*, 2002). As conditional knockout/knockin technology becomes more widely available, genetically manipulated mouse models are sure to yield new insight into PTH anabolism in bone. Finally, few studies have been published on our primate relatives. Those published do, however, demonstrate that anabolic therapy with PTH peptides is as effective in primates as in the rodent models. Several studies have shown that PTH(1–34) treatment results in significant increases in primarily trabecular BMD in cynomolgus monkeys (Jerome *et al.*, 1999; Brommage *et al.*, 1999; Sato *et al.*, 2004). A more recent study in rhesus macaques concurs and demonstrates that PTH(1–84) treatment for 18 months increases both bone formation rates and BMD (Fox *et al.*, 2007). Another important consideration is the quality of the bone produced by PTH therapy. By necessity, bone needs to have an appropriate trabecular structure to provide adequate mechanical strength (reviewed in Dalle and Giannini, 2004; Turner, 2002). Data from the rat have shown that

PTH works primarily by increasing trabecular thickness, not number (Kimmel *et al.*, 1993; Lane *et al.*, 1995; Li *et al.*, 1995; Shen *et al.*, 1993; Sibonga *et al.*, 2007; Fox *et al.*, 2006; Iida-Klein *et al.*, 2006; Akhter *et al.*, 2001; Lane *et al.*, 2003). In the mouse, PTH appears to enhance trabecular number and connectivity, as well as thickness (Xiang *et al.*, 2006; Pierroz *et al.*, 2006; Bouxsein *et al.*, 2005b; Zhou *et al.*, 2003; Iida-Klein *et al.*, 2007; Iida-Klein *et al.*, 2006). Data from primates indicates that PTH may act primarily by increasing trabecular number and connectivity (Fox *et al.*, 2007; Jerome *et al.*, 2001). Finally, human data indicate that PTH increases trabecular bone volume and connectivity with a shift to plate-like structures and a reduction in rod-like structures (Dobnig *et al.*, 2005; Jiang *et al.*, 2003). More detailed information can be obtained in the review of the effects of PTH on bone remodeling and structure by Compston (2006). One last point to bear in mind is the biomechanical strength of PTH-induced bone formation, because nothing is gained if the newly formed bone does not provide the strength and support to protect against fractures [bone qualities that affect strength are reviewed in Davison *et al.* (2006)]. Numerous studies of bone strength have looked at load-to-failure rates in vertebral bodies, femoral shafts and femoral necks, and tibia from various species and all have consistently shown that bone from PTH-treated OVX animals consistently performs better than that from sham-operated controls (Fox *et al.*, 2006; Iida-Klein *et al.*, 2006; Sato *et al.*, 2004; Akhter *et al.*, 2001; Shen *et al.*, 1995, 1998; Li *et al.*, 1995; Mosekilde *et al.*, 1994; Sogaard *et al.*, 1994; Ejersted *et al.*, 1993; Fox *et al.*, 2007; Jerome *et al.*, 2001).

CLINICAL STUDIES

This will not be an exhaustive review of all literature in this area. Systematic reviews of the literature pertaining to the clinical use of PTH will be continually updated, and a recent review is typical of these (Cranney *et al.*, 2006). The focus of this chapter will be to refer to the pertinent literature that illustrates the utility of PTH therapy in a variety of clinical situations.

Since the early studies by Reeve *et al.* (1976a,b, 1980), there have been numerous clinical studies describing the outcomes of therapy with PTH (e.g., Adami *et al.*, 2007; Black *et al.*, 2003; Body *et al.*, 2002; Boonen *et al.*, 2007; Bradbeer *et al.*, 1992; Cosman *et al.*, 2001, 2005, 2007; Finkelstein and Arnold, 1999; Finkelstein *et al.*, 1994, 1998a,b, 2003, 2006; Fujita *et al.*, 1999a,b; Gallagher, 1999; Greenspan *et al.*, 2007; Hesch *et al.*, 1989b; Hesp *et al.*, 1981; Hodsman and Fraher, 1990; Hodsman *et al.*, 1991, 1993b, 1997, 2000, 2003; Kurland *et al.*, 2000, 2004; Lane *et al.*, 1998a,b, 2000; Lindsay *et al.*, 1997; Neer *et al.*, 1987, 1993, 2001; Orwoll *et al.*, 2003; Plotkin *et al.*, 1998; Reeve *et al.*, 1976a,b, 1980, 1981, 1987, 1990, 1993, 1994; Rittmaster *et al.*, 2000; Rehman *et al.*, 2003; Roe *et al.*, 1999; Saag *et al.*, 2007; Slovik *et al.*, 1981, 1986; Sone *et al.*, 1995). Treatment protocols have been very heterogeneous, over periods of 6 to 36 months. Most subjects have been women, over 60 years of age with a diagnosis of osteoporosis, but more recently there have been studies involving younger women with acute estrogen deficiency (Finkelstein and Arnold, 1999; Finkelstein *et al.*, 1998b, 1994), men with osteoporosis (Kurland *et al.*, 2000, 2004; Orwoll *et al.*, 2003), and glucocorticoid-induced osteopenia (Finkelstein and Arnold, 1999; Finkelstein *et al.*, 1998b; Lane *et al.*, 1998b, 2000; Rehman *et al.*, 2003; Saag *et al.*, 2007).

It is only recently that studies have involved a randomized design in which control subjects did not receive PTH (Black *et al.*, 2003; Body *et al.*, 2002; Finkelstein and Arnold, 1999; Finkelstein *et al.*, 1998b, 1994, 2003; Fujita *et al.*, 1999b; Gallagher, 1999; Greenspan *et al.*, 2007; Hodsman *et al.*, 2003; Kurland *et al.*, 2000; Lane *et al.*, 1998b, 2000; Hodsman *et al.*, 2003; Neer *et al.*, 1999, 2001; Rittmaster *et al.*, 2000; Rehman *et al.*, 2003; Ross *et al.*, 1990; Saag *et al.*, 2007). Many studies have included concomitant therapy with the specific intention of minimizing the resorptive properties of PTH; "cotherapy" with estrogen has been widely used (Bradbeer *et al.*, 1992; Cosman *et al.*, 2001; Lane *et al.*, 1998b, 2000; Lindsay *et al.*, 1997; Reeve *et al.*, 1990, 1991, 1993), but other studies have included calcitonin (Hesch *et al.*, 1989b; Hodsman and Fraher, 1990; Hodsman *et al.*, 1991, 1993b, 1997, 2000), calcitriol (Neer *et al.*, 1987, 1991; Reeve *et al.*, 1987; Slovik *et al.*, 1986), and bisphosphonates (Black *et al.*, 2003; Cosman *et al.*, 2005; 2007; Finkelstein *et al.*, 2003). Other studies have examined whether use of antiresorptive therapies following PTH will preserve the anabolic gains achieved with PTH (Adami *et al.*, 2008; Black *et al.*, 2005; Cosman *et al.*, 2007; Kurland *et al.*, 2004; Rittmaster *et al.*, 2000).

There are many issues to be addressed in the assessment of the utility of PTH peptides as osteoporosis therapy. We will discuss these clinical issues under the headings by which regulatory agencies currently examine data for the treatment of osteoporosis. One major problem in evaluating PTH therapy has been the short duration (18 months or less) of the two largest RCTs and most of the other studies with teriparatide. The reason for the short duration of the major trials is the result of a carcinogenicity study being carried out by the sponsor of the teriparatide clinical trial program (Eli Lilly) at the same time as the clinical trials. In that study, rats treated for near-lifetime exposure to extremely high doses of teriparatide were found to have a dose-dependent increased incidence of osteogenic sarcoma (Vahle *et al.*, 2004; Tashjian *et al.*, 2002). The sponsor stopped all clinical trials and temporarily suspended the clinical research program. When further data analysis was available, the drug was successfully submitted for

regulatory approval, based on the data from the truncated clinical trials, but the premature termination of the studies also limited the FDA-approved duration of future studies of PTH to 18 to 24 months.

FRACTURES

Fracture risk reduction, in a randomized clinical trial (RCT), with a placebo-control arm, is the gold standard of efficacy for all osteoporosis treatments. The clinical trials with PTH peptides do not match the size or subject selection of the other major therapeutic agents for osteoporosis, such as the bisphosphonates, estrogen or raloxifene, but it is clear that PTH has antifracture efficacy. Two early trials of PTH mentioned fracture rates as secondary outcomes (Hodsman *et al.*, 1997; Lindsay *et al.*, 1997), but neither study included a placebo-control group for comparison. Hodsman *et al.* (1997) reported a vertebral fracture incidence of 4.5/100 patient years in a group of elderly patients with preexisting vertebral fractures and receiving eight 28-day cycles of hPTH(1–34) over 2 years (Hodsman *et al.*, 1997). Lindsay *et al.* (1997) reported an incidence of 2.5/100 patient years in a comparable group of patients receiving daily hPTH(1–34) injections over 3 years. Because both studies enrolled high-risk female patients with an average of more than two preexisting vertebral fractures, an average age of over 60 years, and comparable BMD measurements, they document fracture incidences in a high-risk population. A reasonable historical comparison can be made with the placebo (calcium-supplemented) arm of the Fracture Intervention Trials, in which new vertebral fracture incidence rates were documented at 10/100 patient years in a cohort of women with only one prevalent osteoporosis-related vertebral fracture who were monitored for 3 years (Black *et al.*, 1997).

More recently, a placebo (calcium and vitamin D supplemented)-controlled RCT of teriparatide, which was specifically designed to evaluate the antifracture efficacy of this analogue in postmenopausal women with prevalent vertebral fractures, was reported (Neer *et al.*, 2001). The significant trial outcomes for reduced incident vertebral and nonvertebral fracture rates together with BMD measurements can be compared with placebo-treated patients and are shown in Figures 6, 7, and 8. Unfortunately, as noted earlier, the clinical trial was stopped at a mean duration of 18 to 19 months of therapy, because of a dose-dependent increased incidence of osteogenic sarcoma in rats receiving near-lifetime high-dose therapy. Despite the shortened duration of the study, with 20μg and 40μg of PTH(1–34) the relative risk (RR) of new vertebral fractures was 0.35 (95% confidence interval [CI] 0.22–0.55) and 0.31 (95% CI 0.19–0.50), respectively [absolute risk reduction (ARR) 9– 10%]. Treatment with 20μg of PTH(1–34) resulted in a RR 0.47 (95% CI 0.25–0.88) for nonvertebral fractures

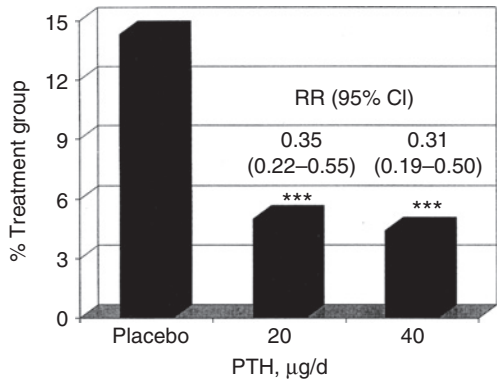

FIGURE 6 Reduction in vertebral fracture rates during a randomized controlled clinical trial of median duration 21 months. Compared with placebo ($n = 544$), both doses of PTH(1–34) (20μg/day, $n = 541$; 40μg/day, $n = 552$) significantly reduced the risk of one or more vertebral fractures (***$P < 0.001$). Adapted from Neer *et al.* (2001).

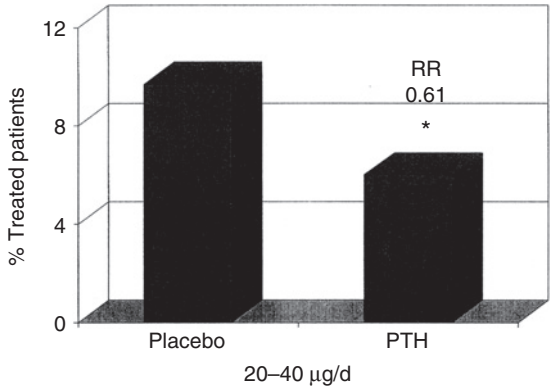

FIGURE 7 Reductions in all nonvertebral fractures during treatment with PTH(1–34) over 21 months. Adapted from Neer *et al.* (2001). Compared with placebo, new fractures were similarly reduced at both doses of PTH (*$P < 0.04$ to < 0.02).

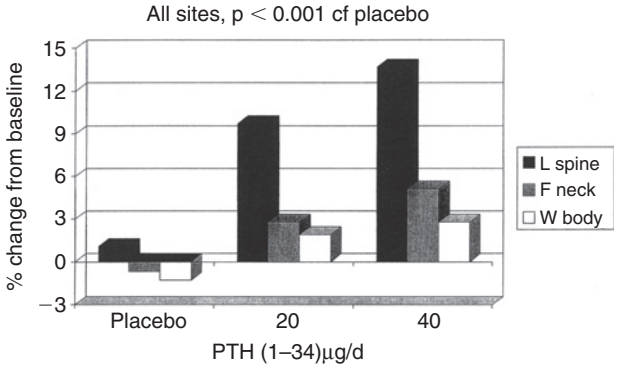

FIGURE 8 Changes in BMD measurements over 21 months during a randomized placebo-controlled clinical trial of PTH(1–34). Adapted from Neer *et al.* (2001).

and an absolute risk reduction of 3% (see Fig. 7). The study was not powered to look at subgroups of nonvertebral fractures, such as hip fractures, but it seems reasonable to conclude PTH therapy has the potential to reduce incident fractures not only in the spine, but also at other sites. An evaluation of the absolute fracture reductions with teriparatide in this study reveals a number needed-to-treat (NNT) estimate of only 10 and 27 women needing treatment to prevent one vertebral or one nonvertebral fracture, respectively. Recognizing differences in subject recruitment and duration of therapy, this compares favorably with the *post hoc* analysis of the Fracture Intervention Trials with alendronate reported by Ensrud *et al.* (1997); in women selected for alendronate therapy who are at comparable risk (prevalent vertebral fractures and femoral neck *T* score of less than 1.6), the NNT calculations to prevent one new vertebral fracture or any new clinical fracture were 16 and 26, respectively, albeit these estimates require up to 60 months of treatment.

The other large RCT of PTH utilized recombinant hPTH(1–84) (Greenspan *et al.*, 2007), which compared 100 μg of PTH to placebo in 2532 postmenopausal women with low bone density. The primary outcome variable was new or worsened vertebral fractures. The study was limited to 18 months of therapy because of the restrictions on duration of PTH therapy arising from the FDA conditions of approval of teriparatide as an osteoporosis therapy. The average age of patients participating in the study was 64 years, and less than 20% had a prevalent vertebral fracture on entry for the study. Because of difficulty recruiting older subjects at higher risk of fracture, the overall fracture rate was very low in this study. The incidence of new or worsened vertebral fracture in the placebo group was 3.4%, and 1.4% in the PTH-treated group. The absolute risk reduction was only 2%, but the relative risk of a new or worsened vertebral fracture in the treatment group was 0.42 (95% C.I. 0.24–0.72), with a NNT of 51. The number of nonvertebral fractures was similar for placebo and treatment groups. Nonvertebral fractures were only reported as adverse events and not fully adjudicated. Hypercalcemia was seen in 27.8% of the subjects receiving PTH compared with 4.5% of the subjects receiving placebo. This complication was usually mild, but contributed to the FDA decision not to grant full approval of the drug for the treatment of osteoporosis in the United States. The drug is, however, approved for this indication in Europe.

A small study by Body *et al.* (2002) compared teriparatide (40 μg/day) with therapy with alendronate (10 mg per day), and found a reduction in nonvertebral fractures compared with alendronate (4.1% versus 13.7%, $P = 0.042$). This was a randomized active treatment comparator study in 146 postmenopausal women, and it suffered from premature termination for the same reason as the major teriparatide study (Neer *et al.*, 2001). Although the reduction in fractures favoring teriparatide was significant, the investigators included fractures of the small bones of the hands and feet, which may or may not be representative of osteoporotic fractures.

An open-label follow-up study of the largest clinical trial of teriparatide (Neer *et al.*, 2001) in 1262 women provided evidence for continuing significant protection against vertebral fracture for at least 18 months after the cessation of teriparatide therapy (Lindsay *et al.*, 2004). The fractures were graded by radiologists blinded to subjects' treatment assignment. In a similar follow-up study of the original clinical trial of teriparatide in men with low bone density (Orwoll *et al.*, 2003), men who received teriparatide had a lower occurrence of all classes of vertebral fractures, but the numbers did not reach significance. However, when the analysis was restricted to moderate or severe vertebral fractures, there were significantly fewer ($P = 0.01$) in the TPTD-treated subjects (2 of 176 subjects) compared with those who received placebo (7 of 103). This effect was seen irrespective of whether the subjects received bisphosphonate or other osteoporosis therapy after teriparatide.

In a comparison of teriparatide and alendronate therapy for prevention of glucocorticoid-induced osteoporosis, 18 months of teriparatide therapy was associated with a significantly lower incidence of vertebral fractures in the teriparatide-treated subjects, but the overall fracture rate was similar between the two groups (Saag *et al.*, 2007).

In summary, there is strong evidence that parathyroid hormone therapy will prevent vertebral fractures in postmenopausal osteoporosis. Prevention of nonvertebral fractures was demonstrated for teriparatide, but not for intact PTH, which has not been tested in a population at high risk for nonvertebral fractures. There have been no adequately powered fracture outcome clinical trials testing PTH against an approved pharmacological agent for the treatment of osteoporosis, but the available trials suggest there might be a slight fracture prevention advantage to teriparatide over alendronate.

BONE MASS MEASUREMENTS

As an anabolic agent, PTH has shown dramatic effects on bone mass, predominantly in skeletal areas rich in trabecular bone, like the spine. Table I selectively summarizes the results of available studies of PTH therapy in which bone mass was measured. The data provided in the table are the percentage increase over baseline or placebo for the highest dose of PTH analogue used in the trial. The method of measurement of bone mass or density (BMD) has varied among these studies and includes both dual-energy x-ray absorptiometry (DXA) and quantitative computed tomography (qCT) for vertebral and femoral neck sites, as well as peripheral areal measurements of the forearm by DXA and qCT. Because these BMD measurements are not entirely comparable, only key points are summarized in this section.

¶*Control group had a significant loss of* BMD *(i.e., PTH prevented loss).*

In the Phase II RCT of hPTH(1–84) (Hodsman *et al.*, 2003), the total body bone mineral density (TBBM) and mineral content showed a decrease of 0.9% compared with placebo over the 1 year of treatment. This finding raises the concern that PTH acts to increase trabecular bone mass at the expense of the cortical bone envelope. Alternatively, it seems likely that PTH causes acceleration of cortical remodeling, resulting in an enlarged expansion of the remodeling space. Increments in cortical bone mass would be expected to occur later, as the anabolic action of PTH gradually leads to a net remodeling gain over time. Within this study, the subsequent treatment of approximately one-third of the study cohort with an antiresorptive agent, alendronate, for a second 12-month interval supports the latter alternative explanation (see later) (Rittmaster, *et al.*, 2000).

In general, it appears that BMD gains achieved with PTH therapy will slowly decline after the therapy is stopped. This BMD loss appears to be preventable by institution of another osteoporosis therapy: bisphosphonate (Rittmaster *et al.*, 2000, Black *et al.*, 2005), raloxifene (Adami *et al.*, 2008; Cosman *et al.*, 2007), or estrogen (Cosman *et al.*, 2001).

Lumbar Spine

Consistent with the anabolic effect on trabecular bone noted in histomorphometric analysis (see earlier), PTH causes a significant increase in BMD in the lumbar spine which exceeds that reported for all other available therapies except sodium fluoride (Riggs *et al.*, 1990) and strontium ranelate (Meunier *et al.*, 2004). The studies of PTH as a monotherapy are of relatively short duration (2 years or less) so it is impossible to determine whether this increase is dose- and duration-dependent or if it reaches a plateau in a manner similar to those of antiresorptive therapies (Riggs and Melton, 1992). There are three RCTs of hPTH(1–84) monotherapy: the Phase II and III studies of recombinant hPTH(1–84) (Hodsman *et al.*, 2003; Greenspan *et al.*, 2007) and the PaTH Study (Black *et al.*, 2003). The BMD response to teriparatide has been documented in a number of small studies over the past two decades, but the two larger Phase III studies of women (Neer *et al.*, 2001) and men (Orwoll *et al.*, 2003) are the most instructive.

In the Phase II study of hPTH(1–84), women with BMD criteria for osteoporosis (Kanis *et al.*, 1994) received daily subcutaneous injections of 50, 75, and 100 μg, in a randomized, placebo-controlled 1-year clinical trial sponsored by Allelix Biopharmaceuticals (Mississauga, ON, Canada). A dose-dependent increase in lumbar spine BMD measured by dual-energy x-ray absorptiometry (DXA) was seen over the baseline measurement, reaching 6.9% in the 100 μg/day group. Changes in bone mineral content were even greater, reflecting an apparent increase in the area of the vertebral bodies examined by DXA (Hodsman *et al.*, 2003).

In the 18-month Phase III RCT of hPTH(1–84) (Greenspan *et al.*, 2007), there was a relatively large number of subjects that discontinued or reduced treatment. A significant 6.9% increase in DXA BMD of lumbar spine was observed versus placebo, with 25% of subjects having more than a 10% increase. A subgroup had volumetric trabecular density of L3 measured by qCT, which showed a 38% increase over placebo (95% CI 24–53%), indicating a dramatic effect on spinal trabecular bone.

The PaTH Study, a three-arm RCT comparing one year of therapy with alendronate 10 mg daily to daily subcutaneous injections of 100 μg of hPTH(1–84) alone, or PTH in combination with alendronate, recruited 238 postmenopausal women with low bone mineral density at the hip or spine (a T score < -2.5, or < -2.0 with an additional risk factor for osteoporosis). BMD at the spine and hip was assessed by DXA and qCT. Spine BMD increased the most in the PTH-treated group, and the increase in qCT spine (volumetric density of trabecular bone) was double the amount seen with alendronate or alendronate in combination with PTH (Black *et al.*, 2003).

In the Eli Lilly Phase III RCT of hPTH(1–34) (Neer *et al.*, 2001), dramatic effects on BMD were observed. In the spine, the increase in BMD was 9.7% and 13.7% in the groups receiving 20 and 40 μg, as opposed to an insignificant increment of 1.1% in the placebo group (see Fig. 4). TBBM increased in the PTH-treated groups (Neer *et al.*, 2001). This is in contrast to the shorter 1-year study of hPTH(1–84) (Hodsman *et al.*, 2003), which reinforces the possibility that an initial decline of BMD reflects the opening of a remodeling space.

The general conclusion from all studies of lumbar spine BMD is that a progressive increase occurs for the duration of therapy (see Table 1). When PTH is stopped, two studies have shown a continuing gain in bone mass that may reflect the filling in of the increased remodeling space (Finkelstein and Arnold, 1999; Lane *et al.*, 2000). On the other hand, cessation of PTH therapy might be expected to result in reestablishment of the pretreatment pattern of bone losses. This is suggested in the spinal BMD measurements of patients participating in the study of Neer *et al.* (2001), if they did not take an osteoporosis drug during the 18 months of post-PTH follow-up (Lindsay *et al.*, 2004).

Hip

There are differences in the BMD responses to PTH among different regions of the skeleton. One of the major concerns about "anabolic agents" is that the increase in spinal (largely trabecular) bone mass may be at the expense of cortical bone, in particular, at important fracture regions such as hip and forearm. Some studies with sodium fluoride have shown dramatic increases in the spine but loss, or no improvement, at cortical bone sites. If PTH causes

a marked increase in cortical bone remodeling, one might expect a decline in BMD in cortical sites during the early stage of PTH therapy, with a later increase if the net effect of PTH is increased bone formation. In reviewing the results of the clinical studies that included BMD measurements at the hip (see Table 1), a net positive effect of PTH is seen.

Several studies showed no change or a decline in femoral neck or total hip BMD within the first year of treatment (Finkelstein *et al.*, 1998a; Lane *et al.*, 1998a), and this is particularly clear in the 1-year study of hPTH(1–84) (Hodsman *et al.*, 2003), in which there was no change in hip BMD. However, in the latter study, there was an increase in the second 6 months of the study.

The few studies that have gone beyond 12 months of therapy have shown a gain in hip BMD (Hodsman *et al.*, 1997; Kurland *et al.*, 2000; Lindsay *et al.*, 1997; Neer *et al.*, 2001; Roe *et al.*, 1999). In the Phase III trial of hPTH (1–34) reported by Neer *et al.* (2001), there were significant BMD gains seen in the hip after just under 2 years of therapy. In the total hip BMD measurements, the placebo group lost 1.6% whereas gains of 2.6% (20μg dose) and 3.6% (40μg dose) were seen in the PTH-treated groups (see Fig. 4). Similar dose-dependent improvements in trochanter, femoral neck, and intertrochanteric regions were observed, and the 5.1% increase in femoral neck is greater than that reported for any antiresorptive therapy after 2 years. A modest but significant increase in hip density was seen after 18 months of treatment with PTH(1–84) (Greenspan *et al.*, 2007). In the study by Greenspan *et al.* (2007) DXA at the femoral neck and total hip increased over placebo by 2.5% and 2.1%, respectively, and volumetric BMD of the femoral neck increased by 4.7% over placebo. Clearly, the effects on BMD in the hip region are not as dramatic as those seen in the spine, but the earlier concern about loss of bone at the hip appears to simply be a function of opening a remodeling space, which is followed by a net increase in bone formation at the femoral neck.

Again, these observations can be explained by postulating the activation of an increased number of bone remodeling units, resulting in an increased remodeling space within the skeleton. During the early stages of PTH therapy, this may cause a decline in BMD in some areas, but as the enlarged remodeling space begins to be filled, increased hip BMD appears as the net result. The clinical trials were not powered to examine effect on hip fracture, but there is no evidence to suggest this initial opening of remodeling space is associated with any clinically important reduction in bone strength.

Forearm

The earlier studies of PTH have shown inconsistent results in the forearm, but the more recent and larger RCTs of both teriparatide and PTH have shown areal BMD by DXA declines. In reviewing studies in which PTH was not being used in combination with estrogen, three small studies showed no change (Hesch *et al.*, 1989b; Neer *et al.*, 1987; Reeve *et al.*, 1987), and three showed significant decline (Hodsman *et al.*, 1991; Neer *et al.*, 1997, 2001). One study, using a PTHrP analogue (semparatide acetate) reported by Gallagher (1999), also showed a decrease in forearm BMD. The best assessment of hPTH(1–34) effects on BMD of the forearm probably comes from the Phase III trial reported by Neer *et al.* (2001), which averaged 21 months of therapy. It showed a significant, though modest 2-3% decline in BMD of the forearm. This may be a concern, but the decline was not progressive in the second year of the study (Neer *et al.*, 2001), and was not associated with any trend to increased risk of wrist fracture. A more recent analysis of a subgroup of patients in the large teriparatide trial suggests that the apparent loss of BMD at the radius is really an artifact of the standard method of calculating areal bone density by DXA. Zanchetta *et al.* (2003), demonstrated that the area of the radius region of interest in the DXA measurements was significantly greater in the teriparatide-treated subjects than in the placebo group. Thus, although the DXA BMD decreased with teriparatide, the biomechanical result of increased bone area (cortical diameter and periosteal circumference) would actually be a stronger bone, which would be more resistant to fracture.

Total Body Bone Mineral

In the 1-year Phase II RCT of hPTH(1–84), there was a significant decline in TBBM content as assessed by DXA (Hodsman *et al.*, 2003). In the subjects receiving 75 and 100μg of PTH(1–84), there was a slight but significant decline (0.3 and 0.9%, respectively) in TBBM, reflecting loss in the arms and legs. This loss was thought to represent a generalized increase in cortical bone turnover and would be expected to be transient. In the 18-month Phase III RCT of PTH(1–84), there was no change in whole-body DXA measurements in the treatment arm, and a nonsignificant trend to lower whole-body BMD in the placebo arm (Greenspan *et al.*, 2007). Longer-term studies with PTH(1–34) have demonstrated small increases in TBBM as shown in Table I and Fig. 4 (Lindsay *et al.*, 1997; Neer *et al.*, 2001).

Finite-Element Analysis

High-resolution QCT studies of bone have allowed use of sophisticated computer-generated modeling to estimate biomechanical properties of bone without having to destroy the bone in the process. Animal studies have indicated that PTH has improvements in mechanical strength out of proportion to that which would be expected simply through increased bone density (Kim *et al.*, 2003). Despite increasing cortical

porosity in ovariectomized monkeys treated with teriparatide, the biomechanical strength of bone at the femoral neck was markedly increased (Sato *et al.*, 2004). Recently, in a clinical trial comparing alendronate and teriparatide, a subset of patients (28 teriparatide; 25 alendronate), who had QCT scans of the spine at baseline and under treatment, were assessed by using finite-element modeling to estimate vertebral body strength changes elicited by the two therapies. Both therapies increased estimated strength of the vertebrae at 6 months in at least 75% of patients compared with baseline, with increased average volumetric density and increased strength in the trabecular bone, but the median percentage increases for these parameters were 5- to 12-fold greater for teriparatide (Keaveny *et al.*, 2007).

PTH IN COMBINATION WITH OTHER TREATMENTS

Several methods of combining PTH with other osteoporosis therapies have been tested. On theoretical grounds, an attractive approach to osteoporosis therapy would be to combine an anabolic agent like PTH, which increases both resorption and formation, with an anticatabolic agent that would reduce the resorption stimulated by PTH while allowing the increased bone formation to continue. Sequential therapy with an anabolic agent (PTH), followed by an anticatabolic agent to preserve the gains achieved with PTH makes eminent sense, and recent evidence supports this approach (Rittmaster *et al.*, 2000; Cosman *et al.*, 2001; Black *et al.*, 2005). In practice, and dictated in part by the high purchase price of PTH therapy, PTH is usually started after the patient has undergone therapy with an anticatabolic agent, often for many years preceding the use of PTH. It is only in the past 8 years that these approaches to combination therapy have been tested systematically in RCTs.

Since the earliest years of study, PTH therapy has been used in a heterogeneous fashion: as a single agent, with or without nutritional calcium and vitamin D supplements (Fujita *et al.*, 1999a; Hesp *et al.*, 1981; Kurland *et al.*, 2000; Neer *et al.*, 2001; Reeve *et al.*, 1980a,b, 1981, 1976a,b), with estrogen or androgen as a concurrent antiresorptive agent (Bradbeer *et al.*, 1992; Lane *et al.*, 1998a; Lindsay *et al.*, 1997; Reeve *et al.*, 1990, 1991; Roe *et al.*, 1999; Cosman *et al.*, 2001), with raloxifene (Deal *et al.*, 2005; Cosman *et al.*, 2007), with calcitriol (Neer *et al.*, 1987, 1991, 1993; Reeve *et al.*, 1987; Slovik *et al.*, 1986), and in several cyclical protocols with or without calcitonin (Hesch *et al.*, 1989b; Hodsman and Fraher, 1990; Hodsman *et al.*, 1991, 1993b, 1997; Reeve *et al.*, 1987).

Despite the heterogeneity of these protocols, the overall effect of PTH has been remarkably consistent: an increase in trabecular bone (as measured by BMD or histomorphometry), with somewhat smaller changes in bone mass in the appendicular skeleton. Some of the studies of combination of PTH with bisphosphonate therapy have raised concerns about diminished response of the skeleton when the bisphosphonate precedes or is concurrent with PTH (Ettinger *et al.*, 2002; Finkelstein *et al.*, 2003, Black *et al.*, 2003; Boonen *et al.*, 2007).

Most reported studies of combination therapies have had small samples of treated subjects and thus a low power to dissect the interactions of concurrent therapies. None have been adequately powered to identify any additional antifracture benefits of the combination therapies being tested.

Estrogen

Estrogen appears to have the best evidence that it does not interfere with the anabolic effects of PTH, and may even augment them. The early literature is confusing. Cosman *et al.* (1993) infused PTH over 20 hours (approximately 800 units to each of 17 estrogen-treated and 15 estrogen-deficient postmenopausal women with osteoporosis). The estrogen-deficient women had a significantly higher excretion of bone resorption markers (urinary OH-proline and deoxypyridinoline) suggesting a protective effect of estrogen on resorption. However, in a similar experiment, Tsai *et al.* (1989) infused 400 units/day for 3 days to three groups of subjects, premenopausal and postmenopausal women with and without osteoporosis. They found no differences in serum calcium or urinary OH-Pro excretion and concluded that estrogen did not have such a protective effect. Using an alternative approach of calcium deprivation to induce endogenous 2° hyperparathyroidism, the same group reached similar conclusions (Ebeling *et al.*, 1992). Marcus *et al.* (1992) gave acute (20 min) infusions of graded doses of PTH to 15 postmenopausal women before and after starting estrogen replacement, and no differences were found in serum $1,25(OH)_2D$ increments or urinary cAMP excretion as a result of estrogen therapy. They concluded that the renal–endocrine axis was not affected by estrogen deficiency. The flaw in these arguments is the fact that clinical responses to PTH infusion favor bone catabolism, whereas intermittent injections favor anabolism (Hodsman *et al.*, 1993b).

In the study by Reeve *et al.* (1991), daily PTH injections and concurrent estrogen therapy were combined in nine women. By comparison with historical controls (women treated with PTH alone) (Reeve *et al.*, 1980b), calcium balance studies were significantly improved; cotreatment with estrogen actually led to a 12% decrease in urinary calcium (Reeve *et al.*, 1991), rather than the 14% increase seen historically (Reeve *et al.*, 1980b). To date, there are no controlled factorial studies to test the estrogen effect independently of PTH.

However, many clinical studies of PTH therapy have incorporated concurrent therapy with estrogen, or estrogen/progesterone therapy (HRT; see Table I). The intent

of these combinations has been to limit the ongoing bone resorption induced by PTH. In this context, Lindsay *et al.* (1997) reported a progressive total 3-year net gain over baseline lumbar spine BMD of 13%. In a study of glucocorticoid-treated women, who were all on stable HRT, Lane *et al.* (1998a) reported similar increments of 11% in the spine (35% by QCT) over 1 year. In a more recent RCT, employing the same dose of PTH(1–34) (40 μg daily) in postmenopausal women receiving HRT, Roe *et al.* (1999, 2000) reported average gains of BMD in the lumbar spine of 29% over 2 years (79% increments at this site as measured by QCT). It is difficult to reconcile the dramatic differences in BMD increments, on the one hand, between the two studies reported by Lindsay *et al.* (1997) and Lane *et al.* (1998a) and, on the other hand, by Roe *et al.* (1999, 2000), despite the reported dose of PTH being similar for all three studies. Possibly the absolute BMD of patients reported by Roe *et al.* (1999, 2000) who were approximately 8 years older was much lower than in the other studies, leading to a much higher relative gain. Alternatively the specific activity of the preparation used by Roe *et al.* may have been higher, leading to a larger functional dose.

More recently, in an expanded follow-up study to that of Lindsay *et al.* (1997), Cosman *et al.* (2001) demonstrated that following PTH therapy with continued HRT preserved PTH-stimulated gains in BMD. Patients who had been taking HRT for 2 years were recruited to receive 3 years of HRT and teriparatide 25 μg/day, or continue HRT. Both groups were then monitored for an additional year receiving HRT alone. The PTH plus HRT group had an increase in BMD by 13.4 ± 1.4% in the spine, 4.4 ± 1.0% in the total hip, and 3.7 ± 1.4% in the total body. One year after stopping the teriparatide, BMD was stable, and vertebral fractures were still significantly fewer in the group that continued HRT than in the control group receiving HRT alone for the 4 years of study.

The weight of evidence would suggest that, at worst, postmenopausal estrogen or estrogen/progestogen therapy has no effect on the skeletal response to PTH, when the two therapies are given concurrently. Under the same conditions, when PTH is stopped but the estrogen therapy is continued, there is minimal change in bone density, indicating that estrogen prevents the expected bone loss when PTH is stopped. There have been no RCTs comparing PTH alone with PTH plus estrogen or a placebo. Consequently, although the gains in bone density appear to be at least the equivalent of what has been reported in the RCTs of PTH alone, it is not clear that estrogen enhances the response to PTH.

Selective Estrogen Receptor Modulators (SERMs)

There have been two clinical trials indicating that the SERM, raloxifene (60 mg daily, taken concurrently), does not inhibit the anabolic response to teriparatide (Deal *et al.*, 2005; Cosman *et al.*, 2007). In a six-month randomized-double blind trial comparing teriparatide plus raloxifene versus 20 μg daily of teriparatide plus placebo, biochemical markers of bone turnover indicated that raloxifene reduced the bone resorption response to teriparatide, whereas the increase in the biochemical marker of bone formation was similar in both treatment groups (Deal *et al.*, 2005). The combination therapy showed a trend to a greater increase in lumbar spine density, and the increase in total hip BMD was significantly greater in the combination group than in the teriparatide-alone group. Interestingly, the teriparatide-induced increase in serum calcium was blunted by the combination therapy with raloxifene. This small study supports the concept that use of an agent, like estrogen or a SERM, acting through the osteoblast to reduce bone resorption without causing major changes in bone formation, does not interfere with the actions of PTH, and might even augment them.

This observation was confirmed in a smaller but longer-duration study by Cosman *et al.* (2007), in which 42 osteoporotic postmenopausal women being treated with raloxifene were randomized to continue on raloxifene alone or take teriparatide 25 μg daily for 12 months while continuing raloxifene. They were then monitored for another 12 months on raloxifene alone. After one year of therapy with teriparatide, spine bone density increased by 9.6% and total hip 2.7%, whereas a 4.3% reduction in BMD at the radius was observed. These changes are typical of, and at least as great as what would be expected with PTH alone. In the year after PTH withdrawal, continued raloxifene prevented significant decline in bone density at the spine or hip, although the BMD at the radius remained significantly lower than in those who never received teriparatide. As noted earlier, change in radius DXA BMD may be partly explained by an increase in cross-sectional area.

In a RCT of one year of teriparatide (20 μg daily) followed by one year of raloxifene or placebo (Adami *et al.*, 2008), the placebo group showed a 4% loss of lumbar spine BMD in the first year after teriparatide, but the loss was 1% in the raloxifene-treated subjects. A second year of raloxifene therapy (open label) for both groups reversed the LS BMD decrease with a placebo, resulting in similar decreases 2 years after randomization (−2.6 ± 0.4% (raloxifene-raloxifene) and −2.7 ± 0.4% (placebo-placebo). Raloxifene therefore appears to prevent the usual loss of lumbar spine bone density after stopping teriparatide therapy, but does not result in further gains; whereas a modest increase in hip BMD occurs when teriparatide is followed by raloxifene.

Bisphosphonates

Concurrent or prior use of bisphosphonates with PTH is an area of major concern and controversy in considering PTH as a therapy for osteoporosis. The data for bisphosphonate

interactions with PTH in animal models are unclear, with contradictory evidence that the concurrent use of bisphosphonates may blunt the anabolic agents of PTH (Cheng *et al.*, 1995; Delmas *et al.*, 1995; Mashiba *et al.*, 1995), although this is not an invariable finding (Mosekilde *et al.*, 1995). This is an important issue.

Concurrent Therapy: PTH and Bisphosphonates

At the time of the first writing of this chapter, there were no clinical trials of PTH in combination with a bisphosphonate. Now there have been several studies, but the results are not entirely consistent nor have they been uniform with respect to patient selection. Although, in theory, the use of an antiresorptive agent might allow the anabolic effects of PTH to predominate, and this may, in fact, be the case with estrogen and raloxifene, the results with the bisphosphonate alendronate have been very different. In 2003, two studies indicated that the bone density response to teriparatide appeared to be blunted by prior and continued therapy with alendronate. The PaTH study of PTH, given with or without alendronate to treatment-naïve individuals, showed a better bone density response by DXA and QCT when PTH was given as a monotherapy. The trabecular bone response to one year of PTH(1–84) was significantly greater at the lumbar spine than the response to alendronate alone or alendronate plus PTH in combination. Volumetric QCT analysis at the spine showed a significantly greater response to PTH alone than PTH in combination with alendronate or alendronate alone. At the hip, alendronate's effect on bone density was slightly superior to that seen with PTH alone.

In a study of men with low BMD, Finkelstein *et al.* (2003) gave teriparatide 40 μg s.c. daily to men with low bone density for 24 months. After prior therapy with alendronate 10 mg daily for 6 months, the subjects were randomly assigned to teriparatide, teriparatide plus continued alendronate, or alendronate alone. Teriparatide caused the greatest increase in BMD by DXA in all areas studied except the distal radius. It was apparent from both spine and hip DXA, as well as volumetric spinal QCT studies, that the combination of alendronate with teriparatide resulted in a diminished bone density response in comparison with teriparatide alone. The BMD response to combination therapy was intermediate between PTH alone and alendronate alone.

In contrast, Cosman *et al.* (2005) randomly assigned patients to alendronate 70 mg p.o. once weekly, weekly alendronate plus teriparatide 25 μg s.c. once daily, or weekly alendronate plus cyclic treatment with teriparatide (three months of daily teriparatide 25 μg s.c. followed by three months off therapy). The subjects were postmenopausal osteoporotic women, and the groups had been receiving alendronate for an average of 2.8 to 3.5 years prior to study entry. Cyclic or continuous teriparatide caused similar increments in BMD (DXA) of the lumbar spine of approximately 5% above the patients who continued alendronate, and there was no apparent blunting of the response to teriparatide by the alendronate, although the response to teriparatide was not as great as might be expected in treatment naïve patients. Biochemical markers of bone formation were increased throughout the 18-month trial, although for the cyclic teriparatide group, the marker of bone resorption was not significantly greater than the alendronate-alone group at 18 months. This suggests that the weekly alendronate may not inhibit bone remodeling as significantly as daily, and that cyclical PTH may be as effective as continuous therapy in the presence of continued bisphosphonate therapy. Although the alendronate may have some inhibiting effect on the anabolic response to PTH, the BMD response to teriparatide while continuing weekly alendronate therapy is still quite significant.

Most investigators believe PTH's effect on bone is somewhat blunted by prior or continued therapy with bisphosphonate, despite the apparent retained response documented by the study of Cosman *et al.* (2005). The recent publication of the EUROFORS study (Boonen *et al.*, 2007) indicates that prior therapy with a bisphosphonate, although perhaps diminishing the bone density effect of teriparatide, does not eliminate it. Further, there is a suggestion that in the final six months of two years of therapy following bisphosphonate treatment, there is a further increment in bone density (Boonen *et al.*, 2007).

There are many cautions in attempting to compare the studies of combination of prior and/or concurrent bisphosphonate therapy and PTH. The study designs, dose, and choice of PTH peptide differ among the available studies. Further, the studies are not powered or designed to look at fracture outcomes. Also, bone biopsies have not been reported in studies comparing PTH therapy with a combination PTH and bisphosphonate, and as noted earlier, DXA may not always be relied upon in assessing the response to PTH.

If prior bisphosphonate therapy does indeed cause blunting of PTH response, this is unfortunate, because most patients currently being treated with PTH have received bisphosphonate therapy first. This is, in part, because PTH therapy has only recently been approved as a therapy for osteoporosis. But because it is much more expensive than bisphosphonate therapy, PTH tends to be reserved for patients who have more severe osteoporosis, or patients who are considered to have failed to respond to other osteoporosis therapies (usually a bisphosphonate among them). Indeed, the regulatory agency approval of PTH in many countries includes an indication for patients who have failed to respond to other osteoporosis therapies. Further, because of the concern about osteogenic sarcoma in carcinogenicity studies performed in rats, most countries' approval of PTH peptides limits the duration of therapy to 18 or 24 months. If a bisphosphonate reduces

or delays response to teriparatide, a longer duration of therapy might be required in those individuals, but is not currently allowed under the terms of most countries' regulatory agency approval.

Although clinical trial results have not been consistent, current data indicate concurrent therapy with a bisphosphonate does not offer additional benefit to the actions of PTH, although it is not certain that bisphosphonate therapy eliminates the response (Cosman *et al.*, 2005). Prior therapy with a bisphosphonate may reduce the BMD response to PTH, although some would argue that the apparent reduction simply is because of the patient already having experienced a positive effect of the bisphosphonate, thus leaving less room for improvement by PTH (Ettinger *et al.*, 2004).

Consecutive Therapy: PTH Followed by Bisphosphonate

Given the increase in skeletal bone remodeling induced by an activation drug such as PTH (at the BMU level), it is likely that the remodeling space within all skeletal bone envelopes will be enlarged as a transient state (Parfitt, 1980). The enlarged remodeling space could be exploited by antiresorptive drugs as maintenance therapy after discontinuing PTH. This hypothesis has been tested in only one published study.

Approximately one-third of the subjects in the Phase II RCT who received PTH(1–84) for 1 year (Hodsman *et al.*, 2003) were subsequently treated with open-label alendronate, 10 mg daily (Rittmaster *et al.*, 2000). Following PTH with alendronate caused a further rapid increment in BMD at all sites, such that the aggregate gain over 2 years in BMD at the highest dose of PTH(1–84) was 14.1% at the spine, 4.5% at the femoral neck, and 3.3% for the whole body. Because there was a slight negative change in whole-body BMD during the 12 months of PTH treatment, the subsequent rapid reduction of bone turnover induced by alendronate, accompanied by a rise in whole-body BMD, was consistent with closing down and filling in of the skeletal remodeling space.

This augmentation of BMD by bisphosphonates after PTH therapy has been stopped was confirmed in the second year of the PaTH study, in which three treatment groups (PTH, PTH plus alendronate, and alendronate alone) received alendronate 10 mg daily for one more year, and one of the PTH arms received placebo instead of alendronate in the second year (Black *et al.*, 2005). After PTH therapy alone, a dramatic further increase in spine and hip BMD was seen with alendronate therapy (4.9% and 3.6%, respectively). The PTH-induced increase in volumetric spinal trabecular density was maintained. In contrast, the group that received PTH and alendronate in combination in the first year saw minimal further gain in BMD at the spine and hip, and the group receiving 2 years of alendronate showed a similar modest improvement of BMD at spine and hip. The PTH-treated group that received placebo in the second year had no change in spinal BMD. All PTH-treated subjects lost BMD at the radius in the first year, and showed no further loss in the second year while taking alendronate.

In follow-up studies of the two large teriparatide RCTs in postmenopausal women (Neer *et al.*, 2001) and men (Orwoll *et al.*, 2003), subgroup analyses showed that those subjects who received bisphosphonate therapy after stopping the teriparatide had modest increments in spine and hip BMD (Lindsay *et al.*, 2005; Kaufman *et al.*, 2005).

All of the available evidence would suggest that, after a course of PTH therapy has been completed, the use of a bisphosphonate will retain or even enhance the gains in bone density that have been achieved (Rittmaster *et al.*, 2000; Black *et al.*, 2005; Lindsay *et al.*, 2005; Kaufman *et al.*, 2005).

Calcitriol

The early studies by Neer and coworkers combined concurrent calcitriol with daily PTH injection therapy (Neer *et al.*, 1987, 1991; Slovik *et al.*, 1981, 1986). This strategy was adopted because the earlier dietary calcium balance studies of Reeve and coworkers demonstrated minimal adaptations of dietary calcium absorption despite obvious histomorphometric restoration of trabecular bone and increased urinary Ca excretion. Because exogenous PTH increases serum $1,25(OH)_2D$ levels in the short term (Hodsman and Fraher, 1990; Lindsay *et al.*, 1993), and is associated with increased fractional ^{45}Ca absorption, the need for the addition of calcitriol therapy remains unproven. The changes in lumbar BMD reported by Neer and coworkers are comparable to other studies but theirs was the first group to report significant losses of BMD at the radius in a controlled clinical trial (15 patients on calcium, 15 patients on PTH + calcitriol 0.25 μg/day, over 2 years) (Neer *et al.*, 1991). The control group lost 1.7% and the experimental group lost 5.7% in radial BMD, all in the first year of treatment. The greater and abrupt loss of appendicular bone mass in the experimental group might indicate a permanent loss to cortical bone but an alternative explanation includes the possibility of an effect consistent with increased intracortical modeling, or an increase in bone size out of proportion to the degree of mineralization.

Cyclical Therapy with PTH and Calcitonin

Cyclical therapy with PTH and an antiresorptive agent, calcitonin, is of interest insofar as it might provide insights as to how the hormone might ultimately be given in the most economical fashion. The concept for the cyclical use of PTH should be distinguished from its direct anabolic effects on the skeleton. Because PTH also activates bone

remodeling, cyclical protocols have attempted to exploit the ADFR hypothesis (A, activate remodeling; D, depress resorption in the activated bone modeling units; F, a treatment-free period of bone formation; R, repeat the treatment cycle). In fact, none of the cyclical protocols can be considered as true ADFR protocols and should be regarded as hybrid anabolic protocols.

Hesch and Hodsman have combined cyclical PTH (1–34) and PTH(1–38) with concomitant or sequential cycles of calcitonin (Hesch *et al.*, 1989b; Hodsman and Fraher, 1990; Hodsman *et al.*, 1991, 1993b, 1997, 2000). There is little evidence that the antiresorptive action of calcitonin provides any additional clinical benefit. Short cycles of PTH (400–500 units/day, approximately 40 μg) for less than 14 days provide little evidence of skeletal activation of bone turnover or anabolism (Hodsman and Fraher, 1990; Hodsman *et al.*, 1991; Reeve *et al.*, 1987), although biochemical responses are detectable within this time frame. However, 28-day cycles of high-dose PTH (800 units, or 65 μg daily) appear to provide a strong stimulus for activation of bone turnover (Hodsman *et al.*, 1993b) and anabolic effects on bone mass (Hodsman *et al.*, 1993b, 1997). The reported changes in lumbar spine BMD, with small increments in femoral neck BMD with 28-day cycles of high-dose PTH may provide an alternative approach to harnessing the anabolic effects of PTH.

USE OF PTH IN CONDITIONS OTHER THAN POSTMENOPAUSAL OSTEOPOROSIS

Glucocorticoid-Induced Osteoporosis

It is clear from the action of PTH on osteoblasts that it would be likely to be of benefit in glucocorticoid-induced osteoporosis. Small studies have indicated that this is the case. As noted previously, PTH has been used successfully to improve BMD in estrogen-treated women with glucocorticoid-induced osteoporosis (Lane *et al.*, 1998a). Of note in that study, BMD continued to increase at the spine and hip measurement site during the 12 months of observation following 12 months of PTH therapy, suggesting that treatment with continued HRT as an antiresorptive therapy effected similar reductions in bone turnover to those seen previously with alendronate (see Table 1) (Lane *et al.*, 2000).

More recently, a larger RCT comparing teriparatide to alendronate in glucocorticoid-induced osteoporosis has shown teriparatide to be at least as effective in preventing glucocorticoid-induced bone loss as a bisphosphonate (Saag *et al.*, 2007).

Hypogonadism

PTH(1–34) has also been shown to prevent the large and rapid loss of bone mass following "medical oophorectomy" induced by the gonadotropin antagonist, nafarelin (Finkelstein *et al.*, 1994). After cessation of nafarelin and PTH therapy, bone mass continued to increase during 1 year of follow-up, such that, in the subjects previously treated with PTH, BMD in the spine was actually higher than it had been at baseline 2 years earlier (see Table I).

Osteoporosis in Men

In early studies, PTH appears to have equivalent anabolic effects in men with osteoporosis (Kurland *et al.*, 2000; Slovik *et al.*, 1986), although the numbers of men studied were very small (see Table 1). The largest RCT of teriparatide in men, sponsored by Eli Lilly, was terminated before most of the subjects had completed a year of treatment, so conclusions are limited. However, comparing the results of the male osteoporosis trial to the first year of the fracture prevention study in postmenopausal women (Neer *et al.*, 2001), the increment in BMD of spine was similar (Orwoll *et al.*, 2003). The investigators enrolled 437 men with BMD more than 2 standard deviations below the young adult male mean, randomized to 20 or 40 μg of teriparatide daily or placebo, but averaged only 11 months of therapy. The study was too short and underpowered to examine fracture prevention, but in 355 men monitored for 30 months after stopping teriparatide or placebo, there were fewer vertebral fractures in the teriparatide treatment group than placebo arm, and this difference was significant if only moderate or severe vertebral compression fractures were counted (Kaufman *et al.*, 2005).

Fracture Healing

Recently, there has been growing interest in PTH as an aid to fracture healing. In animal models of fracture healing, the mechanical strength of callus and fracture union (both cortical and cancellous bone) after osteotomy, with increased osteoblastogenesis and decreased adipocytogenesis (Komatsubara *et al.*, 2005; Nozaka *et al.*, 2008). Local application of teriparatide to a fracture site in rat tibiae increased postfracture callus volume by 20% ($P < 0.01$) 14 days postfracture (Rozen *et al.*, 2007).

In a 28-day rat model of fracture healing, Nakazawa *et al.* (2005) showed daily s.c. teriparatide increased chondrogenesis in the early stages of fracture healing (day 14) but this was not evident at later stages (days 21 and 28). In the earlier stages of chondrogenesis, cell proliferation, expressed as the rate of proliferating cell nuclear antigen-positive cells, was increased in mesenchymal (chondroprogenitor) cells but not chondrocytes in the PTH-treated group compared with controls, suggesting that PTH induces a larger cartilaginous callus, but does not delay chondrocyte differentiation (Nakazawa *et al.*, 2005).

In a 16-week rat tibia fracture healing model, daily s.c. injection of PTH fragments hPTH(1–34), hPTH(1–31),

and monocyclic [Leu27]cyclo (Glu22-Lys26)hPTH(1–31) for 8 weeks resulted in increased fracture strength and callus volume, and the three peptides were equally effective (Andreassen *et al.*, 2004).

In general terms, the animal studies have consistently suggested that systemic therapy with teriparatide enhances fracture healing (Holzer *et al.*, 1999; Alkhiary *et al.*, 2005). These studies raise the possibility of a role for PTH therapy in enhancing bone healing after fracture or orthopedic procedures, and support the design of clinical trials in humans.

BIOCHEMICAL MARKERS OF BONE METABOLISM

Biochemical markers of bone turnover provide noninvasive indicators of the balance between bone resorption and bone turnover (Delmas *et al.*, 1991; Garnero *et al.*, 1994; Riis *et al.*, 1995). Because PTH is regarded as a hormone with potent bone-resorbing properties, leading to concomitant increases in urinary calcium excretion, other markers of bone resorption are of great importance. In this section, discussion of biochemical markers of bone resorption discussed will be collagen breakdown products: urinary hydroxyproline (OH-Pro), deoxypyridinoline (DPD), and the type I collagen cross-linked amino (N)- or carboxyl (C)-telopeptides (NTx and CTx). Markers of bone formation will focus on bone-specific alkaline phosphatase (BSAP), osteocalcin, and the N- or C-terminal propeptide of type I collagen (P1NP, P1CP).

In the initial studies of the biochemical response to PTH, the stimulation of bone resorption was an obvious concern, because clinicians traditionally link hyperparathyroidism with bone loss. However, the early reports suggested fairly minimal increases in bone resorption accompanied the anabolic effect. Reeve *et al.* (1980b) reported a 26% rise in OH-Pro excretion in patients treated with daily PTH, but either no change or a 100% fall in urinary OH-Pro in a small group of 12 patients who were treated with estrogen or androgen as concurrent antiresorptive therapy (Reeve *et al.*, 1987, 1991), lending support to the concept of combining an anabolic with an anticatabolic agent. However, other investigators have variously reported increments in either urinary OH-Pro, DPD, or NTx excretion that are 50% to 350% over baseline (Finkelstein *et al.*, 1998a; Greenspan *et al.*, 2007; Hodsman *et al.*, 1993b; Kurland *et al.*, 2000; Lane *et al.*, 2000; Lindsay *et al.*, 1997; McClung *et al.*, 2005; Neer *et al.*, 2001; Sone *et al.*, 1995). Markers of bone resorption tend to reach maximal levels within the first 6 months of PTH treatment, falling back toward baseline values toward the end of the first year of therapy, and they do not rise any further over longer periods of continuing therapy.

Increments in markers of bone formation, P1NP, P1CP, BSAP, and osteocalcin, are consistently seen earlier than the rise in markers of resorption (Dobnig *et al.*, 2005; Finkelstein *et al.*, 1998a; Fujita *et al.*, 1999a; Greenspan *et al.*, 2007; Hodsman *et al.*, 1997; Kurland *et al.*, 2000; Lane *et al.*, 2000; Lindsay *et al.*, 1997 McClung *et al.*, 2005; Neer *et al.*, 2001). These increases in formation markers are better correlated with increments in bone mass and histological changes than the markers of resorption (Dobnig *et al.*, 2005). More recent studies have suggested that P1NP is a very sensitive indicator of PTH effect on bone, increasing by over 1000% after 6 months in one study (Finkelstein *et al.*, 2006). It has been suggested that if a patient's P1NP level does not increase by 10 μg/L from baseline in 1 to 3 months, the patient should be questioned regarding storage or injection techniques, medical problems interfering with the response to therapy, or adherence (Eastell *et al.*, 2006).

In clinical trials, increments in biomarkers of bone formation precede those of bone resorption, usually by 1 to 3 months, but again are maximal within 6 to 12 months and fall toward baseline values in the longer studies. The earlier rise in markers of bone formation compared with markers of resorption has been characterized as an "anabolic window" by Bilezikian (Canalis *et al.*, 2007). This may reflect the time period in which the imbalance between formation and resorption is at its highest, but the apparent continued anabolic action of PTH on histology (Fox *et al.*, 2005), and BMD (Lindsay *et al.*, 1997), after more than a year of therapy would suggest that the decline of biochemical markers, and the "catching up" of the markers of bone resorption, does not signal a loss of net bone accretion.

As noted earlier, prior treatment with a bisphosphonate appears to reduce or delay the anabolic effects of PTH, and this is reflected in the biochemical markers. In a randomized three-arm (alendronate, teriparatide, or both) study of 63 men with BMD below a T score of −2.0, Finkelstein *et al.* (2003) documented that 6 months of prior therapy with alendronate reduced the BMD response to teriparatide 37 μg s.c. daily, but also markedly blunted the response of the biochemical markers osteocalcin, P1NP, and the resorption marker NTx (Finkelstein *et al.*, 2006). Ettinger *et al.* (2004), in a small study of patients started on teriparatide after long-term prior therapy with alendronate or raloxifene, showed that the response of osteocalcin, P1NP, BSAP, and NTx to teriparatide therapy was reduced by prior therapy with alendronate, but raloxifene did not seem to reduce the response to teriparatide. Boonen *et al.* (2008) showed that prior therapy with bisphosphonates did not prevent a rise in P1NP after one month of teriparatide, although the increment following alendronate therapy was less than if the prior bisphosphonate therapy had been risedronate. This observation has been confirmed in an abstract report of the OPTAMISE clinical trial of teriparatide following 24 months of alendronate or risedronate (Delmas *et al.*, 2007).

In contrast to bisphosphonates, other anticatabolic agents, notably estrogen and raloxifene, do not appear to

reduce the rise in formation markers stimulated by PTH, although there has only been one study comparing the combination of these agents with PTH alone. The reduction in the rise in PTH-stimulated bone resorption markers by cotreatment with raloxifene (Deal *et al.*, 2005) might suggest a mechanism for amplifying the anabolic effect of PTH, but in the absence of longer-term clinical trial data, this remains speculative.

The wide variation in BMD response to PTH therapy is somewhat unusual, and certainly greater than the response to alendronate. The investigators of the PaTH study (Sellmeyer *et al.*, 2007) found that levels of biochemical markers at baseline, or following therapy, could not explain the variability. The PTH-stimulated increase in serum 1,25-$(OH)_2$ vitamin D was the serum parameter best correlated with the BMD response, but only explained 16% of the variance.

In summary, the reported measurements of biochemical markers for bone resorption and formation support the rapid onset of skeletal activation and bone turnover in response to PTH as reported histologically by Hodsman *et al.* (1993b, 2000). Increments in bone formation markers are consistent and of considerable magnitude, in keeping with direct osteoblastic stimulation and bone anabolism (Hodsman *et al.*, 1997; Lindsay *et al.*, 1997). After the first year of therapy, a decline in biochemical markers of bone turnover appears to be a consistent observation, and there are few studies of PTH action on BMD beyond two years, so it is possible that skeletal resistance to the anabolic effects of PTH peptides might develop during the first three years of therapy.

CALCIUM BALANCE STUDIES

Before 1980, there were few methods to document changes in bone mass in response to any agent. Bone biopsies yield important information, but the measured parameters are not precise (typical CV±20%) (Chavassieux *et al.*, 1985). Therefore, early studies relied on classical dietary calcium balance studies and radioisotopic techniques of assessing skeletal calcium accretion to determine the extent to which new therapies for osteoporosis improved skeletal bone mass. The methodology of the reports discussed later is not easy to follow, but the cited references provide a source for such documentation. Moreover, the reader should appreciate that the cited clinical protocols vary widely with respect to dose of PTH (preparations also varied in units of biological activity), duration of therapy, and concurrent medication. Given these limitations, the results indicate enough consistency to describe the results in general terms.

In the initial report by Reeve *et al.* (1976a), four patients treated with PTH (500 units/day), demonstrated an improved dietary calcium balance averaging 7.3 mmol/day. Net diet absorption of ^{47}Ca averaged 3.4 mmol/day. Measured accretion of ^{47}Ca by the skeleton averaged 6.3 mmol/day. These data seemed to confirm that the observed improvements in bone histology were indeed caused by an anabolic effect of the injected hPTH(1–34). A subsequent report on the short-term changes (<1 month) measured in the same subjects defined dose-dependent effects, with calcium balance improving over doses of 500 to 1000 units of hPTH(1–34) per day, but deteriorating at doses of 1500 units/day (Reeve *et al.*, 1976b). In a small group of four patients treated with 450to 750 units of hPTH(1–34) over 1 month reported by Slovik *et al.* (1981), a similar dose dependency was observed, with positive dietary calcium balance (2.2 mmol/day) seen only at the lower doses of PTH.

In summary, kinetic calcium data demonstrate trends toward positive dietary calcium balances during a variety of therapeutic PTH protocols. These techniques have not been as sensitive to changes in bone mass as dual-energy absorptiometric measurements, but they comprise the only existing evidence that prolonged PTH treatment does not result in consistent total body calcium depletion. However, two reports suggest that higher doses of PTH (>1000 units/day) may be deleterious to total body calcium balance (Reeve *et al.*, 1976b; Slovik *et al.*, 1981).

EFFECTS ON SERUM AND URINARY CALCIUM

The biological effects of PTH when given by continuous intravenous infusion, intravenous bolus, or subcutaneous injection are not the same. For example, continuous infusion of hPTH(1–34) caused marked bone resorption in the rat (Tam *et al.*, 1981). When infused into osteoporotic subjects, Hodsman *et al.* (1993b) reported that a given dose of hPTH(1–34) caused significantly larger increments in total serum calcium over 24 hours than the same dose given by a single subcutaneous injection. The PTH infusion led to a significant fall in biochemical markers of bone formation, suggesting, if anything, that continuous intravenous infusion of PTH is antianabolic (Hodsman *et al.*, 1993b). Similar findings in osteoporotic subjects were reported by Cosman *et al.* (1993), albeit that concurrent estrogen therapy might have mitigated the catabolic effects of PTH infusion.

Increments in serum calcium following subcutaneous PTH injection are delayed and do not peak until 4 to 8 hours postdosing (Hodsman *et al.*, 1993b; Lindsay *et al.*, 1993), but they are generally within the normal physiological range. Because the clearance of injected PTH is so rapid, no obvious safety concern has arisen after more than 20 years of PTH therapy. However, persistent hypercalcemia may occur during daily PTH injections. The increment in serum calcium owing to PTH therapy appears to be relatively constant, so that individuals starting with

a high basal level of serum calcium will be at higher risk of hypercalcemia (Antoniucci *et al.* 2007). Dose reduction because of sustained hypercalcemia within the dose ranges chosen in most published trials was seldom necessary, and cessation of nutritional calcium supplementation will often be sufficient to manage increments in serum calcium above the normal physiological range. It is certainly possible for a forgetful patient to accidentally give a second or even third dose in the same day, so there is always a risk of hypercalcemia owing to overdosage of PTH. This appears to be the case in at least one of the serious hypercalcemia episodes in the large clinical trial of PTH(1–84) (NPS Pharmaceuticals, personal communication).

In the largest RCT evaluating teriparatide against placebo, serum calcium measurements 24 hours after daily injections of PTH in a dose of 20 μg/day (approximately 250 units) were mildly elevated (<11.5 mg/dL) in about 10% of patients, and not sustained in a third of these women (Neer *et al.*, 2001). The FDA approval of this drug in the United States did not require monitoring of serum calcium, but many clinicians do so, testing serum calcium 20 to 24 hours postdose, within the first month of therapy.

In the clinical trials of PTH(1–84) 100 μg daily, the incidence of hypercalcemia has been variable, and therefore more of a concern. In the major Phase III trial, 28% of subjects receiving PTH had hypercalcemia, but almost all of these cases resolved with second testing or reduction in calcium intake (Greenspan *et al.*, 2007). A major contributing factor to the high incidence of hypercalcemia in this trial was likely the fact that the recruitment criteria allowed inclusion of patients with mild hypercalcemia (10.5–10.7 mg/dL). In other clinical trials with PTH(1–84), patients with mild hypercalcemia were excluded (Hodsman *et al.*, 2003; Black *et al.* 2003; Antoniucci *et al.*, 2007) and the frequency of hypercalcemia in those studies was approximately the same as described in the teriparatide study by Neer *et al.* (2001) (14% in PaTH vs. 11% in the 20-μg arm of the teriparatide study). It should be noted that the definition and time of testing for hypercalcemia were not the same in the teriparatide and PTH trials—hypercalcemia was defined as =10.7 mg/dL in the teriparatide study and >10.5 mg/dL in the PTH studies, whereas the serum calcium was tested 4 to 6 hours after teriparatide and 20 to 24 hours after PTH (Antoniucci *et al.*, 2007).

Increased fractional absorption of dietary calcium (Hodsman and Fraher, 1990) and hypercalciuria (Hodsman *et al.*, 1993b; Lindsay *et al.*, 1993) are probably or partially contributed to by increments in serum $1,25(OH)_2D_3$, which have been reported after subcutaneous hPTH(1–34) (Fujita *et al.*, 1999a; Hodsman and Fraher, 1990; Lindsay *et al.*, 1993). However, of the three studies reporting long-term biochemical changes in response to hPTH(1–34) injections, sustained increments in serum $1,25(OH)_2D_3$, and hypercalciuria were not of clinical importance (Hodsman *et al.*, 1997; Lindsay *et al.*, 1997; Neer *et al.*, 2001). Miller *et al.* (2007) recently reported the calciuric response in the two major Eli Lilly placebo-control studies of teriparatide 20 or 40μg daily in 1637 women and 437 men. Urinary calcium excretion was increased for as long as 12 months of therapy, compared with placebo and baseline values, but the magnitude of these changes was felt to be unlikely to be clinically relevant or to warrant a recommendation for routine urinary calcium monitoring.

PHARMACOKINETICS OF PTH ADMINISTRATION

Because most therapeutic protocols have reported the response of the skeleton to daily subcutaneous injections, this section focuses on the pharmacodynamic responses to PTH when given by this route.

In a small study involving four healthy young subjects, Kent *et al.* (1995) reported that after subcutaneous administration of 1250 units hPTH(1–34) (100 μg, 20 nmol) the time to reach maximum plasma concentration T_{max} was approximately 15 min, with immunoreactive PTH concentrations decaying to baseline after 180 to 240 min.Two additional reports, in estrogen-treated postmenopausal osteoporotic subjects and in both young and untreated postmenopausal subjects (Fraher *et al.*, 1993; Lindsay *et al.*, 1993) provided very similar data, i.e., peak immunoreactive increments in serum hPTH(1–34) levels at 20 to 30 min postinjection, increasing 10- to 15-fold over baseline (depending on injected dose), and decaying within a $T_{1/2}$ of about 75 min (Fig. 9). Chu *et al.* (2007) conducted a single-dose study in healthy adult Chinese volunteers, and for the 20 μg subcutaneous dose, they confirmed a rapid peak and a slightly shorter $T_{1/2}$ plasma elimination of approximately 60 minutes.

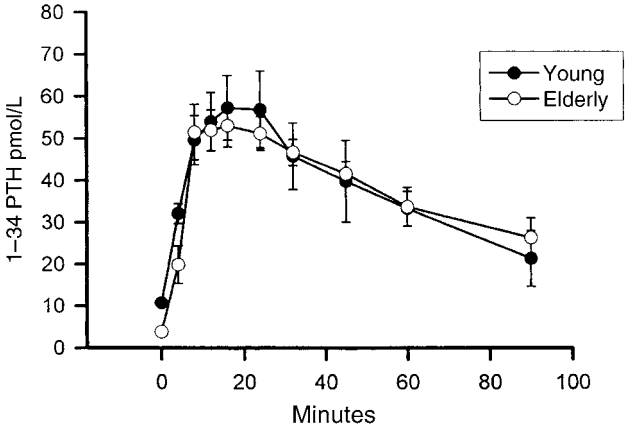

FIGURE 9 Pharmacokinetics of PTH(1–34) given by subcutaneous injection. Serum concentrations of hPTH(1–34) after subcutaneous injection of 800 IU PTH peptide in 10 young adults aged 25±9 (SD) years and 9 elderly women with osteoporosis, aged 67±11 years. Adapted from Fraher *et al.* (1993).

The only detailed pharmacodynamic study published for other PTH peptides is a dose-finding single subcutaneous injection report on hPTH(1–84). Schwietert *et al.* (1997) reported minimal changes in total serum calcium in response to single injections of up to 5 μg of hPTH(1–84)/kg (approximately 0.5 nmol/kg). However, with this peptide, absorption appeared to be associated with a double peak in C_{max} with an early peak occurring less than 20 min postinjection and a second peak appearing 1 1/2 to 2 hours later. This pharmacokinetic profile occurred at all doses of hPTH(1–84) and appears to be different from that observed after hPTH(1–34) dosing. The pharmacokinetics of hPTH(1–84) were recently reviewed by Moen and Scott (2006), and more recent studies have only been published in abstract form or have been made available by the manufacturer. Essentially, the observation of a double peak was again observed in patients receiving daily injections, with a mean serum elimination half-life of 2.5 hours. In addition to the double peak, this half-life appears to be longer than that described for teriparatide. This raises the possibility that teriparatide and PTH(1–84) may have slightly different biological effects. If the anabolic action is dependent upon bone cells receiving a short duration, intermittent exposure to PTH, a longer duration of exposure might enhance the resorptive action of the peptide, and treatment with the intact hormone might therefore have a less potent effect on bone formation.

IMMUNOLOGICAL RESPONSES TO EXOGENOUS PTH

Of the available reports in which antibody formation was deliberately sought, 67 of 1168 patients apparently developed anti-hPTH(1–34) antibodies in low titers (Hesch *et al.*, 1989b; Hodsman *et al.*, 1997; Neer *et al.*, 2001; Reeve *et al.*, 1976a, 1987, 1991). Four patients discontinued hPTH(1–34) therapy because of generalized urticarial reactions or local irritation at the injection site (Reeve *et al.*, 1976a, 1980b). Although the 6% incidence of anti-PTH(1–34) antibodies may seem high, and presence of other impurities in the early preparations is a possibility, it should be pointed out that hPTH(1–34) is not a naturally occurring peptide. In the more recent clinical trial with teriparatide (Neer *et al.*, 2001), antibodies to PTH (1–34) were detected in one woman in the placebo group (<1), 15 (3%) women in the 20-μg and 44 (8%) of the 40-μg treatment group, suggesting a dose-dependent immune response, but there was no evidence of biological effect of these antibodies.

In the large clinical trial of PTH(1–84), 2 (0.2%) placebo-treated and 36 (3.5%) of the PTH-treated subjects had developed positive PTH antibody titers after 12 months, but one-third of these had negative titers at 18 months (Greenspan *et al.*, 2007). Whether these antibodies bind in a manner to reduce biological activity is not known.

OTHER ANALOGUES AND DELIVERY SYSTEMS

The principal analogue used in the reported clinical literature was the presumed bioactive amino-terminal fragment of PTH, namely hPTH(1–34). Several have used hPTH (1–38) (Hesch *et al.*, 1984, 1989a,b; Hodsman and Fraher, 1990; Hodsman *et al.*, 1991), but there is no compelling reason to believe it might be more potent than hPTH (1–34). Other analogues include hPTH(1–31) amide and its lactam (Ostabolin and Ostabolin-C). These analogues stimulate adenyl cyclase with equivalent potency to the holohormone PTH(1–84), but seem to have no effect on the phospholipase C messenger system; in animal models of anabolic bone formation they appear to be equipotent to PTH(1–34) (Whitfield *et al.*, 1997). There is a single report of continuous intravenous infusion of PTH(1–31) amide in young human subjects (Fraher *et al.*, 1999). When compared with an equimolar dose of infused PTH(1–34), comparable urinary and plasma cyclic AMP responses were seen, but the PTH(1–31) amide resulted in no increase of serum and urinary calcium or in urinary NTx. This suggests that analogues can be designed with more selective potency for bone formation over bone resorption.

The parathyroid hormone-related peptide analogue PTHrP(1–36) was evaluated in a small and short-term double-blind randomized placebo-control clinical trial (Horwitz *et al.*, 2003). A significant 4.7% increment in BMD of the lumbar spine was seen, with an increase in osteoblast activity as reflected by serum osteocalcin, but no increase in markers of bone resorption over placebo in the 3 months of therapy. This certainly supports a primarily anabolic effect of this peptide when given by daily s.c. injection.

Although all PTH peptides are currently under clinical development using the subcutaneous injection route, alternative delivery systems include:

1. Automated injection or transcutaneous delivery
2. Intranasal delivery
3. Oral, or buccal delivery
4. Transpulmonary delivery

Alternative delivery systems for PTH peptides are in the early stages of clinical evaluation (Morley, 2005). Intranasal delivery devices have been demonstrated for both PTH and calcitonin peptides, using lyophilized, microparticulate delivery systems (Deftos *et al.*, 1996; Nomura *et al.*, 1996). Transpulmonary systems have been developed in which aerosol delivery to the bronchoalveolar tree leads to 30% to 48% bioavailability of PTH peptide compared with that seen through intravenous routes of administration, with profiles of peptide absorption that are very similar to those delivered by subcutaneous injection (Patton *et al.*, 1994; Pfutzner *et al.*, 2003). Although noninjectable routes of PTH peptide delivery are still in

the realm of experimental medicine, there is no reason to believe that this compliance barrier cannot be crossed in the near future. In the short term, research using injectable PTH peptides has not been a significant barrier to patient compliance.

ADVERSE EFFECTS OF PTH THERAPY

More than 5000 patients have received PTH in published clinical trials. No serious adverse reactions have surfaced beyond the obvious effects on serum and urine calcium concentrations, the majority of which can be handled by appropriate dose reductions during the initial weeks of treatment (Neer *et al.*, 2001; Greenspan *et al.*, 2007). Nausea, headache, dizziness, arthralgia, and leg cramps following injection occur in 5% to 15% of women, in a dose-dependent fashion, but are unrelated to changes in serum calcium and are usually transient (Neer *et al.*, 2001; Greenspan *et al.*, 2007). Hodsman *et al.* (1997) raised a concern about the long-term safety of PTH on renal function. In this report, 39 patients were treated with cyclical high-dose teriparatide (800 units/day for four 28-day cycles per year over 2 years). This patient group experienced a significant 10% increase in serum creatinine (albeit within the normal range of age-related serum creatinine). Thus, PTH-induced hypercalciuria might conceivably affect renal function, but this observation has not been confirmed in the large Phase III clinical trials of teriparatide and PTH.

Osteogenic Sarcoma

A major issue for most patients considering PTH therapy is whether there is a risk of osteogenic sarcoma. The approval of PTH peptides for osteoporosis in most countries requires a warning on the package label, indicating the drug has been shown to cause osteogenic sarcoma in rats, and it is recommended that patients at higher risk for osteogenic sarcoma not be given the drug (i.e., Paget's disease, prior radiotherapy, previous bone tumors, and pediatric patients who are still experiencing skeletal growth). This warning is given because the major clinical trials of teriparatide were prematurely terminated when a concurrent carcinogenicity study documented a consistent dose-dependent appearance of osteogenic sarcomas in Fischer 344 rats. These animals were treated with near-lifetime daily injections of PTH (1–34), and developed an increased incidence of osteosarcoma after 18 months of dosing, by which time teriparatide has caused severe osteosclerosis and compensatory extramedullary hematopoiesis to occur (Vahle *et al.*, 2004). PTH did not increase the incidence of nonskeletal tumors.

Osteosarcoma has also been reported in a similar 2-year carcinogenicity study with hPTH(1–84) (Jolette *et al.*, 2006). There was a dose-related incidence of osteosarcoma in the mid (50 μg), and high (100, 150 μg) dose groups, similar to the incidence seen in the teriparatide studies. However, there was no difference in the low dose (10 μg/kg/d) compared with controls, suggesting that the intact hormone may not be as potent a stimulus to bone neoplasia in the rat skeleton.

Osteogenic sarcoma has not been reported in other species after similar dosing protocols (Neer *et al.*, 2001), and there is reason to believe the tumorogenic potential of PTH is much greater in the rat than in humans. The rat skeleton has an unusually exuberant response to PTH, perhaps related to its continual growth throughout life; the rat skeleton lacks Haversian systems and the cortical remodeling that is characteristic of the human skeleton (Vahle *et al.*, 2004; Tashjian and Chabner, 2002).

Since teriparatide's approval as a treatment of osteoporosis, one case of osteosarcoma has now been reported (Harper *et al.*, 2007). However, because more than 300,000 patients have been treated with teriparatide, this is not outside the expected 1:250,000 incidence in the older adult population (Harper *et al.*, 2007). In the two naturally occurring clinical conditions in which long-term increments in circulating PTH are well documented (primary and secondary hyperparathyroidism associated with chronic renal failure) there is no reported incidence of osteosarcoma (Kaplan *et al.*, 1971; Koppler and Massry, 1988; Maissonneure *et al.*, 1999; Vamvakas *et al.*, 1998). However, these conditions are analogous to continuous rather than intermittent PTH therapy, and the anabolic effect of PTH is much more evident with the intermittent dose regime.

Although the mitogenic potential for PTH has not been confirmed outside of the near lifetime duration of high-dose PTH in rat studies, PTH does appear to act as a growth factor within skeletal tissue and its receptor is widely distributed in other tissues. Therefore the oncogenic potential of these peptides should not be dismissed.

SELECTION OF PATIENTS FOR PTH THERAPY

Given the availability of other very effective anticatabolic therapies, the high cost of 18 to 24 months of PTH therapy governs the definition of the appropriate patient selection guidelines. In countries where PTH therapy of osteoporosis is approved by regulatory agencies, the criteria for patient selection are some variation of "very high risk of fracture" or "patients who have failed other osteoporosis therapies." The ideal patient for PTH therapy would appear to be one with very low bone mass, or multiple previous osteoporotic fractures, and therefore at high risk of fracture, but the definition of what degree of risk constitutes "high risk" is left up to the prescribing physician in most countries. Age is a major contributor to fracture risk, and most experts would avoid prescribing the drug to younger

adults (e.g., premenopausal women or men under age 60) whose only fracture risk is a low bone density.

Patients who have continued to fracture despite appropriate therapy with a bisphosphonate or other anticatabolic agent would also appear to be appropriate candidates for PTH. However, although this is a group of patients for whom many regulatory agencies have approved PTH therapy, no clinical trials with a fracture outcome have been conducted with PTH in patients who appear to have failed other osteoporosis therapies.

The following are typical guideline recommendations regarding the use of PTH (adapted from Hodsman *et al.*, 2006):

- PTH should be considered as a first-line therapy for women 65 years or older who have prevalent vertebral fractures, or other fragility fractures, and low BMD (T score $= -2.5$). Ideally, these patients should be bisphosphonate naïve, given the possibility that bisphosphonates might blunt the effectiveness of PTH. If already taking bisphosphonate therapy, these patients should stop the bisphosphonate prior to starting PTH. However, on the basis of the results of cost-effectiveness studies (Liu *et al.*, 2006; Stevenson, 2005), regulatory agencies will probably recommend that PTH should be reserved for the most severely affected patients (those with more than one fragility fracture and very low BMD).
- Other potential candidates for PTH include postmenopausal women with very low BMD (T score $= -3.5$) and those who continue to have fragility fractures despite an adequate trial of bisphosphonates (2-year period).
- PTH should be considered for men 65 years or older who have severe osteoporosis and prevalent fragility fractures.
- PTH should be considered for patients who are taking long-term corticosteroid therapy and have corticosteroid-induced osteoporosis and prevalent fractures.
- Therapy with an antiresorptive agent after completing teriparatide therapy is recommended to maintain or increase BMD.
- Baseline serum levels of calcium, PTH, uric acid, creatinine and 25-hydroxyvitamin D [25(OH)D] should be measured—and confirmed to be within acceptable normal limits—before PTH therapy is initiated. Serum calcium levels should be measured again, before injection, after the first month of therapy, because mild hypercalcemia will develop in a minority (about 10%) of patients during treatment. In patients with a history of renal stones, calcium levels in 24-hour urine collections should be measured.
- PTH should be avoided in patients who have primary hyperparathyroidism or who have significant renal impairment or vitamin D deficiency, and it should be used with caution in patients with a history of gout.

CONCLUSION

To date, the 25-year clinical experience of PTH therapy indicates that this is an important anabolic agent with the potential to reverse osteoporosis. Very few safety concerns have been raised over treatment periods of 2 to 3 years. The introduction of PTH peptides/analogues holds promise for a new class of anabolic agents that correct the bone mass deficit in addition to reducing fracture risk in osteoporotic individuals. A number of key points can be made:

1. PTH offers the promise of rapid increments in skeletal bone mass in osteoporotic subjects, and antifracture efficacy has been clearly demonstrated in Phase III clinical trials.
2. Data suggest that, although the effect of PTH treatment is most potent in increasing bone formation at trabecular sites, it is not detrimental to cortical bone and there is no evidence of increased risk of fracture in regions where cortical bone predominates.
3. Combining PTH with other osteoporosis therapies is not generally recommended, although it is not necessary to stop postmenopausal estrogen/progestogen therapy or SERMs when administering PTH. To date, clinical studies suggest that concurrent estrogen therapy and daily PTH injections result in significant increments in total body BMD as well as increments at axial sites, and if estrogen is continued, post-PTH bone loss is prevented. Similarly, it is likely that concurrent use of the SERM raloxifene would not interfere with PTH. In contrast, it is likely that concurrent (or prior) use of bisphosphonates (particularly alendronate) may be detrimental to the PTH effect, and certainly does not appear to add any benefit. Consequently, most guidelines would suggest stopping bisphosphonate therapy when giving PTH.
4. After PTH therapy is completed, there is gradual loss of the newly acquired bone mass. The addition of an anticatabolic therapy is therefore usually recommended after completion of a course of PTH. The bisphosphonate alendronate has been tested most often in this setting, and sequential therapy with alendronate results in further gains in both axial and appendicular bone mass. Other anticatabolic therapies (estrogen, SERMs) have also been shown to prevent BMD loss after PTH is stopped.
5. Cycles of PTH injections may be as effective as continued daily dosing, which may be an attractive approach, considering the cost of the available PTH preparations. This is an area for further research question has a significant impact on cost and compliance.
6. The long-term safety profile of PTH peptides remains to be established. Although hypercalcemia during the therapy is usually mild and transient, a small number

of patients have developed sustained hypercalcemia and hypercalciuria, and there is at least one report of declining renal function over time (Hodsman *et al.*, 1997).

7. Other unanswered questions:
   a. Does the skeleton develop resistance to continued PTH therapy?
   b. What is the optimal duration of therapy? The premature cessation of the first Phase III clinical trial, which showed fracture prevention, caused national regulatory agencies to limit duration of PTH therapy to the length of that study (1.5–2 years). Few (if any) investigators believe the occurrence of osteogenic sarcoma in rats receiving high-dose, near-lifetime PTH therapy has relevance to the use of PTH in osteoporotic humans.
   c. Do we have the right dose? The current approved dose of teriparatide is 20 μg daily, but many of the smaller studies (some of longer duration) used 25 μg or higher doses, with significant bone benefit and no appreciable increased risk of side effects. Similarly, for hPTH(1–84), perhaps 75 μg instead of 100 μg might have been as effective in preventing fractures and less likely to cause hypercalcemia.
   d. Would interval rechallenge be effective? If prior bisphosphonate therapy diminishes the therapeutic response to PTH, is there value in delaying PTH therapy until the skeleton recovers from bisphosphonate suppression of turnover?
   e. Although estrogen and SERMs do not seem to inhibit skeletal response to PTH and may even enhance it, what about other anti-catabolic agents currently in clinical trials, such as cathepsin K inhibitors (Kumar *et al.*, 2007) or RANKL inhibition with denosumab (McClung *et al.*, 2006)?
   f. Will analogues of PTH offer advantages as anabolic agents over hPTH(1–34) or hPTH(1–84)?

DEDICATION

Dedicated to the memories of an esteemed mentor, Dr. Louis M. Sherwood, and a treasured friend and laboratory colleague, Howard Cheng, who both passed away in 2007.

Chapter 79

Calcium

Robert P. Heaney*
Creighton University, Omaha, Nebraska

BACKGROUND

Calcium in the Environment in Which Life Arose

Calcium is the fifth most abundant element in the biosphere, after iron, silicon, oxygen, and aluminum. Unlike silicon and aluminum, whose compounds are quite insoluble, calcium salts exhibit an intermediate solubility that both permits them to be present in solution in the waters in which life evolved and to support development of various hard, solid organs for use by evolving life forms. Calcium is dissolved in seawater, for example, at concentrations up to 10 m*M*, about 10 times that which is found in the extracellular fluid of mammals. Even fresh water, if it is to support an abundant biota, must have substantial dissolved calcium (~1 to 2 m*M*, roughly on the order of mammalian extracellular fluid concentrations). Dissolved calcium is needed to keep carbon dioxide in solution for the photosynthetic activity of algae and aquatic plants, thereby establishing the base of the aquatic food pyramid.

The radius of the Ca^{2+} ion is just right to fit naturally into the folds of many proteins, coordinating with up to eight oxygen atoms in the peptide chain and its side groups. Calcium thus stabilizes critical tertiary structures of both catalytic and structural proteins (Carafoli and Penniston, 1985). This binding to key peptides is true, of course, for many metal cations, but most tend to be highly specific for one or two configurations (e.g., Fe, Mn, Cu, Zn, etc.). Magnesium, calcium's closest relative in the cell, and like calcium a divalent alkaline earth element, has a smaller ionic radius and does not bind as strongly as does calcium. Calcium, by contrast, binds avidly to a profusion of proteins, ranging from actin to calmodulin to the various *gla* proteins. Calcium's functionality is so broad, in fact, that essentially all cells have found it necessary to restrict calcium concentration in the cell sap to something like four to five orders of magnitude below that in the extracellularfluid (ECF) surrounding the cell. These low cytosolic concentrations are the context that permits cells to use calcium as a nearly universal second messenger. They do so by admitting controlled quantities into critical cellular compartments when specific functions are to be activated, and promptly pumping it out, either into the extracellular space or into intracellular vesicles, when the cell action is to be shut off. Intracellular storage of calcium is the rule, rather than the exception. Examples include the sarcoplasmic reticulum of muscle and calcium phosphate crystals in mitochondria. Calcium is so critical to intracellular function that most cells have developed means to maintain their own supply. In general, their dependence on extracellular calcium is limited to initiating the cascade by opening calcium channels in the cell membrane. Movement of ECF calcium into the cytosol through these channels then activates a much larger release of calcium from intracellular stores, as in muscle contraction.

However, life at a higher, multicellular level requires integrative functions and, therefore, the maintenance of critical concentrations of many factors in the ECF of complex organisms. Here, a higher calcium concentration (in the range of 1.25 m*M*) is essential for a variety of functions, ranging from neuronal synaptic transmission to blood clotting. Although ECF $[Ca^{2+}]$ is essentially constant across the higher vertebrates, the means whereby it is stabilized vary. Fish and amphibia have access to the calcium in the surrounding water and buffer the concentration of calcium in their extracellular fluids by controlling fluxes across the gill membranes. But terrestrial vertebrates, dependent upon periodic food ingestion for their calcium, need an internal source and sink of calcium for homeostasis. It is partly in this context that bone enters the scene.

Calcium and Bone in Evolutionary Perspective

Although the most obvious feature of bone in terrestrial vertebrates, and particularly in humans, is its structural property, it is likely that bone served somewhat different purposes in the early marine vertebrates (Urist, 1964). The fossil record indicates that bone evolved independently several

*Corresponding author: Robert P. Heaney, Creighton University, Omaha, NE 68178

times over the millennia of evolution—as dermal armor, as teeth, and as internal stiffening, often dropping out again in more modern descendants of ancestral bony members of the same classes. The internal stiffening and mechanical strength provided by bone, so obviously important on dry land, is of less significance in a buoyant medium, and there is a trend for fish to become less bony over the course of evolution. The modern sturgeon, a true bony fish by evolutionary origin, is essentially boneless today (except for the gill covers), but the fossil record shows that early sturgeons were quite as bony as most other modern fish. The *chondrichthyes* (sharks, skates, and rays), to cite another example, have only a cartilaginous skeleton, and yet do not lack for mechanical engineering efficiency.

Evolutionary biologists consider that the skeleton probably served an important homeostatic function, helping the organism maintain the constancy of critical elements in its internal milieu (Urist, 1962). That function is clearly evident in modern mammals, where the ion most prominently buffered by bone is calcium. There is reason to believe, however, that calcium may not have been the critical ion in marine vertebrates, because, as already noted, the surrounding sea provided a relatively large surplus of calcium relative to the ECF in most higher vertebrates. But phosphorus is a trace element in seawater, and the phosphorus essential for intermediary metabolism, for DNA and RNA structure, and for so many catalytic functions, is acquired by marine vertebrates by ingesting the tissues of other organisms lower in the food chain. Hence, phosphorus needs to be rigidly conserved. Bone meets that need.

Although the mechanisms by which bone serves a homeostatic function in terrestrial vertebrates are well worked out, it is less clear precisely how bone functions in maintaining internal homeostasis in fish. Fish produce many of the hormones involved in mammalian calcium and phosphorus homeostasis (calcitonin is an obvious example), but these agents do not seem to have the same effect on ECF [Ca^{2+}] in fish as in mammals. Furthermore, it is not certain in fish how minerals are either added to the bony reserve or withdrawn from it.

Bone as the Body's Calcium Sink and Reserve

Without a constant supply of calcium in the fluid bathing the gill membranes, land-living vertebrates were confronted with the problem of maintaining constancy of extracellular fluid calcium levels in the intervals between feedings. This required a place to put extra calcium acquired from food in the absorptive phase and a place from which to draw calcium during fasting. Bone is that place. However, bone is not simply a passive reservoir. As noted elsewhere in this volume, calcium is stored in bone mainly in the process of mineralizing newly deposited bone matrix, that is, by adding new volumes of bone *tissue*; and it is withdrawn from bone mainly by resorption of old bone *tissue*. Thus, the reservoir functions of bone are mediated by modulating, on a moment-to-moment basis, the balance between new bone formation and old bone resorption.

A good example of this modulation is afforded by what happens during calcium absorption from milk in infant mammals. The quantity of calcium ingested in a short period of time, coupled with the efficiency of absorption in infants and the small volume of the extracellular water into which that calcium is dumped, are such that near-fatal hypercalcemia would ensue if there were not some way to damp the absorptive rise in ECF [Ca^{2+}]. This is accomplished by calcitonin-mediated suppression of osteoclastic bone resorption. Because bone formation is continuing, the mineralization of recently deposited bone matrix effectively soaks up the absorbed calcium. Then, as absorptive input decreases, bony resorption resumes. The result is a nearly steady input of calcium into the ECF, with the relative contributions of bone and gut varying inversely.

It is virtually certain that most of the skeletal control of extracellular calcium levels throughout life is exerted on the resorptive side of the remodeling apparatus, for the simple reason that osteoclastic activity is susceptible to very rapid response to humoral mediators, whereas mineralization is not. Once suitable crystal nuclei are formed (see later), mineralization is mainly passive. The mineralization of newly formed bony units actually constitutes the principal systemic drain to which the control systems must respond (rather than functioning as a rapid response mechanism itself).

An example of the reservoir function of bone is seen during annual spring antler formation in deer (Banks *et al.*, 1968). Rapid bone growth in the antler buds creates a greater calcium demand than the nutrient-poor late-winter and early-spring foliage can satisfy. Because intestinal input cannot meet the demand, parathyroid hormone secretion increases and a burst of bone remodeling occurs throughout the entire skeleton. The first phase of bone remodeling is resorptive; hence, a great deal of calcium is thereby released into the ECF, countering the drain of antler bone mineralization. Several weeks later, when the skeletal remodeling loci reach their own formative stage, more nutrient-rich summer foliage has become available and antler growth has slowed. The deer are then able to pay back the skeletal calcium loan from food calcium sources. Something similar is seen in the deposition of medullary "egg bone" early in the egg-laying cycle in birds. Such bone is then resorbed during later phases of egg formation, when its calcium both supports shell formation and helps solubilize protein being transported to the oviduct. The same type of phenomenon occurs in preparation for lactation in most mammals, with pregnancy commonly being a time of more positive calcium balance than can be

accounted for by fetal mineralization, and then with substantial loss of bone during the hypoestrin state of lactation (Heaney, 1996). For example, the nursing rat, across lactation of a full litter of pups, loses on the order of one-third of the skeletal mass she had at delivery (Brommage and DeLuca, 1985).

Thus, understanding of the comparative biology of the skeleton helps us to see that bidirectional remodeling imbalances (decreasing and then augmenting local bone mass) are capable of both removing and replacing calcium from bone by tiny minute-to-minute alterations of bone mass. Except for the accumulation of remodeling errors, this in-and-out process would not be expected to exert a deleterious effect on bone; in fact, it probably has a net beneficial effect on bone quality, inasmuch as evoked remodeling seems to focus preferentially on old, fatigue-damaged tissue, replacing it with fresh, new bone. However, when withdrawals are protracted or payback is incomplete or absent, structural elements may be lost (Fig. 1). When this occurs, the loss becomes irreversible, inasmuch as the scaffolding for osteoblastic replacement vanishes. Nutrient repletion can be expected only to fatten up existing structures, not replace lost ones. In this sense, calcium differs from a nutrient such as iron for which full repletion of functional iron mass is possible even after loss of a major fraction of total body iron stores.

There is an important asymmetry about this bidirectional flux of calcium in and out of bone through the remodeling cycle. Although bone can be resorbed essentially without limit, there is a practical ceiling that governs how much calcium can be stored. Given an environmental abundance of calcium, bone mass is normally regulated not by nutrient availability but by a mechanical feedback loop that works to maintain bony strain under load at a constant level in all skeletal parts and regions. The bone setpoint (or "mechanostat") is poorly understood (as is true for most biological setpoints), but appears to involve the lipoprotein receptor-5 (LRP-5) that, in turn, controls osteoblast formation through the canonical Wnt signaling pathway (Robinson *et al.*, 2006). Animals with functional mutation of the LRP-5 gene produce more bone in response to mechanical loading than do animals with the wild-type gene (Robinson *et al.*, 2006).

The regulation of this setpoint is complex and poorly understood, but in addition to mechanical loading, it is influenced, at least in part, by estrogen [which explains why bone tissue is added to the skeleton at puberty (Gilsanz *et al.*, 1988) and during pregnancy (Heaney and Skillman, 1971) when estrogen levels rise, and withdrawn from it at menopause and during lactation (Brommage and DeLuca, 1985) when estrogen levels fall]. But under a hormonal steady state, bone balance will become zero when the optimal level of strain is reached. Additional dietary calcium cannot be stored. (See "Defining the Calcium Requirement".) The upshot is that, although the organism can withdraw calcium virtually without limit, storage is limited by the extent to which the skeleton continues to be subject to normal loading stresses, contingent upon preservation of structural elements and consistent with the setpoint of the bone mechanostat.

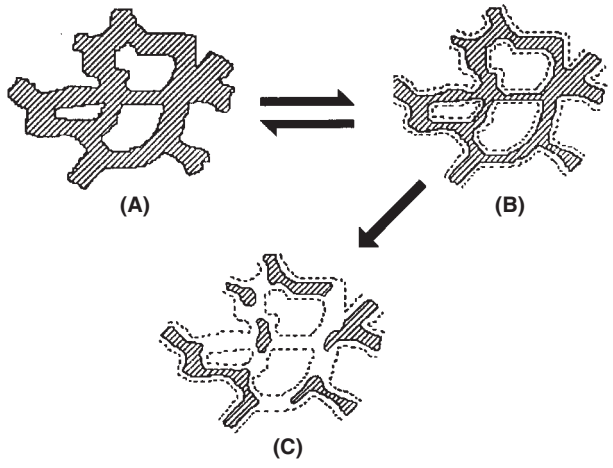

FIGURE 1 Schematic representation of the bidirectional flux of calcium in and out of the skeleton in a small volume of cancellous bone (**A** to **B**). Calcium is mobilized by resorbing bone tissue. So long as the basic structure is preserved (**B**), lost bone can be fully replaced. But when whole structures are resorbed (i.e., trabecular plates penetrated and trabecular beams severed i.e., **C**), replacement of lost bone becomes difficult or impossible. [Copyright Robert P. Heaney 1995. Reproduced with permission].

Calcium in Bone

The adult human body contains, on average, slightly more than 1 kg of calcium, better than 99% of which is in the form of bone and teeth. Calcium is the principal cation of bone, comprising slightly less than 40% of the mass of the bone mineral and slightly less than 20% of the dry weight of bone. Calcium exists in bone in a mineral form that is usually characterized as hydroxyapatite, i.e., $Ca_{10}(PO_4)_6(OH)_2$. This is only approximately correct, and it is more accurate to say, after Posner (1987), that bone mineral is a "structurally imperfect analogue of hydroxyapatite." Bone mineral contains, for example, carbonate, citrate, potassium, and magnesium, among other ionic species. Carbonate content is especially high. It varies fairly substantially from species to species, in humans comprising in the neighborhood of 6% to 9% of the mass of the mineral. Because the carbonate ion does not fit well into the hydroxyapatite crystal lattice, it is generally presumed to be located in superficial positions on the mineral crystals. The lability of bone carbonate, as reflected in changes in carbonate content with metabolic acidosis, suggests also that its location may be mostly on anatomic surfaces.

The crystals of bone exist in intimate association with the collagen fibers of the bone matrix. They are long and

needle-shaped, are ~70 Å in diameter and from 200 to 3000 Å long, and are constrained in size and orientation by the dense, orderly packing of the matrix collagen fibrils, which are laid down before mineralization begins. Matrix, as deposited, consists of about half protein and half water. As mineralization proceeds, mineral crystals displace the water, aligning themselves with the collagen fibrils. Ultimately, at full mineralization, the extracellular bony material contains virtually no free water. One consequence is the fact that mineral ions deep to anatomical surfaces are frozen in place, neither exchanging with nor supporting the level of the corresponding ionic species in solution in the ECF.

The calcification of matrix presents an interesting illustration of the importance of specificity of crystal habitus and takes advantage of the marginal solubility characteristics of calcium phosphate. Both calcium and phosphate, the latter in the form of H_2PO_4 and HPO_4^{2-}, circulate in the body fluids in solution and do not precipitate either in the blood stream or in healthy body tissues. However, the same minerals, in exactly the same concentrations, support mineralization when the blood flows past a bone-forming site. The reason, very simply, is that the concentrations of calcium and phosphate in ECF are such that body fluids are approximately half saturated with respect to $CaHPO_4$ (the most likely crystal form at physiological pH and pCO_2). However, bone mineralization is not simple precipitation. Rather, it involves the creation of a template for formation of a crystal more like hydroxyapatite or tricalcium phosphate [$Ca_9(PO_4)_6$]. Such minerals would not form spontaneously below pH 8; they are much less soluble, and body fluid concentrations of calcium and phosphate are approximately twice their K_{sp}. Local creation of such crystal nuclei is the means by which vertebrates have been able to control deposition of mineral, placing it only in loci specifically prepared to receive it, e.g., where it is needed to provide the necessary rigidity for the structural role of bone.

Noncollagenous matrix proteins are believed to play the critical role in configuring Ca^{2+} and PO_4^{3-} ions in space so as to create the hydroxyapatite template. Alkaline phosphatase, produced by the osteoblast late in the matrix deposition process, is believed to function by hydrolyzing pyrophosphate and organic phosphate esters present in the medium, which both makes extra phosphate available and removes components that otherwise function as crystal poisons, inhibiting crystal growth (Whyte, 1989).

The chemistry of formation of the apatite mineral can be summarized as

$$10\ Ca^{2+} + 3.5\ H_2PO_4^- + 2.5\ HPO_4^{2-} + 2H_2O \rightleftarrows Ca_{10}(PO_4)_6(OH)_2 + 13.5\ H^+$$

The proportion of $H_2PO_4^-$ and HPO_4^{2-} in extracellular fluid at body pH is such that this reaction produces ~13 protons for each unit cell[1] of hydroxyapatite formed. These must, of course, be removed from the mineralizing environment, or the reaction would cease or tend to run in reverse. By the same token, ~13 protons must be produced by osteoclasts to solubilize one unit cell of hydroxyapatite during bone resorption.

THE CALCIUM REQUIREMENT

What the Requirement Ensures

The strength of bone, as with all material structures, resides in four features: the instrinsic strength of the mineral–matrix composite, the massiveness of the structure, the geometric arrangement of the bony elements in space, and the loading history of a structural element, expressed in accumulated fatigue damage. A major mechanism by which calcium is recognized to influence bone strength is through its effect on bone mass. Because bone functions as the calcium nutrient reserve, it follows inexorably that any depletion of that reserve (or failure to produce the genetically programmed skeletal mass during growth) will carry with it a corresponding decrease in bone strength.

Additionally, it has recently been shown that, at prevailing calcium intakes, bone remodeling occurs at a rate considerably in excess of the need to repair fatigue damage (Heaney, 2003; Parfitt, 2004), and that this excess remodeling is a more important fracture risk factor than had been previously recognized. It is likely that contemporary calcium intakes, which are low by Paleolithic standards, are a part of the cause. In any event, supplementation reduces bone remodeling and reduces fracture risk as well (Heaney and Weaver, 2005).

As already noted, the calcium needed for critical cell-metabolic functions is, in most cells, derived from intracellular stores of the mineral. Bone constitutes such a large reserve of calcium that cellular functions could virtually never deplete it, no matter how low the oral intake of the nutrient. The same is true for the maintenance of ECF [Ca^{2+}]. A mere 5 g of bone contains as much calcium as the entire extracellular fluid space of an adult human. The requirement for calcium relates thus, not to the metabolic role of the nutrient, but to building and maintaining the size of the calcium reserve, i.e., to its secondary function, bone strength.

Calcium in the Environment in Which *Homo sapiens* Evolved

The abundance of calcium in the biosphere, previously noted, is expressed in the relatively high calcium content of the foliage, tubers, nuts, and other plant foods available to

[1] A unit cell, in this case containing 10 calcium ions, is the smallest, symmetrical repeating unit of the crystal lattice.

herbivorous and omnivorous mammals. The massive skeletons of extinct herbivores, the exuberant racks of antlers of deer and elk, both prehistoric and modern, and the large volumes of calcium-rich milk produced by dairy cattle today are all testimony to the abundance of calcium in a plant-based diet. Omnivorous animals, in addition to the calcium from plants, had access to the calcium in bones of animal prey, calcium in the chitinous exoskeletons of insects, and calcium in insect larvae and grubs.

Analysis of the foods consumed on a year-round basis by chimpanzees, our closest primate relatives, indicates a calcium nutrient density in their diets of 2 to 2.5 mmol (80 to 100 mg) Ca/100 kCal (Eaton and Nelson, 1991). The Kung people of South Africa have been found to have diets very nearly as high [1.75 to 2.0 mmol (70 to 80 mg) Ca/100 kCal]. Studies of other hunter–gatherer peoples indicate that their diets, too, have calcium nutrient densities in the range of those of the high primates. The energy expenditure of a hunter–gatherer or chimpanzee, scaled up to the body size of contemporary Western peoples, translates these nutrient density figures to a total calcium intake in the range of 50 to 75 mmol (2000 to 3000 mg)/day from plant sources. Riverine peoples, with bony fish in their diets, had still higher calcium intakes. By contrast with these pretechnological kinds of intakes, the diet calcium density of urbanized or industrialized nations is commonly less than 0.6 mmol (24 mg)/100 kCal (Carroll *et al.*, 1983).

The reason for the difference between primitive and contemporary diets is expressed graphically in (Fig. 2), which depicts schematically the effect on calcium nutrient density produced by the agricultural and pastoral revolutions (which can be dated to roughly 10,000 years ago, at least in the fertile crescent, and much more recently in the Western hemisphere and northern Europe). Domestication of animals and the development of flocks led to a nomadic lifestyle heavily dependent upon the milk produced by the pastoralists' herds. Farming, on the other hand, exploited natural hybrid forms of cereal grasses, which required humans for their propagation (mainly because the excess starch of the seed kernels made them too heavy for efficient dispersal by the wind). At the same time, the extra starch of the hybrids made it possible to feed a great many more people. The hunter–gatherer lifestyle makes very inefficient use of the land, and population pressures were one reason for the shift to farming or herding.

With this divergence, the pastoralists thus had a substantial increase in the calcium density of their food supply, whereas the agriculturists had a substantial decrease. By contrast with milks [at calcium densities in the range of 27.5 to 50 mmol (110 to 200 mg)/100 kCal], cereals typically have calcium densities less than 0.25 mmol (10 mg)/100 kCal. A contemporary example of a dominantly pastoral economy is provided by the Masai of East Africa, whose energy needs are largely met by fluid bovine milk, and whose calcium intakes, accordingly, are in the range of 150 to 175 mmol (6000 to 7000 mg)/day. It is likely that the actual calcium intake of the agriculturists was substantially higher than provided by the staple cereal grains, both because of other vegetables in the diet and because of adventitious calcium entering the food supply in the process of flour milling (Molleson, 1994). Grain was typically dehulled in limestone mortars, and the dehulled kernels then ground in limestone querns. Limestone is, of course, a calcium carbonate mineral; it is relatively soft and workable; and it undoubtedly added a great deal of calcium to the flour produced for bread making. Hence, it is likely that only with the development of a more advanced technology, which allowed large-scale milling and the construction of mill stones from harder minerals (silicon based rather than calcium based), that the calcium intake of technologically advanced, urban peoples fell to present levels.

Physiological Adaptations to a High Calcium Intake

The abundance of calcium in the environment in which hominids evolved undoubtedly influenced the physiological mechanisms for extraction of calcium from the food supply and for conservation of absorbed calcium. Mammals typically have low intestinal calcium absorption efficiency, unregulated cutaneous losses, and poor renal conservation. The significance of these features is perhaps seen most clearly by way of contrast with the physiological adaptations to another nutrient, one that was scarce in the early hominid environment, i.e., sodium, for which absorptive efficiency is complete and both cutaneous and urinary losses can be shut down to near zero. There is a cost to such conservation, of course, and it is likely that analogous mechanisms did not evolve for calcium because, given an environmental surfeit, they would have produced no selective

advantage for their bearer. Further, efficient extraction of calcium from food sources would not only have been unnecessary; it would have been dangerous, for the excess would have had to be excreted, lest it lead to hypercalcemia and extraosseous calcification.

Exposure to chronic dietary calcium scarcity is a relatively modern phenomenon, as has been already noted, and fewer than 100 generations have elapsed for most of our lineages between the time of calcium surfeit and the present. This is far too few for the evolution of calcium-conserving mechanisms, particularly when the selective advantage of health at the end of life is much less strong than health during the reproductive years.

Studies Manipulating Calcium Intake

The importance of calcium intake on bone mass has been extensively documented in a number of species. As far back as 1929, Bauer, Aub, and Albright showed that cats developed severe bone loss when placed on low calcium diets. This work has been replicated in rats and dogs (e.g., Bodansky and Duff, 1939) and has been repeated several times in cats (e.g., Jowsey and Gershon-Cohen, 1964). Fig. 3, from one such study, depicts a classical nutritional experiment, in which a nutrient is first removed, the morbid result observed, and then the nutrient restored and recovery noted. The bone loss occurring under these circumstances is dependent upon intact parathyroid function (Jowsey and Raisz, 1968); in the absence of parathyroid hormone, the bone loss is prevented, although at a cost of severe hypocalcemia. These experiments, incidentally, highlight both the central role of bone as the calcium reserve for ECF calcium levels and the importance of parathyroid hormone in releasing calcium from bone to sustain ECF [Ca^{2+}].

Over 20 randomized controlled trials in humans have been published in recent years, establishing that elevating calcium intake enhances bone acquisition during growth, slows bone loss in postmenopausal women, and reduces fracture rates at spine, hip, and other extremity sites. These studies are reviewed in detail elsewhere (Heaney, 2000). One clear example of these effects is seen in the report by Chapuy *et al.* (1992) involving nearly 1800 French women, average age 84 (Fig. 4). Elevating calcium intake from ~13 mmol (520 mg)/day to ~42.5 mmol (1700 mg)/day reduced fracture rate at both hip and other extremity sites by 20% to 40% within 18 months of starting supplementation. The effect on bone mineral density (BMD) was fully as striking as the effect on fracture rate. Control subjects lost ~4.6% of the bone from the hip site over the 18 months of observation (an annual rate of ~3%/year), whereas the supplemented individuals gained 2.7%. The result was a greater than 7% difference in hip bone mass by 18 months. Clearly, 13 mmol Ca/day was not sufficient to prevent erosion of bone mass, whereas 42.5 mmol Ca/day was.

It may be that some of the benefit obtained in this trial was owing to vitamin D repletion, and some also to the added phosphorus contained in the supplement (e.g., on muscle function and coordination); however, the bone mass effect observed in this study was large enough to account for much or all of the fracture difference in its own right. Furthermore, in two further trials in which the control and the calcium-supplemented individuals were both given vitamin D supplements, a similar bone-sparing and fracture-reducing effect was observed in the

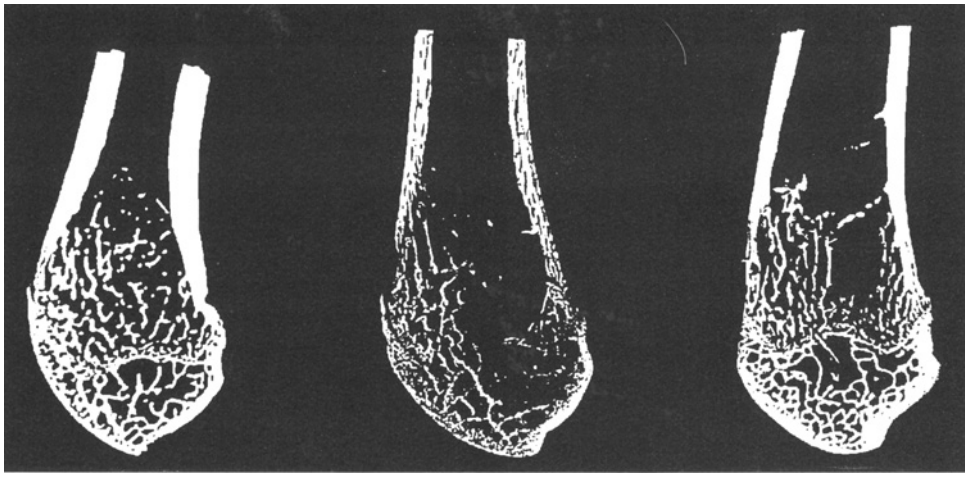

FIGURE 3 Effect of calcium deprivation and repletion on bone mass in cats, as revealed by micro x-rays of thin slices of undecalcified cat femora. The bone structure is shown (*left*) of a cat fed a normal, high calcium diet, a cat fed a low calcium diet for just 20 weeks (*center*), and a cat depleted for 10 weeks and repleted for 10 weeks (*right*). Bone loss in the central panel is evident. The right-hand panel shows partial healing. [Redrawn from Jowsey and Gershon-Cohen (1964).]

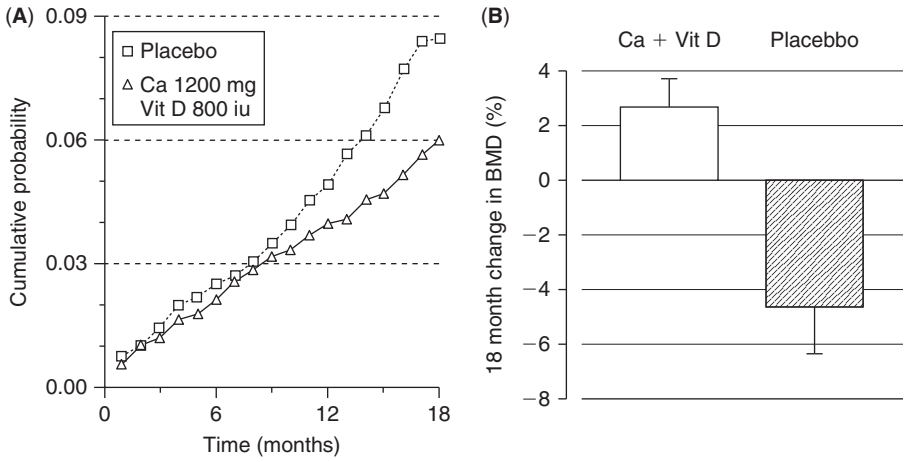

FIGURE 4 Effects of supplementation with calcium phosphate and vitamin D on hip fracture rate and hip BMD. The cumulative probability of fracture for the supplemented and unsupplemented groups is shown (**A**), as is the change from baseline in hip BMD for the two groups (**B**). [Redrawn from the data of Chapuy *et al.* (1992).]

calcium-supplemented individuals (Chevalley *et al.*, 1994; Recker *et al.*, 1996). In a more recent study, contrasting calcium and vitamin D, Peacock *et al.* (2000) showed that, although calcium alone was able to prevent bone loss entirely, vitamin D alone was not. [It should be noted that serum 25(OH)D levels in Peacock's study were substantially higher than in the study by Chapuy *et al.*, and thus some beneficial effect of vitamin D in the French women cannot be excluded.]

Although there is, obviously, a limit to how much fracture reduction can be achieved when one waits to ingest an adequate intake until old age, it is noteworthy that the elderly seem to be both more sensitive to calcium deprivation and more responsive to calcium supplementation than are younger individuals. This is illustrated, for example, in risk gradients for various ages reported by Hui *et al.* (1988) (Fig. 5). Although the risk of fracture rises with declining bone mass at all ages, risk rises also with age itself, even holding bone mass constant. In fact, as Figure 5 makes plain, the age effect is larger than the bone density effect. The gradient of risk on bone density also becomes steeper with age. Thus, whereas reducing bone loss in a 60-year-old woman would be expected to produce a modest fracture benefit, the same reduction in bone loss in an 85-year-old produces a much greater reduction in fracture risk. It is not certain why this should be so, but it is likely that the age effect itself is because of increased falling, poor reflex adjustment during the fall, decreased soft tissue padding over bony prominences, and increased intrinsic skeletal fragility from nonmass causes [trabecular disconnection, excessive remodeling, and accumulated fatigue damage (Heaney, 1993a)]. Interaction among these factors may explain the disproportionately large benefit of altering just one of them (i.e., bone mass or bone remodeling).

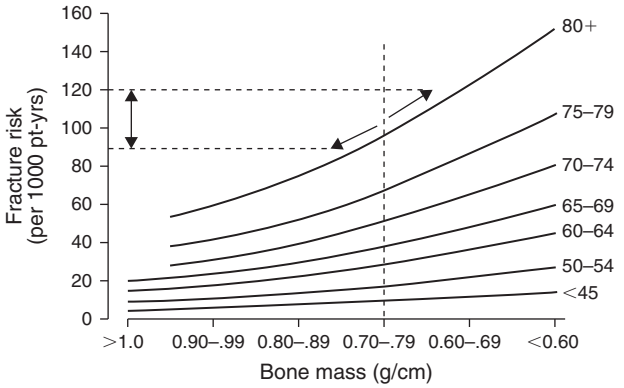

FIGURE 5 Age-specific fracture risk gradients for forearm BMD. Note the rise in risk with age, even holding BMD constant. Note also the increasing steepness of the gradients with age. A relatively small difference in BMD thus produces a greater fracture effect in the elderly than in younger individuals. [Redrawn from the data of Hui *et al.* (1988).]

Defining the Calcium Requirement

The calcium requirement can be defined as the intake needed to support genetically programmed acquisition of bone during growth and to sustain acquired bone during maturity and the declining years of life. Because of differing absorption and retention efficiencies, individuals will inevitably have differing requirements for a skeletal endpoint. A recommended dietary allowance (RDA) is a figure designed to be at about the 95th percentile of individual requirements. Hence, if everyone in a population were ingesting at least as much as the RDA, that intake would ensure that 95% would be getting as much as they need.

Calcium intake recommendations have undergone substantial revision over the past 15 years and the formats for

TABLE I Various Estimates of the Calcium Requirement in Women*

Age	1989 RDA†	NIH‡	1997 DRI§
1–5	800	800	600/1000
6–10	800	800–1200	1000/1600
11–24	1200	1200–1500	1600/1200
Pregnancy/ lactation	1200	1200–1500	1200
24–50/65	800	1000	1200/1450
65–	800	1500	1450

*All values are given in milligrams, because this is how the respective bodies reported their recommendations. To convert to SI units, divide the values in the table by 40.

‡National Institutes of Health (NIH) Consensus Conference: Optimal Calcium Intake. (1994). J. Am. Med. Assoc. **272,** 1942–1948.

§Dietary Reference Intakes (DRIs) for Calcium, Magnesium, Phosphorus, Vitamin D, and Fluoride. Food and Nutrition Board, Institute of Medicine. National Academy Press, Washington, DC, 1997. The figures given are calculated as RDAs to facilitate comparison with earlier estimates. The published values were termed "Ais," which in this instance represent estimated average requirements (EARs). The RDA figures shown here are 20% higher than the corresponding EAR. The presence of two values in this column reflects the fact that the age categories for the DRIs overlapped those of the NIH.

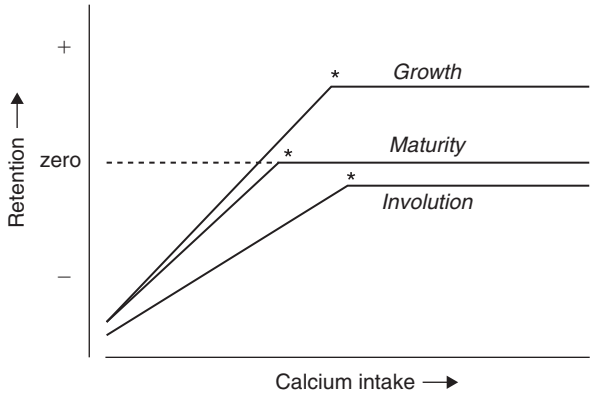

FIGURE 6 Schematic depiction of the relationship between calcium intake and skeletal retention at three life stages. Given sufficient intake, retention is positive during growth, zero at maturity, and variably negative during involution. Intakes above the threshold do not affect retention, but subthreshold intakes limit bone acquisition or lead to bone loss. The location of the minimum requirement is indicated by the asterisk above each line. (Copyright Robert P. Heaney 1998. Used with permission.)

presenting them have been altered as well. Table I sets forth both the earlier and the current recommendations, using a standardized format to facilitate their comparison. Perhaps the most important of the recent changes is the recognition that the requirement rises substantially in the elderly. This elevated need reflects the age-related decline in ability to adapt to low intakes, and thus in a sense uncovers the optimal intake for all ages, i.e., the intake for which no adaptation would be needed. It is worth recalling, in this connection, that even though the recommended intakes may seem high by contemporary practice, they are still only a fraction of what the primitive human intake would have been for individuals of modern body size.

As previously noted, calcium is a threshold nutrient. This means that, at subthreshold intakes, calcium retention is less than optimal. Bone gain during growth is then a direct function of intake (i.e., it is less than is genetically programmed), whereas in the mature organisms, subthreshold intakes lead to actual bone loss. On the other hand, the threshold character of the relationship means that intakes above the threshold produce no additional bone effect. (See also "Bone as the Body's Calcium Sink and Reserve.") These relationships are depicted schematically in (Fig. 6). Because the approach to the threshold is asymptotic, it is difficult to define the precise point at which retention plateaus. For this reason, current recommendations are actually somewhat conservative. Some hint that the optimal intake may be substantially higher than even the newer recommendations is provided by several lines of evidence. One comes from the balance studies of Heaney *et al.* (1978), in which the *mean* requirement to maintain zero balance in estrogen-deprived women was ~37.5 mmol (1500 mg). An RDA would, inevitably, be higher still. Another pointer in that direction is found in a randomized controlled trial in elderly women supplemented with calcium for 3 years (McKane *et al.*, 1996). Unsupplemented individuals, with intakes averaging close to 20 mmol (800 mg)/day (the then applicable RDA for the age), exhibited the high 24-hour mean parathyroid hormone (PTH) levels, the enhanced PTH secretory reserve, and the elevated bone resorption that have all been taken to characterize the calcium and skeletal economies of the aged (Epstein *et al.*, 1986). By contrast, women supplemented to 60 mmol (2400 mg)/day decreased both their bone remodeling and parathyroid functional indices, restoring them to young adult normal values. The inference is that the increases in parathyroid cell mass and function represent not so much characteristics of old age as adaptive responses to longstanding calcium deprivation.

Contributing causes for this increased parathyroid activity in the elderly, aggravating the effect of low calcium intakes, include a decline in vitamin D status with age (reflecting both decreased solar exposure and decreased efficiency of skin conversion of 7-dehydrocholesterol to previtamin D) and declining absorption and conservation efficiency for dietary calcium. Holding calcium intake constant at about 20 mmol (800 mg)/day, gross absorption efficiency declines from a mean at age 40 of ~0.24, at a rate of 0.002/year through at least age 65, with a one-time additional drop of 0.02 at menopause (Heaney *et al.*, 1989). Over that period, the decline thus amounts to 0.07, or a fall

of ~30% in absorptive efficiency. Nordin and others have shown also that renal conservation of calcium deteriorates across menopause (e.g., Nordin *et al.*, 1991). The net result is that extraction of ingested calcium from food falls with age and conservation of that which is absorbed falls as well. These and similar findings from a number of investigators are the basis for the jump to 36 to 38 mmol (1450 to 1500 mg)/day in the 1994 and 1997 recommendations for the elderly in Table I.

It must be noted that the absorption values cited earlier are *gross* absorption, such as would be measured by calcium tracer flux from the intestinal lumen into the blood stream. They do not account for the contrary movement of calcium into the lumen in the digestive secretions and sloughed off mucosa (which turns over at a rate of ~20%/day). In adult women, this calcium from endogenous sources entering the intestinal stream amounts to ~3.5 to 3.75 mmol (140 to 150 mg)/day (Heaney and Recker, 1994). Most of this calcium is subject to the same absorptive probability as is ingested calcium, but given the low efficiency of calcium absorption in general, inevitably most endogenous calcium will be lost into the feces. Thus *net* absorption from intakes in the range of 20 mmol (800 mg)/day is on the order of only 10% to 15% of ingested calcium. Not all of even this small amount of net calcium gain from the intestine can be retained, because the tiny elevation of blood calcium produced when calcium is absorbed elevates the filtered load at the kidney and leads to an increase in urinary calcium loss.[2] The net result of the low net absorption and poor renal conservation is that, even during times of calcium need, only a small fraction of an ingested load is retained. Further, at the higher intakes achieved by calcium supplements, *fractional* retention is smaller still, because absorption fraction declines with the logarithm of the intake load size (Heaney *et al.*, 1990, 2000).

Nutritional Factors Influencing the Calcium Requirement

It is a truism of nutritional science that nutrients interact with one another and thereby alter their mutual requirements. Thus, requirements of certain of the B vitamins and of ascorbic acid vary with total energy intake (and expenditure). The lack of evolutionary development of efficient conservation of calcium has rendered this nutrient unusually sensitive to such nutrient–nutrient interactions. Most of this interaction is expressed in urinary calcium excretion, which, for example, is strongly influenced by the ingested load of, for example, sodium and by the acid/alkaline residue of the diet (Heaney, 1993b; Sebastian *et al.*, 1994). The sodium effect is owing to the fact that sodium and calcium share a common transport mechanism in the proximal tubule, and thus an increased filtered load of either ion will lead to increased excretion of the other. The magnitude of the sodium effect on the calcium economy is an increase of 0.5 to 1.5 m*M* of urine calcium for every 100 m*M* sodium ingested (Devine *et al.*, 1995; Nordin *et al.*, 1993, Itoh *et al.*, 1996).

These effects are linear across the full range of prevailing intakes from low to high, and are not thus consequences only of excessive intakes. With diets characteristic of typical North American and European women, nutrients such as sodium account for ~100 mg/day of obligatory calcium loss through the kidneys. Given the extremely poor net absorption efficiency for calcium, these nutrients can thus easily account for up to 1000 mg/day of the calcium requirement. It has been noted, for example, that individuals with low, but nutritionally adequate, intakes of sodium may have calcium requirements as low as 500 mg/day, whereas those with intakes more typical of contemporary patterns, may have intake requirements closer to 2000 mg/day. This quite extraordinary sensitivity of calcium to the intakes of other nutrients is but one more reflection of the lack of evolutionary acquisition of efficient mechanisms for calcium absorption and conservation.

The well-documented effect of the acid/alkaline residue of the diet (Berkelhammer *et al.*, 1988; Sebastian *et al.*, 1994) is probably a function of the "hard" anions (sulfate, chloride), either ingested with food or produced in metabolism. In any event, substitution of acetate or bicarbonate for chloride produces substantial reductions in urinary calcium loss and therefore in the ability to maintain calcium equilibrium on low calcium intakes.

It is important to stress this latter point, that these nutrient interactions negatively affect calcium balance mainly at low calcium intakes. This is because they limit an individual's ability to adapt to a low intake. At the higher intakes typical of those that prevailed during hominid evolution, adaptation is easily possible, and high protein intakes, for example, do not then have a negative effect on the skeleton. [Indeed, such evidence as is available indicates that the net effect of protein on the skeleton is distinctly positive, overall (Delmi, 1990; Schürch *et al.*, 1998; Hannan *et al.*, 2000).]

Toxicity

It is possible to consume too much of any nutrient, and calcium is no exception. However, in healthy individuals, available evidence indicates that the toxic threshold is quite high. Many young adult males in the Unites States regularly consume more than 75 mmol (3000 mg)/day (Carroll *et al.*, 1983), and in pastoralist societies, such as the Masai of East Africa, calcium intakes regularly average more than

[2]This sensitivity of urine calcium to variations in the filtered load is a reflection of the previously mentioned lack of evolutionary development of efficient calcium conservation mechanisms.

150 mmol (6000 mg)/day. In both instances, there are no known ill effects associated with such intakes.

However, there are special circumstances in which high calcium intakes can definitely be harmful. Even at the low-absorption fractions typical of high intakes, substantial quantities of calcium will enter the body and will need to be excreted in the urine (unless active bone building is occurring). Under conditions of dehydration or hypovolemia, perfusion of both bone and kidney can be sufficiently compromised so that absorbed calcium produces significant hypercalcemia. Likewise, under conditions of systemic alkalosis, large calcium intakes can produce renal calcinosis and severe impairment of kidney function. Furthermore, under these somewhat unusual and extreme circumstances, elements of positive feedback can cause the situation to deteriorate rapidly. Hypercalcemia impairs the ability of the kidney to retain water and thus aggravates a preexisting dehydration, with consequently worsening hypercalcemia. A fatal downward spiral can easily ensue. Published reports of such toxicity have generally involved intakes of more than 150 mmol (6000 mg)/day in individuals with preexisting impairments of water and electrolyte metabolism. Whatever the underlying cause, such problems can be easily handled by rehydration and by correction of the underlying abnormality, so long as these situations are recognized in time.

Kidney stones are perhaps the complication most often thought to be associated with high calcium intakes. However, this association has been largely speculative and is not based on clinical evidence. Most multiple regression analyses of risk factors for renal calculi have found either a very weak or no association at all for calcium intake. Two very large observational studies, in fact, found the converse (Curhan *et al.*, 1993, 1997). In the first, a prospective study of more than 45,000 men, there was an inverse correlation between calcium intake and stone formation; those with the highest calcium intakes had the lowest risk of kidney stones. This seeming paradox is explained by the fact that oxalate excretion in the urine is a more significant risk factor for calculi than is urine calcium. High calcium intakes bind oxalate both of dietary origin and that produced by bacterial fermentation in the gut before it can be absorbed; dietary calcium thereby lowers the renal oxalate burden. In fact, very large calcium supplements have long been standard therapy for the kidney stones occurring with intestinal hyperoxalosis, sometimes found in patients with short-bowel syndromes. A protective effect of high calcium intake on both oxalate loads and stone recurrence was seen in a randomized controlled trial in which those on a reduced calcium intake had twice the rate of stone occurrence as those on a high intake (Borghi *et al.*, 2002).

In summary, the levels of calcium intake discussed in the foregoing sections of this chapter, as well as those needed to support osteoporosis pharmacotherapy (see "Calcium and Osteoporosis Treatment"), are well within the safety limits for the ingestion of this nutrient.

Interpretation of Published Reports

The importance of a high calcium intake for bone health has often been questioned (e.g., Kanis and Passmore, 1989) and, even more often, has been termed "controversial." This is because some studies showed strong effects of calcium intake on bone status, but others showed no benefit at all. "Confusing" would have been a more accurate term. There are several reasons for these apparent discrepancies, now sufficiently understood to remove any confusion that may remain.

First, as already noted, osteoporotic fracture is a distinctly multifactorial affair. Nutrition, and particularly calcium nutrition, is only one of many contributing factors. Although calcium intake is, as the discussion above indicates, of critical importance in many individuals, it plays little or no role in others, just as iron intake is limiting in only certain forms of anemia. One example of this distinction is seen in menopausal bone loss, which is dominantly caused by estrogen deficiency and cannot be substantially influenced by calcium intake (although estrogen-related loss may be exaggerated if calcium intakes are very low) (Heaney, 1990). This is seen, for example, in the fact that even intakes of more than 75 mmol (3000 mg)/day, in the study by Elders *et al.* (1991), were able only to slow menopausal loss, not to prevent it.

However, menopausal loss is self-limited and is mostly confined to the 5-year period surrounding cessation of ovarian function. Every controlled trial of calcium supplementation in women more than 5 years postmenopausal has, without exception, shown a clear benefit on either bone loss or fracture rate or both. By contrast, roughly one of five observational studies performed on women in this same age group have failed to show a calcium effect (Heaney, 1993b, 2000); this is now understood to be because of the weak ability to estimate calcium intake from food records, or food frequency questionnaires, no matter how carefully these methods are applied, resulting in substantial classification bias (Heaney, 1991, 1997).[3] Usually in clinical science, one encounters positive results from observational studies, which are then sometimes not borne out in studies employing the more rigorous design of randomized controlled trials. With calcium, we have the paradoxical situation that the randomized controlled trials are essentially all positive, whereas some of the observational studies are not, and even those that are positive often show what appear to be weak effects. As the controlled trials show, it is not the effects that are weak, but the methods that must be employed in observational studies.

A final consideration relates to the uncritical use of transnational comparisons (e.g., Hegsted, 1986). Differences

[3]There are many sources of this estimation error. One of them, often ignored, is the fact that actual calcium contents of various foods vary over a roughly threefold range (from low to high) around the nominal values in the standard food tables.

in fracture rate between ethnic and national populations have many bases, only some of them nutritional. An example is the lower hip fracture rates of contemporary Chinese and blacks, despite mean calcium intakes for both groups that are lower than those of North American or European Caucasians. Behind this difference there is, first, the large effect of the other nutrients in the diet, previously described. Thus, the predominantly vegetable-based and low protein intakes of many Third World populations would be expected to lower their calcium requirements. Similarly, there are major racial differences in ability to conserve calcium. American blacks, for example, both absorb at higher efficiency for any given ingested intake and conserve better at the kidney than do Caucasians (Abrams *et al.*, 1995; Bell *et al.*, 1985, Aloia *et al.*, 1998, Cosman *et al.*, 1997). Thus they have lower calcium requirements. Finally, there are important racial differences in bone geometry that have their own effect on fracture rate. Hip axis length, for example, explains most or all of the difference between the hip fracture rates of Caucasians on the one hand, and Chinese and Japanese, on the other, after adjusting for bone mass (Faulkner *et al.*, 1993; Nakamura *et al.*, 1994).

Instead of making cross-cultural comparisons, the correct approach is to assess the effect of nutrient intakes *within* a cultural and ethnic group. When this has been done, for example, in both American blacks and in Chinese, bone mass and hip fracture rate are found to be inversely correlated with calcium intake, just as has been found for Caucasian populations (Anderson *et al.*, 1995; Hu *et al.*, 1993; Lau *et al.*,1988).

CALCIUM AND OSTEOPOROSIS TREATMENT

Effective osteoporosis treatments involve a combination of pharmacotherapy designed to reverse the negative remodeling balance prevailing in the skeleton and physical therapy designed both to increase function and to increase mechanical loading on the skeleton. Currently recommended calcium intakes are presumably adequate to sustain bone mass, but they may not be sufficient to support bone gain in most individuals for reasons just noted (i.e., net absorption from such intakes is just sufficient to offset obligatory losses). Furthermore, there is essentially no evidence that calcium alone, in any quantity, will lead to substantial gain in bone in individuals who already have osteoporosis. The small increase noted in the study by Chapuy *et al.* (1992) described earlier (see Fig. 4) probably reflects a remodeling transient (Heaney, 1994) and not a new steady-state rate of change. However, effective *pharmaco*therapy, including fluoride (Pak *et al.*, 1995; Riggs *et al.*, 1990), the bisphosphonates (Liberman *et al.*, 1995; Black *et al.*, 1996; Cummings *et al.*, 1998; Harris *et al.*, 1999), the selective estrogen receptor modulators (SERMS) (Ettinger *et al.*, 1999), and PTH (Kurland *et al.*, 2000; Neer *et al.*, 2001), does increase bone mass, and for some of these agents at a rate of up to 8% per year. To realize this potential gain, and particularly to optimize it, calcium intakes probably need to be above the maintenance level, i.e., for most osteoporotic individuals that means above 37.5 mmol (1500 mg)/day. Few controlled trials at such intakes have been done, so this conclusion is to some extent an inference from the data summarized in the foregoing. Also, it is worth noting that the antiresorptive agents (principally bisphosphonates and the SERMs, as well the RANK ligand and cathepsin K inhibitors), by blocking osteoclastic resorption, force higher levels of PTH secretion and hence better utilization of ingested calcium. Hence, the calcium intake requirement for optimal BMD response to these agents is unclear.

There is, however, some evidence. With respect to fluoride, Dure-Smith and associates (1996) showed, during effective fluoride therapy, an extraordinary degree of bone hunger, suggesting the need for calcium intakes during fluoride therapy of perhaps as much as 62.5 mmol (2500 mg)/day. Other clear examples of the importance of ensuring adequate calcium intake when using other bone active agents are provided by a series of recent papers. First is a meta-analysis of 31 controlled trials of estrogen replacement therapy (Nieves *et al.*, 1998), which showed that estrogen in trials using supplemental calcium (at an average intake of 1187 mg/day) produced bone responses more than twice as great as those that did not (at an average intake of 583 mg/day). Additionally, Recker *et al.* (1999) showed that a reduced dose of estrogen (0.3 mg of conjugated equine estrogens) produced a 5% increase in bone mass in women given supplemental calcium and vitamin D. By contrast, in at least three earlier trials without supplemental calcium, this estrogen dose was essentially ineffective.

SUMMARY

Calcium is the principal cation of bone, making up ~20% of its dry weight. Bone constitutes a very large nutrient reserve for calcium in terrestrial vertebrates, a reserve that has acquired a major mechanical function. The requirement for calcium is related to the protection of this mechanical function, not to the metabolic actions of calcium, which could be adequately protected by a reserve several orders of magnitude smaller. Calcium was abundant in the environment in which hominids evolved and in the foods they ate. Probably as a consequence, efficient calcium conservation mechanisms did not develop. Contemporary diets are low in calcium by comparison, and our Paleolithic physiologies are poorly adapted to them. Yet other features of the modern diet (e.g., salt) increase obligatory calcium loss and thereby reduce the ability to adapt to lowered intakes.

The evidence is compelling that inadequate calcium intake weakens bone and contributes to the growing osteoporosis problem. A fully adequate calcium diet for persons age 65 and older, consuming otherwise typical Western diets, would contain more than 37.5 mmol (1500 mg)Ca/day and perhaps as much as 60 mmol (2400 mg)/day.

Chapter 80

Drugs Acting on the Calcium Receptor

Calcimimetics and Calcilytics

Edward F. Nemeth*
32 Elgin Avenue, Toronto, Ontario, Canada,

INTRODUCTION

Bone and mineral-related diseases are a heterogeneous group of disorders affecting nearly every major organ system in the body. By far the most common disorder is osteoporosis, a disease characterized by reduced bone density and an increased susceptibility to fractures. Less common, but also associated with altered bone metabolism, are primary and secondary hyperparathyroidism. All these disorders are associated with aging, especially in women and, as the world population ages, these diseases are becoming more prevalent. Drugs that alter the circulating levels of parathyroid hormone (PTH) provide one means of treating hyperparathyroidism and possibly osteoporosis.

The secretion of PTH from parathyroid glands can be influenced by a number of factors acting in endocrine or paracrine fashion but the most important is serum calcium. Changes in the level of extracellular calcium are detected by a cell surface calcium receptor, a G protein-coupled receptor whose primary physiological ligand is ionized extracellular calcium (Ca^{2+}). Like many other G protein-coupled receptors, the calcium receptor has recently emerged as a viable drug target.

This chapter reviews the progress made in the discovery and development of calcimimetics and calcilytics, ligands that act as activators and inhibitors, respectively, of the calcium receptor. The most significant advance since the second edition of *Principles* is the regulatory approval of the first calcimimetic for treating some forms of hyperparathyroidism: cinacalcet•HCl. The development of calcilytics for treating osteoporosis has been more challenging but some progress has been made.

THE CALCIUM RECEPTOR

The calcium receptor is a G protein-coupled receptor that shares structural homologies with other members of subfamily C receptors. This subfamily includes the metabotropic glutamate receptors (mGluRs), γ-aminobutyric acid type B receptors ($GABA_BRs$), and some pheromone and taste receptors. All of these receptors are large by G protein-coupled receptor standards, particularly their extracellular domain, which binds the cognate physiological ligand glutamate, γ-aminobutyric acid, or extracellular Ca^{2+} (Brauner-Osborn *et al.*,1999; Hammerland *et al.*, 1999). The human parathyroid calcium receptor encodes a protein of 1078 amino acids and it is 92% and 93% identical with the rat kidney and the bovine parathyroid cell calcium receptors, respectively. At present, only one gene coding for the calcium receptor has been identified; no receptor subtypes have been found and splice variants of the calcium receptor are few and of low abundance (Garrett *et al.*, 1995a). Within family C, the most structurally homologous receptor is GPRC6A, which might use basic amino acids as physiological ligands (Conigrave and Hampson, 2006).

Calcium receptors are expressed on many of the tissues involved in systemic calcium homeostasis. In addition to parathyroid cells, parafollicular cells of the thyroid (C cells) and epithelial cells along the nephron express high levels of calcium receptor messenger mRNA and protein (Brown and MacLeod, 2001). Epithelial cells throughout the gastrointestinal tract and parietal cells and G cells in the stomach likewise express the calcium receptor (Hebert *et al.*, 2004). At all these sites the calcium receptor messenger RNA transcripts appear to be identical and, as assessed by Western blotting, the final protein products expressed at the cell surface are similar. The major differences between calcium receptors expressed in different tissues are post-translational and seemingly involve different patterns of glycosylation (Ray *et al.*, 1998; Bai, 1999). In C cells the calcium receptor

Principles of Bone Biology, 3rd Edition

regulates the secretion of calcitonin (Raue and Scherübl, 1996); in the kidney it is mostly involved in the transport of Ca^{2+} and Mg^{2+} (Ba and Friedman, 2004).

The calcium receptor mediates the initial events of stimulus-secretion coupling in parathyroid cells and is the key element in the primary physiological mechanism regulating PTH secretion. There are three separate lines of evidence supporting this conclusion. The first derives from molecular genetic studies of patients with the inherited disorders familial benign hypercalcemic hypercalciuria (FBHH) or autosomal dominant hypocalcemia (ADH; see Brown, 2007). These disorders result from point mutations in the calcium receptor gene that result in receptor proteins having altered sensitivity to extracellular Ca^{2+}. The mutated calcium receptors in FBHH patients are less sensitive (or completely insensitive) to activation by extracellular Ca^{2+} and this molecular defect is manifest in the phenotype: these patients are hypercalcemic, yet their plasma PTH levels are generally within normal limits. Conversely, the mutant calcium receptors in ADH are more sensitive to activation by extracellular Ca^{2+} and these patients are hypocalcemic, but again, their plasma PTH levels are normal. The second line of evidence is based on *in vitro* studies showing that the loss of responsiveness to extracellular Ca^{2+} of cultured bovine parathyroid cells correlates with loss of mRNA for the calcium receptor (Mithal *et al.*, 1995). Finally, and the focus of the present review, selective pharmacological manipulation of the calcium receptor promptly alters PTH secretion *in vitro* and plasma levels *in vivo*.

PHARMACOLOGY OF THE CALCIUM RECEPTOR

As originally defined, calcimimetic ligands are those that mimic or potentiate the action of extracellular Ca^{2+} at the calcium receptor, whereas calcilytic ligands are calcium receptor antagonists. Calcimimetics can be subdivided into type I and type II ligands. The former activate the calcium receptor in the absence of extracellular Ca^{2+} and behave as true agonists, whereas type II calcimimetics act as positive allosteric modulators to increase the sensitivity of the calcium receptor to activation by extracellular Ca^{2+}. These are operational definitions based on the ability of the ligand to activate the calcium receptor in the presence or absence of extracellular Ca^{2+}. The definition is based on functional cellular responses, typically changes in the concentration of intracellular Ca^{2+} ($[Ca^{2+}]_i$). Importantly, these terms do not imply any knowledge about the site on the receptor to which the ligand binds (Nemeth, 2002b).

Calcimimetics

From the outset, it was appreciated that the calcium receptor is rather promiscuous and responds to a variety of inorganic cations and structurally diverse molecules possessing a net positive charge. A number of inorganic di- and trivalent cations have been studied and include, in rank order of potency: $La^{3+} \cong Gd^{3+} > Be^{2+} > Ca^{2+} \cong Ba^{2+} > Sr^{2+} > Mg^{2+}$ (Nemeth, 1990). Similarly, many organic polycations activate the calcium receptor and include simple polyamines (spermine), aminoglycoside antibiotics (neomycin), polyamino acids (polylysine) or proteins (protamine), and arylamine spider toxins (araxins). All of these charged ligands behave as type I calcimimetics—they are agonists and fully activate the calcium receptor in the absence of extracellular Ca^{2+} (Nemeth and Fox, 1999).

In contrast to these type I calcimimetics are L-amino acids that act as allosteric activators of the calcium receptor (Conigrave and Hampson, 2006). Among the naturally occurring L-amino acids, those possessing an aromatic ring (phenylalanine, tryptophan) are the most potent and, at low millimolar concentrations, can potentiate secretion of PTH *in vitro* (Conigrave *et al.*, 2004). Regulation of calcium receptor activity by L-amino acids might well be physiologically relevant, particularly in the gastrointestinal tract after a meal (Conigrave and Brown, 2006).

Homology modeling of family C G protein-coupled receptors that detect L-amino acids as ligands and *in silico* analysis of the putative amino acid-binding pocket predicted the calcimimetic activity of the tripeptide glutathione (Wang *et al.*, 2006). Both the reduced and oxidized forms of glutathione are active at submicromolar concentrations. These peptides potentiate the effects of extracellular Ca^{2+} when the calcium receptor is studied in heterologous expression systems, but it is not known whether they activate the receptor in the absence of extracellular Ca^{2+}. Binding of radiolabeled glutathione to the secreted extracellular domain of the calcium receptor was dependent on the presence of extracellular Ca^{2+}, so this ligand could be acting as an allosteric modulator. Like the L-amino acids, there might be a physiological and/or pathophysiological role for glutathione that is mediated by the calcium receptor (Conigrave and Hampson, 2006).

Whereas all of these calcimimetic ligands have been useful in defining the pharmacology of the calcium receptor, they are far from therapeutic because they lack specificity and suitable pharmacokinetic properties. The first class of compounds that includes selective, drug-like ligands of the calcium receptor is the phenylalkylamines, typified by NPS R-568 and cinacalcet (Fig. 1). These compounds are selective and do not affect the activity of mGluRs or various other G protein-coupled receptors at concentrations that maximally activate the calcium receptor. Phenylalkylamine compounds, like the amino acids, are stereoselective and, depending on the response measured, the *R*-enantiomers are 10- to 100-fold more potent than the corresponding *S*-enantiomers. For example, NPS R-568 increases $[Ca^{2+}]_i$ and inhibits PTH secretion from bovine parathyroid cells *in vitro* at concentrations between 3 and 100 n*M*, whereas

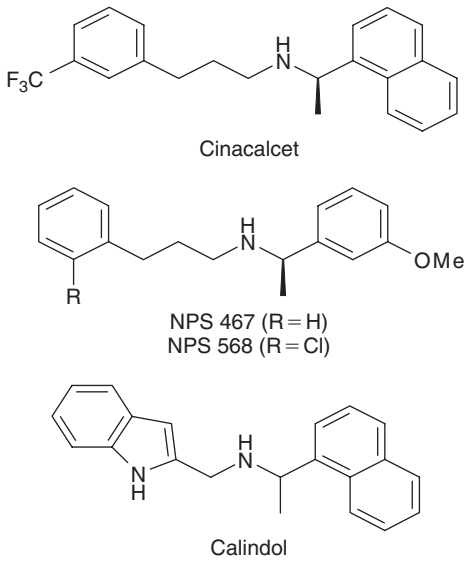

FIGURE 1 Structures of representative calcimimetic compounds. Shown are the *R*-enantiomers.

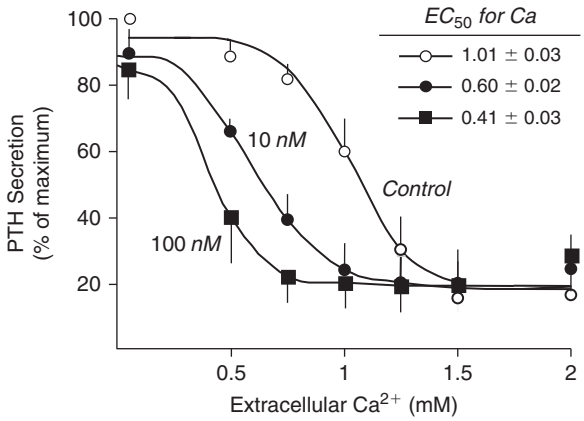

FIGURE 2 Cinacalcet potentiates the inhibitory effects of extracellular Ca^{2+} on PTH secretion. Primary cultures of bovine parathyroid cells were incubated for 20 minutes in the presence or absence of the indicated concentration of cinacalcet. The concentration-response curve for extracellular Ca^{2+} was shifted to the left without changes in the maximal or minimal response. This resulted in a dose-dependent decrease in the EC_{50} for extracellular Ca^{2+} as shown in the inset. (Fig. 7 in Nemeth *et al.*, 2004).

this compound is without effect on either response at concentrations less than 3 μ*M* (Nemeth *et al.*, 1998). These effects are dependent on the concentration of extracellular Ca^{2+} and NPS R-568 fails to alter parathyroid cell function when extracellular Ca^{2+} levels are reduced to levels below 0.1 m*M*. Type II calcimimetic compounds like NPS R-568 and cinacalcet are positive allosteric modulators and they shift the concentration-response curve for extracellular Ca^{2+} to the left without affecting the maximal or minimal responses (Fig. 2; Hammerland *et al.*, 1998; Nemeth *et al.*, 1998, 2004). This effect can be observed in heterologous expression systems, in authentic bovine parathyroid cells, and in rodents *in vivo* (Nagano, 2005).

Other calcimimetics have been synthesized of which the most studied is calindol (see Fig. 1; Dauban *et al.*, 2000; Kessler *et al.*, 2004a). This compound potentiates extracellular Ca^{2+}-induced increases in inositol phosphates and $[Ca^{2+}]_i$ in heterologous expression systems and is inactive in the absence of extracellular Ca^{2+} (Petrel *et al.*, 2004; Ray *et al.*, 2005). As such, it acts as a positive allosteric modulator. Calindol has not been studied *in vivo* and, although it probably does, it has not been shown to affect secretion of PTH *in vitro*.

The use of chimeric or domain-deleted receptor constructs and receptors with single or multiple point mutations has revealed sites within the calcium receptor where different calcimimetics act. Although it is generally true that these approaches provide information about the binding sites in the receptor, this is not always the case, particularly with point mutations. Very few studies have actually measured ligand binding; it is typically a functional response, such as formation of inositol phosphates that is measured. Of course, some calcimimetics, like the L-amino acids, simply lack the requisite potency to be studied in binding assays. Glutathione is one of the few calcimimetics that has been studied in a radiolabeled binding assay (Wang *et al.*, 2006). It does bind to the secreted extracellular domain of the receptor but it is unknown if it binds elsewhere in the receptor. Although the phenylalkylamines, calindol, and L-amino acids share a common mechanism of action, they do not all act at the same site within the calcium receptor. The L-amino acids, like extracellular calcium (Hammerland *et al.*, 1999; Brauner-Osborne, 1999; Silve *et al.*, 2005), bind to sites in the extracellular domain, whereas the phenylalkylamines act in the transmembrane domain (Hauache *et al.*, 2000; Ray and Northup, 2002; Zhang *et al.*, 2002; Miedlich *et al.*, 2004; Mun *et al.*, 2004). Calindol also binds to sites within the transmembrane domain of the calcium receptor (Ray *et al.*, 2005).

In normal rats, the oral administration of NPS R-568 or cinacalcet causes a rapid fall in plasma levels of PTH, which is accompanied by hypocalcemia (Fig. 3). The fall in plasma levels of PTH precedes that of serum calcium and the longer PTH levels are depressed, the greater is the magnitude and duration of the hypocalcemia that is achieved by a given dose of compound (Fox *et al.*, 1999a). It is remarkable that the effect of NPS R-568 on levels of plasma PTH in normal rats parallels that seen *in vitro*: the concentration-response curve for plasma Ca^{2+} and serum PTH is shifted to the left, thereby reducing the setpoint (Nagano, 2005).

Calcimimetics acting on renal calcium receptors might be expected to lower calcium reabsorption, as occurs in genetic disorders resulting from activating mutations of the calcium receptor (Brown, 2007). However, the hypocalcemic response elicited by NPS R-568 persists following an acute, total nephrectomy in rats (Fox *et al.*, 1999a). This finding does not necessarily mean that the compound

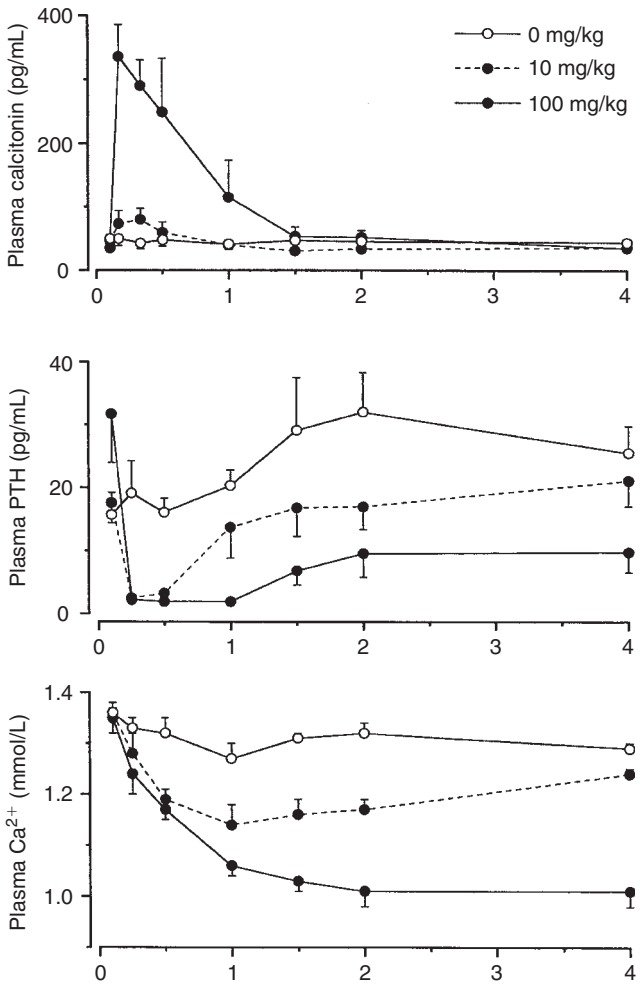

FIGURE 3 A calcimimetic compound decreases plasma levels of PTH and Ca^{2+} and increases those of calcitonin. NPS R-568 (or vehicle) was administered orally at the indicated dose to normal male rats. Note that the 10 mg/kg dose, which is close to the ED_{50} for depressing plasma PTH levels, is without effect on plasma levels of calcitonin. (Fig. 2 in Nemeth *et al.*, 1996).

is without effect on renal calcium receptors; only that any actions on these receptors are not required to explain the hypocalcemic effect observed *in vivo*. Selective surgical ablation of the thyroid, to eliminate C cells but leave the parathyroid glands intact, slowed the rate of onset but did not affect the magnitude of the hypocalcemia following administration of NPS R-568. In contrast, NPS R-568 failed to lower plasma levels of Ca^{2+} in thyroparathyroidectomized animals that were maintained at normocalcemia by continual infusion of PTH (Fox *et al.*, 1999b). Thus, hypocalcemia caused by administering phenylalkylamine calcimimetics results mostly from the ability of these compounds to inhibit secretion of PTH. In the rat, increased levels of calcitonin increase the rate of onset, but not the magnitude of hypocalcemia. With respect to the changes in circulating levels of PTH, calcium and calcitonin, the pharmacodynamics of cinacalcet and NPS R-568 are essentially the same. The differences between these two compounds reside in their pharmacokinetics, as described next.

Pharmacokinetics of Cinacalcet

Cinacalcet has more favorable pharmacokinetic properties than NPS R-568 and has, thus, become the calcimimetic of major clinical interest. NPS R-568 has poor oral bioavailability (5%) and it is metabolized mostly by the hepatic cytochrome P450 enzyme, CYP2D6. Approximately 5% to 7% of the population expresses an isozyme of CYP2D6 that metabolizes NPS R-568 poorly. Together with poor bioavailability, these properties can result in highly variable blood levels of NPS R-568.

The pharmacokinetics of cinacalcet has been assessed in rodents, monkeys, and normal humans (Kumar *et al.*, 2004) and in patients receiving hemodialysis or continuous ambulatory peritoneal dialysis (Harris *et al.*, 2004; Padhi *et al.*, 2005). The pharmacokinetic profile of cinacalcet is essentially the same in normal humans and in those receiving either form of dialysis. Cinacalcet has an oral bioavailability of 74% and maximal plasma concentrations (C_{max})

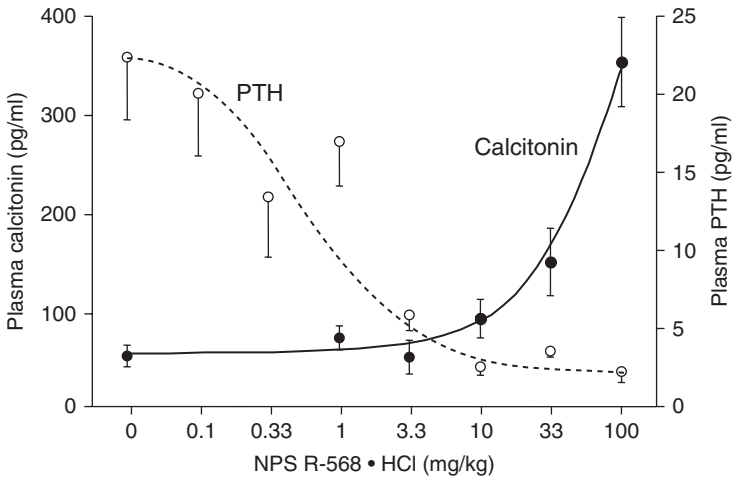

FIGURE 4 NPS R-568 preferentially acts on the parathyroid Ca^{2+} receptor. NPS R-568 was administered orally to normal rats and the changes in plasma levels of PTH and calcitonin determined 15 to 20 minutes later. (Redrawn from data in Fox *et al.*, 1999a,b).

occur within 2 to 3 hours after a single oral dose. There is a dose-proportional increase in C_{max} and area under the plasma concentration-time curve (AUC) with cinacalcet at doses up to 200mg once daily. These pharmacokinetic parameters and the plasma half-life ($t_{1/2}$) of cinacalcet were similar when estimated on days with and without dialysis. Moreover, the degree of renal impairment did not affect the pharmacokinetic profile of cinacalcet (Padhi *et al.*, 2005). The dose-proportional increase in exposure to cinacalcet correlates inversely with plasma levels of PTH. The plasma concentration of cinacalcet that results in a 50% decrease in serum levels of PTH is 6.2 ng/mL (about 15 n*M*), a concentration remarkably similar to that causing a 50% decrease in PTH secretion *in vitro* (27 n*M*; Nemeth *et al.*, 2004).

Cinacalcet is rapidly metabolized by several hepatic cytochrome P450 enzymes, primarily CYP3A4, CYP2D6, and CYP1A2 (Kumar *et al.*, 2004). The major routes of metabolism are by oxidative *N*-dealkylation and by oxidation of the naphthalene ring; none of the metabolites are biologically active on the calcium receptor and most (80%) are eliminated by renal excretion (Kumar *et al.*, 2004). Moderate to severe degrees of hepatic impairment will impede metabolism of cinacalcet and increase plasma exposure. Cinacalcet inhibits CYP2D6 *in vitro* and can therefore retard the metabolism of drugs that are metabolized by this enzyme, such as tricyclic antidepressants (Harris *et al.*, 2006).

Pharmacological Selectivity of Calcimimetics

Despite apparently identical calcium receptors on parathyroid cells and on C cells, their cellular pharmacology differs. An early example of this was noted with Mg^{2+}. Extracellular Mg^{2+} increases $[Ca^{2+}]_i$ bovine parathyroid cells and in HEK 293 cells expressing the human, bovine, or rat calcium receptor. Similar increases in the concentration of extracellular Mg^{2+}, however, fail to increase $[Ca^{2+}]_i$ in the medullary thyroid carcinoma cell lines 44-2 or 6-23 (Nemeth, 1990; Fajtova *et al.*, 1991). Nonetheless, increased concentrations of extracellular Mg^{2+} stimulate secretion of calcitonin from authentic C cells *in vitro* and *in vivo* (see references in Nemeth, 1996). Perhaps this discrepancy for a type I calcimimetic results from comparing medullary thyroid carcinoma cells with authentic C cells because these cells are likely to express different phenotypes. This explanation cannot, however, account for the preferential activity of NPS R-568 on secretion of calcitonin and PTH that is noted in normal rats *in vivo* (Fox *et al.*, 1999b). Similar results were obtained with cinacalcet. The calcium receptor mRNAs expressed in rat parathyroid cells and C cells are identical and the final protein products are likewise similar (Garrett *et al.*, 1995b). Nonetheless, NPS R-568 and cinacalcet depress plasma levels of PTH at doses 30- to 40-fold lower than those that increase plasma levels of calcitonin (Figs. 3 and 4).

The mechanism(s) explaining the preferential inhibitory effects of phenylalkylamine calcimimetics on serum levels of PTH is uncertain. It is now widely recognized that the same receptor, when expressed in different cellular contexts, can display quite distinct pharmacological properties. This so-called phenotypic pharmacology is especially prevalent among G protein-coupled receptors, and a number of different molecular mechanisms have been put forward to explain it (Kenakin, 2005). One relatively simple explanation is that different degrees of receptor occupancy may be required to alter secretion from parathyroid cells and from C cells. In this view, a lower fractional occupancy of the calcium receptor is required to depress PTH secretion than is required to stimulate calcitonin secretion. Cinacalcet is correspondingly more potent in depressing plasma levels of PTH. Alternatively, or additionally, the different signaling

pathways linking the calcium receptor to PTH and to calcitonin secretion might also contribute to the preferential activity of phenylalkylamine calcimimetic compounds on parathyroid calcium receptors.

Calcilytics

The first substance, either atomic or molecular, shown to act as a calcium receptor antagonist is the amino alcohol NPS 2143 (Fig. 5). The inhibitory effects of NPS 2143 are not dependent on the properties of the ligand used to activate the receptor in either heterologous expression systems or authentic cells. The potency and efficacy of NPS 2143 are similar whether blocking cytoplasmic Ca^{2+} responses evoked by extracellular Ca^{2+} or NPS R-467. NPS 2143 is without on the cytoplasmic Ca^{2+} responses elicited by activation of various native or chimeric mGluRs nor does it affect those in cells coexpressing the GABABR1 and R2. Calcilytic compounds like NPS 2143, when used under appropriate conditions, are potent and selective pharmacological tools to study the function of calcium receptors expressed in normal and pathological tissues (Nemeth, 2002c).

The effects of NPS 2143 on PTH secretion from bovine parathyroid cells mirror those of the calcimimetics that act as positive allosteric modulators. In the case of the calcilytic, there is a shift to the right in the concentration-response curve that is unaccompanied by changes in either the maximal or minimal response (Fig. 6). NPS 2143 stimulates secretion of PTH from bovine parathyroid cells *in vitro* at concentrations similar to those that inhibit evoked increases in $[Ca^{2+}]_i$. These changes in the agonist concentration-response curves show that NPS 2143 decreases whereas phenylalkylamine calcimimetics increase the sensitivity of the calcium receptor to activation by extracellular Ca^{2+}.

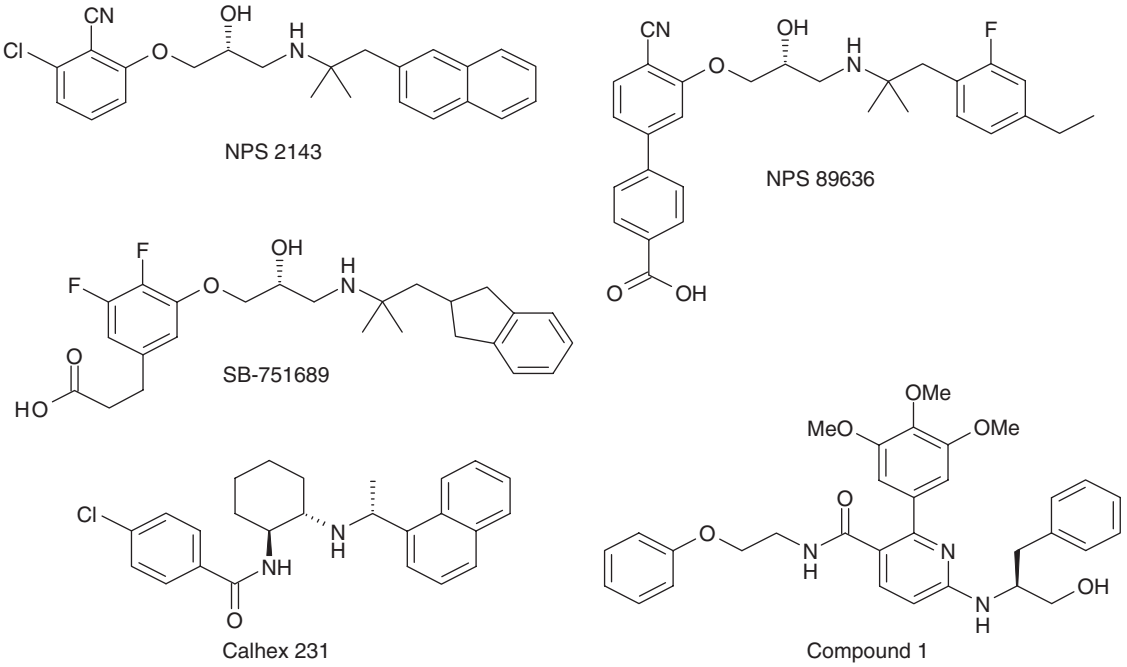

FIGURE 5 Structures of representative calcilytic compounds.

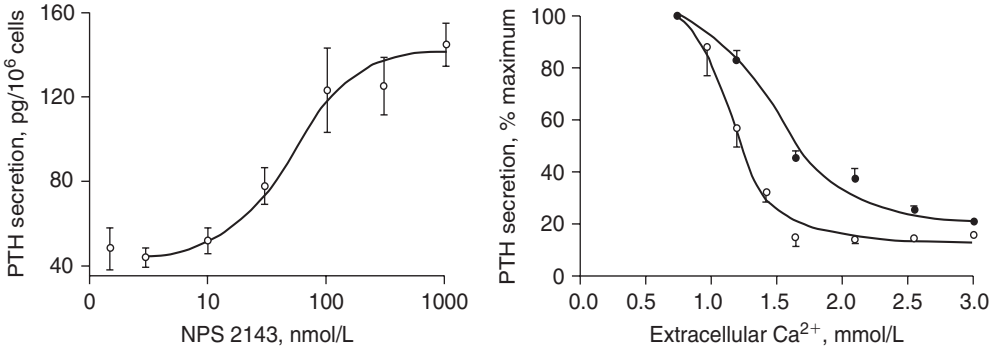

FIGURE 6 NPS 2143 stimulates PTH secretion from bovine parathyroid cells *in vitro*. In the right panel, parathyroid cells were incubated in the presence (closed symbols) or absence of 300 nM NPS 2143. (Fig. 7 in Nemeth *et al.*, 2001).

Although the rightward shift of the concentration-response curve could indicate competitive inhibition by NPS 2143, the shifts in the concentration-response curve shown in Fig. 6 would also be produced by a noncompetitive antagonist acting on a tissue with a large receptor reserve (Zhu, 1993). And, as discussed later, there might be a large reserve of calcium receptors on parathyroid cells.

When administered intravenously or by oral gavage to normal rats, NPS 2143 causes a rapid, 3- to 5-fold increase in plasma levels of PTH (Nemeth *et al.*, 2001). Other compounds of the amino alcohol chemotype (NPS 89636 and SB-751689) also increase circulating levels of PTH. These findings were comforting because it was never a certainty that a calcilytic compound would in fact stimulate PTH secretion. Although intuitively appealing, this assumption rests solely on the finding that lowering the level of extracellular Ca^{2+} stimulates PTH secretion. This is not, however, equivalent to blocking the activity of the receptor in a normocalcemic setting.

Other calcilytic chemotypes are shown in Fig. 5. These compounds were discovered by high-throughput screening of compound libraries or by progressive modifications to the amino alcohol structure of NPS 2143 (Kessler *et al.*, 2004b, 2006; Shcherbakova *et al.*, 2005a, b; Arey *et al.*, 2005). All these compounds are antagonists in *in vitro* assays using heterologous expression of the calcium receptor and all act within the transmembrane domain of the calcium receptor (Petrel *et al.*, 2003; Hu *et al.*, 2006). Compound 1 has been shown to act as negative allosteric modulator (Hu *et al.*, 2006) but the binding of radiolabeled compound 1 was not displaced by an amino alcohol calcilytic, so the binding sites of these two chemotypes differ (Arey *et al.*, 2005). Compound 1 is the only other calcilytic reported to affect plasma levels of PTH *in vivo*. It caused a dose-dependent, 5- to 6-fold maximal increase in circulating levels of PTH when administered intravenously to rats (Arey *et al.*, 2005).

The Calcium Receptor in Hyperparathyroidism

One of the early concerns in developing calcimimetic compounds as treatments for hyperparathyroidism (HPT) was whether the disease process in some way altered the parathyroid calcium receptor so that calcimimetics, although effective in normal animals and humans, were no longer capable of altering plasma levels of PTH in patients with primary or secondary HPT. No mutations, however, have yet been detected in the coding region of the calcium receptor gene in pathological parathyroid glands from patients with primary or secondary HPT (Garrett *et al.*, 1995a; Hosokawa *et al.*, 1995; Cetani *et al.*, 2000). A consistent finding, however, is reduced expression of the calcium receptor in both adenomatous and hyperplastic tissues (Kifor *et al.*, 1996; Farnebo *et al.*, 1997; Gogusev *et al.*, 1997; Kaneko *et al.*, 1999; Taniguchi *et al.*, 2006a). This conclusion is based on semiquantitative analyses of calcium receptor mRNA and staining intensities of parathyroid tissue using mono- or polyclonal antibodies against the calcium receptor. Like the data for the vitamin D receptor, nodular regions showed a greater loss of staining intensity for the calcium receptor when compared with adjacent areas of diffuse hyperplasia (Rodriguez *et al.*, 2005). In patients with primary HPT, there is a correlation between the level of parathyroid calcium receptor expression, as judged by the intensity of staining of tissues with a polyclonal antibody to the calcium receptor, and the PTH-Ca^{2+} setpoint—the setpoint is higher in those patients with glands having the least staining intensity (Cetani *et al.*, 2000). When parathyroid glands excised from hemodialysis patients with refractory HPT were studied *in vitro*, a similar shift in the setpoint was observed. Moreover, there was an inverse relationship between PTH secretion and levels of calcium receptor expression: those glands with the lowest levels of calcium receptor showed a diminished secretory response to changes in the concentration of extracellular Ca^{2+} (Canadillas *et al.*, 2005). Decreases in calcium receptor expression levels appear to be reversible because recipients of renal allografts show increased staining for the receptor in diffuse (but not nodular) regions of hyperplastic parathyroid glands (Taniguchi *et al.*, 2006b). Thus, in contrast to the altered setpoints in genetic diseases that result from changes in the amino acid sequence of the calcium receptor, those in HPT result largely from changing the density of presumably normal receptors.

Several different lines of evidence suggest that the apparently reduced expression of calcium receptor protein in pathological parathyroid glands does not render such glands insensitive to calcimimetic compounds. First, secretion of PTH from adenomatous or hyperplastic parathyroid glands *in vitro* is inhibited by NPS R-568 (Nemeth, 1996) and by cinacalcet (Kawata *et al.*, 2006). In the latter study, it was shown by immunohistochemistry that staining for the calcium receptor was reduced in all tissue samples; at least in these particular surgical tissue samples, there was enough calcium receptor remaining to respond to cinacalcet. Moreover, the potency of NPS R-568 is similar in normal rats or those with secondary HPT resulting from a 5/6 nephrectomy (Fox *et al.*, 2000). Finally, and most significantly, calcimimetic compounds lower plasma levels of PTH in patients with primary or secondary HPT. In the clinic, there seems to usually be enough calcium receptor expressed for cinacalcet to effectively lower plasma levels of PTH. The only exception might be parathyroid carcinoma.

PRIMARY HYPERPARATHYROIDISM

Primary hyperparathyroidism is characterized by chronically elevated circulating levels of PTH and calcium and usually results from an adenoma of a single parathyroid

gland (Heath, 1991). The manifestations of primary hyperparathyroidism may include bone loss, nephrolithiasis and nephrocalcinosis, gastrointestinal distress, and easy fatigability. Although many patients with primary hyperparathyroidism are apparently asymptomatic, it has been argued that these patients will eventually develop specific symptomatology (Fischer, 1993). Moreover, because the incidence of primary hyperparathyroidism increases with age, many of the rather vague symptoms such as muscular fatigue and depressed cognition may be interpreted as part of the normal aging process. Whether these so-called asymptomatic patients should be treated is controversial and at present the most widely followed practice continues to be "watchful waiting" (Bilezikian *et al.*, 2002).

There is somewhat less controversy regarding treatment of moderate and essentially none regarding treatment of severe forms of primary hyperparathyroidism. The treatment of choice is surgical ablation of the offending gland(s) and, when performed by a skilled endocrine surgeon, the success (cure) rate is 95% (Clark, 1995). There are, however, many instances when surgery might not be chosen if effective medical alternatives existed. These include patients who refuse surgery, are elderly, have comorbid conditions, or have undergone previous unsuccessful surgeries. In addition, there are those situations where it would be desirable to delay surgery or to stabilize serum levels of calcium prior to surgery. In these situations, a medicine that safely lowered serum calcium levels would be beneficial.

Vestergaard (2006) provides a comprehensive review of the various pharmacological agents that have been studied as treatments for patients with primary HPT. Of note are a number of recent studies with the bisphosphonate alendronate. Daily dosing with 10 mg/kg alendronate for 48 weeks to two years decreases bone turnover markers and increases bone mineral density (BMD) in patients with mild to moderate primary HPT. Typically, however, there is only a temporary and minor reduction, if any, in serum calcium levels; after 6 months, serum calcium has returned to baseline levels. As noted before (Nemeth, 1996, 2002a), the bisphosphonates treat the hypercalcemia, not the hyperparathyroidism itself. Other approaches using drugs that act directly on parathyroid cells have also been explored but none has proven effective in managing primary HPT (Nemeth, 2002a).

NPS R-568 was the first calcimimetic to be studied in patients with primary HPT. A single oral dose caused a rapid and dose-dependent decrease in circulating levels of PTH and calcium (Silverberg *et al.*, 1997). Two repeat-dosing trials using cinacalcet in patients with primary HPT have now been reported (Shoback *et al.*, 2003; Peacock *et al.*, 2005). Both were randomized, double-blind, placebo-controlled, multisite studies.

The initial study involved 22 male or female patients with mild to moderate degrees of primary HPT as defined by serum levels of PTH (≥45 pg/mL) and calcium (>10.3 mg/dL). The first phase of this study examined the efficacy and tolerability of once-daily dosing with 50 mg of cinacalcet. The dose could be increased in 25-mg increments to 100 mg. Plasma PTH levels fell by 55% compared with placebo at 2 hours after dosing but were nearly back to baseline just before the next dose (24 hours later). With this dosing regimen there was an unacceptably high incidence of nausea and dizziness compared with the placebo-treated subjects. To diminish these adverse events and to achieve a more sustained reduction in plasma levels of PTH, a twice-daily dosing regimen was adopted. Subjects were administered 30, 40, or 50 mg of cinacalcet or placebo twice-a-day for 15 days and then followed for an additional 7 days. There was a rapid reduction in plasma levels of PTH that reached a nadir 2 to 4 hours after the first dose and then gradually returned toward baseline levels but was still below baseline 12 hours later, just prior to the second dose. This rapid decrease in plasma levels of PTH correlates precisely with the C_{max} of cinacalcet following oral administration (Harris *et al.*, 2004). The second dose elicited a pattern of change in plasma PTH levels similar to the first dose: a rapid, 40% to 50% decrease from baseline within 2 to 4 hours that rose to within 15% of baseline levels after 12 hours. The time course and magnitude of change in plasma PTH levels were similar on day 1 and on day 15. Levels of serum calcium fell into the normal range 2 hours after the second dose on day 1 and were maintained within the normal range throughout the 15-day study. Seven days after cessation of dosing, circulating levels of PTH and calcium had returned to baseline levels. There were no consistent changes in levels of plasma PTH and serum calcium compared with baseline in the placebo-treated group. Cinacalcet was well tolerated and no serious adverse events were reported. The most frequent side effect was paresthesia, which reportedly occurred in 33% of the placebo-treated and in 19% of the cinacalcet-treated subjects (Shoback *et al.*, 2003).

The long-term safety and efficacy of cinacalcet was investigated in 78 patients with mild to moderate primary HPT using the same inclusion criteria as in the prior study (Peacock *et al.*, 2005). In this study, subjects were administered 30 mg of cinacalcet twice a day for 1 year. During the first 12 weeks (titration phase), the dose of cinacalcet could be increased to 40 or 50 mg if the patients were still hypercalcemic (>10.3 mg/dL) at weeks 4 and 8. Efficacy endpoints were measured after another 12 weeks (maintenance phase) and patients were monitored for another 28 weeks to gather additional safety and efficacy data. During the maintenance phase, there was a significant 7.6% decrease in fasting plasma levels of PTH in the cinacalcet-treated group compared with a 7.7% increase in the placebo-treated group. The magnitude of this effect might seem small but plasma levels of PTH were measured at a time when they would be highest (12 hours after dosing). When studied at week 24, the morning dose of

cinacalcet elicited a 37% decrease in plasma levels of PTH at 4 hours compared with predose levels. Plasma levels of PTH in the cinacalcet-treated group fell below those in the placebo-treated group by week 4 and remained so for 1 year. Serum calcium levels had normalized by 2 weeks (the earliest time measured) and remained within the normal range for 1 year. In the cinacalcet-treated group, serum calcium was 10.7 mg/dL at baseline and 9.7 mg/dL at week 52, whereas the placebo-treated group had the same baseline value but completed the study with serum calcium levels of 10.9 mg/dL. Ninety percent of the patients who completed the study remained on 30 mg of cinacalcet twice daily during the maintenance phase, and of those, most achieved normocalcemia with a decrease of 0.5 mg/dL from baseline. In this long-term study, the drug was well tolerated and the most common adverse event in the cinacalcet-treated group was nausea (28% compared with 16% in the placebo-treated group).

A number of secondary endpoints were assessed in both the short- and long-term studies described earlier. In the short-term study, levels of serum phosphorous tended to increase but not significantly so. And there were no significant differences between the cinacalcet- and placebo-treated groups in 24-hour urine calcium excretion, the 24-hour urine calcium-to-creatinine ratio, or the fasting urine calcium-to-creatinine ratio were observed in the 15-day study by Shoback *et al.* (2003). In contrast, treatment with cinacalcet for 1 year resulted in significant increases in serum phosphate levels and decreases in fasting urine calcium-to-creatinine ratio compared with placebo. These changes were accompanied by significant increases and decreases, respectively, in tubular reabsorption of phosphorous and calcium (Peacock *et al.*, 2005). Such changes in mineral metabolism are the expected response to a net decrease in circulating levels of PTH. Predose serum levels of 1,25-dihydroxyvitamin D were not altered so a lowered level of PTH might sufficiently explain these changes in mineral metabolism. At present, however, an action of cinacalcet on renal calcium receptors cannot be excluded.

Treatment with cinacalcet for 1 year increased levels of some bone turnover markers when compared with placebo. Serum levels of bone-specific alkaline phosphatase (BSAP) and N-telopeptide (NTx) and urine NTx were slightly but significantly increased; there was no change in urine deoxypyridinoline levels. BMD at the lumber spine, total femur, and distal one-third of the radius was not affected by 1 year of treatment with cinacalcet when compared with placebo. The failure of cinacalcet to affect BMD in patients with mild to moderate degrees of primary HPT is curious because parathyroidectomy in this patient population often does result in significant gains in BMD within the first year (Silverberg, *et al.*, 1995; Nordenstrom *et al.*, 2004).

Another intriguing and somewhat unexpected observation that emerged from these two studies is that, although daily dosing caused cyclic changes in plasma PTH levels, serum calcium levels remained constant for 8 hours after dosing. It appears that after a couple days of dosing, serum calcium levels achieve a new homeostatic setpoint that no longer responds to rapid changes in plasma levels of PTH.

Cinacalcet has been studied in patients with the rare but far more serious form of primary HPT— parathyroid cancer. In contrast to primary HPT resulting from an adenoma or hyperplasia, that caused by a carcinoma is life-threatening. Patients with parathyroid carcinoma present with the signs and symptoms of severe hypercalcemia. Surgical treatment of this malignant form of primary HPT is considerably more difficult because of metastasis and multiple resections are common (Shane and Bilezikian, 1982). The first calcimimetic was studied in a male patient with severe hypercalcemia resulting from parathyroid carcinoma (Collins *et al.*, 1998). Conventional therapy with calcitonin, furosemide, hydration, or the bisphosphonate pamidronate did not consistently lower plasma Ca^{2+} levels (Fig. 7) and plasma PTH levels were unaffected by these treatments. In contrast, daily oral dosing with NPS R-568 lowered plasma levels of PTH and Ca^{2+} for nearly 2 months. At that time, plasma PTH levels began to increase but plasma Ca^{2+} levels did not. This patient was subsequently maintained on high doses of NPS R-568 (100 mg orally, every 6 hours) for more than 600 days without any instances of hypercalcemic crisis or any adverse effects owing to drug.

The regulatory filing of cinacalcet includes a multicenter, open-label study of 21 patients with parathyroid carcinoma and hypercalcemia (Silverberg *et al.*, 2004). All of the patients studied had at least one prior parathyroidectomy and all presented with at least one symptom of hypercalcemia. Most of the patients (81%) had been treated previously with bisphosphonates. There was an initial dose-titration phase starting with 30 mg of cinacalcet twice daily and increasing to a maximum of 90 mg four times a day. This titration phase lasted until serum calcium levels fell to 10 mg/dL or 16 weeks, whichever came first.

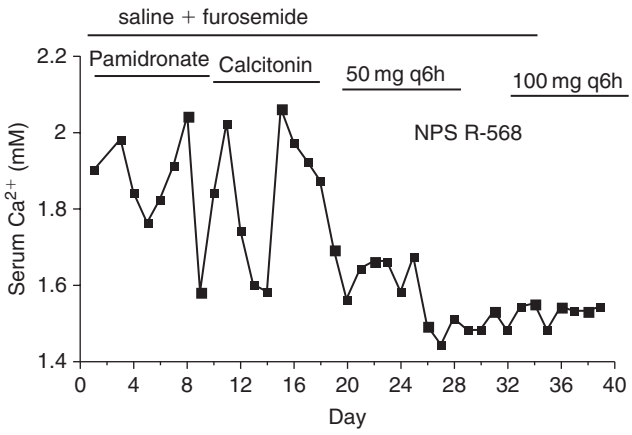

FIGURE 7 NPS R-568 lowers plasma levels of PTH in a male patient with parathyroid carcinoma. (Fig. 1 in Collins *et al.*, 1998).

The mean serum calcium level was 14.5 mg/dL at baseline and by the end of the titration phase it had fallen to 12.4 mg/mL; 71% of the patients achieved a reduction of ≥1 mg/dL. Serum calcium levels were maintained for up to 3 years and there were marked improvements in symptoms of hypercalcemia in all patients.

There was a 15% reduction in mean levels of plasma PTH when measured just before dosing and, as expected, a greater reduction (30%) when measured 2 to 4 hours after dosing. The patients studied were a remarkably heterogeneous group, with plasma PTH values ranging from 232 to 2106 pg/mL and serum calcium ranging from 9.4 to 20.2 mg/dL at entry. These population variances were not diminished by 16 weeks of treatment with cinacalcet.

Treatment of parathyroid carcinoma patients with cinacalcet results in considerably smaller reductions in plasma levels of PTH when compared with patients with HPT resulting from an adenoma or those with secondary HPT (see later). In fact, in a subset of 10 patients that were treated for 1.5 years with cinacalcet, plasma levels of PTH actually increased (by 42%) when compared with baseline, even though serum calcium was maintained at lower level (Rubin *et al.*, 2004). Clearly, parathyroid carcinoma cells display a phenotype quite different from that of adenomatous and hyperplastic parathyroid cells. Secretion of PTH from parathyroid carcinoma cells have long been known to be essentially autonomous and refractory to changes in the concentration of extracellular Ca^{2+}. The meager response of plasma PTH to cinacalcet in patients with parathyroid carcinoma is consistent with this and perhaps results from the loss of calcium receptors to an extreme extent.

Cinacalcet has been used experimentally in three patients with lithium-induced HPT (Gregoor and de Jong, 2007). Daily dosing with cinacalcet lowered serum levels of calcium by about 8% and, despite a 60% drop in plasma levels of PTH, there was no significant increase in serum phosphate levels. It might be noteworthy that these three patients had renal impairment (mean creatinine clearance, 35 μmol/L) and this could have diminished the renal effects of PTH on phosphate reabsorption.

SECONDARY HYPERPARATHYROIDISM

Secondary HPT can result from the normal aging process but it is most often associated with chronic kidney disease (CKD) and most patients with end-stage renal disease (ESRD) suffer from secondary HPT (Coburn and Salusky, 1994). Secondary HPT is characterized by enlargement of all four parathyroid glands, principally through hyperplasia but also involving cellular hypertrophy (Drüeke, 1995). The primary factors that lead to enlargement of the parathyroid glands are hypocalcemia, hyperphosphatemia, and lowered plasma levels of 1,25-dihydroxyvitamin D_3. The mechanisms by which these factors lead to hyperplasia and hypertrophy of the parathyroid glands are not completely understood but each appears capable of acting wholly or partially independent of the others. Plasma levels of PTH increase very early on in the course of CKD and may already be elevated when creatinine clearance is one-half of normal (about 60 mL/min; Fajtova *et al.*, 1995), well before the patient would be started on dialysis. The severity of secondary HPT, as indexed by enlargement of the parathyroid glands and increased circulating levels of PTH, typically increases as the renal disease progresses from mild chronic renal insufficiency (CRI) to ESRD. There is a potentially vicious cycle operating in CKD, because abnormal mineral metabolism and increased circulating levels of PTH seem to increase the rate of progression towards ESRD and dialysis (Ritz *et al.*, 2005; Schwarz *et al.*, 2006)

Chronically elevated levels of circulating PTH and phosphorous and abnormal levels of serum calcium are the major laboratory features of secondary HPT. These blood parameters, in turn, are associated with renal osteodystrophy and soft tissue calcification (London *et al.*, 2005; Ketteler *et al.*, 2005; Goodman, 2006; Moe *et al.*, 2006; Martin and González, 2007). Vascular calcification is most closely associated with hyperphosphatemia and an increase in the calcium-phosphorous product, but increased serum levels of calcium also contribute by augmenting the ability of phosphate to cause vascular calcification. Cardiovascular disease is a major mortality factor in patients on dialysis and it is highly correlated with the degree of vascular calcification (Block and Cunningham, 2006). Disturbances in mineral metabolism are independent risk factors for morbidity and mortality in ESRD patients on dialysis (Block *et al.*, 2004a; Stevens *et al.*, 2004; Melamed *et al.*, 2006). Recognizing this seemingly fundamental relationship between abnormal mineral metabolism and clinical outcomes prompted the National Kidney Foundation/Kidney Disease Outcomes Initiative (NKF-K/DOQI™, 2003) to issue guidelines for circulating levels of PTH (150 to 300 pg/mL), serum calcium (8.4 to 9.5 mg/dL), serum phosphorous (3.5 to 5.5 mg/dL), and the calcium-phosphorous product (less than55 mg^2/dL^2). These target ranges for blood chemistries now define efficacy endpoints for the evaluation of new therapies for secondary HPT in patients with CKD.

The treatment of secondary HPT in CKD essentially involves replacing or removing those serum factors that the kidney can no longer maintain at normal levels. Thus, vitamin D sterols and oral phosphate binders have been the mainstays of medical management (Reichel, 2006; Brown and Slatopolsky, 2007; Torres *et al.*, 2006). Despite their use, it remains difficult to achieve the NKF-K/DOQI™ targets for blood parameters, especially for PTH (Moe and Drueke, 2003; Cunningham, 2004; Wood *et al.*, 2005; Craver *et al.*, 2007). The use of cinacalcet along with vitamin D sterols and phosphate binders increases the proportion of dialysis patients that achieve these targets. The clinical studies that demonstrate this will be discussed after first reviewing the preclinical studies in rodent models of CRI.

Preclinical Studies in Animal Models of Secondary Hyperparathyroidism

The 5/6 nephrectomized rat has been the predominant model used in studies of calcimimetics. This partial nephrectomy model can be combined with diets that differ in their calcium-to-phosphate ratios to produce a range of plasma PTH levels characteristic of mild, moderate, or severe forms of secondary HPT. With minor exceptions, the reported effects of NPS R-568 and cinacalcet on blood parameters and on soft and hard tissues are essentially identical.

Plasma PTH

The oral administration of NPS R-568 caused a dose-dependent decrease in plasma levels of PTH in 5/6 nephrectomized rats with secondary HPT. The magnitude and rate of change of plasma PTH levels following orally administered compound were similar in normal animals or those with secondary HPT (Fox *et al.*, 1999c). Moreover, animals with mild (normal to 150 pg/mL PTH), moderate (150 to 500 pg/mL) or severe secondary HPT (more than 500 pg/mL) all responded similarly to the intra-arterial injection of NPS R-568: the compound reduced plasma PTH levels by 82% to 94% within 20 min of dosing regardless of the initial plasma PTH level (Fox *et al.*, 1999c). Some of these animals had severe hyperphosphatemia and moderate hypocalcemia yet these two stimuli to PTH secretion could not prevent the depressive effect of NPS R-568 on plasma levels of PTH. Thus, activation of the calcium receptor with a calcimimetic markedly lowers circulating levels of PTH irrespective of the severity of the secondary HPT or the magnitude of the hyperphosphatemia. Efficacy independent of disease severity is also observed clinically with cinacalcet (see later).

Despite reports showing a decreased expression of parathyroid calcium receptor mRNA and protein in such animal models of secondary HPT (Mathias *et al.*, 1998; Brown *et al.*, 1999), there is apparently enough calcium receptor expressed to preserve responsivity to calcimimetic compounds. For example, the potencies of NPS R-568 for lowering plasma levels of PTH and Ca^{2+} or for increasing those of calcitonin are the same in normal animals and in those with CRI and moderate to severe secondary HPT (Fox *et al.*, 2000). As noted earlier, this could result if there were a large receptor reserve for the calcium receptor. Another explanation is the recent finding that the phenylalkylamine calcimimetics themselves increase expression of the calcium receptor. In partially nephrectomized rats with severe secondary HPT, daily treatment with NPS R-568 for a week was sufficient to restore normal levels of calcium receptor expression as assessed by mRNA levels and by immunohistochemical staining (Mizobuchi *et al.*, 2004).

The ability of calcimimetics to lower plasma levels of PTH might also involve an inhibitory effect on hormone synthesis. *In vitro* studies using bovine parathyroid cells showed that NPS R-568 also inhibited the synthesis of PTH (Garrett *et al.*, 1995c). As expected, the decreased levels of PTH mRNA were not apparent until 12 hours of exposure to the calcimimetic and reached a maximum within 24 hours. The inhibitory effects of NPS R-568 were stereoselective and they were blocked by the calcilytic compound NPS 89636 and therefore mediated by the calcium receptor. The inhibitory effect of NPS R-568 on the synthesis of PTH also occurs in a rat model of secondary HPT using a diet containing adenine and a high content of phosphorous (Levi *et al.*, 2006). In this animal model, HPT progresses from mild after 7 days to severe (more than 900 pg/mL) after several weeks on the diet. There were corresponding increases in PTH mRNA levels at these times that were totally abrogated at 7 days but only slightly affected after 21 days. It is currently uncertain to what extent the inhibitory effect on synthesis contributes to maintaining a lowered level of plasma PTH.

Bone Quality

Studies in rats with CRI have shown that the decreases in plasma levels of PTH caused by NPS R-568 have beneficial effects on some of the skeletal abnormalities that accompany secondary HPT (Wada *et al.*, 1998). Six weeks following a partial nephrectomy, animals had developed a mild to moderate secondary HPT with profound peritrabecular fibrosis; static and dynamic histomorphometry revealed a high-turnover bone lesion. The daily oral administration of NPS R-568 during the last five weeks completely prevented the development of osteitis fibrosa and tended to normalize histomorphometric parameters. Daily treatment with NPS R-568 additionally restored the decreases in volumetric cortical bone mineral density and in cortical bone stiffness at the femoral midshaft that was observed in vehicle-treated CRI animals. Similar improvements in bone quality were observed when rats were treated with cinacalcet (Wada *et al.*, 2003).

The results obtained by using rodent models of CRI-induced secondary HPT show that calcimimetics reduce plasma levels of PTH over prolonged periods of daily dosing and that there is no development of tolerance. Moreover, the daily cyclic decrease in circulating levels of PTH caused by treatment translates into positive effects on bone quality including the prevention or reversal of osteitis fibrosa.

Parathyroid Gland Hyperplasia

Parathyroid gland hyperplasia begins within days after a partial nephrectomy in the rat (Denda *et al.*, 1996; Wada and Nagano, 2003) and the initial studies examined the effects of NPS R-568 on parathyroid cell proliferation during the first five days of CRI in rats (Wada *et al.*, 1997).

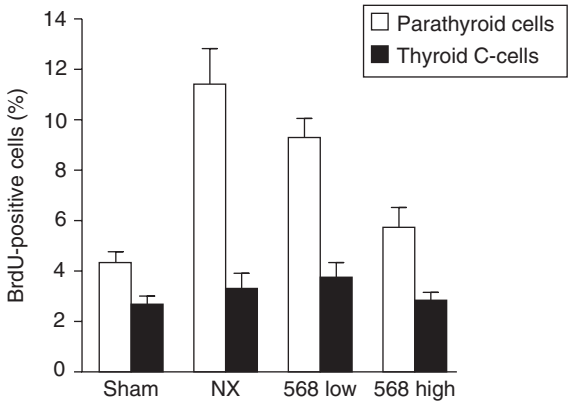

FIGURE 8 NPS R-568 blocks parathyroid cell proliferation in partially nephrectomized rats. NPS R-568 was administered orally twice a day at a dose of either 1.5 (568 low) or 15 mg/kg (568 high). (Fig. 4 in Wada *et al.*, 1997).

Bromodeoxyuridine (BrdU) was infused intraperitoneally throughout and NPS R-568 was administered orally twice a day during the last four days. As shown in Fig. 8, there was a 3-fold increase in cellular labeling with BrdU in partially nephrectomized animals which was blocked in a dose-dependent manner by treatment with NPS R-568. The inhibitory effect of NPS R-568 on BrdU labeling was specific for parathyroid cells and did not affect labeling of C cells, even at the high dose that stimulated calcitonin secretion. These findings suggest that the calcium receptor mediates the effects of hypocalcemia on parathyroid cell proliferation. If the glands responded to the prevailing low calcium levels by a mechanism other than the calcium receptor, then NPS R-568 would have been unlikely to prevent the proliferative response to partial nephrectomy. The mechanisms linking the calcium receptor to the regulation of cellular proliferation are present in parathyroid cells but not in C cells.

These initial findings prompted two long-term studies in rats with CRI. The first assessed whether initiating treatment with NPS R-568 soon after the development of CRI would prevent parathyroid gland hyperplasia (Wada *et al.*, 2000). CRI was induced by ligating the renal arteries and feeding the animals a diet high in phosphate content. Treatment with NPS R-568 was started 6 days after renal artery ligation and continued for 56 days. The vehicle-treated CRI animals developed severe secondary HPT with 10-fold elevations in circulating levels of PTH compared with sham-operated animals. Parathyroid gland volume was 2.8-fold higher in the former group of animals and this resulted mostly from an increase in cell number rather than cell volume. The enlargement and cellular hyperplasia of the parathyroid glands was completely prevented by treatment with NPS R-568.

The second study assessed whether treatment with NPS R-568 could halt the progression of parathyroid gland hyperplasia in animals with CRI (Chin *et al.*, 2000). Secondary HPT was allowed to develop for eleven weeks following a 5/6 nephrectomy before initiating treatment with NPS R-568 for eight weeks. At eleven weeks following surgery, parathyroid gland volume was 1.9-fold larger in CRI animals and the glandular volume continued to increase in these animals another 2-fold by the end of the study. Parathyroid gland enlargement was paralleled by a 5.4-fold increase in plasma levels of PTH in vehicle-treated CRI animals which continued to increase another 2.6-fold during the last eight weeks (Fig. 9). Secondary HPT continued to worsen during the course of this study as indicated by continually rising levels of circulating PTH and progressive enlargement of the parathyroid glands. Daily oral administration of NPS R-568 completely blocked the progression of secondary HPT as indicated by either parameter (see Fig. 9). Moreover, progressive increases in plasma PTH levels and parathyroid gland volume were completely prevented by NPS R-568 even when there was profound hypocalcemia, hyperphosphatemia, and lowered plasma levels of 1,25-dihydroxyvitamin D_3 (Wada *et al.*, 2000b; Chin *et al.*, 2000). Essentially the same results were obtained when cinacalcet was used and proliferating cell nuclear antigen staining was used to quantify cellular proliferation (Colloton *et al.*, 2005). Even in rats with severe secondary HPT, as indexed by plasma PTH levels greater than 3000 pg/mL and a 5-fold increase in parathyroid gland weight, daily treatment with a calcimimetic for just 7 days completely halted parathyroid cell proliferation and lowered plasma levels of PTH (Mizobuchi *et al.*, 2004).

Soft Tissue Calcification and Cardiovascular Function

The effects of calcimimetics on soft tissue and vascular calcification have been examined in two studies (Henley *et al.*, 2005; Lopez *et al.*, 2006). Both used 5/6 nephrectomized rats and included 1,25-dihydroxyvitamin D as a comparator and both began daily dosing one week after partial nephrectomy in a design that tested calcimimetics alone or in combination with 1,25-dihydroxyvitamin D. In many respects, the results of the two studies were similar. Daily treatment with NPS R-568 for 56 days or with cinacalcet for 26 days did not increase vascular calcification as indexed by von Kossa staining or aortic content of calcium and phosphorous. In contrast, 1,25-dihydroxyvitamin D-treated animals showed marked increases in both indices of vascular calcification. Curiously, and seemingly without explanation, the combination of NPS R-568 and 1,25-dihydroxyvitamin D, but not that with cinacalcet, abolished the effects on vascular calcification. Moreover, animals treated with 1,25-dihydroxyvitamin D suffered a very high mortality rate that was lowered by coadministration of NPS R-568 (Lopez *et al.*, 2006); this high rate of mortality was not observed in the shorter-term study using cinacalcet (Henley *et al.*, 2005).

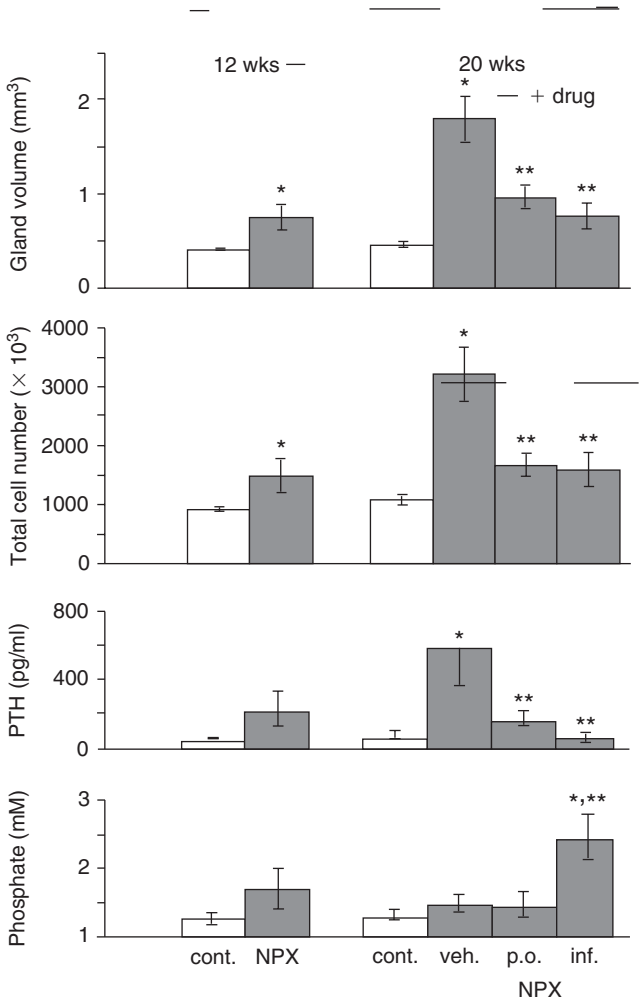

FIGURE 9 NPS R-568 blocks the progression of secondary hyperparathyroidism in CRI rats. NPS R-568 or vehicle was administered orally once a day (p.o.; 10 μmol/kg) or continuously infused (inf.; 20 μmol/kg/day) for 8 weeks beginning 11 weeks after a 5/6 nephrectomy. (Redrawn from data in Fox *et al.*, 2000, Chin *et al.*, 2000).

Cardiovascular and renal functions deteriorate in the partially nephrectomized rat model, as they tend to do in CKD patients whose mineral metabolism is not adequately controlled (Ritz *et al.*, 2005; Schmitt *et al.*, 2006). Using this rodent model, Ogata *et al.* (2003) showed improvements in a number of functional renal and cardiovascular readouts following daily administration of NPS R-568 for four or eights weeks. The rate of progression of renal failure, as assessed by serum creatinine or albumin excretion and by histological examination of the remnant kidney, was reduced by treatment with NPS R-568. Treatment with the calcimimetic also lowered systolic blood pressure and serum levels of high- and low-density lipoprotein and total cholesterol. Cardiac structure at the light microscopic levels was also improved. In general, the treatment effects of the calcimimetic were similar to those achieved by parathyroidectomy.

Beneficial effects of calcimimetics on renal functions have also been noted in other animal models. In a rat model of nephrocalcinosis, treatment with NPS R-467 ameliorated the furosemide-induced increase in kidney calcium content (Pattaragarn *et al.*, 2004). Cinacalcet has also been studied in genetically hypercalciuric rats (Bushinsky *et al.*, 2006). Treatment with cinacalcet did not further augment the hypercalciuria in these rodents.

Cyclic vs. Sustained Decreases in Circulating Levels of PTH

Inherent in the mechanism of action of calcimimetic compounds is their ability to alter plasma PTH levels in a manner that has not been possible previously. The only treatments that directly affect parathyroid cell function act on the synthesis, rather than the secretion of PTH (Naveh-Many and Silver, 1990). This is certainly true for the vitamin D sterols and, if phosphate acts directly on parathyroid cells, this might be how it acts as well. Because

of this action, the suppressive effects of vitamin D sterols on plasma levels of PTH, when they do occur, are slow in onset and in recovery. In contrast, because it targets the calcium receptor, a single oral dose of a calcimimetic compound can lower plasma levels of PTH to a nadir within a couple of hours and levels can return to near baseline within 24 hours. Thus, a calcimimetic compound causes a daily cyclic, rather than sustained decrease in circulating levels of PTH (Fig. 10). The overall profile of the change in plasma PTH will vary depending on the dosing regimen and the pharmacokinetic properties of the particular calcimimetic compound being studied.

The catabolic effect of PTH on bone resulting from sustained elevations reverses to an anabolic effect when plasma levels of PTH increase intermittently. It has been proposed that cyclic decreases in abnormally raised levels of plasma PTH might have effects on bone quality similar to those achieved by daily cyclic increases of PTH above normal levels (Nemeth and Bennett, 1998). A treatment for secondary HPT that causes a cyclic decrease in circulating levels of PTH might achieve improvements in bone quality that are superior to those of a treatment that causes a sustained decrease in PTH. There is some evidence to support this hypothesis.

Using a partially nephrectomized rat model of uremia, Schmitt *et al.* (2000) compared the effects of the PTH peptide fragment 1−37 on longitudinal growth when administered intermittently by subcutaneous injection or continuously by infusion. The twice daily administration of PTH fragment 1−37, but not its continuous infusion, improved longitudinal growth in uremic animals.

The effects of cyclic or sustained decreases in plasma levels of endogenous PTH were studied in a rodent model of uremia produced by adriamycin. Rats treated with adriamycin develop glomerular sclerosis, which, after several months, results in a mild secondary HPT. Plasma levels of Ca^{2+} and phosphate are normal but vitamin D sterols are greatly reduced and there is massive proteinuria (Ishii *et al.*, 2000). The renal osteodystrophy in this model is characterized by a low-turnover bone lesion with osteopenia and osteomalacia. Circulating levels of PTH were decreased in a cyclic manner by the daily oral administration of NPS R-568 or they were continuously suppressed by the subcutaneous infusion of this compound. Oral administration, but not continuous infusion of NPS R-568, increased trabecular bone volume and bone mineral density (Fig. 11). Thus, cyclic decreases in plasma levels of PTH have markedly different effects on bone than do sustained decreases and, at least in this animal model of CRI, the daily cyclic decreases in plasma PTH levels had an "anabolic-like" effect on bone.

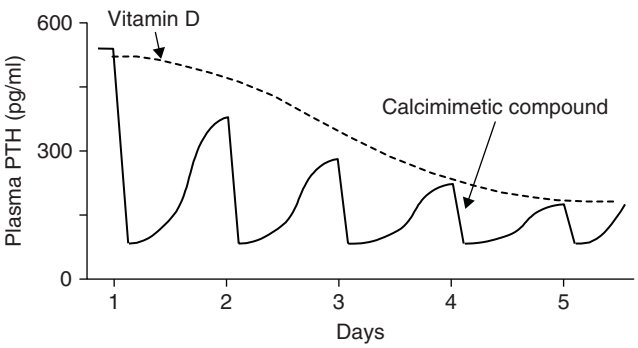

FIGURE 10 Contrasting effects of calcimimetic compounds and vitamin D sterols on the dynamics of changes in circulating levels of PTH. (modified Fig. 1 in Nemeth and Bennett, 1998).

Clinical Studies in Patients with Secondary Hyperparathyroidism

ESRD Patients on Dialysis

The initial clinical investigations of NPS R-568 in renal dialysis patients and the preliminary results obtained with cinacalcet in phase II studies were discussed in the second edition (Nemeth, 2002a). Full reports of these phase II trials have now been published (Goodman *et al.*, 2002; Lindberg *et al.*, 2003; Quarles *et al.*, 2003). Reviewed in this edition are the phase III studies (Block *et al.*, 2004b; Lindberg *et al.*, 2005; Moe *et al.*, 2005a,b) that that formed the basis for regulatory filing of cinacalcet to the Food and Drug Administration. With the exception of the dose-ranging study (Goodman *et al.*, 2002) all were randomized, placebo-controlled, double-blind trials that followed a similar design consisting of an initial titration phase followed by a maintenance phase. Patients on renal dialysis

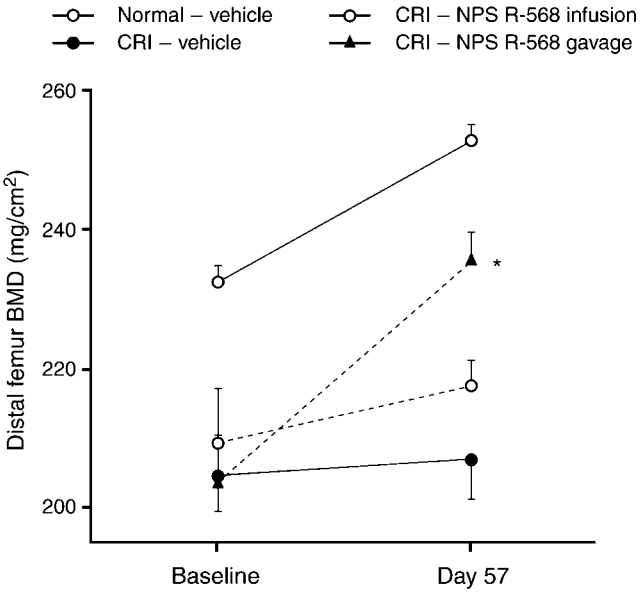

FIGURE 11 Bone mineral density in the distal femur is increased by daily oral administration of NPS R-568 (10 mg/kg) for 56 days in rats with CRI induced by adriamycin. In contrast, the continuous infusion of NPS R-568 (4.5 mg/kg/day) was without effect. (Fig. 3 in Ishii *et al.*, 2000).

with plasma PTH levels higher than 300 pg/mL and serum calcium levels greater than 8.4 or 8.8 mg/mL were eligible for enrollment. Other contemporary reviews of these trials have been published (Goodman, 2004, 2005; Szczech, 2004; Torres, 2004; Gal-Moscovici and Sprague, 2006).

The combined results from two identical trials conducted at 125 sites and involving 741 patients on hemodialysis were reported by Block *et al.* (2004b). There was a 12-week dose-titration phase and a 14-week efficacy-assessment phase and the primary endpoint was the percentage of patients who achieved PTH levels of 250 pg/mL. A 30-mg dose of cinacalcet was administered once daily and could be increased to 180 mg during the dose-titration phase. Treatment with cinacalcet for a total of 26 weeks significantly lowered plasma levels of PTH by 43% compared with baseline levels, whereas PTH levels in the placebo-treated group increased by 9%; 43% of the cinacalcet-treated patients reached the primary endpoint. Patients treated with cinacalcet had significantly lower levels of serum calcium (−6.8%) and phosphorous (−8.4%) compared with those treated with placebo. The calcium-phosphorous product decreased by 14% in the cinacalcet group but remained unchanged in the placebo group, and 89% of those who reached the primary endpoint had a reduction in the calcium-phosphorous product. The most common adverse events in patients treated with cinacalcet were nausea and vomiting and these occurred significantly more often than in those treated with placebo. The frequency of nausea was unrelated to the dose of cinacalcet whereas that of vomiting was. Transient episodes of hypocalcemia (less than 7.5 mg/mL) occurred significantly more often in cinacalcet-treated (5%) than in placebo-treated subjects (1%) but were rarely associated with symptoms and could be managed by adjusting the doses of calcium-containing phosphate binders and/or vitamin D sterols.

All the patients in the two trials reported by Block *et al.* (2004b) were on hemodialysis; a third phase III trial included patients on peritoneal dialysis (Lindberg *et al.*, 2005). The dose-titration phase was 16 weeks and the efficacy-assessment phase was 10 weeks and involved 395 patients of whom 46 were receiving peritoneal dialysis; the primary efficacy endpoint was the proportion of patients achieving a ≥30% reduction from baseline in plasma levels of PTH. The results were essentially the same as in the Block *et al.* (2004b) report. During the efficacy phase, 46% of the cinacalcet-treated patients achieved plasma levels of PTH = 300 pg/mL compared with 9% in the placebo-treated group. The proportion of patients with a ≥30% reduction from baseline in plasma PTH levels was 65% for patients treated with cinacalcet but only 13% for those treated with placebo. Serum levels of calcium and phosphorous decreased by 6.5% and 7.2%, respectively, and the calcium-phosphorous product decreased by nearly 13% compared with baseline in cinacalcet-treated subjects but remained unchanged in those treated with placebo. The results obtained in patients on peritoneal dialysis were similar to those on hemodialysis with 50% of the former achieving a plasma PTH level of 300 pg/mL and similar reductions in serum calcium and phosphorous levels and the calcium-phosphorous product. The most frequent adverse events were nausea and vomiting. Transient episodes of hypocalcemia occurred more frequently in cinacalcet-treated subjects but they were not associated with symptoms and could be readily managed by changing dialysate calcium concentration and/or comedications (Lindberg *et al.*, 2005).

The data from all the phase III studies were combined to assess the overall efficacy of cinacalcet relative to the guidelines established by the NKF-K/DOQI™ (Moe *et al.*, 2005a). At baseline, the median plasma PTH levels of cinacalcet-treated and control subjects were similar (596 and 564 pg/mL, respectively). After treatment for 6 months with cinacalcet, 56% of the subjects achieved mean plasma PTH levels at or below the upper limit of the NKF-K/DOQI™ target (less than 300 pg/mL) compared with 10% of control subjects (Fig. 12). Serum levels of calcium and phosphorous were within the NKF-K/DOQI™ target range in 49% and 46% of cinacalcet-treated subjects compared with 24% and 33%, respectively, in placebo-treated subjects. The target value for the calcium-phosphorous product was achieved in 65% of patients treated with cinacalcet compared with 36% of those treated with placebo (Fig. 13). All of these between-group differences were highly significant. The differences resulting from treatment with cinacalcet are larger than these comparisons suggest because about one-third of all subjects were already in the NKF-K/DOQI™ range for these serum parameters at baseline. Perhaps the most impressive index of efficacy is the percentage of patients achieving the targets for both serum PTH levels and calcium-phosphorous product, which none of the subjects met at baseline. After 6 months, this endpoint was achieved in 41% of cinacalcet-treated subjects but only 6% of placebo-treated subjects (Moe *et al.*, 2005a).

The long-term safety and efficacy of cinacalcet was assessed in a 2-year open-label extension study (Moe *et al.*, 2005b). Subjects who had completed one of the four phase II studies were enrolled and all (59 patients) were treated with cinacalcet. After 2 years of daily dosing with cinacalcet, 59% of subjects had plasma PTH levels of 300 pg/mL. At baseline, 39% of patients treated previously with cinacalcet and 19% of patients treated previously with placebo had plasma PTH levels of 300 pg/mL. After 2 years of treatment with cinacalcet, 66% of subjects had achieved a ≥30% reduction in plasma levels of PTH. The proportion of patients with serum levels of calcium and phosphorous and the calcium-phosphorous product within the NKF-K/DOQI™ target range did not change over 2 years when compared with baseline values at entry. Sixteen patients had participated in a 1-year phase II and therefore received cinacalcet daily for 3 years. After 3 years of treatment with cinacalcet, 70% of subjects achieved a ≥30% reduction in

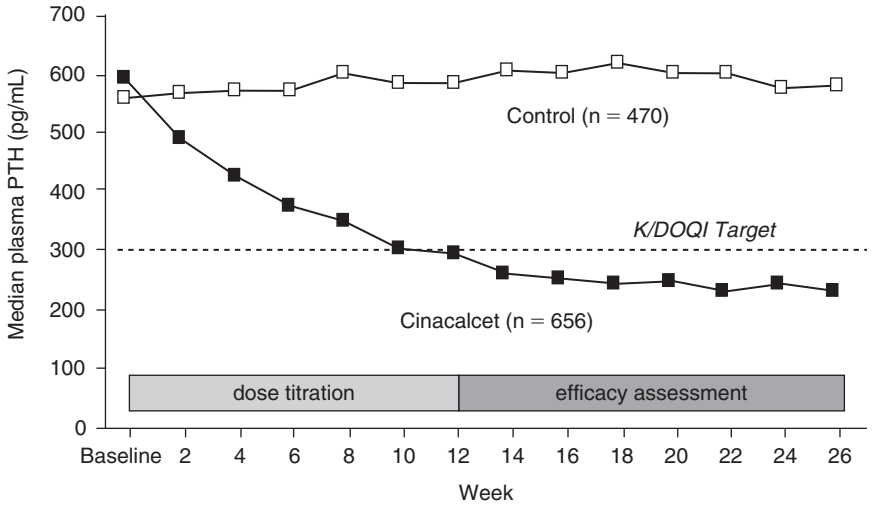

FIGURE 12 Once daily dosing with cinacalcet reduces plasma levels of PTH in patients with secondary HPT on dialysis. (Fig. 2A in Moe *et al.*, 2005).

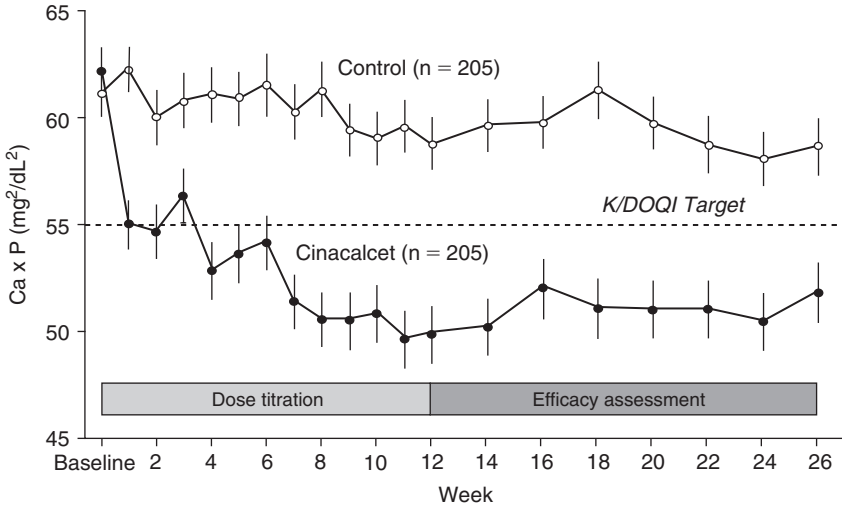

FIGURE 13 Once daily dosing with cinacalcet reduces the calcium-phosphorous product in patients with secondary HPT on dialysis. (Modified Fig. 2 in Moe *et al.*, 2005).

plasma levels of PTH. Adverse events were mild to moderate in severity and the most common were nausea and vomiting, both of which resolved spontaneously in about a third of the patients (Moe *et al.*, 2005b).

Clinical studies with cinacalcet were underway when it was realized that commercial assays for PTH were detecting some large C-terminal peptide fragments of PTH in addition to the intact hormone. This discovery led to the development of improved immunometric assays that detect solely the intact hormone (D'Amour, 2006). A head-to-head comparison of plasma PTH levels using a first-generation ("intact-PTH") and a second-generation immunometric assay ("bio-intact-PTH") was performed in 410 patients (Martin *et al.*, 2005). Treatment with cinacalcet for 26 weeks lowered plasma levels of PTH in the same percentage of subjects (56%) and by the same magnitude (38%) using either assay. In the control group, plasma PTH levels increased compared with baseline and the percent increase was significantly greater (23%) with a second-generation than with a first-generation assay. The bioactive PTH/intact PTH ratio remained constant at 56% throughout the study. Thus, the absolute level of plasma PTH is assay-dependent but the magnitude percent decrease from baseline and the proportion of patients responding to cinacalcet is independent of the assay used to measure PTH.

The collective results of all these prospective clinical trials are consistent and demonstrate the efficacy and safety of cinacalcet in the treatment of secondary HPT in patients in on dialysis. A meta-analysis of these studies confirms that treatment with cinacalcet improves biochemical

parameters and the proportion of patients that achieve the NKF-K/DOQI™ targets (Strippoli *et al.*, 2006). Similar improvements were obtained in everyday practice by using a treatment algorithm that includes cinacalcet (Spiegel *et al.*, 2006).

Several points deserve mention when considering the efficacy of cinacalcet in the treatment of secondary HPT. First, in all of the studies with cinacalcet, plasma PTH levels were measured 24 hours after the last dose of drug but prior to the dose on the following day. Yet the maximal decrease in plasma levels of PTH occurs 2 to 4 hours after dosing with cinacalcet. Thus, the levels of PTH reported in all these studies are an underestimate of the average levels over a 24-hour period. A much higher percentage of patients would have achieved the primary endpoint if plasma PTH levels were measured at 2 to 4 hours after dosing. These studies thus provide a rather conservative estimate of efficacy. Second, most of the patients studied were already receiving medications to manage secondary HPT. For example, in the study of Block *et al.* (2004b), 67% of the total patient population was already taking vitamin D sterols and 93% were taking phosphate binders. So nearly all the patients' labeled "control" in Figures 12 and 13 were receiving what was then standard of care. The fact that all these patients had plasma PTH levels greater than 300 pg/mL highlights the difficulty of lowering circulating levels of PTH prior to the introduction of cinacalcet. Third, more than 20% of all patients studied had severe HPT (greater than 800 pg/mL) yet most of those treated with cinacalcet achieved the NKF-K/DOQI™ target for serum PTH or a 30% reduction from baseline levels. Thus, like the results obtained in rodent models, the degree of severity of secondary HPT does not impact the efficacy of calcimimetics in lowering circulating levels of PTH. In patients with secondary HPT, the efficacy of cinacalcet is the same regardless of the severity of the disease and the length of time on dialysis, at least within the first 6 months of treatment.

At present, there are only limited data describing the effect of cinacalcet treatment on skeletal parameters relevant to renal osteodystrophy. BMD of the proximal femur and the lumbar spine was assessed in a small number of patients on dialysis or with stage 4 chronic kidney disease (Lien *et al.*, 2005). Treatment of dialysis patients with cinacalcet for 26 weeks lowered plasma levels of PTH by 44% compared with baseline. Plasma PTH levels in predialysis patients were reduced by 73% following treatment with cinacalcet for 6 weeks. When analyzed collectively, treatment with cinacalcet significantly increased BMD and *T* score of the proximal femur but did not affect either parameter in the lumbar spine. There was a positive correlation between femur BMD and absolute decrease in plasma level of PTH. In the subset of dialysis patients, treatment with cinacalcet resulted in a 2.2% increase in proximal femur BMD, whereas BMD decreased by 1.9% in patients treated with placebo.

Bone biopsy samples were collected from 32 patients at baseline and after 1 year of treatment with cinacalcet (19 patients) or placebo (13 patients; Mallauche *et al.*, 2004). At baseline, 84% of patients in each group had high bone turnover as assessed by the numbers of osteoblasts and osteoclasts and the activation frequency. After 1 year of treatment with cinacalcet, there were reductions in activation frequency and bone cell numbers; these parameters were also reduced in the placebo group but to a lesser extent. Treatment with cinacalcet did improve marrow fibrosis compared with the placebo-treated group. Three patients treated with cinacalcet developed adynamic bone disease but in two of these, plasma levels of PTH were suppressed below 100 pg/mL. It is difficult to draw any conclusions from the limited data available but there are some trends toward improvements in skeletal parameters following treatment with cinacalcet.

The ability of cinacalcet to lower plasma levels of PTH and the calcium-phosphorous product, and the association of these blood biochemistries with vascular calcification and renal osteodystrophy, offers some reason to suppose that the drug will reduce morbidity and mortality in patients with secondary HPT. The cumulative safety data from all the trials with cinacalcet support this. The combined data, based on 1184 subjects (697 cinacalcet-treated subjects) showed that randomization to cinacalcet significantly reduced the relative risk of parathyroidectomy, fracture, and cardiovascular hospitalization compared with placebo (Cunningham *et al.*, 2005). There were also some significant improvements in quality of life, such as self-reported physical function and diminished bodily pain.

Pre-dialysis Patients

The results of one prospective study in patients with chronic kidney disease (CKD) and secondary HPT but not yet on dialysis have been reported (Charytan *et al.*, 2005). This randomized, double-blind, placebo-controlled study assessed the safety and efficacy of cinacalcet in 54 subjects with secondary HPT as indicated by plasma levels of PTH greater than 130 pg/mL. Cinacalcet was administered daily during a 12-week dose-titration phase followed by a 6-week phase to determine efficacy. The primary endpoint was again a 30% fall in plasma levels of PTH when measured 24 hours after the last dose. The baseline level of plasma PTH was 240 pg/mL and 28% and 43% of the patients were on vitamin D sterols and phosphate binders, respectively. In cinacalcet-treated subjects, plasma levels of PTH fell by 33% after 2 weeks and remained at 30% to 40% of baseline throughout the study, whereas patients receiving placebo maintained PTH levels at about baseline. Most patients treated with cinacalcet (56%) reached the primary endpoint. There was a decrease in serum levels of calcium and an increase in the serum levels of phosphorous that occurred within one week and persisted throughout the study. Twenty-four hour urinary calcium increased whereas that of phosphorous

decreased. All these changes in serum and urine parameters might be explained by a decrease in plasma levels of PTH in the setting of a mostly functional kidney, but an action of cinacalcet on renal calcium receptors cannot be excluded.

Renal Transplant Patients

Kidney transplant in ESRD patients is typically successful and over time the secondary HPT spontaneously resolves. There remain, however, a variable percentage of patients (anywhere from 2% to 20%) that present with persistent HPT after kidney transplantation (Lewin and Olgaard, 2006). These patients are logical candidates for treatment with cinacalcet. Several independent studies, each comprising a small number of transplant patients, have been reported (Kruse *et al.*, 2005; Serra *et al.*, 2005; Apostolou *et al.*, 2006a, b; Leca *et al.*, 2006; Srinivas *et al.*, 2006; Szwarc *et al.*, 2006; Dorsch, 2007; El-Amm *et al.*, 2007). A total of 83 renal allograft recipients with persistent HPT have been treated with cinacalcet daily for 10 weeks to 6 months. Treatment with cinacalcet lowered serum calcium levels in every patient studied and returned into the normal range in most patients within 2 weeks. All but two reports (Kruse *et al.*, 2005; Srinivas et al, 2006) observed a fall in plasma levels of PTH after treatment with cinacalcet. Serum phosphorous levels did not change in five of the studies and slightly increased in the other three. Overall, the results of these small observational studies suggest that cinacalcet might be useful in managing persistent secondary HPT following renal transplantation. Appropriately designed clinical trials are required to establish the efficacy and safety of cinacalcet in this patient population.

Calciphylaxis

This rare but serious condition is characterized by cutaneous ischemia and necrosis, vascular calcification, and refractory infections; it is typically fatal (Wilmer and Magro, 2002). There have been two case reports of renal dialysis patients who developed calciphylaxis and were successfully treated with cinacalcet (Velasco *et al.*, 2006; Robinson *et al.*, 2007). In both instances, treatment with cinacalcet lowered plasma levels of PTH and normalized serum levels of calcium and phosphorous; skin ulcerations healed following several months of treatment.

Cinacalcet Indications

Cinacalcet•HCl is marketed by Amgen as Sensipar® in North America and Mimpara® in the European Union. Sensipar® is approved for the treatment of secondary HPT in patients with CKD on dialysis. It is also approved for the treatment of hypercalcemia in patients with parathyroid carcinoma. At present, it is approved for the treatment of other forms of primary HPT only in Switzerland. Cinacalcet has recently been approved in Japan.

OSTEOPOROSIS

PTH increases bone turnover and the resulting overall effect on the skeleton is highly dependent on the temporal changes in the circulating levels of PTH. Thus, sustained elevations in plasma PTH levels, such as occur in HPT, lead to increased bone resorption and a net decrease in bone mass, especially at cortical sites. In contrast, temporary increases in plasma levels of PTH achieved by daily (or near daily) injection, stimulate new bone formation in animal models of osteopenia (Dempster *et al.*, 1993) and in postmenopausal osteoporotic women (Rittmaster *et al.*, 2000). The results of these studies using intermittent administration demonstrate that PTH is an effective anabolic agent.

The effects of parathyroid hormone (PTH) on the skeleton are mediated by a G protein-coupled receptor, the PTH-R1. This receptor is also activated by N-terminal-intact peptide fragments of PTH or parathyroid hormone-related peptide (PTHrP) and such peptide fragments likewise stimulate new bone formation. The 1–34 fragment of PTH, teriparatide (Forteo®), is the first anabolic therapy for osteoporosis to reach the market; the intact hormone (Preotact®) is approved for use in Europe. Other anabolic peptides in clinical development are PTHrP(1–36) and the cyclic peptide analog Ostabolin C™ (Fox, 2002). However, the therapeutic use of all these peptides is compromised by the need for systemic administration of a costly biological product. Calcilytic compounds might provide an alternative approach to systemic administration of PTH peptides by increasing the circulating levels of endogenous PTH (Nemeth, 2002c).

Preclinical studies using the calcilytic compound NPS 2143 in ovariectomized (OVX) rat models of osteopenia have generated results consistent with this hypothesis and were discussed in the second edition (Nemeth, 2002a). Daily oral administration of NPS 2143 for five weeks increased circulating levels of PTH and increased bone turnover in osteopenic OVX rats (Gowen *et al.*, 2000). When administered together with 17β-estradiol, this compound increased new bone formation in the proximal tibial metaphysis and increased bone mass in the distal femur. An anabolic effect of NPS 2143, however, required coadministration of 17β-estradiol and it did not increase (or decrease) BMD when administered alone; although it stimulated new bone formation, it also stimulated bone resorption so no net gain in BMD was achieved. The failure to achieve a net anabolic effect with NPS 2143 probably results from the pharmacokinetic profile of this compound: although orally active, it has a very long plasma $t_{1/2}$ and causes sustained increases in circulating levels of PTH. Despite the long plasma $t_{1/2}$, daily dosing of OVX rats with NPS 2143 for five weeks did not increase parathyroid cell proliferation, either by itself or when administered together with estradiol (Gowen *et al.*, 2000). These initial studies provided

proof of concept that an antagonist of the calcium receptor could increase circulating endogenous PTH to levels sufficient to stimulate new bone formation and do so without causing parathyroid gland hyperplasia.

To be useful therapeutically, a calcilytic compound must possess some challenging pharmacokinetic properties. The compound must be orally bioavailable and it must rapidly reach a C_{max} yet have a short plasma $t_{1/2}$; there can be no active metabolites that linger in the circulation. These are the pharmacokinetic properties that will facilitate patient compliance and achieve a rapid and transient increase in plasma levels of PTH. Calcilytic compounds with at least some of these properties have now been obtained.

Compound 1 (see Fig. 5) has improved pharmacokinetic properties when compared with NPS 2143. Compound 1 inhibits extracellular Ca^{2+}-induced increases in $[Ca^{2+}]_i$ and inositol phosphates in HEK 293 cells expressing the human calcium receptor with potencies of 64 and 229 n*M*, respectively (Arey *et al.*, 2005). It is orally bioavailable and reaches a C_{max} of about 2 μ*M* at 1 hour following a single oral dose (30 mg/kg). At this dose, there was a 2- to 3-fold increase in plasma levels of PTH that coincided with the C_{max} of the compound and returned to baseline levels within 3 hours. The effects of compound 1 in an animal model of osteoporosis have yet to be reported but the magnitude and time course of change in plasma levels of PTH are appropriate to increase net bone formation.

Structural modifications to NPS 2143 have yielded several analogues with improved pharmacokinetic profiles, similar to those of compound 1. One of these analogues has been studied in the OVX rat model. Aged female rats were OVX and osteopenia was allowed to develop for 6 weeks before treatment. Daily oral dosing with the calcilytic was for 12 weeks either alone or together with estradiol. The single oral administration of the calcilytic caused a 2- to 3-fold increase in plasma PTH levels that peaked within 20 minutes and returned to baseline levels by 2 hours. After 3 months of daily dosing, there was an increase in bone formation rate at the lumbar spine. Treatment with estradiol alone did not increase bone formation rate nor did it diminish the stimulatory effect of the calcilytic. Significantly, treatment with the calcilytic alone increased BMD at the lumbar spine and increased vertebral bone strength as assessed by compression force. These findings in the OVX rat model provide proof of concept that a calcilytic compound can, by itself, increase BMD when orally administered daily.

In postmenopausal women, the oral administration of another amino alcohol chemotype, SB-751689 (see Fig. 5), caused a dose-dependent, rapid and transient increase in serum levels of PTH. After 28 days, there were increases in serum levels of the bone formation markers procollagen type I amino-terminal peptide, BSAP, and osteocalcin that were similar in magnitude to those produced by 28 days of daily dosing with teriparatide or PTH. Serum levels of the bone resorption marker C-terminal telopeptide of type I collagen were not different from baseline following one month of daily dosing with the calcilytic. A phase II clinical trial of SB-751689 in postmenopausal osteoporotic women has recently been initiated.

In the aggregate, the preclinical and clinical data suggest that enough PTH can be released from the parathyroid glands by a calcilytic compound to stimulate new bone formation. Calcilytics therefore have the potential to become an orally active, cost-effective anabolic therapy for osteoporosis.

CONCLUSION

It has always been difficult to separate the effects of calcium, phosphorous, and vitamin D on parathyroid gland function because their homeostatic mechanisms are so interwoven. Calcimimetic and calcilytic compounds permit the study of parathyroid physiology without changing the level of any of these serum factors and allow circulating levels of endogenous PTH to be altered at will. The use of these compounds has shown that the calcium receptor regulates a number of distinct parathyroid cell functions beyond secretion and including the synthesis of PTH and parathyroid cell proliferation. All of these functions were either known or suspected to be regulated by the calcium receptor, and altering its activity pharmacologically reinforces or solidifies our understanding of parathyroid physiology. What calcimimetics and calcilytics reveal uniquely is the principal role of the calcium receptor in parathyroid physiology—cellular functions coupled to this receptor will dominate those mediated by phosphate and/or vitamin D.

The most significant use of calcimimetics and calcilytics, of course, is therapeutically. Cinacalcet is a welcome addition to the armamentarium used to manage secondary HPT in patients on dialysis. Dialysis patients treated with cinacalcet can achieve NKF-K/DOQI™ targets even when other therapies fail. Cinacalcet is also the only medical treatment for parathyroid cancer. Yet the drug is not without its limitations and it has yet to be approved for treating patients not on dialysis or those with primary HPT not owing to carcinoma. What might be needed in these patient populations is a calcimimetic that maximally activates calcium receptors on parathyroid cells without activating those in the kidney and gastrointestinal tract. Cinacalcet does selectively target parathyroid cells when compared with C cells, but its relative potency on calcium receptors in the parathyroid gland, the kidney, and the gut is still unknown. Nonetheless, cinacalcet can still claim several "firsts." It is the first drug for parathyroid carcinoma. It is also the first drug to act on the calcium receptor. Significantly, cinacalcet is the first drug to act allosterically on any G protein-coupled receptor. As such, it defines an entirely new class of pharmaceutical for this large family of drug targets.

We dedicate this chapter to the memories of Herbert Fleisch and Gideon Rodan. Herbie and Gideon played major roles in the development of the bisphosphonates, and were authors of the chapter that appeared in earlier versions of this book. They are both sadly missed by their many friends and colleagues, and we hope they would have been pleased to see the continued progress being made in the field they helped to create.

INTRODUCTION

The bisphosphonates are a class of drugs developed since the late 1960s for use in various diseases of calcium metabolism. Known to chemists since the mid-nineteenth century, they were first synthesized in Germany (Menschutkin, 1865) and were used mainly in the textile, fertilizer, and oil industries to prevent scaling because of their property to inhibit calcium carbonate precipitation (Blomen, 1995). This chapter will cover the history of the development, chemistry, biological actions, and molecular mechanisms of action of bisphosphonates. Emphasis will be given to newer developments, but we will not deal with details of clinical efficacy and therapeutics. The reader is encouraged to consult other recent reviews for additional information (Rogers, 2004; Roelofs *et al.*, 2006a; Coxon *et al.*, 2006; Kimmel, 2007; Russell *et al.*, 2007, 2008).

[1]Corresponding author: R. Graham G. Russell, The Oxford University Institute of Musculoskeletal Sciences, The Botnar Research Centre, Nuffield Department of Orthopaedic Surgery, Nuffield Orthopaedic Centre, Headington, Oxford, United Kingdom.

HISTORY OF BISPHOSPHONATE DEVELOPMENT FOR USE IN BONE DISEASES

Our knowledge of the biological characteristics of bisphosphonates dates back about 40 years, the first report appearing in 1968 (Fleisch *et al.*, 1968). The concept of using bisphosphonates was derived from earlier studies on inorganic pyrophosphate (PPi), which was found to prevent both the formation (Fleisch and Neuman, 1961) and dissolution of calcium phosphate *in vitro* (Fleisch *et al.*, 1966). Because pyrophosphate was subsequently shown to prevent ectopic calcification *in vivo* and to be present in urine and plasma (Fleisch and Bisaz, 1962), it was suggested that PPi was a physiological regulator of calcification and perhaps also of decalcification *in vivo* (Fleisch *et al.*, 1966). Owing to its rapid hydrolysis, pyrophosphate found therapeutic use only in scintigraphy and in toothpaste, added to prevent dental calculus. This prompted the search for analogues with similar physicochemical properties, but that resisted enzymatic hydrolysis and metabolism. The bisphosphonates fulfilled these criteria.

CHEMISTRY AND GENERAL CHARACTERISTICS

Bisphosphonates are compounds characterized by two C–P bonds. When the two C–P bonds share a single carbon atom (P–C–P), they are deemed to be analogues of pyrophosphate (P–O–P) and are called geminal bisphosphonates (so-called because the carbon is at the central or geminal position) (Fig. 1). The P–C–P bonds of the geminal bisphosphonate are stable to heat and most chemical

Principles of Bone Biology, 3rd Edition

reagents and are completely resistant to enzymatic hydrolysis. Only geminal bisphosphonates seem to have a strong activity on the skeleton. For the sake of simplicity they are generally called bisphosphonates.

A key pharmacological feature of bisphosphonates is their ability, like pyrophosphate, to bind to bone mineral. Binding of bisphosphonates to bone mineral can be bidentate through the two phosphonates, as is the case for clodronate, or it can be tridentate (Barnett and Strickland, 1979) through a third moiety, such as a hydroxyl or a nitrogen attached to the carbon atom, as is the case for most of the bisphosphonates in current clinical use. Tridentate binding increases the affinity for mineral.

The P–C–P structure allows a great number of possible variations by changing the two side chains on the carbon atom (Fig. 2). Many bisphosphonates have been studied in animals. It is becoming more apparent that each bisphosphonate has its own physicochemical and biological profile, which implies that one cannot automatically extrapolate the findings from one compound to another, with respect to its actions.

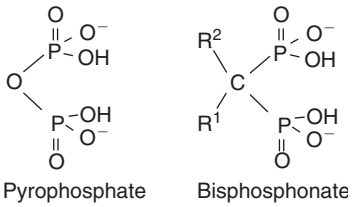

FIGURE 1 The structure of pyrophosphate and a geminal bisphosphonate.

PHARMACOKINETICS

Bisphosphonates are synthetic compounds, not found to occur naturally in animals or humans. No enzymes capable of cleaving the P–C–P bond have been discovered. The bisphosphonates studied and reported so far, including alendronate, clodronate, etidronate, pamidronate, and several others, appear to be absorbed, stored, and excreted from the body unaltered, except for the incorporation of

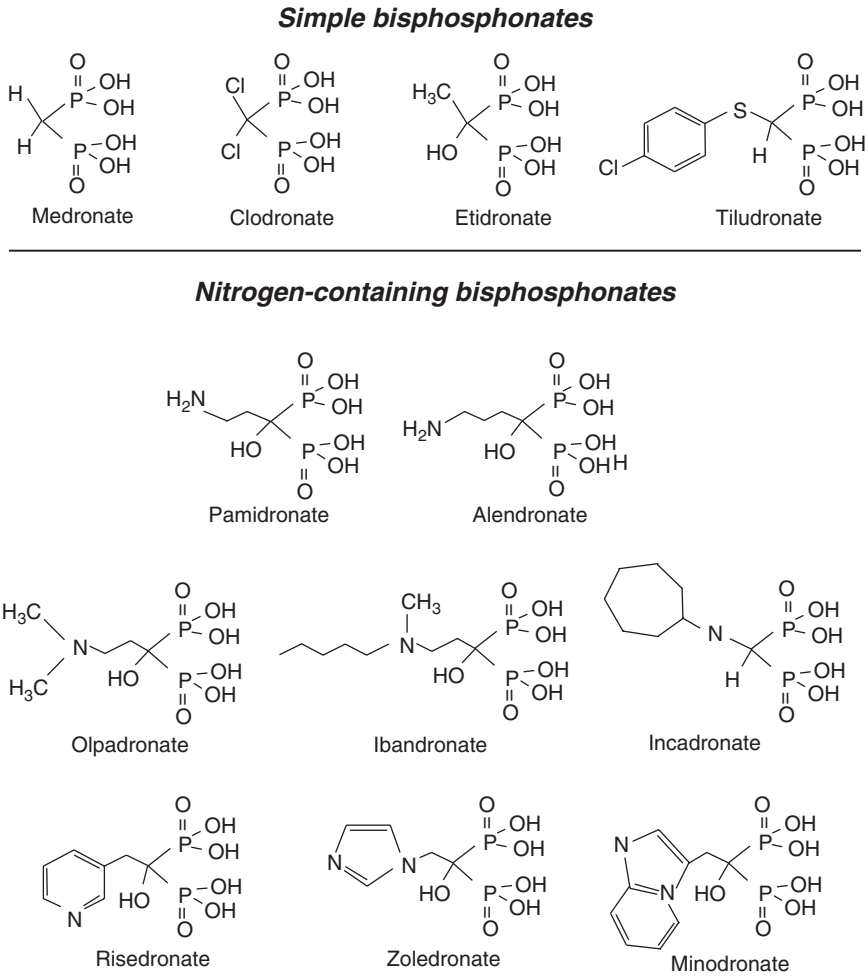

FIGURE 2 Structures of bisphosphonates (shown as the protonated, bisphosphonic acid forms).

etidronate, clodronate, and tiludronate into ATP inside the osteoclast, described later (for reviews, see Papapoulos, 1995; Lin, 1996; Porras *et al.*, 1999).

Intestinal Absorption

The oral bioavailability both in animals and in humans is low, probably because of low lipophilicity and high negative charge. It ranges from less than 1% to 10% of an oral dose, is generally higher in the young, sometimes higher at higher doses, and shows some inter- and intraspecies variation (Michael *et al.*, 1972; Recker and Saville, 1973; Yakatan *et al.*, 1982). Absorption occurs primarily in the small intestine and appears to occur by passive diffusion, possibly through a paracellular pathway (Boulenc *et al.*, 1993). It is diminished when the drug is given with meals, in the presence of calcium, and, interestingly, also even when given with beverages such as coffee, tea, or orange juice (Gertz *et al.*, 1995).

Circulating Half-Life

The half-life of circulating bisphosphonates is short, in the order of minutes in the rat (Bisaz *et al.*, 1978) and approximately 0.5 to 2 hours in humans. While in the circulation, variable amounts of different bisphosphonates are ultrafiltrable. The values are strongly species dependent. The remainder is either bound to proteins, especially albumin (Lin *et al.*, 1994), or present in very small aggregates (Wiedmer *et al.*, 1983).

Renal Clearance

Between 30% and 70% of absorbed bisphosphonates are taken up by bone, the remainder being rapidly excreted in the urine (Michael *et al.*, 1972; Yakatan *et al.*, 1982). The renal clearance of bisphosphonates is high. When taking into account that they are only partially ultrafiltrable, the renal clearance can exceed glomerular filtration rate, suggesting that renal secretion can occur (Troehler *et al.*, 1975; Lin *et al.*, 1992). Urinary excretion is decreased in renal failure and their removal by peritoneal dialysis is poor, which should be taken into account when the compounds are administered to patients with renal insufficiency.

Uptake and Retention in the Skeleton

The rate of uptake by bone is very fast, bone clearance being compatible with complete first-passage extraction from the circulation by the skeleton (Bisaz *et al.*, 1978). Skeletal uptake might therefore be determined to a large extent by bone vascularization. Soft tissues are thus exposed to these compounds for short periods only, which explains their bone-specific effects.

The uptake of bisphosphonate by the skeleton varies with species, gender, and age and can differ among compounds. Sometimes bisphosphonates can deposit in other organs such as the stomach, liver, and spleen. Some of this extraosseous deposition appears to be caused by the formation of complexes, occurring when large amounts are infused rapidly. If given at therapeutic doses and infused slowly, extraosseous deposition seems to be negligible.

When bisphosphonates are given at clinical doses to humans, there seems to be no saturation of the total skeletal uptake, at least not within periods as long as years or decades. In contrast, the antiresorbing activity rapidly reaches a maximum value, both in animals (Reitsma *et al.*, 1980) and in humans (Garnero *et al.*, 1994). The fact that a plateau of activity is reached, despite continuous bisphosphonate accumulation in the skeleton, is consistent with entombment of the compound, where it is inactive because it is not accessible to the osteoclasts on the bone surface.

The bisphosphonates are probably liberated from the skeleton by both passive and active processes; release by physicochemical mechanisms, such as desorption, outward diffusion, and ion exchange, may occur to a lesser extent than release when the bone in which they are deposited is resorbed (Kasting and Francis, 1992). The notion of skeletal retention being described in terms of "half-life" of retention in the body has led to some confusion, because calculated half-lives depend on the experimental design and duration of studies, in addition to any inherent differences between compounds (Russell *et al.*, 2008). Skeletal retention also depends on the rate of bone turnover, which, in turn, is influenced by bisphosphonates themselves. The drugs can therefore prolong their own survival in the skeleton. Retention times and terminal half-lives have been estimated to be up to 1 year in mice or rats (Mönkkönen, *et al.*, 1990), and even longer, up to 10 years, in humans (Kasting and Francis, 1992; Lin 1996). It is possible that some of the administered bisphosphonate can stay buried in the skeleton for life, although in inactive form. This is also true for other "bone-seeking" substances such as tetracyclines, heavy metals, and fluoride.

BINDING AFFINITIES FOR BONE

Recent studies have measured and compared the relative affinities of various clinically used bisphosphonates for hydroxyapatite or human bone (Nancollas *et al.*, 2006; Leu *et al.*, 2006).

Binding to Hydroxyapatite

The binding of bisphosphonates to human bone restricts their tissue distribution almost entirely to the skeleton. In doing so, the molecular mechanisms of action (discussed later) are limited to the bone microenvironment. Hydroxyapatite in pure form is related to hydroxyapatite in bone, although it lacks both the carbonate content and

TABLE I Binding affinities of BPs for natural bone and hydroxyapatite

Bisphosphonate	Relative affinity for natural bone (μM)*	Estimated affinity for hydroxyapatite (μM)†
Clodronate	806	1.39
Etidronate	90.7	0.84
Risedronate	84.6	0.46
Ibandronate	116	0.42
Alendronate	60.9	0.34
Zoledronate	80.8	0.29
Pamidronate	82.7	nd
Tiludronate	173	nd

*Based on Leu et al., 2006.

†Based on Nancollas et al., 2006

associated protein components. Binding affinities of bisphosphonates for the pure chemical components of hydroxyapatite have been calculated through constant composition kinetic studies of crystal growth (Nancollas *et al.*, 2006). These studies suggest a narrow range for binding affinities (0.3 to 1.4 μM, as shown in Table I). Notably and curiously, the affinities in these studies are approximately two orders of magnitude greater than have been reported for human bone (see later). The ranking order for affinity of the various bisphosphonates for hydroxyapatite showed clodronate to bind with weakest affinity, whereas risedronate and ibandronate fell into the middle of the range, and alendronate and zoledronate bound with highest affinity.

Binding to Human Bone

Binding constants representing bisphosphonate affinity for human bone have been calculated by using several different methodologies. The direct binding affinity of alendronate for human bone was measured by Scatchard analysis, with a measured K_d of 110 μM (Leu *et al.*, 2006). The difference with the reported affinity for pure hydroxyapatite (0.34 μM) is potentially attributable to differences in methodology and/or the composition of the binding surface (hydroxyapatite versus bone). For example, a more recent study demonstrated that the more soluble carbonated apatite gave a similar rank order of affinities, but with somewhat less variation (Henneman *et al.*, 2008). Independent measurements of the on-rate (69/M/min) and the off-rate (0.033/min) for binding to human bone yielded a K_d of 470 μM, which was about 4-fold higher than the observed K_d of 110 μM and about 1000-fold higher than that seen with hydroxyapatite. The measurement of an off-rate for alendronate demonstrated that it does not irreversibly bind to the bone surface. Once released, the bisphosphonate can engage in any of three activities: (1) reattachment, (2) redistribution to other sites on bone, or (3) excretion in the urine. The ability of bisphosphonate to rebind to newly resorbed surfaces during osteoclastic bone resorption has recently been visualized *in vitro* by using fluorescently labeled alendronate (Coxon *et al.*, 2008). This suggests that the long relative retention of bisphosphonates on bone is (in part) attributable to their ability to rebind after being released. Thus, bone affinity may influence not only the initial distribution to bone, but also the redistribution within the skeleton.

The affinity of different bisphosphonates for bone varies based on the chemical groups at the R^1 and R^2 positions. In an effort to make comparisons between the various bisphosphonates, competition binding assays were used to assess relative affinity for human bone (Leu *et al.*, 2006). In these studies, the ability of nonradiolabeled bisphosphonates to compete with radiolabeled alendronate for binding sites was used as a measure of affinity. This showed that bisphosphonates bearing a hydroxyl (OH) at R^1 (see Table I) bind in a relatively narrow (60 to 120 μM) range. Etidronate, alendronate, ibandronate, pamidronate, risedronate, and zoledronate thus all bound within an approximate twofold affinity range. Others have measured similar affinities toward mouse long bones (Van Beek *et al.*, 1994, 1996, 1998). Tiludronate and clodronate, both of which lack an R^1 hydroxyl group, displayed significantly weaker binding affinities to human bone (about 170 μM and about 800 μM, respectively). An additional study on the relative binding of bisphosphonates to human bone was recently reported (Mukherjee *et al.*, 2008). In this study, binding affinity was compared by utilizing nuclear magnetic resonance spectroscopy where binding was found to be well-described by Langmuir-like isotherms. Pamidronate, zoledronate, and alendronate were found to bind more strongly than risedronate and compelling arguments were made that this difference was strongly influenced by the different charge states at the nitrogen moiety at physiological pH.

Clinical Relevance of Differences in Affinity for Bone

The clinical relevance of differences in bone affinity between bisphosphonates continues to be debated (Leu *et al.*, 2006; Nancollas *et al.*, 2006; Papapoulos, 2006; Russell *et al.*, 2008), because variations in binding affinity for bone may have an impact on the speed of onset and duration of action on the skeleton (reviewed by Russell *et al.*, 2008).

One head-to-head clinical study investigated the uptake and release of a single dose of ^{14}C-labeled risedronate

and alendronate during ongoing administration of weekly doses of the corresponding drugs (Christiansen *et al.*, 2003). After 72 hours, a significantly greater percentage (approximately 20%) of the ^{14}C-labeled alendronate was retained versus risedronate as measured by urinary excretion, consistent with the *in vitro* affinity studies described earlier. However, even the relatively lower-affinity bisphosphonates such as risedronate (as measured in some of these models) have demonstrated extended BMD maintenance and antifracture protection for up to a year despite a resolution of turnover markers within that time frame. This indicates that the primary determinant of antiresorptive potency for the bisphosphonates is more likely to be the biochemical and cellular effects of bisphosphonates on bone cells, as illustrated by correlations between potency for effects at the molecular/cellular level and antiresorptive potency in animal models (Dunford *et al.*, 2001; Lundy *et al.*, 2007). These cellular and molecular mechanisms of action of the bisphosphonates will be discussed in the following sections.

PHYSICOCHEMICAL EFFECTS

As anticipated, the physicochemical effects of most bisphosphonates are very similar to those of pyrophosphate. Thus, most inhibit the formation and aggregation of calcium phosphate crystals (Francis, 1969; Francis *et al.*, 1969; Fleisch *et al.*, 1970) and slow down their dissolution (Fleisch *et al.*, 1969; Russell *et al.*, 1970). These effects are related to the marked affinity of these compounds for the surface of solid-phase calcium phosphate (Jung *et al.*, 1973), where they interfere with both crystal growth and dissolution.

Like pyrophosphate, bisphosphonates can inhibit calcification *in vivo*. Thus, they prevent experimentally induced calcification of many soft tissues when given parenterally or orally (Fleisch *et al.*, 1970), as well as ectopic ossification. Topical administration leads to a decreased formation of dental calculus (Briner *et al.* 1971).

If administered in sufficiently high doses, bisphosphonates can also impair the mineralization of normal calcified tissues such as bone, cartilage, dentine, and enamel (King *et al.*, 1971; Schenk *et al.*, 1973). The amount required to produce these effects varies somewhat according to the bisphosphonate used, the animal species, and the length of treatment. However, in contrast to bone resorption where the different compounds vary greatly in their activity, they inhibit mineralization at similar doses. For most species that dose is in the order of 1 to 10 mg of compound phosphorus per kilogram per day parenterally. There is a close relationship between the ability of a bisphosphonate to inhibit calcium phosphate precipitation *in vitro* and its effectiveness at inhibiting calcification *in vivo* (Fleisch *et al.*, 1970; Trechsel *et al.*, 1977; van Beek *et al.*, 1994). Therefore, the mechanism for this effect is likely to be a physicochemical one. It is possible that other cellular effects, for example, changes in the bone matrix, are involved, but this remains unproven. The inhibition of mineralization can lead to fractures (Flora *et al.*, 1980) and to impaired healing of the fractures (Fleisch, 2001). Although the inhibition is eventually reversed after discontinuation of the drug, the propensity to inhibit the calcification of normal bone has hampered the therapeutic use of bisphosphonates for ectopic calcification. However, this is not the case for their use to inhibit bone resorption, because several bisphosphonates can inhibit resorption at doses 1000 times lower than those inhibiting mineralization. The doses used to inhibit resorption do not impair fracture healing either, when assessed by estimating biomechanical properties (Fleisch, 2001). Indeed, bisphosphonates may actually enhance fracture repair by stabilizing the fracture callus (Little *et al.*, 2005).

Although the ability of bisphosphonates to prevent bone loss was initially ascribed to their physicochemical properties, it has become clear over the years that bisphosphonates act by inhibiting osteoclastic bone resorption.

ANTIRESORPTIVE EFFECTS IN PRECLINICAL MODELS

Bisphosphonates have been shown to be very powerful inhibitors of bone resorption when tested in a variety of preclinical *in vitro* and *in vivo* models.

In vitro

Bisphosphonates block bone resorption induced by various means in organ and cell culture. They decrease the destruction of bone in embryonic long bones and in neonatal calvaria (Fleisch *et al.*, 1969; Russell *et al.*, 1970; Reynolds *et al.*, 1972). In cell culture, the bisphosphonates inhibit the formation of pits by isolated osteoclasts cultured on mineralized substrata (Flanagan and Chambers, 1989; Sato and Grasser, 1990). With few exceptions, the correlation between bisphosphonate potency *in vitro* and that *in vivo* was rather poor (Green *et al.*, 1994). As described earlier, this may be because the relative affinity for bone has not generally been considered in *in vitro* models (Leu *et al.*, 2006).

Normal Animals

In growing rats, bisphosphonates block degradation of both bone and cartilage, thus suppressing the remodeling of the metaphysis which becomes club-shaped and radiologically denser than normal (Schenk *et al.*, 1973). This effect is used as a model, the "Schenk assay," to study the potency

of bisphosphonates (Schenk *et al.*, 1986). The inhibition of endogenous bone resorption has also been documented by ^{45}Ca kinetic studies and by markers of bone resorption (Gasser *et al.*, 1972). Effects occur within 24 to 48 hours and are therefore somewhat slower than that of calcitonin (Mühlbauer and Fleisch, 1990).

The decrease in resorption caused by bisphosphonates is accompanied by a positive calcium balance (Gasser *et al.*, 1972) and an increase in mineral content of bone. This is possible because of an increase in intestinal absorption of calcium consequent to an elevation of $1,25(OH)_2$ vitamin D. Bone formation also decreases after a certain time, attributed to "coupling" between formation and resorption. The main effect is, therefore, a reduction in bone turnover and some increase in bone mineral content. Less is known about the effect in normal adult animals. In dogs and minipigs, long-term administration of alendronate did not lead to an increase in bone mass (Peter *et al.*, 1996). This might be explained by the physiological biomechanical homeostasis of bone structure, which would eliminate an unnecessary excess of bone. A 3-year clinical study of alendronate showed normal bone quality in transiliac bone biopsies (Chavassieux *et al.*, 1997), whereas a 7-year study showed safe and continuous increases in bone mineral density (Tonino *et al.*, 2000). These and similar studies (reviewed in Russell *et al.*, 2008) suggest that concerns about dangers of long-term use of therapeutic doses may not be warranted.

Models of Hyperresorptive Diseases

Bisphosphonates can prevent experimentally induced increases in bone resorption. They impair resorption induced by agents such as parathyroid hormone, $1,25(OH)_2$ vitamin D, and retinoids (Fleisch *et al.*, 1969; Russell *et al.*, 1970). The effect on retinoid-induced hypercalcemia was developed into a rapid screening assay for new compounds (Trechsel *et al.*, 1987).

Osteoporosis Models

The first experimental model in which bisphosphonates prevented bone loss was limb immobilization by sciatic nerve section (Michael *et al.*, 1971; Mühlbauer *et al.*, 1971). Frequently used models also involve ovariectomy (Shiota, 1985; Thompson *et al.*, 1992) or orchidectomy (Wink *et al.*, 1985) in various species. However, it should be noted that many of these experiments were performed in growing animals, in which it is often difficult to assess to what extent the effect on bone density or bone mass is owing to inhibition of sex steroid deficiency-induced bone loss, or of the bone resorption associated with modeling and remodeling during growth. Bisphosphonates were also effective in preventing bone loss in animals treated with corticosteroids (Jee *et al.*, 1981) or thyroid hormone (Yamamoto *et al.*, 1993).

Tumor-Induced Bone Resorption

Bisphosphonates very effectively inhibit tumor-induced bone resorption, both *in vitro* and *in vivo*, when osteolysis is induced by circulating humoral factors as well as by local tumor invasion. When added *in vitro*, bisphosphonates inhibit the bone-resorbing effect of supernatants of various cancers in mice calvaria (Galasko *et al.*, 1980). Inhibition was also seen when the bisphosphonates were injected into the mice before explantation of the calvaria (Jung *et al.*, 1981). Many types of tumor cells have been used in various *in vivo* models, such as bladder tumors, rat mammary adenocarcinoma, prostate adenocarcinoma, myeloma, and melanoma. Perhaps the best host is the nude mouse (Nemoto *et al.*, 1990; Sasaki *et al.*, 1995, 1998, 1999; Hiraga *et al.*, 1996a,b; Yoneda *et al.*, 2000). The first such studies performed showed that the humoral hypercalcemia induced by subcutaneously implanted Walker 256 carcinoma cells or by implanted Leydig tumor cells (Martodam *et al.*, 1983; Jung *et al.*, 1984; Guaitani *et al.*, 1985) could be partially prevented.

Arthritis Models

Several bisphosphonates inhibit local cartilage resorption, preserve the joint architecture, and prevent local and systemic bone loss in several types of experimental arthritis, e.g., induced by Freund's adjuvant, carrageenin, or collagen (Francis *et al.*, 1972, 1989; Dunn *et al.*, 1993; Österman *et al.*, 1994; Zao *et al.*, 2006; Herrak *et al.*, 2004; Sims *et al.*, 2004; Matsuo *et al.*, 2003), although effects on the inflammatory component in these disease models is inconsistent. Although zoledronate was found to preserve joint architecture in a recent clinical trial (Jarrett *et al.*, 2006), the effectiveness of other bisphosphonates at preventing joint destruction in other clinical studies in patients with rheumatoid arthritis have been less convincing, perhaps because of insufficient dosing (Breuill *et al.*, 2006; Ritchlin *et al.*, 2004; Maksymowych *et al.*, 2003; Eggelmeijer *et al.*, 1996).

Other Models of Hyperresorptive Diseases

Of interest in the dental field is the fact that bisphosphonates slow down periodontal bone destruction in animal models of spontaneous and induced periodontitis (Shoji *et al.*, 1995; Reddy *et al.*, 1995; O'Uchi *et al.*, 1998). Furthermore, they inhibit tooth movement and alveolar bone resorption induced by orthodontic procedures, and these effects can be achieved when the compounds are administered topically (Adachi *et al.*, 1994; Yaffe *et al.*, 1997; Kaynak *et al.*, 2000). Finally, in a model developed

to mimic osteolysis and aseptic loosening around total hip arthroplasty, alendronate also inhibited bone destruction (Shanbhag *et al.*, 1997).

Combination Therapy with Anabolic Agents

Treatments such as prostaglandins, IGF-1, and parathyroid hormone (PTH), which increase bone formation, remain effective when coadministered with bisphosphonates in animal models, sometimes resulting in additive effects on bone mass (Jee *et al.*, 1993; Takano *et al.*, 1996). However, several clinical studies have shown that prior or concurrent treatment with alendronate appears to interfere with the anabolic response to PTH (Finkelstein *et al.*, 2006; Black *et al.*, 2003), although the exact mechanism underlying this effect remains unknown. Recent clinical studies suggest that prior treatment with risedronate may impair the subsequent response to PTH less than alendronate (Delmas *et al.*, 2007). Experimental studies in animals suggest that the action of PTH may be less compromised after single, rather than repeated, doses of bisphosphonates (Gasser *et al.*, 2000).

ANTIFRACTURE MECHANISM IN OSTEOPOROSIS

The antifracture effect of bisphosphonates in osteoporosis may not be caused solely by an increase in bone mass, as was once thought, but also by an improvement in microarchitecture and probably a reduction in bone remodeling. Numerous preclinical studies have shown that, when not given in excess, bisphosphonates produce an improvement in bone biomechanical properties, including torsional torque, ultimate bending strength, stiffness, maximum elastic strength, Young's modulus of elasticity, and others, both in normal animals and in experimental models of osteoporosis. This is the case for a variety of bisphosphonates and was seen in various animals, although most experiments have been performed in the rat (Geusens *et al.*, 1992; Toolan *et al.*, 1992; Ammann *et al.*, 1993; Balena *et al.*, 1993; Guy *et al.* 1993; Ferretti *et al.*, 1993; Motoie *et al.*, 1995; for review, see Ferretti, 1995). These positive effects on bone quality in preclinical studies have since been confirmed in the clinical setting (Chavassieux *et al.*, 1997; Recker *et al.*, 2004; Ericksen *et al.*, 2002). Furthermore, although several studies have shown that high doses in animals may prevent naturally occurring microscopic cracks in bone from healing and thus increase microdamage, which may reduce bone toughness, this may be offset by an increase in bone strength (Mashiba *et al.*, 2005; Komatsubara *et al.*, 2004).

The higher number of bone-remodeling sites that occurs in osteoporotic bone leads to the development of areas of stress concentration and hence to increased fracture risk. Because bisphosphonates decrease remodeling they serve as a means of reducing this effect, thus reducing the incidence of new fractures. The prevention of bone loss is probably explained to a large extent by the decrease in bone turnover. The initial rise in bone mass is because of "filling of the remodeling space"; in other words, bone formation continues to rebuild basic multicellular units (BMUs) initiated prior to bisphosphonate treatment, whereas fewer new BMUs are initiated. In addition, some bone can be lost at each BMU, because a greater amount of bone is resorbed than formed. The decrease in turnover would therefore slow down total bone loss. Furthermore, bisphosphonates also act at individual BMUs by decreasing the depth of resorption (Balena *et al.*, 1993; Boyce *et al.*, 1995). Both effects will lead to a decreased number of trabecular perforations, thus reducing the decrease in bone strength and the occurrence of fractures.

Another mechanism may be related to the increase in mineralization associated with lower bone turnover (Meunier and Boivin, 1997; Boivin *et al.*, 2000). A lower turnover will lengthen the life span of the BMU, thus permitting it to mineralize more completely, which will increase mineral content, measured as BMD, independent of effects on bone mass. This has been described in alendronate-treated baboons (Meunier and Boivin, 1997) and more recently in osteoporotic women (Boivin *et al.*, 2000).

RELATIVE POTENCY OF BISPHOSPHONATES FOR INHIBITION OF RESORPTION

The activity of bisphosphonates on bone resorption in the models described earlier varies greatly from compound to compound (Shinoda *et al.*, 1983), which is not the case for the inhibition of mineralization. For etidronate, one of the first bisphosphonates to be investigated, the dose required to inhibit resorption is relatively high, greater than 1 mg/kg/day parenterally. Because this dose is similar to that which impairs normal mineralization, one of the early aims of bisphosphonate research was to develop compounds with a more powerful antiresorptive activity and less effect on inhibition of mineralization. The first of these, clodronate, was more potent than etidronate (Fleisch *et al.*, 1969; Russell *et al.*, 1970) and less active in inhibiting normal mineralization (Schenk *et al.*, 1973). Later, pamidronate was found to be still more active (Lemkes *et al.*, 1978), and several compounds have subsequently been developed that are up to 10,000 times more powerful than etidronate in inhibiting bone resorption in animals (reviewed in Fleisch, 2000). Perhaps the best way to compare potency in humans, bypassing the differences in oral bioavailability, is to examine maximally effective intravenous doses in hypercalcemia of malignancy, a condition produced by

massive bone resorption. Bisphosphonate treatment is typically given in one or two intravenous doses. As a result, urinary and serum markers for resorption are typically normalized within 48 hours and resorption control can last up to about a month. Maximally effective doses of alendronate (15 mg), ibandronate (6 mg), pamidronate (90 mg), and zoledronate (2-4 mg) result in normalization of serum calcium in 77% to 100% of patients, depending on the study (Nussbaum *et al.*, 1993a,b; Ralston *et al.*, 1997; Body *et al.*, 1999). This suggests an overall spread in potency of about 40-fold, 6-fold if pamidronate is excluded. In animal studies the spread in potency is approximately 1000-fold for these bisphosphonates (Fleisch, 2000). Therefore, whereas rank ordering for potency in animals is predictive, the actual potency range is narrower in patients and has to be determined in clinical studies.

STRUCTURE–ACTIVITY RELATIONSHIP FOR INHIBITION OF BONE RESORPTION

Prior to elucidation of the mechanisms of action of bisphosphonates, it was difficult to establish a detailed structure–activity relationship. The length of the aliphatic carbon was found to be important and adding a hydroxyl group to the carbon atom at position 1 increased potency and binding to bone (Shinoda *et al.*, 1983; van Beek *et al.*, 1996). Derivatives with an amino group at the end of the side chain are very active, the highest activity being found with a backbone of four carbons, as present in alendronate (Schenk *et al.*, 1986). A primary amine is not necessary for this activity, and in fact dimethylation of the nitrogen of pamidronate, as seen in olpadronate, increases potency (Boonekamp *et al.*, 1987). Potency is still further increased when other groups are added to the nitrogen, as seen in ibandronate (Mühlbauer *et al.*, 1991). Cyclic geminal bisphosphonates are also very potent, especially those containing a nitrogen atom in a heterocyclic ring, such as risedronate (Sietsema *et al.*, 1989). The most potent compounds described so far, zoledronate (Green *et al.*, 1994) and minodronate, also contain nitrogen atoms in heterocyclic ring structures.

CELLULAR EFFECTS OF BISPHOSPHONATES ON BONE CELLS

Our understanding of the mode of action of the bisphosphonates has made great progress in the past two decades. There is no doubt that the action *in vivo* is mediated mostly, if not completely, through mechanisms other than the physicochemical inhibition of crystal dissolution, initially postulated. Many of these mechanisms have been unraveled and more than one mechanism may be operating simultaneously.

The Osteoclast Is the Main Target Cell Type of Bisphosphonates

Although many studies have demonstrated that bisphosphonates (BPs) are capable of affecting a wide variety of cell types, such as macrophages (Rogers *et al.*, 1996; Coxon *et al.*, 1998), endothelial cells (Fournier *et al.*, 2002; Wood *et al.*, 2002), and a wide variety of tumor cells (reviewed in Green, 2004) *in vitro*, these compounds have a high selectivity for bone-resorbing osteoclasts *in vivo*, which is owing to a combination of factors. First of all, their high affinity for calcium-rich bone ensures the efficient adsorption and retention of bisphosphonates in the skeleton, resulting in a low bioavailability of these drugs outside the skeleton (Russell *et al.*, 2006). In addition, BPs have been shown to preferentially bind to exposed bone mineral at surfaces undergoing osteoclastic bone resorption (Sato *et al.*, 1991; Azuma *et al.*, 1995; Masarachia *et al.*, 1996), although the relative deposition on bone forming and bone resorbing areas depends on the amount of bisphosphonate administered (Masarachia *et al.*, 1996). Furthermore, osteoclasts acidify the resorption lacuna underneath the cell by secreting protons, which aids in the digestion of matrix proteins (Baron, 2003). This is believed to facilitate the release of bisphosphonates from the bone mineral surface owing to protonation of the phosphate groups and the resulting decrease in ability to chelate Ca^{2+} ions, which could give rise to locally high concentrations of bisphosphonates in solution in the osteoclast resorption lacunae (Ebetino *et al.*, 1998). It was calculated that the concentration of alendronate achieved in the resorption lacunae underneath osteoclasts could be as high as 0.1 to 1 mM (Sato *et al.*, 1991). Finally, it has recently become clear that the cellular uptake of the negatively charged bisphosphonates primarily occurs via fluid-phase endocytosis followed by acidification of intracellular vesicles and release of bisphosphonate into the cytosol (Thompson *et al.*, 2006). This is likely to contribute to the selective targeting of bisphosphonates to highly endocytic bone-resorbing osteoclasts.

The efficient uptake of bone-bound bisphosphonate by osteoclasts has recently been demonstrated by using fluorescently labeled bisphosphonate to visualize mineral binding and cellular uptake of bisphosphonate *in vitro*. Although nonosteoclast cell types can internalize bisphosphonate from solution (to various extents depending on endocytic activity), only osteoclasts are able to efficiently internalize bisphosphonate from the bone surface (Coxon *et al.*, 2008). Intracellular uptake of bisphosphonate by osteoclasts *in vivo* has been shown using radiolabeled bisphosphonate, whereas intracellular levels in osteoblasts were below the limit of detection (Sato *et al.*, 1991; Masarachia *et al.*, 1996).

Cellular Effects on Osteoclasts

Bisphosphonates have been shown to induce apoptosis in osteoclasts *in vitro* (Hughes *et al.*, 1995; Hiroi-Furuya *et al.*,

1999; Benford *et al.*, 2001) and *in vivo* (Hughes *et al.*, 1995; Ito *et al.*, 1999). In addition to causing apoptosis, bisphosphonates induce more subtle ultrastructural changes in mature osteoclasts. It was reported long ago that, after bisphosphonate administration, osteoclasts show changes in morphology and appear inactive (Schenk *et al.*, 1973). The changes are numerous (Sato and Grasser, 1990), but perhaps the most striking feature is the shrinkage, or complete loss, of the ruffled border (Schenk *et al.*, 1973; Sato *et al.*, 1991), which is associated with disruption of the cytoskeleton and loss of F-actin rings (Murakami *et al.*, 1995; Hiroi-Furuya *et al.*, 1999). Following these observations, the decrease in bone resorption in response to bisphosphonate treatment has been mainly attributed to the detrimental effects of these compounds on mature resorbing osteoclasts, although inhibition of osteoclastogenesis may also contribute to the antiresorptive effects (Boonekamp *et al.*, 1987; Löwik *et al.*, 1988; Hughes *et al.*, 1989; Van Beek *et al.*, 2002). It should be noted that apoptosis appears to be the primary mechanism of the inhibition of bone resorption by clodronate and etidronate, but is not required for the inhibition of resorption by the nitrogen-containing bisphosphonates (discussed later) (Halasy-Nagy *et al.*, 2001).

Potential Effects on Osteocytes

The effects of bisphosphonates on osteocytes have only recently been studied. Plotkin *et al*., 1999) found that very low concentrations of bisphosphonates prevented apoptosis of osteocyte-like cells induced by etoposide, TNFα or dexamethasone *in vitro*, and treatment of mice with alendronate *in vivo* prevented the increase in apoptosis of osteocytes and osteoblasts following prednisolone administration. More recently, bisphosphonates were shown to also prevent the apoptotic effects of glucocorticoids or cyclic mechanical loading in experimental animal models (Follet *et al.*, 2007). The antiapoptotic effect of bisphosphonates is in stark contrast to their proapoptotic effects on osteoclasts and appears to involve the rapid activation of extracellular signal-regulated kinases (ERKs) following opening of hexameric connexin-43 hemichannels and calcium influx (Plotkin *et al.*, 2002, 2005), suggesting that these effects may be mediated through extracellular effects and do not require intracellular uptake of bisphosphonate. The potency of individual bisphosphonates to prevent osteocyte apoptosis is independent of their ranking as inhibitors of osteoclastic activity, and, in particular, those with little antiresorptive activity are also able to increase osteocyte survival (Plotkin *et al.*, 2006; Kogianni *et al.*, 2004), supporting the view that the effects of bisphosphonates on osteocytes are mediated via a separate mechanism. The importance of these effects *in vivo* remains to be determined, but these findings raise the possibility that potential interactions of bisphosphonates with osteocytes *in vivo* may contribute to antifracture efficacy independently of the better known classical actions via osteoclasts.

Potential Effects on Osteoblasts

Several *in vitro* studies have shown that bisphosphonates can affect bone-forming osteoblasts. They have been shown to stimulate the proliferation of osteoblast-like cells at very low concentrations (Fast *et al.*, 1978; Endo *et al.*, 1996). As with the antiapoptotic effects of bisphosphonates on osteocytes, the proliferative effect on osteoblasts has been attributed to opening of calcium channels and activation of ERKs (Mathov *et al.*, 2001). Furthermore, alendronate can stimulate the expression of collagenase-3 by rat calvarial osteoblasts (Varghese *et al.*, 2000), whereas pamidronate and zoledronate can stimulate the differentiation and bone mineral-forming ability of osteoblasts *in vitro* (Reinholz *et al.*, 2000). In addition, several studies reported that osteoblast-like cells inhibited osteoclastic bone resorption when exposed to low concentrations of bisphosphonate *in vitro*, believed to involve the release of an osteoclast inhibitory factor (Sahni *et al.*, 1993; Yu *et al.*, 1996; Nishikawa *et al.*, 1996, Vitté *et al.*, 1996), although the exact mechanism involved has not been elucidated. However, despite many studies, direct effects of bisphosphonates on osteoblasts *in vivo* have been hard to demonstrate using clinically relevant concentrations of bisphosphonates. Most of the clinical effects on osteoblast function (e.g., suppression of osteoblast-derived biochemical markers) can be attributed to indirect effects on the remodeling cycle mediated through reduction of bone resorption.

MOLECULAR MECHANISMS OF ACTION OF BISPHOSPHONATES

Studies over the past two decades examining the mechanisms of action of bisphosphonates have uncovered the primary sites of inhibition that account for most of the potency of clinically used bisphosphonates. These studies paint a compelling picture pointing to two general classes of bisphosphonates: those that are metabolized within the cell to form toxic analogues of ATP (the "simple" bisphosphonates clodronate, etidronate, and tiludronate) and those that inhibit farnesyl diphosphate synthase (alendronate, ibandronate, incadronate, olpadronate, pamidronate, risedronate, and zoledronate). The properties that segregate bisphosphonates into these two classes appear to be a function of the moieties attached to the geminal carbon at R^2, which can vary in size and complexity (Fig. 2). Without regard to size or shape, the prevailing determinant for the mechanism of action of the bisphosphonates used in the clinic is the presence or absence of a nitrogen atom located

three to five positions away from the geminal carbon of the P–C–P backbone in the R^2 group. Bisphosphonates that contain nitrogen, hereafter referred to as N-BPs, inhibit farnesyl diphosphate (FPP) synthase with IC_{50}s in the nanomolar range, whereas the simple BPs that lack a nitrogen are metabolized to cytotoxic ATP analogues. Throughout the remainder of this section, the salient features of these two classes of bisphosphonate are discussed.

Mechanism of Action of Simple Bisphosphonates

Simple Bisphosphonates are Metabolized into ATP

Analogues

Studies in the 1970s suggested that clodronate and etidronate could affect a variety of intracellular metabolic processes, including glycolysis, lactate production, fatty acid oxidation, adenylate cyclase, and phosphohydrolases (Fast *et al.*, 1978; Felix *et al.*, 1976, 1981). Because bisphosphonates are close structural analogues of inorganic pyrophosphate, it is perhaps not surprising that they can affect a wide variety of enzymes and metabolic pathways. However, none of these effects satisfactorily explain the ability of clodronate and etidronate to inhibit osteoclast function and cause osteoclast apoptosis.

The first clue to the likely molecular mechanism of action of clodronate and etidronate arose from studies using methylenebisphosphonate (medronate) as a marker to study intracellular pH in single-celled amebae of the slime mold *Dictyostelium discoideum* (Klein *et al.*, 1989; Rogers, 2004). Using ^{31}P NMR to study the pH-dependent δ-shift of the phosphonate groups in medronate, new peaks were identified in the ^{31}P NMR spectrum of medronate-treated amebae. These peaks were identified as nonhydrolyzable, methylene-containing analogues of adenosine triphosphate (ATP) and diadenosine tetraphosphate (Ap4A). The metabolites, AppCH2p and App-CH2ppA, contained the P–C–P moiety of medronate in place of a P–O–P moiety (Fig. 3), and were thus resistant to hydrolysis. FPLC and UV absorbance, as well as ^{31}P NMR analysis, showed that clodronate and certain other bisphosphonates (etidronate, fluoromethylene bisphosphonate, difluoromethylene bisphosphonate, and hydroxymethylene bisphosphonate) are metabolized to methylene-containing (AppCp-type) analogues of ATP, but not to analogues of Ap4A (Rogers *et al.*, 1992, 1994; Pelorgeas *et al.*, 1992). Interestingly, bisphosphonates with larger R^2 side chains (such as the amino-alkyl bisphosphonates and heterocycle-containing bisphosphonates), which poorly resemble pyrophosphate, are not metabolized (with the exception of tiludronate). Similar results were obtained using cell-free extracts of human HL60 cells as well as other cell lines, in particular J774 macrophages which (like osteoclasts and *Dictyostelium* amebae) are highly endocytic and may internalize bisphosphonates more efficiently than most other cell types (Rogers *et al.*, 1996, 1997; Frith *et al.*, 1997; Benford *et al.*, 1999). Liposome-encapsulated bisphosphonates are internalized even more effectively by phagocytic cells, leading to greater accumulation of intracellular AppCp-type metabolites (Frith *et al.*, 1997). Up to 50% of clodronate internalized intracellularly is metabolized by macrophages *in vitro* to AppCCl2p, which may reach an intracellular concentration as high as 1 mM (Mönkkönen *et al.*, 2001). The metabolism of clodronate, etidronate, and tiludronate (see Fig. 3), but not alendronate, pamidronate, or ibandronate, has been unequivocally demonstrated using a combination of ion-pairing HPLC and electrospray ionization mass spectrometry (Auriola *et al.*, 1997; Benford *et al.*, 1999; Mönkkönen *et al.*, 2000).

Mechanism of Formation of Bisphosphonate Metabolites

The incorporation of bisphosphonates into AppCp-type nucleotides is probably achieved through interactions with the family of type II aminoacyl-tRNA synthetases (which utilize the amino acids Asn, Asp, Gly, His, Lys, Phe, and Ser) (Rogers *et al.*, 1994, 1996). These enzymes play an essential role in protein synthesis (Fig. 4), because they catalyze the condensation of an amino acid with ATP (Appp) to form an aminoacyl-adenylate (amino acid-AMP), releasing pyrophosphate (P–O–P) in a reversible reaction (reaction I). The aminoacyl-adenylate then condenses with a molecule of tRNA to form aminoacyl-tRNA, utilized for ribosome-dependent translation of mRNA into protein (reaction II). It appears that tiludronate and bisphosphonates with short side chains (but not more potent bisphosphonates that contain a nitrogen in the R^2 side chain) can replace P–O–P in the active site of type II aminoacyl-tRNA synthetases, but not type I enzymes. Because bisphosphonates (P–C–P) resemble pyrophosphate (P–O–P) in structure, the reverse reaction of (I) can occur with P–C–P in place of P–O–P, to form an analog of ATP (AppCp) containing the bisphosphonate (reaction III), a reaction demonstrated more than 30 years ago (Zamecnik and Stephenson, 1968). For medronate, difluoromethylenebisphosphonate, and hydroxymethylenebisphosphonate (but not clodronate or etidronate), AppCp can be further metabolized (to AppC-ppA, an analogue of AppppA), by the condensation of ATP with AppCp to form AppCppA + AMP (reaction IV) (Rogers *et al.*, 1994; Zamecnik, 1983). It should be noted that a recent report also described the ability of T4 RNA ligase to catalyze the synthesis of ATP analogues of methylenebisphosphonate, clodronate, and etidronate (Sillero *et al.* 2006).

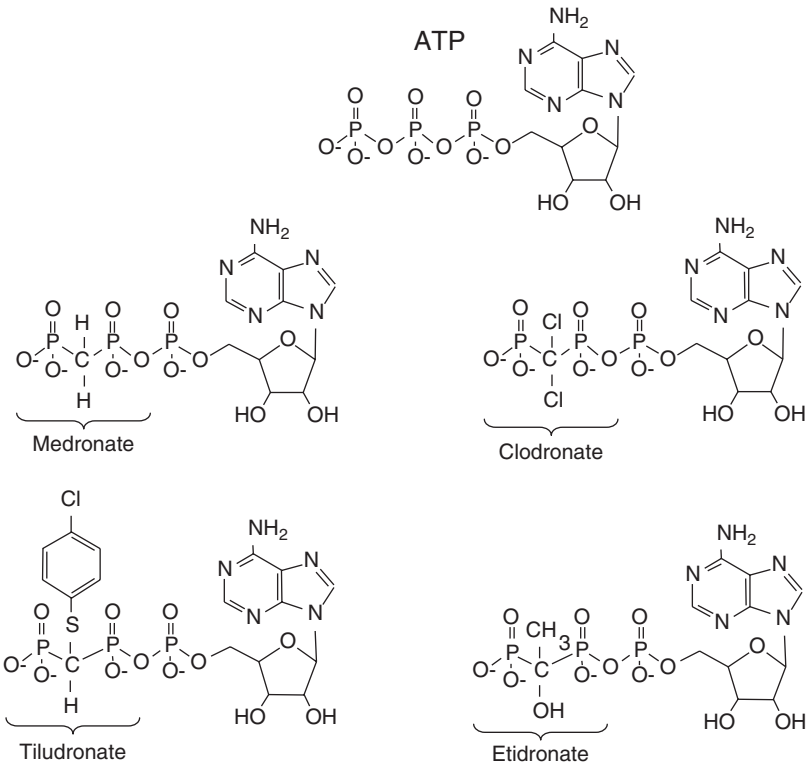

FIGURE 3 The structure of ATP and the AppCp-type metabolites of medronate, clodronate, etidronate, and tiludronate.

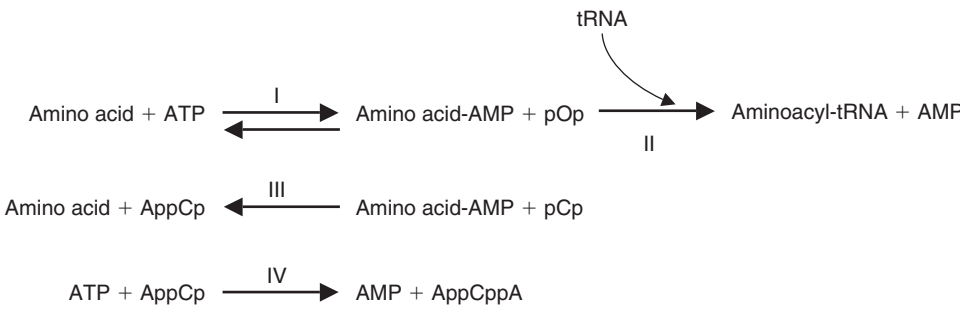

FIGURE 4 The mechanism by which aminoacyl-tRNA synthetase enzymes catalyze the formation of AppCp-type metabolites of bisphosphonates. An amino acid condenses with ATP (Appp) to form an aminoacyl-adenylate (amino acid-AMP), releasing pyrophosphate (pOp) in a reversible reaction (I). The aminoacyl-adenylate then condenses with a molecule of tRNA to form aminoacyl-tRNA (reaction II). Because bisphosphonates (pCp) resemble pyrophosphate in structure, the reverse reaction of (I) can occur with pCp in place of pOp, to form an analogue of ATP (AppCp) containing the bisphosphonate. AppCH2p, the metabolite of medronate, can condense with another molecule of ATP (reaction IV) to form an AppCppA-type nucleotide (i.e., AppCH2ppA).

Metabolism of Simple Bisphosphonates in Osteoclasts in Vivo

Although for many years bisphosphonates were considered to be metabolically inert, the discovery that some could be metabolized intracellularly to AppCp-type nucleotides by cells *in vitro* suggested the possibility that their antiresorptive effect may be caused by the accumulation of these metabolites in osteoclasts *in vivo* (Frith *et al.*, 1997). The ability of osteoclasts to metabolize clodronate and etidronate *in vitro* has been confirmed using HPLC-electrospray mass spectrometry to identify AppCCl2p in extracts of purified rabbit osteoclasts. Furthermore, the AppCCl2p metabolite of clodronate was found in extracts of osteoclasts purified by magnetic bead separation following injection of rabbits with clodronate, confirming that osteoclasts can metabolize clodronate *in vivo* (Frith *et al.*, 2001).

Metabolites of Simple Bisphosphonates Induce Osteoclast Apoptosis

The functional significance of the conversion of bisphosphonates into nonhydrolyzable analogues of ATP was demonstrated by showing that treatment of osteoclasts with AppCCl2p induced osteoclast apoptosis and inhibited bone resorption (Fig. 5), effects that were indistinguishable from the effects of clodronate treatment (Frith *et al.*, 2001). It has been suggested that these ATP analogues may induce toxicity by inhibiting the activity of ATP-dependent intracellular enzymes such as the mitochondrial adenine nucleotide translocase (ANT). ANT is thought to be involved in controlling apoptosis by regulating the permeability transition pore in the mitochondrial membrane. It is suggested that by inhibiting ANT AppCCl2p may cause opening of the permeability transition pore (Lehenkari *et al.*, 2002), which would lead to disruption of the mitochondrial membrane potential and the release of Apaf-1 and cytochrome C, causing the subsequent activation of proapoptotic caspases (Cohen, 1997; Crompton *et al.*, 1999; Nicholson, 1999; Benford *et al.*, 2001). Induction of osteoclast apoptosis appears to be the primary mechanism by which the simple, non-N-BPs inhibit bone resorption, because the ability of clodronate and etidronate to inhibit resorption *in vitro* is blocked when osteoclast apoptosis is prevented by using a caspase inhibitor (Halasy-Nagy *et al.*, 2001).

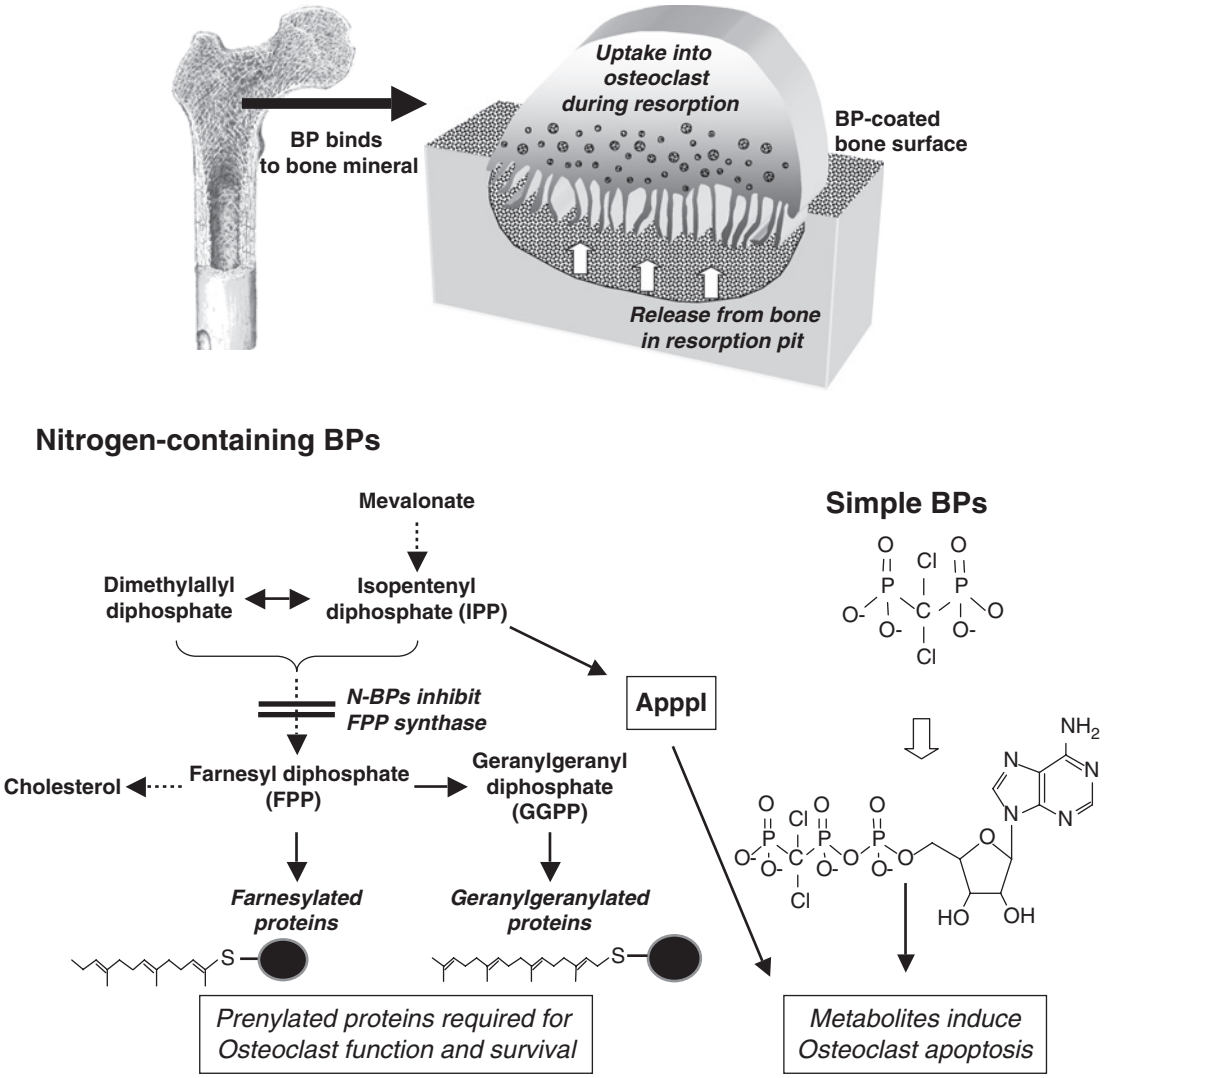

FIGURE 5 Mechanisms of action of bisphosphonates on osteoclasts. After binding to bone mineral, the drugs are internalized into bone-resorbing osteoclasts by endocytosis. Simple bisphosphonates (e.g., clodronate, etidronate) are metabolized in the osteoclast cytosol to ATP analogues that induce osteoclast apoptosis. Nitrogen-containing bisphosphonates inhibit FPP synthase, thereby preventing the prenylation of small GTPase proteins essential for the function and survival of osteoclasts. Inhibition of FPP synthase also causes the accumulation of IPP, which is incorporated into ApppI (an analogue of ATP capable of inducing osteoclast apoptosis).

Mechanism of Action of Nitrogen-Containing Bisphosphonates

Inhibition of the Mevalonate Pathway by N-BPs

Studies seeking to identify squalene synthase inhibitors first led to the finding that the N-BPs incadronate (YM175), ibandronate, pamidronate, and alendronate inhibit the mevalonate/cholesterol biosynthetic pathway (Amin *et al.*, 1992, 1996). Etidronate and clodronate, which lack nitrogen in the R^2 side chain, were inactive in the same assays. Whereas incadronate and ibandronate were shown to potently inhibit squalene synthase, alendronate and pamidronate were inactive, yet nonetheless inhibited sterol biosynthesis with IC_{50}s of 170 and 420 nM, respectively. This suggested the presence of a target upstream in the mevalonate pathway (see Fig. 5).

FPP Synthase as the Molecular Target of the N-BPs

The upstream enzyme inhibited by all of the N-BPs examined to date was identified as FPP synthase (Table II; Van Beek *et al.*, 1999a,b; Bergstrom *et al.*, 2000; Dunford *et al.*, 2001). The most potent antiresorptive N-BPs such as zoledronate and minodronate (YM-529) are extremely potent inhibitors of FPP synthase (IC_{50} 3nM with respect to recombinant human FPP synthase; Dunford *et al.*, 2001). The discovery of these inhibitory activities revealed several interesting findings: (1) Although alendronate is a specific inhibitor of FPP synthase, some other N-BPs inhibit other enzymes of the mevalonate pathway, including squalene synthase (Amin *et al.*, 1992; van Beek *et al.*, 1999b; Bergstrom *et al.*, 2000; Dunford *et al.*, 2001) and geranylgeranyl diphosphate (GGPP) synthase, albeit with lower potency than their potency for inhibiting FPP synthase (Guo *et al.*, 2007). (2) In enzymatic assays risedronate is 90-fold more potent than alendronate for inhibition of purified FPP synthase (Bergstrom *et al.*, 2000, Dunford *et al.*, 2008), but only 5-fold more potent in crude enzyme preparations (Van Beek *et al.*, 1999, Dunford *et al.*, 2001), although it is now clear that the time-dependent nature of the slow-tight inhibition (Dunford *et al.*, 2008) by N-BPs may result in different values of IC_{50} depending on the conditions of the assay. Nonetheless, because these two bisphosphonates appear to be approximately equipotent for increasing bone mineral density after oral administration (5 mg p.o. q.d., 2 years) in the clinic (Bone *et al.*, 1997; Fogelman *et al.*, 2000), this suggests that differences in pharmacokinetics, pharmacodynamics, binding to bone (van Beek *et al.*, 1994, 1998), osteoclast targeting, cell permeability, or intracellular protein binding between these mechanistically similar bisphosphonates contribute significantly to their ultimate potency *in vivo*. (3) Although risedronate is a potent inhibitor of FPP synthase, modifications (e.g., addition of a methyl group) to the structure of the R^2 side chain that influence the position of the nitrogen group in relation to the phosphonate groups give rise to analogues that are markedly less potent inhibitors of FPP synthase and less effective inhibitors of bone resorption *in vivo*. Furthermore, for a wide range of N-BPs, there is a significant correlation between potency for inhibition of FPP synthase and antiresorptive potency *in vivo*, pointing to FPP synthase as the major molecular target of the N-BPs

TABLE II Inhibition of FPP synthase by various bisphosphonates

Bisphosphonate	IC_{50} (nM) human*[a]	IC_{50} (nM) human†[b]	IC_{50} (nM) murine endogenous‡[c]	Isomerization constant§
Alendronate	340	50	500	6.3
Ibandronate		20	310	53
Incadronate		30		
Minodronate		3		
Pamidronate	500	200	850	
Risedronate	3.9	10	100	226
Zoledronate		3	20	1244
Clodronate	NA ≤ 350,000	NA ≤ 100,000	NA ≤ 100,000	
Etidronate	80,000	NA ≤ 100,000	NA ≤ 100,000	

Analyses of FPP synthase inhibition were performed using purified (NA, *not active/negligible inhibition*):

*[a] *Recombinant human enzyme* (Bergstrom *et al.*, 2000),

†[b] *Recombinant human enzyme in* E. *coli lysate* (Dunford *et al.*, 2001), *or*

‡[c] *Endogenous murine enzyme in* J774 *macrophage lysate* (Dunford *et al.*, 2001).

§ *The isomerization constant* (Russell *et al.*, 2007; Dunford *et al.*, 2008) *reflects the reversibility of enzyme inhibition* (*the greater the value, the less reversible the inhibition*).

(Dunford *et al.*, 2001, 2008). (4) Consistent with the initial findings (Amin *et al.*, 1992), neither clodronate nor etidronate showed any significant inhibitory activity against FPP synthase (van Beek *et al.*, 1999b; Bergstrom *et al.*, 2000; Dunford *et al.*, 2001).

Mechanism of FPP Synthase Inhibition

Initially, computer modeling was used to try to understand how N-BPs inhibit FPP synthase, which suggested that N-BPs may inhibit the enzyme by acting as isoprenoid transition-state analogues (Martin *et al.*, 1999). More recently, the generation of x-ray crystal structures of the human FPP synthase enzyme, cocrystallized with various N-BPs (Rondeau *et al.*, 2006; Kavanagh *et al.*, 2006), revealed that N-BPs bind in one of the two isoprenoid lipid-binding pockets in the enzyme-active site, namely the dimethylallyl pyrophosphate (DMAPP)/geranyl pyrophosphate (GPP) binding site of the enzyme, with the phosphonate groups bound to a cluster of three magnesium ions. The R^2 side chain is positioned in the hydrophobic cleft that normally accommodates an isoprenoid lipid, with stabilizing interactions occurring between the nitrogen moiety of the N-BP and a conserved threonine and lysine residue in the enzyme (Fig. 6). Crystal structures of bacterial FPP synthase (Hosfield *et al.*, 2004) and FPP synthase from *Trypanosoma cruzi* (Gabelli *et al.*, 2006) in complex with N-BPs showed a similar mode of binding. Enzyme kinetic analysis with human FPP synthase indicated that the interaction with N-BPs is highly complex and characteristic of "slow, tight binding" inhibition (Kavanagh *et al.*, 2006). Initially, N-BPs appear to compete directly with DMAPP or GPP for binding to the DMAPP/GPP-binding pocket. This is followed by more complex interactions that promote binding of isopentenyl diphosphate (IPP) in the second isoprenoid binding site, causing conformational changes in the enzyme that stabilize the final ternary complex of enzyme + N-BP + IPP (Rondeau *et al.*, 2006; Kavanagh *et al.*, 2006). The determination of an isomerization constant that reflects these changes in enzyme conformation following binding of N-BP gives a more accurate indication of the extent of inhibition of the enzyme by different N-BPs (Russell *et al.*, 2007; Dunford *et al.*, 2008), because this illustrates the extent to which N-P binding and the changes in enzyme conformation are reversible (see Table II). From these values it is apparent that inhibition of FPP synthase by zoledronate and risedronate is virtually irreversible, but that inhibition by ibandronate and alendronate is more reversible in nature. These differences probably relate to the strength of the interaction between the N-BP side chain and amino acids in the GPP pocket (for example, between the nitrogen moiety and the Lys200 and Thr201 residues), which appear to be similar for zoledronate and risedronate but weaker for ibandronate, alendronate, and pamidronate (Russell *et al.*, 2007; Dunford *et al.*, 2008).

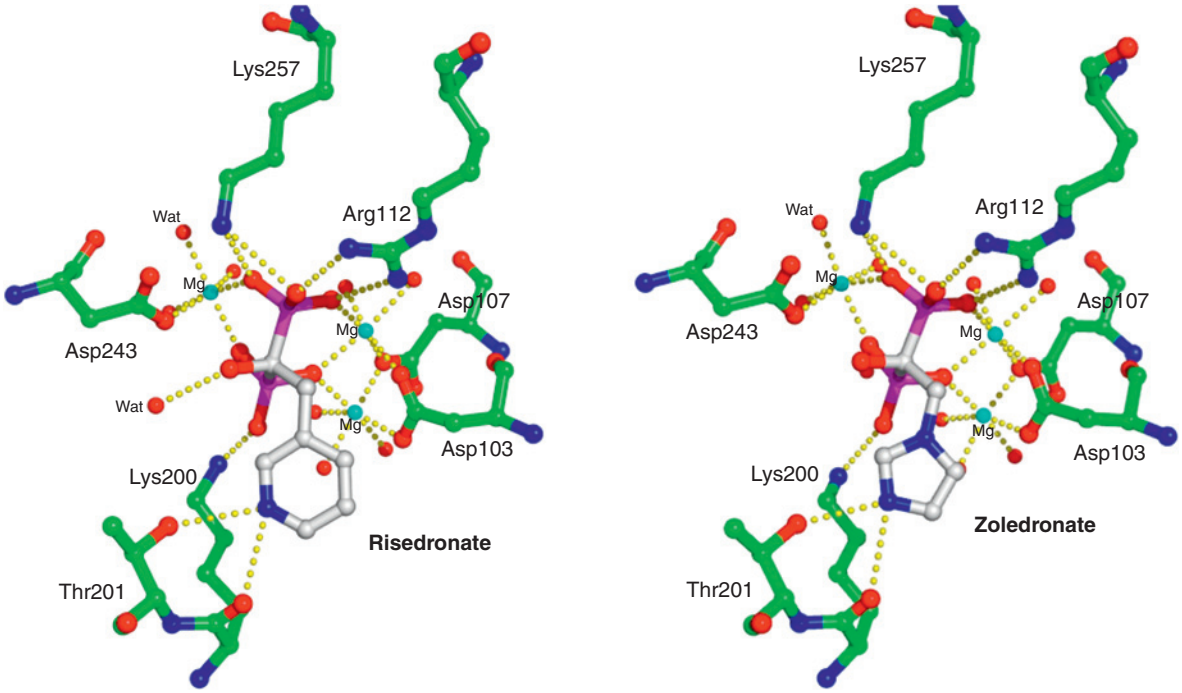

FIGURE 6 Binding of risedronate and zoledronate in the GPP pocket of FPP synthase. Interactions between the nitrogen (blue) of the bisphosphonate side chain and a conserved Lys200 and Thr201 help to stabilize the binding, hence explaining why the position and orientation of the nitrogen atom plays a crucial role in determining antiresorptive potency. (See plate section)

This detailed understanding of exactly how the N-BPs interact with FPP synthase helps to explain the inhibitory potency of some N-BPs toward this enzyme. The interaction of the phosphonate groups with magnesium ions in the aspartate-rich diphosphate-binding site of the enzyme explains why modifications to either or both of the phosphonate groups (such as methylation) prevents these compounds from inhibiting protein isoprenylation (discussed later) and reduces antiresorptive potency (Ebetino and Jamieson, 1990; Luckman *et al.*, 1998a). This confirms the earlier view that the two phosphonate groups have a dual purpose (Rogers *et al.*, 1995; Luckman *et al.*, 1998a), being required for the molecular mechanism of action as well as for targeting to bone mineral (as discussed previously). Furthermore, the length and orientation of the bisphosphonate R^2 side chain affects the interaction of the nitrogen in the side chain with the threonine and lysine residues in the active site cleft (Russell *et al.*, 2007), hence explaining why minor changes to the structure or conformation of the side chain also affect the ability to inhibit protein isoprenylation (Luckman *et al.*, 1998b) and markedly influence antiresorptive potency (Shinoda *et al.*, 1983; Schenk *et al.*, 1986; Sietsema *et al.*, 1989; van Beek *et al.*, 1994; Rogers *et al.*, 1995).

Inhibition of FPP Synthase Blocks Protein Isoprenylation and Sterol Synthesis

The mevalonate pathway is not only responsible for the production of cholesterol but also isoprenoid lipids such as IPP (five carbon), FPP (15 carbon), and GGPP (20 carbon), the latter two being substrates for protein isoprenylation (see Fig. 5). Isoprenylation involves the transfer of a farnesyl or geranylgeranyl lipid group onto a cysteine residue in characteristic carboxy-terminal (e.g., CAAX) motifs (Zhang and Casey, 1996; Sinensky, 2000), giving rise to farnesylated and geranylgeranylated proteins. Most of the isoprenylated proteins identified to date are small GTPases (the majority of which are geranylgeranylated) (Zhang and Casey, 1996), which are important signaling proteins that regulate a variety of cell processes important for osteoclast function, including cell morphology, integrin signaling, membrane ruffling, trafficking of endosomes, and apoptosis (Ridley *et al.*, 1992; Ridley and Hall, 1992; Zhang *et al.*, 1995; Clark *et al.*, 1998; reviewed in Coxon *et al.*, 2003). Isoprenylation is required for the correct function of these proteins, because the lipid isoprenyl group serves to anchor the proteins in cell membranes and may also participate in protein–protein interactions (Zhang and Casey, 1996).

The ability of N-BPs to inhibit protein isoprenylation was first directly demonstrated by using J774 macrophages, where the N-BPs risedronate, incadronate, ibandronate, and alendronate were found to prevent the incorporation of [^{14}C]mevalonate into isoprenylated proteins (both farnesylated and geranylgeranylated proteins), whereas the bisphosphonates that lack a nitrogen in the R^2 side chain (clodronate and etidronate) had no effect (Benford *et al.*, 1999; Luckman *et al.*, 1998b). Risedronate almost completely inhibited protein isoprenylation at a concentration of 10^{-5} M, which is similar to the concentration that affects osteoclast viability *in vitro* (Sato and Grasser, 1990; Carano *et al.*, 1990; Breuil *et al.*, 1998) and, based on findings for alendronate, could be achieved within the osteoclast resorption lacuna (Sato *et al.*, 1991). N-BPs (zoledronate, risedronate, ibandronate, alendronate, and pamidronate) also inhibit protein isoprenylation in osteoclasts *in vitro*. Alendronate has been shown to inhibit incorporation of [^{14}C]mevalonate into either isoprenylated proteins or sterols (nonsaponifiable lipid) in purified murine osteoclasts (Bergstrom *et al.*, 2000), whereas another study found that the N-BPs alendronate, ibandronate, pamidronate, risedronate, and zoledronate, but not the non-N-BPs clodronate, etidronate, or tiludronate, prevented incorporation of mevalonate into isoprenylated proteins in purified rabbit osteoclasts (Coxon *et al.*, 2000). Inhibition of protein isoprenylation in osteoclasts was dose-dependent, with alendronate inhibition at $\geq 15\,\mu$M, whereas zoledronate was effective at $\geq 10\,\mu$M (Bergstrom *et al.*, 2000; Coxon *et al.*, 2000).

Evidence of Inhibition of the Mevalonate Pathway in Vivo

The molecular actions of the N-BPs described earlier, have been confirmed in osteoclasts *in vivo* (Fisher *et al.*, 2000; Frith *et al.*, 2001). Direct demonstration of inhibition of FPP synthase *in vivo* is not possible, thus necessitating the use of surrogate markers for measuring this effect. In one study, the previously documented feedback regulation of hydroxymethyl glutaryl-CoA (HMG-CoA) reductase expression by mevalonate pathway metabolites, illustrated by the induction of HMG-CoA reductase in the liver of lovastatin-treated rats (Singer *et al.*, 1988), was examined (Fisher *et al.*, 2000). Rats were therefore administered bisphosphonate and expression of HMG-CoA reductase was examined in the proximal tibia. The N-BPs alendronate, ibandronate, and risedronate, but not clodronate or etidronate (which lack nitrogen), suppressed expression of HMG-CoA reductase in the osteoclast., but no changes were seen in other bone- or marrow-associated cells. This decrease in HMG-CoA reductase expression appeared to be mediated, at least in part, by the accumulation of metabolites upstream of FPP synthase, because coadministration of simvastatin along with alendronate partially blocked the effect. In other studies (Frith *et al.*, 2001; Coxon *et al.*, 2005), geranylgeranylation of the small GTPase Rap1A or of Rab GTPases was measured as a surrogate marker for inhibition of FPP synthase in osteoclasts isolated and purified from rabbits that had been administered N-BPs *in vivo*. Alendronate and risedronate suppressed protein geranylgeranylation in osteoclasts, but not other marrow- and bone-derived cells.

Cellular effects of N-BPs are primarily due to inhibition of FPP synthase

Inhibition of isoprenylation of small GTPases such as Rho, Rac, cdc42, and Rab accounts for many or all of the various effects on osteoclast function, including loss of the ruffled border and disruption of the actin cytoskeleton (Sato *et al.*, 1991; Sato and Grasser, 1991; Selander *et al.*, 1994), altered trafficking of membranes and intracellular proteins such as the osteoclast proton ATPase (Carano *et al.*, 1990; Zimolo *et al.*, 1995), disrupted intracellular signaling by integrins (Fong and Ingber, 1996), and the induction of osteoclast apoptosis (Hughes *et al.*, 1995; Ito *et al.*, 1998, 1999; Reszka *et al.*, 1999).

Several lines of evidence support the current view that the primary mechanism of action of N-BPs is inhibition of FPP synthase and the subsequent prevention of post-translational prenylation of proteins (see Fig. 5). First, the inhibitory effect of N-BPs on osteoclast formation and function, and the induction of osteoclast apoptosis, can be overcome by bypassing the inhibitory effect on the mevalonate pathway and geranylgeranylation of proteins by supplementing cells with geranylgeraniol (Van Beek *et al.*, 1999a; Fisher *et al.*, 1999; Reszka *et al.*, 1999). Geranylgeraniol is intracellularly metabolized to geranylgeranylpyrophosphate (Crick *et al.*, 1997), which serves as substrate for protein prenylation, thus bypassing the inhibition of FPP synthase by N-BPs. Addition of farnesol, mevalonate, or squalene had little or no effect in these studies (Van Beek *et al.*, 1999a; Fisher *et al.*, 1999; Reszka *et al.*, 1999). Second, structure–activity relationships demonstrated a clear correlation between the potency of different N-BPs to inhibit protein prenylation (Luckman *et al.*, 1998a), and inhibit FPP synthase (Dunford *et al.*, 2001) *in vitro*, and the potency to inhibit bone resorption *in vivo*. Third, the effect of N-BPs can be mimicked *in vitro* by other inhibitors of the mevalonate pathway. Lovastatin and mevastatin, which inhibit the upstream enzyme HMG-CoA reductase, also inhibit bone resorption, prevent osteoclast formation in bone marrow cultures, and disrupt the actin cytoskeleton of osteoclasts, and these effects can also be completely blocked by addition of geranylgeraniol, but not farnesol or squalene, to osteoclast cultures (Fisher *et al.*, 1999; Woo *et al.*, 2000). Furthermore, selective inhibition of protein geranylgeranylation by an inhibitor of geranylgeranyl transferase I (GGTI-298) also inhibits bone resorption *in vitro* (Coxon *et al.*, 2000). Taken together, these observations strongly suggest that the ability to inhibit bone resorption is a consequence of inhibition of protein geranylgeranylation.

Effects on Downstream Signaling Pathways

It was noted that N-BP- and statin-induced macrophage apoptosis occurs after a lag period of 15 to 24 hours, whereas in the osteoclast apoptosis is observed at ≥12 hours, although other inducers can act within 2 to 4 hours (Reszka *et al.*, 1999). This seems to be because of the requirement of protein synthesis for the induction of apoptosis by N-BPs and statins (which also prevent isoprenylation) (Coxon *et al.*, 1998). This raised the possibility that apoptosis, and possibly other cellular effects of N-BPs, are the result of the accumulation of unprenylated proteins rather than the loss of normal prenylated ones.

Interestingly, it has been demonstrated recently that the unprenylated forms of Rho family GTPases that accumulate after treatment with N-BPs are in the active GTP-bound form, most likely owing to their inability to interact with regulatory proteins such as Rho-GAP (Dunford *et al.*, 2006). Other studies have shown that inhibition of protein prenylation by statins also results in increased levels of unprenylated, GTP-bound Ras and Rac (Vecchione and Brandes 2002; Cordle *et al.*, 2005). These unprenylated proteins could have dominant negative effects on normal cellular function by inappropriate activation of downstream signaling pathways. In support of this, N-BPs were found to cause sustained activation of p38 in macrophages and breast cancer cells, which was found to be downstream of Rac in macrophages (Merrell *et al.*, 2003; Dunford *et al.*, 2006). However, p38 activation in these cells acted as a survival factor, rather than mediating the cytotoxic and growth inhibitory effects of N-BPs. Nevertheless, these findings raise the possibility that mevalonate pathway inhibitors such as N-BPs may exert their effects through inappropriate stimulation, rather than inhibition, of small GTPase-mediated signaling pathways (Coxon *et al.*, 2006).

It should be noted that an alternative mechanism by which inhibition of FPP synthase can lead to induction of apoptosis, independent from inhibition of prenylation, has recently been proposed. Inhibition of FPP synthase causes intracellular accumulation of upstream metabolites in the mevalonate pathway, including IPP (Bergstrom *et al.*, 2000). This IPP can be intracellularly converted into a toxic ATP analogue called ApppI (see Fig. 5) in osteoclasts and macrophages *in vitro* (Mönkkönen *et al.*, 2006), and accumulation of IPP and ApppI was detected in peritoneal macrophages *in vivo* following an i.p. injection of zoledronate (Mönkkönen *et al.*, 2007). Although ApppI is capable of inducing apoptosis in osteoclasts (Mönkkönen *et al.*, 2006), its functional significance in the induction of apoptosis *in vivo* following N-BP treatment is presently unclear.

ADDITIONAL MOLECULAR TARGETS

Although the primary molecular mechanisms of action of bisphosphonates are now well understood (as discussed earlier), it is likely that (some) bisphosphonates inhibit additional molecular targets that may contribute to (some of) their effects on osteoclasts or other cell types. This

is supported by a recent study showing that, in contrast to other N-BPs, the antiresorptive effect of pamidronate could only partially be overcome by replenishing cells with geranylgeraniol (Van Beek *et al.*, 2003), suggesting that mechanisms distinct from inhibition of protein geranylgeranylation may contribute to the effects of this bisphosphonate on osteoclasts.

Prior to the identification of FPP synthase as the major molecular target of N-BPs, bisphosphonates were shown to inhibit protein tyrosine phosphatases (Schmidt *et al.*, 1996; Endo *et al.*, 1996; Murakami *et al.*, 1997; Opas *et al.*, 1997; Skorey *et al.*, 1997). However, the IC_{50}s for inhibition of several protein tyrosine phosphatases by the bisphosphonates tested correlated poorly with their potency for inhibition of bone resorption, suggesting this was not the major antiresorptive mechanism. In another study, tiludronate was shown to inhibit the osteoclast vacuolar H^+-ATPase at micromolar concentrations (David *et al.*, 1996).

In addition, it has become clear in recent years that some N-BPs and N-BP analogues are capable of inhibiting enzymes other than FPP synthase in the mevalonate pathway. Prior to the discovery that N-BPs are potent inhibitors of FPP synthase, it was demonstrated that some N-BPs, most notably incadronate, are inhibitors of squalene synthase (Amin *et al.*, 1992). More recently, a bisphosphonate was discovered that, in addition to inhibiting FPP synthase, is also a weak inhibitor of IPP isomerase (Thompson *et al.*, 2002), and replacement of one of the phosphonate groups of risedronate by a carboxylate group gives rise to a compound (3-PEHPC, also referred to as NE10790) that specifically inhibits Rab geranylgeranyl transferase (Coxon *et al.*, 2001, 2005; Roelofs *et al.*, 2006b). Even more recently, it was demonstrated that some N-BPs, most notably zoledronate and minodronate, are also inhibitors of GGPP synthase, albeit with lower potency than their potency for inhibiting FPP synthase in enzyme activity assays (Guo *et al.*, 2007).

The exact relevance of these various additional molecular targets is presently unclear, but it is worth considering the possibility that the primary mechanism of action for a given bisphosphonate (i.e., inhibition of FPP synthase by N-BPs or metabolism of non-N-BPs to cytotoxic analogues of ATP) may occur in addition to background inhibition of other enzymes. Furthermore, as intracellular concentrations of bisphosphonates increase, inhibition of secondary enzyme(s) may assume greater prominence in their overall effect.

ANTITUMOR EFFECTS OF BISPHOSPHONATES

In addition to the well-characterized antiresorptive effects of bisphosphonates on osteoclasts, these agents also have antitumor effects in a variety of *in vitro* and *in vivo* models.

In Vitro

Bisphosphonates exert antitumor effects on a wide variety of cancer cells *in vitro*. It has been demonstrated that BPs inhibit proliferation and induce apoptosis in human myeloma cells (Shipman *et al.*, 1997, 1998; Aparichio *et al.*, 1998) and osteosarcoma cells *in vitro* (Mackie *et al.*, 2001; Sonneman *et al.*, 2001). Furthermore, BPs exert cytostatic and proapoptotic effects on a variety of other tumor cell types that often metastasize to bone, including breast (Fromigue *et al.*, 2000; Senaratne *et al.*, 2000), pancreatic (Tassone *et al.*, 2003), and melanoma cancer cells (Riebeling *et al.*, 2002 ; Forsea *et al.*, 2004). Whereas tumor cell proliferation and survival are affected at relatively high concentrations (generally $>10\mu M$) of bisphosphonate, which may not be attainable *in vivo*, bisphosphonates inhibit invasion of breast and prostate cancer cells *in vitro* at much lower (nanomolar or even picomolar) concentrations (Boissier *et al.*, 2000; Virtanen *et al.*, 2002). In addition, they inhibit adhesion of breast and prostate cancer cells to bone and unmineralized matrices *in vitro* at low micromolar concentrations (Van der Pluijm *et al.*, 1996; Boissier *et al.*, 1997; Virtanen *et al.*, 2002).

In Vivo

Multiple Myeloma

Several studies using animal models of multiple myeloma reported that bisphosphonates are effective in reducing tumor burden *in vivo* (Sasaki *et al.*, 1995; Yaccoby *et al.*, 2002; Croucher *et al.*, 2003), and one study showed that survival of 5T2MM mice receiving zoledronate treatment was increased (Croucher *et al.*, 2003). In addition, some studies demonstrated an increase in apoptosis of tumor cells *in vivo* following BP treatment (Hiraga *et al.*, 2001; Yaccoby *et al.*, 2002). In contrast, other studies failed to demonstrate an increase in the proportion of plasma cells undergoing apoptosis in 5T2MM mice receiving treatment with either ibandronate (Shipman *et al.*, 2000) or zoledronate (Croucher *et al.*, 2003), or a reduction in tumor burden in a murine model of human myeloma following treatment with ibandronate (Dallas *et al.*, 1999; Cruz *et al.*, 2001). It is unclear whether the differences reflect the use of different bisphosphonates, or differences in animal models used.

Bone Metastases

Bisphosphonates have been demonstrated to exert antitumor activity in various animal models of bone metastasis (reviewed in Green, 2004; Clézardin *et al.*, 2005; Stresing *et al.*, 2007). In most studies, bisphosphonate administration was either started on the day of tumor cell inoculation (preventative protocol), or was initiated after tumors were established in bone (treatment protocol). Zoledronate

inhibited the progression of bone metastasis in the B02 metastatic breast cancer model (Peyruchaud *et al.*, 2001). Using intracardiac injection of MDA-MB-231 breast cancer cells in severe combined immunodeficient (SCID) mice to simulate human metastatic breast cancer, Yoneda and colleagues showed that risedronate, ibandronate, and zoledronate inhibited the development of new bone metastases as well as progression of established bone metastases (Yoneda *et al.*, 2000). In a more recent study, using a similar animal model, N-BP treatment was most effective in the preventative setting, and was much less effective in reducing tumor burden already established (Van der Pluijm *et al.*, 2005). Bisphosphonates also prevented development of bone metastasis in a mouse model of breast cancer in which 4T1 mouse breast cancer cells are injected into the mammary fat pad of syngeneic mice. Tumor burden in bone was decreased and an increase in apoptosis of metastatic 4T1 tumor cells was observed (Yoneda *et al.*, 2000). Bisphosphonates have also been shown to inhibit the development and/or progression of bone metastases secondary to other types of cancer, such as small-cell lung (Yano *et al.*, 2003) and prostate cancer (Corey *et al.*, 2003).

Soft-Tissue Tumors

Although some studies showed no effect on visceral metastases (Kostenuik *et al.*, 1993; Sasaki *et al.*, 1995; Michigami *et al.*, 2002; Yano *et al.*, 2003), several more recent studies reported an inhibitory effect of bisphosphonate therapy on the development and progression of soft-tissue tumors (Hiraga *et al.*, 2004; Hashimoto *et al.*, 2005; Ory *et al.*, 2005).

Patients

Despite studies in preclinical models that have clearly shown the potential of bisphosphonates as antitumor agents, the current dosing regimens of bisphosphonates in humans fail to show any convincing antitumor effects. This may in part be because of the relatively high total cumulative doses of bisphosphonate administered in many animal studies, far exceeding the current recommended dose for humans. In this respect, it is interesting to note that results from a recent study in a mouse model of breast cancer metastasis suggest that, while maintaining the same total cumulative dose, treatment with frequent (i.e., daily or twice weekly) low-dose zoledronate may be more effective in decreasing tumor burden than the currently used once monthly treatment regimen in cancer patients (Daubine *et al.*, 2007). This suggests that altering the dosing regimen to a more frequent administration may improve efficacy in cancer patients.

MECHANISMS OF ANTITUMOR EFFECTS

The exact mechanisms for the observed antitumor effects in preclinical models are presently unclear. Bisphosphonates could exert antitumor effects *in vivo* via direct effects of the bisphosphonate on the tumor cells, potentially resulting in inhibition of tumor cell adhesion, invasion, migration, survival, and proliferation, as described preciously. Alternatively, the effects of bisphosphonates on skeletal metastasis or tumor burden in bone could result from inhibition of bone resorption, by reducing the levels of tumor growth and survival factors in the bone microenvironment. Bisphosphonates have also been suggested to exert indirect antitumor effects via inhibition of angiogenesis and/or immunomodulatory effects (reviewed in Roelofs *et al.*, 2006a; Stresing *et al.*, 2007). Owing to the rapid accumulation of bisphosphonate in bone, the brief serum half-life, and low serum concentrations (nM), effects of bisphosphonates are produced primarily by the bisphosphonate on the bone surface. The degree to which tumor cells or any other nonosteoclast cells are exposed to bisphosphonate *in vivo*, therefore, remains to be established.

Indirect Antitumor Effects via Inhibition of Bone Resorption

In the bone marrow microenvironment, the interaction between the tumor cells and the osteoclasts, via cell-to-cell contact and/or secretion of various growth factors and cytokines, leads to expansion of the tumor burden on the one hand, and exacerbates the osteolytic bone disease on the other. Local decreases in the liberation or production of tumor-stimulating cytokines such as transforming growth factor (TGF-β) and insulin-like growth factors (IGFs) following a reduction in osteolysis would interfere with the "seed and soil" interactions between tumor cells and the bone microenvironment (Martin *et al.*, 2005; Matsumoto and Abe, 2005; Guise *et al.*, 2006;). This raises the possibility that the reduction in tumor burden observed in some animal models could be accounted for by inhibition of osteoclast activity. In support of this, a recent study demonstrated that treatment with the osteoclast inhibitor osteoprotegerin resulted in similar decreases in tumor burden, increases in tumor cell apoptosis, and decreases in tumor cell proliferation in a mouse model of breast cancer metastasis as that observed following treatment with ibandronate (Zheng *et al.*, 2007). However, conclusive evidence for either a direct or indirect antitumor activity of bisphosphonates is currently lacking.

Antiangiogenic Effects

Results from *in vitro* and *in vivo* studies have indicated that bisphosphonates have antiangiogenic properties. In *in vitro* experiments, bisphosphonates have been shown to inhibit endothelial cell proliferation, adhesion of endothelial cells to matrix proteins, and capillary-like tube formation (Fournier *et al.*, 2002; Wood *et al.*, 2002; Bezzi *et al.*,

2003). In addition, Fournier *et al.,* 2002) demonstrated that bisphosphonates such as ibandronate and zoledronate reduced revascularization of the prostate gland in a testosterone-stimulated angiogenesis model in castrated rats, and Wood *et al.,* 2002) demonstrated antiangiogenic effects of ZOL in the rat aortic ring assay and the chicken egg chorioallantoic membrane assay. Recently, zoledronate treatment of 5T2MM-bearing mice has been shown to result in a decrease in microvessel density in areas of tumor cell infiltration (Croucher *et al.*, 2003). Zoledronate also decreased vessel density and increased apoptosis of endothelial cells in tumors in a mouse model of cervical carcinoma (Giraudo *et al.*, 2004). Similarly, minodronate treatment has been shown to decrease tumor blood vessel density in a mouse model of melanoma (Yamagishi *et al.*, 2004). In all animal models, this was associated with decreases in tumor burden. In patients with solid tumors, pamidronate and zoledronate treatment has been shown to result in lower circulating levels of proangiogenic vascular endothelial growth factor (VEGF) and platelet-derived growth factor (Santini *et al.*, 2002, 2003; Vincenzi *et al.*, 2005). It is presently unclear whether bisphosphonates directly affect endothelial cells *in vivo* to cause antiangiogenic effects and subsequent decreases in tumor growth and survival, or whether the antiangiogenic effects observed *in vivo* are the indirect result of a decrease in secretion of angiogenic factors such as VEGF by the tumor cells and/or other cells affected by bisphosphonates.

Immunomodulatory Effects

Another way in which N-BPs could exert indirect antitumor effects is by activating γδ T cells. Specifically, bisphosphonates are able to activate Vγ9 Vδ2 T cells, the major γδ T cell subset in humans. Activation of these γδ T cells is believed to be the initiating factor in causing the acute-phase response to an intravenous infusion with bisphosphonates (Fig. 7; see also later). These Vγ9 Vδ2 T cells are, however, also important players in tumor surveillance by the innate immune system (Kunzmann *et al.*, 2005), and activation of this subset of T cells by bisphosphonates may have antitumor effects. Activated Vγ9 Vδ2 T cells are capable of directly recognizing and killing tumor cells, or they may exert antitumor effects indirectly via release of interferon-γ, which has inhibitory effects on tumor growth and angiogenesis (reviewed in Thompson and Rogers, 2006). Activation and expansion of γδ T cells has been observed *in vivo* in some patients with lymphoid malignancies receiving pamidronate therapy in combination with IL-2 (to support γδ T cell expansion), which correlated with response to therapy in terms of tumor regression (Wilhelm *et al.*, 2003). A further study by Dieli *et al.*, 2003) in cancer patients treated with 4 mg of zoledronic acid (without IL-2) every 3 weeks reported increased IFNγ production from peripheral blood mononuclear cells (PBMCs) *in vitro*.

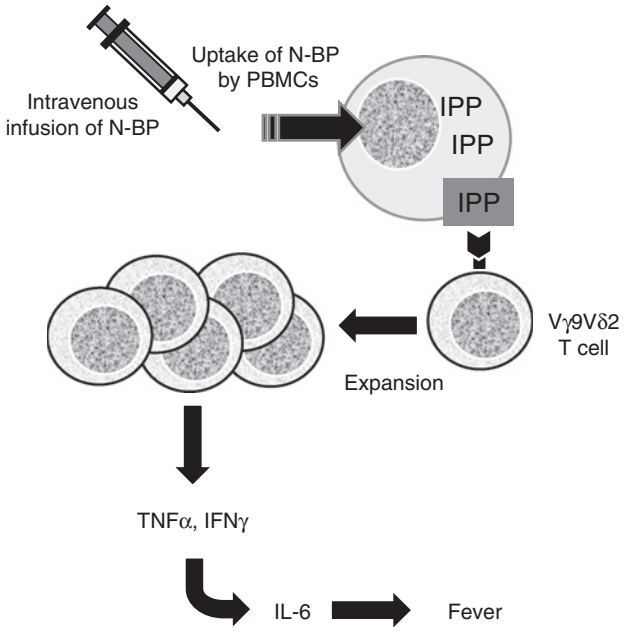

FIGURE 7 The acute phase reaction to N-BPs. After IV infusion, transient uptake of nitrogen-containing bisphosphonates by peripheral blood mononuclear cells (PBMCs) causes inhibition of FPP synthase and thus the accumulation of IPP. Recognition of IPP by γ-δ T cells triggers their activation and expansion and causes release of pro-inflammatory cytokines, resulting in a flu-like response.

Tumor cells are able to directly stimulate Vγ9 Vδ2 T cells following uptake of bisphosphonate *in vitro* (Kunzmann *et al.*, 2000; Gober *et al.*, 2003). However, whether tumor cells take up sufficient amounts of bisphosphonate *in vivo* to directly stimulate these γδ T cells, or whether activation of γδ T cells is mediated indirectly by other cells is presently unclear.

SAFETY AND ADVERSE EFFECTS

Toxicological animal studies have been published for several bisphosphonates. Acute, subacute, and chronic administration in several animal species have, in general, revealed little toxicity. Teratogenicity, mitogenicity, and carcinogenicity tests have been negative. When bisphosphonates are administered subcutaneously, local toxicity can occur, with local necrosis. Mild hypocalcemia owing to inhibition of bone resorption has been observed at high doses. Acute systemic toxicity and hypocalcemia can also be caused following intravenous administration of high doses of less potent bisphosphonates by the formation of complexes with calcium.

The chronic toxicity of the bisphosphonates is extremely low. This probably owes, in part, to their strong affinity for bone, which allows them to be cleared rapidly from blood. The toxic effects occur, in general, when doses

substantially larger than those that inhibit bone resorption are used. As for polyphosphates and phosphate itself, the first alterations are usually seen in the kidney (Alden *et al.*, 1989; Cal and Daley-Yates, 1990). The liver, as well as the testis, the epididymis, the prostate, and possibly the lung, can in some cases also show changes.

The most relevant toxicity associated with the low-potency bisphosphonate etidronate is the inhibition of bone and cartilage calcification, as described earlier (King *et al.*, 1971; Schenk *et al.*, 1973). This effect starts to occur in animals at parenteral doses of approximately 5 to 10 mg P/kg daily. The radiological appearance resembles rickets or osteomalacia, although there are some histological differences. Fractures can occur after long-term administration of high doses and are probably the result of defective mineralization (Flora *et al.*, 1980). Developmental disturbances of enamel can also appear at high systemic doses. This problem is not observed with the more potent bisphosphonates in current use, as these are administered at far lower doses.

Some bisphosphonates, such as etidronate and pamidronate, cross the placenta and can affect the fetus. Very large doses can lead to a decrease in the number of live pups, to abnormalities of the fetal skeleton and the skin, and to malformations and hemorrhages (Eguchi *et al.*, 1982; Graepel *et al.*, 1992; Okazaki *et al.*, 1995). In view of these results, bisphosphonates should not be administered to pregnant women.

Gastrointestinal Toxicity

Following the appearance in humans of gastrointestinal adverse events after oral administration of N-containing bisphosphonates (De Groen *et al.*, 1996), the effects of oral bisphosphonates were studied in animals. Alendronate, given orally to rats at suprapharmacological doses, has been reported to occasionally induce gastric and esophageal erosions and ulcerations and delay healing of indomethacin-induced gastric erosions. These effects are not attributable to changes in gastric acid secretion, or prostaglandin synthesis, but are thought to be caused by a topical irritant effect. Similar effects were reported with etidronate, risedronate, and tiludronate when given at pharmacologically equivalent doses. These effects were obtained at doses equivalent to (Peter *et al.*, 1998a) or much larger than the ones given in humans (Blank *et al.*, 1997; Elliott *et al.*, 1998; Peter *et al.*, 1998b).

Recent studies have examined potential mechanisms by using *in vitro* models for the esophageal stratified epithelium and the large intestine (Suri *et al.*, 2001; Reszka *et al.*, 2001). N-BPs were shown to induce apoptosis in CACO-2 intestinal epithelium cells and in Ch1.Es esophageal fibroblasts, and to decrease proliferation in normal human epidermal keratinocytes and CACO-2 cells (Suri *et al.*, 2001; Reszka *et al.*, 2001). These effects were associated with an inhibition of protein prenylation and could be prevented by geranylgeraniol, suggesting that N-BP inhibition of protein geranylgeranylation was instrumental in the antiproliferative and apoptotic response. These *in vitro* studies thus suggest that the N-BP-induced gastrointestinal irritation and/or delayed repair of irritation may be mediated by inhibition of FPP synthase in the affected tissues. These findings await *in vivo* validation. It has also been shown that N-BPs compromise the surface hydrophobic phospholipid barrier of gastrointestinal tissue in rats, which may cause mucosal injury and ulceration (Lichtenberger *et al.*, 2000).

Acute-Phase Reaction

Intravenous administration of N-BPs is commonly associated with a flu-like syndrome known as the acute-phase reaction, which occurs in roughly one-third of patients receiving some N-BPs for the first time (Adami *et al.*, 1987; Schweitzer *et al.*, 1995). The molecular mechanism underlying this response was first revealed by Kunzmann *et al.* in 1999, who reported that patients that suffered an acute-phase reaction to pamidronate had increased circulating levels of γδ T cells up to 28 days after the infusion (Kunzmann *et al.*, 1999). It is now clear that activation and proliferation of γδ T cells (Kunzmann *et al.*, 1999, 2000) and the release of pro-inflammatory cytokines such as TNFα, and IFNγ (Schweitzer *et al.*, 1995; Sauty *et al.*, 1996; Thiebaud *et al.*, 1997) underlie the acute-phase reaction (see Fig. 7).

N-BPs were previously thought to directly activate Vγ9 Vδ2 T cells by acting as antigens for the Vγ9 Vδ2 T cell receptor (Das *et al.*, 2001). However, more recent evidence suggests that N-BPs indirectly activate Vγ9 Vδ2 T cells through inhibition of FPP synthase in PBMCs, and the resulting intracellular accumulation of upstream metabolites such as IPP and DMAPP (see Fig. 7; Gober *et al.*, 2003; Thompson *et al.*, 2004; Hewitt *et al.*, 2005; Thompson *et al.*, 2006b), which are known antigens for the Vγ9 Vδ2 T cell receptor (Tanaka *et al.*, 1995). This hypothesis is supported by the finding that N-BPs must be internalized in order to activate Vγ9 Vδ2 T cells *in vitro* (Gober *et al.*, 2003), that the ability to activate Vγ9 Vδ2 T cells closely matches the ability to inhibit FPP synthase (Thompson *et al.*, 2004), and that statins, which inhibit the upstream enzyme HMG-CoA reductase, can prevent Vγ9 Vδ2 T cell activation *in vitro* most likely by preventing the intracellular accumulation of IPP, DMAPP, and possibly other mevalonate pathway metabolites (Gober *et al.*, 2003; Thompson *et al.*, 2004; Hewitt *et al.*, 2005).

Osteonecrosis of the Jaw

Recently, osteonecrosis of the jaw (ONJ) has emerged as a potential complication, particularly with long-term, high-dose intravenous bisphosphonate therapy in malignant diseases (Maerevoet *et al.*, 2005). Although many of the

clinical and pathological features are debated, the current definition is of nonhealing lesions involving exposed bone in the mandible or maxilla. Most reported ONJ cases have been in cancer patients, especially those with myeloma or breast cancer metastases, who received i.v. bisphosphonates (pamidronate and zoledronate), although some cases of ONJ have also been reported in patients on oral bisphosphonate therapy for benign disorders. ONJ appears to be frequently triggered by dental interventions, such as tooth extraction. There are no prospective properly controlled trials that show an excess of ONJ cases associated with bisphosphonate therapy (Grbic *et al.*, 2008). The etiology of osteonecrosis of the jaw is at present unknown, and relevant prospective clinical trials to study pathogenic mechanisms are currently not available. Many cancer patients presenting with ONJ had also received other drugs, including glucocorticoids or chemotherapeutic agents, making the potential pathogenic mechanisms complex. Recent reviews and guidelines emphasize that any causal role for bisphosphonates remains unproven (Van den Wijngaerten *et al.*, 2006, 2007; Khosla *et al.*, 2007; Glick, 2008).

SUMMARY

Great progress has been made over the past two decades in understanding the mechanism of action of the bisphosphonates. This class of drugs is widely used in the treatment of osteoporosis, Paget's disease, tumor-associated bone disease, with potential uses in several other skeletal conditions. Bisphosphonates target to the skeleton owing to their bone-binding characteristics, where they primarily act by inhibiting osteoclastic bone resorption, although it is presently still debated whether they might directly affect other cell types such as osteoblasts, osteocytes, and tumor cells *in vivo*. The simple bisphosphonates, clodronate, etidronate and tiludronate, are intracellularly metabolized to cytotoxic analogues of ATP, whereas the more potent, nitrogen-containing bisphosphonates act by inhibiting the enzyme FPP synthase, thereby preventing the prenylation of small GTPases that are necessary for the normal function and survival of osteoclasts. With emerging differences between bisphosphonates in bone affinity and enzyme inhibitory potency, it is becoming apparent that each bisphosphonate may have a unique pharmacological profile. Unraveling the exact molecular mechanisms underlying differences in efficacy and adverse effects may help to expand the utility of bisphosphonates and to ensure their overall safe use in the treatment of a variety of bone diseases characterized by excessive osteoclastic bone resorption.

Chapter 82

The Pharmacology of Estrogens in Osteoporosis

Robert Lindsay*
Helen Hayes Hospital, West Haverstraw, New York

Felicia Cosman
Department of Medicine, Columbia University, New York

INTRODUCTION

Control of bone remodeling is intimately linked to estrogen status in the human female and perhaps also in the human male. Loss of estrogen production by the ovary, at the time of menopause, produces and an alteration in the equilibrium between bone resorption and formation (Lindsay, 1995). The consequence is loss of bone tissue with accompanying microarchitectural damage that leads to increased bone fragility, commonly called osteoporosis (Consensus Development Conference, 1993). Estrogen intervention restores bone remodeling to its premenopausal equilibrium and prevents bone loss. Observational and some clinical trial data suggest that estrogens also reduce the risk of fractures (Weiss *et al.*, 1979; Hutchinsen *et al.*, 1979; Paganini-Hill *et al.*, 1981; Kreiger *et al.*, 1982; Kiel *et al.*, 1987; Lindsay, 1995; Lindsay, 1980; Komulainen, 1998; Herrington, 2000 add), the only clinical consequence of osteoporosis. The precise mechanism by which estrogens control bone remodeling is still relatively poorly understood, although significant advances in our understanding have been made in recent years. In this chapter, we will review the current status of our knowledge of the actions of sex steroids in both prevention and treatment of osteoporosis in postmenopausal women.

RESPONSES TO ESTROGEN ADMINISTRATION

Biochemistry

When estrogens are administered to estrogen-deficient women, there is a reduction in bone remodeling that can be monitored biochemically (Siebel *et al.*, 1993). During the initial weeks of therapy, there is a gradual decline in biochemical markers of bone resorption aminoterminal and carboxyterminal telopeptides such as the pyridinoline cross-linking molecules [NTX or CTX] (Delmas, 1995). There is a similar but more delayed decline in biochemical measures of bone formation, such as osteocalcin and bone-specific alkaline phosphatase. The timing of these biochemical changes is presumed to represent an initial rapid reduction in activation of new remodeling sites, and a reduction in the work rate of active osteoclasts. Because resorption is the initial event in remodeling, a decline in the rate at which new remodeling sites are coming "on-line," initiated at the start of treatment, would produce a reduced supply of the products of resorption into the circulation. Formation follows resorption and is a more prolonged process. Consequently, formation would be expected to continue unabated in those remodeling sites activated before treatment until the osteoblast teams complete their work. These modifications in skeletal remodeling may occur through direct effects of estrogens on bone cells and in part indirectly by increased resistance to the bone-resorbing effects of parathyroid hormone (PTH). Accompanying these changes in skeletal metabolism are modifications in calcium homeostasis, including reduced renal excretion of calcium, improved hydroxylation of 25(OH)D to $1,25(OH)_2D$, and improved calcium absorption across the intestine. In some studies, declining remodeling within the skeleton is also associated with a small fall in serum calcium and a rise in PTH that might affect the renal and intestinal calcium handling.

Bone Density

The consequence of these alterations in skeletal homeostasis is preservation of bone mass, which has been detailed in many controlled studies (Lindsay, *et al.,* 1976, 1978a, 1980, 1984; Horsmann *et al.*, 1977; Christiansen and Rodbro, 1983 add PEPI(Postmenopausal Estrogen Progestin Intervention

*Corresponding author: Robert Lindsay, Helen Hayes Hospital, West Hawerstraw, New York

Study) and WHI). Most studies in which estrogens are given during active bone loss provide evidence of a gradual increase in measured bone mass or density that occurs primarily during the first 1 to 2 years of treatment. It has been assumed that this phenomenon results from the reduced activation of remodeling, which would mean that at any time point after initiation of therapy, there would be a smaller proportion of the skeleton undergoing the remodeling process. The consequence would be an apparent gradual increase in bone mass, without the necessity of an anabolic effect of estrogen. This increment would be time dependent during the early months of treatment as completing remodeling sites gradually filled with new bone tissue, and bone mass would be expected to be relatively stable thereafter (Delmas, 1995). Indeed, all agents that act by reducing bone remodeling produce the same effect during the first 1 to 2 years of treatment. The magnitude of the effects vary depending upon the site measured (the spine usually shows greater increases) and the magnitude of the reduction in remodeling (bisphosphonates and estrogen are most potent of the currently available agents but RANK-ligand antibody (denosumate) may be even more potent). Additionally, with slower rates of remodeling there may be a longer period of secondary mineralization that would also appear as an increase in bone mineral density (BMD) by DXA(Dual X ray absorptiometry).

In long-term studies with estrogens, there are somewhat divergent results, possibly owing to a variety of issues. First, it is clear that the long-term compliance with estrogen is less than perfect, and consequently bone loss, which is known to restart when treatment is stopped, might be expected to be seen among some individuals who are not compliant with treatment (Lindsay *et al.*, 1978; Christiansen and Christiansen, 1981). Second, the response of the skeleton may be variable and dependent upon the bone measured. For example, the vertebral bodies contain the highest proportion of cancellous bone and produce the greatest initial response to estrogen. Some data suggest that there is very little subsequent loss in the vertebrae, whereas the hip may be more sensitive to other factors, especially physical activity (Lindsay, 1995; Orwoll *et al.*, 1996). Thus, although initial cross-sectional data suggested very little loss of bone from any skeletal sites, more recent longitudinal data have confirmed some slow loss (~0.5% per year) from the hip in patients who have been on long-term estrogen (more than 5 years).

When estrogen therapy is discontinued, there is an immediate increase in bone remodeling that is reminiscent of ovariectomy (Lindsay *et al.*, 1978; Christiansen and Christiansen, 1981). The consequence of this is an increase in the rate of bone loss (Lindsay *et al.*, 1978; Greenspan *et al.*, 1999). The longer the process of bone loss continues, the more the treated population will begin to resemble an untreated population in terms of bone density. More than 20 years ago, we demonstrated that the effects of 4 years of estrogen intervention were virtually lost 4 years after estrogens had been discontinued (Lindsay *et al.*, 1978).

Effects on Fracture

The consequence of reduced bone turnover and prevention of bone loss is a reduction in the risk of fracture. Numerous epidemiological studies have shown that estrogen exposure is associated with a reduction in the risk of fractures of the hip and wrist (Lindsay *et al.*, 1976, 1978a; 1978b; 1980a; 1984; Horsman *et al.*, 1977; Christiansen and Christiansen, 1981; Christiansen and Rodbro, 1983). In general, there appears to be about a 50% reduction in hip fracture risk. More recent data indicate that the estrogen effect is greatest among those currently taking treatment, and those who began earliest (Cauley *et al.*, 1995). These epidemiological data are compatible with the prospective effects on bone mass and emphasize the importance of continued therapy to obtain the maximum effects on fracture. Because menopause occurs at the average age of 50, and hip fractures affect mostly women over 70, this may mean 20 to 30 years of treatment, or even treatment for life may be necessary. Controlled clinical trial data suggest a reduction of 50% to 80% in the risk of vertebral fractures, when estrogens are used for prevention (Lindsay *et al.*, 1980a) or treatment (Lufkin, 1992). One recent clinical trial has confirmed the effects of hormone replacement therapy (HRT) on clinical nonvertebral fractures in a recently menopausal population (Komulainen, 1998). However, in one study of HRT's effects on cardiovascular disease (the largest outcome study completed as yet using HRT), there was an equal number of fractures in the HRT and placebo arms, casting doubt on fracture efficacy (Hulley *et al.*, 1998). It is important to emphasize that this particular study recruited women based upon cardiac history without regard to skeletal status, which was largely unknown. Moreover, there was a high incidence of obesity in that population, which might have reduced the likelihood of a significant estrogen effect on fractures. There was no comprehensive evaluation of vertebral compression fracture because spine radiographs were not routinely performed. However, there did not appear to be a reduction in height loss. In another smaller study in which cardiac outcomes were also assessed by cardiac catherization, although there was no effect on atheroma, there was a reduction in the number of clinical fractures. Thus, despite one negative study, most data support a fracture benefit for estrogens.

These data are supported by the results from the Womens Health Initiative (WHI). This study comprises the two largest clinical trials completed with hormonal therapy. The results have been published in detail (Writing Group for the Women's Health Initiative Investigators, 2002). Briefly, roughly 16,000 asymptomatic women between ages 50 and 79 who had transitioned through a natural menopause were randomized to conjugated equine estrogens (CEE; 0.625 mg/day) plus medroxyprogesterone acetate (MPA; 5 mg/day) or placebo. The outcomes were cardiovascular disease, breast and other cancers, and fractures. The second WHI study

randomized 10,000 hysterectomized women to CEE 0.625 mg/day or placebo, with the same outcome measures (Writing Group for the Women's Health Initiative Investigators, 2004). Both studies were discontinued prior to completion, the former because of an increase in the "global index" that suggested overall harm to the population, and the second because of an increase in the risk of stroke. In both studies there were significant reductions in the risk of all fractures, and particularly fractures of the hip and spine (Cauley *et al.,* 2003; Jackson *et al.,* 2006). More recent data from WHI suggest that much of the risk occurs in the older population (Roussow *et al.,* 2007) and CEE alone was not associated with an increased risk of breast cancer. BMD was performed in only a small segment of the overall groups and a small minority had osteoporosis by BMD. WHI, therefore, provides the most robust data for fracture reduction in individuals with relatively normal BMD. Although it is clear from WHI that giving hormone therapy (HT) or estrogen therapy (ET) to older individuals cannot be recommended, the studies suggest that in selected younger women who are close to menopause ET/HT remains a viable option for prevention of bone loss and osteoporosis-related fractures.

Route of Administration and Dosing

The evidence suggests that the route of estrogen administration required to obtain a skeletal effect is irrelevant and that if adequate doses are given, reduced bone remodeling results (Christiansen and Lindsay, 1991). Thus, data obtained from transdermal, percutaneous, and subcutaneous as well as oral administrations all confirm skeletal conservation. For transdermal estrogens, the 50-μg patch, which results in estradiol levels in circulation of ~50 pg/ml, appears sufficient (Lufkin *et al.*, 1992) Prestuad *et al.* have shown that 0.25mg micronized estradiol increases BMD with minimal estrogen target organ effects. In contrast, vaginal estrogen administration does not appear to result in high enough estrogen levels in circulation to exert an effect on skeletal remodeling.

After WHI, there was renewed interest into whether doses of estrogen lower than 0.625 mg CEE or its equivalent could provide skeletal benefit. Although no fracture data exist for these lower doses, BMD and turnover data clearly demonstrate skeletal activity. For CEE, 0.3 mg is the lowest dose examined in clinical trials (Lindsay, 2002; Lindsay *et al.,* 2005). For transdermal estrogen, a dose of 0.014 mg/day appears to have at least some activity (Ettinger *et al.,* 2004).

Presently, data demonstrate that all estrogens used in the postmenopausal population produce skeletal effects. For some, such as CEEs, the data include dose-response and fracture outcomes. For others, more limited data on bone mass are available, often without good dose-response data. Synthetic estrogens such as those used in the oral contraceptive also produce skeletal effects in estrogen-deficient individuals (Lindsay *et al.*, 1976). Indeed ethinyl-estradiol in doses between 5 and 10 μg per day prevent bone loss. In addition, at the 5-μg dose there appears to be a modest increase when norethindrone (1 mg/day) is combined with the estrogen (Rowan *et al.,* 2006).

However, the use of oral contraceptives, with doses of ethinyl-estradiol between 20 and 30 μg per day, probably inhibits skeletal maturation in growing teenagers. Whether this results in long-term effects is not clear. Whether the use of oral contraceptives among premenopausal but skeletally mature women produces much in the way of alterations in skeletal homeostasis is not clear but seems unlikely.

Reduction in skeletal remodeling is an effect that can be produced with other steroids. Progestins given to postmenopausal women also produce reductions in bone remodeling and prevention of bone loss (Lindsay *et al.*, 1978). The required doses are greater than those normally used in estrogen-deficient women when given with estrogen to protect the uterus (20 mg/day for medroxyprogesterone acetate [MPA] and 5 mg/day for norethindrone) (Lindsay *et al.*, 1978; Gallagher and Kable, 1991). The addition of a C-21 progestin in more conventional doses to estrogen therapy does not modify the estrogen response significantly (PEPI). However, there may be a modest additive effect when doses lower than 0.625 mg are supplemeneted with an MPA (Lindsay, 2001). As noted in earlier, there are some data suggesting an additive effect of the 19-nortestosterone derivative norethindrone when given in combination with 5 μg of ethinyl-estradiol (Speroff, 1996). On the other hand, evidence suggests that the progestins, when used by themselves for contraceptive purposes (Depo-MPA) in premenopausal estrogen-replete women, will actually be detrimental to skeletal health, presumably by reducing endogenous production of estrogen by the ovary (Mark, 1994). Although there is clear evidence of bone loss in that situation, no fracture data exist. There is no evidence that progestin creams can result in high enough circulating levels of progesterone to produce skeletal effects.

The activity of progestins on bone is also evident in the data published on tibolone (Lindsay *et al.*, 1980; Milner *et al.*, 2000; Castelo-Branco, 2000). This steroid is a pro-drug related to norethindrone and thus is a 19-nortestosterone derivative. It has androgenic, progestogenic, and weak estrogenic activity. In doses that do not appear to stimulate the endometrium, it produces estrogen-like effects in bone. Thus, tibolone is a unique tissue-selective compound, that produces some effects related to its androgenicity and progestin activity rather than its estrogen action.

Estrogens are potent hormones with effects on multiple tissues. Some of these effects confer significant benefit and some significant risk to the postmenopausal women. One clear-cut benefit of HRT is the suppression of menopausal symptoms, such as hot flashes and vaginal dryness. Many of

the other potential benefits of HRT, however, have not been proven. WHI results suggest that estrogens do not decrease the risk of cardiovascular disease, although this may differ in younger women close to menopause (Clarkson, 2007). A large body of clinical trial data indicates that estrogen improves intermediate markers of cardiovascular health, including cholesterol and other lipoproteins, and the vasodilatory coronary artery response to acetylcholine (Hodis *et al.,* 2003; Manson *et al.,* 2003; Writing Group for PEPI, 1995). In addition to WHI, two other studies found a lack of efficacy against clinical heart disease outcomes in patients with active cardiovascular disease (HERS) Health and Estrogen Replacement Study (Hulley *et al.*, 1998) and a lack of regression of coronary artery plaque (Herrington *et al.*, 2000) in those women assigned to estrogen or HRT. Clarkson has developed the interesting hypothesis based on data from nonhuman primates that suggests that there is a window of opportunity for cardiovascular protection that may close a few years after menopause (Clarkson, 2007). The reanalyses of WHI seem in part to support this hypothesis because the majority of the risk occurred among the older population.

Women's Health Initiative Mental Status Study (WHIMS), a substudy of WHI, suggested that HT may be associated with a worsening of cognitive function. However, WHIMS was a study of women over age 65, and if the Clarkson hypothesis applies to the brain also (for which we have no evidence) then a positive result would not be expected. HT appears also to worsen urogenital symptoms such as incontinence in some studies. HRT increases the risk of venous thromboembolic disease threefold and the risk of gallbladder disease twofold.

Estrogens also cause endometrial hyperplasia and increase the risk of endometrial malignancy (Jick *et al.*, 1979; Shapiro *et al.*, 1985). Protection of the endometrium is the only rationale for the prescription of a progestin along with estrogen to postmenopausal women (Woodruff and Pickar, 1994). Consequently, there has been considerable interest in the idea that estrogen analogs (Selective Estrogen Receptor Modulators – SERMs) might be found that would provide the beneficial effects of estrogen on bone, brain, and heart, without endometrial or breast stimulation. There are at least two forms of the estrogen receptor (alpha and beta) with dimerization required for gene activation, and heterodimerization possible and thus separation of estrogen effects by tissue might be possible. In addition, multiple coactivator and corepressors exist with different tissue distribution, further emphasizing how estrogens and estrogen-like drugs might act differently in different tissues.

ESTROGEN ACTIONS

The molecular actions of estrogens have been reviewed in detail elsewhere in this book. Estrogen receptors (ER) are members of the steroid receptor family that include thyroid hormone, vitamin D, and retinoids among their ligands as well as sex steroids and adrenal steroids (Auchus and Fugue, 1994). In cells that express estrogen receptors, estrogens produce a potential cascade of gene activation that is dependent on a variety of intracellular factors. Generally responsive cells contain 10,000 to 100,000 receptors, and clearly the concentration of receptors is one variable that might affect response (in general, lower levels appear in nonreproductive cells) (Brown, 1994). After ligand binding the receptor complex dimerizes and complex binds to DNA with high affinity that is dependent on the integrity of the amino acid sequence related to the base of the first zinc finger on the C region of the receptor (Picard *et al.*, 1990). In addition, ligand binding alters the conformation of the receptor, exposing the DNA-binding domain. In addition, while ligand binding is usual for dimerization, DNA binding, and subsequent transcription activity, the ERs can activate genes in the absence of ligand. DNA binding and transcription is also modulated by a variety of cellular proteins (coactivators and corepressors plus other transcription activators that may modulate the responsivity of the genome to ER even in the presence of ligand) (Ronies and Spelsberg, 1989; Brown, 1994).

Given the complexity of the system, it is not difficult to suggest how estrogen responsivity might be modulated. Abnormal receptors, or abnormal conformational changes in the receptor upon ligand binding, the absence of cofactors, or the alteration in the response elements of target genes all might modify the cellular responses to estrogen (Auchus and Fugue, 1994). Tissue selectivity of estrogen response could be obtained by differences in receptor number or the expression of factors within the cells of that tissue influencing the cascade, for example, the capability to phosphorylate the ER ligand complex.

Several genes are targets for estrogen actions including nuclear proto-oncogenes (c-*fos*, c-*myc*, and c-*jun*), and the estrogen responses include expression of several genes including growth factors and cytokines (Murphy and Murphy, 1994).

The estrogen target that is responsible for the effects of these agents in bone is still not clearly understood. Osteoblasts have been shown to have ERs (Eriksen *et al.*, 1988; Komm *et al.*, 1988), but very variable responses to estrogen in osteoblasts or osteoblast cell lines have been published (Turner *et al.*, 1994). Indeed some evidence suggests that only cells transfected with a functional ER will respond to estrogens (Ernst *et al.*, 1991). Some data suggest that osteoclasts also respond directly to estrogens (Oursler *et al.*, 1991). The strongest evidence of ERs in osteoclasts comes from studies of avian osteoclasts. Rat osteoclasts probably do not respond to estrogens, and there is almost no information on human osteoclasts (Arnett *et al.*, 1996). The most likely cell targets for estrogen appear to be other constituent cells of bone marrow. Release of second messengers, such as TGF-β (transforming growth factor-beta), or reduction in secretion of cytokines, such as IL-1 or IL-6, could produce estrogen

effects by reducing the recruitment and maturation of osteoclasts (Oursler *et al.*, 1991; Turner *et al.*, 1994). Estrogen has also been reported to cause osteoclast apoptosis, although not in all systems (Arnett *et al.*, 1996). Finally, estrogens also have effects on calcium homeostasis. Estrogens reduce urinary calcium loss and, at the renal level, cause an increase in PTH activity. Estrogens, however, increase skeletal resistance to the resorptive stimulatory effects of PTH without appearing to interfere with the anabolic effects of PTH (Cosman *et al.*, 1993). Estrogens also stimulate intestinal absorption of calcium, perhaps directly or by modulating the effects of PTH on the renal 1α-hydroxylase, thereby increasing the supply of 1,25-dihydroxyvitamin D. Whether these effects of estrogen on the calcium homeostatic system are primary or secondary to the skeletal effects of estrogens is not clear.

The knowledge that estrogen responsivity may vary from tissue to tissue has clearly heightened interest in the concept of the ideal estrogen. Such a compound would produce the beneficial effects of estrogen on bone, cardiovascular system, brain, and urogenital tissues without stimulating endometrial growth or producing effects on mammary tissue that might increase the risk of breast cancer. Several compounds are under investigation for such activities. The first noted is tibolone, which clearly produces bone effects at doses that do not appear to produce much endometrial stimulation. It is not clear, however, whether tibolone can reduce the risk of ischemic heart disease. Because the effects of estrogen on the cardiovascular system probably include multiple effects on lipid metabolism and on the physiology of the circulatory system, further investigation of this compound would seem to be warranted, even though it does not produce an estrogen-like response in terms of circulating lipoproteins. The realization that tamoxifen exerted estrogen-like effects in some cell systems stimulated evaluation of its effects in women who were being given tamoxifen as adjuvant treatment for breast cancer (Cosman and Lindsay, 1999). Surprisingly, these women were not losing bone when compared with postmenopausal controls. Formal controlled clinical trials confirmed that tamoxifen does appear to conserve bone mass and produce estrogen-like effects on lipoprotein metabolism (Cosman and Lindsay, 1999). Tamoxifen also stimulates the endometrium, albeit weakly, and endometrial cancer is a recognized risk of long-term tamoxifen treatment. Knowledge of these effects awakened interest in the pharmaceutical industry in compounds that might have tamoxifen-like effects on breast cancer but would produce estrogen-like effects on bone and cardiovascular diseases. Raloxifene, a benzothiaphene, is now available for prevention and treatment of osteoporosis. Raloxifene and tamoxifen produce similar estrogen-like effects on bone in ovariectomized rats (Black *et al.*, 1994). However, raloxifene appears to have little stimulatory effects on rat uterus. Raloxifene reduces bone remodeling and prevents bone loss in postmenopausal women. Raloxifene reduces the risk of vertebral fractures, but did not have a statistically significant effect on nonvertebral fractures (Ettinger *et al.*, 1999). The use of raloxifene in clinical practice is strongly influenced by its capacity to reduce the clinical appearance of ER-positive breast cancer over a 4-year period. Raloxifene also lowers circulating low-density lipoprotein similar to estrogen, although no increase in high-density lipoprotein was seen as is usually the case with oral estrogens (Draper *et al.*, 1996). Raloxifene increases the risk of deep vein thrombosis and pulmonary embolism to the same degree as HRT. Clearly, compounds such as raloxifene will be powerful tools in the dissection of the mechanisms of estrogen action at the molecular level. The realization that different cells respond to estrogen-like molecules in different ways also raises the intriguing question of whether compounds can be found that reduce the recruitment and activity of osteoclasts, like estrogen, and produce lesser effects on bone formation. Tamoxifen, for example, appears to have more potent effects on bone resorption *in vitro* than estrogens, perhaps by being a more potent stimulator of osteoclast apoptosis. Clomiphene also increases trabecular thickness in rats, an effect not usually associated with estrogens.

Chapter 83

Vitamin D and Analogues

Glenville Jones*
Department of Biochemistry, Queen's University, Kingston, Ontario, Canada

INTRODUCTION

Vitamin D, its metabolites and analogues constitute a valuable group of compounds that can be used to modulate many aspects of osteoblast and osteoclast biology. The parent vitamin (or UV light that substitutes for any vitamin D pharmaceutical preparation as a source of the parent vitamin) has been used as a treatment for rickets and osteomalacia since its discovery in the 1920s. The first analogue of vitamin D, dihydrotachysterol, was developed for use in metabolic bone disease in the 1930s before the elucidation of the metabolism of vitamin D. In fact, it was not until the discovery of the principal metabolites: 25-hydroxyvitamin D_3 (25-OH-D_3) and 1α,25-dihydroxyvitamin D_3 (1α,25-$(OH)_2D_3$), in the early 1970s that further generations of vitamin D analogues were developed (DeLuca, 1988; Jones and Calverley, 1993; Jones *et al*., 1998). With the understanding of the molecular action of the hormonal form, 1α,25-$(OH)_2D_3$, has come an appreciation that it is not only a *calcemic agent*, regulating calcium and phosphate transport, but also a *cell-differentiating agent*, promoting the terminal development of a number of cell types, including the osteoclast, the enterocyte, and keratinocyte (Miyaura *et al.*, 1981). Thus, pharmaceutical companies have striven hard over the past three decades to separate these two properties and thereby develop synthetic vitamin D analogues with specialized "calcemic" and "noncalcemic" (cell-differentiating) uses (Calverley and Jones, 1992; Bouillon *et al.*, 1995). From this type of research has come several "low-calcemic" agents in recent years in the form of calcipotriol, OCT, 19-nor-1α,25-$(OH)_2D_2$, and 1α-OH-D_2, which have found widespread use in dermatology and the treatment of secondary hyperparathyroidism. Not only do newer analogues include specialized selective vitamin D receptor (VDR) agonists but also VDR antagonists and compounds that target CYP24, a component of the calcitriol metabolism machinery that extends the life of calcitriol within the target cell. These other analogues are thus under development for use in metabolic bone diseases, osteoporosis, and cancer (Jones *et al.*, 1998; Masuda and Jones, 2006). This chapter will review the spectrum of compounds available, possible uses of these compounds, and their potential mechanisms of action.

PHARMACOLOGICALLY IMPORTANT VITAMIN D COMPOUNDS

Vitamin D compounds can be subdivided into three major groups, listed in Tables I through III and described below.

Vitamin D and Its Natural Metabolites

Table I shows the structures of vitamin D_3 and some of its important metabolites. Ironically, vitamin D_3, the natural form of vitamin D, is not approved for use as a drug in the United States, whereas it is available as a pharmaceutical agent or as an over-the-counter supplement in virtually every other country in the world.

During the late 1960s and early 1970s, most of the principal vitamin D metabolites were first isolated and identified by GC-MS and then their exact stereochemical structure determined (DeLuca, 1988). This led to chemical synthesis of the naturally occurring isomer and its testing in various biological assays *in vitro* and *in vivo*. Currently, only the compounds representing the main pathway of vitamin D activation, namely vitamin D_3, 25-hydroxyvitamin D_3 (25-OH-D_3), and 1α,25-$(OH)_2D_3$, are synthesized and available for use as drugs.

Vitamin D Prodrugs

Table II lists some of the important prodrugs of vitamin D. All of these compounds require a step (or more) of activation *in vivo* before they are biologically active. Included here is vitamin D_2, which is derived from the fungal sterol, ergosterol, by irradiation. Because vitamin D_2 is found rarely in nature and is hard to detect in humans eating

nonfortified foods, we can consider it to be an artificial form of vitamin D or prodrug. Vitamin D_2 is used as a substitute for the natural form, vitamin D_3, in pharmaceutical preparations or over-the-counter supplements in the United States. Vitamin D_2 possesses two specific modifications of the side chain (see Table II) but these differences do not preclude the same series of activation steps as vitamin D_3, these giving rise to 25-OH-D_2, 1α,25-$(OH)_2D_2$, and 24,25-$(OH)_2D_2$, respectively. Recently, there has been much debate in the vitamin D field, particularly in the United States where vitamin D_2 is the sole agent available, about the relative utility of vitamin D_2 and vitamin D_3 to raise the circulating 25-OH-D level (Vieth, 2005). Evidence from research studies suggests that oral doses of vitamin D_3 are significantly more effective than equivalent doses of vitamin D_2 for increasing the 25-OH-D level into the sufficient range (more than 40 ng/mL) (Trang *et al.*, 1998; Armas *et al.*, 2003).

25-OH-D_3 was developed and approved as the pharmaceutical preparation Calderol in the 1970s by Upjohn, later acquired by Organon, but was withdrawn recently and is currently unavailable. Two other prodrugs, 1α-OH-D_3 and 1α-OH-D_2, were synthesized in the early 1970s (Barton *et al.*, 1973; Paaren *et al.*, 1978) as alternative sources of 1*a*,25-$(OH)_2D_3$ and 1*a*,25-$(OH)_2D_2$, respectively, that in the process circumvent the renal 1α-hydroxylase enzyme, which was shown to be tightly regulated and prone to damage in renal disease.

The final compound in the list, dihydrotachysterol (DHT) has lived a complex history as a prodrug. Originally it was believed to be "active" when converted to 25-OH-DHT by

virtue of an A ring rotated 180° such that the 3β-hydroxy1 function assumes a pseudo-1α-hydroxy1 position (Jones *et al.*, 1988). The mechanism of action of DHT has become less clear with the description of the extrarenal metabolism of 25-OH-DHT to 1α,25-$(OH)_2$-DHT and 1β,25-$(OH)_2$-DHT, two further metabolites that have greater biological activity than either 25-OH-DHT or DHT itself (Qaw *et al.*, 1993).

Vitamin D Analogues

Table III lists some of the most promising vitamin D analogues of 1α,25-$(OH)_2D_3$ already approved by governmental agencies or currently under development by various industrial or university research groups. Because the number of vitamin D analogues synthesized now lists in the thousands, the table is provided mainly to give a flavor of the structures experimented with thus far, the worldwide scope of the companies involved, and the broad spectrum of target diseases and uses.

The first generation of calcitriol analogues included molecules with fluorine atoms placed at metabolically vulnerable positions in the side chain and resulted in highly stable and potent "calcemic" agents such as 26,27-F_6-1α,25-$(OH)_2D_3$. A second generation of analogues focused on features that make the molecule more susceptible to clearance, such as in calcipotriol (MC903), where a C22–C23 double bond, a 24-hydroxy1 function, and a cyclopropane ring have been introduced into the side chain or in 22-oxacalcitriol (OCT) where the 22-carbon has been replaced with an oxygen atom. Both modifications have given rise to highly promising analogues marketed initially in Europe and Japan, respectively (Kragballe, 1992; Abe-Hashimoto *et al.*, 1993).

The C-24 position is a favorite site for modification and numerous analogues contain 24-hydroxy1 groups, e.g., 1α,24(*S*)-$(OH)_2D_2$ and 1α,24(*R*)-$(OH)_2D_3$ (Strugnell *et al.*, 1995). Other analogues contain multiple changes in the side chain in combination, including unsaturation; 20-epimerization, 22-oxa replacement; and homologation in the side chain or terminal methyl groups. The resultant molecules such as EB1089 and KH1060 attracted strong attention of researchers because of their increased potency *in vitro* and were pursued as possible anticancer and immunomodulatory compounds, respectively.

TABLE III Analogues of 1α,25-$(OH)_2D_3$

Vitamin D analogue [ring structure]*	Side-chain structure	Company	Possible target diseases	Mode of delivery	Reference

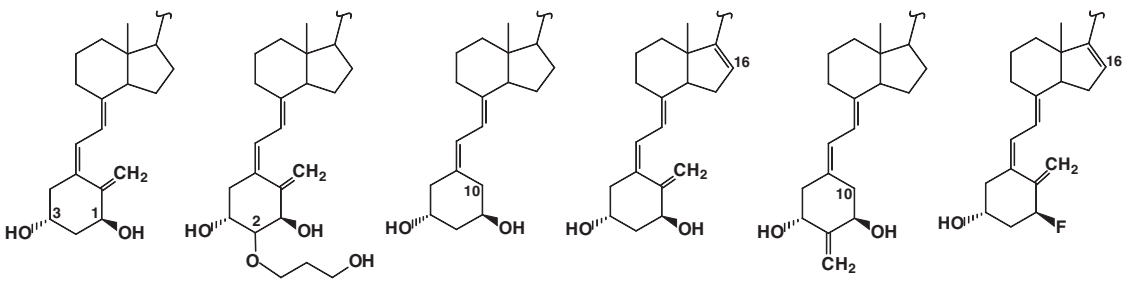
*Structure of the vitamin D nucleus (secosterol ring structure).

Vitamin D nucleus



[3] [4] [5] [6] [7] [8]

A few attempts have been made to modify the nucleus of calcitriol. The Roche compound 1α,25-$(OH)_2$-16-ene-23-yne-D_3, touted as an antitumor compound *in vivo,* possesses a D-ring double bond. Declercq and Bouillon have introduced a series of biologically active analogues without the C/D rings but with a rigid backbone to maintain the spatial arrangement of the A-ring hydroxy1 groups and the side chain (Verstuyf *et al.*, 2000). Relatively recently, the A-ring-substituted 2-hydroxypropoxy-derivative, ED71, has been tested as an antiosteoporosis drug. Other bulky modifications at the C2 position of the A ring are accommodated well by the vitamin D receptor, as indicated by retention of biological activity (Suhara *et al.*, 2001; Shevde *et al.*, 2002). The Abbott compound, 19-nor-1α,25-$(OH)_2D_2$, lacks a 19-methylene group and is styled upon the *in vivo* active metabolite, 1α,25-$(OH)_2$ DHT_2, formed from dihydrotachysterol, which retains biological activity though the C-19 methylene, is replaced by a C-19 methyl. Many other compounds have been developed with rigid or altered *cis*-triene structures (Okamura *et al.*, 1995) or modifications of the 1α,3β-, or 25-hydroxy1 functions, not for the purpose of developing active molecules for use as drugs, but to allow us to establish minimal requirements for biological activity in structure/activity studies (Calverley and Jones, 1992; Bouillon *et al.*, 1995).

Two recent compounds, Bioxell's BXL-628 and Deltanoids' 2-MD, combine modifications in the side chain with those in the nucleus. BXL-628 combines 1-fluorination, 16-ene and 23-ene unsaturations, 26,27-homologation, and 20-epimerization all found in earlier generations of analogues to make a antiproliferative agent currently in clinical trials for the treatment of prostate cancer and prostatitis (Crescioli *et al.*, 2003; Adorini *et al.*, 2007). Likewise, 2-MD, touted as being bone-specific, combines a novel 2-methylene substitution and the 19-nor feature with side chain 20-epimerization (Shevde *et al.*, 2002).

One series of compounds depicted in Table IV are the substituted biphenyls originally developed by Ligand, representing nonsteroidal scaffolds selected by high-throughput screening, which show weak VDR-binding but good transactivation through VDRE-driven, vitamin D-dependent genes and produce hypercalcemia *in vivo* (Boehm *et al.*, 1999). This family has recently been extended by the synthesis of some highly potent, tissue-selective nonsecosteroidal VDR modulators with nanomolar affinity (e.g., LY2109866) by a research group at Eli Lilly (Ma *et al.*, 2006). This is the first class of vitamin D mimics that lack the conventional *cis*-triene secosteroid structure while maintaining the spatial separation of the A-ring and side-chain hydroxy1 functions needed to bind to certain key residues of the ligand-binding pocket of the VDR. Though these nonsecosteroidal compounds exhibit a 270-fold improvement of the therapeutic index over calcitriol in animal models, they are still to be tested clinically. On the contrary, Table IV also shows the structures of two different classes of VDR/cacitriol antagonists made by Teijin and Schering, respectively. The former compounds, most notably TEI-9647, are based on the natural metabolite 1α,25-$(OH)_2D_3$-26,23-lactone and have found clinical utility in the treatment of Paget's disease (Ishizuka *et al.*, 2005; Saito and Kittaka, 2006).

Another group of compounds which impact the vitamin D field that are under development are the CYP24 inhibitors. By blocking CYP24A1, the main catabolic pathway within the vitamin D-target cell, these agents extend the life of the natural agonist, calcitriol, giving rise to a longer-lasting biological effect (Prosser and Jones, 2004). Sandoz/Novartis developed a group of molecules that have greater specificity toward CYP24 and CYP27B1 from the general cytochrome P450 (CYP) inhibitor, ketoconazole, which showed utility to block cell proliferation *in vitro,* but these compounds were discontinued after early clinical trials (Schuster, 2001). Cytochroma has synthesized a group of inhibitors based on vitamin D templates and these have currently reached phase IIB human clinical trials for the treatment of psoriasis (Posner *et al.*, 2004; Kahraman *et al.*, 2004). Some of these molecules show promise for use in secondary hyperparathyroidism, presumably because they counter the role of CYP24 in attenuating the effect of calcitriol on preproPTH gene suppression.

CLINICAL APPLICATIONS OF VITAMIN D COMPOUNDS

The clinical usefulness of vitamin D analogues has been reviewed comprehensively by both Bikle (1992) and Bouillon *et al.* (1995) in overviews and also within this book. This chapter summarizes some of the highlights in this area.

Rickets and Osteomalacia

When the nutritional basis of rickets and osteomalacia became apparent in the first half of the twentieth century, vitamin D (particularly vitamin D_2 because it was less expensive) became the treatment of choice for these diseases. Of course, low-dose prophylactic vitamin D (400 IU) in the form of supplements to milk, margarine, and bread replaced much of the need for therapeutic vitamin D to abolish overt rickets and osteomalacia. In fact, since then full-blown vitamin D deficiency rickets (defined as plasma 25-OH-D levels below 10 ng/mL or 25 nmol/L) has become very uncommon in North America because vitamin D supplementation is required by law, whereas it was quite common before the practice of food fortification and it is still more prevalent in the world where food fortification is not permitted. On the other hand, vitamin D insufficiency (defined as plasma 25-OH-D levels in the range 10 to 40 ng/mL or 25 to 100 nmol/L) remains common in the general

TABLE IV Miscellaneous Vitamin D Compounds

Name	Structure	Name	Structure

population and is being increasingly correlated with poor outcomes in several health-related areas including optimal bone mineral density (Bischoff-Ferrari *et al.*, 2006).

Vitamin D deficiency and insufficiency are also quite prevalent in the elderly and are usually treated with modest doses of 800 to 1000 IU of vitamin D (Chapuy *et al.*, 1992). In recent years, several world, continent-wide, and national food agencies have put out new guidelines raising the recommendations for vitamin D intake for all age groups, but particularly for those in the elderly or postmenopausal category, to try to ensure adequate intakes irrespective of geographical, dietary, and sun exposure differences (National Academy of Sciences Reference Intakes, 1997; FAO/WHO Nutritional Guidelines, 2000). However, the need for the use of expensive pharmaceutical preparations containing calcitriol or its analogues to cure simple rickets and osteomalacia is usually not warranted.

Though many of the hallmarks of rickets and osteomalacia are successfully relieved by doses of vitamin D in the range of 400 to 800 IU/day (10 to 20 μg/day), there are epidemiological data to suggest that current recommended dietary allowances (also known as DRIs) do not result in plasma 25-OH-D levels greater than 40 ng/mL which correlate with maximal bone mineral density (Holick, 2007; Bischoff-Ferrari *et al.*, 2004) or the other health benefits of vitamin D (Bischoff-Ferrari *et al.*, 2006). Consequently, there has been much recent debate over the optimal level of vitamin D intakes and this has led to a general view that vitamin D intakes might need to be increased above 1500 IU/day (Heaney, 2004) and possibly higher (Dawson-Hughes

et al., 2005) in order to achieve target plasma 25-OH-D levels greater than 40 ng/mL. However, many quasi-governmental agencies have yet to translate the latest recommendations for increase into new public health guidelines.

Osteoporosis

Although the etiology of this disease is complex and likely to be multifactorial (Seeman *et al.*, 1995; Nordin, 1997), there have been consistent claims that levels of 1α,25-$(OH)_2D_3$ are low in osteoporosis (Riggs and Melton, 1992; Eastell and Riggs, 2005). In addition, the recent debate over VDR genotypes correlating with bone mineral density (Morrison *et al.*, 1994; Whitfield *et al.*, 2000; Uitterlinden *et al.*, 2005) suggests some genetically inherited basis involving vitamin D exists leading to increased susceptibility to osteoporosis. As a consequence it is not surprising that clinical trials of 1α-OH-D_3 (Orimo *et al.*, 1987), 1α-OH-D_2 (Gallagher *et al.*, 1994), and 1α,25-$(OH)_2D_3$ (Gallagher *et al.*, 1989; Ott and Chestnut, 1989; Tilyard *et al.*, 1992) have been undertaken. Modest gains in bone mineral density and reductions in fracture rates are reported in many of these studies, and this subject has been reviewed by Seeman *et al.* (1995).

With the demonstration that ovariectomy results in enhanced production of osteoclastogenic cytokines such as interleukin-6, tumor necrosis factor (TNF), and interleukin-1 as well as cytokine-mediated osteoclast recruitment and increased bone resorption has come a clearer understanding of the molecular processes underlying postmenopausal osteoporosis (Manolagas and Jilka, 1995; Teitelbaum and Ross, 2003). Theories focusing on osteoblast/osteoclast communication led to the discovery of receptor activator of nuclear factor κB (RANK), its ligand RANKL, and the decoy receptor, osteoprotegerin, and how agents such as 1α,25-$(OH)_2D_3$ can influence osteoclastogenesis and bone resorption (Aubin and Bonnelye, 2000). Although 1α,25-$(OH)_2D_3$ treatment might be expected to exacerbate the excessive bone-resorptive component of osteoporosis, the vitamin D hormone also raises plasma Ca^{2+} levels and stimulates synthesis of bone matrix formation in osteoblasts. In fact, Raisz and coworkers (Hock *et al.*, 1986) have shown that pharmacological doses of 1α,25-$(OH)_2D_3$ administered to rats, in great excess over the doses used in osteoporosis, result in hypercalcemia and nephrocalcinosis that is accompanied by a hyperosteoid or undermineralized condition in the long bones.

Although small doses of vitamin D (800 to 1000 IU) have proven effective in treating vitamin D deficiency accompanying osteoporosis and even reduce fracture rates (Chapuy *et al.*, 1992), the use and effectiveness of active vitamin D metabolites in the treatment of osteoporosis are controversial. Nevertheless, the experience seems to have been that beneficial effects can be observed and bone loss reduced, but at the expense of occasional hypercalcemia. In North America, where dietary Ca intakes and absorption rates are higher, this has led to intolerable side effects and the discontinuation of the use of 1α,25-$(OH)_2D_3$ and 1α-OH-D_3 for the treatment of osteoporosis. In the United Kingdom, Australia, Italy, Japan, New Zealand, and 16 other countries in rest of the world, these drugs are approved or side effects tolerated. Nevertheless, some pharmaceutical companies have sought to develop "milder" but "longer-lived" calcitriol analogues for use in osteoporosis. ED-71 represents such an analogue, which by virtue of an A-ring substituent at C-2 and tighter-binding affinity to DBP has a longer $t_{1/2}$ in the plasma (Nishii *et al.*, 1993). ED-71 has performed well at restoring bone mass without causing hypercalcemia in long-term studies involving ovariectomized rats (Okano *et al.*, 1991) and in phase I and II clinical trials (Matsumoto and Kubodera, 2007). Another bone-specific analogue with potential for treatment of osteoporosis, 2-MD (Shevde *et al.*, 2002) is at a relatively early stage of development.

Renal Osteodystrophy

Chronic renal disease (CKD) is accompanied by the gradual loss of renal 25-OH-D_3-1α-hydroxylase (CYP27B1) activity over the five-stage natural history of the disease which culminates in dialysis (stage 5). As early as stage 2 of CKD, the 1α-hydroxylase declines leading to reduced plasma levels of 1α,25-$(OH)_2D_3$, which results in hypocalcemia and secondary hyperparathyroidism. Unchecked, these biochemical events, together with the other sequelae of renal failure such as phosphate retention, can result in renal osteodystrophy. Active vitamin D analogues, such as 1α-OH-D_3 and 1α,25-$(OH)_2D_3$, raise plasma Ca^{2+} concentrations and, in addition, lower PTH levels by direct suppression of PTH gene transcription at the level of the PTH gene promoter. Slatopolsky and colleagues (Delmez *et al.*, 1989) showed that intravenous infusion of "active" vitamin D preparations results in a more effective suppression of plasma PTH levels without such a profound increase in plasma [Ca^{2+}] in end-stage renal disease. Subsequent work has employed "low-calcemic" vitamin D analogues such as OCT or 19-nor-1α,25-$(OH)_2D_2$ as substitutes for the more calcemic natural hormone (Brown *et al.*, 1989; Slatopolsky *et al.*, 1995). More recently, the Food and Drug Administration (FDA) approved both oral and intravenous, 1α-OH-D_2 (trade name, Hectorol) for the treatment of secondary hyperparathyroidism at earlier stages 3 and 4 of the disease. In clinical trials, 1α-OH-D_2 effectively suppressed PTH in renal failure patients with very few incidences of hypercalcemia and hyperphosphatemia (Frazao *et al.*, 2000). Recently, oral formulations of 19-nor-1α,25-$(OH)_2D_2$ were also approved.

In 2003, a body of leading nephrologists released guidelines (KDOQI, 2003) recommending more aggressive use of vitamin D preparations and "active" vitamin D analogues in the treatment of secondary hyperparathyroidism in CKD. KDOQI guidelines suggested that treatment as early as

stage 3 [glomerular filtration rate (GFR) less than 60] might benefit the patient by limiting the extreme rises in plasma PTH levels and preventing the parathyroid gland resistance to vitamin D treatment often observed in end-stage renal disease (ESRD). KDOQI guidelines also recognized the high frequency of vitamin D deficiency (25-OH-D less than 10 ng/mL) and vitamin D insufficiency (25-OH-D 10 to 30 ng/mL) in the CKD and ESRD population (Gonzalez *et al*., 2004) and recommended an initial attempt at vitamin D repletion with escalating doses of vitamin D_2 prior to administration of "active" vitamin D analogue replacement therapy. Currently, both oral and intravenous formulations of various active vitamin D analogues are available for use in stage 3, 4, and 5 patients to take over, if and when vitamin D repletion fails to regulate PTH levels.

The emergence of the potential importance of the extrarenal 1α-hydroxylase in normal human physiology has led to a reevaluation of the vitamin D repletion and "active" hormone replacement arms of the CKD therapy (Jones, 2007). The value of the vitamin D repletion is now seen as providing the substrate 25-OH-D for both the renal 1α-hydroxylase, which is the main determinant of circulating 1α,25-$(OH)_2D_3$, and the extrarenal 1α-hydroxylase, which is postulated to augment 1α,25-$(OH)_2D_3$ synthesis for local or paracrine actions around the body. Although the decline of the renal enzyme during CKD is well established, the fate of the extrarenal 1α-hydroxylase in the face of uremia is largely a matter of conjecture. Evidence from anephric patients treated with large doses of 25-OH-D_3 (Dusso, *et al.,* 1988) suggests that the extrarenal enzyme survives in CKD patients, arguing that provision of a source of 25-OH-D to vitamin D-deficient and -insufficient patients throughout all stages of CKD is warranted. It also argues for the more judicious use of "active" vitamin D analogues as hormone replacement therapy layered on top of conventional vitamin D repletion therapy. Early attempts at this type of combined vitamin D/"active" vitamin D analogue approach in a pediatric population have resulted in a more efficient PTH control without many of the usual problems of soft-tissue calcification observed in patients treated only with active vitamin D analogues (Briese *et al*., 2006; Fournier *et al*., 2007).

Psoriasis and Cancer

The demonstration that 1α,25-$(OH)_2D_3$ is an antiproliferative, prodifferentiating agent for certain cell types *in vivo* and many cell lines *in vitro* suggested that vitamin D analogues might offer some relief in hyperproliferative disorders such as psoriasis and cancer. Early psoriasis trials with 1α,25-$(OH)_2D_3$ were moderately successful but plagued with hypercalcemic side effects. Modifications to the protocol included: (1) administration of calcitriol overnight when intestinal concentrations of $[Ca^{2+}]$ were low, (2) substitution of "low-calcemic" analogues for the calcitriol.

According to Holick (1995), oral calcitriol is an effective treatment for psoriasis when administered using an overnight protocol. However, by far the most popular treatment for psoriasis is the topical administration of the "low-calcemic" analogue calcipotriol, formulated as an ointment (Kragballe, 1992). When given orally, calcipotriol is ineffective because it is rapidly broken down (Binderup and Bramm, 1988). When given topically as an ointment, calcipotriol survives long enough to cause improvement in more than 75% of patients (Kragballe *et al.*, 1991). Both 1α,25-$(OH)_2D_3$ and calcipotriol are effective in psoriasis because they block hyperproliferation of keratinocytes, increase differentiation of keratinocytes, and help suppress local inflammatory factors through their immunomodulatory properties. Calcipotriol has now been marketed worldwide for use in psoriasis for more than 15 years. The success of calcipotriol has spawned the development of second-generation analogues.

Several hundreds of vitamin D analogues have been tested *in vitro* and *in vivo* with some degree of success in controlling the growth of tumor cells offering potential for use as anticancer drug therapies (reviewed extensively in Masuda and Jones, 2006). Many vitamin D compounds are extremely effective antiproliferative or pro-differentiation agents *in vitro* using a variety of mechanisms involving gene expression of cell division and pro-apototic genes to produce their effects. Preclinical studies in laboratory animals have also resulted in promising data (Masuda and Jones, 2006). For example, in mice inoculated with fulminant leukemia, moderate leukemia, or slowly progressive leukemia, the Roche compound 1α,25-$(OH)_2$-16-ene-23-yne-D_3 administered at 1.6 μg q.o.d. was significantly more effective than 0.1 μg q.o.d. 1α,25-$(OH)_2D_3$ at increasing survival time even though the 1α,25-$(OH)_2D_3$-treated group developed mild hypercalcemia and the analogue-treated animals remained normocalcemic (Zhou *et al.*, 1990). With the analogue EB1089, the promising antiproliferative effects observed *in vitro* and in the NMU-induced mammary tumor and in LNCaP prostate cancer xenograft models (Colston *et al.*, 2003; Blutt *et al.,* 2000) were also extended into the clinic. Early trials in limited numbers of breast cancer patients have been followed up with more extensive ongoing phase II and phase III clinical trials in a number of different cancers (Gulliford *et al.*, 1998; Evans *et al.*, 2002; Dalhoff *et al.,* 2003). Several other analogues have entered clinical trials for the treatment of a variety of hyperproliferative diseases, usually involving VDR-positive tumors (see Masuda and Jones, 2006). Many trials are still ongoing including the testing of BXL-628 (see Table III) in prostate-related diseases (Crescioli *et al*., 2003)

Despite the enormous promise of vitamin D analogues as anticancer agents, this has yet to result in an approved vitamin D analogue for use in any type of cancer (Masuda and Jones, 2006). The principal problem in anticancer studies involving orally administered vitamin D compounds is

hypercalcemia. Though the newer analogues appear to be less calcemic than calcitriol itself, they still retain some ability to raise serum calcium; they are not "noncalcemic" as is sometimes claimed. Another problem emerging from experience with clinical trials is that effective doses needed to retard cell growth (~1 n*M* or higher) cannot be attained *in vivo* because of low bioavailability (Beer *et al*., 2004; Trump *et al*., 2004). One of the principal determinants of tumor cell vitamin D analogue levels is the catabolic enzyme CYP24A1, which is upregulated in vitamin D-target cells, and limits the effective drug concentration reached. Another approach to effective vitamin D therapy in cancer patients is the potential use of CYP24-inhibitors (see Table IV). Nevertheless, it remains uncertain whether we will ever develop a vitamin D compound sufficiently devoid of calcemic activity while retaining sufficient antiproliferative activity to be valuable in cancer and also deliver it to target cells in appropriate concentrations

Immunosuppression

The immunosuppressive properties of 1α,25-$(OH)_2D_3$ and its analogues have been the subject of several excellent reviews (Bouillon *et al.*, 1995; Van Etten, 2000; Mathieu and Adorini, 2002). 1α,25-$(OH)_2D_3$ is believed to work by regulation of the expression of various cytokines, particularly those involved in suppressing inflammation and which raise the Th2/Th1 ratio. The hormone also stimulates the transcription of a natural bacterial peptide, cathelicidin, which kills *Mycobacterium tuberculosis* resulting in increased resistance to tuberculosis (Wang *et al.*, 2004; Holick, 2007). The spectrum of effects exhibited by 1α,25-$(OH)_2D_3$ and its analogues on the immune system results in beneficial effects on a wide variety of autoimmune diseases. Researchers have demonstrated the ability of calicitriol to suppress the onset of experimental encephalitis (Lemire and Clay, 1991) and type I diabetes in NOD mice (Mathieu *et al.*, 1995), and to work synergistically with cyclosporine to provide immunosuppression in transplantation medicine (Mathieu *et al.*, 1994a). This latter development has led to some optimism that coadministration of a vitamin D analogue with cyclosporin can reduce the dosage of the latter drug and minimize the serious side effects associated with its use. Several studies (Mathieu *et al.*, 1995, 1994b; Veyron *et al.*, 1993) have focused on the immunosuppressive effects of Leo drugs KH1060 and 20-epi-1α,25-$(OH)_2D_3$, both of which contain the 20-*S* side-chain configuration. Recent generations of compounds such as BXL-628, that contain multiple modifications found in the Leo Pharma drugs, are being tested in prostatitis, an inflammation of the prostate (Adorini, 2007). Again, it remains unclear whether analogues that show promise in immunological studies will prove to be effective immunomodulators in the clinic.

CRITERIA THAT INFLUENCE PHARMACOLOGICAL EFFECTS OF VITAMIN D COMPOUNDS

Activating Enzymes

It has been shown by using *in vitro* models that some vitamin D compounds lacking 1α-hydroxylation (e.g., 24(*R*),25-$(OH)_2D_3$) are capable of interacting with the vitamin D receptors (VDRs) and transactivating reporter genes but this occurs only at high concentrations of ligand (Uchida *et al.*, 1994). It seems unlikely that these concentrations will be reached *in vivo* except in hypervitaminosis D. Consequently, most of the compounds described in Tables I and II lack lack vitamin D biological activity *unless* they are activated *in vivo*. This is particularly the case for the parent vitamin D_3 itself, for its main circulating form 25-OH-D_3 or for any of the prodrugs listed in Table II. Vitamins D_2 and D_3 depend on both the liver 25-hydroxylase and kidney 1α-hydroxylase enzyme systems in order to be activated, whereas most prodrugs require only a single step of activation. Indeed, the 1α-OH-D drugs were designed to overcome the tightly regulated 1α-hydroxylase step that is easily damaged in chronic renal failure. In essence, prodrugs depend on the weakly regulated 25-hydroxylase step in the liver for activation. In recent years, the cytochrome P450 originally thought to be responsible for 25-hydroxylation of vitamin D_3, CYP27A1, has been cloned and shown to be a bifunctional polypeptide that executes both activation of vitamin D_3 and the 27-hydroxylation of cholesterol during bile acid biosynthesis (Okuda *et al.*, 1995). However, the CYP27A1 enzyme has a relatively low affinity for vitamin D, does not 25-hydroxylate vitamin D_2, and when mutated results in cerebrotendinous xanthomatosis not rickets. Consequently, another "physiologically relevant" 25-hydroxylase may exist and there are now several candidate P450s (Prosser and Jones, 2004), the main one being CYP2R1 (Cheng and Russell, 2003), a high-affinity microsomal enzyme with known human mutations that cause rickets, that has been recently shown to 25-hydroxylate the prodrug 1α-OH-D_2 (Jones *et al*., 2006). However, it is clear that the mitochondrial CYP27A1 efficiently 25-hydroxylates 1α-OH-D_3 to give 1*a*,25-$(OH)_2D_3$ (Guo *et al.*, 1993); and is present in a variety of tissues as well as the liver (e.g., kidney and bone). In fact, studies using cultured bone cells and even keratinocytes *in vitro* are able to demonstrate synthesis of 1α,25-$(OH)_2D_3$ from 1α-OH-D_3 (Ichikawa *et al.*, 1995; Jones *et al.*, 1999a) or 1α,24-$(OH)_2D_2$ from 1α-OH-D_2 (Masuda *et al.*, 2006). If these findings can be extrapolated to the *in vivo* situation, the implications of this work are that in CYP27A1, vitamin D target cells may have some ability to synthesize the active form from a prodrug *without* the need for the hormone to enter the bloodstream.

The ability of extrarenal tissues to 1α-hydroxylate various 25-hydroxylated metabolites and analogues has

always been a controversial story. However, it was widely accepted that extrarenal 1α-hydroxylase activity is associated with certain granulomatous conditions (e.g., sarcoidosis) (Adams and Gacad, 1985). Currently, there is little information for why the enzyme is overexpressed in sarcoidosis. In these patients, 25-OH-D can be converted to 1α,25-$(OH)_2$D, a step that, unlike the renal case, is not subject to tight regulation and thus potentially more likely to result in hypercalcemia. Exposure of such patients to sunlight or administration of 25-OH-D can result in excessive plasma levels of 1α,25-$(OH)_2$D. The cloning of the cytochrome P450 representing the 1α-hydroxylase (officially named CYP27B1) (St. Arnaud *et al.*, 1997; Takeyama *et al.*, 1997) has been followed by confirmation that the cytochrome can be expressed extrarenally in skin and lung cancer cells (Fu *et al.*, 1997; Jones *et al.*, 1999b). This has extended over the past decade with further studies of CYP27B1 mRNA levels using real-time PCR and specific anti-CYP27B1 antibodies (Hewison and Adams, 2005) to show the widespread distribution of this enzyme in many normal tissues as well as pathological situations.

As alluded to earlier, the concept of the extrarenal 1α-hydroxylase suggests that this enzyme plays an important physiological as well as pathological role (Jones, 2007) and this has in turn raised the level of importance given to ensuring maintenance of adequate 25-OH-D levels by vitamin D or direct 25-OH-D_3 supplementation rather than just by calcitriol hormone replacement.

Most of the calcitriol analogues listed in Table III are thought to be active as such, not requiring any step of activation prior to their action on the transcriptional machinery or in nongenomic pathways. It remains a theoretical possibility, though, that the biological activity of one of these parent analogues could be altered by enzyme systems *in vivo*, either by the generation of a more potent metabolite or by giving rise to a less active but more long-lived catabolite.

Vitamin D-Binding Protein

The vitamin D-binding protein (DBP) serves several functions including providing transport for a lipid-soluble vitamin D analogue. Most of the analogues of calcitriol, designed to date, contain modifications to the side chain and this is usually detrimental to binding to DBP. Several analogues, for example, calcipotriol or OCT, have very weak affinities for DBP, reduced by two to three orders of magnitude relative to 1α,25-$(OH)_2D_3$. This property has important implications for metabolic clearance rates, delivery to target cells, and tissue distribution (Bouillon *et al.*, 1991; Kissmeyer *et al.*, 1995). Detailed studies with one analogue, OCT, have shown it to bind primarily to β-lipoprotein and exhibit an abnormal tissue distribution *in vivo*, with abnormally high concentrations (ng/g tissue) in the parathyroid gland (Tsugawa *et al.*, 1991). It was thus proposed that this unusual distribution may make OCT a useful systemically administered drug with a selective advantage in the treatment of hyperparathyroidism.

Another vitamin D analogue with a modified side chain is 20-epi-1α,25-$(OH)_2D_3$, where the 20-*S* configuration of the side chain is opposite to the normal 20-*R* configuration. The DBP binding affinity of this analogue is virtually unmeasurable because it does not displace [^{3}H]25-OH-D_3 from the plasma-binding protein (Dilworth *et al.*, 1994). Confirmation that this is indeed the case comes from GH-reporter gene transactivation assays where 20-epi-1α,25-$(OH)_2D_3$ transactivates equally well in COS cells incubated in the presence and absence of fetal calf serum (as a source of DBP). On the other hand, 1α,25-$(OH)_2D_3$-induced GH reporter gene expression is sensitive to DBP in the external growth medium, requiring 2-fold less hormone in the absence of DBP as in its presence (Dilworth *et al.*, 1994). It therefore appears that analogues that bind DBP less well than 1α,25-$(OH)_2D_3$ derive a target cell advantage over the natural hormone, *if they are able to find alternative plasma carrier proteins to transport them to their target cells.* However, these same alternative plasma carriers presumably result in changes in the tissue distribution and hepatic clearance of analogues over the natural metabolites of vitamin D. The recent development of a DBP-knockout mouse (Safadi *et al.*, 1999) suggests that 25-OH-D_3 clearance is more rapid in the absence of DBP. The availability of the model permits the study of alternate vitamin D analogue transport mechanisms in an *in vivo* setting.

Vitamin D Receptor/RXR/VDRE Interactions

Previous chapters in this book have established that 1α,25-$(OH)_2D_3$ is able to work through a VDR-mediated genomic mechanism to stimulate transcriptional activity at vitamin D-dependent genes. Considerable progress has been made recently toward delineating the precise conformational changes that take place when the natural ligand binds to the VDR (Wurtz *et al.*, 1997; Rochel *et al.*, 2001); and the nature of the postligand binding transcriptional events that occur, particularly the nature of the coactivator proteins involved (Rachez and Freedman *et al.*, 2000; Kato *et al.*, 2000). These developments have improved our thinking about how and where analogues might act differently from 1α,25-$(OH)_2D_3$ in the transcriptional cascade. Whether 1α,25-$(OH)_2D_3$ works through other non-VDR-mediated mechanisms to produce physiologically relevant effects is a question that currently remains unproven, but this question is also important to our understanding of the pharmacological effects of vitamin D analogues.

Much evidence exists to support the viewpoint that vitamin D analogues mimic 1α,25-$(OH)_2D_3$ and use a genomic mechanism. The first clue that vitamin D analogues can

work through a VDR-mediated transcriptional mechanism came 25 years ago from the bone resorption studies reported by Stern in her classic review "Monolog on Analogs"(1981). Stern showed that there exists a strong correlation between chick intestinal VDR binding of an analogue and its potency in a [^{45}Ca] rat bone resorption assay. This suggests that a vitamin D analogue is only as good as its affinity for the VDR. Over the past 25 years since Stern's article, there have been many claims that VDR-binding affinity is not the only factor in determining biological activity of a given analogue but also that VDR-binding affinity is not even the major factor, transactivation activity stemming from a series of parameters such as conformation of the ligand/VDR complex, binding of the RXR partner, stability of the VDR/RXR/ligand complex, or even the nature of the coactivator proteins recruited to the complex. Examples of these apparent discrepancies between VDR affinity and biological activity will be provided later but it should be pointed out that some of these discrepancies are almost certainly explained by other considerations such as DBP binding or pharmacokinetics. Preliminary results with the analogues KH1060, EB1089, and 20-epi-1α,25-$(OH)_2D_3$ (Binderup *et al.*, 1991) suggested that they might be active in immunoregulatory roles at concentrations orders of magnitude below their affinities for the VDR (e.g., at as low as 10^{-15} *M* for KH1060, whereas it binds VDR at $10^{-11}M$). More recent results (Yang and Freedman, 1999; Dilworth *et al.*, 1994, 1997) suggest that 20-epi compounds including KH1060 are consistently only one to two orders of magnitude more potent than 1α,25-$(OH)_2D_3$ in gene transactivation assays and in differentiation assays, a difference that could be explained by fine-tuning the transcriptional model of analogue action (e.g., by including pharmacokinetic considerations) rather than discarding the genomic hypothesis altogether. The majority of researchers are keeping an open mind on this subject and are searching for differences in the newly delineated transcriptional machinery that might explain qualitative and quantitative differences between 1α,25-$(OH)_2D_3$ and its analogues.

Over the past decade it has been clearly established that the liganded VDR functions transcriptionally as a vitamin D-VDR-RXR heterodimer (Macdonald *et al.*, 1993; reviewed in Haussler *et al.*, 1998) and not as a VDR-VDR homodimer (Carlberg, 1995). The role of the RXR ligand is still controversial, many studies suggesting that pan RAR and RXR ligands such as 9-*cis*-retinoic acid inhibit VDR-RXR heterodimer formation, whereas other studies demonstrate the synergistic effects of pure RXR ligands (so-called rexinoids) and 1α,25-$(OH)_2D_3$ on VDR-RXR-driven transcription at a CYP24-VDRE (Zou *et al.*, 1997). Whether vitamin D analogues might differ from 1α,25-$(OH)_2D_3$ and act transcriptionally through VDR-VDR homodimers or other VDR-nuclear transcription factor heterodimers are ideas that have been considered as theoretical possibilities, and in some cases even shown to occur weakly *in vitro*, but largely dismissed as occurring *in vivo*.

Adding to the complexity of the target cell action of 1α,25-$(OH)_2D_3$, and thus that of vitamin D analogues, is the type and context of the VDRE involved (Haussler *et al.*, 1998). One possibility is that vitamin D analogues could show selectivity for certain genes based on the type of VDRE within their promoter. Morrison and Eisman (1991) showed that a noncalcemic analogue such as calcipotriol is easily capable of transactivating a calcemic VDRE such as the human osteocalcin promoter-VDRE placed in front of the CAT reporter gene and stably transfected into ROS 17/2 cells provided that it can get into the target cell. One interpretation of this experiment is that a noncalcemic analogue with good VDR affinity is just as calcemic as 1α,25-$(OH)_2D_3$ if it can be delivered to the target cell. Another idea put forward by Morrison and Eisman (1991) is that noncalcemic analogues may be capable of stimulating both cell-differentiating and calcemic genes but that the former genes require only a short pulse of analogue to effect a switch in the cell cycle, whereas the latter genes require a sustained concentration of the vitamin D ligand. The concentration of 1α,25-$(OH)_2D_3$ may be sustained *in vivo* by renal synthesis and some protection by DBP, whereas systemically administered noncalcemic analogues reach a high initial concentration but do not bind DBP and are rapidly metabolized and cleared. This hypothesis remains to be adequately tested.

Carlberg *et al.* (1994) has also tested the idea that other vitamin D analogues (EB1089 and KH1060) might favor one specific VDRE using the mouse osteopontin gene VDRE (DR3-type) and the same human osteocalcin VDRE that Morrison and Eisman used. Carlberg *et al.* (1994) found that 1α,25-$(OH)_2D_3$ and the two analogues are unable to differentiate between the two different types of VDRE. Though many VDREs have been postulated in the literature, the direct repeat-3 spacer type (DR3) of VDRE seems to be the sequence that is gaining widespread acceptance as the most physiologically relevant (Haussler *et al.*, 1998; Jones *et al.*, 1998). Whether other more exotic DR4, DR6, or inverted palindrome (IP9) nucleotide sequences are recognized by the analogue-VDR/RXR complex *in vivo* still remains unclear (Carlberg, 1995). Even with the DR-3 type of VDRE, the gene and cell context seems to be important in determining the transactivation produced by the vitamin D analogue. The work of Williams' laboratory (Brown *et al.*, 1994; Williams *et al.*, 1995; Kane *et al.*, 1996) suggests that 1α,25-$(OH)_2D_3$, KH1060, and EB1089 show different patterns of gene activation in bone marrow, osteoblastic cells (ROS17/2, ROS25/1, and UMR106), and intestine (HT29 and CaCo-2) that appear to be gene and cell-specific. Part of the explanation for gene- and tissue-specific effects probably lies in the influence of neighboring response elements to the VDRE and the binding of tissue-specific transcription factors at these sites. More recent work (Lin *et al.*, 2002) using expression profiling (gene array) to investigate the differences in gene expression exhibited by squamous

carcinoma cells (SCC25) in response to EB1089 and 1α,25-$(OH)_2D_3$ concluded that the two agents did not have qualitatively different effects. In fact, the differences in gene expression between EB1089 and 1α,25-$(OH)_2D_3$ were the result of potency differences and nullified by coadministration of a general P450 inhibitor such as ketoconazole, implying that they were the result of excessive metabolism of 1α,25-$(OH)_2D_3$. On the other hand, the laboratories of Lian and Stein have elegantly demonstrated (Guo *et al.*, 1997) that the response to 1α,25-$(OH)_2D_3$-VDR-RXR complex to the gene promoter of the osteocalcin gene in osteoblasts depends on occupancy of an adjoining YY1-binding site that allows for temporal changes in responsiveness to 1α,25-$(OH)_2D_3$. Though this work explains why 1α,25-$(OH)_2D_3$ might have gene- and tissue-specific effects, it does not explain the analogue-specific differences in Williams' work, whereas the work of Lin *et al*. suggests that there are differences of potency not selectivity.

As alluded to earlier, the emergence of important new information about (1) the structure of the ligand-binding domain of the VDR and (2) coactivator characterization and involvement in the 1α,25-$(OH)_2D_3$-VDR-RXR transcriptional machinery have opened up additional possibilities about where vitamin D analogues might differ in their action from the natural ligand. Evidence suggests that the "Trap Door Hypothesis" for retinoid binding to RAR/RXR (Renaud *et al.*, 1995) also applies to 1α,25-$(OH)_2D_3$ binding to VDR. In this model, 1α,25-$(OH)_2D_3$ binding to a central binding pocket triggers a dramatic conformational change of helix 12, a domain close to the C terminus of the VDR, such that it moves from a position on the exterior of the VDR to one within the interior of the receptor, thereby closing the access channel to the ligand-binding pocket. In the process, amino acid residues of the AF-2 domain that are hidden in the unliganded VDR become exposed in the liganded VDR and are now available to interact with coactivator proteins. The recruitment of coactivators to the 1α,25-$(OH)_2D_3$-VDR-RXR subsequently leads to the recruitment of other transcription factors which result in chromatin remodeling and gene transcription (Whitfield *et al.,* 2005).

In the execution of this work, members of Moras' laboratory have modeled the ligand-binding pocket of VDR and shown it to be able to accommodate with ease several other analogues depicted in Table III (Rochel *et al.*, 2001). Though many of the active vitamin D analogues, especially the 20-epi analogues, have bulky side-chain substituents or radically different side-chain orientations (Yamamoto *et al.*, 1999), the pocket appears to have a great reserve capacity for binding (Rochel *et al.*, 2001). As a result, from modeling alone it is difficult to forecast radical changes in VDR conformations as a result of binding to these different analogues. Nevertheless, there is some indirect evidence, most notably from experiments measuring susceptibility to protease digestion, that subtle differences do occur in VDR-RXR-containing transcription complexes when different ligands are used (Peleg *et al.*, 1995; Carlberg *et al.*, 1995; Van den Bemd *et al.*, 1996). Binding of 20-epi-analogues (e.g., MC1288 and KH1060) to the VDR results in increased resistance to protease digestion compared with 1α,25-$(OH)_2D_3$, which has been interpreted as evidence for differences in accessibility of protease to cleavage sites (Peleg *et al.*, 1995). Interestingly, there appears to be a direct correlation between transactivation activity of an analogue and the resistance of the VDR-transactivation complex to protease, a relationship that applies to different analogues and even to metabolites from a single analogue (Peleg *et al.*, 1995; Liu *et al.*, 1997; Van den Bemd *et al.*, 2000). Because the rearrangement in helix 12 of the VDR brings about exposure of the AF-2 domain and this is critical to coactivator binding, it might be expected that subtle conformational differences in VDR observed for different vitamin D analogues might also be reflected in differences in coactivator recruitment.

Consequently, several groups have looked for qualitative differences in the pattern of coactivators recruited or quantitative differences in the strength of RXR heterodimerization or coactivator binding following ligand binding. Liu *et al.*, (2001) used a series of AF-2 domain mutants to reach the conclusion that the conformational changes occurring in the VDR upon hormone or 20-epi-1α,25-$(OH)_2D_3$ binding have a bigger impact on RXR-heterodimerization than on coactivator recruitment. This is in complete contrast to the work of Freedman and coworkers, who have shown repeatedly (Cheskis *et al.*, 1995; Yang and Freedman, 1999) that analogue binding [20-epi-1α,25-$(OH)_2D_3$ or 1α,25-$(OH)_2$-16-ene, 23-yneD_3] to VDR results in no difference in RXR-heterodimerization compared with binding of 1α,25-$(OH)_2D_3$. Instead, Freedman's group reports that the ability of a various analogues to transactivate vitamin D-dependent genes or to stimulate differentiation of cells is best correlated with their ability to recruit the coactivator, DRIP-205, one of the many components of the DRIP complex isolated by Freedman's group (Rachez *et al.*, 1999; Freedman and Reszka, 2005). Among the other coactivators/transcription factors implicated in vitamin D analogue action is GRIP-1 (TIF-2), which has been purported to have a particular propensity to interact with the analogue OCT (Takeyama *et al.*, 1999). In another study by Issa *et al.* (2002), a broad panel of vitamin D analogues showed that GRIP-1 was more consistently recruited at levels closer to that of 1α,25-$(OH)_2D_3$ than was another coactivator AIB-1. Work by Peleg *et al.* (2003) offers an insight into the purported bone tissue selectivity of the Roche analogue Ro 26-9228 (see Table III, renamed BXL-628) which recruits GRIP-1 in osteoblasts but not CaCo-2 colon cancer cells; though these authors may now need to explain why BXL-628 is now being pursued clinically in prostatic diseases rather than osteoporosis as was originally attempted. Thus, it appears that there is a fairly strong basis for the hypothesis that differences in the biopotency advantage of certain vitamin D analogues over 1α,25-$(OH)_2D_3$ are caused in part by

changes in the recruitment of dimerization partner and/or coactivators, but there is no clear consensus on which of these coactivator proteins is the important one or if these different coactivators can explain tissue/cell selectivity.

Target Cell Catabolic Enzymes

In recent years, much evidence has accumulated to support the hypothesis that 1α,25-$(OH)_2D_3$ is subject to target cell catabolism and side-chain cleavage to calcitroic acid via a 24-oxidation pathway (Makin *et al.*, 1989). The cloning of CYP24, the cytochrome P450 involved, has confirmed that it is vitamin D-inducible because its gene promoter contains a VDRE, carries out multiple steps in the side-chain modification process, and is present in many (if not all) vitamin D-target cells (Akiyoshi-Shibata *et al.*, 1994; Prosser and Jones, 2004). We have postulated that the purpose of this catabolic pathway is to desensitize the target cell to continuing hormonal stimulation by 1α,25-$(OH)_2D_3$ (Lohnes and Jones, 1992). Recently, support for this hypothesis has emerged when St. Arnaud's group engineered a CYP24-knockout mouse that exhibits 50% lethality at weaning, death resulting from hypercalcemia and nephrocalcinosis (St. Arnaud, 1999). Surviving mice show an inability to rapidly clear a bolus dose of 1α,25-$(OH)_2D_3$ from the bloodstream and tissues (Masuda *et al.*, 2005) and a metabolic bone disease reminiscent of the excessive osteoid bone pathology observed in rodents given excessive amounts of 1α,25-$(OH)_2D_3$ (Hock *et al.*, 1986). Recent work with this model has shown that the bone defect is probably caused by excessive 1α,25-$(OH)_2D_3$ levels because crossing the CYP24-knockout mouse with the VDR-knockout mouse results in a phenotype without the bone defect (St. Arnaud *et al.*, 2000). Given the demonstrated importance of CYP24 to 1α,25-$(OH)_2D_3$ clearance, one must ask the question of whether vitamin D analogues might be subject to the same catabolic processes that determine their pharmacokinetics? If not, what other drug-catabolizing systems are present within vitamin D-target cells to inactivate the vitamin D analogue?

Certainly there are vitamin D analogues such as calcipotriol, OCT, EB1089, and KH1060 that are metabolized by vitamin D-target cells to clearly defined and unique metabolites (Masuda *et al.*, 1994, 1996; Shankar *et al.*, 1997; Dilworth *et al.*, 1997), which resemble products of the 24-oxidation pathway for 1α,25-$(OH)_2D_3$ or which are unique to the particular analogue. Furthermore, some of these metabolites are products only of vitamin D target cells and are D-inducible, implying that CYP24 is involved in their formation, and this has been confirmed with some analogues such as calcipotriol (Jones *et al.*, 2006). Moreover, in the case of several analogues blocked at C-24 and subject to metabolism elsewhere on the side chain, the direct involvement of CYP24 is strongly implicated or proven. Examples where CYP 24 involvement is strongly suspected include 23-hydroxylation of 26,27-hexafluro-1α,25-$(OH)_2D_3$ (Sasaki *et al.*, 1995); 26-hydroxylation of 24-difluro-1α, 25-$(OH)_2D_3$ (Miyamoto *et al.*, 1997); 26-hydroxylation of 1α,25-$(OH)_2$-16ene-23yne-D_3 (Satchell and Norman, 1995); and 26- and 28-hydroxylation of 1α, 25-$(OH)_2D_2$ (Rao *et al.*, 1999; Shankar *et al.*, 2001). Because many of these same products are observed *in vitro* and *in vivo* and because pharmacokinetic parameters often parallel target cell metabolic parameters (Kissmeyer *et al.*, 1995; Jones, 1997), one concludes that target cell metabolism of vitamin D analogues must contribute to the pharmacokinetics and biological activity observed *in vitro* and *in vivo*. In fact, there is little doubt that the poor performance of some promising vitamin D analogues during *in vivo* testing is because of their poor metabolic stability. Accordingly, greater attention to the metabolic potential of *in vitro* testing systems and/or greater use of defined target cell (and hepatic) metabolic systems is warranted.

One factor regarding target cell metabolism considered in recent years is the possibility that vitamin D analogues might be *activated* rather than *catabolized* by the same enzymes (Siu-Caldera *et al.*, 1999; Swami *et al.*, 2003). Although this is potentially more important for prodrugs (see Table II), the generation of large numbers of metabolites from such analogues as KH1060 (Dilworth *et al.*, 1997) or the formation of long-lived metabolites such as 26,27-hexafluro-1α,23,25-$(OH)_3D_3$ from 26,27-hexafluro-1α,25-$(OH)_2D_3$ (Sasaki *et al.*, 1995) complicates the picture. In most cases, however, this issue can be resolved on pharmacokinetic grounds.

Other Factors

Hepatic Clearance of Vitamin D Analogues

The poor DBP-binding properties of many side-chain modified calcitriol analogues open up the possibility of alternative plasma carriers and accelerated degradation. The liver plays a major role in such metabolic clearance and a small number of detailed studies performed to date have included *in vitro* incubation with liver preparations. Calcipotriol (Sorensen *et al.*, 1990), OCT (Masuda *et al.*, 1996), EB1089 (Kissmeyer *et al.*, 1997), and KH1060 (Rastrup-Andersen *et al.*, 1992) are all subject to metabolism by liver enzymes. One such liver enzyme capable of 23- and 24-hydroxylation of 1α,25-$(OH)_2D_3$, and possibly some of its analogues, is the abundant general cytochrome P450, CYP3A4 (Xu *et al.*, 2006). Indeed, this enzyme is upregulated by 1α,25-$(OH)_2D_3$ in duodenum suggesting that a physiologically relevant loop exists (Thummel *et al.*, 2001). Because, over the years, there have been frequent reports of drug-induced osteomalacia associated with coincidental use of anticonvulsants (e.g., diphenylhydantoin) or barbiturates and vitamin D preparations (e.g., Onodera *et al.*, 2002), the direct association between CYP3A4 and 1α,25-$(OH)_2D_3$ is potentially important to explain the putative accelerated clearance of vitamin D metabolites (Gascon-Barre *et al.*, 1984).

These cytochrome P450 enzymes give rise to intermediate polarity molecules or truncated metabolites, which can be further glucuronidated and excreted in bile (e.g., OCT; Kobayashi *et al.*, 1991). A recent study has defined UGT1A3 as the isoform of UDP-gluronosyltransferase involved in glucuronidation of the 23-hydroxylated metabolite of the analogue 26,27-F_6-1α,25-$(OH)_2D_3$ (Kasai *et al.*, 2005), whereas UG1A4 appears to be the isoform involved in conjugation of 1α,25-$(OH)_2D_3$ (Hashizume *et al.*, 2008).

Few, if any, studies have separately considered the *rate* of catabolism or glucuronidation relative to 1α,25-$(OH)_2D_3$. However, data are available comparing the *in vivo* rate of metabolic clearance of vitamin D analogues with 1α,25-$(OH)_2D_3$, though inevitably this probably measures a few *in vitro* parameters, such as the rate of both hepatic and target cell metabolism, in addition to the affinity of DBP binding within a single *in vivo* parameter. Thus, in lieu of detailed *in vitro* metabolic analyses, the $t_{1/2}$ of the vitamin D analogue is a useful term for indicating the general survival of the vitamin D drug *in vivo*. Data for this parameter have been published for some of the most interesting analogues (Kissmeyer *et al.*, 1995).

Nongenomic Actions of Vitamin D Analogues

The nongenomic actions of 1α,25-$(OH)_2D_3$ have been reviewed elsewhere (Norman *et al.*, 1992; Bouillon *et al.*, 1995) and were described in detail in Chapter 35 and will not be repeated here. One analogue purported to discriminate between genomic and nongenomic actions is 1β,25-$(OH)_2D_3$, the epimeric form of 1α,25-$(OH)_2D_3$, which is an antagonist of nongenomic but not genomic actions (Bouillon *et al.*, 1995). The membrane VDR initially described by Nemere *et al.* (1994) and identified as annexin II (Baran *et al.*, 2000) may be involved in mediating putative nongenomic effects. It will be interesting to see whether an annexin-II knockout mouse will possess a distinct phenotype that will aid in delineating the nongenomic actions of vitamin D in the same way that the VDR-knockout mouse has aided our understanding of the genomic actions. In recent years, further attempts to purify and identify the putative membrane receptor have resulted in a newly-named membrane-associated response system (MARRS) in chick intestinal cells (Rohe *et al.*, 2005) that may explain rapid nongenomic actions (Norman, 2005).

But at this point in time, little work has been performed on the specificity of the vitamin D-binding site of membrane VDR/annexin II or MARRS complex and thus the possibility that the nongenomic actions/membrane VDR might explain vitamin D analogue actions seems premature.

PROPOSED MOLECULAR MECHANISMS OF ACTION OF VITAMIN D COMPOUNDS

Building on the data acquired from a variety of *in vitro* tests performed over the past 20 years and described briefly in the previous section of this chapter, one is able to identify those criteria that are important to vitamin D analogue action. This in turn allows us to put forward a model for how vitamin D analogues may work *in vivo*. This is depicted in Figure 1. As a general model, it allows for consideration of both prodrugs (those requiring 25-hydroxylation by CYP27A1 or CYP2R1; those requiring 1α-hydroxylation by the kidney or extrarenal 1α-hydroxylase) and 1α,25-$(OH)_2D_3$ analogues. This model therefore makes a distinction between those target cells that express an extrarenal 1α-hydroxylase (CYP27B1) and therefore have the ability to make and respond to their own "local" 1α,25-$(OH)_2D_3$ and those that simply respond to circulating hormonal 1α,25-$(OH)_2D_3$ through their VDR with altered transcription. This model features a conventional VDR-RXR heterodimer working through a DR-3 type VDRE in most genes. Crucial characteristics for each new analogue (all measurable *in vitro*) are in our opinion:

1. affinity for DBP,
2. affinity for VDR,
3. ability to recruit RXR and coactivators followed by transactivation of genes,
4. rate of target cell metabolism (reflected partly in pharmacokinetic measurements), and
5. rate of hepatic clearance (reflected partly in pharmacokinetic measurements).

All parameters contribute significantly to the overall biological activity. Target cell distribution differences might be expected for those analogues that do not bind DBP and this model does not explain the differences observed at different genes within the same or different cells.

However, it might be useful to outline broad expectations for a new compound. Based on this model one would predict that those analogues that have good VDR binding affinity but slow rates of target cell metabolism owing to side-chain blocks, such as strategically placed fluorine atoms or double bonds, might be more active than 1α,25-$(OH)_2D_3$ *in vitro* and perhaps also *in vivo*. Hexa-fluoro-1α,25-$(OH)_2D_3$ and EB1089 are such compounds; looking alike *in vitro* and differing *in vivo* owing to differences in DBP binding and metabolism. On the other hand, a compound such as calcipotriol binds VDR moderately well but is rapidly metabolized in both the liver and the vitamin D target cell; is very active *in vitro* or when applied to the skin topically; but is inactive when administered orally and is forced to enter the bloodstream and pass the liver to get to its target site. It remains to be seen if this general model can be applied to all vitamin D analogues (e.g., the 20-epi- superanalogues such as KH1060, which has a very complex metabolic picture but very high biological activity *in vitro*) or must be adapted.

FUTURE PROSPECTS

A number of researchers remain optimistic that the unraveling of the genomic (or nongenomic) mechanism of action

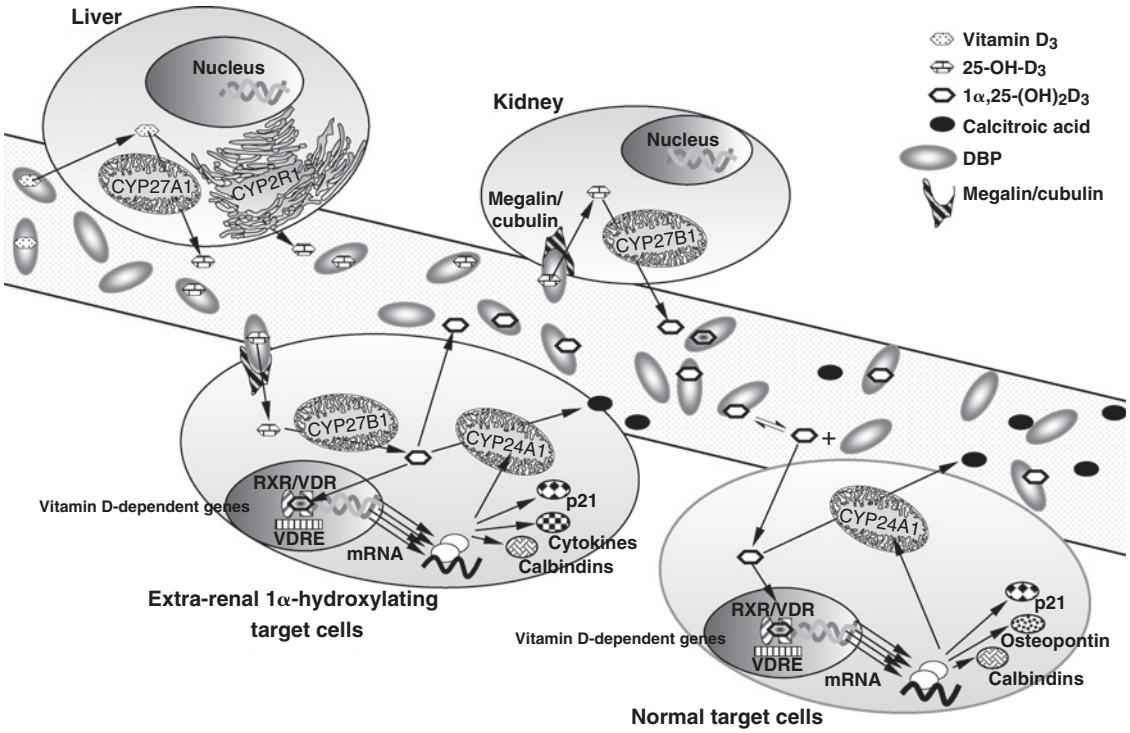

FIGURE 1 Current concepts of the activation, mechanism of action, and catabolism of vitamin D. The model incorporates a plasma-binding protein (DBP) that acts as a carrier of vitamin D metabolites and analogues; activating enzymes (CYPs) involved in activation of vitamin D or prodrug; target cell transcriptional machinery (VDR, RXR, coactivators) involved in biological actions of $1\alpha,25\text{-}(OH)_2D_3$ or its analogues; and target cell catabolic enzyme system (CYP24A1) involved in degradation of $1\alpha,25\text{-}(OH)_2D_3$ or its analogue. The figure shows the metabolism of vitamin D in the context of the cells involved. Clockwise: (*Top Left*) *Hepatocyte* showing some of the candidate cytochrome P450s shown to 25-hydroxylate vitamin D and its prodrugs; note that VDR is believed to be absent from liver cells. (*Top Middle*) *Proximal Tubular Cell* showing the key elements in the uptake of 25-OH-D_3 and its conversion to $1\alpha,25\text{-}(OH)_2D_3$. Megalin/cubulin are cell surface receptors that execute endocytosis of the DBP/25-OH-D_3 complex, whereas CYP27B1 is the main component of the 1α-hydroxylase, responsible for synthesis of circulating $1\alpha,25\text{-}(OH)_2D_3$. (*Lower Right*) *Conventional Target Cell* that lacks megalin/cubulin and takes up only the free ligand, $1\alpha,25\text{-}(OH)_2D_3$, but not the DBP originally involved in transporting the ligand to the target cell. The key elements of the transcriptional machinery are shown, including VDR/RXR as well as representative gene products such as cell division protein p21, the bone matrix protein osteopontin, the calcium transport protein calbindin, and the autoregulatory protein CYP24A1. The role of the highly inducible CYP24A1 is to convert the hormone (or analogue) into inactive degradation products, such as calcitroic acid, which enter plasma and are excreted in bile. (*Lower Left*) *Target Cell that expresses extrarenal 1α-hydroxylase* (*CYP27B1*) and the megalin/cubulin machinery to take up 25-OH-D_3, and thus is capable of making $1\alpha,25\text{-}(OH)_2D_3$ locally. The cell can also respond in a likewise manner to the conventional target cell because it also possesses the VDR and other transcriptional machinery. The expectation is that cells involved in cell differentiation or controlling cell division require higher concentrations of $1\alpha,25\text{-}(OH)_2D_3$ in order to modulate a different set of genes, and the CYP27B1 boosts local production to augment that *circulating* $1\alpha,25\text{-}(OH)_2D_3$ arriving from the kidney in the bloodstream. Under normal physiological processes, locally produced $1\alpha,25\text{-}(OH)_2D_3$ would not enter the general circulation, though in pathological conditions (e.g., sarcoidosis) this could occur. At this time, it is not clear how many cell types can be considered simple target cells and how many possess the CYP27B1 and megalin/cubulin to allow for local production of hormone.

of $1\alpha,25\ (OH)_2D_3$ will reveal new approaches by which the vitamin D signaling cascade can be exploited. Certainly, the significant progress made in characterizing the coactivator proteins and the rest of the transcriptional apparatus will continue. One is able to predict fairly confidently from success in related steroid hormone fields that a fully functional vitamin D-dependent *in vitro* reconstituted VDR-RXR transcriptional system, devoid of the complications of metabolic enzymes, will be the perfect model to test the transactivation activity of future vitamin D analogues. It seems likely that this approach will allow us to dissect out the exact features that give certain analogues a transcriptional advantage to provide increased potency and/or selectivity over $1\alpha,25\text{-}(OH)_2D_3$.

Studies of the vitamin D-binding pockets of VDR, DBP, and the three (or more) vitamin D-related cytochrome P450s will continue to be a major goal now that all these specific proteins have been cloned, overexpressed, and crystallized. Although the ligand-binding domains of the nuclear receptors have been studied, the full-length proteins are beyond the current limits of NMR or x-ray crystallography. It is also likely that technical problems with these procedures will be overcome shortly and the full-length proteins can be tackled. The initial work of the Moras group (Rochel *et al.*, 2001) on the ligand-binding domain of the VDR will be extended to new analogues and there will also be a growing focus on the other major proteins in the vitamin D signal transduction pathway.

The wide availability of recombinant proteins for hundreds of cytochromes P450 from species across the phylogenetic tree, including 58 CYPs in the human genome, has allowed for the elucidation of some crystal structures and also modeling studies of the enzymes involved in vitamin D metabolism (Prosser *et al*., 2006; Hamamoto *et al*., 2006; Masuda *et al.,* 2007). Current models are starting to reveal key substrate side-chain contact residues (e.g., Ala326 within CYP24A1) associated with hydroxylation (Prosser *et al*., 2007). The membrane-associated region of cytochromes P450 has posed problems for expression and crystallization but enormous strides have been made based on models built with x-ray data from soluble prokaryotic isoforms and with truncated mammalian isoforms such as CYP2C5 (Williams *et al.*, 2000) and the first crystal structures of vitamin D-related CYPs e.g., CYP2R1 are now emerging (Strushkevich *et al*., 2008).

Access to full-length CYP241 and CYP27B1 has also permitted a more efficient search for potential inhibitors. Such specific inhibitors of CYP241 and CYP27B1 (Schuster *et al.*, 2001, 2003; Muralidharan *et al.*, 1997; Posner *et al.*, 2004) may be of value in blocking 1α,25-$(OH)_2D_3$ catabolism or synthesis in certain clinical conditions where excessive breakdown is suspected. In general, modeling of VDR and cytochromes P450 is expected to lead to more rational vitamin D analogue design to take advantage of structural idiosyncrasies of all of these key proteins. Meanwhile, the not-so-rational synthesis of new analogues is likely to continue.

The list of applications for vitamin D compounds continues to increase (reviewed in Jones *et al.*, 1998; Holick, 2007; Jones, 2007). These applications have been further rationalized with the availability of VDR knockout mice to demonstrate vitamin D-dependent processes (Yoshizawa *et al.*, 1997; Li *et al.*, 1997). Elucidation of the mechanism by which 1α,25-$(OH)_2D_3$ and its analogues regulate the cell cycle and proliferation remains an important priority of the field. Current applications of vitamin D analogues still fall mainly into calcium-related and cell-proliferative/differentiating arenas but the "rediscovery" of the wide effects of vitamin D deficiency and insufficiency has reinvigorated the whole field. The goal of developing analogues that can completely separate the "calcemic" and "nonclassical" properties of 1α,25-$(OH)_2D_3$ has not yet been fully realized. However, some promising compounds have been synthesized and interesting idiosyncrasies of their biological actions have surfaced (e.g., tissue, cell, gene, and VDRE differences). It remains to be seen whether these differences can be exploited. On the other hand, it must be stated that if vitamin D analogues work *only* through a VDR-mediated genomic mechanism, it is difficult to appreciate how the "calcemic" properties of 1α,25-$(OH)_2D_3$ can ever be fully resolved from the "cell-differentiating" properties given that pharmacokinetic differences have provided only a partial separation. On a more optimistic front, it can be stated that since the first/second editions of this book were published, several new vitamin D analogues (OCT, 1α,24-$(OH)_2D_3$, 1α-OH-D_2, and 19-nor-1α,25-$(OH)_2D_2$) have received governmental approval to be used in the treatment of various clinical conditions worldwide. We must remain upbeat that more vitamin D analogues will be developed and important new applications of vitamin D, particularly in the area of bone biology, remain to be uncovered.

Chapter 84

Estrogen Effects on Bone in the Male Skeleton

Over the past decade, we have seen fundamental changes in the landscape that used to describe osteoporosis as a rather exclusive disease of postmenopausal women. We now appreciate that the prevalence of osteoporosis in older men is substantial (Orwoll, 1998; Bilezikian, 1999; Gennari and Bilezikian, 2007), and that the consequences of a hip fracture in terms of morbidity and mortality are more severe in men than in women (Center *et al*., 1999a). Importantly, partly because the world population is aging, it is estimated that the total number of hip fractures in men in 2025 will be similar to current estimates for women (Genant *et al*., 1999; Cooper *et al*., 1992). To highlight this point, the 2004 Invest in Your Bones Campaign of the International Osteoporosis Foundation was fully dedicated to the problem of osteoporosis in men. Moreover, these observations have led, in turn, to efforts to understand better the physiology of the male skeleton, in terms of both protective factors and factors that place the male skeleton at risk. The purpose of this chapter is to review this information in the context of the developing and adult male skeleton and the role of estrogens.

Cartoons that describe the change in bone mass with time have tended to emphasize the role of aging per se because it is associated with a rather constant rate of decline in bone density from the middle years onward (Fig. 1). The downslope of this curve is more telling in women because they are exposed to an additional insult, besides age, namely the abrupt cessation of ovarian estrogen production at the time of the menopause. The accelerated bone loss characteristic of the early postmenopausal period is believed to place women at greater risk for osteoporosis than men, because men, under normal circumstances, do not experience a menopause equivalent during their middle years.

Such observations help to explain differences between men and women in their differential susceptibility to osteoporosis. However, equally important is the upswing in the curve describing acquisition of bone mass during the youthful years of skeletal accrual. Factors responsible for the establishment of peak bone mass are also key aspects to any discussion of the osteoporotic process. For example, the attainment of peak bone mass helps to define the reserve that is called upon during the period of age-related bone loss. Someone who has achieved optimal peak bone mass is likely to be relatively more protected from losing so much bone mass that places him/her at risk for osteoporotic fracture. In contrast, someone whose peak bone mass is suboptimal may show evidence for fracture risk earlier in the aging process. Although a number of factors help to account for the degree to which an individual achieves optimal peak bone mass (e.g., genetics, nutrition, environmental, exercise, calcium intake), this discussion will deal only with the role of the sex steroids, with particular emphasis on estrogens.

Estrogen deficiency states such as delayed puberty, amenorrhea of any cause, and, perhaps, the use of progestational agents for contraception, can lead to suboptimal acquisition of peak bone mass. In the male, similarly, androgens are thought to be critical to the establishment of peak bone mass. Finkelstein has shown, for example, that delayed puberty in otherwise normal boys is associated with reduced bone density for as long as 10 years thereafter compared with boys who entered puberty "on time" (Finkelstein *et al*., 1992, 1996). Although these results have been disputed by Bertelloni *et al*. (1998), who argue that volumetric bone density is not reduced among boys with delayed puberty, this point has been clarified by a recent study employing peripheral quantitative computer tomography (pQCT) in which both cortical and trabecular volumetric bone mineral density (BMD) were shown to be compromised in growing boys who are not exposed to androgens at a critical

Principles of Bone Biology, 3rd Edition

time in their skeletal development (Kindblom *et al.*, 2006). This study also demonstrates that late puberty is a risk factor for previous fractures in young male adults.

In sex steroid-sufficient, growing boys and girls, a 7% to 10% difference in the achievement of peak bone mass is believed to be a key protective factor in the male. Thus, not only do men not normally experience an abrupt cessation of androgen production in their middle years, but they also achieve a greater reservoir of bone owing to the attainment of greater peak bone mass in youth. Different observations have helped to clarify these differences in the achievement of peak bone mass as a function of androgens and estrogens. When true bone density is measured, that is as a volumentric quantity (g/cm^3), there is relatively little difference between the growing male and female skeleton throughout childhood (Gilsanz *et al.*, 1994; Schoenau *et al.*, 2001). The major difference in bone density between the growing female and male skeleton at puberty relates to areal density (g/cm^2) as determined by dual-energy x-ray absorptiometry (DXA). Thus, the difference appears to be bone size, a parameter that has been attributed to androgens (Beck *et al.*, 1992).

Recent pQCT studies have demonstrated that reductions in trabecular volumetric BMD begin before midlife in both sexes, and that they are greater in women than in men at central sites, but similar at peripheral sites (Riggs *et al.*, 2004, 2007). Cortical bone loss begins in the perimenopause in women and later in life in men, and is higher in women than in men, consistent with the menopausal-induced increases in bone turnover and skeletal porosity. Seeman and other investigators emphasize the point that androgens have region-specific actions on bone growth and remodeling so as to lead to larger bones (Orwoll, 1995b; Duan *et al.*, 1999; Seeman, 2001, 2002, 2004; Kim *et al.*, 2003). Bones that are exposed to androgen display greater periosteal apposition, which, in turn, leads to larger cross-sectional diameter. Under the influence of androgens, therefore, bones are bigger, but not necessarily more "dense." Although young men clearyly have larger bones than young women, age-related increases in bone size (at least as assessed by QCT) appear to be similar at most sites in men and women (Riggs, 2004); these findings are in contrast to measurements with DXA, which do suggest greater periosteal apposition over life in men compared with women (Duan *et al.,* 2003). Structural and biomechanical basis of sexual dimorphism in femoral neck fragility has its origins in growth. Nonetheless, at any age, for a given reduction in cortical bone mass, an expected concomitant of aging, the male achieves a relative mechanical advantage by increased cross-sectional diameter. This effect may well be a specific androgen action, although estrogen and IGFI may play a role as well (Vanderschueren *et al.*, 2006).

Of interest, consistent gender differences in the age-related changes of bone microstructure at the ultradistal radius have also been described in recent population-based cross-sectional studies using high-resolution pQCT (HRpQCT; Khosla *et al.*, 2006a). This is a new technology that can image the skeleton noninvasively with a resolution that is as high as 100 μm. Using HRpqCT, women show a progressive loss of trabeculae with an increase in trabecular separation with age, whereas men show trabecular thinning but no substantial loss of trabecular number or any major increase in trabecular separation. Because decreases in trabecular number have been shown to have a much greater impact on bone strength compared with decreases in trabecular thickness, these findings may help to explain how men maintain their skelelal strength with aging better than women.

Although it may have seemed clear that differences between the growing female and male skeleton as well as the skeleton in decline could be attributable satisfactorily, if not completely, to the sex-specific steroids (estrogens in women; androgens in men), recent observations have shattered this simple concept. It is no longer straightforward. The new observations underscore the normal biosynthetic

pathway by which estrogens are made. C-18 estrogens are derived from androgens via the activity of aromatase, a cytochrome P450 product of the CYP 19 gene (Bulun *et al*., 1993). The obligate precursors are the C-19 androgenic steroids. The human P450 aromatase enzyme is found in many tissues such as placenta, ovary, testis, brain, and adipocyte. In human bone, aromatase activity is reported to be expressed in osteoblast or osteoblast-like cells from fetal and normal tissue, in articular cartilage chondrocytes, in adipocytes adjacent to bone trabeculae, and in osteocytes, but not in osteoclasts (Sasano *et al*., 1997). Apart from contributing to the circulating estrogen pool, extragonadal sources of estrogen may be locally active in a paracrine or intracrine fashion (Simpson *et al*., 2001; Labrie *et al*., 1997). Thus, although the total amount of estrogen synthesized at any site could be small, local tissue concentrations could be substantial. Regulation of aromatase activity occurs through tissue-specific promoters and alternative splicing mechanisms (Simpson *et al*., 1997, 2001). The translated gene product, however, is the same among all tissues that harbor an active aromatase gene.

With this background, one can quite reasonably revisit the classical observation assigning differences among male and female skeletal growth to androgens or estrogens, respectively. It is possible that the growing male skeleton is also dependent upon estrogens and that some skeletal events previously noted to be androgenic may actually be caused, at least in part, by estrogens. Such thinking has received seminal support by two fundamental experiments of nature. In two rare syndromes, the estrogen receptor or the aromatase gene has been "knocked out" by a point mutation, rendering subjects either estrogen resistant (receptor defect; Smith *et al*., 1994) or estrogen deficient (aromatase defect; Morishima *et al*., 1995; Carani *et al*., 1997). A key role of estrogens in male skeletal development has emerged from insights gleaned from the study of these unusual subjects.

ALPHA-ESTROGEN RECEPTOR DEFICIENCY IN THE MALE

The pivotal importance of estrogen in the growing male skeleton was first demonstrated by the single case report of complete estrogen resistance in a young 28-year-old male owing to a disruptive homozygous mutation in exon 2 of the alpha-estrogen receptor gene (ERα) (Smith *et al*., 1994). The gene defect was inherited as an autosomal recessive from his consanguineous parents who were heterozygotes for the gene defect. A cytosine to thymidine transition at codon 157 resulted in a stop codon and an alpha estrogen receptor that is severely truncated and cannot bind estrogen. He had no detectable response to administration of large doses of exogenous estrogen (transdermal ethinyl estradiol), achieving serum concentrations of estradiol 10-fold higher than the typical male, 270 pg/mL (nl, 10 to 50). His own baseline estradiol (119 pg/mL) and estrone (145 pg/mL) levels were markedly above normal. Although bound and free testosterone as well as dihydrotestosterone concentrations were normal, luteinizing hormone (LH; 37 mIU/mL) and follicle-stimulating hormone (FSH; 33 mIU/mL) levels were in the mildy castrate range. He was extremely tall (204 cm) without acromegalic features and still growing with open epiphyses (bone age, 15 years) and genu valgum. The growth curve did not show a pubertal growth spurt, although his puberty in all other respects was normal. His body proportions were eunuchoid. Bone density of the lumbar spine as measured by dual energy x-ray densitometry was 0.745 g/cm^2, corresponding to 2 standard deviations below average for a 15-year-old boy.

AROMATASE DEFICIENCY IN THE MALE

So far, there are eight known cases of aromatase deficiency in men, owing to inactivating mutations in the CYP19A1 gene (Morishima *et al*., 1995; Carani *et al*., 1997; Deladoey *et al*., 1999, Hermann *et al*., 2002; Herve *et al*., 2004; Boullion *et al*., 2004; Maffei *et al*. 2004, 2007). The disorder occurs in an autosomal recessive pattern, and in at least 6 of the 8 described subjects parental consanguinity was evident. A summary of described mutations is reported in Table I. All known mutations exhibit no or minimal enzyme activity in transient expression systems. Accordingly, circulating estrogen levels are markedly low or undetectable but androgens are normal or elevated. Serum FSH was elevated or in the upper range, whereas serum LH was normal except in one patient.

Interestingly, the skeletal phenotypes of aromatase-deficient men are virtually identical to the man with a loss-of-function mutation at the ERα gene (Table II and Table IV). Common characectistics include tall stature, continued longitudinal growth, unfused epiphyses, delayed bone age, lack of pubertal growth spurt, eunuchoid skeletal proportions (upper segment/lower segment ratio from 0.84 to 0.92), genu valgum, elevated bone resorption markers, and reduced bone mass. Lipid abnormalities, increased body mass index, hyperinsulinemia, and various degrees of glucose impairment (including diabetes and achantosis nigricans in one and two cases, respectively) have also been reported. When some of these subjects were treated with intramuscular testosterone, there was no benefit, an understandable observation because aromatase deficiency does not lead to low testosterone levels. Indeed, in two cases (Morishima *et al*., 1995; Hermann *et al*., 2002), testosterone levels were markedly elevated. On the other hand, estrogen treatment in all cases of aromatase deficiency is associated with marked changes in the skeletal phenotype (Fig. 2 and Fig. 3). Epiphyses closed quickly, longitudinal growth ceased, and BMD increased dramatically (Carani *et al*., 1997; Deladoey *et al*., 1999; Bilezikian *et al*., 1998; Maffei *et al*., 2004; Rochira *et al*., 2000). A comparison between the syndromes of estrogen resistance and estrogen deficiency in the male is shown in Table III.

TABLE I Human Aromatase Gene (CYP19A1) Mutations

Herve *et al.*, 2004	26	–	190	–	–
Maffei *et al.*, 2004	29	15.0	177	Yes	−3.30 (lumbar spine) −2.30 (femoral neck)
Boullion *et al.*, 2004	17	12.5	176	Yes	−2.31 (lumbar spine) −0.46 (femoral neck) −3.40 (ultradistal radius) −3.63 (mid radius)
Maffei *et al.*, 2007	25	15.3	192	Yes	−1.80 (ultradistal radius) −3.70 (mid radius)

Importantly, a dose-dependent effect of estrogen replacement therapy on bone mass in aromatase-deficient men exists, because a very low dose of estradiol (below 25 μg twice weekly) was not sufficient for maintaining a normal bone mineral density (Rochira *et al.*, 2000). Long-term data are available with a 5-year follow-up in the patient described by Morishima, Bilezikian, and their colleagues. Starting on low-dose conjugated estrogen, 0.3 mg, he was quickly raised to 0.75 mg daily, the dosage that he has consistently taken for most of the period of observation. Estradiol levels rose from undetectable into the normal range for men. Androgen levels fell from markedly elevated levels to normal. The concomitant return of the gonadotropins, LH and FSH, to normal illustrates well the role of estrogens in controlling gonadotropin production in the male (Fig. 4). He immediately stopped growing with closure of all open epiphyses within 6 months of starting estrogen therapy (see Fig. 2). Bone markers that were elevated at baseline returned slowly to normal (Fig. 5). Most impressively, this man has experienced a dramatic increase in bone density with estrogen therapy. During the first 3 years, increases in the lumbar spine, femoral neck, and forearm were 20.7%, 15.7%, and 12.9%, respectively. Over the next 2 years of estrogen therapy, the gains in the lumbar spine and femoral neck were maintained with further marked increases in the forearm bone density, now totaling 26% (see Fig. 3). The improvement in bone mass is seen

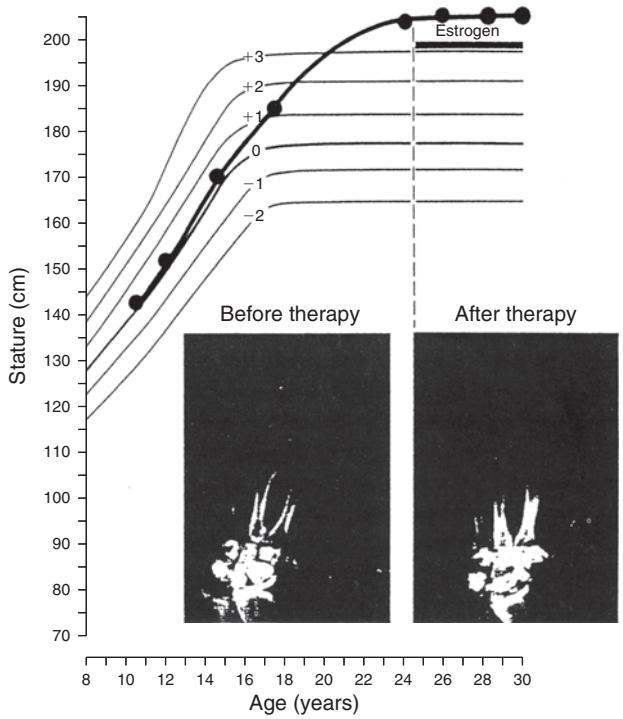

FIGURE 2 Growth curve and bone age before and after 5 years of estrogen therapy in a man with aromatase deficiency. After conjugated estrogen therapy was begun (bar), linear growth ceased immediately. Height has remained at 204 cm since therapy, whereas previously it was showing continued increases. All epiphyses were closed within 6 months (*insets*). The curves with + and – numbers represent the mean and standard deviations for normal young men.

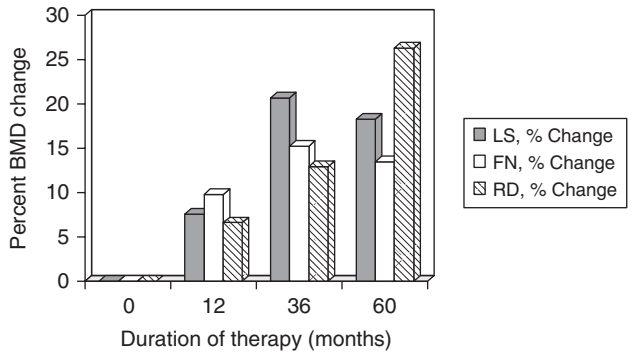

FIGURE 3 Change in lumbar spine (LS), femoral neck (FN), and radial (RD) BMD with estrogen therapy in a man with aromatase deficiency.

also by the change in *T* score with normal values at the lumbar spine and femoral neck and from markedly osteoporotic levels in the forearm to mildy osteopenic levels ($T = -4.65$ to -1.84). The effect of estrogen to improve bone mass is best described as anabolic because of the magnitude of the change and also because further bone growth did not occur. This anabolic action of estrogen is quite different from effects in the postmenopausal woman, in whom the estrogen effect is more accurately described as antiresorptive.

A recent report of a 16-year-old boy with aromatase deficiency has sharpened our views of how bone density is abnormal in this syndrome (Boullion *et al.*, 2004). All reports up to this recent one assessed BMD by dual-energy x-ray absorptiometry (DXA), an approach that gives only areal density, not true volumetric bone density. In this case, the skeleton of the 16-year-old boy with congenital aromatase deficiency was assessed by pQCT of the radius as well as by DXA. The use of pQCT allows measurements not easily made or even possible by DXA, such as cross-sectional area (CSA), cortical thickness, trabecular volumetric BMD, and cortical volumetric BMD. As expected, estrogen replacement in this boy was associated with normalization of sex hormone levels, reduced bone turnover rate, and increased areal BMD of the lumbar spine (23%) and femoral neck (14%). However, the gain in volumetric BMD, either estimated by the calculation of the bone mineral apparent density from DXA or assessed directly by pQCT was limited at the lumbar spine and even absent at the femoral neck and the radius. Interestingly, longitudinal bone growth, CSA, and cortical thickness, as measured by pQCT, increased significantly by 8.5%, 46%, and 12%, respectively. Thus, the observed increase in areal BMD at peripheral sites was mainly driven by an increase in bone size, rather than bone density. These changes are similar to those associated with normal pubertal growth and support the notion that in growing bones, except for the spine, true density does not increase (Seeman *et al.*, 2001; Sundberg *et al.*, 2003). Moreover, these observations not only account more completely for the densitometric observations but they also lead to a reconsideration of functional sex steroid assignments on bone size. It is well known that during normal male puberty, periosteal diameter continues to expand and cortical thickness increases because of reduced endocortical expansion and accelerated periosteal apposition (Seeman, 2002). These effects, leading to increased bone size, have classically been attributed to androgens and in fact help to account for greater areal density in the male skeleton. Conversely, when females enter puberty, periosteal apposition is inhibited, an action classically believed to be an estrogen effect. According to the results of the parameters altered by estrogen administration to the young boy with aromatase deficiency (Boullion *et al.*, 2004), some actions on bone size, previously attributed to androgens, must at least in part be an estrogen effect. It is likely that estrogen, rather than androgens, at least in this single example of a growing boy, is helping to drive periosteal bone apposition. A biphasic, dose-dependent effect of estrogen could exist. At low levels (as observed in males and in early pubertal females) estrogen may stimulate periosteal apposition and increase bone size, whereas at higher concentrations (as observed in late pubertal and adult females) estrogen may inhibit cross-sectional bone growth. This latter effect could be caused by stimulation of the estrogen receptor β.

Recently, the concomitant presence of mild hypogonadism in a man with aromatase deficiency has offered a useful

TABLE III Extraskeletal Characteristics of Aromatase-Deficient Men

Reference	Obesity (BMI)	Diabetes	Insulin resistance	Achantosis nigricans	Dyslipidation	Steatohepatitis

Tallness	Yes	Yes
Eunuchoid proportions	Yes	Yes
Masculinized	Yes	Yes

model to study the effects of testosterone and estradiol replacement, separately or in combination (Rochira *et al.*, 2007). In this man, estradiol treatment alone increased BMD with a greater gain than the one obtained with testosterone alone. Interestingly, the combination of testosterone (6 mg/day) and estrogen (25 μg twice weekly) replacement led to a further increase in cortical thickness at the radius and the tibia as measured by pQCT, further supporting the concomitant importance of both sex steroids for periosteal apposition. In this case, however, an increase in volumetric BMD at the tibia and the radius as well as an increase of areal BMD of the lumbar spine and the femoral neck was also described after 2 years of combined therapy.

The converse of the inactivating mutation of the aromatase gene, namely a mutation leading to overly active aromatase activity, has also been instructive with regard to assigning a role for estrogens in the male skeleton (Hemsell *et al.*, 1977; Bulun *et al.*, 1999; Stratakis *et al.*, 1998). The observations are opposite to those made in the aromatase-deficient male. Characteristic findings are accelerated bone growth, advanced bone age, and short stature, features that are all consistent with the precocious presence of estrogen in an immature skeleton. Other common characteristics of this syndrome include prepubertal gynecomastia and mild hypogonadotropic hypogonadism. Despite increased estrogen levels and testosterone levels that are frankly low or in the lower range of normal, males with aromatase excess appear to be fertile. In some cases, short-term treatment with an aromatase inhibitor (testolactone or anastrozole) was successful in reducing serum estrogen levels, restoring gonadotropin

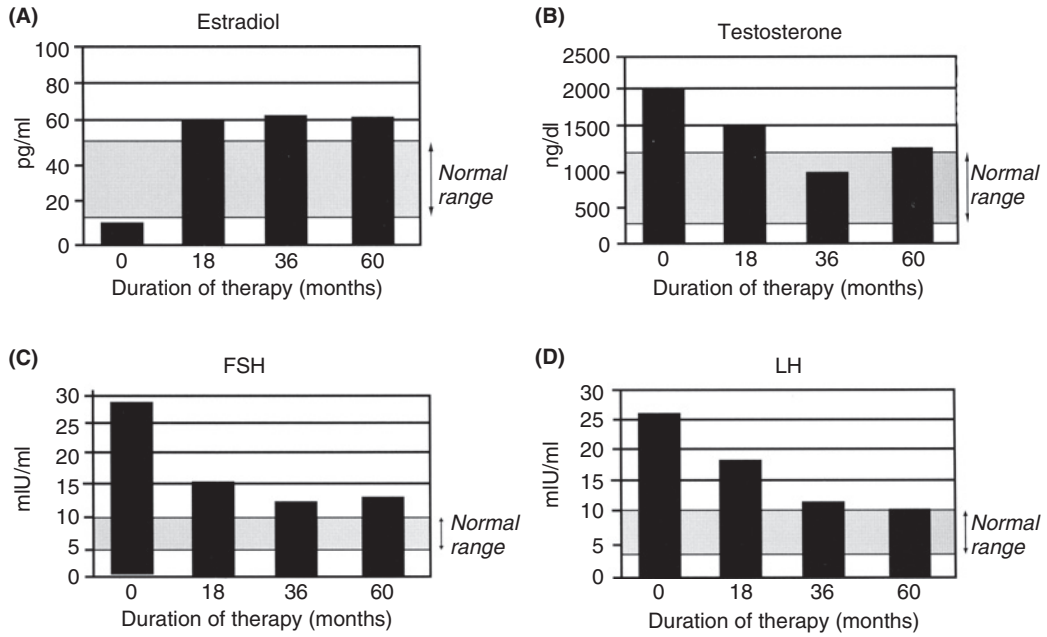

FIGURE 4 Changes in sex steroids and in gonadotropins with estrogen therapy in a man with aromatase deficiency. The data are shown for estradiol (**A**), testosterone (**B**), FSH (**C**), and LH (**D**). Over 5 years, estradiol levels initially rose and then were maintained at levels in the normal range for males when administered at 0.75 mg/day. Testosterone levels fell into the normal range, as did FSH and LH levels.

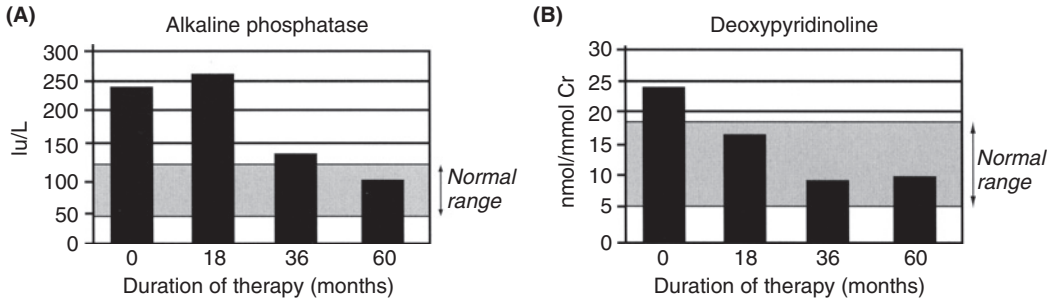

FIGURE 5 Changes in bone markers with estrogen therapy in a man with aromatase deficiency. The data are shown for alkaline phosphatase (**A**) and for deoxypyridinoline (**B**). The resorption markers, deoxypyridinoline, appear to fall faster over time than did the formation marker, alkaline phosphatase.

and testosterone levels to normal, and arresting skeletal aging (Stratakis *et al.*, 1998; Shozu *et al.*, 2003; Martin *et al.*, 2003). Even though at least 5 families with 13 affected male subjects and 2 sporadic cases of aromatase excess syndrome have been described, the effects of estrogen excess on bone turnover and bone density in men remain as yet unknown. The only available data in this respect relate to bone density that has been described to be in the upper limits of the normal range in two siblings with familial hyperestrogenism. It is a remarkable observation considering the additional point that the man had hypogonadism and the woman had irregular menses (Martin *et al.*, 2003).

Of special note is the relationship between the pubertal growth spurt and estrogen. In the syndromes of estrogen deficiency or resistance, the tallness and continued growth well into adulthood was not associated with a pubertal growth spurt. Conversely, in the example of aromatase excess, owing to an activating mutation of the aromatase gene, with elevated estrogen levels, puberty occurs early and is accompanied by skeletal maturation. Additional evidence for an important role of estrogens in the pubertal growth spurt is the testicular feminization syndrome in which XY males do not respond to androgens because of a mutation in the androgen receptor. Responsiveness to estrogens is normal. In this syndrome, the pubertal growth spurt is seen (Grumbach and Auchus, 1999; Zachmann *et al.*, 1986). Finally, in estrogen-secreting tumors, similar observations of premature skeletal maturation have been made (Coen *et al.*, 1991; Simpson *et al.*, 1994; Grumbach and Styne, 1998). These observations, therefore, argue rather persuasively that in the male, as in the female, the pubertal growth spurt is a function of estrogens, not androgens. It is

interesting to speculate that the difference in height among women and men may reflect the difference in the time of onset of puberty. Boys gain a few more years of linear growth because their puberty occurs later. The notion, namely, that the additional stature in the male is owing to estrogen, not androgens, is particularly intriguing.

From these human experiments of nature, it seems reasonable to conclude that in the male, estrogens are important in the control of linear growth, in the pubertal growth spurt, in epiphyseal maturation, and in the achievement of optimal peak bone mass and size. Such conclusions, obviously, must be tempered by an appreciation that androgens are also important in the acquisition of peak bone mass. In the testicular feminization syndrome, for example, the peak bone mass achieved is consistent with expectations for an estrogenic influence only because these XY boys had bone density most consistent with expectations for an XX girl (Kelch *et al*., 1972). In either event, the failure to achieve peak bone mass may be a risk factor for the development of osteoporosis later in life. Although one does not expect to "find" many examples of complete estrogen deficiency or resistant syndromes, more subtle abnormalities are possible in those genes (i.e., polymorphisms) that would render men at risk for osteoporosis on this basis (Gennari *et al*., 2004a).

ANIMAL "KNOCKOUTS" OF THE ESTROGEN RECEPTOR AND AROMATASE GENES

Male and female mice in which either of the two ERs or the aromatase genes have been knocked out (KO), generated by several different investigative groups, include the following phenotypes: ERα KO, ERβ KO, or deletion of both ERα and ERβ (DERKO) mice. Overall, these models show a less dramatic phenotype than corresponding alterations in human subjects born with inactivating mutations of either the ERα or the aromatase gene. Particularly, deletions of both the ERα and the ERβ in these mice do not seem to completely account for loss of estrogen action in bone, because the impact of DERKO is seemingly not as great as the impact of gonadectomy on the skeleton (Gentile *et al*., 2001; Bilezikian, 2002). Initial studies reported a reduction in BMD and a tendency toward an increase in bone turnover in male ERα KO mice (Couse *et al*., 1999; McCouley *et al*., 2003). Conversely, male ERβ KO mice have a skeletal phenotype that is identical to that of the wild type, whereas ERβ KO females showed an increase in cortical bone that was associated with enhanced periosteal apposition, and diminished age-related bone loss (Windahl *et al*., 1999, 2001; McDougall *et al*., 2002; Chagin *et al*., 2004). Some male DERKO models showed reductions in bone density that are similar to single ERα KO animals suggesting that the ERα is more protective than the ERβ in bone (Vidal *et al*., 2000; McCouley *et al*., 2003; Tozum *et al*., 2004). However, more recent and extensive investigations of KO models by histomorphometry, DXA, and pQCT have been puzzling, showing different and contrasting skeletal phenotypes (Sims *et al*., 2002, 2003; Lindberg *et al*., 2002; Parikka *et al*., 2005). In this respect, it should be emphasized that ERα and DERKO, but not ERβ, KO mouse models have clearly increased serum levels of testosterone and estradiol. These elevated, supraphysiological sex hormone levels could have accounted for the lack of some of the expected skeletal changes. Importantly, variations in IGF-I levels have also been observed in ERα and DERKO animals (Vidal *et al*., 2000). Moreover, some of these KO models do not seem to be completely functional KOs, because it has been shown that they express truncated ER transcripts that are able to bind estradiol and, in the case of ERα, capable of activating transcription in an estrogen-dependent manner (Couse *et al*., 1995; Krege *et al*., 1998). Finally, the recent generation of mice carrying a mutation that eliminates classical (estrogen-responsive element mediated) but not nonclassical (non-estrogen-responsive element mediated) ERα signaling (nonclassical ERα knockin mice, NERKI) suggest that there is a critical balance between classical and nonclassical ERα pathways, which, when altered, can result in markedly aberrant responses to estrogen (Syed *et al*., 2005). It is possible that the expressed truncated ER transcripts in some of these ER KO models, together with supraphysiological estrogen levels, may alter this balance and account for these apparent but unexpected estrogen effects. To address this issue, Nakamura *et al*. (2007) recently generated mice with deletion of ERα specifically in osteoclasts and demonstrated osteopenia in female, but not male mice, suggesting that in this model androgen action via the AR was sufficient to compensate for loss of ERα in male, but not female mice. Overall, however, the data from the ER KO models indicates that ERα mainly regulates bone remodeling in male mice, whereas in female mice both ERα and ERβ influence this process and could partially compensate for each other.

Recent findings from ERs KO mice also suggest that the activity of ERα may explain the positive interaction between estrogen and exercise at endocortical and trabecular bone surfaces (Jessop *et al*., 2004). In contrast estrogen may inhibit the anabolic exercise response at the periosteal surface by the activation of ERβ. Signaling through this receptor retards periosteal bone formation and suppresses gains in bone size and bone strength, thus acting as an antimechanostat (Saxon *et al*., 2005).

The skeletal consequences of estrogen deficiency are illustrated further by studies of the aromatase knockout mouse (ArKO) model (Fisher *et al*., 1998; Honda *et al*., 1998; Toda *et al*., 2001). The newborn skeleton of ArKO animals demonstrates no consistent differences in bone and mineralized cartilage from wild-type littermates

(Oz *et al*., 2001). In contrast, growing and adult male and female ArKO mice show reduced BMD and micro-CT parameters, particularly at trabecular sites (Oz *et al*., 2000, 2001; Miyaura *et al*., 2001). The reduction in BMD in these mice was completely prevented by estrogen replacement (Miyaura *et al*., 2001). Histologically, knockout animals of both sexes have significant reductions in trabecular bone volume, trabecular thickness, and cortical thickness, compared with wild-type littermates (Oz *et al*., 2000). Analysis of the effects of aromatase inactivation on bone-remodeling parameters in different ArKO mice models has shown conflicting results. In one study on static and histomorphometric parameters of the spine, adult ArKO males showed a low-turnover pattern, with significant reductions in osteoblastic, osteoid, and eroded surfaces and with reduced mineralizing surface as observed from tetracycline uptake (Oz *et al*., 2000). In contrast, adult ArKO females showed a high-turnover pattern, suggesting a sexual dimorphism in bone remodeling of 5- to 7-month-old ArKO animals (Oz *et al*., 2000). These observations were confirmed in a subsequent study utilizing fluorine-18 PET imaging (Oz *et al*., 2001). By this technique, ArKO males clearly demonstrated reduced vertebral remodeling compared with wild-type littermates, and estradiol treatment in these mice increased fluorine-18 uptake to normal levels. The sexual dimorphism in bone remodeling in ArKO animals was not appreciated in another ArKO mice model, in which increased bone resorption was observed in both male and female animals (Miyaura *et al*., 2001). Treatment with estrogen restored the increased parameters of bone remodeling to the wild-type level in both sexes (Miyaura *et al*., 2001). Although it is not clear how to account for the differences in these observations, what is clear is that aromatase deficiency profoundly influences processes associated with bone turnover in both male and female animals. To further clarify the relationship between estrogen and androgen in bone, male ArKO mice were orchidectomized to induce a double deficiency of estrogen and androgen (Matsumoto *et al*., 2006). In this model, ORX induced a further decrease in BMD and in endosteal bone resorption compared with sham-operated ArKO mice, without any major difference in periosteal bone formation.

In different experiments, aromatase inhibition in aged male rats by vorozole has been associated with increases in bone resorption and bone loss to an extent similar to that of orchidectomy (ORX) (Vanderschueren *et al*., 1996, 1997, 2000). Importantly, vorozole treatment does not significantly affect cortical thickness in contrast to ORX, suggesting a direct role of androgens on this geometric property at cortical sites (Vanderschueren *et al*., 1997). Consistently, androgen receptor KO mice and ORX mice show a similar degree of reduction in cortical area and thickness, as a result of a reduced bone formation at the periosteum (Venken *et al*., 2006). Moreover, testosterone replacement stimulated periosteal bone formation in ORX but not ARKO mice, again supporting the concept that androgen receptor activation plays a major role at the periosteum (Venken *et al*., 2006). Interestingly, administration of an aromatase inhibitor in these mice partly reduced testosterone action on periosteal bone formation in ORX but not ARKO mice.

Taken together, these studies on ERs and CYP19 KO mice, as well as other rodent models of altered sex steroid action in the male, provide general confirmation of the human gene KO disorders and suggest that estrogen may be more protective in the skeleton than androgens in males. A minimum circulating estrogen level is also required for maximal androgen-induced stimulation of periosteal apposition. In contrast, higher circulating estrogen levels may have negative effects on the periosteum. This concept has been further emphasized by the observation that transgenic male mice overexpressing aromatase activity have increased trabecular BMD, but decreased bone formation rate at the periosteum (Peng *et al*., 2004). Moreover, ERα appears to be the main effector of estradiol's protective function in bone in both male and female, as also indicated by *in vivo* animal studies on the use of ERα-selective ligands (Harris *et al*., 2002).

STUDIES IN HUMANS-OBSERVATIONAL DATA

The data noted earlier from the human "experiments of nature" clearly indicate that estrogen plays a significant role in the male skeleton. In particular, they demonstrate that estrogen is required for epiphyseal closure, that it has significant effects on skeletal modeling during growth, and that it is necessary for optimal acquisition of bone mass and size during puberty in boys. These observations, however, leave several major questions unresolved. In particular, they leave open the issues of what, if any, are the roles of estrogen in regulating bone remodeling in adult men with mature skeletons, whether estrogen is necessary for the maintenance of bone mass in adult men, and what, if any, is the role of estrogen (or estrogen deficiency) in mediating age-related bone loss in men.

Before addressing these issues, it is useful to review the available data on age-related changes in serum sex steroid levels in normal men. As shown in Figure 6A, serum total testosterone levels do not change significantly in otherwise healthy men until the ninth decade. Similarly, there is little or no change in serum total estradiol levels in men over life (see Fig. 6B). By contrast, serum bioavailable (or non-sex hormone-binding globulin (SHBG) bound) testosterone levels decrease by approximately 70% and serum bioavailable estradiol levels decrease by approximately 50% over life. To the extent that the non-SHBG bound sex steroid fraction is the one that has access to target tissues (Manni *et al*., 1985; Giorgi and Moses, 1975), available data from

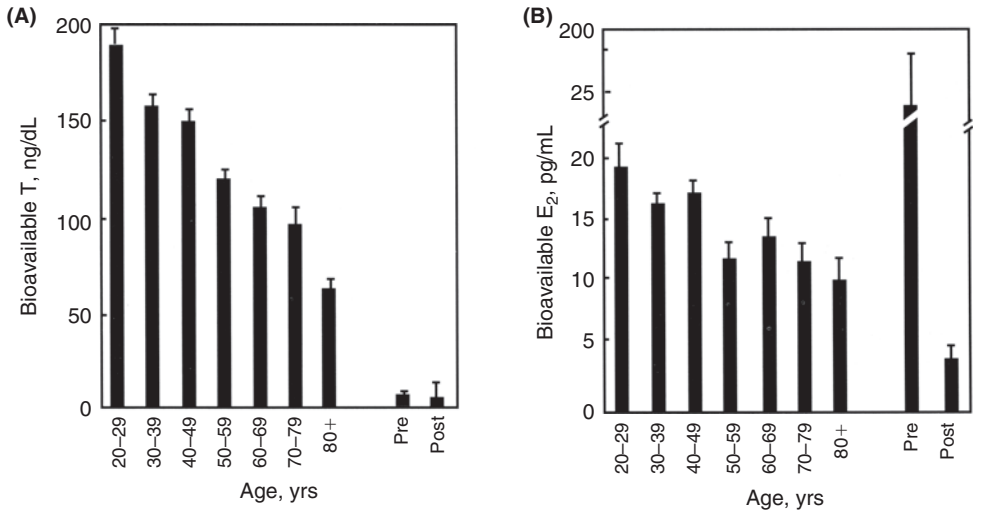

FIGURE 6 Serum total testosterone (**A**) and estradiol (**B**) levels as a function of age in a population-based sample of men. Data are adapted from Khosla *et al.* (1998), with permission.

either cross-sectional or longitudinal studies in different populations indicate that while men do not have the equivalent of the menopause, they clearly have significant (but gradual) age-related decreases in bioavailable testosterone and estradiol levels over life (Harman *et al.*, 2001; Khosla *et al.*, 2001; Gennari *et al.*, 2003; Orwoll *et al.*, 2006; Liu, 2007). These changes are primarily owing to a large increase (of approximately 125%) in serum SHBG levels over life in men (Khosla *et al.*, 1998). Although the reason(s) for this increase in SHBG levels are unclear, it is apparent that the age-related increase in SHBG serves to limit the availability of testosterone and estradiol to target tissues in elderly men.

A first indication about the relative roles of estrogen versus testosterone in the male skeleton came from cross-sectional observations in middle-aged and elderly men relating sex steroid levels to BMD at various sites. It was shown that BMD is more directly related to declining estrogen levels than declining androgen levels, particularly when circulating bioavailable fractions of these steroids were considered (Slemenda *et al.*, 1997; Greendale *et al.*, 1997; Khosla *et al.*, 1998; Center *et al.*, 1999b; Ongphiphadhanakul *et al.*, 1998; Amin *et al.*, 2000; Barret-Connor *et al.*, 2000; Szulc *et al.*, 2001). Indeed, serum estradiol levels were more robust predictors of BMD than serum testosterone levels even in a sample of androgen-deficient men from the Framingham Study (Amin *et al.*, 2000). Conversely, more conflicting data have been presented regarding the association between testosterone and BMD. Although these findings add to the evidence from the ER-alpha and the aromatase-deficient males in building the case for an important role for estrogen in the male skeleton, there are clear limitations to cross-sectional observational data. Thus, because BMD in adult men is a function both of peak bone mass and bone loss with aging, these studies cannot dissociate the effects of estrogen on the acquisition of peak bone mass in early adulthood from its effects on bone loss later in life. Moreover, existing differences on the relative contribution of estrogen versus androgen among cross-sectional studies may be also related to site-specific effects of sex steroids on BMD as well as to additive effects on bone geometric properties that cannot be completely addressed by the measurements of areal BMD. A recent study in a large cohort of elderly men suggests that testosterone is an independent positive predictor of BMD particularly at cortical (hip and forearm) rather than at trabecular (spine) sites (Mellström *et al.*, 2006). In the same cohort, estradiol was an independent predictor of BMD at all bone sites, with the highest predictive value seen for lumbar spine. Moreover, the predictive effect of testosterone for prevalent fractures was not affected by adjustement for BMD. In a different pQCT-based study on young Swedish men at the age of peak bone mass, free estradiol was a positive predictor of volumetric BMD, whereas it was a negative independent predictor of cortical cross-sectional area, periosteal circumference, and endosteal circumference. Conversely, free testosterone did not significantly affect volumetric BMD, but positively regulated cortical cross-sectional area, periosteal circumference, and endosteal circumference (Lorentzon *et al.*, 2005). Age- and sex hormone-related differences on bone microstructure have also been described in a recent HRpQCT cross-sectional study (Khosla *et al.*, 2006b).

Importantly, cross-sectional data have been confirmed in general in longitudinal studies. Over a 2-year period, Slemenda *et al.* (1997) described lower estradiol levels in men losing BMD at more than 1% per year compared with men with higher estradiol levels and lower rates of bone loss. In a more recent 4-year study by Khosla *et al.* (2001), elderly men with bioavailable estradiol levels below the

median value of 40 pmol/L showed higher rates of bone loss at the midradius and ulna than men with bioavailable estradiol levels above the median. A similar longitudinal 4-year study on 200 elderly Italian men (Gennari *et al.*, 2003) confirmed and extended these observations by showing a negative correlation between estrogen levels and bone turnover markers or rates of bone loss at the lumbar spine and the distal femur (see Fig. 8). In the same study, the ratio between estradiol and testosterone, presumed to be an indirect index of aromatase activity, increased significantly with age and was higher in normal than in osteoporotic subjects. In a larger cohort of older subjects, rapid bone loss at the hip was more likely in men with low testosterone or estradiol levels (Fink *et al.*, 2006; Ensrud *et al.*, 2006), while in male participants from the Tromso study (mean age, 25 80 years), the correlation between sex steroids and forearm bone loss was only modest (Bjornerem *et al.*, 2007). Taken together, these observations illustrate an important role for estrogen in the maintenance of bone mass in aging men. In a longitudinal observation within the Framingham Study cohort, men with low estradiol levels were at greatest risk for hip fracture (Amin *et al.,* 2006). Fracture risk further increased when both low estradiol and low testosterone levels were considered.

Considerable indirect evidence also suggests that a threshold value for estrogen in the male skeleton is needed to control bone remodeling and to maintain bone mass (Khosla *et al.*, 2002). In a cross-sectional analysis from the MINOS Study, men in the lowest quartile for bioavailable estradiol level showed significantly lower BMD at multiple sites than men in the upper three estradiol quartiles (Szulc *et al.*, 2001). Moreover, in two longitudinal studies in older men, rates of bone loss at different skeletal sites were unrelated to serum estradiol levels if they were above the median value, but clearly associated with estradiol levels if they were below the median value (Khosla *et al.*, 2001; Gennari *et al.*, 2003) (see Figs 7 and 8). The threshold concentration of bioavailable estradiol appears to be remarkably similar across all studies, ranging from 40 to 55 pmol/L. This apparent threshold value is higher than typical estradiol concentrations for postmenopausal women who are not receiving exogenous estrogens. On the other hand, premenopausal women and young men are typically above this apparent threshold level. Because about 50% of middle-aged men fall below this estradiol threshold, it could be a determinant in age-related bone loss in a large number of men. A recent cross-sectional study in which volumetric BMD and bone geometry at different sites were assessed by QCT further extended these observations, and indicated that in men the relationship between bioavailable estradiol and volumetric BMD at cortical versus trabecular sites appears to be different (Khosla *et al.*, 2005a). The supposed threshold level for estrogen deficiency appeared to be lower for cortical than for trabecular bone. In other words, trabecular bone seems to be more sensitive than cortical bone to small

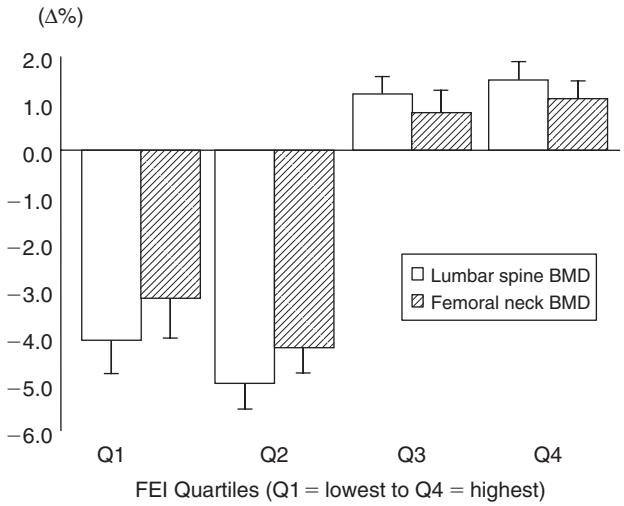

FIGURE 7 Rates of BMD loss (percentage per 4 year) and in elderly men grouped according to free estrogen index quartiles. The free estrogen index, as indirect measure for bioavailable estradiol, has been calculated by the ratio of total estradiol to SHBG. Data are adapted from Gennari *et al.* (2003), with permission.

age-related declines in estrogen levels. The same associations were confirmed in a similar QCT study in women (Khosla *et al.*, 2005b).

Because only a small fraction of circulating estradiol is derived directly from the testes, it is likely that peripheral aromatization of testicular and adrenal androgen precursors to estrogen exerts a key role in maintaining estradiol levels above the threshold with aging (Gennari *et al.*, 2004a). It is also likely that individual differences in aromatase activity with aging may help to distinguish among men and their rates of bone loss. Recent studies on aromatase CYP19 gene suggested that polymorphic variation at this gene may account, at least in part, for these differences in aromatase

activity (Gennari *et al*., 2004a, 2004b). A major unsolved issue is which tissue site of aromatase activity is the most important in terms of bone metabolism in men. The consistent association between circulating estradiol levels, BMD, and fracture risk, reported in a large number of cross-sectional and longitudinal studies, suggests that although local aromatization in bone may contribute significantly to skeletal homeostasis (Simpson *et al*., 1999, 2000), a minimum circulating level of estradiol (derived from nonskeletal peripheral aromatization) is necessary to prevent bone loss in elderly men. However, it is possible that circulating estrogen levels simply reflect local estrogen status within the bone, and that locally produced estradiol exerts an even greater impact on bone physiology than circulating plasma estradiol levels.

STUDIES IN HUMANS—INTERVENTIONAL DATA

In order to definitively dissect out estrogen versus testosterone effects on the adult male skeleton, more dynamic short-term interventional observations have been performed. Falahati-Nini *et al*. (2000) studied 59 elderly men (mean age, 68 years) in whom they eliminated endogenous testosterone and estrogen production using a GnRH agonist (leuprolide acetate) and an aromatase inhibitor (letrozole). Physiological testosterone and estrogen levels were maintained by concurrently placing the men on testosterone and estradiol patches. Following baseline studies in which markers of bone resorption (urinary deoxypyridinoline, Dpd, and N-telopeptide of type I collagen, NTx) and formation (serum osteocalcin and amino-terminal propeptide of type I procollagen, PINP) were measured, the men were randomized into one of four groups: group A had both patches withdrawn, group B continued the estradiol patch but had the testosterone patch withdrawn, group C continued the testosterone patch but had the estradiol patch withdrawn, and group D continued both patches. After 3 weeks, the baseline studies were repeated. As shown in Figure 9, estrogen had the dominant effect in preventing the increase in both urinary Dpd (Fig. 9A) and NTx (Fig. 9B) excretion that was observed in group A. In the same study (Fig. 10A), serum osteocalcin levels decreased following acute sex steroid withdrawal in these men, and either estrogen or testosterone was able to prevent the decrease in serum osteocalcin levels. By contrast, estrogen, but not testosterone, was effective in preventing the decrease in serum PINP levels (Fig. 10B). Because osteocalcin is produced primarily by mature osteoblastic cells and osteocytes (Lian *et al*., 1999), these findings are consistent with an important role for both estrogen and testosterone in maintaining the functional integrity of these cells, perhaps by preventing apoptosis (Manolagas, 2000). Type I collagen, by contrast, is produced by cells of the entire osteoblastic lineage (Orwoll, 1995b), and these data would suggest that it is primarily estrogen that regulates

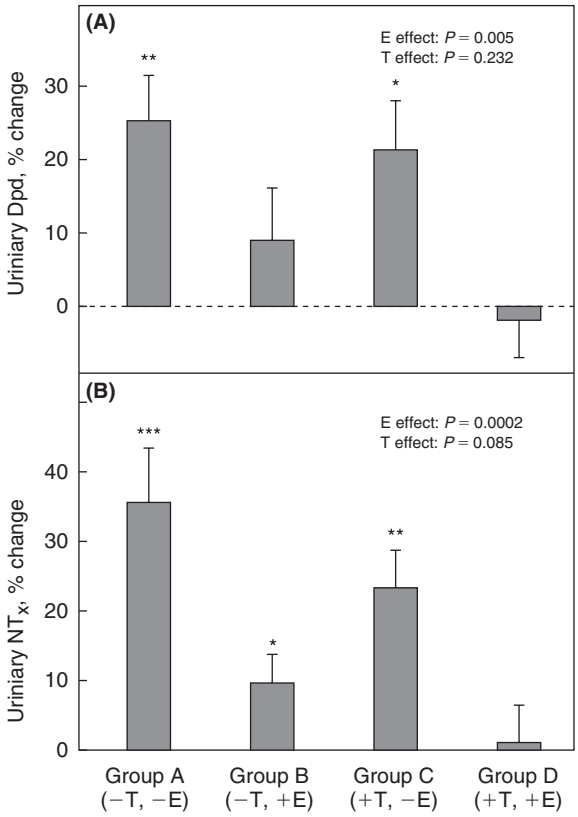

FIGURE 9 Changes in urinary Dpd (**A**) and NTx (**B**) excretion between the baseline and final visits in the four groups as described in the text. $***P < 0.001$, $**P < 0.005$, and $*P < 0.05$ for change from baseline. The overall estrogen (E) and testosterone (T) effect on the bone markers was analyzed using a two-factor ANOVA model. Adapted from Falahati-Nini *et al*. (2000), with permission.

this process. In a similar study in younger individuals, Leder *et al*. (2003) confirmed an increase in bone resorption markers following induction of the hypogonadal state by the GnRH agonist, goserelin acetate. In this model, evidence was provided for independent effects of testosterone and estrogen on bone resorption. Moreover, in that study, bone formation markers also appeared to be dependent both on androgens and estrogens. These observations are in keeping with the increase in bone formation markers described in aromatase-deficient or gonadectomized men (Stepan *et al*., 1989). A study by Taxel *et al*. (2001) with a longer observation period (9 weeks) gave similar results, further indicating that treatment of elderly men with an aromatase inhibitor produces significant increases in bone resorption and decreases in bone formation. Conversely, a similar approach to boys with constitutional delay of puberty has given different results. Suppression of estrogen production by aromatase inhibitor, letrozole, for 1 year during testosterone treatment did not negatively affect bone mineral content, BMD, or apparent BMD, an estimate of true volumetric BMD, with respect to testosterone treatment alone (Wickman *et al*., 2003). In testosterone alone and testosterone

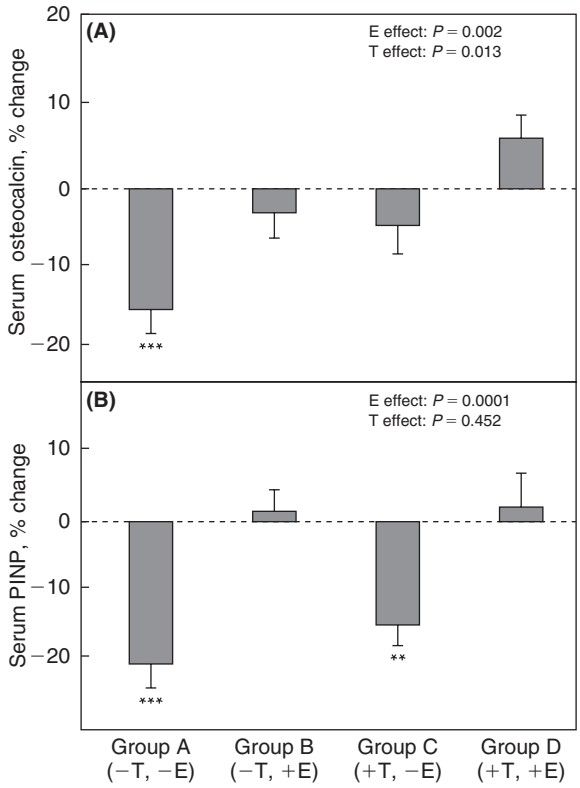

FIGURE 10 Changes in serum osteocalcin (**A**) and PINP (**B**) levels between the baseline and final visits in the four groups as described in the text. $***P < 0.001$ and $**P < 0.005$ for change from baseline. plus letrozole groups, bone mass parameters increased with respect to baseline values and those in the untreated group. However, the increase in apparent BMD in the testosterone plus letrozole group was statistically significant only at 18 months, 6 months after discontinuation of letrozole treatment. Moreover, a decrease in BMD was observed in four letrozole-treated boys, but in only one of the boys treated with testosterone alone. These findings suggest that 1-year treatment with an aromatase inhibitor in pubertal boys is unlikely to have any major harmful effect on BMD and the attainment of peak bone mass, but such short-term studies do not diminish the clear effects of long-term estrogen deficiency (i.e., aromatase deficiency) on the developing male skeleton.

Consistent with these findings, several other interventional studies have found significant effects of estrogen on the adult male skeleton. Thus, in a preliminary study, Taxel and Raisz *et al.* (1997) treated nine elderly men with either 0.5 mg or 2.0 mg daily of micronized 17β-estradiol and found significant reductions in bone resorption markers. In addition, Anderson *et al.* (1997) treated 21 eugonadal men with osteoporosis with intramuscular testosterone and found a significant increase in lumbar spine BMD, which was correlated with changes in serum estradiol, but not testosterone levels.

Collectively, then, the observational and direct interventional data now provide conclusive evidence for an important and, indeed, dominant role for estrogen in the male skeleton. Moreover, given the data noted earlier on age-related decreases in serum bioavailable estradiol levels over life in men, a plausible hypothesis is that this decline is primarily responsible for age-related bone loss in men. Clearly, further studies are needed to address this issue.

SKELETAL EFFECTS OF ESTROGENIC COMPOUNDS IN MEN

Results from the short-term interventional observations also opened the way to studies on the use of estrogenic compounds in men. Indeed, short-term low doses of estradiol have been successfully employed to increase growth velocity in prepubertal boys (Caruso-Nicoletti *et al.*, 1985). Major concerns of either androgen and estrogen treatment in men relate to their possible collateral negative implications in other estrogen targets, such as the gonads, the prostate, and the cardiovascular system. Of interest, in the study on androgen supplementation in eugonadal men with osteoporosis, the increase in BMD and the reduction in bone turnover positively correlated with change in estradiol, but not in testosterone levels (Anderson *et al.*, 1997). Thus, it is likely that the therapeutic skeletal effects of androgens in men are owing, at least in part, to their conversion to estrogens.

Evaluating the potential of estrogen replacement therapy in healthy men is ethically and socially problematical because of the potential risk of estrogen-induced feminizing effects. To date, available data about estrogen replacement and bone in men pertain almost exclusively to the short-term and long-term treatment of aromatase-deficient subjects. Under estradiol (but not testosterone) treatment, these men experience the desired effects, namely ephiphyseal closure, bone maturation, and restoration of bone mass and size. Importantly, a threshold estradiol treatment dosage was evident in these studies, with doses of transdermal estradiol below 25 μg twice weekly (corresponding to achieved serum estradiol levels below 88 pmol/L) being ineffective in preventing bone loss (Rochira *et al.*, 2000). In these cases, treatment with estradiol did not induce gynecomastia, hyperprolactinemia, behavioral or sexual dysfunction.

Given their preliminary *in vitro* inhibitory effects in human prostate cancer cell lines (Kim *et al.*, 2002) and the lack of feminizing effects, selective estrogen receptor modulators (SERMs) such as raloxifene, have been recently regarded for potential application in men, including the prevention of bone loss. Indeed, another first-generation SERM, tamoxifene, has been administered to men as a fertility-promoting drug, without relevant adverse side events (Vandekerckhove *et al.*, 2000). Its effects on male bone are

unknown, but increases in serum LH, FSH, and testosterone were observed. In a single study of men receiving a GnRH agonist for prostate cancer, raloxifene treatment (60 mg/day) for 12 months increased BMD at the hip and the spine and decreased bone turnover markers (Smith *et al*., 2004). The changes in BMD were comparable to those observed in postmenopusal women treated with raloxifene at the same doses (Delmas *et al*., 1997). Apart from these observations in men with GnRH-induced severe hypogonadism other studies recently investigated the skeletal effects of raloxifene in healthy men. In a first study of 50 elderly men, raloxifene treatment (60 mg/day) for 6 months was no different from placebo in terms of its effects on urinary cross-linked N-telopeptide of type I collagen (NTX) (Doran *et al*., 2001). However, consistent with the threshold estradiol hypothesis, changes in urinary NTX were related directly to baseline serum estradiol levels. Subjects with serum estradiol levels below 96 pmol/L (26 pg/mL, corresponding approximately to serum bioavailable levels of 9 pg/mL) responded to raloxifene with a decrease in bone resorption marker. In this group, raloxifene was serving as an agonist. Above this estrogen value, raloxifene caused an increase in bone resorption. In this group with higher estrogen levels, raloxifene was acting as an estrogen antagonist. This seems to be remarkably comparable to the findings of a similar study in which raloxifene was given at a greater dose (120 mg/day) for 6 weeks in middle-aged eugonadal men (Uebelhart *et al*., 2004). In fact no major relevant effect on bone resorption and formation markers was observed in the overall raloxifene-treated group, whereas in the group of subjects with estradiol levels below a threshold value of 101.8 pmol/L, raloxifene treatment was associated with a significant decrease in bone turnover markers. In this study, as well as in a somewhat longer study (Duschek *et al*., 2004), 120 mg/day doses of raloxifene significantly increased serum concentrations of LH, FSH, estradiol, and total or bioavailable testosterone. The increase in estradiol after raloxifene treatment was more pronounced in those subjects with a low baseline serum estradiol level. No major treatment-related adverse events or feminizing effects were observed in these studies.

Thus, in men, raloxifene treatment might exert beneficial effects on bone metabolism only if serum concentrations of estradiol are low. Additional studies on raloxifene and other SERMs under development are needed to determine whether these compounds can be useful in the treatment of osteoporosis in hypogonadal men.

INTRODUCTION

By increasing peak bone mass and subsequently maintaining or decelerating bone loss, exercise is a critical deterrent to osteoporosis, a goal achieved through bone tissue's sensitivity to its mechanical loading environment. There is mounting evidence from clinical and animal studies that these physical stimuli are strong influences on both the quantity and quality of the skeleton, yet identifying those specific components of the loading milieu that can be both anabolic as well as antiresorptive has proven difficult. Perhaps improving our understanding of the biological mechanisms by which these physical signals regulate skeletal tissues will help to translate this information to the clinic, and enhance the potential of a non-drug-based deterrent and/or treatment for osteoporosis.

A host of human-based studies have worked toward quantifying the impact of general and specific exercise regimens on bone mass and morphology, taking into account interdependent variables such as gender, age, and nutritional status of the individuals. Although some studies have provided encouraging results, the large majority of data have been equivocal, perhaps as much a reflection of our limited understanding of which specific components of the mechanical signal are perceived as anabolic and anticatabolic by the resident bone cell populations (e.g., osteocytes, osteoblasts, lining cells, and osteoclasts), and which are irrelevant byproducts of loading. The design of an "optimal" exercise intervention (e.g., least amount of physical exertion for the greatest gain in skeletal strength) will require many critical questions to be addressed, such as: should the exercise protocol incorporate large loads or could they be small if they are applied rapidly? How long does an individual have to exercise to maximize benefits? Are the attributes of mechanical loading accumulated, or is there a threshold past which additional challenges no longer are perceived as regulatory influences to the skeleton? Can exercises be designed to stimulate bone formation at skeletal sites most prone to fracture or is the response systemic to a given skeletal segment?

Here, we define the functional mechanical environment of bone to demonstrate that the ability of physical signals to influence bone morphology strongly depends on the character of the signal, and we provide an overview of the molecular and cellular events that play a role in transducing the mechanical signal into a biochemical message. Understanding the precise physical and molecular factors of the mechanically derived signal is critical toward developing biomechanical prophylaxes that are clinically feasible, enjoy high compliance, and can prevent the bone loss leading to osteoporosis. If components of exercise can also suppress muscle loss and preserve postural stability, then these physical signals may represent a more comprehensive strategy than drugs to prevent the degradation of the musculoskeletal system and thus reduce chance of injury. As an example that mechanical signals need not be large to be effective and that the application of mechanical signals is not synonymous with strenuous exercise, the potential of extremely low-level, high-frequency mechanical signals is described.

BONE'S SENSITIVITY TO MECHANICAL SIGNALS

The skeleton's ability to adapt to altered levels and patterns of mechanical loading is well established but the difficulty lies in defining the specific osteoregulatory component(s)

*Corresponding author: Clinton T. Rubin, Department of Biomedical Engineering, Psychology A, State University of New York at Stony Brook, Stony Brook, NY, 11794-2580, Phone: 631-632-8521, FAX: 631-632-8577, E-mail: clinton.rubin@sunysb.edu

that is embedded within the bone's complex loading environment. Numerous clinical exercise studies have failed to relate adaptive changes in bone to specific aspects of a particular exercise regimen including exercise mode (e.g., running, swimming, weightlifting), intensity (e.g., percent of maximal heart rate), duration, and frequency (number of times per month, week, day), reflecting the need to characterize bone's mechanical environment directly by the prescribed exercise parameters. Considering that bone adaptation is site-specific and focal in nature at both the organ and the tissue level, it should not be surprising that altered levels of bone formation or resorption are only weakly related to parameters that are systemic to the entire skeleton such as exercise mode or intensity.

At the organ level, the site specificity of exercise-induced bone adaptation is particularly obvious in tennis and squash players who display significant bone hypertrophy in the playing extremity but not in the contralateral arm that is not subjected to significant changes in loading. During physical activity, changes in the loading environment are not only very heterogeneous across the entire skeleton, but also within a bone. Reflecting this nonuniform environment, adaptation within a bone is also site-specific and some bone surfaces will change their osteoblastic or osteoclastic activity but others will not. For example, subjecting an adult rooster to high-speed running may activate as little as 23% of previously quiescent periosteal surfaces in the middiaphysis of the tarsometatarsus (Judex *et al*., 1997).

To define the mechanical osteogenic components, experimental, analytic, and empiric models have been developed. Through the past three decades, specific components of the mechanical milieu have been proposed as the dominant stimulus for bone adaptation, including strain magnitude (Rubin and Lanyon, 1985), strain rate (O'Connor *et al*., 1982), electrokinetic streaming currents (Pollack *et al.*, 1984), piezoelectric currents (Bassett, 1968), fluid shear flow (Weinbaum *et al*., 1994), and strain energy density (Fyhrie and Carter, 1986). Although several of these parameters correlate with specific skeletal morphologies, few have validated their regulatory role with an accurate, prospective prediction of adaptation as stimulated by changes in loading conditions (Gross *et al.*, 1997). The difficulty in identifying a unifying principle that can anticipate the mechanical control of bone adaptation may be aggravated by an underlying "structural" assumption that tissue efficiency (minimal skeletal strain/minimal skeletal mass) is itself the driving stimulus that regulates the remodeling process.

Alternatively, bone cells may be responding to "biologically relevant" parameters of the functional milieu that are not necessarily linked to minimizing deformation of the structure under load. In support of "other than peak" signals regulating bone adaptation, examples of biological systems that perceive and respond to exogenous stimuli, such as vision, hearing, and touch are regulated in this fashion. It is also well accepted that too much loading will damage the bone, leading to failure (just as too much light, noise, or pressure will overwhelm sight, hearing, and touch). To identify the criteria by which the skeleton responds to its loading environment, it is important to look beyond the material consequences of a structure subject to load and consider the biological benefit of a viable tissue subject to functional levels of strain.

BONE'S MECHANICAL MILIEU ENGENDERED BY PHYSICAL ACTIVITY

Strains in Bone

To gain insight into the structural demands that are placed onto the skeleton during daily activities, the mechanical environment that bone is subject to can be characterized. In contrast to the notion that bone is purely loaded under compression, these experiments have definitively demonstrated that the long bones of the appendicular skeleton are also subject to a complex array of forces and moments produced by torsion and bending even during very simple activities such as steady-state locomotion. The mechanical state in the bone matrix is commonly quantified by spatial and temporal measures that are based on mechanical strain (ε), the dimensionless expression of deformation as explained elsewhere in this book (ε = change in length, ΔL, normalized to the original length, L, of any given specimen). Because of the very small deformations that bone experiences during physiological loading, strain is typically expressed as microstrain (1% deformation = 0.01 strain = $10{,}000 \times 10^{-6}$ strain = $10{,}000\,\mu\varepsilon$).

Strain is a ubiquitous product of a functionally loaded skeleton, regardless of its specific design or function. Mechanical strain and its derivatives are therefore considered an efficient means of translating exercise intensity, duration, and manner into a site-specific regulatory signal that can be recognized by the cells that control bone adaptation. One obvious goal of this strain-mediated form/function adaptation is to avoid catastrophic failure, or bone fracture. This requires that bone loading and architecture must be coordinated to avoid tissue's yield strain over 0.7% (7,000 microstrain). Through strain gauges surgically implanted onto bone's surface, strain magnitudes have been determined during functional activities in a great variety of species including humans, dogs, primates, roosters, horses, sheep, and rats (Burr *et al.*, 1996; Gross *et al.*, 1992; Lanyon, 1971). Although these gauges only record deformation from the specific sites that they are attached to, mechanical models can be used to extrapolate measured deformations to other sites within the bone.

Peak strain magnitudes measured in diverse vertebrates range from 2000 to 3000 microstrain (Rubin and Lanyon, 1984a). Whether measured in the third metacarpal

of a galloping horse, the tibia of a running human, the humerus of a flying goose, the femur of a trotting sheep, or the mandible of a chewing macaque, this "Dynamic Strain Similarity" suggests that skeletal morphology is adjusted such that functional activity elicits a very specific (and perhaps beneficial) level of strain to the bone tissue (Rubin *et al*., 1990). That strains of this magnitude are at least a factor of two below the yield point of bone material emphasizes that bone has a safety factor of about 2 to 3 to accommodate abnormal loading events. However, the realization of a mechanism by which the skeleton anticipates to be loaded to about half its yield strength seems overly complex and unlikely. Instead, *in vivo* and *in vitro* data suggest that the functional criteria that regulate adaptation, and the means by which bone cells perceive and respond to their functional milieu are more sophisticated than a mechanism that simply focuses on the magnitude of the deformation generated in the tissue. In fact, accumulating data suggest that morphological adaptation to biophysical stimuli occurs to encourage specific components of the strain milieu, as a means of promoting site-specific adaptation.

Locomotion Induces a Nonuniform Strain Environment

During locomotion, bending is the dominant form of loading in the middiaphysis of limb bones; more than 85% of the strain measured in diaphyseal long bones is accounted for by bending moments (Rubin and Lanyon, 1982). These middidphyseal bending moments are caused by bone curvature as well as applied bending moments and generate compressive strains on one side of the cortex and tensile strains on the opposite side (Fig. 1). The dominance of bending in the functional loading environment is somewhat counterintuitive because far less bone mass would be required to support the same loads if the bone were loaded axially. Nevertheless, bending may be beneficial to bone because it creates a nonuniform strain environment that is more diverse than uniform compression, thereby enabling signaling pathways that could not be generated by uniform loading. Perhaps more importantly, bending causes consistent, predictable loading conditions in which specific regions within the cortex are loaded in a similar fashion independent of the functional activity. To demonstrate this stability of the functional strain environment, roosters were subjected to three distinct loading environments engendered by treadmill walking, treadmill running, or drop jumps for which roosters were released from a 50- to 60-cm height. Tarsometatarsal middiaphyseal strain magnitudes and distribution were determined via strain gauges and linear beam theory (Judex and Zernicke, 2000b). We found that peak compressive strains produced by these three activities increased from −1570με for walking to −1870με for running and −2070 με for jumping. Despite this increase in peak strains, the relative distribution of strain across the middiaphysis was qualitatively identical across the three activities.

With bending causing tension on one surface and compression on another, the transition between these two areas creates a region of the cortex that experiences very low peak strain magnitudes. Even though this neutral axis is far removed from the area of the cortex subject to the peak strains, somehow tissue is retained in this low-magnitude strain state. A conceivable mechanism to save bone from resorbing in this region could be differential coupling of bone cells to the matrix with cells in low-strain regions being tightly coupled and cells from peak strain regions being more loosely coupled to the matrix. In this way, the cells have "tuned" themselves to the mechanical strain environment, a means of functional adaptation at the level of the cell.

Although a high degree of bending in loaded bone may provoke nonuniform strain distributions, it does not necessarily preclude the possibility of an adaptive mechanism mediated by some aspect of strain. It might be suggested that bone cells in different regions of the cortex are differentially sensitive to strain (e.g., some cells strive to 3000 με in compression, some to 1500 με in tension; others—near

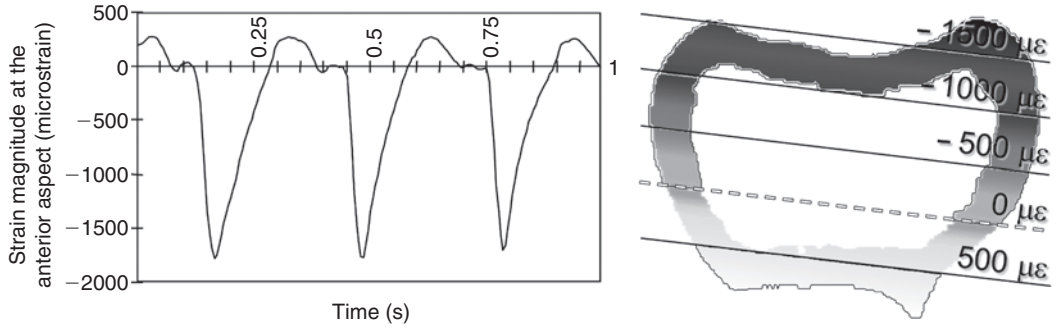

FIGURE 1 Recording from a strain gauge attached to the anterior aspect of the middiaphyseal tarsometatarsus while the animal is running on a treadmill at a high speed (*Left*). The distribution of longitudinal normal strain magnitude about the middiaphysis of the rooster tarsometatarsus. The distribution above was recorded at that point in the stride in which peak strain is achieved. Although the distribution of peak strain is very spatially very nonuniform, the manner in which the bone is loaded remains constant (i.e., the site of peak strain varies very little during the stance phase of a gait cycle. Adapted from Judex *et al*. (1997).

the neutral axis—are content with strains of 50 or 100 με). Although this is appealing in its simplicity, the apparent limitations of a spatially specific strain sensitivity are apparent with respect to the required genetic logistics. Alternatively, it is possible that strain information is spatially integrated in three dimensions via a cell network facilitated by gap junction intercellular communication (Donahue *et al.*, 1995), such that the area of the cortex subject to 100 με resists resorption owing to sufficient homeostatic signals received from neighboring areas subject to much higher strains. This "information integration" perspective is supported by the observation that the bone loss that parallels disuse occurs uniformly about the cortex and through the diaphysis, even though the net change in bone strain caused by the absence of function varies widely (Gross and Rubin, 1995).

The Influence of Muscle on Bone's Strain Environment

Although the symbiotic relationship between muscle and bone is inherently obvious, only seldom is it explicitly considered in the context of one defining the other. In the absence of ground reaction forces, the spectral components of muscle contraction typically impose smaller strains on the skeleton than those caused by functional impact loading. Even though muscle-induced strains may be small, they are sustained for extended periods of time (e.g., in postural muscle activity), and thus, over time, may dominate a bone's characteristic "strain history." Examining this hypothesis, strain data from a variety of animals reveal the existence of a broad frequency range of strains in the appendicular skeleton, even during activity such as quiet standing (Fritton *et al.*, 2000) (Fig. 2).

From a stimulus standpoint, these persistent, low-amplitude, high-frequency signals may, when summed, be at least as important as the seldom occurring, and somewhat unpredictable, peak strain events. If there is an age- or pathologically-induced change in the dynamics of these muscle oscillations, it could be argued that bone mass may deteriorate because these muscle-based signals also attenuate. To determine the role of muscle dynamics in the etiology of osteopenia, the spectral characteristics of muscle activity as a function of age were obtained through measurements of muscle surface vibration (Huang *et al.*, 1999).

During the contraction of a muscle, radial expansion of the individual fibers results in fiber collisions and the production of muscle sound or acoustic vibrations of the muscle body. The frequency of these vibrations reflects the firing rate of the motor units, and correspondingly, the force output of the motor unit. When recorded in 40 volunteers (20 to 83 years of age) using a low-mass accelerometer, the spectra of the acoustic vibrations normal to the surface of the soleus muscle showed that muscle activity in the frequency range above 20 Hz decreased by a factor of three in the elderly compared with that seen in young adults, a sarcopenia consistent with loss of fast oxidative-type fibers. Simultaneous with the decay of high-frequency signals, there is a marked decrease in the amount of type IIa and IIb fibers (Lee *et al.*, 2006), compounding the suppression of the source of the signal.

As the high-frequency components seen in bone during load bearing almost certainly arise through muscle activity, the deterioration of the muscle contraction spectra with age would consequently decrease the spectral content of bone strain above 20 Hz. From this perspective, it can be argued that the sarcopenia of aging may be a principal etiological factor in osteoporosis, as this portion of the strain spectra is demonstrably osteogenic. If aging leads to the loss of specific muscle fibers critical to the maintenance of bone mass, osteoporosis could presumably be inhibited by providing a "surrogate" for the lost spectral strain history.

REGULATION OF BONE MORPHOLOGY BY MECHANICAL STIMULI

Toward Identifying the Osteogenic Parameters of the Strain Milieu

It is clear that the skeleton is subject to a wide range of mechanical signals, including low- to high-frequency strains, normal and shear strains, and compressive and tensile strains. It is also clear that the cells on and within the mineralized matrix are subject not only to mechanical parameters such as strain, but derivatives of tissue deformation such as fluid flow and electrokinetic currents, parameters that may represent an important physiological pathway in mediating an adaptive response. But which physical parameters are most important to regulating the adaptive response?

Models that have been used to investigate bone's adaptive response to its mechanical environment include overloads by osteotomies (Lanyon *et al.*, 1982), vigorous exercise (Judex and Zernicke, 2000a), or exogenous loading models in which external forces are applied to the bone. Physical exercise represents a physiological means of enhanced mechanical loading but the limited exercise repertoire of most laboratory animals makes it difficult to generate and control distinct mechanical milieus. Exogenous loading models such as the functionally isolated avian ulna (Rubin and Lanyon, 1984b), the axially loaded rat ulna (Torrance *et al.*, 1994), or the rat tibia placed in a four-point bending apparatus (Turner *et al.*, 1991) allow the generation of controllable mechanical environments, but a disadvantage of some these models is that the morphological response may be confounded by injury caused by the means of load application.

Perhaps guided by putative form–function relations between bone's strain environment and modeling and remodeling processes in bone, researchers' attention has focused primarily on strain magnitude as the dominant determinant of

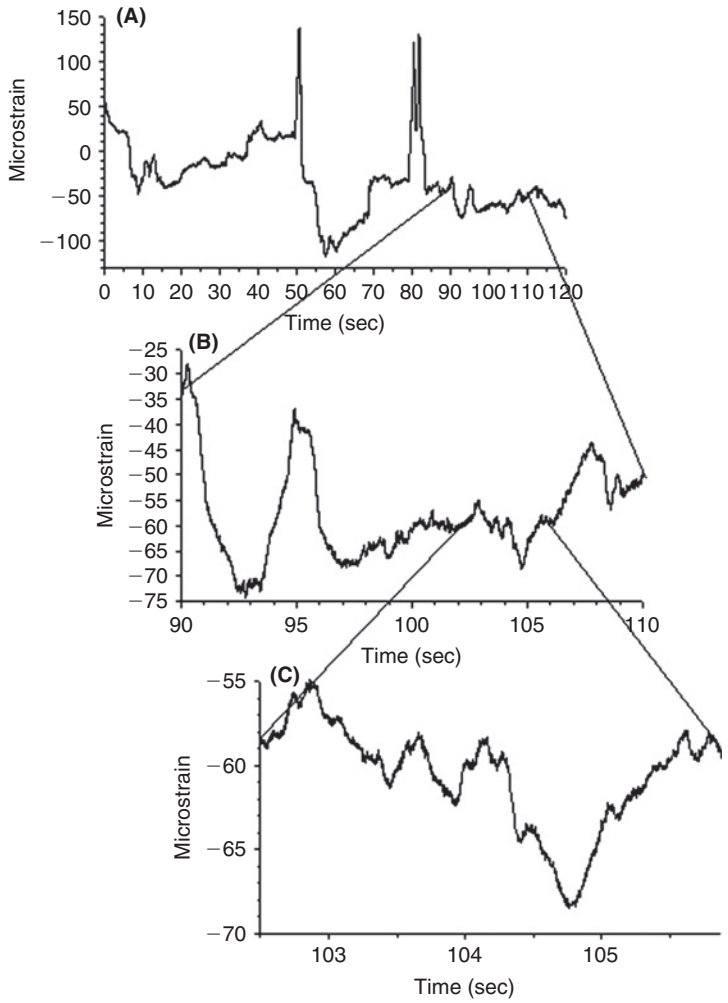

FIGURE 2 (**A**) A 2-minute strain recording from the caudal longitudinal gauge of the sheep tibia while the animal took a few steps with peak strains on the order of 200 με. (**B**) A 20-second portion of that strain record shows peak strain events as large as 40 με. (**C**) Further scaling down to a 3-second stretch of the strain recording illustrates events on the order of 5 με. Adapted from Fritton *et al*. (2000).

bone mass and morphology. Other parameters have received only limited attention. Isolating the effect of a single mechanical parameter is not trivial owing to the interdependence of many of the parameters. For a commonly used sinusoidal loading pattern, changing strain magnitude while maintaining a constant loading frequency, for example, results in a concomitant change in strain rate. Despite these difficulties, several mechanical parameters have emerged from controlled experimental studies that related the mechanical environment to induced morphological changes.

Strain Magnitude

When holding strain frequency and number of loading events constant, longitudinal normal strain magnitude (strain in the direction of bone's longitudinal axis) is highly related to the osteogenic response. In other words, the larger the maximal deformation that is generated in the bone, the larger the overall response of the bone. Strains, when applied at 1 Hz and to not reach a certain magnitude are permissive to bone loss. This relationship was first demonstrated in the functionally isolated turkey ulna preparation to which strains in the range of 500 to 4000 με were applied for 100 cycles per day. In this model, the ulna of adult male turkeys is functionally isolated by proximal and distal epiphyseal osteotomies, leaving the entire diaphyseal shaft undisturbed. The only stimuli applied to the diaphysis are the mechanical regimen prescribed by the investigators, with no aberrant biophysical signals entering the preparation. In this model, strains smaller than 1000 με caused bone loss with strains larger than 1000 με leading to new bone formation in a dose-dependent relationship.

The question as to how much strain in bone has to be generated to obtain an osteogenic effect depends on the interrelationship between strain magnitude, strain rate, and strain frequency. Although in the previously described isolated turkey ulna preparation, 100 loading cycles per day at 1 Hz

inducing 1000 με prevented bone loss from occurring, this threshold can be reduced to 700 με when 600 loading cycles are applied at 1 Hz, to 270 με when 36,000 loading cycles are applied at 60 Hz, or to 100 με when 108,000 loading cycles are applied at 30 Hz (Qin *et al.*, 1998). This demonstrates that the search for a particular strain (loading) threshold has to take other mechanical parameters into account as well and that this relationship can be exploited to design safer exercise regimens using smaller loads.

Differential Modeling/Remodeling to Distinct Components of the Strain Tensor

This goal of investigating the osteogenic effects of different aspects of the strain tensor has been approached using the turkey ulna model of disuse osteopenia, in which the modeling and remodeling response was quantified following 4 weeks of either axial or torsional loading or disuse (Rubin *et al.*, 1996). Each of the two load groups were subject to peak principal strains of 1000 με (predominately normal strain in the axial case, and shear strain when subject to torsion). Of the three distinct groups, only disuse caused a significant change in gross areal properties compared with controls (13% loss of bone). This suggests that both axial and torsional loading conditions are substitutes for the functional signals normally responsible for retention of bone mass, leaving the periosteal and endosteal envelopes unphased by disparate components of the strain tensor.

The intracortical response, however, was found to depend strongly on the manner in which the bone was loaded. Disuse failed to increase the number of sites within the cortex actively involved in bone turnover (intracortical events), yet significant area was lost within the cortex owing to a threefold increase in the mean size of each porotic site. Axial loading increased the degree of intracortical turnover compared with intact controls, yet the average size of each porotic event remained identical to that of control. Conversely, compared with control, torsion elevated neither the number of porotic events, the area of bone lost from within the cortex, nor the size of the porotic event. It appears that bone tissue can readily differentiate between distinct components of the strain tensor, with strain per se necessary to retain coupled formation and resorption, shear strain achieving this goal by maintaining the status quo, whereas normal strain elevates intracortical turnover, but retains coupling. Thus, not the aggregate of strain per se may define bone remodeling, but independent components of the strain tensor may have differential responsibilities in achieving and maintaining bone mass.

Strain Rate

Although strain magnitude appears to be an important determinant of bone mass, it is critical to realize that dynamic but not static strains have osteogenic potential. At the extreme, static loading (strain rate = 0) at strain magnitudes capable of stimulating formation when applied dynamically produces a remodeling response similar to disuse resulting in bone resorption (Lanyon and Rubin, 1984). Several studies support the notion that bone is sensitive to the applied strain rate, with higher strain rates being more osteogenic (Lamothe *et al.*, 2005).

For instance, high-speed running ($1.7\,ms^{-1}$) increases peak strain magnitudes by approximately 20% in the middiaphyseal tarsometatarsus of roosters compared with walking ($0.5\,ms^{-1}$). This increase in strain magnitude was not accompanied by additional bone formation in the tarsometatarsal middiaphysis when growing roosters were exercised for 15 minutes per day (~2600 loading cycles) for 8 weeks. An exercise intervention was then designed, that employed high-impact drop jumps for which growing roosters were lifted off the ground and released. Middiaphyseal tarsometatarsal peak strain magnitudes induced by this exercise were similar to those induced by high-speed running but strain rates were increased by 260% (0.32 ε/s vs. 0.09 ε/s). In contrast to the running protocol, 200 drop jumps per day for 3 weeks significantly increased bone formation rates at periosteal (+40%) and endocortical surfaces (+370%). As the other mechanical parameters considered between running and drop-jumping were similar, the differential osteogenic effect associated with these two exercise protocols could be attributed directly to the large difference in generated strain rates. Site-specific analyses within the middiaphyseal cortex revealed that drop-jumping deposited additional bone preferentially in those regions that were subjected to the largest strain rates, further emphasizing bone's sensitivity to high strain rates.

Extrapolated for the design of exercise interventions, these results imply that loads should be applied rapidly. Although exercise studies have been unable to identify a specific exercise intervention that is most effective in producing beneficial skeletal effects, a trend has emerged with high-impact exercise being more efficient than low-impact exercises in terms of stimulating new bone formation. This trend may support the notion that high strain rates have a critical impact on bone morphology as high-impact exercises ostensibly induce higher strain rates.

Cycle Number

A threshold behavior exists for the number of loading cycles. The full response can be triggered after only a limited number of loading cycles (Umemura *et al.*, 1997). In the functionally isolated turkey ulna preparation, a loading regime inducing peak strains of approximately 2000 με maintained bone mass with only four cycles a day. When the cycle number was increased, this particular loading regime stimulated new bone formation. Thirty-six load cycles saturated the osteogenic response, with as many as 1800 cycles being not

more effective than 36 cycles. The notion that a finite number of loading cycles employing large loads may increase BMD or inhibit bone loss is supported by exercise studies involving weight lifters. It is critical to realize, though, that the saturation threshold to cycle number is influenced by other mechanical parameters including strain magnitude.

Further, recent studies have indicated that the manner in which loading cycles are distributed plays an important role in defining the magnitude of the anabolic response. Partitioning a given bout of loading cycles into several loading sessions can increase bone's response to the mechanical intervention (Robling *et al.*, 2002). Going one step further, recent studies have shown that this concept can be exploited to produce a mechanical intervention that is more efficacious despite providing fewer loading cycles (Gross *et al.*, 2004). This loading paradigm that has been labeled rest inserted loading adds as little as ten seconds of rest after each loading cycle within a bout and has been shown to transform an otherwise ineffective loading regime into a highly osteogenic stimulus. The mechanisms by which the sensitivity of cells to mechanical signals is increased by rest inserted loading may be associated with high cell refractory periods that, upon the application of a single loading event, impose a "time out" to the cells during which it cannot respond to another cycle. Alternatively or in addition, including rest into the loading regime may enhance bone fluid flow, synchronize osteocytic activity, and enhance cell communication.

Strain Distribution

Although a relation between peak strain magnitude generated in a bone and the resulting adaptive response has been proposed, bone also appears to be sensitive to how the strains are distributed across a bone section. Simply imposing a strain distribution that produces similar peak strain magnitudes as habitual loading conditions—but at different locations within the section (i.e., rotating the strain distribution)—may initiate new bone formation (Rubin and Lanyon, 1987). Thus, unusual strain events (strain errors) have been suggested to drive bone adaptation. Running, for instance, may not be the osteogenically optimal exercise partly because it may generate strain distributions that are very similar to strain distributions induced by normal walking. Interestingly, sports that involve a great variety of changes in loading directions such as soccer or badminton have been suggested to possess a higher osteogenic capacity, although it has not been confirmed that these changes in loading directions actually cause altered bone strain distributions.

Strain Gradients

Parameters such as peak strain magnitude or strain rate were primarily tested at the organ level. In other words, the region of the bone that was studied in response to a given mechanical stimulus was large (e.g., the middiaphysis of a long bone) and encompassed a large range of strain magnitudes. Rather than simply considering the peak magnitude of the stimulus and averaging the morphological response across a section, one could investigate whether new bone is actually deposited in those regions where the applied stimulus is the largest (i.e., the distribution of a mechanical parameter can be correlated with the distribution of bone's response). If such a site-specific relationship exists, then the knowledge of this specific osteogenic component may provide information about a mechanism by which bone cells perceive their mechanical environment. Further, if a particular mechanical parameter is capable of consistently predicting the specific sites of bone formation in different models, then exercise interventions could be designed that deposit bone at sites where additional structural strength is required.

This issue was addressed in an exercise study in which young adult roosters were ran on treadmill for 9 minutes per day (~1500 gait cycles) for 3 weeks. Strain gauges were attached to the tarsometatarsus to determine the distribution of candidate mechanical parameters across a middiaphyseal section. Periosteal activation (as measured by histomorphometry) as well as mechanical parameters, such as strain magnitude, strain rate, and strain gradients, were spatially quantified in transverse section thus, enabling a site-specific correlation with each other. The brief daily running regime activated periosteal surfaces but the amount of periosteal mineralizing surfaces per sector was only weakly associated with strain magnitude ($R^2 = 0.24$, negative correlation). In contrast, circumferential strain gradients (changes in strain magnitude across a volume of tissue) correlated strongly ($R^2 = 0.63$) with the sites of periosteal activation, consistent with earlier results from an external loading model. In general, circumferential strain gradients are largest where strains (deformations) are the smallest. Although it is counterintuitive from a structural (engineering) perspective that new bone formation is activated at sites subjected to low strains rather than large strains, strain gradients drive fluid flow in bone in the matrix, a process that has been implicated to play an important role in mechanotransduction in bone. These data further emphasize that bone adaptation is not necessarily guided by form–function relations, rather that bone cells respond to a biological signal resulting from the application of mechanical loads.

Fluid Flow

It is clear that the cells on and within the mineralized matrix are subject not only to mechanical parameters such as strain, but derivatives of tissue deformation such as fluid flow and electrokinetic currents, parameters that may represent an important physiological pathway in mediating an adaptive response. Bone cells, in particular osteocytes, are surrounded by extracellular fluid. The driving force for fluid to

flow is a pressure differential between two ends of a lucanar–canalicular system that experience different amounts of mechanical strain, both temporally and spatially. Fluid flow is thus a direct by-product of mechanical strain and a large body of *in vitro* studies has shown the sensitivity of bone cells to flow (Rubin *et al*., 2006). Because of the tight coupling between mechanical strain and fluid flow under physiological conditions *in vivo*, only few studies have successfully increased fluid flow in controlled animal models (Qin *et al*., 2003). Similar to *in vitro* data, raising intramedullary pressure, and thus enhancing interstitial bone fluid flow, can increase bone formation (Stevens *et al*., 2006). The *in vivo* mechanism(s) by which bone cells sense and respond to fluid flow have not been elucidated but may be related to one of the following processes: (1) fluid pressurization directly stimulates cells, (2) interstitial fluid flow fluid excites osteocytes through fluid shear stresses, (3) drag forces perturb the osteocytic processes in the pericellular matrix, (4) fluid flow aids in the transport of nutrients to bone cells, or (5) electrokinetic effects such as streaming potentials. Together, *in vitro* and *in vivo* studies clearly demonstrate that bone fluid flow is capable of transducing mechanical signals from the matrix to the cell but it should be noted that no definite study has been performed to demonstrate that biophysical events produced by fluid flow are involved in mechanotransduction of physiological loading events *in vivo*.

LOW-MAGNITUDE, HIGH-FREQUENCY MECHANICAL SIGNALS

A common theme of the mechanical parameters described earlier is that only peak events are considered (e.g., peak strain magnitude, peak strain rate, peak strain gradients). From this, one could conclude that mechanical modulation of bone physiology depends on large signals to have any morphological impact. However, the weak correlation of new bone formation with exercise intensity or with the specific sites of peak strain magnitudes suggests that other factors may also be relevant for defining bone mass and morphology. As discussed earlier, *in vivo* data suggest a nonlinear interdependence between cycle number, strain frequency, and strain magnitude. When the turkey ulna was loaded at 1 Hz, peak strains larger than 700 με were necessary to maintain bone mass. This loading threshold can be reduced to 400 με at 30 Hz and to 70 με at 30 Hz. Although the reduction in strain threshold could be associated with an increase in cycle number, it is most likely that the increase in frequency at which loading occurred played a large role. Indeed, over the past decade, we and others have demonstrated that bone can sense and respond to even extremely small mechanical signals if they are applied at high frequencies. Below are examples of studies suggesting that the skeleton can benefit from these small mechanical signals under normal as well as disturbed physiological conditions.

Low-Level Mechanical Signals Increase Bone Quantity and Strength

To examine the long-term influence of applying short bouts of extremely low-magnitude, high-frequency signals, adult sheep stood in a chute such that only the hind limbs were subject to a vertical ground-based vibration, oscillating at 30 Hz, to create peak–peak accelerations of 0.3 *g* (Rubin *et al*., 2001a). When the animals were not being treated, they pastured with controls. After 1 year of stimulation, pQCT at the lesser trochanter demonstrated a 34.2% increase in trabecular density in mechanically stimulated sheep ($P < 0.01$). Microcomputed tomography indicated that not only the quantity of trabecular bone had benefited but also its microarchitecture (Rubin *et al*., 2002b). Trabecular Bone Pattern factor, an index of connectivity, decreased 24.2% in animals subject to the noninvasive stimulus ($P < 0.03$), reflecting an increase in connectivity of the trabecular struts. Histomorphometry emphasized that the increase in volume fraction was achieved through an anabolic stimulus (Rubin *et al*., 2002a). The elastic modulus and stiffness of the bone subject to the low-level mechanical stimulus also increased significantly (Fig. 3) and analyses of the tissue-level stresses and strains indicated that, micromechanically, the bone had to adapt to become a mechanically more efficient structure (Judex *et al*., 2003).

Low-Level Mechanical Signals Normalize Bone Formation

The one-year sheep experiments indicated the anabolic potential of low-level mechanical signals. The rat tail-suspension

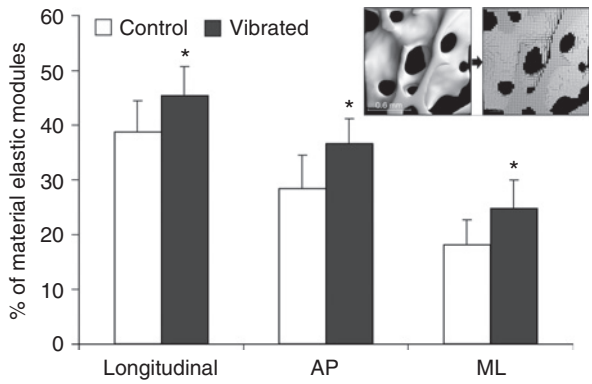

FIGURE 3 Finite-element modeling was used to convert the trabecular structure into a mechanical model (see *Inset*). Simulated mechanical testing in all three orthogonal loading directions indicated that the application of short bouts of high-frequency mechanical signals increased trabecular stiffness. Shown is the apparent elastic tissue modulus expressed as percentage of the tissue elastic modulus for control and experimental sheep in the three directions (mean + SD). model of disuse osteopenia was to determine whether resorptive remodeling, as stimulated by disuse, could be suppressed with brief exposure to the vibrating plate (Rubin *et al.*, 2001b). A single-element strain gauge, attached to the tibia of calibration rats showed that the oscillation, at 0.3 *g*, generated strains less than 5 με at 45 Hz. Compared with long-term controls, 28 days of tail suspension caused mineralizing surface (MS/BS) of the tibiae to drop 52% ($P < 0.004$), and bone formation rate per bone volume (BFR/BV) to drop 72% ($P < 0.0002$). The suppression of formation was not significantly different from the animals subject to disuse for most of the day (23 hours, 50 minutes) and then allowed to freely bear weight for 10 minutes per day. However, 10 min/day of weight bearing on an active vibration platform normalized mineralizing surfaces and bone formation rates to normal weight-bearing levels. Based on these observations, high-frequency, low-magnitude, mechanical strains effectively served as a "surrogate" for musculoskeletal forces and, thus, may represent a countermeasure to the osteopenia that parallels disuse.

Vibrations can Decrease Resorptive Activity

To test the effects of these mechanical signals in the growing skeleton in which resorptive activity is relatively high, 8-week-old mice were subjected to daily 15-min bouts of whole-body vibrations at 45 Hz and 0.3 *g*. After three weeks, osteoclastic activity in the trabecular metaphysis and epiphysis of the tibia was 30% lower ($P < 0.05$) in vibrated mice than in age-matched controls. Bone formation rates (BFR/BS) on the endocortical surface of the metaphysis were 30% greater ($P < 0.05$) in WBV than in age-matched control mice, but trabecular and middiaphyseal BFR were not significantly altered. Importantly, the intervention did not negatively influence body mass, bone length, or chemical bone matrix properties of the tibia. These data indicate that, in the growing skeleton, short daily periods of extremely small, high-frequency mechanical signals can inhibit trabecular bone resorption, site-specifically attenuate the declining levels of bone formation, and maintain a high level of matrix quality. If WBV prove to be efficacious in the growing human skeleton, they may be able to provide the basis for a nonpharmacological and safe means to increase peak bone mass and, ultimately, reduce the incidence of osteoporosis or stress fractures later in life.

Genetic Variations Modulate Bone's Response to Mechanical Signals

It is well accepted that the genetic makeup of any given individual is a strong predictor of their risk of osteoporosis (Deng *et al.*, 2001). What is not as clear is if the genetic template can account for variability in the response to bone's ability to adapt to mechanical signals. To address this question, inbred mouse strains with distinct bone phenotypes (Judex *et al.*, 2004) were used to examine whether they were differentially sensitive to changes in their habitual mechanical environment (Judex *et al.*, 2002). Adult female mice, with relative thin (C57BL/6J), medium (BALB/cByJ), and robust (C3H/HeJ) skeletons were subjected to 10 min/day of low-level, high-frequency mechanical signals (0.25 *g* at 45 Hz). After three weeks, bone formation rates, with tissue volume as referent of C57BL/6J mice subject to the low-level mechanical signal, was 69% greater ($P < 0.04$) than in intrastrain control mice. Increased trabecular bone formation rates coincided with an 85% ($P < 0.01$) larger bone volume (BV/TV) and 50% larger trabecular thickness ($P < 0.009$) in the vibrated mice. In BALB/cByJ mice, the low-level mechanical signals increased BFR/BV by 34% ($P < 0.02$), but bone structural indices including BV/TV remained unaffected. In contrast to the responsiveness of the C57BL/6J and BALB/cByJ strains, no significant effects of mechanical stimulation were measured in tibial trabecular bone of C3H mice. Extrapolating these results to the human skeleton may provide insight into the preferential efficacy of mechanical interventions, such as exercise or low-level vibrations. The results of this study also suggest that some people who benefit from a genetically predetermined higher bone mass may ultimately be less sensitive to any form of physical intervention (Torvinen *et al.*, 2003).

Inhibition of Postmenopausal Bone Loss by Low-Level Vibrations

With the demonstration that mechanical factors can be anabolic and anticatabolic to the skeleton, a challenge becomes whether these "regulatory factors" can be safely and effectively administered in the clinic to inhibit or reverse osteopenia. The ability of a low-magnitude (0.2 *g*), high-frequency (30 Hz) mechanical stimulation to inhibit postmenopausal osteopenia was evaluated in a prospective, randomized, double-blind, placebo-controlled clinical trial (Rubin *et al.*, 2004). Sixty-two postmenopausal women were enrolled in the study. Thirty-one women underwent mechanical loading of the lower appendicular and axial skeleton for two ten-minute periods per day, induced via floor-mounted devices that produced the mechanical stimulus, whereas 31 women received placebo devices and underwent daily treatment for the same period of time.

An intention to treat analysis of DXA data of the spine (L1–4), proximal femur, and nondominant radius showed little effect of the intervention. In a *post hoc* analysis of those subjects that used the device at least 60% of the prescribed time, a linear regression of the means was used to show that lumbar spine bone mineral density (BMD) declined by −3.3% (±0.83) in the placebo group compared with only −0.8% (±0.82) in the treated group ($P < 0.03$), reflecting

a 2.5% benefit of the biomechanical intervention. A 3.3% treatment benefit was observed in the trochanter region of the hip, with a −2.9% (±1.2) loss observed in the placebo group, yet with a 0.4% (±1.2) gain in the treated group ($P < 0.03$). At the distal radius, no significant differences were observed as a function of time or between groups, emphasizing the mechanical influence to be locally delivered.

Stratifying the results based on patient body mass index (BMI), endpoint analysis confirms the relationship between svelte stature and a greater degree of osteoporosis (Aloia *et al.*, 1995; Martin *et al*., 1993); subjects with a BMI of less than 24 lost 2.5% (±0.6) BMD over the course of the year, whereas those with a BMI greater than 24 did not show any change over the 12-month period. This stratification also demonstrates the ability of mechanical stimulation to inhibit this bone loss in the group at greatest risk; in subjects with a BMI of less than 24 who received the mechanical stimulus, the bone loss in the spine was not significantly different than zero (+0.2%±0.7). The 2.7% difference between placebo and treatment groups was significant at $P < 0.01$. Treated subjects with BMI greater than 25 showed no apparent affect of treatment, perhaps because there was no bone loss to inhibit. Overall, these results indicated the potential of a noninvasive biomechanical therapy for osteoporosis, representing a nondrug means of inhibiting the decline of bone mineral density that typically follows the menopause.

Low-Level Mechanical Signals Are Anabolic to the Musculoskeletal System

Susceptibility to osteopenia is present early in life, the amount of bone gained during adolescence is a main contributor to peak bone mass in the young adult, and peak bone mass in the young adult is a determinant of osteoporosis in the elderly (Loro *et al*., 2000). A study was designed to establish if brief, daily exposure to extremely low-level mechanical stimuli were anabolic to musculoskeletal development in young females, 15 to 20 years of age, each in the lowest quartile of bone density in this age cohort and who had already sustained a fracture (Gilsanz *et al.*, 2006).

Half of the 48 enrolled subjects were subject to brief (10 min/day), low-level whole-body vibration (30 Hz, 0.3 *g*), with the remaining women serving as controls. CT performed at baseline and the end of study was used to establish changes in muscle and bone mass in weight-bearing regions of the skeleton. Using an Intention to Treat (ITT) analysis, cancellous bone in the lumbar vertebrae and cortical bone in the femoral midshaft of the experimental group increased by 2.1% ($P = 0.025$) and 3.4% ($P < 0.001$), respectively, compared with 0.1% ($P = 0.74$) and 1.1% ($P = 0.14$), in controls. Increases in cancellous and cortical bone were 2.0% ($P = 0.06$) and 2.3% ($P = 0.04$) greater, respectively, in the experimental group when compared with controls. Cross-sectional area of paraspinous musculature was 4.9% greater ($P = 0.002$) in the experimental group versus controls. When a per protocol (PP) analysis was performed, gains in both muscle and bone were strongly correlated to a threshold in compliance, where the benefit of the mechanical intervention compared with controls was realized once the device was used for at least two minutes per day ($n = 18$), as reflected by a 3.9% increase in cancellous bone of the spine ($P = 0.007$), 2.9% increase in cortical bone of the femur ($P = 0.009$), and 7.2% increase in musculature of the spine ($P = 0.001$), compared with controls plus the low-compliers (Fig. 4).

Short bouts of extremely low-level mechanical signals, several orders of magnitude below that associated with vigorous exercise, increased both trabecular and cortical

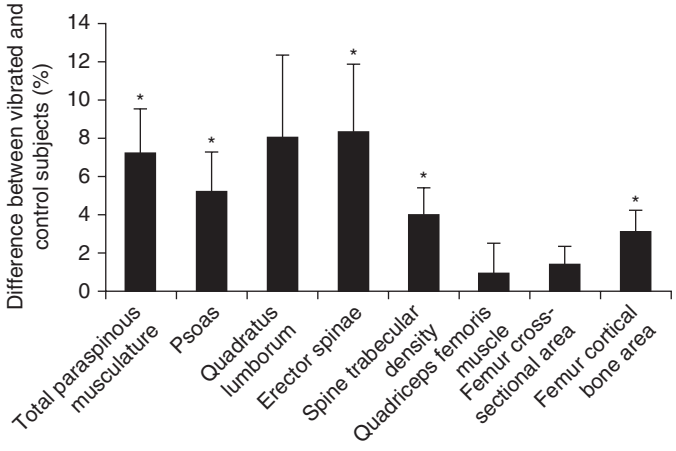

FIGURE 4 The difference in the change (mean + SE) of musculoskeletal parameters measured over the one-year period for young women who used the device for more than two minutes per day, compared with controls and women who stood on the vibrating plate for less than two minutes per day. With the exception of musculature around the femur and femoral cross-sectional area, the musculoskeleton of the experimental group benefited significantly (*) from the brief low-level mechanical intervention. Adapted from Gilsanz *et al*. (2006).

bone in weight-bearing regions of the skeleton. Further, muscle mass of the paraspinous region increased, suggesting that risk factors for fracture beyond bone quantity and quality could be mitigated. Low-level, high-frequency mechanical signals, even lower than those used in this study, have also been shown to preserve postural stability in an aging population (Gravelle *et al*., 2002), providing evidence that physical signals can serve to reduce risk factors of osteopenia, falling, and sarcopenia. Should these musculoskeletal enhancements be preserved through adulthood, this intervention may prove a deterrent to osteoporosis in the elderly.

Can Bone Differentiate between Two High-Frequency Signals?

To determine whether the responsiveness of bone to low-magnitude, high-frequency parameters is modulated by endocrine imbalance and whether one high-frequency signal may be more effective than another, ovariectomized (OVX) Sprague–Dawley rats were subjected to whole-body vibrations (WBV, 0.15 g) at 45 Hz ($n = 6$) or 90 Hz ($n = 6$) for 10 min/day, and compared to OVX age-matched controls ($n = 6$) (Judex *et al.,* 2007). Five additional rats were used, *in vivo*, to establish the induced bone surface strain magnitudes (and strain rates). Following a 28 day protocol, bone formation rates in the metaphysis of the proximal tibia were 159% greater in 90 Hz rats when compared with age-matched controls, but 45 Hz rats were not significantly different from controls. Bone morphology of 90 Hz rats indicated significantly greater trabecular bone volume (22% and 25%) and thicker trabeculae (11% and 12%) over either controls or 45-Hz rats in the epiphysis of the distal femur, respectively. Despite the enhanced sensitivity of the skeleton toward the 90-Hz signal, the strain magnitudes and strain rates induced by this frequency were significantly lower than during 45-Hz vibration. These data suggested that the efficacy of the low-level mechanical signal is maintained even in the absence of estrogen and factors other than matrix strain are driving the anabolic response.

How can Bone Sense a Signal so Small?

The studies above, contrasting with a more-is-better principle, suggest that matrix strains two orders of magnitude below a previously suggested threshold (Frost, 1987) can be anabolic to bone. The means by which such low-level mechanical signals can be anabolic to a tissue such as bone is not clear. If cortical matrix deformations of less than 0.001% strain, measured at the periosteum, were transduced directly to the resident osteoblast or osteocyte population, the deformation of the cell itself would be less than one Angstrom. Given that such deformations may be too small to be recognized by cells (Han *et al*., 2004), byproducts of matrix deformation, such as fluid flow-induced shear stresses, streaming potentials, fluid drag on pericellular processes, or enhanced nutrient transport, may contribute to a cell's responsiveness to mechanical signals (Malone *et al*., 2007a). Yet even these alternative pathways are dependent on matrix deformation and therefore will be very small in magnitude during low-level mechanical stimulation.

In contrast to a matrix deformation-dependent pathway for mechanotransduction, the frequency sensitivity of the adaptive system points toward a more fundamental, perhaps unrecognized, pathway by which physical signals interact with the tissues and cells. Indeed, a mechanism that would allow a cell to sense mechanical signals directly without reliance on matrix strain would obviate the need for compensatory tissue-level amplification mechanisms, reduce complexity in the system, and may provide cells with mechanical information without the potential for damaging the surrounding tissue. Our hypothesis is that the physical acceleration of a cell may present such a signal that can transmit physical challenges to a receptive cell population in an efficient and safe manner (Garman *et al*., 2007a). By removing bone's habitual loading environment and imposing very-small-amplitude oscillatory accelerations that induce motion but no direct deformation, we have recently tested this hypothesis (Garman *et al*., 2007b).

To this end, a device was developed that can deliver high-frequency accelerations to skeletal segments in the absence of weight bearing (Fig. 5). In an anesthetized murine model, the left tibia of each mouse was subjected to oscillatory 0.6 g accelerations at 45 Hz for 20min/day and the right tibia served as control. Oscillatory accelerations, applied in the absence of weight bearing, resulted in 70% greater bone formation rates in the trabeculae of the metaphysis, but similar levels of bone resorption, when compared with contralateral controls. Quantity and quality of trabecular bone also improved as a result of the acceleration stimulus, as evidenced by a significantly greater bone volume fraction (17%) and connectivity density (33%), and significantly smaller trabecular spacing (−6%) and structural model index (−11%). As expected, the matrix deformations induced by these motions are extremely small,

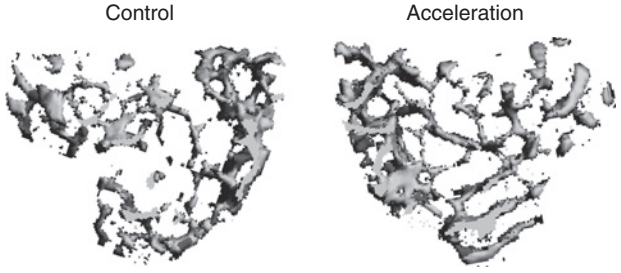

FIGURE 5 By applying very-low-level oscillatory accelerations to one leg of the anesthetized mouse while the other leg serves as a contralateral control, the efficacy of very small unconstrained motions that do not directly apply deformation to the matrix can be tested. Adapted from Garman *et al*. (2007).

however, and on the same order as those produced by postural stability. These *in vivo* data indicated that mechanosensory elements of resident bone cell populations can perceive and respond to acceleratory signals, and point to an efficient means of introducing intense physical signals into a biological system without putting the matrix at risk of overloading. Teleologically, accelerations represent a fundamentally efficient means of delivering regulatory physical information to the cell, and can be readily achieved even in the absence of matrix strains and large cellular deformations. In contrast to the previous studies in which transmission of the high-frequency mechanical signals relied on weight bearing (e.g., whole-body vibrations), the unique nature of the external applications of oscillatory motions ("shaking") may ultimately serve as an effective intervention for the prevention of bone loss in non-weight-bearing skeletal sites or in patients whose skeleton is incapable of bearing weight, such as during bed rest or space flight.

BIOCHEMICAL MODULATION OF MECHANICAL SIGNALS

Which Cells Sense the Stimulus?

It is clear that bone cells are able to sense their mechanical environment via a number of proposed mechanisms including direct matrix deformations, pressure and transient pressure waves, accelerations, fluid shear stresses, fluid drag forces, or even dynamic electric fields as interstitial fluid flows past charged bone crystals (Fig. 6). It is much less clear, however, which of the cells within a bone are the key sensory elements in mechanotransduction.

Mechanical responses of osteoprogenitor cells, including stromal cells, osteoblasts, and osteocytes, have all been documented without identifying the critical responding cell: for example, exposure to microgravity results in a decreased number of osteoblasts—but what cell senses and responds to the loss of gravity, the undifferentiated mesenchymal precursor, the differentiated osteoblast, or the distant, entombed osteocyte? Bone marrow stromal cells change their proliferation rate and gene expression patterns in response to mechanical stimulation (Li *et al*., 2004) and

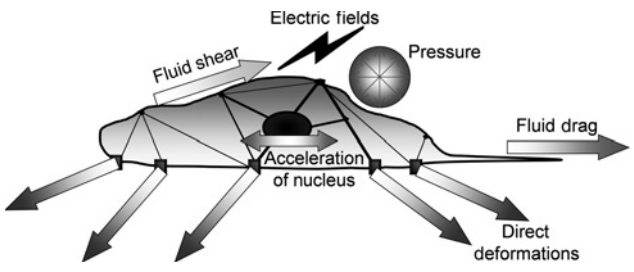

FIGURE 6 Proposed mechanisms by which bone cells may sense the application of mechanical forces to the skeleton.

alter lineage selection as well (David *et al*., 2007). With respect to osteoclasts and bone resorption: stromal cell expression of the osteoclastogenic factor, RANKL, is sensitive to mechanical force (Rubin *et al*., 2002c), suggesting that the number of osteoclasts present is controlled through mechanical regulation sensed by stromal cells. The osteoclast itself has also been shown to respond to mechanical signals adding another layer of control by which mechanical force might limit bone resorption (Wiltink *et al*., 1995).

Other cells present in bone, such as endothelial and smooth muscle cells in the penetrating vasculature, might also contribute to the skeleton's adaptive response to loading. After all, endothelial cells respond to shear stress and tensile strain generated by increased heart rate during exercise, by producing nitric oxide (Boo and Jo, 2003). Nitric oxide is an important humoral factor to transduction of mechanical input in vascular cells (Lane and Gross, 1999). Increased vascular release of nitric oxide is likely to regulate bone cell response: nitric oxide has pleiotropic effects in bone cells, and potently decreases resorption through decreasing osteoclast formation and activity (Fan *et al*., 2004a). But bone stromal cells also release nitric oxide as a result of mechanical input (Rubin *et al*., 2003) providing a secondary cell target for mechanical induction of this freely diffusible antiresorptive agent. Thus, targets of skeletal loading may include extraskeletal cells and systems.

Finally, the majority of cells in cortical bone are osteocytes, and owing to their pervasive, three-dimensional distribution throughout both trabecular and cortical bone, these cells are potentially well placed to sense the magnitude and direction mechanical strain within the tissue. Osteocytes, although enclosed in calcified tissue, are interconnected through a network of cannaliculi through which these cells cast long cell processes. Osteocytes respond to strain *in vivo* as shown by increased glucose-6-phosphate dehydrogense activity (Skerry *et al*., 1989), or earlier response of c-*fos* mRNA (Inaoka *et al*., 1995) after loading. As well, unloading causes osteopontin expression in osteocytes (Gross *et al*., 2005). Dentin matrix protein (DMP1), which is a secreted matrix protein expressed in late osteoblasts and osteocytes, has been shown to increase in osteocytes after tooth movement in the jaw (Gluhak-Heinrich *et al*., 2003).

If we consider that strain signals of even very low magnitude can stimulate an anabolic response in bone tissue, the osteocyte may be best placed to sense such a signal. This might occur through fluid flow through cannaliculi, as well as through deformation, both of which have been shown to cause changes in osteocyte function (Plotkin *et al*., 2005). It has also been suggested that, owing to the modulus mismatch of the bone material and the lacunae, that the osteocyte within the cavity would be subject to strains as high as 30,000 microstrain, even though the bulk material was strained only to 3,000 microstrain (Nicolella *et al*., 2005). In other words, the microarchitecture of the bone tissue could serve to indirectly (fluid pressure through cannaliculi)

or directly (strain amplification via the lacunae) amplify the strain signal. Although some have suggested that osteocytes might be more sensitive to shear than, for instance, transient pressures (Klein-Nulend *et al.,* 1995), there are divergent opinions, e.g., substrate strain prevents osteocyte apoptosis. A recently developed three-dimensional model for the osteocyte process used large-deformation "elastica" theory to predict the deformed shape of the cell. Because the model predicts a cell process that is very stiff, hard tissue strains will be amplified through the cell process, indeed into the magnitudes that have been studied *in vitro* in many systems. In any case, cells contributing to bone remodeling directly (osteoblasts) and indirectly (osteoprogenitor cells and osteocytes) and distantly (muscle and vascular systems) are all known to be mechanosensitive.

Mechanoreceptors in Bone Cells

The ability of cells to read their biomechanical environment requires that their mechanoreceptors must either be in contact with the outside, through the cell membrane and its attachment to substrate, or that the mechanoreceptor be able to sense changes in a loading-induced physical intermediary such as fluid shear on the apical membrane. Although there are examples of channels that are regulated by movement of mechanosensory bristles (Sukharev and Corey, 2004), or by tension waves (Morris, 1990), a unified model of the most proximal events that lead to intracellular signal transduction in nonsensory tissues does not yet exist. Theoretical considerations may be moving toward an architectural/spatial concept that integrates positional changes between signaling proteins, scaffolds, membrane domains, and structural components of the cell. All can be perturbed by mechanical force. Whether each aspect is a mechanoreceptor in itself, or works in a holistic context combining many aspects of cell architecture and response is yet to be determined. With the multiplicity of mechanical signals presented to the cell, it is at least likely that no single mechanosensor or receptor mechanism is responsible for all of the integrated cell response to the mechanical environment.

Integrins and Integrin-Associated Proteins

Membrane deformation and shear across the membrane, as well as pressure transients, can be transmitted to the cytoskeleton and ultimately to the cell-matrix adhesion proteins that anchor the cell in place (Katsumi *et al.,* 2004). Thus, the cell represents a load transmission network whereby surface forces will affect proteins that span or are associated with the plasma membrane including the cytoskeleton, linker proteins at sites of cell attachment, and membrane-spanning integrin adhesion proteins. In this way, mechanotransduction might be expected to depend on the mechanical integrity of this network with constituents of this network serving as molecular mechanotransducers.

Indeed, in particular the β1 integrin subunit has been implicated in mechanotransduction on ostecytes and osteoblasts (Bennett *et al.*, 2001). In osteoblasts, steady fluid flow can upregulate β1 expression (Kapur *et al*., 2003) even though blocking β3 with RGD-containing peptides did not affect ERK activation (Weyts *et al*., 2002). Other focal adhesion proteins such as focal adhesion kinase (FAK) may be critical to integrin clustering as well as molecular signaling in bone cells (Rezzonico *et al*., 2003). Mechanical stimulation stimulates tyrosine phosphorylation, predominantly in FAK, in osteoblasts (Boutahar *et al*., 2004). Upon phosphorylation, FAK contributes to MAPK activation via interaction with c-src, Grb2, and the small GTPase Ras (Schlaepfer *et al*., 1999). This is significant because MAPK activation is also one of the effectors of oscillatory flow in bone cells and this pathway has been observed in response to fluid flow in endothelial cells (Berk *et al.*, 1995). More molecular definition has lately been assigned to this pathway: involvement of an β1 integrin-linked kinase is stimulated through mechanical input via, leading to Akt activation (Nho *et al.*, 2005), a pathway that links to downstream processes regulated by canonical Wnt/catenin.

Connexins

Connexins are membrane-spanning proteins that form regulated channels that allow the direct exchange of small molecules with adjacent cells resulting in intercellular communication between cells. Intercellular communication via gap junctions has been suggested to be central to the transmission of information about the mechanical environment of a given cell and ultimately allowing a sensing cell to elicit a change in behavior at an actor cell some distance removed from the mechanosensing event (Yellowley *et al*., 2000). Interconnected cells have also been proposed to form a cellular network that can exhibit an enhanced sensitivity to biophysical stimuli than occur in individual cells. This application might occur owing to the larger area occupied by a cell network, and therefore larger net effect of the biophysical signal, than by individual cells. Indeed, when the communication of an ensemble of cells is interrupted, a reduced sensitivity has been observed in response to biophysical signals such as electric fields (Vander Molen *et al.*, 2000) or fluid flow (Saunders *et al*., 2001). In addition, mechanical signals may increase the expression of connexins *in vitro* and *in vivo*, suggesting that cells become better connected with their neighbors perhaps acting as a sort of positive feedback loop (Alford *et al*., 2003).

Channels

Alterations in ion channel activity in osteoblasts have been associated with bone cell activation, whether through alteration in conductance stimulated by PTH (Ferrier *et al.*, 1986), or by stretch/strain (Duncan *et al.*, 1992). There are at least

three classes of mechanosensitive ion channels in human osteoblasts (Davidson *et al.*, 1990). Through this set of channels, a mechanical stimulus could induce membrane hyper- and depolarization or a complex multiphasic response. Cyclical strain has been shown to modulate the activity of certain channels—chronically strained osteoblasts had significantly larger increases in whole-cell conductance when subjected to additional mechanical strain than unstrained controls (Duncan and Hruska, 1994). More recently, radial membrane strains of 800% were shown to be necessary to open half of the mechanosensitive channels in bone cells (Charras *et al.*, 2004). Mechanosensitive channels have also been implicated in the response of bone cells to fluid shear stress (Ryder and Duncan, 2001). In addition to direct activation of intracellular signaling cascades, influx of a charged species such as calcium can also alter membrane potential and activate voltage-sensitive channels that are not directly mechanosensitive (Li *et al.*, 2002). Taken together, it is clear that mechanically sensitive ion channels exist in bone, but the exact identification of such channel(s) remains elusive.

Membrane Structure

Cells possess a complex organizational structure that supports compartmentalization of signals within an equally complex plasma membrane. Certain proteins are integral to membrane structure while creating docking positions for signaling complexes. Caveolin 1 and 2 have been described in human fetal osteoblasts and in murine MC3T3-E1 cells along with multiple caveolar flasks in the membrane (Solomon *et al.*, 2000) and in osteoblasts in adult bone (Lofthouse *et al.*, 2001). Bone cell caveolae are associated with important signaling molecules including G proteins, Ras, nitric oxide synthase, and tyrosine kinases. These membrane domains, whether caveolae or noncaveolar lipid rafts provide a microenvironment that modulates efficiency and fidelity of mechanical signal transduction.

The organized membrane may have greater significance for mechanical response than for parsing signals arising from liganded receptors. Noncaveolar and caveolar organized membranes have been shown to be critical for mechanically induced signals in a variety of cells. In the vascular endothelium, for instance, increased flow causes the translocation of signaling molecules to caveolae; if caveolae are disassembled, both proximal and downstream signaling events, including activation of the MAPK pathway, are abrogated (Rizzo *et al.*, 1998). Stretch activation of small GTPases in cardiac myocytes has, as well, been associated with caveolae: the stretch activation of the GEFs RhoA and Rac1 fails to occur when caveolae are disrupted by treatment with methyl-β-cyclodextrin (MβCD) (Kawamura *et al.*, 2003).

The role of caveolae in processing signals in bone is being studied: caveolin-1 null mice have bigger bones, perhaps resulting from accelerated development (Rubin *et al.*, 2007). The spatial interaction between molecules of the wnt/catenin signaling system and caveolin-containing membrane (Bilic *et al.*, 2007) suggests that mechanical effects on these membrane domains will be important.

Primary Cilium

A new development in mechanical signal transduction has arisen with the reevaluation of the role of the primary cilium, a microtubule-based structure extending from almost every mammalian cell studied. The primary cilium has been known to function as a sensory organelle, but is now recognized to receive both mechanical and chemical signals from the environment (Michaud and Yoder, 2006). Epithelial cells in the kidney have been shown to recognize fluid shear stress in the lumen of the nephron through their primary cilium, and mutations leading to abnormal cilia, such as are found in polycystic kidney disease, lead to gross abnormalities in function (Nauli and Zhou, 2004). Indeed, when ciliary polycystin-1 is knocked out, besides causing polycystic kidney disease, mice have delayed endochondral and intramembramous bone formation (Xiao *et al.*, 2006). Further, interesting data have shown that bone cell primary cilia translate fluid flow into calcium signals (Malone *et al.*, 2007b).

Mechanically Activated Intracellular Signaling

Application of mechanical force to bone cells causes modulation of cell function, including changes in proliferation and function. Indeed, most aspects of cell behavior can be elucidated by a number of mechanical forces. Thus, straining osteoprogenitor cells can cause them to proliferate (Zhuang *et al.*, 1996) and to secrete extracellular matrix (Harter *et al.*, 1995). Similarly, shear stress, in addition to strain-induced effects, can induce beta-catenin signaling (Norvell *et al.*, 2004) and secretion of osteopontin (You *et al.*, 2001). To achieve these ends, it is quite clear that multiple classic signaling pathways are activated after force application.

Because the distal responses to mechanical factors are similar to those elicited by ligand–receptor pairing, and result in changes in gene expression, mechanotransduction must eventually end up utilizing similar intracellular signaling cascades. In essence, mechanical forces have been shown to activate every type of signal transduction cascade, from increases in intracellular cAMP (Lavandero *et al.*, 1993), IP3 and intracellular calcium, guanine regulatory proteins (Gudi *et al.*, 2003), and MAPK (Rubin *et al.*, 2002d). Next, rather than reviewing each mechanosignaling cascade, we provide four examples.

MAPK Signaling

Mechanical force can activate mitogen-activated protein kinases in every cell type studied to date. In bone cells many groups have shown activation of ERK1/2, in particular.

Mechanical activation of ERK1/2 is required for certain measurable responses to strain in bone stromal and osteoblast-like cells. The strained bone cell downregulates its expression of RANKL, and upregulates expression of eNOS. Although strain also activates c-jun kinase (JNK), JNK inhibition does not prevent strain effects on either RANKL or eNOS. Reduced display of RANKL by cells present in bone diminishes the local osteoclastogenic potential. As a result of increased eNOS expression, nitric oxide (NO) synthesis is enhanced.

ERK1/2 activation by mechanical stress has been linked to other specific genes such as strain induction of collagenase-3 (Yang *et al*., 2004), as well as to proliferation. Both fosB and its spliced variant, deltafosB, which has been shown to stimulate increases in bone density *in vivo*, are induced by mechanical loading of the mouse hind limb and by fluid shear stress in mouse calvarial osteoblasts (Inoue *et al*., 2004). The ERK1/2-dependent increase in the fos gene targets a CRE/AP-1 type element in the promoter that binds CREB. The proximal events leading to ERK1/2 activation are the subject of much continued research. This may certainly involve integrins (Whedon, 1984) as well as multiple other effectors, including small GEFs (Jin *et al*., 2005) or changes in membrane structure (Boyd *et al*., 2003).

Activation of Wnt/Catenin Signals

Increased expression of Wnt/β-catenin target genes is another response of osteoblasts to mechanical loading (Robinson *et al*., 2006). Multiple known genes with catenin response elements are quickly transcribed when strain is applied to osteoblast cells in culture, or when bone cells are studied after whole-animal loading; these are likely related to the anabolic response of bone tissue to exercise. Increased canonical β-catenin signaling through a gain of function mutation in LRP5 (G171V) has further been shown to increase the response of osteoblasts to mechanical loading (Sawakami *et al*., 2006). Mechanical activation of catenin signaling, of crucial importance to osteoprogenitor proliferation and lineage selection, will continue to be of great interest to this field.

Nitric Oxide Signaling

Nitric oxide has pleiomorphic effects on bone cells (Ralston, 1997), and may have a role in mechanical signaling in bone. Nitric oxide is released shortly after shear stress from osteoblasts and osteocytes (Smalt *et al*., 1997) likely owing to activation of endothelial nitric oxide synthase (Klein *et al*., 2004) similarly to known effects of shear in vascular cells. The rapid activation of nitric oxide in endothelial cells requires, in part, an intact plasma membrane, including lipid rafts (Park *et al*., 1998) and cytoskeleton (Knudsen and Frangos, 1997), and this is likely to be true for mechanical release of nitric oxide in bone cells. Endothelial nitric oxide synthase is the predominant nitric oxide synthase isoform in adult bone (Helfrich *et al*., 1997), and expression of this gene with subsequent increase in nitric oxide production is upregulated by strain in marrow stromal cells. Downstream nitric oxide signaling can depend on activation of guanylate cyclase or on direct actions of the molecule to nitrosylate proteins as has been shown for NO action to decrease the RANKL/osteoprotegerin ratio in stromal cells (Fan *et al*., 2004b). Nitric oxide has also been shown to be necessary for the response to *in vivo* loading in rodents, although whether the nitric oxide derives from bone or the vasculature in bone is not yet clear (Kunnel *et al*., 2004).

Prostaglandins

In bone's anabolic response to loading, prostaglandins may be important as indicated by their increased levels during loading (Rawlinson *et al*., 1991). Indeed, a variety of mechanical signals, including direct stretch (Zaman *et al*., 1997), pressure (Burger *et al*., 1992) and fluid flow (Klein-Nulend *et al*., 1997) can markedly upregulate prostaglandin production, whereas the disruption of the osteocyte cytoskeleton, and thus the transmission of the signal to the nucleus, completely disrupted the responsiveness of the cell (Ajubi *et al*., 1996). Although greater detail in the mechanism of action of prostaglandins is provided elsewhere in this book, it is important to note that administration of PGE2 to rodents will increase the stiffness of trabecular bone (Akhter *et al*., 2001), and that perhaps the EP2 receptor is most important in coordinating the prostaglandin response to mechanical signals into improved bone strength. Considering the role of prostaglandins as potent regulators of bone remodeling (Raisz, 1995), and their responsiveness to both mechanical and humoral signals, it will ultimately be important to more definitively understand the physiological responses of the skeleton to exercise and mechanical signals, and the role of biochemical messengers such as prostaglandins that can modulate bone quantity and quality.

SUMMARY

The critical contribution of mechanical stimuli in the achievement and maintenance of bone quantity and quality is clear. In contrast to systemic, pharmaceutical interventions, the attributes of such biophysical prophylaxes are that they are native to the bone tissue, safe at low intensities, incorporate all aspects of the remodeling cycle, and will ultimately induce lamellar bone. Further, these signals appear to influence tissues beyond "simply" bone, with evidence that they can help retain musculature and postural stability, thus providing a more "systems-based" intervention for osteoporosis. However, the design and widespread

use of effective and clinically acceptable prophylaxes and treatments that are based on bone's sensitivity to biophysical stimuli will be delayed until we achieve a better understanding of the operative mechanisms at the levels of the tissue, cell, and gene.

Methods in Bone Research

Chapter 86

Application of Transgenic Mice to Problems of Skeletal Biology

Stephen Clark, PhD and David Rowe, MD
Department of Genetics and Developmental Biology University of Connecticut Health Center Farmington, CT

INTRODUCTION

Transgenic mice provide an excellent setting to study complex regulatory systems that cannot be modeled or fully appreciated in isolated experimental systems *in vitro* or *in cellulo*. This potential is particularly important in the analysis of the cells that synthesize the extracellular matrix because their response to regulatory signals from the external environment is dependent on their state of cellular differentiation. Because these variables cannot be reliably modeled in isolated systems, the challenge is to develop assay systems within an intact animal that can still ask a focused molecular question. This chapter is designed to illustrate examples where transgenic animals have answered subtle questions about protein structure and gene regulation affecting bone structure or bone cell differentiation that could not have been performed in any other experimental system. In addition, newly developed transgenic approaches that are now being applied to bone and have great potential in this research arena will be discussed.

ANALYSIS OF STRUCTURAL MACROMOLECULES IN BONE

Type I collagen is the major structural protein of bone, whereas type II is the primary collagen of cartilage. Mutations in type I collagen are associated with osteogenesis imperfecta (OI) while certain chondrodysplasias are the result of defects in type II collagen. Because of the multimeric structure of mature type I and type II collagen molecules, a dominant negative mechanism is associated with the pathogenesis of both classes of inherited traits. Although molecular genetic studies of humans affected with these disorders have illustrated that the spectrum of disease severity can be correlated to specific mutations (Prockop *et al.,* 1993; Prockop *et al.,* 1994), a clearer understanding of how these mutations affect protein function was obtained from transgenic mice.

A collagen transgene carrying a glycine substitution demonstrated the concept of a dominant negative mutation as these transgenic mice displayed a perinatal lethal OI (Stacey *et al.,* 1988). In these transgenic mice only relatively small amounts of the mutant protein were required to destabilize the matrix and produce a dramatic affect on the entire skeleton. Transgene expression levels as little as 10% of the normal endogenous gene production of collagen were associated with a mutant phenotype. In a series of transgenic mice bearing a large internal deletion of the collagen gene, a less severe and more variable phenotype was observed and the phenotype correlated with the level of transgene expression (Khillan *et al.,* 1991; Pereira *et al.,* 1993). In this case, the severity was more variable, predominantly less severe, and correlated with the degree of expression. Furthermore, the level of transgene expression in an inbred strain was equivalent to the endogenous gene indicating that variations in phenotypic severity were not the result of genetic background but related to the structure of the mutated gene (Pereira *et al.,* 1994). Collectively, these data indicated that the severity of the mutant phenotype is dependent upon the amount of incorporation of a mutant collagen molecule into the matrix. Thus, if the collagen gene has a major alteration, as is the case with a large internal deletion, fewer mutant molecules are incorporated into the matrix compared with the case of a mutation that has only a moderate impact of molecular assembly. In this latter case, more mutant molecules are incorporated into matrix with dramatic affects on its structural integrity. Clearly understanding how a mutation leads to the presentation of a skeletal phenotype requires a comprehension of the impact the mutant allele has on the assembly secretion and incorporation of the mutant molecule into the extracellular matrix. This concept is further highlighted by studies with a targeted deletion of the cartilage matrix associated protein (Crtap). Crtap-null mice display a severe osteopenia that is associated with a failure of prolyl hydroxylation, a post-translational step required for proper molecule maturation (Morello *et al.,* 2006). The link between defects in

Principles of Bone Biology, 3rd Edition

this locus in humans and OI was established by the observation that 3 out of 10 children with lethal or severe OI who lacked defects in type I collagen had mutations at the Crtap locus. This recessive form of OI was associated with a loss of prolyl 3-hydroxylation and altered production of mature triple helical collagen molecules (Barnes *et al.,* 2006). In addition to illustrating the importance of mutations that disrupt the collagen helix and lead to defective extracellular matrix formation, mutations at other sites within the molecule can demonstrate biological properties of type I collagen (Kivirikko, 1993). The turnover of collagen in the extracellular matrix begins with a site-specific cleavage by a collagenase. If this site is altered by a mutation, a resistance to collagenase degradation results (Wu *et al.,* 1990). The first step in the enzymatic turnover of collagen from the extracellular matrix is cleavage at a specific site within the helix by mammalian collagenase. Collagen molecules containing a mutation at the site of cleavage are more resistant to degradation (Wu *et al.,* 1990). Transgenic mice bearing a collagenase-resistant Col1a1 transgene display embryonic lethality; however, mice with a targeted endogenous gene with the same resistance mutation survive and develop a dermal fibrosis similar to human scleroderma (Liu *et al.,* 1995a). The role of collagenase in parathyroid hormone (PTH) stimulated bone resorption was evaluated utilizing this model. Mice homozygous for the targeted collagenase resistant allele when treated with PTH did not show elevated bone resorption compared to wild-type controls (Zhao *et al.,* 1999). Furthermore, when the resistant allele was combined with a transgene constitutively active of PTH/PTHrP receptor (CL2+) (Calvi *et al.,* 2001), trabecular bone volume was increased despite a reduction in bone formation rate. Interestingly, osteoclast number was elevated in CL2+ mice homozygous for the resistance collagen allele compared to wild types or CL2+ mice, suggesting that altered collagen cleavage impacts osteoclast function (Chiusaroli *et al.,* 2003). Finally, osteocyte and osteoblast apoptosis was elevated in homozygous-resistant mice consistent with a role of matrix degradation in the regulation of skeletal remodeling via the modulation of osteocyte and osteoblast survival (Zhao *et al.,* 2000b). Similar observations have been made for type II collagen. Changes of single amino acids in the Col2a1 transgenes have a significant impact on the skeleton. Col2a1 transgenes with glycine to cysteine or glycine to serine amino acid substitution produce the phenotype of chondrodysplasia in mice (Garofalo, 1991; Maddox *et al.,* 1997) and abnormal craniofacial morphology (Rintala *et al.,* 1993). An Arg to Cys mutation reduces the density of type II collagen fibrils in articular cartilage and a delayed skeletal development (Arita *et al.,* 2002) as well as degenerative intervertebral discs and osteoarthritic joints that were more severe in the absence of a normal endogenous Col2a1 gene (Sahlman *et al.,* 2004). A Col2a1 transgene with a small deletion (Del1) produces several skeletal defects including retarded development (Savontaus *et al.,* 1996), craniofacial abnormalities (Rintala *et al.,* 1997), and axial skeletal defects associated with abnormalities in the vertebra and discs (Savontaus *et al.,* 1997). Furthermore, as Del1 transgenic mice age a progressive degeneration of articular cartilage was observed beginning at age 3 months (Saamanen *et al.,* 2000). A transgene with a large in frame deletion lacking 12 exons in the central coding region of the gene produces a shortened procollagen chain that, when interacting with chains of normal size, leads to degradation of the chimeric molecules, termed procollagen suicide (Vandenberg *et al.,* 1991). Many of these transgenic mice display a chondrodysplasia that is affected by genetic background and older mice show an osteoarthritis phenotype associated with articular cartilage degeneration (Helminen *et al.,* 1993). Mice homozygous for a targeted knockout of the type II collagen gene develop a skeleton containing membranous and periosteal bone, lack endochondral bone, and die shortly after birth (Li *et al.,* 1995a). Homozygous mutant mice fail to dismantle their notochord during embryogenesis and thus do not develop intervertebral discs (Aszodi *et al.,* 1998). Mice heterozygous for the null allele are viable, however, have skeletal deficiencies including shorter long bones, vertebrate and cranial defects (Sahlman *et al.,* 2001) as well as ocular abnormalities similar to human Stickler syndrome (Kaarniranta *et al.,* 2006). Finally, excessive expression of a normal Col2a1 gene produces abnormally thick fibrils and mice with the highest proportion of abnormal fibrils are perinatal lethal (Garofalo *et al.,* 1993). This observation is of great significance in the design of gene therapy approaches for the management of diseases of bone. Although great strides have been made in the field of regenerative medicine, clearly careful consideration must be given for the proper regulation of a correcting gene as well as interaction with endogenous mutant alleles before application of a curative therapy.

The integrity of the skeleton relies not only on the proper structure and function of type I and II collagen but also on the interplay of minor collagens and noncollagenous proteins with the major collagen molecules. This interaction can be appreciated in transgene models bearing alterations in genes encoding minor collagens. Type X collagen functions as a homotrimer and is primarily expressed in hypertrophic chondrocytes. A transgene with a large internal deletion behaves in a dominant negative fashion and mice carrying this transgene display a phenotype similar to human spondylometaphyseal dysplasias and metaphyseal chondrodysplasias (Jacenko *et al.,* 1993). Further study of this transgenic mouse revealed moderate craniofacial skeletal abnormalities (Chung *et al.,* 1997) as well as a significant deficit in hematopoietic cell differentiation (Jacenko *et al.,* 2002). An initial study with a targeted null allele of the Col10a1 gene unexpectedly did not have any major consequences on long bone development as mice either heterozygous or homozygous for the

null mutation displayed a normal phenotype (Rosati *et al.,* 1994). However, a subsequent targeting experiment that produced type X deficient mice resulted in animals that displayed abnormalities in growth plate development resulting in altered bone content. Furthermore, a reevaluation of the original knockout mice revealed a skeletohematopoietic phenotype and compressions in the growth plane in the proliferative zone (Gress and Jacenko, 2000). Most recently a transgenic mouse bearing a construct equivalent to a human metaphyseal chondroplasia type Schmid mutation was created. The phenotype of mice carrying this transgene paralleled the human condition and included shortened long bones and coxa vara (Ho *et al.,* 2007). Col9a1 have been the most extensively studied Type IX collagens using transgenic approaches. A mild chondrodysplasia is observed in transgenic mice expressing a truncated Col9a1 chain that predisposes these animals to a degenerative osteoarthritis (Nakata *et al.,* 1993) while a milder form of joint degeneration is observed in mice bearing Col9a1 null alleles (Fassler *et al.,* 1994; Hu *et al.,* 2006). The cartilage defect in null mice is associated with a lack of matrilin-3 in cartilage fibrils (Budde *et al.,* 2005). Furthermore, this cartilaginous failure influences bone formation in bone fracture repair as the time course of cartilaginous callus formation is impaired in type IX deficient mice (Opolka *et al.,* 2007). While genetically engineered mutant alleles of the Col11a1 gene have not been generated, a naturally occurring mutation has been observed that is associated with a frame shift mutation that results in a premature stop codon. Mice homozygous for this autosomal recessive chondrodysplasia (cho) mutation have a perinatal lethal phenotype with severe skeletal abnormalities including limbs approximately half the normal length (Li *et al.,* 1995b) whereas heterozygous animals present with an osteoarthritis-like joint phenotype (Xu *et al.,* 2003). In contrast to homozygous cho mutant mice, a mild cartilage phenotype is observed in a targeted allele that also has a premature translation termination (Li *et al.,* 2001). Type XIII is a transmembrane protein expressed in many tissues and is involved with cell adhesion. Recently it was observed that overexpression of type XIII collagen in transgenic mice surprisingly impacted on the skeleton. Although early skeletal development was unaffected, postnatally an aberrant high bone mass was detected, associated with an elevated formation rate rather than increased resorption, suggesting that type XIII collagen has a function in bone remodeling (Ylonen *et al.,* 2005). Type V collagen is another molecule that is important for type I collagen fiber formation. A targeted deletion of the N-globular region of the Col5a2 gene causes an Ehlers-Danlos type I phenotype in mice homozygous for the deleted allele. Collagen fibrillogenesis is disrupted in the dermis consistent with a regulatory role for Col5a2 in proper matrix deposition (Andrikopoulos *et al.,* 1995). The noncollagenous proteins are important in the homeostasis of connective tissue as some are likely to have a modifying role on type I and type II collagen function. However, there appears to be some redundancy in the system as knockouts of genes that are vigorously expressed in bone do not display a skeletal phenotype in the absence of gene function. Tenascin-C is strongly expressed in bone (Mackie, 1992), however, homozygous knockout mice do not have a connective tissue phenotype (Saga *et al.,* 1992; Forsberg *et al.,* 1996). Interestingly, knockout mice show neurological deficiencies including alterations in circadian rhythm control and delayed onset of odor detection (Morellini and Schachner, 2006; Cybulska-Klosowicz *et al.,* 2004). Homozygous matrilin 1, matrilin 2, or matrilin 3 knockouts develop normally without any obvious skeletal defects (Aszodi *et al.,* 1999; Mates *et al.,* 2004; Ko *et al.,* 2004), suggesting redundant function of these genetic units. However, while gross skeletal defects are not apparent, matrilin 3 knockout animals have premature chondrocyte maturation that is associated with an elevation of bone mineral density and osteoarthritis in older mice (van der Weyden *et al.,* 2006). Furthermore, both matrilin 1- and matrilin 3-deficient mice display an increase in collagen fibril diameter in the epiphysis and growth plate as well as altered ultrastructure in the knee joint cartilage (Nicolae *et al.,* 2007). Similarly, mice homozygous for a knockout of the osteocalcin gene do not present with a dramatic skeletal phenotype; however, bone remodeling is altered as osteocalcin-deficient mice have higher bone mass (Ducy *et al.,* 1996). The initial evaluation of osteonectin knockout mice did not detect any significant skeletal alterations (Gilmour *et al.,* 1998). However, subsequent analyses revealed that osteonectin-deficient mice have an osteopenia (Delany *et al.,* 2000) that is associated with decreased bone formation that is a reduction in the number of osteoblast precursors (Delany *et al.,* 2003). More recently, it has been observed that null mice display defects in intervertebral discs as mice age (Gruber *et al.,* 2005). It is obvious that as more is learned about relatively minor molecular components of skeleton, the importance of detailed analysis and the study of older animals have become apparent.

Although the functional role of the extracellular matrix contributing to the structural integrity to skeletal structures is clear, the role of extracellular matrix macromolecules in the maintenance of bone homeostasis is more clearly defined. Perhaps the best example is fibrillin 1, a large matrix glycoprotein that is a major component of extracellular microfibrils. In humans, Marfan syndrome (MFS) is an autosomal dominant connective tissue disorder that dramatically impacts the skeleton and is linked to mutations at the fibrillin 1 (FBN1) locus (Lee *et al.,* 1991; Dietz *et al.,* 1991). It was initially believed that mutant fibrillin molecules acted in a dominant negative fashion and the pathogenesis of the disease was the consequence of an alteration in microfibril structure resulting in the formation of an inferior connective tissue. Recently this paradigm

has been abandoned and a new hypothesis has emerged. This new hypothesis proposes that storage of latent TGF-β involves fibrillin and that in patients with MFS there is dysregulation of TGF-β activation (Dietz *et al.,* 2005). Further data from murine models of MFS support haploinsufficiency rather than a dominant negative mechanism for the pathogenesis of MFS (Judge *et al.,* 2004). Biochemical studies have established an association between latent TGF-β binding protein(s) (LTBP) and regulation of TGF-β activity (Rifkin, 2005) and a relationship between LTBP-1 and fibrillin (Dallas *et al.,* 1995; Isogai *et al.,* 2003). Specifically, the N-terminal domain of fibrillin binds to the C-terminal end of LTBP-1, a component of the large latent complex (LLC). The LLC is involved in the regulation of TGF-β signaling as it has a role in both the sequestering and the release of active TGF-β (Kaartinen and Warburton, 2003). It has been shown that mice homozygous for a centrally deleted Fbn1 allele ($Fbn1^{mgdelta}$) who develop destructive emphysema (Pereira *et al.,* 1997) display a dysregulation of TGF-β activation and signaling in the developing lung, and treatment of these mice with TGF-β neutralizing antibody rescues the alveolar septation (Neptune *et al.,* 2003). Utilizing a targeted mutation in mouse that contained a cysteine to glycine substitution (C1039G) in the cbEGF domain of fibrillin ($Fbn1^{C1039G}$) (Judge *et al.,* 2004), Ng *et al.* documented a reversal of the development of myxomatous changes of the atrioventricular valves with the perinatal administration of TGF-β neutralizing antibody (Ng *et al.,* 2004). Finally, an extremely exciting report by Habashi *et al.* showed a correction of both aortic aneurysms and lung disease in $Fbn1^{C1039G/+}$ mutant mice with following treatment with TGF-β antagonists (Habashi *et al.,* 2006).

CIS REGULATION OF STRUCTURAL MACROMOLECULES IN BONE AND CARTILAGE

Production of major structural macromolecules constitutes the major synthetic activity of a bone or cartilage cell and can be used to define a particular stage of differentiation. Although transient and stable transfection studies can provide insight into the biochemical and molecular interaction, it is only within the intact tissue that the true biological importance of the promoter and transcriptional environment can be appreciated. This is the rationale for the extensive and expensive effort required to carry out a promoter analysis in intact mice. However, when a promoter fragment is identified that controls expression of a transgene in defined subpopulations of cells, it has great value for studies in which tissue-directed expression is required as discussed in the following sections.

The Col1a1 and Col1a2 promoters have received the greatest attention. Sequences extending a minimum of 2.3 to 3.6 kb upstream of the minimal promoter are required for high expression in most type I collagen-producing cells (Krebsbach *et al.,* 1993; Rossert *et al.,* 1995) whereas sequences as distant as 17 kb are required for strong Col1a2 activity (Antoniv *et al.,* 2001). The role of the first intron is subtle but does direct expression to a subset of type I collagen-producing cells. Specifically, a knockout of most of the intron produces a subtle reduction on type I collagen synthesis in skin and lung that was insufficient to have a physical phenotype (Hormuzdi *et al.,* 1998). However, when these transgenic mice are challenged with a stimulus for pulmonary fibrosis, an exaggerated transcriptional response from the mutant allele was observed (Hormuzdi *et al.,* 1999). Although the interpretation of this result is not fully understood, this experimental approach reveals regulatory subtleties that would not be appreciated in cell culture experiments.

A similar type of analysis has demonstrated that there are distinctly separate DNA elements that are important for high expression in different type I collagen-producing cells. The complex nature of the promoter appears to allow a single gene to be differentially regulated in different type I collagen-producing cells such as bone, tendon, and skin (Bogdanovic *et al.,* 1994). The best-defined element is the one required to regulate type I expression in bone. This "bone" element has been delineated to a 6-bp segment homeobox binding domain located 1.7 kb from the transcription start site (Dodig *et al.,* 1996; Rossert *et al.,* 1996). Mutations within this 6 bp segment inactivate the transgene in bone while transgene activity persists in tendon. The Col1a1 promoter contains another domain upstream of the bone element that is essential for high expression in skin and tendon. An element that is essential for high expression in vascular smooth muscle cells is not located within the 5' region of the gene (Bedalov *et al.,* 1994). Mapping these elements and defining the transcription factors that interact with them will be an essential step in understanding developmental pathways and signals used by cells that express the same collagen gene to varying levels in different tissues.

The osteocalcin promoter has received major attention in transient transfection studies to map transcription factor binding domains. A more complex regulatory structure becomes apparent in transgenic studies. A broader spectrum of tissue expression is seen in versions of the transgene than occurs in the endogenous gene and it has been difficult to ensure that all osteocalcin-producing cells express the osteoclacin (OC) promoter transgene (Kesterson *et al.,* 1993; Clemens *et al.,* 1997; Frenkel *et al.,* 1997). A similar complexity is seen for the bone sialoprotein promoter (Chen *et al.,* 1996; Chen *et al.,* 1999; Benson *et al.,* 2000).

The analysis of the type II collagen gene first drew attention to large fragments necessary for activity followed by identifying specific transcription factor

binding domains. The importance of the first intron became fully appreciated in transgenic mice (Metsaranta *et al.,* 1995; Seghatoleslami *et al.,* 1995; Zhou *et al.,* 1995). Specific transcriptional domains that bind Sox 9 and the SRY-related high mobility group (HMG) have now been identified (Zhou *et al.,* 1998). Analysis of the Type XI promoter (Li *et al.,* 1998; Tsumaki *et al.,* 1998; Liu *et al.,* 2000) in chondrocytes and the Type X (Beier *et al.,* 1996) in hypertrophic chondrocytes has also been performed.

USE OF TISSUE-DIRECTED TRANSGENES TO ASSESS FUNCTION OF GENES AFFECTING SKELETAL DEVELOPMENT AND MAINTENANCE OF BONE MASS

Although targeted inactivation of genes by homologous recombination has contributed greatly to understanding the role of genes to embryonic development, the importance of these genes to bone and cartilage development is often obscured by the fact that other developmental systems are more severely affected and thus preclude analysis of the gene in bone. Examples include knockouts of the Wnt and notch pathways, the bHLH family of transcription factor including twist and id, and extracellular modifying factors such as noggin all have skeletal components to their embryonic phenotype indicating an essential role in skeletal biology. This section will review transgenic approaches that had been used to overcome problems associated with global knockouts. In addition, the section will review approaches for directing expression of growth factors to the bone environment.

The fundamental tool that is used in this experimental approach is a promoter that has tissue-restricted activity. This strategy creates a biological situation that rarely occurs in nature and can be considered a targeted gain of function mutation. The outcome of transgenic expression can be dramatic, but the interpretation of the biological meaning of the experiment can be complex. Uncertainties include the spectrum of cells that express the transgene. For example, the OC and bone sialoprotein (BSP) expression is specific to bones and thrombocytes, but many versions of the OC and BSP promoter have ectopic expression that includes brain. Within the lineage of bone and cartilage cells, the type I and type II collagen promoters can be designed to have preferential expression at specific stages of differentiation. However, low-level expression at other stages of differentiation or for that matter in other cell types may exist and even the low level of activity may be sufficient to disrupt cells in an unintended manner. The other uncertainty is the manner in which the expressed transgene acts, i.e., either within the cell of synthesis (cell autonomous) or on neighboring cells (cell nonautonomous). For example, OC-driven production of TGF-β will influence the entire bone cell and osteoclasts lineage (Serra *et al.,* 1997) whereas OC-driven expression on a dominant negative TGF-β receptor construct will limit its biological affect to the cells that express osteocalcin (Filvaroff *et al.,* 1999). Experimental strategies that achieve inappropriate expression of a growth or transcription factor may produce levels of the product that are never found in a normal cell and affect pathways that normally would never be utilized. This concern always arises when constructs that act in the dominant negative manner on an endogenous transcription complex or signaling pathway in which multimeric interaction exert subtle changes in gene regulation. It cannot be assumed, particularly when the dominant negative protein is highly expressed within its cell, that only the targeted partner will be affected by the interaction.

Despite these reservations, valuable insights into the role of growth and transcription factors and signaling molecules have been achieved using targeted expression techniques. For example, the global knockouts of cbfa1 dramatically demonstrated its central role for bone cell differentiation because mice deficient in this transcription factor fail to develop a mineralized skeleton. Unclear from that work was the effect of cbfa1 on the development of the hypertrophic zone of the growth plate and the role of this structure on endochondral bone formation. When cbfa1 is expressed under control of type II collagen promoter in the background of the cbfa1 knockout mouse, the hypertrophic zone does develop accompanied by vascular invasion and osteoclasts. However, osteoblasts still do not differentiate (Takeda *et al.,* 2001). This experiment is strong evidence against transdifferentiation of the hypertrophic chondrocyte to osteoblasts. In contrast, when a dominant negative cbfa1 is targeted to the chondrocyte with a different Col2a1 promoter, the cartilage remains in a proliferative stage without development and osteoblasts fail to differentiate in a pattern very similar to the global cbfa1 knockout (Ueta *et al.,* 2001). These observations suggest that the formation of the hypertrophic zone is essential for endochondral bone, but that cbfa1 expression within the osteoblast lineage is required for differentiation in the presence of an intact growth plate.

To assess the role that cbfa1 has in maintaining the osteoblastic phenotype, a dominant negative cbfa1 was expressed under control of the OC promoter. This ingenious design allows the mice to complete embryogenesis normally because OC is not expressed during prenatal life. Osteoblasts do differentiate and the dominant negative is only expressed in late osteoblast differentiation. Mice have an osteopenic phenotype with normal osteoblastic cell number and primary osteoblastic cultures derived from these mice fail to form mature bone nodules. Although this work supports the role of cbfa1 for maintenance of osteoblast lineage even in adult life, it is likely that the dominant negative can act on other members of the family of cbfa1 transcription factors, all of which can influence osteoblast differentiation (Harada *et al.,* 1999).

The role that other transcription cofactors have within the osteoblast lineage have been studied by expressing them with promoters that are more broadly expressed but

that include the osteoblast lineage. The most surprising results involve the role that the fos subfamily (fra-1 and fos B) of the AP-1 helix loop-helix transcription family have in the osteoblast lineage. Even though these factors are widely expressed and their knockout either has no bone phenotype (c-fos knockout have osteopetrosis, whereas c-fos overexpressing mice get osteosarcomas and chondrosarcomas), their overexpression stimulates osteosclerotic bones by stimulating bone formation without enhancing bone resorption (Jochum *et al.,* 2000). A supporting observation is the reciprocal increase in bone mass and reduction of fat tissue in mice transgenic for FosB overexpression (Sabatakos *et al.,* 2000). Although the observations are important because this is a biological effect that has great appeal as a therapeutic agent for diminished bone mass, their interpretation of the molecular mechanism is extremely difficult. Because the factors act by forming either homodimers or heterodimers with other members of the AP-1 family and are very dosage sensitive, it is difficult to know if they work directly by partnering with another factor to stimulate an osteogenic molecular pathway or titrate out another factor that is inhibitory to an osteogenic pathway (Aubin, 2001).

Overexpression studies point to the complexities that can influence the differentiation pathway of the osteoblast. Although the role of PTHrP has received the greatest attention in the growth plate (see later discussion), it clearly has an equally important effect on the osteoblast lineage. Targeted expression of the constitutively active form of the PTHrP receptor to the osteoblast with a Col1a1 promoter results in a profound increase in trabecular and endochondral bone formation but loss in cortical bone (Calvi *et al.,* 2001). In addition, osteoclastic activity was increased in the marrow compartment. Because of its cell autonomous effect of the transgene within the osteoblast lineage, the primary effect of PTHrP in this experimental model is at the level of the osteoblast and the osteoclast response is a consequence of the activated osteoblast lineage. Although the physiological implication of the model will require further evaluation, this well-understood pathway in cartilage will have important implications for manipulation of the bone lineage.

Targeting expression of a factor secreted by osteoblast cells affects the regulation of the entire osteoblast and osteoclast lineage, making interpretation of the biological role of the factor difficult. The first example was the expression of TGFβ under control of the OC promoter producing the paradoxical outcome of high bone turnover osteoporosis with an additional component of impaired matrix mineralization. When the effect of TGFβ was limited to the osteoblasts lineage either by addition of bisphosphonates or expression of the transgene in a c-fos -/- background, enhanced differentiation of cells into mature osteoblasts was observed. When the deficiency of TGFβ was limited to mature osteoblasts by expression of a dominant negative form of the TGFβ receptor driven by OC promoter, osteoclastic activity was diminished and resulted in an increase in trabecular bone mass even though the number of mature osteoblasts was reduced (Erlebacher *et al.,* 1998; Filvaroff *et al.,* 1999). Although this experimental approach further underlines the complex interrelationship between bone formation and resorption, it does not adequately discriminate the opposing cellular regulators of bone mass. Although expression of a dominant negative or constitutively active receptor can limit the growth factor effect to a particular lineage, the subpopulation of cells within the lineage, the manner (intermittent vs. continuous) in which the stimulus is applied and age/growth rate of the mouse when the analysis is performed can all impact on the phenotype observed. The same type of experiments has now been performed with IGF1 driven either with the OC (Zhao *et al.,* 2000a) or Col1a1 promoter. Both enhance bone formation and increase bone turnover leading to a similar problem of interpretation as TGFβ forced expression. Targeted expression of noggin (producing bone loss) and the calcitonin gene-related peptide (increase bone mass) (Ballica *et al.,* 1999) are other examples of targeted secretion of a factor affecting the coupling of bone formation and resorption. Even overexpression of the TRAP enzyme results in a phenotype of high bone turnover osteoporosis (Angel *et al.,* 2000). The model utilized the SV40 enhancer and TRAP transgene and resulted in high TRAP activity in osteoclasts of bone and macrophages in non-osseous sites. Although defining the cellular control mechanisms for bone remodeling can only be fully appreciated in the integrated system of intact mouse bone, the experimental design has improved so as to limit the effect of the probing transgene to a defined subset of cells before an unambiguous interpretation of the experimental data can be made.

Because structural organization of the growth plate provides definition of the stage of differentiation of cells within the cartilage lineage, overexpression studies are more easily understood. The global knockout of PTHrP and its receptor leads to premature differentiation of hypertrophic chondrocytes whereas expression of a constitutively active form of the PTHrP receptor causes delayed maturation of hypertrophic chondrocytes. This fundamental observation has lead to a series of experiments in which targeted expression of the constitutively active PTHrP receptor in an ihh -/- or PTHrP receptor -/- background can separate the contribution of ihh and PTHrP to chondrocyte proliferation and hypertrophic differentiation (Schipani *et al.,* 1997; Karp *et al.,* 2000). A similar approach has been used to define the role of cbfa1 in the chondrocyte lineage beyond its role in supporting endochondral bone formation. Overexpression of cbfa1 via the Col2a1 promoter in an otherwise normal background is disruptive to normal joint formation and induces hypertrophic chondrocyte differentiation and vascular invasion at a site that normally never supports bone formation. Of particular interest is a

disruption of pattern of tenascin expression characteristic of the chondrocytes lining an articular cartilage with the reaction of the surrounding tissues suggestive of a degenerative joint. In contrast, targeting the dominant negative form of cbfa1 to chondrocytes leads to failure of hyperchondrocyte differentiation and expression of tenascin throughout the articular cartilage (Ueta *et al.,* 2001). This work suggests more subtle levels of chondrocyte differentiation can be controlled by cbfa1 and the possibility that it might play a role in the development of degenerative joint disease (Liu *et al.,* 1995b; Ma *et al.,* 1996). TGFβ may also play a role in maintaining the articular cartilage in its appropriate state of differentiation. When the same dominant negative TGFβ receptor transgene that was used to remove TGFβ signaling to the osteoblast is targeted to the chondrocyte, a state of degenerative joint disease is observed with hypertrophic chondrocytes and synovial thickening (Serra *et al.,* 1997).

Thus, ability to assess the state of differentiation by their position or morphology adds to the interpretation of the transgenic experiments. In regards to the osteoblastic lineage, the level of differentiation is probably best appreciated in the sutures of the calvaria. Murine phenocopies of human forms of craniodystosis caused by either overexpression of the normal gene or an activated form of the transcription factor Msx2 leads to early fusion. These studies suggest that Msx2 acts to keep the cells of the osteogenic front in a proliferative and nondifferentiated state (Dodig *et al.,* 1999; Liu *et al.,* 1999). This conclusion is supported by studies of Msx2 -/- mice that fail to close their suture and demonstrate a diminished number of osteoprogenitors on the osteogenic front (Satokata *et al.,* 2000). The generalized reduction in bone mass seen in the calvaria and axial skeleton is likely to result from a similar cellular mechanism but would not have been appreciated without the analysis of the lineage within the calvarial suture. It would not be surprising that mis-expression of other molecular pathways affecting calvarial suture development such as FGF2, twist, and id are likely to act by regulating proliferation and differentiation of the osteogenic front (Rice *et al.,* 2000).

USE OF THE GFP TRANSGENE FAMILY TO ASSESS OSTEOBLAST LINEAGE

The previous section stressed the value of recognizing the level of cellular differentiation with the osteoblast and chondrocyte lineage for interpreting the effect of transgenic animal models that alter the biology of bone or cartilage by affecting the regulation of lineage progression. When position or cell morphology is not available to assist in assessing the state of differentiation with a cell population, *in situ* hybridization, immunohistochemistry, or lac Z staining for activity of stage-specific promoter-β-gal transgene can be employed (Rossert *et al.,* 1995; Antoniv *et al.,* 2001). *In situ* hybridization can localize a signal to a specific population of cells and immunohistology is best suited for extracellular molecules and both procedures are laborious and technically demanding. β galactosidase has been the traditional enzymatic marker for assessing transgene expression and has been most useful in development studies. However, its use for marking cells in adult tissue is limited because of background endogenous activity and variation of staining intensity owing to uncertainties in the diffusion of the substrate into mature tissue. The same techniques can be used to assess lineage in primary culture, but the culture has to be terminated so that progression of a specific cell to later stages of differentiation cannot be recorded.

The green fluorescent protein (GFP) family of autofluorescent proteins may provide an approach to overcome limitations of β galactosidase in both intact bone and in primary cultures derived from transgenic mice. Despite some reports that GFP can have toxic effects in transgenic mice, there are sufficient numbers of examples where viable lines have been produced and have been useful for studying cell lineage and transplantation experiments. Currently, there are fluorescent colors that can be distinguished using appropriate filter cubes. Three are isomers of GFP (topaz or yellow, sapphire, cyan) and the fourth is from another species (DS red). The most widely used form of GFP is enhanced GFP (eGFP) because its autofluorescent properties are very similar to fluorescein conjugated probes commonly used in most immunohistological studies. However, its emission spectrum spills into GFP sapphire and GFP topaz, limiting its use in multicolor experiments.

Sample preparation appears to be important for preserving GFP fluorescence in histological section. eGFP does not appear to tolerate standard paraffin embedding and instead requires frozen sections to be prepared from histological studies. However, GFP topaz, sapphire, and emerald do maintain a strong fluorescent signal in paraformaldehyde fixed, EDTA decalcified and paraffin embedded sections of bone. This allows regions of fluorescence within the histological section to be examined under optimal tissue-preserving conditions. Once the fluorescent image is recorded, standard histological staining is performed for optimal interpretation of the section. Bone has the additional problem of a high autofluorescent background in the bone marrow and to a lesser degree in the bone matrix. Use of a dual filter cube optimized for GFP and in the Texas red or rhodamine spectrum allows the green GFP signal to be separated from an orange to yellow autofluorescent color. The section can be examined by either laser confocal microscopy or standard mercury bulb illumination.

The power of the GFP transgenes in primary culture is the detection of the fluorescent signal in the same plate as it progresses from initiation of the culture to full osteoblast differentiation. In this setting, the time that the cells activate the transgene can be accurately determined and

the transcription profile of that subpopulation of cells can be determined by FAC sorting for the GFP-positive cells. For example, a pOBCol3.6 promoter fragment activates GFP concomitant with the expression of alkaline phosphatase and type I collagen synthesis, which is at the stage of preosteoblast differentiation. Once bone nodules form and begin to mineralize, the pOBCol2.3 promoter fragment becomes active along with osteocalcin expression marking the stage of mature osteoblast/osteocyte differentiation. The two promoter GFP constructs have a different pattern of cellular fluorescence in sections of bone. The pOBCol3.6GFP transgenic mice show expression in the periosteal fibroblasts and lining osteoblast but with little expression in osteocytes. The pOBCol2.3GFP is not expressed in the periosteum but is found on lining osteoblasts and throughout the bone matrix. We envision building a series of promoter-GFP transgenic mice in which different stages of cellular differentiation are marked by a different color of GFP. These mice will provide the ability to recognize stages of differentiation within a complex tissue much like the cell surface markers that are used to identify precursor cells within the hematopoietic lineage. If these reagents become widely disseminated, they can provide a way to standardize the analysis of factors affecting bone biology at the level of lineage control whether in intact animals or primary culture derived from the mice.

The availability of GFP transgenes making stages of cell differentiation will have a wide variety of uses. In primary cell culture, the activation of GFP transgenes can be used to assess the tempo of differentiation and the proportion of clusters of preosteoblasts that form nodules with full bone cell differentiation. Transgenes marking differentiation of adipocytes, smooth muscle cells, and chondrocytes (Grant *et al.,* 2000) as well as vascular and endothelial cells (Kishimoto *et al.,* 2000) are available and need to be modified to a GFP that will function in paraffin-embedded tissues. These markers will allow the investigator to appreciate the complexity of primary marrow stromal cultures and factors that can modulate the culture to various lineages. Possibly its most useful application will be in microarray analysis of the osteoblast lineage. Interpretation of a complex array pattern is extremely difficult in a heterogeneous cell population. Is the change in an expression pattern a consequence of the change that occurred in a subpopulation that only represents 25% of the entire cell population? Are important patterns lost because of an increase in one subpopulation and a fall in another? The GFP also allows the isolation of a specific cell population from a heterogeneous population. The cells can be analyzed by Fluorescent-activated cell sorting (FACS) and even collected by cell sorting for biochemical or cellular analysis. This isolation may be in an essential requirement for interpreting microarray experiments.

In intact bone, direct visualizing the cells that express the transgene, which in turn reflect a level of attained differentiation during development, in a knockout model or in response to a drug intervention, will assist in the interpretation of experimental data. Building mosaic mice in which the identity of donor cells are distinguished by transgene expression can reveal cell-cell interactions that could not be appreciated in any other way. For example, mosaic mice created with β-Gal marked chondrocytes obtained from the PTHrP receptor -/-mouse produce islands of β-gal positive hypertrophic chondrocytes within an elongated zone of proliferating and β-gal negative chondrocytes. This outcome affirmed the model molecular pathway that coordinates lineage maturation within the growth plate. Loss of the PTHrP pathway induced early differentiation and these hypertrophic cells secrete ihh, which stimulates the surrounding PTHrP intact cartilage, and color osteoblastic cells into a proliferative and nondifferentiating state (Chung *et al.,* 2001). A third application is in transplantation studies of marrow stromal cells for somatic gene therapy for diseases of bone. Most of these studies to date have used nonspecific markers genes, which did not reflect differentiation into the bone lineage. Engraftment of cells expressing the OC CAT transgene has been demonstrated by *in situ* hybridization providing the most convincing data to date that osteoblastic precursor cells can engraft bone and participate in endogenous bone formation (Hou *et al.,* 1999). In the future, GFP will be a more robust and versatile marker for quantitative studies of cellular engraftment and demonstration of transplanted stem cells by direct marrow stromal cell culture of the transplanted mice.

TRANSGENES AS TOOLS TO ABLATE A SPECIFIC POPULATION OF CELLS AFFECTING BONE BIOLOGY

Defining progenitor cells that differentiated into specialized cell types is important to understanding the pathogenesis of disease as well as for the development of new therapies that incorporate tissue regenerative approaches. The skeleton is no exception to this area of biomedical research. The development of transgenic technology has permitted the production of experimental systems that remove or destroy specific types of cells. The approach is to develop a transgene that produces a peptide that is lethal or results in a lethal condition with the addition of a specific compound or reagent. The A chains of the diphtheria toxin have been exploited to created paradigms that result in direct cellular lethality (Breitman *et al.,* 1990) while conditional lethality is accomplished with the herpes thymidine kinase gene (Borrelli *et al.,* 1989; Zhang *et al.,* 2005). Although the viral thymidine kinase (tk) gene when expressed in mammalian cells shows no deleterious affects, the addition of nucleoside analogs that are only phosphorylated by the viral tk results in lethality of cells expressing the viral enzyme. However, this conditional lethality has limitations as it only impacts dividing cells that incorporated

the analogs into DNA. In addition, male sterility is also a limitation; however, this has been minimized with the development of a truncated version of the gene that maintains catalytic activity but does not cause male sterility (Salomon *et al.,* 1995). Corral *et al.* (1998) employed the unmodified form of viral tk to examine the association of bone form with resorption. A transgenic line was developed using the mouse osteocalcin gene 2 (OG-2) promoter to drive viral tk expression. Treatment of transgenic mice with ganciclovir resulted in the development of an osteoporotic phenotype that recovered after the cessation of drug treatment. The osteopenia was associated with a destruction of osteoblasts; however, osteoclasts were still present. These observations were interpreted as documenting an uncoupling of bone formation and bone resorption. A second model employed a Col1a1 promoter to control the expression of the truncated form of the tk gene. This transgene contained a 2.3 kilobase fragment of the rat Col1a1 promoter that restricted transgene expression to early osteoblasts (Visnjic *et al.,* 2001). After a 2-week treatment with ganciclovir, there was a complete loss of osteoblasts; however, osteocytes were unaffected. Further osteoclasts were absent and there was substantial destruction of the hematopoietic compartment. A more detailed evaluation of hematopoietic parameters showed that in treated transgenic mice there was a loss of lymphoid, erythroid, and myeloid progenitors in the bone marrow. This bone marrow loss was complemented by an elevation of extramedullary hematopoiesis in the spleen and liver (Visnjic *et al.,* 2004). A more recent study by Boban *et al.* (2006) employing conditional ablation in a parabiotic model reported a rescue of the bone marrow destruction consistent with the circulation of hematopoietic stem cells. The significant differences observed between the osteocalcin promoter-driven transgenic model and the Col1a1 system is most likely the result of differences in the temporal expression of the transgenes in the osteoblast lineage. The osteocalcin-driven expression occurs in late lineage osteoblasts and osteocytes. These cells are not involved with the synthesis of new osteoid and thus do not have a significant impact of the activity of osteoclasts. Furthermore, early-stage osteoblasts are actively making osteoid and undergoing some cell division and are more susceptible to ganciclovir toxicity.

PROBING SKELETAL BIOLOGY WITH STRATEGIES THAT DISRUPT THE ENDOGENOUS GENES

The completion of the sequencing of the mouse genome has changed the landscape of mammalian genetics. The availability of gene sequence data has refocused research initiatives away from understanding genome structure and has directed efforts toward understanding gene function. The availability of gene targeting technologies has lead to the development of new experimental paradigms utilizing genetically engineered strains of mice with alterations that disrupt or modify the function of an endogenous gene. Tools that have been developed have made the creation of gene targeting vectors easier and more rapid (Copeland, *et al.,* 2001; Chan *et al.,* 2007). Mouse models have been developed that permit both the spatial and temporal modulation of a specific gene's function. The Cre/loxP recombinase system is the centerpiece of the new experiment models. Cre (causes recombination), an enzyme from P1 bacteriophage, directs recombination at loxP (locus of X-ing over) recombination recognition sites. A segment of DNA flanked by two directly orientated loxP sites is excised from the genetic material, resulting in a deletion of this genetic information. The application of the Cre/loxP recombinase system generally involves two genetically engineered strains of mice. One strain is a transgenic line expressing Cre recombinase under the control of a tissue-specific promoter. The other transgenic lines typically bear a targeted allele in the locus of interest. This targeted allele is generated by homologous recombination in ES cells and contains loxP sites that flank (floxed) a region of the gene in such a way that upon Cre-mediated recombination the function of the targeted allele is altered, typically gene activity is lost. The first knocking model of osteogenesis imperfecta was developed using this system (Forlino *et al.,* 1999). This experimental paradigm bearing a floxed gene, referred to as the brittle IV mouse, is a model for osteogenesis imperfecta IV that has been used to study whole bone architecture in various age groups (Kozloff *et al.,* 2004). Several Cre-expressing lines have been developed that directed Cre expression to specific skeletal cell types. Chondrocyte and hypertrophic chondrocyte specific Cre transgenic mice have been developed using the Col2a1 and Col10a1 promoter, respectively (Ovchinnikov *et al.,* 2000; Sakai *et al.,* 2001; Hao *et al.,* 2002; Yang *et al.,* 2005). An alpha2 type XI Cre transgene also is expressed in cartilage (Fujimaki *et al.,* 2005). The type I collagen promoter has been utilized to drive Cre expression in cells of the osteoblasts (Dacquin *et al.,* 2002; Cochrane *et al.,* 2007) and the dentin matrix protein gene has been used to express Cre in odontoblasts and osteocytes (Lu *et al.,* 2007). Transgenic lines bearing TRAP (tartrate-resistant acid phosphatase)-Cre and Ctsk (cathepsin K)–Cre permit rearrangement of floxed genes in osteoclasts (Chiu *et al.,* 2004). In the utilization of various Cre-expressing lines, it is important to confirm the expression of the Cre transgenes as unanticipated results have been observed. Cochrane *et al.* (2007) observed germline loxP rearrangement of a loxP-flanked Ifg1 allele by both Col3.6Cre and Col2.3Cre transgenes. Further rearrangement was seen without the inheritance of the Cre-bearing transgene. As a tool to assist in the evaluation of the Cre transgene expression several reporters transgenic lines have been developed. These lines bear transgenes

consisting of a ubiquitous promoter fused to a visible reporter (i.e., GFP or lacZ) flanked by loxP sites in such a fashion as to prevent expression without Cre-mediated loxP excision (Mao *et al.,* 2001; Soriano, 1999). By crossing a Cre-expressing line with a ubiquitous Cre activity reporter bearing line an evaluation of the reporter's colorimetric expression (GFP or lacZ) in tissues of progeny bearing the Cre-expressing transgene and the reporter will be informative as to the tissue specificity of Cre expression as well as the efficiency of Cre-driven loxP site rearrangement. Finally, information of extant Cre lines, numerous floxed genes, lines under development as well as up-to-date information on Cre reporter systems can be obtained from a website maintained by Andras Nagy (http://www.mshri.on.ca/nagy/). The tissue-specific regulation of Cre recombinase expression is an effective tool to examine genetic function of a defined locus, experimental paradigms have been developed that permit both spatial and temporal control of Cre function. One experimental system involves combining the Cre recombinase with a modified version of the human estrogen receptor. This fusion protein, referred to as Cre-ERT, lacks recombinase activity without the addition of the receptor's ligand. The receptor component of the chimeric protein has been modified so that the receptor does not respond to the natural ligand, estradiol; however, the recombinase function is activated by tamoxifen, an estradiol analog (Brocard *et al.,* 1997). A second-generation, more sensitive version (Cre-ERT2) of this system has been developed. The modified Cre-ERT2 is 10 times more sensitive to tamoxifen than the original Cre-ERT (Indra *et al.,* 1999). Lines of transgenic mice bearing inducible Cre recombinase have been developed that control the expression of Cre in specific bone cell types. Specifically, a Cola1CreERT2 transgene that utilizes a 2.3 kb segment of the mouse Col1a1 promoter is expressed in skeletal osteoblasts as well as odontoblasts in teeth (Kim *et al.,* 2004). The type II collagen gene has been employed to regulate an inducible Cre in chondrocytes (Nakamura *et al.,* 2006; Chen *et al.,* 2007; Hilton *et al.,* 2007). The inducible Cre system permitting both temporal and spatial deletion of a specific gene's function also allows an investigator to study the role of a particular genetic unit in the development or homeostasis of a particular tissue or cell type that might not be possible with a non-inducible system because of embryonic lethality.

INTRODUCTION

Biochemical markers of bone metabolism have been used in clinical practice for decades. Over the years, major advancements involved the development of assays to measure markers that more precisely reflect the process of bone resorption or formation, as well as sensitive, high-throughput techniques. This has made the measurement of bone markers a widely used practice in the clinical management of metabolic bone disease. In addition, their application in clinical studies and trials has provided a sound knowledge base in regard to the relationship between markers of bone turnover and specific clinical outcomes such as bone mass or fractures. In the clinical development phase of new drugs for metabolic bone disease, these established correlations are particularly important, as most markers respond rapidly to pharmacological interventions and can therefore be considered in the evaluation of drug effects.

Although bone turnover markers can be valuable in the management of patients with metabolic bone disease and in drug development, their application has caveats and limitations related both to the practical aspects of assays and sample handling and to the interpretation of data.

This chapter discusses currently available biochemical markers of bone turnover and related aspects that are relevant to correct utilization of these laboratory tests. Several examples follow to illustrate their application in clinical medicine and clinical drug development.

BIOCHEMICAL MARKERS OF BONE METABOLISM

Bone Turnover

The skeleton is continually renewed by a process called bone turnover, involving osteoclast-mediated bone resorption, osteoblast-mediated bone formation, and remineralization of newly formed bone. Bone turnover, which takes place in bone multicellular units, is usually initiated by osteoclasts eroding a mineralized surface (see Chapter 8). When osteoclasts resorb bone, they secrete a mixture of acid and neutral proteases that act sequentially to degrade the collagen fibrils into fragments. Biochemical markers of bone resorption therefore include these collagen breakdown products such as hydroxyproline, hydroxylysine glycosides, and the pyridinoline cross-links. These cross-links range in size from free amino acids to larger segments of the N-telopeptide and C-telopeptide domains. Other markers of bone resorption are enzymes secreted by the osteoclast involved in the degradation of collagen type I, such as tartrate-resistant acid phosphatase and cathepsin K, and a noncollagenous protein of the bone matrix, bone sialoprotein.

The initial step of bone resorption is followed by the recruitment of osteoblasts to the outer edge of the erosion cavity. The osteoblasts secrete new bone matrix (osteoid) that gradually fills in the resorption cavity. Biochemical markers of bone formation are products of this osteoblastic activity. These osteoblast products include the amino (N) and carboxy (C)-terminal propeptides of type I collagen, osteocalcin, and bone-specific alkaline phosphatase. Figure 1 is a schematic representation of the currently known biochemical markers of bone formation and resorption.

Principles of Bone Biology, 3rd Edition

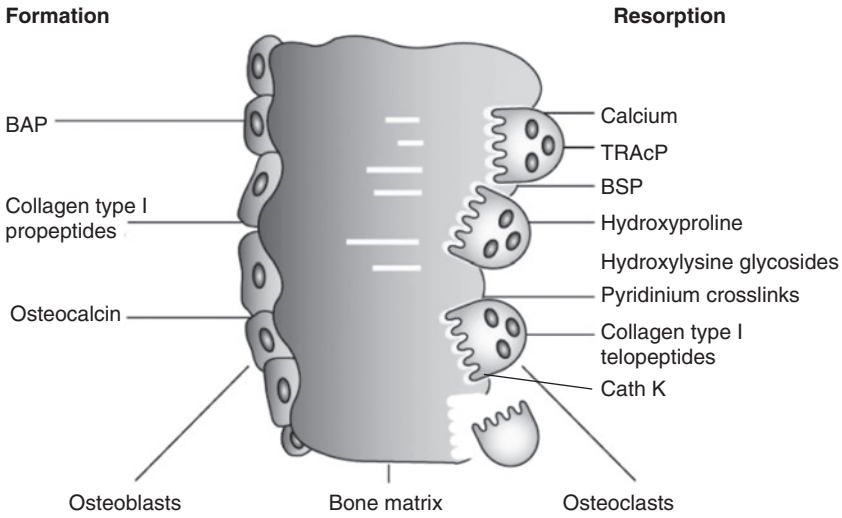

FIGURE 1 Biochemical markers of bone turnover (adapted from Seibel, 2005).

In addition to assigning bone turnover markers specifically to the process of bone resorption or bone formation, certain markers appear to reflect different stages of these cellular activities. On the other hand, bone turnover markers cannot distinguish between diseases nor do they reflect disease-specific processes. The markers are also unable to distinguish between activities occurring at cortical or trabecular bone elements of bone.

Variability

The level of any bone turnover marker in body fluids such as serum or urine depends only in part on the production rate of the marker, which can vary substantially between diseases and between individuals. In addition, concentrations of bone markers in serum and urine are influenced by factors unrelated to bone turnover, such as the rate of their elimination or clearance as well as their extraskeletal metabolism. Such factors lead to substantial intra- and interpatient variability in the measurement of markers. Finally, factors related to the analyses themselves can contribute substantially to the variability of these parameters, such as sample storage and technical assay considerations. Thus, storage-associated enzymatic, photo- and/or thermodegradation may occur. Sample handling in which hemolysis occurs can also be a confounding issue.

Analytical Variability

At present, most markers of bone turnover are measured by either immunoassays such as enzyme-linked immunosorbant assay (ELISA), electrochemiluminescence immunoassay (ECLIA), and radioimmunoassay (RIA) or by chromatographic assays such as high-performance liquid chromatography (HPLC) or liquid chromatography/ mass spectrometry (LC/MS) (Seibel, 2005). Most immunoassays are now available on automated platforms. At relevant concentrations, the intra- and interassay variability of most assays with automated platform technology is less than 10%, a considerable improvement over previous assay methods. The contribution of analytical imprecision to overall variability in the level of the markers is relatively small, but substantial differences can exist among different methods for the same marker, which may be relevant for relating results obtained with one method to data collected with another. Therefore, new assays always need to be cross-validated, and potential discrepancies between results from one assay and results of another should always be taken into consideration (Seibel, 2001).

Biological Variability

The level of each bone turnover marker is a result of production, distribution, and elimination of the marker, all of which can be described by the kinetic parameters production rate, clearance, volume of distribution, and half-life. These parameters and thus the level of the markers and their variability depend on factors such as growth, age, gender and body weight, ethnicity and geography, pregnancy and lactation, diet, exercise and mobility, menstrual and seasonal cycles, previous fracture, the metabolic bone disease, and hepatic and renal (dys-)function (Hannon, 2000). Moreover, all bone turnover markers exhibit a circadian rhythm (see Fig. 2) (Ju, 1997). The extent of circadian variability is a function of both the variation in the production rate and the half-life of the marker. Thus, a marker with a relatively short half-life may show more circadian variability than a marker with a longer half-life. Another factor known to influence levels of some markers of bone

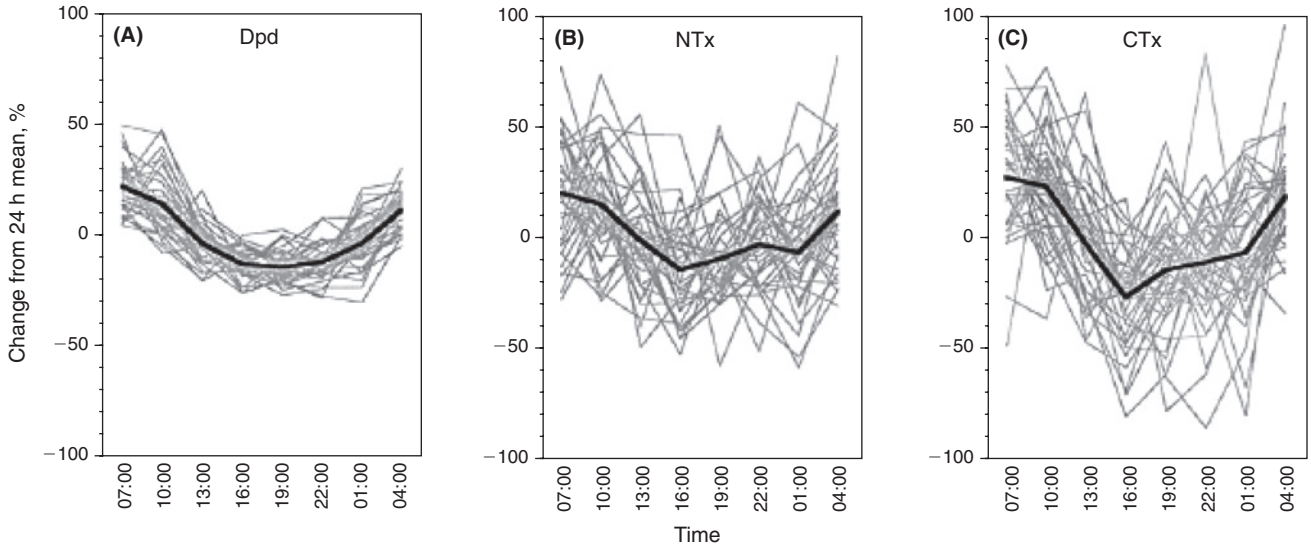

FIGURE 2 Diurnal variation in excretion of creatinine-corrected Dpd (**A**), NTx (**B**), and CTx (**C**) in 17 women and 21 men. The heavy line represents the mean; thin lines represent individuals.

metabolism is food intake (Hannon, 2000), which appears to be mediated in part by glucagon-like peptide-2 (GLP-2) (Henriksen, 2003).

A number of recent studies address the influence of factors such as renal dysfunction on the concentration range of the markers (Tsuchida, 2005), whereas other studies go even further trying to quantify the effect of potentially perturbing factors such as renal function on the kinetic parameters of the markers (Holford, 2006). Although at present no adequate guidelines exist, potentially perturbing factors should be taken into consideration when interpreting the level of a marker in a population or an individual patient (Hannon, 2000; Seibel, 2005).

In an individual patient, some of these factors can be accounted for and are therefore controllable. Examples of such factors are circadian rhythms, fasting status, menstrual status, diet, and exercise. Standardizing the timing and conditions of sample collection, for example, by always obtaining second morning void urine samples, and by asking patients to refrain from exercise 24 hours before a sample is collected are ways to control for these variabilities (Hannon, 2000). Uncontrollable factors contributing to variability are age, gender, ethnicity and geographic location, previous fractures, season, pregnancy and lactation, drugs, immobility, and comorbidities.

Bone Turnover Markers during Drug Treatment

Monitoring of treatment is one of the most important clinical applications of bone markers. It is also complicated because, in this case, not just the aforementioned factors causing variability should be taken into consideration when interpreting levels of a marker, but also the pharmacokinetics of the drug and its mechanism of action and potency are important. Finally, bone resorption and bone formation strongly differ in their kinetics. It takes osteoclasts only a few days to resorb bone, whereas the formation of bone by osteoblasts takes months.

The relevance of some of these factors is illustrated by the difference in response of bone resorption and formation markers to anabolic and antiresorptive therapy, respectively. For example, rhPTH, when given intermittently (single daily injection) is anabolic, stimulating osteoblast function. This is reflected by an increase in bone formation markers such as PINP once treatment has commenced, and a slower and later increase in bone resorption markers such as S-CTX (Fig. 3); (Bauer, 2006). This pattern is in line with anabolic mechanisms of rhPTH actions as well as with the coupling between bone formation and resorption. In contrast, potent antiresorptive agents such as the bisphosphonates induce a rapid initial decrease in the level of bone resorption markers, which is usually followed by a slower and later decrease in the levels of bone formation markers (Fig. 4); (Reid, 2002). The different patterns of change in bone markers observed between the anabolic and antiresorptive agents can be explained, at least in part, by the difference in mechanism of action as well as pharmacokinetic properties of these drug classes.

MARKERS OF BONE FORMATION

Alkaline Phosphatase

The enzyme alkaline phosphatase (ALP) belongs to a large group of proteins attached to the extracellular surface of cell

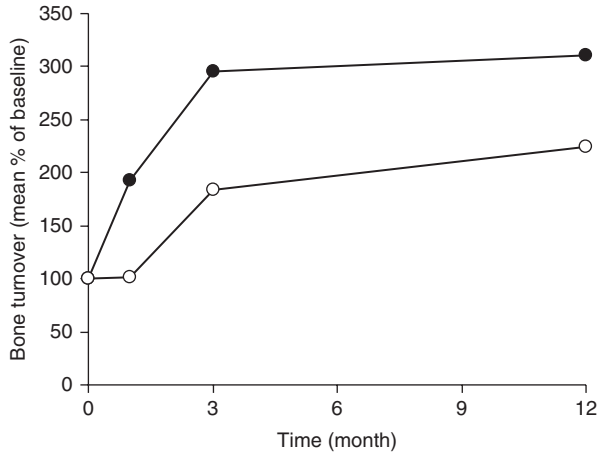

FIGURE 3 Mean levels of PINP (*filled circle*), and S-CTX (*open circle*) as a percentage of baseline in 119 osteoporotic women treated with intermittent s.c. PTH(1–84) 100 μg/day for 1 year (adapted from Bauer, 2006).

membranes via a carboxy-terminal glycan-phosphatidylinositol anchor (Low and Saltiel, 1988). Four gene loci code for ALP: three tissue-specific genes encode the intestine, mature placenta, and germ-cell enzymes; the tissue-nonspecific gene for ALP is expressed in numerous tissues (including bone, liver, kidney, and early placenta). Tissue nonspecific ALPs are the products of a single gene, but tissue-specific differences are found in their electrophoretic mobility, stability to heat, and sensitivity to a variety of chemical inhibitors. These differences are caused by variations in their carbohydrate side chains (Weiss, 1988). Because the two most common organ sources of elevated ALP levels are liver and bone, a number of techniques have been developed to distinguish between bone and liver isoforms. They rely on the differences in the carbohydrate side chains. Early methods included heat denaturation, chemical inhibition of selective activity, gel electrophoresis, and precipitation by wheat germ lectin (Calvo, 1966). Now, commercially available bone-specific immunoassays utilize monoclonal antibodies with preference for the bone isoform. They are the most commonly used method today.

A two-site immunoassay (Tandem-R-Ostase, Hybritech Inc, San Diego, CA) relies on the use of two monoclonal antibodies, both of which react preferentially with the bone isoform. This assay measures mass of the enzyme (Garnero and Delmas, 1993). Alkphase-B (METRA Biosystems, Mountain View, CA) uses a single monoclonal antibody and measures activity of the enzyme (Gomes, 1995). Comparisons of mass and activity-based immunoassays show that two methods generally provide similar clinical information. However, demonstrated variations in glycosylation patterns raise the question of immunological heterogeneity in the bone isoform which may affect the mass-to-activity ratio (Kress, 1998). Bone ALP is stable for 5 days at 2 to 8° C, for 12 months at −40° C, and for 36 months at −80° C (Metra BAP kit, package insert).

There is a great deal of interindividual variation in ALP levels, but for any one individual, values are stable over time. Bone ALP has a half-life of about 40 hours and like other glycoproteins is cleared by the liver (Crofton, 1982). Levels of bone ALP were higher in chronic kidney disease patients compared with age-matched controls and were inversely correlated with creatinine clearance (Tsuchida, 2005). Biological within-day variation of total ALP is estimated to be less than 4%. There is some evidence of a small diurnal variation in ALP activity that may be caused by the bone component (Nielsen, 1990). Like other bone formation markers, bone ALP is elevated during the luteal phase of the menstrual cycle, albeit only slightly (Nielsen, 1990). Seasonal variations have been described (Devgun, 1981; Douglas, 1996). Bone ALP levels are affected by age, gender, and hormonal status (Calvo, 1996), and levels have been reported to change in pediatrics with dramatic increases during puberty (Blumsohn, 1994; Crofto, 1992). In the third trimester of pregnancy bone ALP levels are significantly elevated (Naylor, 2000; Cross, 1995; Black, 2000). Fractures cause an increase that can last for at least one year (Bowles, 1996, 1997; Woitge, 1996).

Osteocalcin

Osteocalcin is a small protein synthesized by mature osteoblasts, odontoblasts, and hypertrophic chondrocytes. It has three residues of the calcium-binding amino acid, γ-carboxyglutamic acid (Gla). Osteocalcin is thought to interact directly with hydroxyapatite in bone through its Gla residue (Hauschka, 1989). Vitamin K is required for the post-translational gamma-carboxylation of osteocalcin (Lee, 2000).

Osteocalcin is primarily deposited in the extracellular matrix of bone, but a small amount enters the blood. Serum osteocalcin is a sensitive and specific marker of osteoblastic activity and its serum level thus reflects the rate of bone formation (Brown, 1984; Weaver, 1997; Charles, 1992).

There is some evidence that serum osteocalcin may also be derived from activities associated with bone resorption. There are several commercial kits for measuring human osteocalcin in serum, although obtained results do not correlate well between the various assays and wide variations are reported in control and patient populations (Gundberg, 1998; Gundberg and Nishimoto, 1999). Various fragments of osteocalcin can circulate (Gundberg and Weinstein, 1986; Garnero, 1994a; Taylor, 1990), and the observed assay variability is thought to be the result of differences in the ability of the various antibodies to bind these fragments. Several laboratories have developed two-site immunoassays with the intention of measuring only the intact molecule. However, rapid loss of immunoreactivity is observed with these assays when samples are left at room temperature for a few hours (Colford, 1999; Garnero, 1992; Monaghan, 1993; Parvianen, 1994).

A new generation of osteocalcin assays is based on studies which suggest that the intact molecule is degraded to a large amino(N) to midmolecule fragment in the range of residues 1–43 (OC1-43). The large N to midmolecule fragment is thought to be generated by proteolysis in the circulation or during sample processing and storage, but there is some evidence that the osteoblast is an additional source of the fragment (Gundberg, 2000). In one study, the intact molecule represents only about one-third of the circulating osteocalcin immunoreactivity. One third is composed of the N to midmolecule fragment, and another third by several other smaller fragments (Garnero, 1994a). Osteocalcin levels fall with incubation at room temperature when measured by conventional radioimmunoassays (RIAs) or by intact assays, but values are stable with an assay that recognizes both the intact and large N to midmolecule fragment. With this assay apparent instability of osteocalcin in the circulation and during sample handling is eliminated and the correlation with bone density is improved (Minisola, 1997; Dumon, 1996; Rosenquist, 1995). Immunoreactive fragments of osteocalcin have also been reported in the urine (Taylor, 1990), and recently, assays were also reported for osteocalcin fragments in urine (Ivaska, 2005). Urinary osteocalcin holds promises as a marker of bone metabolism, which is illustrated by its ability to monitor antiresorptive bisphosphonate treatment (Ivaska, 2005, 2005b).

The main route of circulating osteocalcin catabolism is renal glomerular filtration and degradation. The plasma half-life is about 20 minutes in humans. Levels of intact osteocalcin are higher in patients with chronic kidney disease compared with age-matched controls. The levels are inversely correlated with creatinine clearance (Tsuchida, 2005). Osteocalcin levels follow a circadian rhythm characterized by a decline during the morning to a low around noon, followed by a gradual rise that peaks after midnight (Gundberg, 1985). The difference between the peak and nadir in a 24-hour period can range from 10% to 20% depending on the assay used. Higher levels in the winter and spring have been reported as compared with summer and fall (Woitge, 1998. Douglas, 1996.Thomsen, 1989), and there is a significant increase in osteocalcin levels during the luteal phase of the menstrual cycle (Nielsen, 1990). Osteocalcin levels in children are higher than in adults and correlate with growth velocity, reaching a peak at puberty. Levels are higher in men than women. An age-related decline but a transient increase after the fifth decade in women have been described (Vanderschueren, 1990). Serum osteocalcin is increased after a fracture with levels remaining elevated for at least 3 months (Obrant, 1990). Although bone formation is normally increased during the third trimester of pregnancy, osteocalcin levels are not, a point that may be caused by placental degradation (Rodin, 1989).

Procollagen Peptides

All collagens contain triple-helical molecular domains. The newly translated polypeptide, a pre-pro-α chain, includes a signal sequence and amino (N)- and carboxyl (C)-terminal propeptide extensions. During collagen synthesis, the C propeptides guide the selection and association of the individual pro-αchains and prevent premature intracellular fiber formation. Specific extracellular endoproteinases cleave the procollagen molecule at precise sites in each chain. The C-terminal endoproteinase is identical to bone morphogenic protein (BMP-1) (Kessler, 1996). The C propeptide (PICP), which is a trimeric globular glycoprotein, is stabilized by disulfide bonds and circulates as a single molecule (Olsen, 1977). It has a serum half-life of 6 to 8 minutes and is cleared by hepatic endothelial cells by the mannose 6-phosphate receptor (Smedsrod, 1990). The procollagen type I amino-terminal propeptide (PINP) is a partly globular, partly helical (collagenous) 35-kDa protein. PINP circulates mainly as the intact trimeric molecule but monomers are also found (Brandt, 1999). The intact molecule is cleared from the circulation by the scavenger receptor of liver endothelial cells (Kivirikko and Myllyla, 1980). There have been suggestions that a low-molecular-weight, degraded form of PINP monomer also circulates (Melkko, 1996). PINP has a half life of 1 minute as determined in the rat model. Levels of PINP are higher in chronic kidney disease patients than age-matched controls and inversely, but not significantly, correlate with creatinine clearance (Tsuchida, 2005).

The procollagen extension peptides are cleaved from the newly formed molecule in a stoichiometric relationship with collagen biosynthesis. Therefore, they should reflect bone formation in a manner analogous to the assessment of C peptide for endogenous insulin production. However, because type I collagen is also a component of several soft tissues (fibrocartilage, tendon, skin, gingiva, intestine, heart valve, large vessels, and muscle) there is a potential

contribution to circulating procollagens from soft tissue synthesis of type I collagen, as is the case for almost all collagen type I-related markers, including NTX and CTX. Nevertheless, because the rate of turnover of collagen in bone is faster than in other tissues, changes in procollagen concentrations are assumed to reflect changes primarily in bone collagen synthesis. Indeed, good correlations have been shown between PICP serum levels and the rate of bone formation (Eriksen, 1993; Hassager, 1991). Similar to other markers, PICP and PINP demonstrate a circadian rhythm with peak values occurring in the early morning hours and nadirs in the afternoon (Hassager, 1992; Saggese, 1994).

There are several assays available for the measurement of PICP and PINP, including RIA and ELISA methods. Recently, a PINP assay has become available on an automated platform (Roche Diagnostics). Some assays measure only the high-molecular-weight (trimeric) forms, whereas others also measure the low-molecular-weight (monomeric) forms (Orum, 1996; Jensen, 1998, Brandt, 1998). Serum samples are stable at 2 to 8° C for up to 5 days and for a longer period at −20° C. Repeated freeze-thaw cycles should be avoided.

Measurement of intact PINP appears to be more sensitive than total PINP and may provide more specific clinical information (Brandt, 1999; Orum, 1996; Chandani, 2000; Dominguez, 1998).

Seasonal variation in PICP levels appears to be small (Woitge, 1998; Blumsohn, 2003). PICP and PINP levels are higher in children than in adults with an increase during puberty (Blumsohn, 1994). Fractures increase levels of PINP significantly within 1 to 4 weeks, which remain elevated during at least 1 year (Ingle, 1999; Ingle, 1999b).

Markers of Bone Resorption

Hydroxyproline

Hydroxyproline (OHP) is present in essentially all tissues and all genetic types of collagen. Hydroxyproline is derived from the breakdown of collagen. The majority of the breakdown products are reabsorbed by the renal tubules and broken down in the liver, whereas only about 10% is excreted in the urine. Most are contained in di- and tripeptides (Prockop and Kivirikko, 1967; Smith, 1980). The remaining peptides in the urine are of approximately 5 kDa. There is a small amount of the free amino acid in urine. Hydroxyproline can never be reincorporated into newly synthesized collagen (Prockop, 1964), but both collagen synthesis and tissue breakdown contribute to urinary hydroxyproline. Colorimetric methods or high-performance liquid chromatography (HPLC) are commonly used to measure urinary hydroxyproline.

Urinary OHP is historically important as a marker of bone resorption, and is still a good marker when applied correctly. As a matter of fact, studies using calcium kinetics show a better correlation between bone resorption and OHP than some supposedly more specific markers. Nevertheless OHP has now largely been replaced by other bone resorption markers, mainly because of its lack of specificity for bone, including a large contribution from the C1q fraction of the complement, the need to restrict intake of gelatin and other collagen-rich foods to avoid the contributions of exogenous OHP to urinary measurements, and the contributions of OHP from the degradation of newly synthesized collagen (Calvo, 1996).

Collagen Cross-Links

Pyridinoline and Deoxypyridinoline

Newly deposited collagen fibrils in the extracellular matrix are stabilized by intramolecular and intermolecular cross-links. The main cross-links in skeletal tissues are the trivalent structures, deoxypyridinoline (DPD) and pyridinoline (PYD). The pyridinoline cross-links occur at two sites placed symmetrically at about 90 residues from the ends of the 1000-residue helical domain of the collagen fibril. Pyridinolines act as mature cross-links in fibrillar collagens of all major connective tissues other than skin (Eyre, 1984, 1988). This includes type I collagen, which is present in bone, dentin, ligaments, fascia, tendon, vascular walls, muscle, and intestine (but absent from skin). In all tissues PYD predominates, with DPD being the minor component. However, DPD is most abundant in bone and dentin and is considered the more specific bone marker because bone represents the major reservoir of total collagen in the body and turns over faster than most other connective tissues (Eyre, 1984; Seibel, 1992; Robins, 2006). This conclusion is supported by the strong correlations between DPD and bone resorption rates as determined by radio-tracer kinetics (Eastell, 1997).

Pyridinoline cross-links are released during collagen breakdown and are cleared by the kidneys. In serum and urine, PYD and DPD are present as both free amino acid derivates (about 40%) and as oligopeptide-bound fractions (about 60%) with the rate of bone turnover potentially influencing the unbound (free) fraction (Robins, 1991; Delmas, 1993; Eastell, 2003; Randall, 1996). The free form can be measured directly, whereas the conjugated form has to be hydrolyzed before assay, in which case the total amount of PYD and DPD is determined (Black, 1988; Colwell, 1993). Such acid hydrolysis is followed by solid-phase extraction, separation by HPLC, and quantitation by fluorescence (Eyre, 1984; Black, 1988, 1989; Seibel, 1989; Colwell, 1993, 1996). Good correlations between free and total cross-links are found in normal subjects and in patients with disorders associated with increased bone resorption (Robins, 1990l Abbiati, 1993) allowing direct analysis of urine samples without the need for the hydrolysis step. Specific immunoassays have been developed for DPD (Robins, 1994) and for both pyridinium cross-links (Gomez, 1996).

The cross-link markers provide distinct advantages over urinary OHP. First, they are not influenced by dietary collagen intake (Colwell, 1993). Second, they are formed only at the final stages of fibril formation and are therefore unaffected by degradation of newly synthesized collagen (Robins, 1983; Eyre, 1980). They are not reused in collagen biosynthesis, but there is evidence that some free PYD and DPD excreted into urine is produced by the kidney (Colwell, 1996), which may depend on the rate of bone turnover (Eastell, 2003). DPD excretion seems relatively unaffected by changes in renal function (McLaren, 1993), yet significant relationships have been described between creatinine clearance and serum PYD and DPD levels (Tsuchida, 2005).

Several direct immunoassays for the cross-links and a number of ELISA systems have been reported (Seyedin, 1993; Robins, 1994; Gomez, 1996). Commercial kits are available, which measure both DPD and PYD in combination (Metra PYD, METRA Biosystems) or DPD alone (Metra DPD, METRA Biosystems). Direct comparison of the immunoassays with HPLC shows a high correlation between the methods. Commercial kits are also available to measure free PYD in serum (Metra Serum PYD, METRA Biosystems), and HPLC methods for total PYD and DPD in serum have also been described (Tsuchida, 2005).

Free and conjugated forms of Figure PYD and DPD are stable in urine samples kept at room temperature for several weeks. They can be stored at −20° C and repeated freeze-thaw cycles have no effect on their concentration in urine samples (Colwell, 1996b). DPD in urine shows diurnal variation (Ju, 1997; see 2), as well as seasonal variability (Woitge, 1997). Pyridinium cross-link levels are gender-specific and also depend on age, although this relationship is complicated. In elderly subjects the proportion of free pyridinolines is smaller than in adolescents and in healthy adults, but the excretion of total pyridinoline cross-links is higher, potentially owing to a change in the molecular distribution of pyridinoline cross-links (Kamel, 1995). To circumvent the problem of the variable excretion of free pyridinolines, the total amount can be determined.

Cross-Linked Telopeptides

C-telopeptides Two biochemical markers reflecting degradation of the C-terminal telopeptide of type I collagen have been described: CTX, which is released by cathepsin K cleavage of intact bone collagen and can be detected by an antibody raised against the EKAHDGGR amino acid sequence, and ICTP, which is a larger fragment produced by matrix metalloproteinase (MMP) cleavage (Risteli, 1999; Garnero, 2003).

The product of the MMP degradation of collagen type I, the large C-telopeptide fragments of type I collagen in serum (ICTP of CTX-MMP) can be used as biochemical marker of bone resorption, and a RIA and an EIA (Orion Diagnostics) are available (Risteli 1993). The antigenic determinant requires a trivalent cross-link, including two phenylalanine-rich domains of the telopeptide region of type I collagen. Cathepsin K cleaves the telopeptide structure between the phenylalanine-rich region and the cross-link moiety: cathepsin K therefore abolishes immunoreactivity in the ICTP assay (Garnero, 2003).

ICTP is cleared from the blood by the kidney and circulating levels are reportedly elevated in the majority of patients with chronic renal failure (Magnusson, 2001). ICTP showed a modest but significant circadian rhythm in premenopausal women, with about 20% higher values at night than in the afternoon (Hassager, 1992), and levels vary approximately 20% over the menstrual cycle, being higher in the luteal phase (Hannon, 2000). There is a considerable age and sex influence on ICTP levels in healthy children between 2 months and 18 years (Rauchenzauner, 2007), and fractures have been reported to increase ICTP levels by 73%, which may remain elevated for one year after fracture (Akesson, 2005).

The cross-linked C-terminal telopeptide of type I collagen, or CTX-I, is a sensitive but also rather variable marker of bone resorption, and several assays for the cross-linked telopeptide are commercially available. The development of the assays for this marker is characterized by differences in ELISA design (competitive versus sandwich), antibodies (polyclonal versus monoclonal), and antigens (nonisomerized [alpha] versus isomerized [beta] synthetic octapeptide EKAHDGGR). The assays are based on antibodies raised against a synthetic eight-amino-acid peptide (EKAHDGGR) derived from a segment of the C-telopeptide of the collagen α1(I) chain, and the cross-linking molecules can contain two of such peptides.

Some antibodies specifically recognize a form of the peptide containing an β-aspartyl peptide bond (AHD-β-GGR). The isomerization of aspartyl to beta-aspartyl residues occurs over extended periods of time and is associated with the aging of proteins and peptides (Bonde, 1997) and thus bone (Cloos, 2000). The equilibrium of the isomerization reaction is reached after about 150 days (Cloos, 2000) and, thus, the assay recognizing the beta-form measures the degradation of relatively old bone (Fledelius, 1997). Another antibody binds only the nonisomerized form of this octapeptide and presumably measures the degradation of relatively young bone (α-Ctx) (Bonde, 1997).

Currently, sandwich assays are available for serum and urine with two monoclonal antibodies recognizing only a form of the peptide with two beta-aspartyl peptide bonds (beta-beta CTX, Serum Crosslaps). Another sandwich assay with two monoclonal antibodies recognizes only a form of the peptide with two alpha-aspartyl peptide bonds (alpha-alpha-CTX, ALPHA Crosslaps) and is available only for urine. The assays are available in microtiter plate form (Nordic Bioscience) and on an automated platform (Roche Diagnostics for serum beta-beta CTX only). Results of the manual ELISA are comparable to the results

of the automated platform. The CTX assays measure a mixture of molecular entities rather than a single molecular entity (Fledelius, 1997). CTX has been reported stable in serum and urine, and freeze-thaw cycles have no effect on the levels (Ju, 1997).

Systemic CTX is excreted by the kidney as well as metabolized, with a renal excretion fraction of about 44% (Fall, 2000). CTX levels depend on renal (Okuno, 2003) and liver function (Seibel, 2005; Guanabens, 1998). By using modeling techniques, the half-life of serum beta-CTX in subjects with a normal renal and liver function has been estimated to be about 1 hour (Holford, 2006). Urine and serum CTX show considerable diurnal variation with a maximum at about 5 am, a minimum at about 2 pm, and a magnitude of about 40% around the 24-hour mean. Moreover, a significant influence of fasting has been described (Qvist, 2002). Urinary levels of CTX show a significant yet relatively small variation during the menstrual cycle (Gorai, 1998). Urinary excretion of CTX has been reported highest in early puberty in both girls and boys (Yang, 2006). Levels of serum CTX are highest in neonates and then markedly decrease in children after 1 year of age. A second peak is observed in girls 11 to 13 years of age and in boys who were 14 to 17 years old (Crofton, 2002; Yang, 2006).

NTX Another highly sensitive marker of bone resorption is cross-linked N-terminal telopeptide of collagen type I, also referred to as NTX. The assay is based on a monoclonal antibody raised against a peptide isolated from urine of a patient with Paget's disease of bone (Hanson, 1992). The antibody specifically recognizes the cross-linked α2(I)N-telopeptide sequence, QYDGKGVG, and in which K (lysine) is involved in the trivalent cross-linkage (Eyre, 1995). Because the rest of the molecule can differ, the NTX immunoassays actually determine a mixture of molecular entities (Hanson, 1992) rather than a single molecule. However, *in vitro* studies show that NTX can be quantitatively released from bone by the action of cathepsin K, a specific protease of the osteoclast. (Atley, 2000), and good relationships with calcium kinetics and histomorphometry data on bone resorption have been shown for NTX in urine (Weaver, 1997, Franke, 1998). Systemic NTX is excreted by the kidney and metabolized with a renal excretion fraction of 0.20 ± 0.07 (Fall, 2000).

The NTX ELISA is available as a commercial, microtiter-plate format (Osteomark, Inverness Medical Innovations Inc, Waltham, MA) and on an automated platform (Vitros ECu, Ortho Clinical Inc., Rochester, NY). The assays measure the NTX peptide in urine, calibrated in molar equivalents of type I collagen, and results are normalized to urinary creatinine concentrations. The manual ELISA has also been developed for measuring NTX in serum (Clemens, 1997), but this assay has not been widely used. NTX levels in serum and urine appear to be stable at room temperature and at $-80°$ C. Samples are stable below $-20°$ C (Ju, 1997) and during freeze-thaw cycles (Woitge, 1999; Seibel, 2005). The levels in urine have been described to increase during exposure to UV light (Blumsohn, 1995), and an aspartate residue in the α2(I) part of NTX has been shown to undergo beta-isomerization (Brady, 1999).

By using modeling techniques the serum half-life of NTX in subjects with normal renal function has been estimated to be 10.8 to 11.8 hours (Holford, 2006). Serum levels of NTX as well as renal excretion of NTX are related to renal function (Hamano, 2006). uNTX/Cr has been described as elevated in patients with primary biliary cirrhosis (Guanabens, 1998).

Both urine and serum NTX levels follow a pattern of diurnal variation, although this seems less pronounced for serum NTX (Gertz, 1998; Greenspan, 1997). Variations in the level of urinary NTX have been described during the menstrual cycle (Gorai, 1995; Abrahamsen, 2003), as well as a circannual rhythm and influence of gender (Woitge, 2000). NTX was slightly decreased one year after an ankle fracture (Ingle, 1999), but increased slightly after a forearm fracture (Ingle, 1999b). Urinary excretion of NTX has been reported highest in early puberty in both girls and boys (Yang, 2006).

Galactosyl Hydroxylysine

Hydroxylysine, another modified amino acid particular to collagens, is glycosylated to varying degrees depending on the tissue type (Segrest and Cunningham, 1970). Two glycosides are formed, galactolysyl hydroxylysine (Gal-Hyl) and glucosyl galactosyl hydroxylysine (Glc-Gal-Hyl). Because of tissue-specific differences, Gal-Hyl is considered to be relatively specific to bone collagen degradation (Krane, 1977). Glycosylated hydroxylysine residues appear not to be reused or catabolized when collagen is degraded. Furthermore, they do not appear to be absorbed in significant levels from a normal diet (Segrest and Cunningham, 1970). An HPLC method has been employed for measuring urinary Gal-Hyl involving dansylation of the lysine, resolution by reversed-phase HPLC, and detection by fluorescence (Moro, 1984; Yoshihara, 1993). This assay generally shows good correlations with other resorption markers (Moro, 1997). An immunoassay has also been described (Leigh, 1998). Urinary galactosylhydroxylysine determined by HPLC showed higher intrasubject variability when compared with CTX and DPD (Plebani, 2000). The absence of an immunoassay format that is commercially available is a major disadvantage of the marker, and may be the reason why relatively few studies have incorporated the measurement of this marker.

Tartrate-Resistant Acid Phosphatase

During bone resorption, osteoclasts secrete protons and enzymes into the space between the ruffled border of

the osteoclast and the surface of the bone. The enzyme, tartrate-resistant acid phosphatase (TRAcP), has been identified in both the ruffled border of the osteoclast membrane and the secretions in the resorptive space (Minkin, 1982). Six isoenzymes (types 0 to 5) of acid phosphatase have been identified by electrophoresis of human tissues (Yam, 1974). Band 5 is expressed by osteoclasts, alveolar and monocyte-derived macrophages, and the placenta (Cheung, 1995). On the basis of the catalytic and ionic properties and carbohydrate content, two isoenzymes (a and b) of band 5 TRAcP have been identified. Both band 5 acid phosphatases are resistant to tartrate inhibition. Band 5a TRAcP is sialylated, whereas band 5b, which is predominant in bone, lacks sialic acid, and the pH optima of the two isoforms differ (Whitaker, 1989; Lam, 1978, 1980; Schiele, 1988). Partly degraded type I collagen is taken up by the osteoclast into vesicles (Salo, 1996; Nesbitt, 1997; Salo, 1997). To these vesicles TRAcP5b is added intracellularly, which can degrade the type I collagen breakdown products even further (Halleen, 1999). The contents of this vesicle are ejected from the cell on the apical side (Salo, 1996; Nesbitt, 1997; Salo, 1997).

TRAcP activity in serum has been reported to reflect bone resorption rates (Yam, 1974). However, the distinction between the osteoclastic enzyme and other tissue acid phosphatases in serum and the instability of the enzyme in serum have presented the greatest technical challenge. TRAcP activity in serum has been measured kinetically (Whitaker, 1989; Lam 1978, 1980; Schiele, 1988; Lau, 1987), and more recently by immunoassay (Cheung, 1995; Kraenzlin, 1990; Halleen, 2000), but these methods vary in specificity for the osteoclast-derived isoenzyme. Recent assays employed an antibody produced against TRAcP from a bone extract. This method showed good correlation between immunoreactivity and enzyme activity, little cross-reaction with acid phosphatases from nonosteoclastic sources, and sensitivity to changes in bone turnover after 6 months of estrogen replacement therapy (Halleen, 2000). Although TRAcP has been reported to reflect the rate of bone resorption (Yam, 1974), more recent reports show that TRAcP5b mainly reflects the number of osteoclasts (Chao, 2005; Alatalo, 2004; Chen, 2004).

TRAcP5b shows a relatively small but significant diurnal variability (14%) and negligible effect of food intake (2%) (Hannon, 2004). The half-life of the marker may therefore be relatively long when compared with the half-life of a marker such as CTX, which does show considerable diurnal variability and effect of feeding (Qvist, 2002). This results in a slightly better signal-to-noise ratio for TRAcP5b when compared with the collagen type I telopeptide markers (Hannon, 2004). Because TRAP 5b does not accumulate in patients with end-stage renal disease, the marker does not seem to be cleared directly by the kidney (Hannon, 2004; Stepan, 1987). TRAP 5b has been reported stable up to 2 days at room temperature (+20/+30° C), 3 days in the refrigerator, 1 month at −20° C, and longer at −70° C or lower (Halleen, 2006).

Bone Sialoprotein

Bone sialoprotein (BSP) is an acidic, phosphorylated glycoprotein that is synthesized by osteoblasts and osteoclastic-like cells in culture. It has an unglycosylated mass of 33 kDa (glycosylated, 70–80 kDa). Although the function of BSP is still not fully understood, BSP stimulates hydroxyapatite formation *in vitro* and appears to mediate cell − cell interactions via an integrin binding site. BSP is relatively restricted to bone but it is also expressed by trophoblasts and is strongly upregulated by many malignant tumors (e.g., breast and prostate cancers). Recently, it has been suggested that BSP may play a role in angiogenesis associated with bone formation, tumor growth, and metastasis (Bellahcene, 2000). A small amount of BSP is found in the circulation and as such is a potential marker of bone turnover (Seibel, 1996; Shaarawy, 2001). An RIA kit has been described for BSP in serum (Seibel, 1996; Karmatchek, 1997; Woitge, 1997) but is presently not commercially available.

Serum BSP levels are reported to be increased in malignant bone disease (Diel, 1999; Woitge, 2001) and postmenopausal osteoporosis, and are decreased by anti-resorptive treatment (Seibel, 1996; Shaarawy, 2001). BSP is stable at −80° C (Li, 1998), but little is known about the kinetics and metabolism of BSP in serum. The marker could be useful in the early detection of bone metastases and other bone disorders, and a new and improved assay for immunoreactive BSP is presently being developed (Robins S.P. and Seibel M.J., unpublished data).

Cathepsin K

Pycnodysostosis, an autosomal recessive disease characterized by osteopetrosis, is the result of mutations in the cathepsin K gene (Gelb, 1997). The enzyme cathepsin K is a member of the cysteine protease family that, unlike other cathepsins, has the unique ability to cleave both helical and telopeptide regions of collagen type I (Garnero, 1998; Kafienah, 1998; Li, 2004). The enzyme is located intracellularly in vesicles, granules, and vacuoles throughout the cytoplasm of osteoclasts and is secreted into bone resorption lacunae for extracellular collagen degradation (Goto, 2003). The enzyme is produced as a 329-amino-acid precursor ProCathepsin K, which is cleaved to its active form with a length of 215 amino acids, which *in vivo* is believed to occur in the bone resorption lacunae, having a low-pH environment. Cathepsin K has a low optimal pH and degrades many matrix proteins, including type I collagen, osteocalcin, and osteopontin (Bossard, 1996; Bromme, 1996; Garnero, 1998). To our knowledge, no data are available on the peripheral circulatory kinetics, metabolism, and/or elimination of cathepsin K.

Commercially, two kits are available for determining cathepsin K in serum, an immunocapture enzyme activity assay from Biovendor that measures enzyme activity (Biovendor, Candler, NC), and an enzyme immunoassay from Biomedica that measures the concentration of the enzyme (Biomedica, distributed in the United States by ALPCO, Windham, NH). Although cathepsin K is potentially an interesting marker of osteoclast activity, only limited data on its clinical use are available (Meier, 2006) and further research is needed for its routine clinical use. The marker may be of specific interest for the development of so-called cathepsin K inhibitors. However, the currently available assays lack sensitivity and, therefore, do not allow accurate measurements of circulating cathepsin K levels.

CLINICAL USE OF BIOCHEMICAL MARKERS OF BONE TURNOVER

In clinical practice, bone turnover markers can be used to aid in the diagnosis and prognosis of certain disease entities, and for the monitoring of specific treatment regimens. However, for each metabolic bone disorder and treatment, it is important to consider which marker, measured with what assay will provide the most relevant clinical information. In addition, knowledge of the relationship between the level of a certain marker and clinical outcome creates the potential of using this as a surrogate marker of outcome, similar to bone mineral density in osteoporosis.

Paget's Disease of Bone

Biochemical markers of bone turnover play a clear-cut role in the diagnosis of Paget's disease of bone and therapeutic monitoring. The markers are helpful in the differential diagnosis of a Pagetoid skeleton lesion, together with bone scintigraphy and radiographic techniques. Turnover markers are invariably elevated in active disease (Papapoulos, 1997; Shankar and Hosking, 2006). Alterations in the rate of bone turnover in this disease are so pronounced that bone marker measurements require relatively little sensitivity and specificity, and in most cases, total ALP and hydroxyproline are sufficient for diagnostic purposes (Papapoulos, 1997; Shankar and Hosking, 2006). More sensitive and specific bone turnover markers, such as urinary alpha-alpha CTX/Cr, uNTX/Cr, or serum BoneALP and PINP, seem to provide little additional value in Paget's disease of bone, although these markers have been shown to be superior to others (Shankar and Hosking, 2006; Alexandersen, 2005; Alvarez, 2000, 2001). These new and more specific markers may be particularly useful in cases of monostotic disease in which the elevations in bone turnover may not be marked. Although the initial response to antiresorptive treatment may be reliably monitored with a bone resorption marker, biochemical remission and relapse are often based on a bone formation marker (Papapoulos, 1997; Shankar and Hosking, 2006). Time to relapse is related to the level of bone formation at its nadir (Eekhoff, 2003; Papapoulos, 1997). Levels of bone turnover markers are related to skeletal complications from the disease, and achieving normal levels of bone turnover is the primary aim of treatment (Papapoulos, 1997; Shankar and Hosking, 2006).

Serum TRAcP5b has been shown to be significantly elevated in patients with Paget's disease of bone, with TRAP 5b activity at above normal reference values in 71% of patients (Halleen, 2001). In patients with mild biochemical disease assessed by total ALP activity, serum cathepsin K levels were significantly higher compared with healthy men and postmenopausal women (Meier, 2006).

Postmenopausal Osteoporosis

In postmenopausal osteoporosis, elevated bone markers do correlate with bone loss and fracture risk, both in treated and untreated patients. The mean levels of most of bone turnover markers may be elevated in patients with postmenopausal osteoporosis, and bone turnover markers generally show a modest inverse correlation with BMD (Melton, 1997; Garnero, 1996). However, the relationships with BMD are not strong and bone markers are never used to diagnose postmenopausal osteoporosis (Becker, 2003). In contrast to postmenopausal osteoporosis, glucocorticoid-induced osteoporosis does not show an overall elevation of bone turnover markers. In this disease, bone formation markers are generally suppressed, whereas bone resorption markers are initially increased (Reid, 2006).

With the current performance of bone markers, it appears that a single measurement of biochemical markers of bone turnover can not predict the absolute rate of bone loss in an individual woman (Stepan, 2000). However, clearly increased levels of bone markers in postmenopausal women can be regarded as a risk factor for rapid bone loss in the subsequent years (Johansen, 1988; Garnero, 1999; Garnero, 2006). Yet, if bone turnover markers are not markedly elevated, one cannot know that substantial bone loss will not occur in subsequent years.

The fracture risk for untreated patients has been shown to correlate with the level of bone markers (Van Daele, 1996; Garnero, 1996, 2000; Garnero and Delmas, 2004). This correlation is even stronger when bone markers are combined with BMD assessments (Fig. 5) (Garnero, 1996). Interestingly, data from the OFELY study, e.g., showed that 47% of the incident fractures actually occurred in nonosteoporotic patients. Among these women, the combination of bone markers and history of previous fractures was highly predictive of fracture risk (Garnero, 2000). Thus, bone markers may be used in the assessment of fracture risk in selected cases in which BMD and clinical risk factors are not sufficient to make a treatment decision (Garnero, 2004).

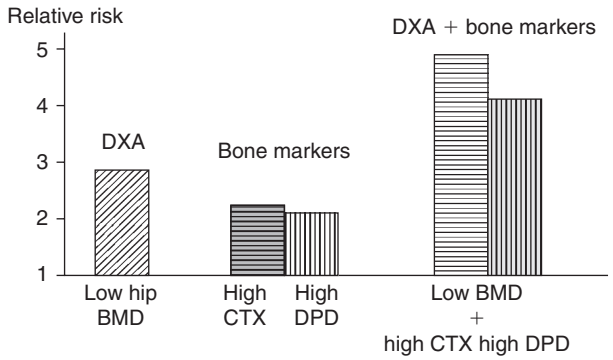

FIGURE 5 Combination of bone mineral density (BMD) at the hip assessed by dual x-ray absorptiometry (DXA) and of bone resorption to predict hip fracture risk in elderly women monitored prospectively for 2 years: The Epidos study. Low BMD was defined according to the WHO guidelines, i.e., by a value lower than 2.5 SD below the young adult mean (*T* score = 2.5). High bone resorption was defined by urinary CTX or free DPD values higher than the upper limit (mean + 2 SD) of the premenopausal range (Garnero, 1996).

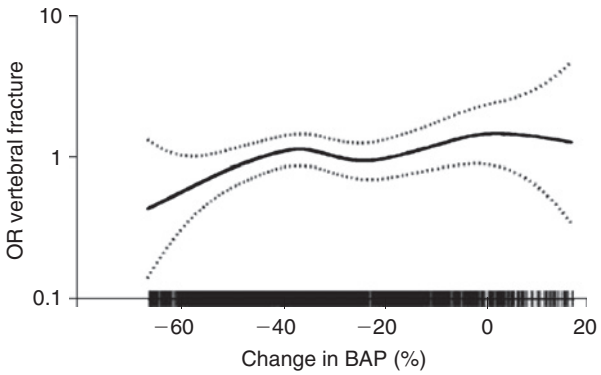

FIGURE 6 One-year change in bone ALP and spine fracture risk among alendronate-treated women. Percentage change in bone ALP and predicted risk (log OR) of spine fracture (solid line) and 95% CI (dotted lines) from logistic regression model. Individual data points represented on the *x* axis. Departure from linearity *P* value = 0.34.20 (Bauer, 2004).

Clinically, bone turnover markers are used to monitor pharmacological treatment, whether this is anticatabolic, such as bisphosphonates, hormone replacement therapy, and selective estrogen receptor modulators, or anabolic, such as teriparatide and PTH 1 − 84 (see Figs. 3 and 4). The markers may be used to identify patients with drug absorption problems or patients who show lack of compliance. Pretreatment levels of bone turnover were shown to correlate both with fracture rate and with changes in BMD during antiresorptive treatment in postmenopausal women with osteoporosis. Therefore, measurement of bone turnover may prove to be useful in identifying women with osteoporosis who are likely to benefit most from therapy (Seibel, 2004; Bauer, 2006; Gonelli, 1997, 1999). In postmenopausal women without osteoporosis (by bone density criteria) measurement of bone turnover markers can potentially identify a subset of patients for whom bisphosphonate therapy to prevent fracture is cost-effective (Schousboe, 2007). Relationships between pretreatment levels of bone turnover markers and fracture risk have also been shown during anabolic therapy with teriparatide in postmenopausal women (Delmas, 2006). The observation that short-term change in bone marker levels correlate, with long-term change in bone mineral density indicates that the markers can also predict the long-term effect of treatment on bone loss (Greenspan, 1998, 2000, 2005; Iwamoto, 2005; Bjarnason, 2000; Delmas, 2000; Lane, 2000; Chen, 2005). Moreover, changes in the level of bone turnover markers have been related to fracture reduction during treatment as illustrated for alendronate in Figure 6 (Bauer, 2004). Therefore, biochemical markers of bone turnover may be useful to predict clinical outcomes, at least on a group level.

Serum cathepsin K levels were elevated in patients with postmenopausal osteoporosis (Meier, 2006). However, this finding needs to be confirmed in larger studies. Several studies have shown that TRAcP5b is elevated in postmenopausal osteoporosis (Halleen, 2001, 2002; Rosenbrock, 2002) and can predict fracture risk (Gerdhem, 2004). The marker can also be used to monitor antiresorptive treatment (Halleen, 2005). In the OFELY prospective study an increased urinary ratio between native (alpha) and isomerized (beta) CTX was found to correlate significantly with increased fracture risk independent of BMD and bone turnover (Garnero, 2002), suggesting that alterations of type I collagen isomerization may be associated with bone fragility. BSP levels were elevated in postmenopausal osteoporosis and decreased during antiresorptive treatment (Shaarawy, 2001).

Table I lists the biochemical markers of bone turnover and their relationships with clinical outcome in postmenopausal osteoporosis (Cremers and Garnero, 2006).

Male Osteoporosis

About one quarter of all osteoporotic hip fractures occur in men (Orwoll, 1995). Several hormonal and biochemical parameters known to affect bone metabolism in women, such as gonadal hormones, vitamin D and its metabolites, and growth factors, have been shown to change with age in both genders and have therefore been proposed to be involved into the age-related decline in BMD in males (Nicolas, 1994; Gray, 1991; Center, 1999). In men, similar to postmenopausal women, low BMD is associated with increased risk of osteoporotic fracture (Nguyen, 1993, 2001), and high bone resorption, as assessed by serum ICTP levels, also appears to be associated with an increased risk of osteoporotic fracture in elderly men, independent of BMD (Meier, 2005). Combining measurements of BMD and bone turnover improved fracture

risk prediction in elderly men (Meier, 2005) as it does in postmenopausal women. In contrast to postmenopausal women, pretreatment levels of bone turnover markers were not related to change in BMD in men treated with alendronate. Also IGF-1 and sex steroids were not related to change in BMD, suggesting that neither biochemical nor hormonal marker allows the identification of patients who may benefit most from alendronate therapy (Drake, 2003). Much remains to be understood about the male skeleton, the pathogenesis of male osteoporosis, and the factors that determine the response to therapy.

Cancer Metastatic to the Bone

Biochemical markers of bone turnover may be helpful in the diagnosis of cancer metastatic to bone. They may also be used for predicting skeletal morbidity and monitoring treatment efficacy (Seibel, 2005).

In patients with solid tumors and bone metastases, the mean level of the bone turnover markers is elevated (Coleman, 2002). And in patients with predominantly osteoblastic skeletal lesions from prostate cancer (PC), both markers of bone formation and resorption are elevated, similar to patients with predominantly osteoclastic bone lesions such as from breast cancer (BC) (Smith, 2006).

For the detection of bone metastases from solid tumors, bALP and uNTX/Cr seem to be the most useful established biomarkers (Tanko, 2006): Approximately 75% of patients with bone metastases from solid tumors are found to have elevated uNTX/Cr and bALP levels at the time of diagnosis. In patients with multiple myeloma (MM), abnormally high levels of uNTX and bALP are seen in about 60% and 40%, respectively (Coleman, 2005).

Of the newer markers, urinary alpha-alpha-CTX and serum TRAcP5b are promising for the diagnosis of bone metastases from solid tumors, alone or in combination with other markers (Tanko, 2006; Leeming, 2006). In a retrospective study in breast cancer patients serum BSP was shown to predict development of bone metastases (Diel, 1999), and may also be a useful marker in the early diagnosis of bone metastases from prostate cancer (Jung, 2004). Currently, the assessment of a single biochemical marker is unlikely to replace bone scintigraphy for the early diagnosis of skeletal metastases from solid tumors. However, given their specificity, a combination of biochemical markers may be useful for monitoring patients between bone scintigram assessments, although this concept needs to be further explored (Voorzanger, 2006, 2007; Tanko, 2006).

In multiple myeloma biochemical markers of bone resorption, including serum TRAcP5b, are elevated and correlate with the stage of the disease (Pecherstorfer, 1997;

Terpos, 2005). In contrast, bone formation markers are usually within normal ranges, and reports on correlations with disease stage are inconclusive (Terpos, 2005).

The level of the markers reflects the severity of metastatic bone disease from solid tumors, with tumor load being well reflected by urinary alpha-alpha-CTX, uNTX/Cr, and serum bone ALP (Leeming, 2006; Garnero, 2000; Tanko, 2006).

Serum BSP levels have been reported to be associated with skeletal involvement and tumor cell burden in MM patients (Woitge, 2001). Interestingly, bone marrow plasma levels of dickkopf 1 (DKK-1), an inhibitor of the Wnt signaling pathway, which is crucial for osteoblast differentiation, has been reported as elevated in patients with multiple myeloma and skeletal involvement (Tian, 2003), and may therefore also be used as a bone marker in patients with MM. Increased serum Dkk-1 levels have also been reported in patients with breast cancer and bone metastases compared with healthy controls and patients with breast cancer with no bone metastases (Voorzanger-Rousselot, 2006)

The risk of developing skeletal-related events (SREs) from metastatic bone disease, multiple myeloma included, without and with bisphosphonate treatment, has been shown to be correlated with the level of bone turnover markers (Brown, 2003, 2005; Coleman, 2005; Vinholes, 1997). For instance, in patients ($n = 121$) with metastatic bone disease treated with bisphosphonates, those with a strongly increased urinary uNTX/Cr level (=100 nmol/mmol), determined on a monthly basis, were 19 times more likely to develop a SRE during the first 3 months than patients with uNTX/Cr <100 nmol/mmol (Brown, 2003). Normalization of bone turnover thus seems a rational treatment goal (Clamp, 2004), and may even allow individualization of dose regimens. This concept is currently being evaluated in a prospective study.

CLINICAL DRUG DEVELOPMENT

Biochemical markers of bone metabolism are a powerful tool for clinical development of drugs for bone diseases (Cremers and Garnero, 2006). They provide critically important information for key decisions in the costly drug development process, such as whether or not to continue the development of a certain drug and which dose to select during phase I/II trials. Bone markers can also assist in the optimization of dose regimens after drug approval, and in exploring the efficacy of a registered drug for other indications. For these latter applications established relationships between levels and clinical efficacy of a drug can be helpful (see Table 1). For clinical drug development in general, however, their fast response to pharmacological treatment is by and large the most important characteristic of bone turnover markers, especially when compared with the response of other biomarkers such as BMD. Such a rapid response can decrease costly drug development time significantly.

Successful application of bone markers to clinical drug development is illustrated by the various phases of the clinical development of zoledronic acid. This bisphosphonate was first developed for metastatic bone disease, followed by other indications such as postmenopausal osteoporosis. At the start of clinical development there were no data on the relationship between the level of bone turnover markers and clinical outcome. However, during early phases of development of the drug, it was found that an intravenous administration of 4 mg suppresses bone resorption markers maximally for at least 3 to 4 weeks (Fig. 7). Four milligrams every 3 to 4 weeks was further explored, and later it was shown that this dose regimen reduces the risk for SREs in metastatic bone disease (Saad, 2004; Rosen 2003, 2004). Recently, Coleman *et al*. showed that the risk for SREs during bisphosphonate therapy is correlated with normalization of bone turnover (Coleman, 2005), and partially because of concerns of the potential side effects of high-dose bisphosphonates, such as nephrotoxicity and osteonecrosis of the jaw, these data are now used to explore new, lower dose regimens (Brown, 2005). In osteoporotic women a single dose of intravenous zoledronic acid was shown to increase BMD and suppress bone turnover markers for at least one year (Reid, 2002), both to levels associated with antifracture efficacy as observed for other bisphosphonates such as alendronate, risedronate, and ibandronate (Harris, 1999; Ravn, 1996; Garnero, 1994; Devogelaer, 1996; Chesnut, 1995; Liberman, 1995). These observations suggested antifracture efficacy of the drug in this dose regimen. And indeed, recently, a single dose of 5 mg of zoledronic acid was shown to significantly decrease vertebral, nonvertebral, and hip fractures in postmenopausal osteoporosis (Black, 2007). Sufficient and continued suppression of bone turnover combined with an increase in BMD therefore seems to predict antifracture efficacy of bisphosphonates. This concept has been used successfully during the switch from daily to weekly dose regimens of alendronate and risedronate (Schnitzer, 2000; Brown, 2002), as well as for the registration of bisphosphonates for closely related indications such as glucocorticoid-induced osteoporosis. The combination of sufficient and continued suppression of bone turnover and increase in BMD may also be used in the clinical development of other antiresorptive drugs such as the RANKL antibody Denosumab (McClung, 2003) and cathepsin K inhibitors. These drugs show highly favorable effects on bone turnover markers and BMD, and are therefore likely to show antifracture efficacy. However, because these drugs have new mechanisms of action their effect on bone markers and BMD cannot be translated automatically into antifracture efficacy or an effect on SREs. Thus, bone markers are helpful, but randomized clinical trials are still needed for the development of drugs with new mechanisms of action.

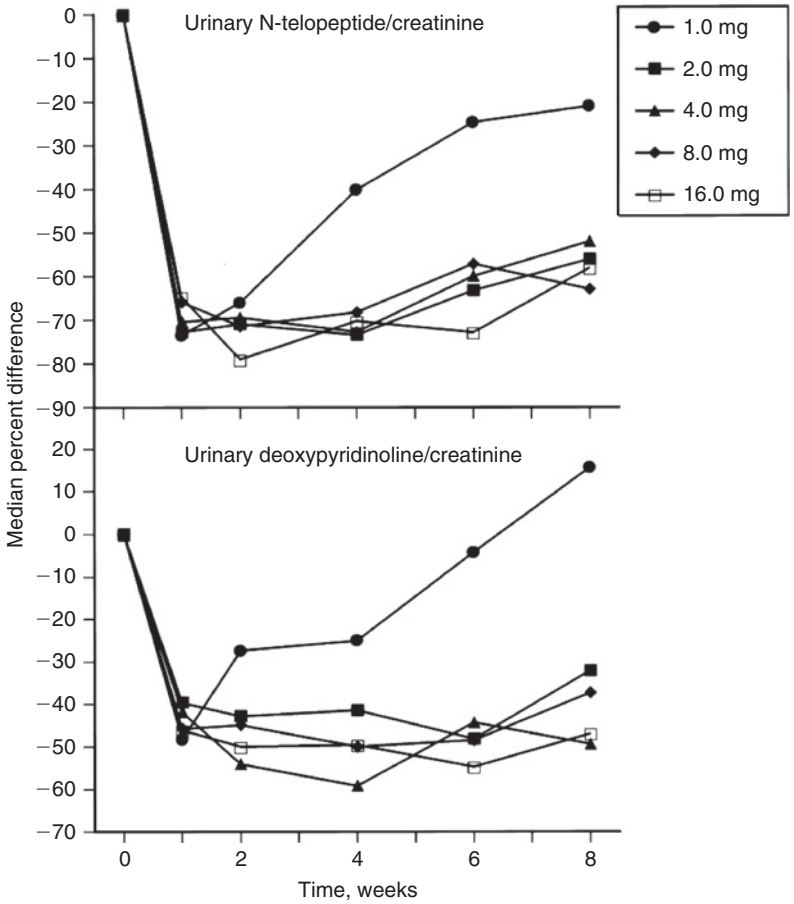

FIGURE 7 Effects of a single dose of zoledronic acid on the ratios of urinary levels of N-telopeptide of the cross-links of collagen to creatinine (*upper*) and urinary levels of deoxypyridinoline to creatinine (*lower*) in patient with cancer and bone metastases (Berenson, 2001).

Chapter 88

Methods and Clinical Issues in Bone Densitometry

Glen M. Blake* and Ignac Fogelman
King's College London School of Medicine, London, United Kingdom

INTRODUCTION

Osteoporosis is widely recognized as an important public health problem because of the significant morbidity, mortality, and costs associated with its complications, namely fractures of the hip, spine, forearm, and other skeletal sites (Cummings *et al*., 2002). It is estimated that every year 1.5 million people in the United States experience an osteoporosis-related fracture, including 300,000 cases of hip fracture (Surgeon General's report, 2004). One in every two white women will suffer an osteoporosis-related fracture in her lifetime, and one in six will have a hip fracture (Kanis *et al*., 2002). There is particular concern about hip fractures because these have the greatest effect on an individual's quality of life and incur the greatest cost for health services (Ray *et al*., 1997). However, other fractures are also associated with significant morbidity and costs (Melton *et al*., 2003) and both hip and vertebral fractures are associated with an increased risk of death (Cooper *et al*., 1993; Centre *et al*., 1999) and increased dependence on nursing homes and private and public care services for the basic activities of daily living. Because of the aging population and the previous lack of attention to bone health, the annual number of hip fractures in the United States is set to double by the year 2020 (Surgeon General's report, 2004).

Although for many years there was awareness of the morbidity and costs associated with fragility fractures, real progress only came with the ability to diagnose osteoporosis before any fractures occur, and with the development of preventive treatments. Bone density scanning played an important role in both these developments. Until the mid-1980s measurements of bone mineral density (BMD) were used mainly in research, and it was only with the introduction of dual-energy x-ray absorptiometry (DXA) scanners in 1987 that they entered routine clinical practice (Genant *et al*., 1996). Further significant developments included the first study showing that bisphosphonate treatment can prevent bone loss (Storm *et al*., 1990), the publication of the World Health Organisation (WHO) report defining osteoporosis in postmenopausal white women as a BMD *T* score at the spine, hip, or forearm of −2.5 or less (WHO, 1994) (Table I), and the Fracture Intervention Trial confirming that bisphosphonate treatment reduced fracture risk (Black *et al*., 1996). Since then a number of international trials have demonstrated the effectiveness of bisphosphonates (BPs) (Cummings *et al*., 1998; Harris *et al*., 1999; McClung *et al*., 2001; Chesnut *et al*., 2004; Black *et al*., 2006), selective estrogen receptor modulators (SERMs) (Ettinger *et al*., 1999), recombinant human parathyroid hormone (PTH) (Neer *et al*., 2001; Greenspan *et al*., 2007), and strontium ranelate (Meunier *et al*., 2004; Reginster *et al*., 2005; Seeman *et al*., 2006) in the prevention of fragility fractures.

THE CLINICAL ROLE OF BONE DENSITY MEASUREMENTS

Bone density measurements have an important clinical role in the evaluation of patients at risk of osteoporosis and in ensuring the appropriate use of antifracture treatment (Kanis *et al*., 1997; NOF, 1998; Genant *et al*., 1999; Kanis and Gluer, 2000). A helpful list of clinical indications for performing a bone density examination was published by the International Society for Clinical Densitometry (ISCD) and is summarized in Table II (ISCD, 2005). The most widely used method of patient investigation is DXA scanning of the lumbar spine and hip (Fig. 1A and B). BMD examinations have three principal roles, namely the diagnosis of osteoporosis, the assessment of a patient's risk of fracture, and monitoring response to treatment. The reasons for choosing to measure the hip and spine include

TABLE I The WHO Definitions of Osteoporosis and Osteopenia (WHO, 1994)

Terminology	T-Score definition
Normal	$T \geq -1.0$
Osteopenia	$-2.5 < T < -1.0$
Osteoporosis	$T \leq -2.5$
Established osteoporosis	$T \leq -2.5$ in the presence of one or more fragility fractures

TABLE II Indications for Bone Mineral Density (BMD) Testing (ISCD, 2005)

- Women aged 65 and older
- Postmenopausal women under age 65 with risk factors
- Men aged 70 and older
- Adults with a fragility fracture
- Adults with a disease or condition associated with low bone mass or bone loss
- Adults taking medication associated with low bone mass or bone loss
- Anyone being considered for pharmacological therapy
- Anyone being treated, to monitor treatment effect
- Anyone not receiving therapy in whom evidence of bone loss would lead to treatment

the fact that the hip is the best site for predicting hip fracture risk (Marshall *et al.*, 1996; Stone *et al.*, 2003; Johnell *et al.*, 2005), the spine is the best site for monitoring response to treatment (Eastell, 1998; Gluer, 1999), and the consensus that hip and spine BMD results should be interpreted by using the WHO *T*-score definition of osteoporosis (see Table I) (Kanis *et al.*, 1997; NOF, 1998; Genant *et al.*, 1999; Kanis and Gluer, 2000; ISCD, 2005). *T* scores are calculated by taking the difference between a patient's measured BMD and the mean BMD in healthy young adults, matched for gender and ethnic group, and expressing the difference relative to the young adult population standard deviation (SD):

$$T\text{-score} = \frac{\text{Measured BMD} - \text{Young adult mean BMD}}{\text{Young adult population SD}}$$

Other practical advantages of DXA scanning include short scan times, easy patient setup, low radiation dose, and good measurement precision. These and other advantages of spine and hip DXA are summarized in Table III. Most of the rest of this chapter is devoted to discussing these advantages in greater detail.

In addition to central DXA systems that measure the spine and hip, a wide variety of other types of bone densitometry equipment are also available (Genant *et al.*, 1996; Fogelman and Blake, 2000). These include quantitative computed tomography (QCT) measurements of the spine and hip (Guglielmi and Lang, 2002; Lang *et al.*, 2002), peripheral DXA (pDXA) systems for measuring the forearm, heel, or hand (Blake and Fogelman, 2002), and quantitative ultrasound (QUS) devices for measurements of the heel and other peripheral sites (Stewart and Reid, 2002). In principle, pDXA and QUS devices offer a quick, cheap, and convenient way of evaluating skeletal status that makes them attractive for widespread use. In practice, however, these alternative types of measurement correlate poorly with hip and spine BMD, with correlation coefficients in the range $r = 0.5$–0.7 (Lu *et al.*, 2001). This lack of agreement with measurements made using hip and spine DXA has proved a barrier to reaching a consensus on the best way of introducing these other methods into wider clinical practice (Lu *et al.*, 2001; Faulkner *et al.*, 1999).

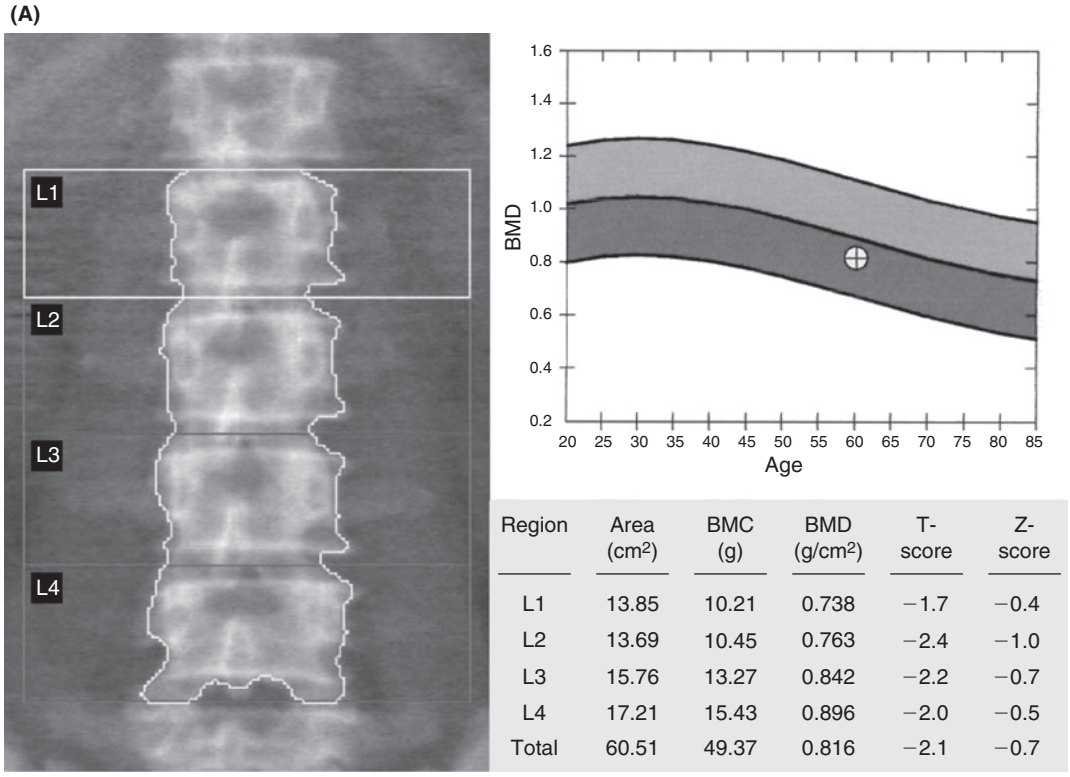
WHICH MEASUREMENT IS BEST?

Given the choice of so many different types of measurement, how do we decide which technique is the most effective for decisions about patient treatment? Fundamental to the clinical use of any type of bone densitometry examination is its ability to predict fracture risk, and the most reliable way to evaluate and compare the alternative techniques is through prospective studies of incident fractures (Marshall *et al.*, 1996). Figure 2 illustrates how data from a fracture study are analyzed to quantify the relationship between BMD and fracture risk. When the study subjects are divided into quartiles on the basis of their baseline BMD measurements, an inverse relationship is found between fracture risk and BMD. To describe this relationship the BMD figures are converted into *Z* scores. *Z* scores are similar to *T* scores except that instead of comparing the patient's measured BMD with the mean and SD for young adults, it is compared with the mean BMD and SD for healthy normal subjects matched for age, gender, and ethnic group:

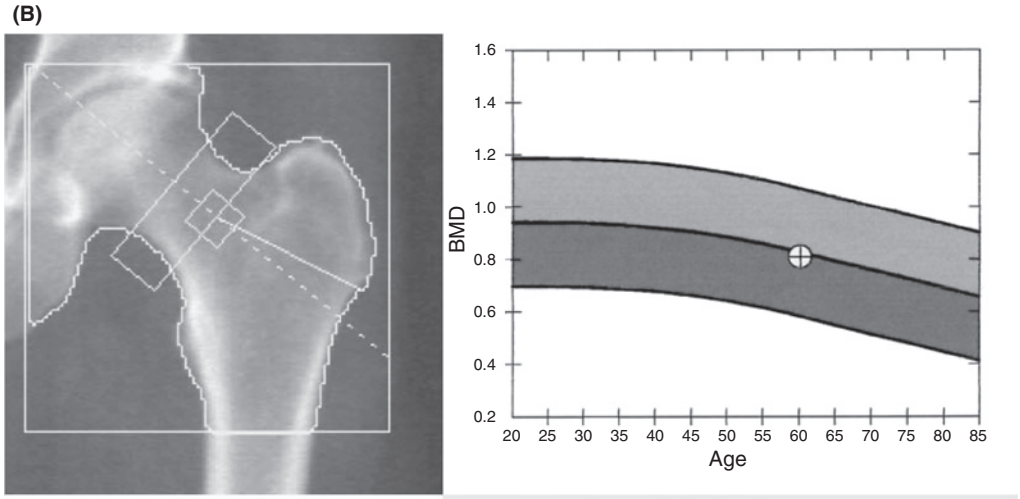
$$Z\text{-score} = \frac{\text{Measured BMD} - \text{Age matched mean BMD}}{\text{Age matched population SD}}$$

Data from fracture studies are fitted by using a gradient-of-risk model in which the fracture risk increases exponentially with decreasing *Z* score (Fig. 2, *inset*). Results are usually expressed in terms of the relative risk (RR), which is defined as the increased risk of fracture for each unit decrease in *Z* score.

The larger the value of RR (or equivalently, the steeper the gradient of risk β in Fig. 2), the more effective a technique is at discriminating between patients who will suffer



Region	Area (cm^2)	BMC (g)	BMD (g/cm^2)	T-score	Z-score
L1	13.85	10.21	0.738	−1.7	−0.4
L2	13.69	10.45	0.763	−2.4	−1.0
L3	15.76	13.27	0.842	−2.2	−0.7
L4	17.21	15.43	0.896	−2.0	−0.5
Total	60.51	49.37	0.816	−2.1	−0.7



Region	Area (cm^2)	BMC (g)	BMD (g/cm^2)	T-score	Z-score
Neck	5.28	3.25	0.614	−2.1	−0.8
Troch	9.32	5.52	0.592	−1.1	−0.2
Inter	18.16	17.75	0.978	−0.8	−0.1
Total	32.76	26.52	0.809	−1.1	−0.1
Ward's	1.15	0.45	0.396	−2.9	−0.9

FIGURE 1 (**A**) Scan printout of a spine dual-energy x-ray absorptiometry (DXA) examination. The printout shows: (left) scan image of the lumbar spine; (*top right*) patient's age and bone mineral density (BMD) plotted with respect to the manufacturer's reference range; (*bottom right*) BMD figures for individual vertebrae and total spine (L1 − L4), together with the interpretation in terms of *T* scores and *Z* scores. (**B**) Scan printout of a hip DXA examination. The printout shows: (*left*) scan image of the hip; (*top right*) patient's age and total hip BMD plotted with respect to the National Health and Nutrition Examination Survey (NHANES III) reference range (Looker *et al.*, 1998); (*bottom right*) BMD figures for five different regions of interest in the hip (femoral neck, greater trochanter, intertrochanteric, total hip, and Ward's triangle), together with the interpretation in terms of *T* scores and *Z* scores by using the NHANES III reference range.

TABLE III Clinical Advantages of Hip and Spine DXA

- Proven ability to predict fracture risk
- Consensus that BMD results can be interpreted using WHO T scores
- Proven for effective targeting of antifracture treatments
- Effective for monitoring response to treatment
- Basis of new WHO algorithm for predicting fracture risk
- Many systems can perform vertebral fracture assessment
- Short scan times
- Easy patient setup
- Low radiation dose
- Good precision
- Availability of reliable reference ranges
- Stable calibration
- Effective instrument quality control procedures

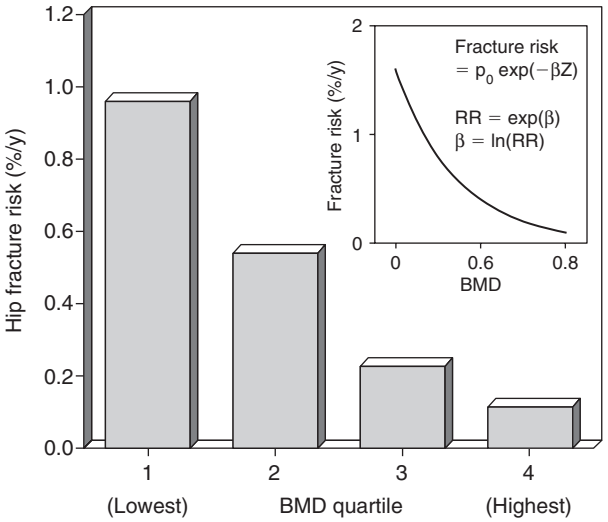


FIGURE 2 Incidence of hip fracture risk by bone mineral density (BMD) quartile for femoral neck BMD. Data are taken from the 2-year follow-up of the Study of Osteoporotic Fractures (SOF) (Cummings *et al.*, 1993). (*Inset*) Data from fractures studies are fitted using a gradient-of-risk model, in which the fracture risk varies exponentially with Z score with gradient β. Results are expressed in terms of the relative risk (RR), the increased risk of fracture for each unit decrease in Z score. The value of RR is found from β using the exponential function ($RR = \exp(\beta)$). Alternatively, the gradient of risk is found by taking the natural logarithm of RR ($\beta = \ln(RR)$).

a fracture in the future and those who will not. To understand the reason for this, consider a large group of subjects chosen randomly from the general population. For such a group the distribution of Z-score values approximates to a Gaussian curve (Fig. 3A). The distribution of Z-score values for the group of patients who will at some future date experience an osteoporotic fracture is found by multiplying the Gaussian curve representing the general population by the gradient-of-risk curve shown in the inset in Figure 2. When this is done the distribution of Z-score values for the fracture population is found to be a second Gaussian curve with the same SD as the first but with its peak offset to the left by an amount ΔZ equal to the gradient-of-risk β (or equivalently to the natural logarithm of RR) ($\Delta Z = \beta = \ln(RR)$) (see Fig. 3A) (Blake and Fogelman, 2001).

To understand the importance of selecting a technique with a high RR value, consider choosing some arbitrary Z-score value in Fig. 3A as the threshold for making decisions about patients' treatment (for example, this might be the Z-score value equivalent to a T score of -2.5). The areas under the two curves can be evaluated to find the percentages of patients in the fracture population and the general population with BMD values below the chosen threshold. As the threshold is varied and the two percentages plotted against each other, we obtain a receiver operating characteristic (ROC) curve (see Fig. 3B) in which the percentage of true positives (those patients who will suffer a fracture in the future and were correctly identified to be at risk) is plotted against the percentage of false positives (those patients identified to be at risk but who never have a fracture). Fig. 3B is fundamental to understanding the clinical value of any type of bone density measurement used to identify and treat patients at risk of fracture. It shows that the larger the RR value of the measurement technique the more successful clinicians are at targeting preventive treatments on those patients at greatest risk of having a fracture.

DATA FROM FRACTURE STUDIES

One of the important clinical advantages of DXA compared with other types of bone density measurements is that its ability to identify patients at risk of fracture has been assessed and proven in a large number of epidemiological studies (Marshall *et al.*, 1996; Stone *et al.*, 2003; Johnell *et al.*, 2005). The most informative studies are meta-analyses of prospective fracture studies. Two such meta-analyses have been published, the well known study by Marshall *et al.* (1996), and a more recent study by Johnell *et al.* (2005). The Marshall meta-analysis was based on more than 2000 osteoporotic fractures from 90,000 person-years of follow-up. The subjects were all women. The authors concluded that different BMD measurement sites all have a similar ability to predict fractures (RR = 1.5; 95% confidence interval: 1.4 to 1.6), with the exception of hip BMD predicting hip fractures (RR = 2.6; 95% CI: 2.0 to 3.5) (Fig. 4) and spine BMD predicting vertebral fractures (RR = 2.3; 95% CI: 1.9 to 2.8). The authors concluded that hip and spine BMD values were the best measurements for predicting

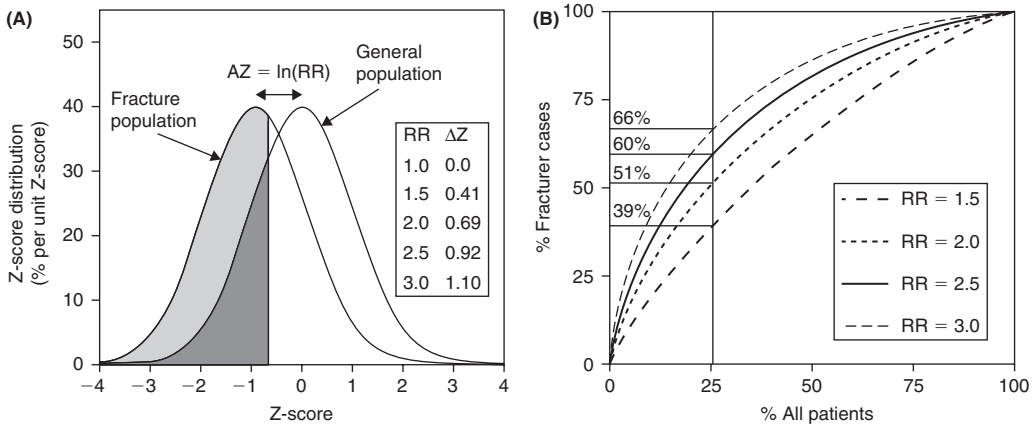

FIGURE 3 (**A**) Distribution of *Z*-score values in a fracture population compared with the age-matched general population. The curve for the general population is a bell-shaped curve symmetrically distributed around its peak at $Z = 0$. The corresponding curve for the population of patients who will suffer an osteoporotic fracture is a similar bell-shaped curve that is offset from the general population by a *Z*-score difference of $\Delta Z = \ln(RR)$, where RR = relative risk. The inset table lists values of RR and ΔZ. (**B**) Plot of the receiver operating characteristic (ROC) curves obtained by evaluating the areas under the two bell-shaped curves shown in A up to an arbitrarily chosen *Z*-score threshold and plotting the two areas against each other for different values of the relative risk (RR). The ROC curve shows the percentage of fracture cases that fall below the bone mineral density (BMD) threshold (shaded area under the fracture population curve in **A**) plotted against the percentage of subjects in the general population who fall below the same threshold (shaded area under the general population curve in **A**). It therefore shows the true-positive fraction (those patients who sustain a fracture and were correctly identified as being at risk) against the false-positive fraction (those patients identified as being at risk but who never actually have a fracture). The larger the value of RR, the wider the separation of the two curves in **A** and the more effective BMD measurements are at discriminating the patients who will have a fracture. For example, if patients in the lowest quartile of BMD are identified for treatment, then for RR values of 1.5, 2.0, 2.5, and 3.0 this group will include 39%, 51%, 60%, and 66%, respectively, of all patients who will suffer a fracture.

hip and spine fractures, respectively. A limitation of the Marshall study was that these latter conclusions were based on a relatively small number of fracture cases (80 hip fractures and 98 vertebral fractures, respectively).

The Johnell meta-analysis examined the relationship between hip fracture and hip BMD based on data from 12 different fracture studies from Australia, Canada, Europe, and Japan including both men and women (Johnell *et al.*, 2005). There were data on 971 hip fractures from a total of 168,000 person-years of follow-up. As would be expected given the much larger number of hip fractures, the statistical errors are considerably reduced and, consequently, the results are more informative. When corrected to the population SD of the female reference range of the Third National Health and Nutrition Examination Survey (NHANES III) (Looker *et al.*, 1998), the RR figure for men and women combined was 2.21 (95% CI: 2.03 to 2.41) (see Fig. 4). There was no significant difference between men and women (women: RR = 2.18; 95% CI: 1.99 to 2.39; men: RR = 2.28; 95% CI: 1.81 to 2.87). Interestingly, the relative risk figures decreased progressively with increasing age varying from RR = 3.68 (95% CI: 2.61 to 5.19) at age 50 to RR = 1.93 (95% CI: 1.76 to 2.10) at age 85. Relative risk figures for hip fracture did not vary significantly with the length of follow-up (0 to 10 years) or baseline *Z* score ($-4 < Z < +4$).

Among individual fracture studies, the most informative is the Study of Osteoporotic Fractures (SOF), a study of 9704 white U.S. women aged 65 years and older who

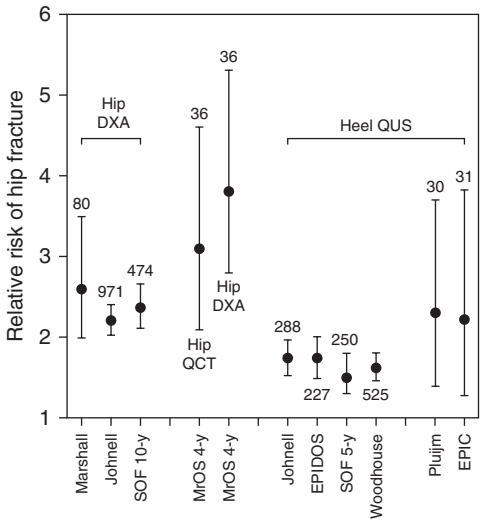

FIGURE 4 Values of the relative risk (RR) (defined as the increased risk of fracture for a 1 standard deviation decrease in bone mineral density) for hip fracture for: (1) hip DXA measurements [Marshall meta-analysis (Marshall *et al.*, 1996), Johnell meta-analysis (Johnell *et al.*, 2005), Study of Osteoporotic Fractures (SOF) 10-year study (Stone *et al.*, 2003)]; (2) QCT and DXA hip BMD measurements [MrOS study (Orwoll *et al.*, 2006)]; (3) heel QUS measurements [Johnell meta-analysis (Johnell *et al.*, 2005), EPIDOS study (Hans *et al*, 2004), SOF 5-year study (Black *et al.*, 2000), Woodhouse meta-analysis (Woodhouse *et al.*, 2000), Amsterdam study (Pluijm *et al.*, 1999), and EPIC study (Khaw *et al.*, 2004)]. The error bars show the 95% confidence intervals. The number above or below each data point shows the number of hip fractures in the study. The graph illustrates the importance of having a large number of fractures in order to reduce the error bars and allow a meaningful comparison between different bone densitometry techniques.

had baseline measurements of hip, spine, forearm, and heel BMD when the study commenced in the late 1980s (Stone *et al.*, 2003). One of the strengths of the SOF study is the large number of recorded fracture cases, with the recently published 10-year follow-up including 474 hip fractures and 2044 fractures at all sites. A second important strength is that the baseline measurements included a variety of bone densitometry sites including DXA of the hip and spine, peripheral absorptiometry of the forearm and heel, and QUS of the heel. A large number of fracture cases are essential for achieving adequate statistical power if meaningful comparisons are to be made between different bone density techniques. This is illustrated in Fig. 4, which shows RR values for hip fracture from various studies with their 95% confidence intervals and the number of fractures recorded in the study. As the SOF study has progressed the results have consistently confirmed the ability of hip BMD measurements to predict hip fracture risk with an RR value of about 2.5 (Cummings *et al.*, 1993; Black *et al.*, 2000; Stone *et al.*, 2003). The 10-year follow-up data confirm the association between BMD and fracture risk with high statistical reliability for many types of fracture and show that the prediction of hip fracture risk from a hip BMD measurement has the largest RR value and is the most effective single type of DXA examination (Fig. 5) (Stone *et al.*, 2003).

In comparison with DXA, until recently there were no prospective studies of QCT and fracture risk. However, the first results of a prospective study of QCT and hip fracture risk from the Osteoporotic Fractures in Men (MrOS) study were recently announced (Orwoll *et al.*, 2006). The MrOS study enrolled 5995 white men aged 65 and older from six U.S. centers. As well as baseline DXA scans, 3357 men had spine and hip QCT scans. The first results based on 36 hip fracture cases recorded after an average follow-up period of 4.4 years show comparable RR values for femoral neck BMD measured by QCT or DXA (see Fig. 4). As can be seen, because of the small number of fracture cases so far recorded, the statistical errors are still too large to make any meaningful comparison between QCT and DXA.

In contrast with QCT, there are a large number of published studies of QUS and fracture risk (Hans *et al.*, 1996; Bauer *et al.*, 1997; Pluijm *et al.*, 1999; Woodhouse *et al.*, 2000; Bauer *et al.*, 2001; Miller *et al.*, 2002; Khaw *et al.*, 2004; Hans *et al.*, 2004; Durosier *et al.*, 2006). The Johnell meta-analysis includes QUS data from two cohorts (EPIDOS and Sheffield) with a total of 288 hip fractures (Johnell *et al.*, 2005). RR values were 1.74 (95% CI: 1.53 to 1.97) for broadband ultrasonic attenuation (BUA) and 1.50 (95% CI: 1.31 to 1.70) for speed of sound (SOS). These and some other data for QUS are plotted in Fig. 4. Comparison of the various results plotted in Fig. 4 illustrate the importance of having studies with a large number of recorded fracture cases in order to reduce the error bars and allow a meaningful comparison between different techniques.

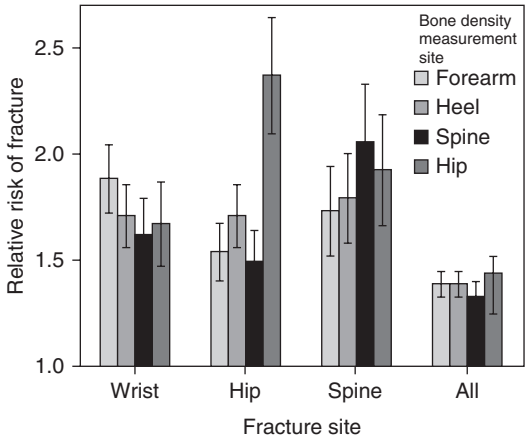

FIGURE 5 Values of the relative risk (RR) [defined as the increased risk of fracture for a 1 standard deviation decrease in bone mineral density (BMD)] for fractures at different skeletal sites (wrist, hip, spine, and any fracture) for BMD measurements made at four different sites (forearm, heel, spine, and femoral neck). The errors bars show the 95% confidence intervals. Data are taken from the 10-year follow-up of the Study of Osteoporotic Fractures (SOF) study population (Stone *et al.*, 2003). In the SOF data the largest value of RR is for the prediction of hip fracture risk from a hip BMD measurement (RR = 2.4). From the ROC curves shown in Figure 3B this means that the clinically most effective DXA scan measurement is to use hip BMD to predict hip fracture risk.

APPROPRIATE TARGETING OF ANTIFRACTURE TREATMENTS

Another of the clinical advantages of hip and spine BMD scans are their proven ability to identify patients who will respond successfully to treatments for preventing fractures. Table IV lists the principal clinical trials of the pharmaceutical agents proven to prevent vertebral and/or nonvertebral fractures. It is notable that all of the trials listed enrolled patients on the basis of study entry criteria that included a DXA scan *T* score at the hip or spine demonstrating either osteoporosis or severe osteopenia. In a number of these trials the data analysis showed that treatment was effective only in those subjects with a hip or spine *T* score of −2.5 or less (Cummings *et al.*, 1998; McClung *et al.*, 2001; Chesnut *et al.*, 2004; Reginster *et al.*, 2005). These findings have created difficulty in selecting patients for treatment using techniques other than hip or spine DXA because of the poor correlation between different techniques and the lack of evidence that patients selected by using other techniques will respond to treatment (Barr *et al.*, 2005).

AVAILABILITY OF RELIABLE REFERENCE RANGES

For the past 10 years the interpretation of DXA scans has been guided by the WHO *T*-score definition of osteoporosis (see Table I). However, if scan results are to be interpreted reliably care is necessary in the choice of reference

TABLE IV Fracture Prevention Studies That Have Selected Patients Using Central DXA

Class of agent	Name of drug	Study name*	T-score thresholds for patient enrollment†

§*Study entry criteria also included clinical risk factors.*

data for the calculation of *T* scores. For consistency, ISCD recommends the use of the NHANES III reference database (Looker *et al.*, 1998) for *T*-score derivation in the hip (ICRP, 2005). This recommendation was made following the publication of a study comparing the spine and hip *T*-score results obtained on the two principal brands of DXA scanner (manufactured by GE-Lunar and Hologic) and calculated by using the manufacturers' reference ranges (Faulkner *et al.*, 1996). Although good agreement was found for spine *T* scores measured on the two manufacturers' systems, a systematic difference of almost one *T*-score unit was found between the hip *T* scores. The discrepancy was resolved by all the manufacturers agreeing to use the NHANES III hip reference range (Hanson *et al.*, 1997), which is based on measurements of more than 14,000 randomly selected men and women from across the entire United States. There was insufficient time in the NHANES III study to perform spine as well as hip scans, so spine BMD results are generally interpreted by using the manufacturers' reference ranges.

Comparison of reference ranges for pDXA equipment for the same anatomical site can show surprisingly large differences in the plots of mean *T*-score against age owing to factors that include the use of inappropriate populations, different conventions for deriving the reference curve from the data, and insufficient numbers of subjects (Blake *et al.*, 2005). When the principal DXA manufacturers adopted the NHANES III hip BMD reference range with its large, randomly selected population this was an important factor in improving confidence in the interpretation of scan results.

INTERPRETATION OF *T* SCORES USING THE WHO CRITERIA

As explained earlier, one of the important clinical advantages of DXA is the widespread consensus that spine, hip, and forearm BMD measurements should be interpreted using the WHO *T*-score definition of osteoporosis (see Table I). However, the WHO definition should not be applied to QCT or QUS measurements, or pDXA results at sites other than the 33% radius (ICRP, 2005). The reason why this rule is so important can be understood from Figure 6. When the reference ranges for different types of bone density measurement are plotted as graphs of mean *T* score against age, the curves obtained are found to be very different for different techniques (Faulkner *et al.*, 1999) (see Fig. 6). For example, the curve for spine QCT decreases rapidly with age and crosses the WHO threshold of $T = -2.5$ at age 60. This means that if QCT measurements were interpreted using the WHO definition 50% of 60-year-old women would be diagnosed with osteoporosis. In contrast, for some types of heel pDXA and QUS measurements the curve decreases so slowly with age that patients need to be age 100 before 50% of them have osteoporosis. For spine, femoral neck, and 33% radius DXA measurements the three curves decrease in a similar manner crossing the $T = -2.5$ threshold at age 75. It is clear that if care is not taken in applying the WHO criteria appropriately then cases of osteoporosis may be either seriously underdiagnosed or overdiagnosed depending on the measurement technique (Lu *et al.*, 2001). In principle, measurements other

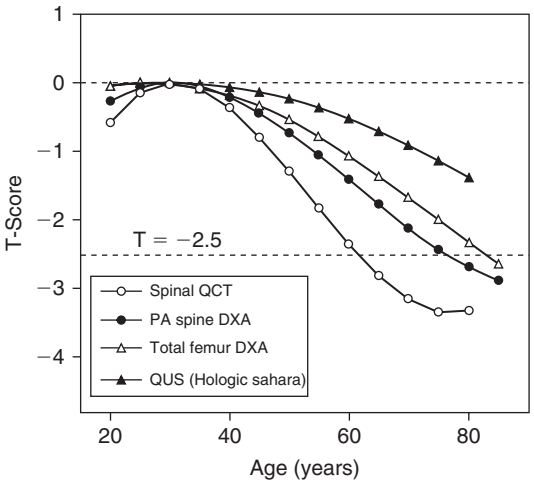

FIGURE 6 Age-related decline in mean T scores at different bone mineral density sites for healthy white female subjects. The hip DXA data are taken from the National Health and Nutrition Examination Survey (NHANES III) study (Looker *et al.*, 1998; Hanson, 1997). The DXA normative data for the lumbar spine (L1−L4) and forearm (total forearm region) were obtained from the Hologic manufacturer's reference ranges. Heel data are for the Hologic Sahara device. Spinal QCT is that used by the Image Analysis reference system. Filled circles, lumbar spine; open triangles, total hip; open circles, QCT spine; filled triangles, QUS heel.

than spine and hip DXA can be used with appropriate device-specific thresholds to identify a group of patients with high peripheral BMD that are unlikely to be at risk, and another group with low BMD and who can be treated for osteoporosis. Patients with intermediate peripheral BMD results can be referred for a central DXA examination for a definitive diagnosis. However, the clinical application of this triage algorithm requires the availability of adequate information about the device-specific thresholds (Blake *et al.*, 2005).

THE NEW WHO FRACTURE RISK ALGORITHM

Views on the best way of using the information from DXA scans to advise patients about the use of antifracture treatment continue to evolve (Kanis *et al.*, 2002; Kanis, 2002; Kanis *et al.*, 2005a; De Laet *et al.*, 2005a). As emphasized earlier, the clinical value of a BMD examination lies in the information it provides about fracture risk. An important limitation of the WHO *T*-score approach to making decisions about patient treatment is that age as well as BMD is an important factor in determining the patient's short-term risk of having a fracture (Kanis *et al.*, 2001a, 2002, 2005a). For any hip *T*-score figure, fracture risk in men and women between the ages of 45 and 85 years varies greatly according to age (Kanis *et al.*, 2001a, 2002). A new approach to the use of BMD scans to guide treatment decisions is based on the ten-year probability of the patient sustaining an osteoporotic fracture (Kanis *et al.*, 2001a, 2005a). This

TABLE V Clinical Risk Factors Included in WHO Fracture Algorithm (Kanis *et al.*, 2005a)

- Age
- Low body mass index
- Prior fracture after age 50
- Parental history of hip fracture
- Current smoking habit
- Current or past use of systemic corticosteroids
- Alcohol intake >2 units daily
- Rheumatoid arthritis

has a number of important advantages, including the targeting of osteoporosis treatment according the patient's risk of fracture (Kanis *et al.*, 2002), the incorporation of additional risk factors such as a history of prior fracture to refine the algorithm for estimating fracture risk (Kanis *et al.*, 2005a), and the use of health economic criteria to set intervention thresholds based on the costs of treatment, savings to health services, and the contribution of fracture prevention to patients' quality of life (Kanis, 2002).

The value of taking account of additional risk factors that give independent information about fracture risk over and above that provided by age and BMD can be explained by reference to the ROC curve shown in Fig. 3B. With all types of bone densitometry measurement, the fracture and nonfracture patients have overlapping BMD distributions (see Fig. 3(A), leading to ROC curves (see Fig. 3B) in which, at any given *T*-score threshold, only a certain percentage of future fracture cases are identified for treatment at the cost of also having to treat a large number of patients who are not going to have a fracture. As explained earlier, the best that can be done with bone densitometry alone is to choose the BMD measurement site with the highest RR value that will optimize the ROC curve. However, by combining BMD data with age and other appropriately chosen risk factors (Table V), the ROC curve can be further improved so that treatments are better targeted on the patients at highest risk.

The new WHO fracture risk algorithm is based on a series of meta-analyses of data from 12 independent fracture studies from North America, Europe, Asia, and Australia (Kanis *et al.*, 2004b, 2004c, 2004d, 2005b, 2005c; De Laet *et al.*, 2005b). The DXA scan information required is femoral neck BMD. Because of the need to build the correct parameters into the statistical model, including the interdependence of the various risk factors, there is a specific requirement that the BMD information is provided by a hip DXA scan. The reliance on BMD information from a single skeletal site raises the important question of whether fracture risk prediction is improved by combining BMD measurements from more than one site. A meta-analysis of spine and femoral neck BMD data showed that use of the lowest *T* score did not improve the ROC curve (Kanis *et al.*, 2006). This finding

TABLE VI Comparison of Different Bone Densitometry Techniques

	Central DXA	Peripheral DXA	QCT	QUS
Compatible with WHO T scores	✓	×	×	×
Proven to predict fracture risk	✓	✓	?	✓
Compatible with new WHO fracture risk algorithm	✓	×	×	×
Proven for effective targeting of treatment	✓	?	?	?
Suitable for patient follow-up	✓	×	?	×
Stable calibration	✓	✓	✓	×
Good precision	✓	✓	✓	×
Reliable reference ranges available	✓	?	?	?

is perhaps surprising, but mathematical analysis provides the reason: although hip and spine BMD measurements are quite poorly correlated ($r = 0.5$ to 0.7), even this degree of correlation is too high for a second BMD site to provide significant additional information about fracture risk (Blake *et al*., 2003). A further point that follows from the WHO fracture risk algorithm is that not all patients necessarily require a DXA scan (Johansson *et al*., 2004). For some the use of age, fracture history, and the other risk factors is sufficient to place them in either the high-risk group requiring antifracture treatment, or the low-risk group who can be reassured that their likelihood of having a fracture is small. Thus, in future, a triage approach could be adopted for BMD scanning in which the fracture risk algorithm is used to select those patients for a DXA examination in whom BMD information is most likely to contribute to their management.

Another advantage of the new WHO algorithm is that it enables fracture risk thresholds for intervention to be established based on economic criteria that can be adjusted for practice in different countries (Kanis *et al*., 2001b; Borgstrom *et al*., 2006a). A series of health economic analyses have examined the rationale for fracture prevention and the cost effectiveness of different osteoporosis treatments (Kanis *et al*., 2005d, 2005e; Borgstrom *et al*., 2006b, 2006c; Zethraeus *et al*., 2007). These analyses show that, taking account of all types of fracture, the cost-effective intervention thresholds correspond to *T*-score values between −2 and −3 over a range of ages from 50 to 80 years (Kanis, 2002; Kanis *et al*., 2005a). At the present time it is unclear how quickly the new fracture risk approach will become the new paradigm for the management of osteoporosis.

MONITORING RESPONSE TO TREATMENT

Verifying response to treatment using follow-up DXA scans is widely believed to have a beneficial role in encouraging patients to continue taking their medication, and also in identifying nonresponders who may benefit from a different treatment regimen. DXA has a number of advantages as a technique for monitoring patients' response, of which one of the most important is the good precision of the measurements. Precision is usually expressed in terms of the coefficient of variation (CV) which is typically about 1% to 1.5% for spine and total hip BMD and 2% to 2.5% for femoral neck BMD (Patel *et al*., 2000). DXA scanners have good long-term precision because, among other reasons, their calibration is extremely stable and there are effective instrument quality control procedures provided by manufacturers to detect any long-term drifts (see Table III). A second requirement for effective patient monitoring is a BMD measurement site that shows a large response to treatment. The best DXA site for follow-up measurements is the spine because the treatment changes are usually largest and the precision error is as good as or better than that at most other sites (Faulkner, 1998; Blake *et al*., 1996).

SUMMARY AND CONCLUSIONS

Table VI compares and contrasts the clinical and technical advantages of central DXA scans compared with alternative types of bone densitometry measurement such as QCT, pDXA, and QUS. A tick sign (✓) indicates where an alternative technique is known to perform in a comparable manner to central DXA. For example, there is strong evidence that pDXA and QUS can effectively predict fracture risk, although the presently available evidence suggests that the optimum measurement is the use of hip DXA to predict hip fracture risk (see Figs. 3 and 4). A question-mark sign (?) indicates where our knowledge is limited by an absence of suitable studies. For example, it is quite possible that pDXA, QCT, and QUS can effectively target patients for fracture prevention treatment. However, because no studies have been published we simply do not know whether

patients treated on the basis of these techniques achieve the same reduction in fracture risk as those treated on the basis of a central DXA examination. Finally, a crossout sign (×) indicates that alternative types of measurement are definitely unsuitable in these roles. For example, pDXA (with the exception of the 33% radius), QCT, and QUS measurements cannot be interpreted by using the WHO *T*-score definition of osteoporosis and are also unsuitable for use with the new WHO fracture risk algorithm. It is clear that there are important clinical and practical reasons why central DXA scanning should continue to be the preferred method of performing bone densitometry examinations and that as the osteoporosis community adopts the new fracture risk approach to treating patients these arguments will become even stronger.

Chapter 89

Controversial Issues in Bone Densitometry

Paul D. Miller*

Distinguished Clinical Professor of Medicine, University of Colorado Health Sciences Center, Medical Director, Colorado Center for Bone Research, Lakewood, Colorado

Bone densitometry measurements performed by dual-energy x-ray absorptiometry (DXA) have provided the foundation for treatment of patients with osteoporosis (Miller and Bonnick, 1999; Miller *et al*., 1999; Miller and Leonard, 2007).

DXA utilization formed the framework for the criteria to diagnose osteoporosis in the postmenopausal population (PMO) before the first fragility fracture has occurred (Kanis JA *et al.* 1994. These criteria may now be applied to men after the age of 50 years and to patients with secondary causes of osteoporosis (Lenchick *et al.*, 2002; Kahn *et al.*, 2004). DXA is also an important tool for fracture risk prediction and for monitoring the course of untreated osteoporosis or pharmacological therapy to treat this disease (Miller *et al.*, 2005; Miller, 2005; Bonnick and Shulman, 2006; Lewiecki, 2003; Miller, 2007). The international application of DXA in the clinical as well as the technical fields has been spearheaded by the International Society for Clinical Densitometry (ISCD) and the ISCD principles of quality control and clinical interpretation have been adopted by multiple medical and professional societies. In addition, the ISCD has initiated and completed four adult and the first pediatric position development conferences (PDCs) (Baim *et al.*, 2008). These intense assessments of data have set standards and guidelines for performance and interpretation of DXA. As knowledge in densitometry and osteoporosis expands and concepts evolve, controversies develop as well. In the earlier edition of this chapter, four controversial issues were discussed:

1. Discrepancies in *T* score determination among bone densitometers,
2. Prevalence versus risk in reporting bone mineral density device results;
3. Differences in ethnic and gender-specific databases among different bone density devices; and,
4. The value and limitations of serial bone mineral density measurements.

In this revised edition, I provide a brief update of the aforementioned controversies and also address new controversies in the field of bone mass measurements:

1. Using *Z* scores (age-matched) rather than *T* scores (young-normal) to define prevalence and/or risk in younger (premenopausal women, younger men, and adolescent and pediatric populations).
2. DXA as opposed to other emerging technologies to define "bone quality," bone strength, and risk prediction.
3. Utilization of vertebral fracture assessment (VFA) by DXA to define risk independent of BMD.
4. Application of the World Health Organization (WHO) 10-year absolute fracture risk algorithm in clinical practice.

DISCREPANCIES IN *T*-SCORE DETERMINATION AMONG BONE DENSITOMETERS

There has been little progress since the first edition of this chapter in standardization of young-normal reference population databases for the spine, forearm, or total body bone mineral density (BMD. In addition, despite the recognized validation and worldwide utilization of peripheral bone mass measurement devices for risk assessment, a consistent young-normal reference population database among all of these devices is lacking, leading to discrepant *T*-scores among these devices even in the same population or individual patient.

Principles of Bone Biology, 3rd Edition

Despite this lack of a common young-normal reference population database for central DXA of the spine between the two major DXA manufacturers (Hologic and Lunar-GE), a recently published detailed analysis suggests that there is agreement (same women classified by WHO criteria the same way) for *T* scores in 90% for the spine even with these discrepant young-normal reference population databases for the spine. Using the common reference population database (National Health and Nutrition Examination Survey III, NHANES III) for the hip (Kiebzak *et al*., 2007) the agreement is 92% at the total hip. However, it is important to point out that in this study, all diagnostic disagreements occurred at the transition points between normal and osteopenia and between osteopenic and osteoporosis classifications. The extent of disagreement in the total hip was 0.11 SD and in the spine 0.32 SD. Although this study emphasizes diagnostic agreement in *T*-score calculation, it also points out that there may be the potential for disagreement among DXA manufacturers. In clinical practice, this may become important in the International Classification of Diseases (ICD-9) diagnostic classifications. Health care providers, health economists, and patients use the WHO diagnostic label to define disease severity as well as often determining payment thresholds for pharmacological intervention, e.g., a shift in a *T* score from 2.49 to 2.50, changes the WHO classification from osteopenia to osteoporosis and has large diagnostic but not risk implications. In addition, these observations highlight the importance of interpreting BMD or *T* scores within the clinical context of other data relevant to the patients' clinical state. In other words, the same *T* score can be interpreted quite differently depending on other factors in the patient's evaluation for other risk for fractures (Kanis *et al*., 2001).

There are other issues, however, even if one were to have available a common database for all sites. We have an example, actually, because hip *T* scores have been standardized among the manufacturers. Although one might expect, therefore, that hip measurements among different DXA instruments would result in "perfect agreement," *T* scores at the hip still vary. Why?

The entire NHANES III database was performed on Hologic DXA machines (Looker *et al*., 1998). The *young-normal* reference population used in NHANES III for *T*-score calculation is, therefore, derived from Hologic calibrations and software. When these Hologic data are incorporated into Lunar-GE DXA systems using different statistical software (GE Encore software, version 7.0 to 8.8), it modified the reference SDs, which, in turn, created errors of about 0.5 SD at the femoral neck and about 0.7 SD at the trochanter with the *T*-score values being lower for GE-Lunar than Hologic (Binkley *et al*., 2005). This issue has not yet been rectified. Yet, for most people, this discrepancy is not a clinical problem. Nevertheless, these papers, as well as the following paper comparing *T* scores with *Z* scores in *young-normal* populations between DXA manufacturers, highlight the value and need for standardization, an issue recently highlighted by the joint workshop held by the National Institutes of Standardization and Technology and the ISCD (Bennett *et al*., 2006). For clinicians, the knowledge that *T* scores may not always be identical even at the hip and hip regions between manufacturers in the same patient is important to recognize (Ahmed *et al.,* 2007; Ribom *et al*., 2008).

For similar reasons, the *T* score and *Z* score may not be the same (as they theoretically should be) in the *young-normal* (20- to 49-year-old population) when measured even on the same DXA manufacturer. The line of identity between these standard deviation scores should be unity if the *T* and *Z* scores are calculated in *young-normal* healthy patients after peak adult bone mass is achieved and before bone loss has occurred (20 to 49 years) and if the SD score is derived from the same *young-normal* reference population database as shown in the equations for these calculations:

$$T \text{ score} = \frac{\text{patients BMD} - \text{mean BMD of the young age-matched reference population}}{\text{SD of the aged-matched references population}}$$

$$Z \text{ score} = \frac{\text{patients BMD} - \text{mean BMD of the young age-matched reference population}}{\text{SD of the aged-matched reference population}}$$

However, observations that the *T* and *Z* may not be identical in the same young patient even on the same DXA manufacturer has recently been suggested by a large cross-sectional study reported by Carey *et al.* from The Cleveland Clinic (Carey *et al*., 2007). These investigators compared *T* and *Z* scores between Hologic and Lunar-GE systems in 4275 women, and mostly aged 20 to 49 years. There were significant differences between *T* and *Z* scores at the lumbar spine, and all hip regions using either DXA manufacturer ($P < 0.001$) (Figs. 1 and 2). The differences were at times large (range, −1.95 to + 1.54 standard deviations), and remained when stratified by decade, even for the 20- to 29-year-old age group where there is agreement that this is the decade of achievement of peak adult bone mass and where there is no bone loss. The reasons for these discrepancies are not well defined but are probably multifactorial: different *young-normal* reference population databases even within the same DXA manufacturer; methods of adjustments for NHANES III in Lunar-GE or adjusting for body weight; or statistical methodology used to fit the reference population curves. The importance of statistical methodology has also been recently highlighted by several experts in this area (Shepherd and Blake, 2007a, 2007b; Kiebzak *et al*., 2007). The solution lies in standardization of reference population databases both within the same and between DXA manufacturers and consistent statistical methods for fitting regression lines, because even

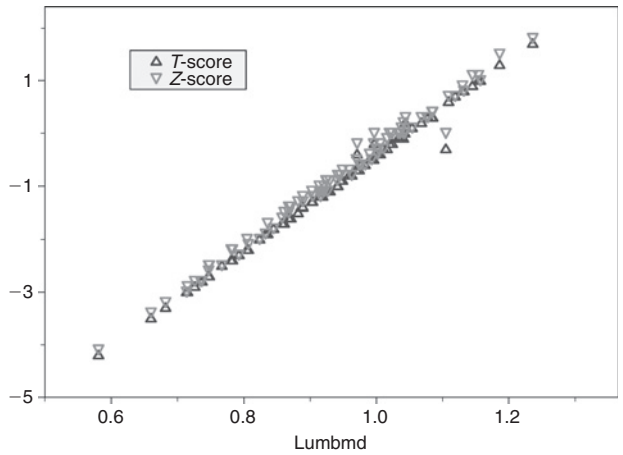

FIGURE 1 Relationship of spine *T* score and *Z* score to BMD value for 20- to 29-year-old females scanned using hologic DNA technology.

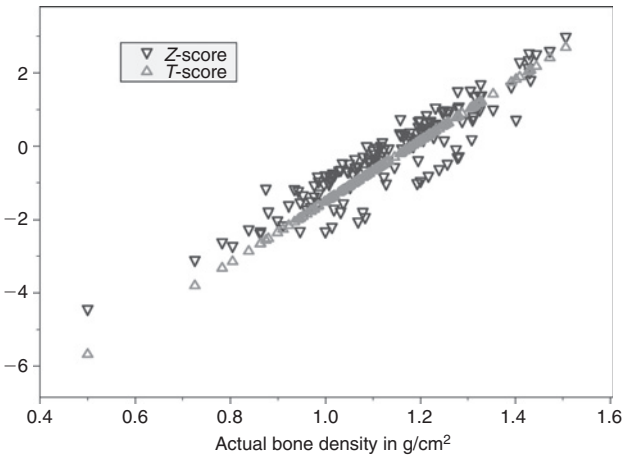

FIGURE 2 Relationship of *T* scores and *Z* scores to actual spinal BMD for 20- to 29-year-old females scanned using lunar, GE DXAs.

very small differences in the SD of the reference population can profoundly influence the calculated *T* or *Z* score. In the meantime, the ISCD Position Development Guidelines to use *Z* scores rather than *T* scores for *young-normal* and the pediatric populations to classify degrees of low bone mass is the correct position (Baim *et al*., 2008). This ISCD recommendation is, in part, based on the knowledge that the utilization of *T* scores, intended in 1994 for defining the prevalence of osteoporosis or osteopenia in the postmenopausal and aging population, but used in young-normal healthy populations that may have low peak adult bone mass but no increase in the risk for fracture, would lead to overdiagnosis of osteoporosis and overtreatment in young healthy individuals with very low fracture risk. In addition, the utilization of a *T* score in patients under the age of 50 years often classifies an otherwise healthy patient with a "disease" that is not even present.

The ISCD PDCs (including the first Pediatric PDC) have, however, provided suggestions of how to clinically employ the *Z* score for patient treatment in the young population, emphasizing that osteoporosis cannot be diagnosed based on a BMD (*Z* score) level alone. For the pediatric population the diagnosis of osteoporosis requires the presence of a clinically significant low trauma fracture in the lower extremity or more than one fracture in the upper extremity and that a *Z* score less than −2.0 can be called "low bone density" after adjusting for age, body size, and gender. In addition the ISCD Pediatric PDC wisely cautions against making therapeutic decisions based on a BMD alone. Therapeutic intervention decisions must be made in the context of the total clinical picture of the patient.

DXA AS OPPOSED TO OTHER EMERGING TECHNOLOGIES TO DEFINE BONE MASS, BONE "QUALITY," AND RISK ASSESSMENT

Single-energy x-ray absorptiometry (SXA) of the forearm was the first technology utilized in prospective longitudinal studies to show the association between degrees of low bone mineral density and fracture risk prediction in the postmenopausal population (Hui *et al*., 1998). In addition, this landmark study was the first to show that with ageing fracture risk increases at equivalent levels of BMD. Since these pivotal studies, several decades of data have been accumulated consistently documenting the reliability of determining areal BMD to predict fracture risk in postmenopausal women and in men aged 50 years and older in multiple population studies, as well as in virtually all clinical trials of osteoporosis (Black *et al*., 1992; Bonnick, 1998; Marshall *et al*., 1996; Melton, 1998; Ross *et al*., 1998; Barrett-Conner *et al*., 2005; Cauley *et al*., 2005; Kanis *et al*., 2001, 2002; Siris *et al*., 2004; Miller *et al*., 2004). The power of these DXA-derived data led to the widespread application of DXA for diagnosis and risk assessment in clinical practice. In addition, trust in the consistent capacity of DXA to treat patients with osteoporosis led to reimbursement for specific indications by most private and governmental health care authorities and to recommendations by the U.S. Prevention Services Task Force (USPSTF) and the U.S. Surgeon General's Report on The Status of America's Bone Health that DXA be used for population screening in the postmenopausal population over 60. In fact, DXA is the second medical technology embraced by U.S. policy for mass screening—the first being mammography for the detection of breast cancer (USPSTF, 2006; U.S. Surgeon General, 2006). Central DXA of the spine, hip, and forearm as well as a peripheral DXA of the forearm were the first devices that defined the relationship between prevalence of

low bone mass at different cut points (e.g., the "*T* score") and the lifetime risk for hip, forearm, and clinical vertebral fracture (Miller and Leonard, 2007). This type of data has not been developed with any other bone mass measurement device [non-forearm peripheral DXA, ultrasound, central or peripheral quantitative computerized tomography (QcT)]. It is for this reason that WHO diagnostic criteria are to be used only with central or forearm DXA.

However, even though two-dimensional measurements of bone mineral density captures about 80% of the bone strength as measured by biomechanical strength testing (Blake *et al*., 2006; Riggs *et al*., 2006), there are clear observations that other factors, independent of areal DXA measurements or even true volumetric bone density (g/cm^3) contribute to bone strength. These non-BMD factors have generally been lumped under the term "bone quality" (Bouxsein, 2003). In the past 10 years many technologies have been developed to attempt to capture these non-BMD factors, including high-resolution peripheral quantitative computerized technology (HRpQCT); macro and micro ultrasound, micromagnetic resolution imaging (MRI); and hip structural analysis (HSA) (Kleerekoper, 2006; Genant and Jiang, 2006; Jiang *et al.*, 2005; Hans *et al*., 2003; Krieg *et al*., 2008; Hans *et al*., 2008; Wehrli *et al*., 2006; Kazakia, 2007; Prevrhal *et al.*, 2008; Bonnick, 2007; Yates *et al*., 2007).

The challenge for all of these methodologies is to determine whether they are also useful in predicting fracture risk and whether measurements by these different technologies are independent of BMD measurements performed by DXA. Both ultrasound of different skeletal sites, peripheral DXA (pDXA), peripheral quantitative computerized tomography (pQcT), and spine QCT have been shown in head-to-head clinical studies to predict fracture risk in specific populations as well as central (spine and hip) DXA (Genant and Jiang, 2006; Krieg *et al.*, 2008; Hand *et al*., 2008). In the National Osteoporosis Risk Assessment (NORA) longitudinal population study, peripheral devices predicted the relative risk for all (global) fractures with the same predictive value and area under the curve in receiver operating analysis (ROC) as central DXA (Miller *et al*., 2002). Although micro-MRI and micro-CT can quantitative the extent of bone properties such as trabecular architecture and separation, there are no head-to-head fracture studies in human beings comparable to central DXA. Although hip structural analysis (HSA) has been shown in clinical trials to be an independent measure of hip fracture risk (independent of hip DXA), there are no data in population studies to validate HSA to predict risk. Moreover, there are inconsistencies in the results obtained by several currently available HSA software programs.

A major challenge is to develop practical technologies to measure components of bone strength that are independent of BMD. If this challenge can be met, many paradoxes such as fractures occurring at "normal" DXA-derived *T* scores could be explained. In addition, means to study and apply measurements of bone quality (and the more relevant equivalent, bone strength) will help explain how our osteoporosis therapies reduce fracture risk in ways that appear to be independent of DXA-determined changes in BMD.

ETHNIC AND GENDER DIFFERENCES: PREVALENCE VERSUS RISK

The WHO criteria for the diagnosis of osteoporosis were established in Caucasian postmenopausal women (Miller and Leonard, 2007). However, as bone mass measurement technologies have evolved, manufacturers of DXA equipment have incorporated various ethnic as well as gender-specific reference population databases for both *T*- and *Z*-score calculation. It is therefore important to consider how the initial WHO criteria can be applied to non-Caucasian female and in male populations. Currently the ISCD suggests using a non-race-adjusted (Caucasian-only) reference population database for risk assessment (Binkley *et al*., 2002). Much of this recommendation is based on historical knowledge that for many years in the early development of densitometry, the manufactures only had Caucasian reference databases; and that in the NORA head-to-head multiethnic fractures study (the only head-to-head long-term population-based fracture study available among multiple ethnicities of postmenopausal women) the relative risk (RR) for global fracture risk per SD reduction in BMD from the *young-normal* Caucasian reference database (*T* score) was similar among five U.S. ethnicities: Caucasian, Hispanic, Asians, African Americans, and Native Americans (Barrett-Conner *et al*., 2005). There are valid arguments for and against a common single ethnicity reference population database (Leslie. 2006). If race/ethnicity is simply a proxy for other determinants of health (such as socioeconomic status, latitude, or diet) then approaches should focus on the specific factors that are directly implicated in the causal chain rather than on race/ethnicity. Arguably, race/ethnicity should only be used when it is the only available proxy for important unmeasured variables (Miller and Bonnick, 1999; Outram and Ellison, 2005). Continentally defined populations are not homogeneous and can be subdivided along national, religious, linguistic, and other lines. Many still adhere to the system of continental population groups, but recognize that this is an imperfect approach. The need for population-specific reference data in order to calculate *T* scores is controversial (Leslie, 2006). In part, this derives from differences in fracture rates and bone density that have been observed between countries and different ethnic groups, as well as different countries with similar ethnic groups but with a concern that *T* scores derived from a single reference population (usually taken to be whites) may be inappropriate. In addition, any dissimilar reference population

data will yield differences in prevalence of osteoporosis among different ethnicities owing to the effect of small differences in the SD of the mean BMD of different young-normal reference populations. On the other hand, the need to develop specific reference data for every combination of country, race/ethnicity, and gender on every bone density instrument is virtually impossible. In fact, even within a relatively homogeneous population, variation in bone density and fracture rates can be observed (Miller and Bonnick, 1999). To follow this argument to its logical conclusion would require reference data for each subgroup within a country that shows a different average bone density and/or fracture rate. How daunting and impractical a task this would be is best illustrated in The People's Republic of China that officially recognizes 56 nationalities. The economic implications cannot be ignored, given cultural differences in health priorities and regional inequities in health care resources (Leslie *et al.,* 2006).

Individual population data suggest that vertebral fracture prevalence as a function of age may not be dissimilar in Hispanic (United States, Mexico, Spain, South America), Asian (United States, China, Japan, Hong Kong), or Native American (United States and Canada) populations compared with Caucasians (Riggs and Melton, 2008). However, for nonvertebral fracture risk, especially hip fracture risk, the absolute fracture risk (prevalence and incident) is lower worldwide in Asians and African-Americans than it is in Caucasians, and Hispanics (Barrett-Conner E *et al.*, 2005). It follows that population-specific reference data cannot resolve the inherent discordance in fracture rates, since there may be socio-economic, nutritional, geographic and other bone-specific issues (geometry) that may also contribute to ethnic differences in fracture rates that are not captured by BMD, BMI or other "bone" factors. Meanwhile, use of a common reference population enhances consistent reporting and reduces confusion. White reference data are the most complete and best validated as a tool for fracture prediction and treatment initiation, and by default is the most convenient. While prevalence of WHO classifications of osteopenia and osteoporosis will differ among ethnicities and between genders using a Caucasian-only female reference database for T-score calculation, differences in relative fracture risk calculated from a Caucasian-specific female reference data may not differ enough among most ethnicities and between genders to justify the enormous expense of developing a multiethnic and gender specific reference databases to sub classify prevalence(s) linked to prospective risks. Absolute fracture risk captured from head-to-head gender comparative population studies (Cummings SR *et al.,* 2006; Bergstrom U. *et al.,* 2008; Bischoff-Ferrari HA *et al.,* 2007; Rivedeneria *et al*., 2007) suggest that risk in men may be similar as in women when BMD is measured by DXA from a female reference population database. Thus, Although at the current time the ISCD PDC suggests using gender-specific reference population databases for WHO criteria and risk assessment, arguments could be advanced to justify using a non-gender-specific database for risk prediction.

USING BONE DENSITOMETRY FOR MONITORING

Bone densitometry, either with central (spine and hip) DXA or spine QCT, can be used for monitoring the effects of disease on bone mass (such a celiac, Cushings disease, etc.); for monitoring the effects of drugs that can negatively effect bone strength or BMD (aromatase inhibitors, depoprovera, glucocorticoids, etc.), or for monitoring the effect of treatments designed to treat osteoporosis (Miller *et al.*, 2005; Miller, 2005, 2007; Bonnick and Shulman, 2006; Lewiecki, 2003).

There are no other accepted modalities available to measure and help guide clinical decisions in the area of osteoporosis other than serial measurements with DXA or QCT. Many experts feel strongly that clinical treatment of patients with osteoporosis cannot be achieved without serial BMD measurements.

The controversies surrounding serial BMD measurements are:

1. The frequency of measurements.
2. The adequacy among DXA/QCT measuring centers in performance of both *in vitro* as well as *in vivo* quality control to know their precision (or the opposite, precision error) in order to know their least significant change (LSC) (Bonnick, 1998).
3. The misinterpretation by some health care insurance carriers on the intent of the Medicare bone mass measurement act of 1997 on the allowed frequency of reimbursements of serial BMD measurements.
4. The relationship between the magnitude of change in BMD and the magnitude of change in bone strength.

The frequency of serial BMD measurements is not a fixed interval. Frequency of BMD measurements is determined by the disease the physician is treating, the anticipated rate of bone loss (or gain), the *in vivo* least significant change of the DXA/QCT machine (LSC), and the results of other aspects of the patient's evaluation.

Disease processes or the use of medications that are associated with rapid bone loss: post solid organ transplantation, high-dose glucocortiocoid use, aromatase inhibitor use, immobilization, thyroid "storm" or severe primary hyperparathyroidism, for instance, all often require annual and at times every-6-months determination. Postmenopausal women or men initiating treatment with FDA-approved therapies for osteoporosis should have a BMD measurement 12 months after initiating treatment. If the treatment is successful, then the monitoring frequency is recommended to

be every 2 years, unless a change in management of other important factors that could impact bone health intervenes. Such an intervention could be a change in the pharmacological agent [e.g., a different bisphosphonate, or switching to teriparatide or a selective estrogen receptor modulator, or route of administration (oral to intravenous or transdermal)], the development of a new fracture on treatment, or the development of a new disease state that can be associated with bone loss. In these circumstances, the repeat BMD should be done within 12 months, not after 2 years.

The bone mass measurement act (BMMA) statute stating an every-23-month BMD testing interval was intended to be language directed only at a specific population: stable postmenopausal women (Department of Health and Human Services, 1998. It is both medically as well as ethically wrong to restrict reimbursement to other less stable and more ill populations where clinical decisions may change rapidly and require the knowledge of the bone mass determination.

Bone density testing centers that do not know their own *in vivo* precision cannot competently interpret changes in serial BMD measurements. *In vitro* (phantom) scanning is inadequate because patients move and phantoms have a fixed region of interest (ROI). Each facility that performs bone mass measurements should do correct *in vivo* precision studies to determine their LSC (Gluer *et al.*, 1995; Shepherd and Lu, 1997). Guidance on how to perform precision studies and calculate the LSC can be found on the ISCD website (ISCD.ORG).

In addition, because precision differs from manufacturer to manufacturer, it is ideal to perform serial BMD measurements on the same DXA or QCT machine. Although there are equations and calculations to compare serial BMD changes from one manufacturer to another (Hui *et al.*, 1997), cross-calibration is also associated with a substantial loss of precision making comparative studies on change in BMD problematical. In the ideal world the patient should be measured on the same DXA/QCT machine. It is very difficult to have confidence in serial measurements when compared between different manufacturers.

DETERMINATION OF VERTEBRAL FRACTURES BY DXA (VFA)

In the past several years research and clinical observations have documented the importance of assessing not only clinical (painful) but also asymptomatic vertebral compression fractures (VCFs). The prevalence of VCFs is high in all populations especially over the age of 60 years. Moreover, these asymptomatic VCFs predict future fractures at both vertebral and nonvertebral sites risk (Schousboe *et al.*, 2002; Vokes *et al.*, 2006; Lewiecki and Laster, 2007; Laster and Lewiecki, 2007; Genant *et al.*, 2000; Doboeuf *et al.*, 2007; Chapurlat *et al.*, 2006; Greenspan *et al.*, 2001). This increased risk of fracture is independent of the prevailing BMD (*T* score). The risk is higher as either the severity (grade 1 to 3) or the number of vertebral fractures increase (Genant *et al.*, 2007; Grigoryan *et al.*, 2003). A prior fragility fracture "trumps" all other risk factors as a predictor of future fracture risk.

Routine anterior-posterior (AP) and lateral spine x-rays have been the gold-standard for detecting VCF. But DXA technology has advanced to the point that now VFA by DXA is a recognized methodology for detecting VCF and at far lower radiation than routine x-ray. In addition, there is now a Medicare code for VFA reimbursement. The ISCD Position Development Conferences have documented this development (Vokes *et al.*, 2006). Utilizing the best available evidence the ISCD has suggested specific indications for VFA (Table I). Yes, there is no universal agreement across all Medicare carriers as to which indications for VFA will be reimbursed. In addition, although VFA by DXA has sensitivity and specificity similar to routine spinal x-rays for the detection of VCF, VFA loses some sensitivity for mild (grade I) fractures between T4 and T8 (Doboeuf *et al.*, 2007; Chapurlat *et al.*, 2006). Hence, it is suggested that if a clinician is uncertain about a Grade I VCF assessed by VFA-DXA at those vertebral levels, a follow-up x-ray should be considered.

Wider utilization of VFA by DXA in the right population will detect a large number of patients who have osteoporosis independent of their prevailing *T* score.

WORLD HEALTH ORGANIZATION (WHO) VALIDATED 10-YEAR ABSOLUTE FRACTURE RISK PROJECT

Published in March 2008, the long-awaited validated WHO absolute fracture risk model will help put osteoporosis risk assessment into a clinical arena the equivalent of The Framingham study for cardiovascular risk factors. This 10-year project spearheaded by John Kanis is an enormous scientific effort to validate individual risk factors for fracture (hip as well as global all-fracture risk) in the untreated postmenopausal population and how these risk factors interact to facilitate risk prediction (Kanis *et al.*, 2008). In addition, the WHO effort facilitates treatment (intervention) decisions by utilizing disutility calculations to assess the cost of fractures for any specific population and what that country can afford in order to reduce risk according to their individual gross domestic product and cost of treatments. For example, in the United States at the current costs of most osteoporosis therapies it becomes cost-effective to treat at a 10-year absolute fracture risk of 10% or greater. In addition to helping physicians and health economists decide on appropriate levels of treatment, the WHO absolute risk model will remove some

TABLE I Indications for VFA (ISCD Official Position)

Consider VFA when the results may influence clinical management
When BMD measurement is indicated, performance of VFA should be considered in clinical situations that may be associated with vertebral fractures. Examples include:

- Documented height loss of greater than 2.0 cm (0.75 in) or historical height loss greater than 4 cm (1.5 in) since young adult.
- History of fracture after age 50 years
- Commitment to long-term oral or parenteral glucocorticoid therapy
- History and/or findings suggestive of vertebral fracture not documented by prior radiological study

From Vokes et al. (2006).

of the confusion and debate surrounding the treatment of "osteopenia" because the *T* score level will be incorporated into the total risk model to come up with a 10-year risk for both hip and global fracture risk. The model can be applied to both postmenopausal women and elderly men.

The model is published both in its totality and the U.S. adaptation of the models (Hughes *et al.*, 2008). In addition, access to the formulas to calculate the risk is available through several websites (ISCD.ORG, NOF.ORG, and FRAX.ORG). Implementation of the WHO absolute fracture risk in the United States is being shepherded by The National Osteoporosis Foundation in collaboration with many other professional organizations with interest in osteoporosis as well as the bone mass measurement manufacturing companies. The U.S. NOF Clinicians Guide is intended to be an adaptation of FRAX that is unique to the U.S. clinical practice and reimbursement system. The NOF Clinicians Guide will clearly allow use of *T* score at the spine for WHO diagnosis and the use of gender-specific reference population databases for diagnosis as well, whereas all risk calculations from FRAX are based on hip-only measurements with Caucasian female reference population databases. In addition the U.S. Guide will be more flexible on the recommendations of the frequency of repeated BMD measurements in special clinical circumstances that require closer BMD monitoring and the use of morphometric vertebral deformities as a independent risk for high future fracture risk. It is important to stress that the models will not remove individual clinical judgment and individual patient treatment and specific treatment recommendations can still be personalized through shared decision making between patient and physician.

It should be pointed out that the WHO validation captured risk factors known to be predictive of fracture risk during the term of the population studies used for validation. Since then, other risk factors not captured in the WHO model have been identified as risk factors for fracture and will need to be utilized by clinicians for management decisions: bone turnover rates as measured by serum and/or urinary bone turnover markers, hip structural analysis, cortical porosity, fall rates, etc. Nevertheless, the WHO risk model will greatly facilitate both clinical and health-economic decisions with regard to timing of and need for osteoporosis intervention.

CONCLUSIONS

Bone mass measurements have paved the way for the clinical management of patients with either low bone mass and/or fragility fractures. The place of this measurement technology is ingrained in their applications and supported by consistent scientific evidence and clinical data. Bone mass measurements are still underutilized for the detection of osteoporosis and at-risk patients. The devices and their data output are still being improved. The need for the use of other non-DXA bone mass measurement devices to compliment DXA measurements for assessing bone strength and quality is great—and devices are currently either in research and development or are currently available to perform such additional analysis.

INTRODUCTION

Bone and therefore bone architecture is a generic term used for many different entities. At the macroscopic level the term bone is used for the organ bone as a distinct entity of the skeleton. At this level bone architecture describes the overall shape and geometry of bone as well as the differentiation into cancellous (also referred to as trabecular) and cortical bone. Typical parameters describing architecture are cortical thickness, moment of inertia and other geometrical measures. Bone mineral density (BMD) of the whole bone or of well-defined subvolumes is another important parameter. At this level bone architecture is typically assessed *in vivo* with x-ray-based imaging modalities either using planar methods such as conventional radiography and dual x-ray absorptiometry (DXA), or volumetric methods such as quantitative computed tomography (QCT). DXA and QCT are also preferred methods for the determination of BMD.

At the microscopic level, i.e., if the spatial resolution of the acquired images is better than 100 μm, bone architectural assessment is predominantly associated with trabecular structure, i.e., the interconnecting lattice of bone tissue filled with marrow (Fig. 1). Typical parameters are trabecular thickness and separation of trabeculae and parameters comprehensively describing the network architecture, such as the structure model index (SMI). Methods of choice are three-dimensional (3D) microcomputed tomography (μCT) and less frequently three-dimensional micromagnetic resonance imaging (μMRI). Excised bones, bone specimen, or complete small laboratory animals such as mice or rats can be investigated. Historically, trabecular structure has been measured by two-dimensional (2D) stereological methods applied to thin sections using optical microscopes or x-ray based microradiography. However, the preparation of thin (≈10 μm) bone sections typically embedded in epoxy resin is tedious and therefore these methods have been widely replaced by 3D μCT.

Owing to the high radiation exposure associated with this level of spatial resolution, *in-vivo* investigations with μCT are limited to small animals and cannot be carried out in humans. Although μMRI does not use ionizing radiation, its low signal-to-noise ratio is a limiting factor for large sample volumes, which also precludes *in vivo* measurements in humans. If the resolution is further increased to levels below 10 μm, cortical architecture, which can, for example, be characterized by porosity, can be accurately assessed. At even higher spatial resolution, bone architecture describes the structure of the compound of minerals embedded in the organic collagen matrix. This is the domain of techniques such as electron microscopy and fourier-transform infrared microscopy which is beyond the scope of this chapter.

Although it is not precisely defined, the range between macro- and microimaging i.e., from approximately 100 μm to 500 μm, is usually denoted as high-resolution CT (hrCT) and MRI (hrMRI) imaging for CT and MRI (see Fig. 1). These methods push existing such clinical scanners to their technical limits. Their main aim is the 3D assessment of trabecular architecture in humans *in vivo*; however, the spatial resolution is not high enough to accurately separate

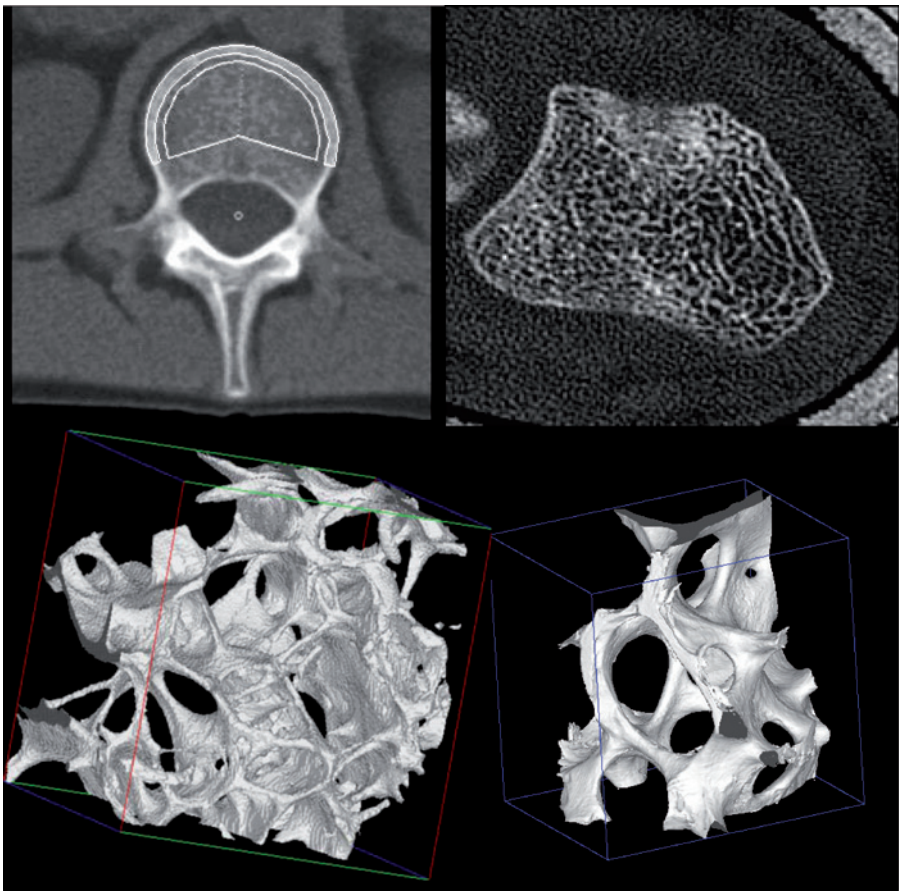

FIGURE 1 Visualization of bone architecture using x-ray tomography. (*Top left*) CT of vertebral body (in-plane pixel size, 550 μm; slice thickness, 10 mm) to determine BMD and macrostructure (details in sections 4.1 and 4.2). (*Top right*) hrCT of ultradistal forearm (inplane pixel size, 200 μm; slice thickness, 0.5 mm) to determine texture and structure of the trabecular network (details in section 4.3). (*Button*) μCT of vertebral spongiosa (isotropic voxel size, left, 30 μm; right, 10 μm) to determine structure of the trabecular network (details in section 4.4). (See plate section)

and quantify individual trabeculae. Thus, the use of standard stereological analysis methods in these images is problematic. As a consequence, advanced image-processing methods that quantify different parameters of the trabecular network such as texture or statistical features have been developed. Some of these methods have also been used to quantify trabecular architecture by using plain radiographs.

From the clinician's point of view the determination of bone architecture is a tool to improve the assessment of bone strength in order to more accurately predict fracture risk and its dependence on age, disease, and treatments. Bone mineral density is currently the most important predictor of fracture risk because it correlates well with bone strength and because it can easily be measured *in vivo* in humans with high precision and accuracy. However, BMD values in normal and osteoporotic people overlap widely, and many osteoporotic fractures occur in osteopenic subjects that still have relatively high BMD. Obviously bone strength and fracture risk cannot be fully explained by a global measurement of bone mineral density. The spatial distribution of BMD or, in other words, the bone architecture at the macroscopic and microscopic levels and their combination with BMD in finite-element analysis methods as well as multivariate models is thought to perhaps ultimately be a better predictor of bone strength than BMD and further improve our ability to understand the pathophysiology and progression of osteoporosis and other bone disorders.

RADIOGRAPHY

Conventional Radiography

Conventional radiography is the most widely available noninvasive technique of visualizing bone structure. The term osteopenia, "paucity of bone," is used to describe visually decreased bone density—or radiolucency—on radiographs. Thus, it also provides qualitative information on bone density. However, plain films are rather insensitive to changes in bone mineral density. In the spine, for example, it has been estimated that as much as 20% to 40% of bone mass must be lost before a decrease in bone visual density can

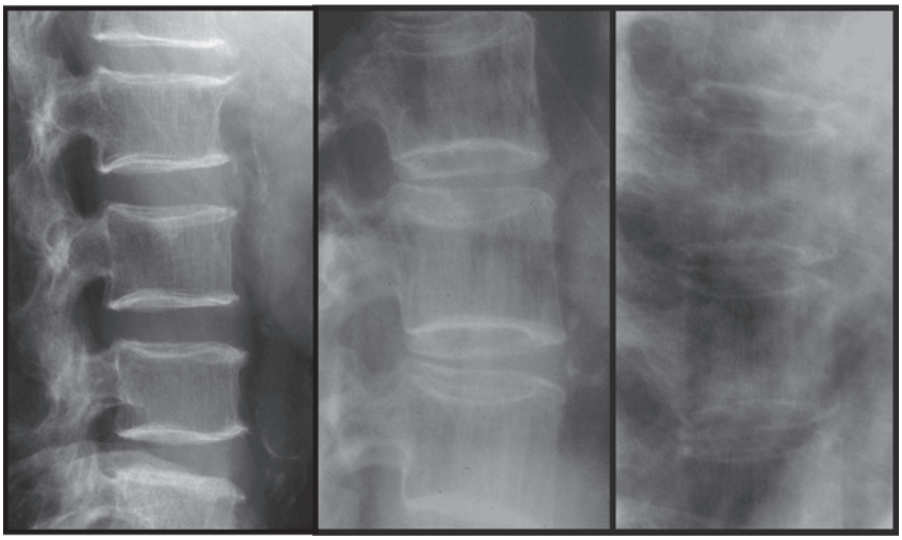

FIGURE 2 (*Left*) General decreased visual bone density results in increased radiolucency of the vertebrae with relative accentuation of the cortical rim, or "picture framing." (*Center*) Increased vertical striation owing to the proportionally greater loss of horizontal trabeculae and compensatory hypertrophy of the vertical trabeculae. (*Right*) Severe osteoporosis: the vertebrae can hardly be distinguished on the lateral lumbar spine radiograph. There are multiple endplate and compression fractures.

be seen in lateral spine radiographs. The decrease in density is primarily a result of a decrease in mineralized bone volume rather than a decrease in mineralization of remaining bone; in osteoporosis and osteopenia, the amount of calcium per unit of mineralized bone volume remains constant at about 35%. Alone or in conjunction with other advanced imaging techniques, conventional radiography is still widely used to diagnose osteoporotic fractures and to differentiate various disorders associated with osteoporosis and osteomalacia.

Changes in the axial skeleton and the ends of the long tubular bones are most prominent because these sites have a relatively greater proportion of trabecular bone that has more surface and responds more quickly to overall shifts in bone metabolic rate than cortical bone. As bone is lost, non-weight-bearing connecting trabeculae are resorbed first, leaving the remaining weight-bearing trabeculae more widely separated. Some may undergo compensatory thickening in the direction of mechanical stress. Trabecular anisotropy increases, resulting in distinct patterns on radiographs, such as the organized sequential trabecular changes along the compressive and tensile stress in the proximal femur, and an appearance of vertical striation in the lumbar spine in early stages of osteopenia caused by rarefaction of the horizontal trabeculae and a relative reinforcement of the vertical trabeculae (Fig. 2). Vertebrae may appear on radiographs as a "picture frame" or as an "empty box" because of accentuation of the cortical margins surrounding the lucent trabecular center. Osteopenic vertebrae may also demonstrate increased bioconcavity of the vertebral endplates owing to protrusion of the intervertebral disk into the weakened vertebral body.

Vertebral fracture, the hallmark of osteoporosis, has a wide range of morphological appearances from increased concavity of the endplates and anterior wedging to a complete destruction of the vertebral anatomy in vertebral crush fractures (Fig. 3). Fractures can be graded by radiologists or experienced clinicians and quantified with morphometric methods to reduce the subjectivity inherent in grading (Genant *et al.,* 1996; Wu *et al.,* 2000). The Genant scoring method (Genant *et al.,* 1993; Lentle *et al.,* 2007) shown in Figure 4 grades 0 for normal, 1 for mildly deformed (20% to 25% reduction in anterior, middle, and/or posterior height, and 10% to 20% reduction in the projected area of the vertebral body), 2 for moderately deformed (25% to 40% reduction in height, and 20% to 40% in area), and 3 for severely deformed (40% or greater reduction in height and in area). This method offers high reproducibility on conventional as well as on digitized radiographs (Wu *et al.,* 2000). It has been widely used to evaluate fracture endpoints in the majority of epidemiological studies and of clinical trials investigating the efficacy of osteoporotic drugs (Ettinger *et al.,* 1999; Harris *et al.,* 1999; Szulc *et al.,* 2001; Grados *et al.,* 2004; Genant *et al.,* 2005).

Of most concern in osteoporosis are fractures of the hips, vertebral bodies and wrists. Changes in the bone cortex or spongiosa may make such injuries more likely to occur. Fractures of the vertebral bodies are a result of predominantly axial compressive loads. One reason for the decreased load-bearing capacity is the increased absorption and removal of the horizontal trabeculae or lateral support crossties (Mosekilde *et al.,* 1985). The vertical trabecular bone, therefore, behaves as a column and is prone to critical buckling loads (Townsend *et al.,* 1975). A 50%

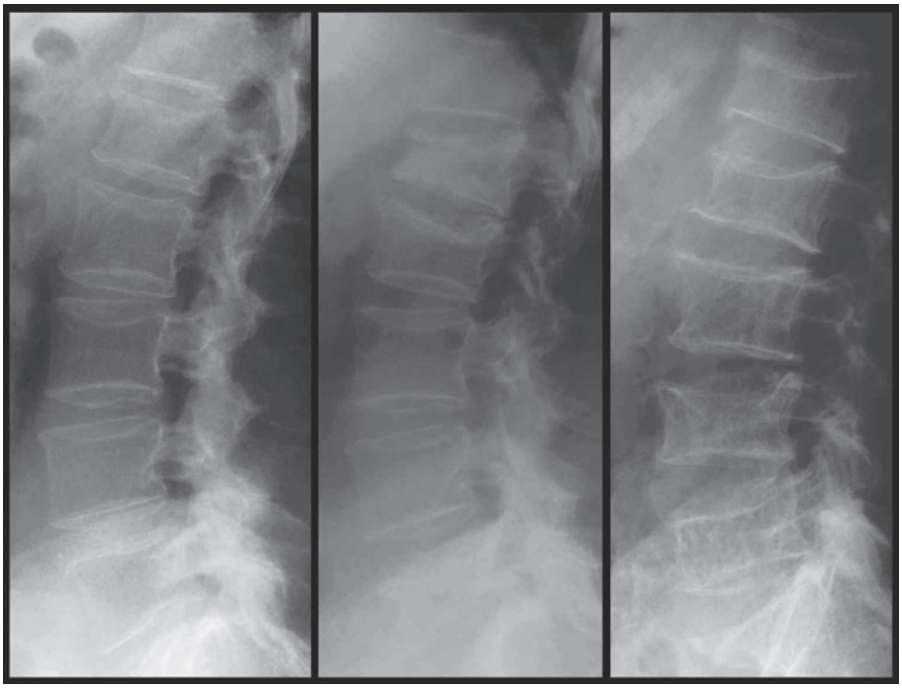

FIGURE 3 Multiple fractures in the thoracic spine in advanced involutional osteoporosis, including endplate, wedge, and compression fractures.

decrease in cross-sectional area as a result of absorption of the horizontal trabeculae is associated with a 75% decrease in the load-bearing capacity of the vertebral body (Einhorn, 1992).

In the hip and the forearm, radiographs are typically used to diagnose and classify a fracture and to develop a strategy for a potential surgical intervention. Quantitative radiographic grading of osteoporosis has not gained much attention, although in the hip the Singh index has been developed to grade differences in the trabecular pattern (Singh *et al.,* 1973). The trabecular compartment is of interest because osteoporotic fractures of the hip and the forearm typically occur in trabecular-rich locations: at the femoral neck and trochanter in the hip and at the ultradistal site of the forearm, whereas osteoporotic fractures are much less frequent in the shaft where bone strength only depends on compact bone (Smith *et al.,* 1976).

The Singh index grades the trabecular pattern of the proximal femur from I to VII. Grade VII denotes individuals with dense trabeculae even in the region of the Ward's triangle. Grade VI down to grade I denotes normal pattern of all compressive and tensile trabeculae (VI) to marked reductions in the principal compressive trabeculae (I). Although in several cadaver studies the Singh index correlated with $r > 0.5$ with bone strength (Delaere *et al.,* 1989; Krischak *et al.,* 1999; Wachter *et al.,* 2001) the diagnostic value of the Singh index has been criticized because it has been shown to suffer from high interobserver variation (Koot *et al.,* 1996) and different results regarding its relationship with bone mass (Disen *et al.,* 1979; Eriksson *et al.,* 1988; Kawashima *et al.,* 1991; Barondess *et al.,* 2002) and vertebral or femoral fracture (Heneghan *et al.,* 1997).

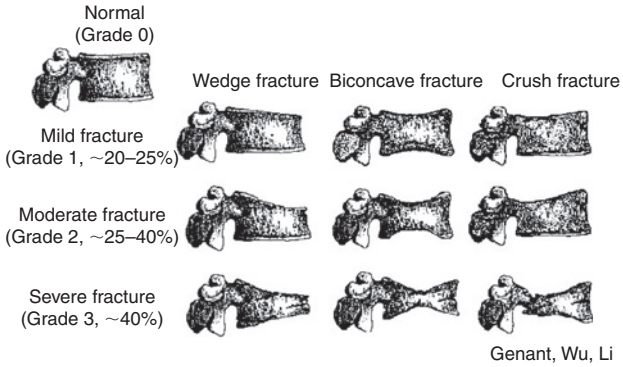

FIGURE 4 The Genant grading method for a semiquantitative evaluation of osteoporotic vertebral fracture grades; fracture severity from normal (grade 0) to severe deformity (grade 3). The scoring scheme illustrates reductions of the anterior height that correspond to the grade of deformity. Reductions of the middle or posterior heights or combinations thereof can be evaluated accordingly.

Radiogrammetry

By common definition, radiogrammetry refers to the morphometric assessment of tubular bones in the hands or wrists from projection radiographs; i.e., dimensions of structures such as the cortical thickness of finger bones are assessed. The method can be applied more generally to any bone suitable for such an evaluation. Several authors have

applied radiogrammetric techniques to radiographs of the humerus (Meema *et al.,* 1963; Bloom *et al.,* 1970) and the femur (Barnett *et al.,* 1960; Saville *et al.,* 1976; Horsman *et al.,* 1982; Glüer *et al.,* 1994) as well as to DXA scans of the proximal femur (Faulkner *et al.,* 1994).

In radiogrammetry, a nonscreen acquisition using fine-grain film is most often used but some investigators have used high-detail industrial film (Meema, 1981). Periosteal (D) and endosteal (d) diameters at the midshaft are the primary measurements; they are directly determined on the x-ray film using a simple ruler or caliper (Fig. 5). From these measurements, indices of bone shape can be calculated, such as combined cortical thickness, the metacarpal index CCT = D − d or the metacarpal index MCI = $(D - d)/D$, with the latter accounting for skeletal size differences. Annual decreases in CCT of 0.4% before menopause and of 1.3% after menopause have been reported (Falch *et al.,* 1990), which is comparable to a decline of 1.45% in untreated women after oophorectomy (Genant *et al.,* 1982).

Under the assumption of a circular bone cross section, cortical area can be defined as: $A_{cort} = A_{tot} - A_{med} = (\pi/4)(D^2 - d^2)$, where A_{tot} denotes the total area of the metacarpal and A_{med} denotes the area of the medullary space. Another parameter is percent cortical area: $PCA = A_{cort}/A_{tot} = 1 - (d^2/D^2)$. Because the absolute measurement of area is not important to the clinical interpretation of these results, the scaling factor of $\pi/4$ is typically disregarded.

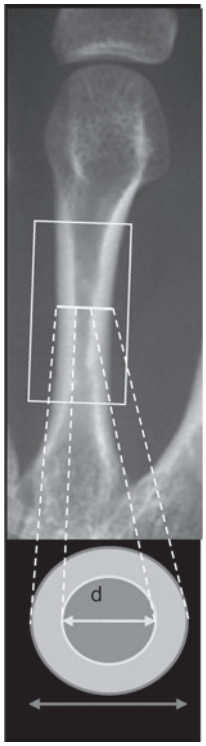

FIGURE 5 Radiogrammetry of the second metacarpal; originally, only the midshaft, as indicated by the horizontal line, was used for measurements. Newer direct digital x-ray methods use a larger ROI covering a large part of the diaphysis, as indicated by the box.

Digital Radiogrammetry

Newer direct digital x-ray methods like computed radiography (Rico *et al.,* 1994) combined with computer-assisted analysis that allowed for analysis of continuous segments of the metacarpal bone rather than single measurements at the midshaft (see Fig. 5) (Cosman *et al.,* 1991; Derisquebourg *et al.,* 1994; Matsumoto *et al.,* 1994; Adami *et al.,* 1996; Jorgensen *et al.,* 2000; Rosholm *et al.,* 2001) reduced precision errors from about of 6% to 11% (Adams *et al.,* 1969; Naor *et al.,* 1972) in film-based implementations to about 1% to 2% (Dey *et al.,* 2000).

In the late 1990s, digital x-ray radiogrammetry (DXR) was introduced as an extension to radiogrammetry. This technique estimates areal BMD from radiogrammetry and cortical porosity. It employs a fully automated approach in a total of five regions in the metacarpals, radius, and ulna (Jorgensen *et al.,* 2000; Rosholm *et al.,* 2001). The innovation was to use the results to estimate a mean bone volume per projected bone area (VPA) to gain higher independence of bone size. In DXR, areal BMD (BMD_a) is estimated by empirically calibrating VPA to BMD_a as measured in the midregion of a DXA forearm scan and correcting for cortical porosity p: $BMD_a = c \bullet VPA(1 - p)$, where c is a constant obtained empirically from the calibration process. In principle, this is the same as assuming a constant mass density of compact bone. DXR takes into account that porosity increases with age. An estimate of porosity is made by a simple texture analysis in the medullary space derived for each individual measurement (Rosholm *et al.,* 2001). The value of p is an average porosity estimated in the five bone regions and typically has a value of less than 2%. Precision of BMD_a as measured by DXR was reported to be in the range of 0.5% to 1% (Jorgensen *et al.,* 2000; Rosholm *et al.,* 2001; Ward *et al.,* 2003).

High-Resolution Radiography and Microradiography

High-Resolution Radiography

In order to improve the spatial resolution of conventional radiographs for a better visualization of bone structure, contact radiography with high-resolution films or magnification radiography with fine- or microfocus x-ray tubes have been used (Genant *et al.,* 1975; Doi *et al.,* 1976; Fodor *et al.,* 1987; Pruneau *et al.,* 1987; Jonsson *et al.,* 1995; Boyce *et al.,* 2006). Actually radiogrammetry, where the hand is typically placed directly on the film, is one example of high-resolution contact radiography. However, historically, for *in-vivo* applications, magnification radiography, a technique in which the size of the focal spot of

the x-ray tube determines the spatial resolution, has been more widely used than high-resolution contact radiography, where the spatial resolution is determined by the film. Advanced techniques of magnification radiography use electronic detectors and μ-focus x-ray tubes with focal spot sizes down to 10 μm (Link *et al.,* 1994). Advanced systems for contact radiography use high-resolution digital detectors and can be used for the calcaneus and the forearm (Wilkie *et al.,* 2004; Lespessailles *et al.,* 2007), which ensures that the object–detector distance is small.

Microradiography versus Histomorphometry

In bone and mineral research, the most commonly applied microradiography technique is contact microradiography of prepared sections of excised bone tissue with a thickness of about 50 to 100 μm. It has been used for decades to determine bone mineralization with an in-plane spatial resolution of less than 10 μm (Cosslet *et al.,* 1960; Engstrom, 1962). The images are recorded on film or spectroscopic plates (Conlogue *et al.,* 1987) and are then analyzed using optical microdensitometry. Results are typically calibrated with an aluminum step wedge imaged simultaneously with the bone specimen. Newer systems digitize the microradiogram for further computer-aided analysis (Kalebo *et al.,* 1988; Strid *et al.,* 1988; Boivin *et al.,* 2002).

As an alternative, the technique of histomorphometry has been developed. It facilitates the very time-consuming and difficult x-ray exposure but requires even thinner sections (≈10 μm), which are stained and then investigated using an optical microscope. A "stained thickness" of 10 μm can be achieved either by grinding or by special surface-staining techniques (Hahn *et al.,* 1991). Owing to a decrease of partial volume artifacts in histomorphometry, the accuracy of the quantification of bone structure is improved compared with microradiography (Engelke *et al.,* 1993). Because histomorphometry is based on principles of stereology, some basic assumptions of the underlying structure of the trabecular network are required. Typically either a rod- or a plate-like structure is assumed (Parfitt, 1983; Parfitt *et al.,* 1987). Relative bone volume (BV/TV), trabecular thickness (Tb.Th), trabecular spacing (Tb.Sp), and trabecular number (Tb.N) are most prominent among the long list of standard histomorphometric parameters.

Mineralization of the trabecular bone can be divided into primary and secondary mineral apposition. Primary mineral apposition is mineralization of the unmineralized organic matrix (osteoid). Secondary mineral apposition is a slow and gradual maturation of the mineral component, including an increase in the amount of crystals and/or an augmentation of crystal size toward their maximum dimensions. Increased bone turnover, as in postmenopausal osteoporosis, results in hypomineralization, because resorption begins prematurely, before mineralization is complete. The least mineralized bone is highly radiotranslucent and is the most recently formed, or has just achieved its primary mineralization, and represents about 75% of the complete mineralization. It contrasts with the adjacent fully mineralized interstitial bone, with low radiotranslucency. Thus, the differentiation between the degree of mineralization and the volume of the mineralized bone is important. For example, oral administration of alendronate for 2 or 3 years in osteoporotic women increases BMD, but in iliac crest bone biopsies does not increase trabecular bone volume, which can be explained by an increase in secondary mineralization as a result of reduced bone turnover (Meunier *et al.,* 1997).

Histomorphometry of stained grindings is the method of choice to quantify bone architecture and BV/TV, whereas contact radiography is superior in quantifying bone mineral density. With histomorphometry, areas of primary and secondary mineral apposition can be distinguished, but for a finer differentiation of mineralization, x-ray based techniques such as microradiography are required. Alternative techniques to microradiography are backscattered electron imaging and small-angle x-ray scattering imaging and, of course, μCT (see section below), although the spatial resolution of most μCT systems still does not reach that of microradiography.

Analysis of Trabecular Texture using Radiographs

On radiographs, the projection of the 3D trabecular architecture results in a 2D texture. The binarization of such a texture and a subsequent 2D stereological analysis to quantify bone structure is not very promising. Sophisticated image-processing techniques based on digitized gray-scale images have been designed to extract a large variety of parameters such as fractal dimension, morphological gradients, Fourier descriptors, or bone anisotropy. For *in-vivo* studies radiographs of the calcaneus are well suited because the effect of overlying soft tissue is minimized (Benhamou *et al.,* 1994; Lespessailles *et al.,* 1996; Brunet-Imbault *et al.,* 2005; Chappard *et al.,* 2005), although other skeletal sites such as the spine (Caligiuri *et al.,* 1994), the femur (Geraets *et al.,* 1998; Gregory *et al.,* 2004), the wrist (Geraets *et al.,* 1990; Lespessailles *et al.,* 1996; Majumdar *et al.,* 2000), or the knee (Lynch *et al.,* 1991; Podsiadlo *et al.,* 2007) have been used as well. For *in vitro* studies excised vertebrae are preferred (Link *et al.,* 1997; Ouyang *et al.,* 1998; Veenland *et al.,* 1998; Majumdar *et al.,* 1999; Dougherty 2001). Two studies have also been reported of the femur (Jennane *et al.,* 2007; Pulkkinen *et al.,* 2007). In the calcaneus *in vivo* precision errors of below 1.5% have been reported for a variety of texture measures (Lespessailles *et al.,* 2007).

A combination of 2D texture parameters determined in radiographs simulated from 3D μCT images of femoral neck and calcaneal bone specimen predicted up to

93% of the variance of microarchitecture parameters other than BV/TV (Apostol *et al.,* 2006). Similar results were reported for iliac crest specimen (Guggenbuhl *et al.,* 2006). However, it remains unclear whether this highly interesting result can improve the prediction of fractures in clinical practice. So far, one *in vivo* study has found that the combination of fractal and anisotropy parameters measured in radiographs of the calcaneus and BMD as measured by DXA at the spine or femoral neck could better discriminate between groups with and without spinal fractures (Benhamou *et al.,* 2001; Chappard *et al.,* 2005) than BMD alone, but no prospective data have been published so far.

DUAL X-RAY ABSORPTIOMETRY

Hip Geometry

Several investigations have found that projectional measurements of parameters describing femur geometry can predict hip fractures independent of BMD. One prominent example is hip axis length, determined from conventional radiographs or with DXA. It predicts hip fracture, because a longer hip axis length is associated with an increase in femoral neck and trochanteric fracture risk (Faulkner *et al.,* 1994; Glüer *et al.,* 1994). Instead of varying with age after midadolescence, the hip axis length seems to be mainly influenced by genetic factors (Flicker *et al.,* 1996), which supports other reports that differences in the hip axis length may partially explain racial differences in hip fractures (Cummings *et al.,* 1994).

Hip axis length adds information to BMD and appears to be useful for cross-sectional studies of risk factors for osteoporosis, but has little value in longitudinal studies. The neck-shaft angle as determined from DXA scans was also associated with hip fractures in two studies (Gnudi *et al.,* 2002; Pulkkinen *et al.,* 2004), but one *in vivo* study (Bergot *et al.,* 2002) showed negative results. This was supported by an *in-vitro* study of femoral cadavers where no association was found between neck-shaft angle and breaking strength. In this study the neck width correlated with breaking strength (Cheng *et al.,* 1997).

Hip Structural Analysis

A more comprehensive approach to estimate geometrical and mechanical properties from DXA of the hip is hip structural or hip strength analysis (HSA), which was first applied to cross-sectional bone mineral absorption curves generated by single-photon absorptiometry at the forearm (Martin *et al.,* 1984). This early work has been extended to DXA at the proximal femur to automatically estimate cross-sectional moments of inertia (CMSI) and cross-sectional areas (CSA) of the neck, the trochanter, and the shaft, as well as the femoral neck-shaft angle, bending moments, and the hip axis length (HAL) (Beck *et al.,* 1990; Yoshikawa *et al.,* 1994).

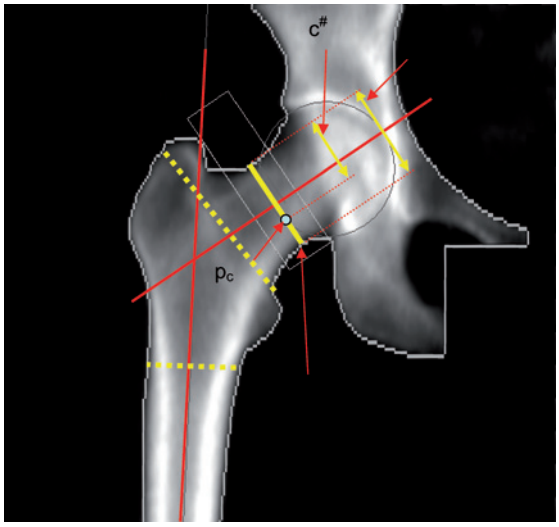

FIGURE 6 HSA analysis: p_c center of mass of cross section. *c as defined by hip structure analysis (Beck *et al.*, 1990); #c as defined by hip strength analysis (see text). In hip structure analysis, CSMI is estimated along the three yellow profiles; in hip strength analysis CSMI is only estimated along the solid yellow profile. (See plate section)

For HSA one-dimensional profiles are extracted from narrow regions across the neck, the intertrochanter, and the shaft by averaging pixel values perpendicularly to the profile directions (Fig. 6). For each pixel along the profile, areal BMD (BMD_a) is obtained from the DXA measurement, and bone mineral content (BMC) is determined using the known pixel dimensions. The BMC distribution along the profile is used to calculate *pc*, the position of its center of mass. Under the assumption that the specific axis through *pc* which is perpendicular to the plane of the DXA image is also the main bending axis, the CSMI of the cross section defined by the profile can (apart from a multiplicative constant) be accurately calculated from the DXA images by

$$CSMI = \frac{1}{BMD_{cort}} \sum_i BMC_i[\Delta(p_c - i)]^2$$

BMD_{cort} is the areal density of cortical bone and a value of 1.051 g/cm^2 is assumed. Δ denotes the length of a profile pixel.

From the CSMI the section modulus $Z = CSMI/c$ is estimated, where c denotes the distance from the bending axis to the furthest edge of the section and is defined as half the periosteal width is taken from the DXA image (Beck *et al.,* 2001). The section modulus is an important physical property that relates the bending moment M to the bending stress F by $Z = M/F$. The buckling ratio B is another parameter estimated from CSMI and assumes a circular cross section of the femur. It is computed as $B = r/t$,

where r is the radius of the cross section and t the cortical thickness. Beck and coworkers estimated mean cortical thickness by using simple models of neck and shaft cross sections as hollow annuli (Beck *et al.,* 2001). Obviously the estimation of the variables c, r, and t form a projected density profile of a 2D cross section, which, in particular for the femoral neck and the trochanter, is not circular, shows limitations of the HSA analysis of DXA images.

Currently two different implementations of HSA are more widely used. The first one termed hip *structure* analysis was implemented by Beck and coworkers and is available on some Hologic scanners (Beck *et al.,* 1990). The second version of HSA termed hip *strength* analysis, which is implemented on GE Lunar DXA devices, additionally estimates a femur strength index calculated as the ratio of estimated compressive yield strength of the femoral neck to the expected compressive stress of a fall on the greater trochanter. The compressive forces are calculated from the bending moments and the distance d between the center of the head and the extracted profile. The bending moment caused by a fall on the greater trochanter is estimated from an individual's height and weight (Robinovitch *et al.,* 1991). In this implementation, c is defined as distance from the superior aspect of the femoral neck to the center of mass of the extracted profiles (see Fig. 6). Thus, in essence, the femur strength index is a combination of neck length, neck diameter, and the regional distribution of BMC across the selected neck profiles combined with the height and weight of the patient.

HSA was successfully used in several studies to better understand changes of femoral strength and geometry under pharmaceutical treatment (Beck *et al.,* 2001; Greenspan *et al.,* 2005; Uusi-Rasi *et al.,* 2005; Burnham *et al.,* 2007; Knapen *et al.,* 2007), to investigate population (Crabtree *et al.,* 2000; Nelson *et al.,* 2000, 2004) or gender (Kaptoge *et al.,* 2003; Nissen *et al.,* 2005) related differences, or to improve fracture risk prediction (Karlamangla *et al.,* 2004; Ahlborg *et al.,* 2005; Faulkner *et al.,* 2006). However, only a few studies adjusted HSA results for BMD and anthropometric parameters or used multivariate statistics (Crabtree *et al.,* 2002; Karlamangla *et al.,* 2004; Faulkner *et al.,* 2006). In Faulkner et al's cross-sectional study, the diagnosis of prior fractures was improved only slightly. The area under the ROC curve increased from 0.71 using BMD alone to 0.74 when including hip axis length and femur strength index in a logistic model (Faulkner *et al.,* 2006).

Further detailed comparisons with 3D QCT should be performed to assess the value of HSA. From these studies it should be possible to determine optimized parameters and analysis volumes of interest (VOIs). For example, it has been shown *in vitro* that in DXA a novel neck region of interest (ROI) which only included the upper part of the neck better predicted bone strength than the standard DXA regions (Boehm *et al.,* 2005). Also, a circular ROI in the central neck better discriminated hip fractures than the standard regions (Prevrhal *et al.,* 2004). Thus, an appropriate regional analysis of BMD may have a larger effect than combining BMD and HSA.

VXA

Volumetric DXA, also termed VXA, is a further step toward a volumetric assessment of BMD and 3D geometry is (Ahmad *et al.,* 2007) or 3D-XA (Kolta *et al.,* 2005; Le Bras *et al.,* 2006; Kolta *et al.,* 2007). In the 3D-XA approach developed by Skalli and coworkers, orthogonal 2D projections of 3D contours extracted from a CT dataset of an arbitrary femur are fitted to two orthogonal DXA images of the femur under investigation. The resulting deformed 3D contours define a personalized 3D model of the proximal femur. In a study on excised femurs, comparison of these 3D models with real 3D CT data showed a mean difference of only 0.06 ± 1.02 mm, although maximum errors were as high as 7.8 mm in the greater and lesser trochanter (Kolta *et al.,* 2005). However, the *in-vivo* situation is more complicated because both femurs and potentially bone from the acetabulum overlap in the lateral DXA projection. As a consequence, an *in-vivo* application of this technique so far has only been reported for the spine (Kolta *et al.,* 2007).

For the femur, the VXA approach is more promising than 3D-XA (Ahmad *et al.,* 2007): Several (less than 10) 2D projections are taken from the proximal femur using different projection angles by rotating the C-arm of the DXA scanner. In contrast to the 3D-XA method the total angle covered by all projections is considerably smaller than 90 degrees, thus avoiding the overlap with other bone structures. The VXA projections are fitted to a statistical 3D atlas of the femur generated from volumetric CT data of a larger number of persons. It was shown that individual anatomical variations from the atlas can be described by 10 to 20 different parameters, the so-called Eigenvectors. This demonstrates that a limited number of 2D projections is sufficient to obtain reasonably accurate 3D geometrical and densitometric information of the femur. Figure 7 shows a comparison between one of the measured DXA images and the 2D projection obtained from the 3D atlas-based VXA dataset using the same projection angle.

COMPUTED TOMOGRAPHY

The term Quantitative computed tomography (QCT) denotes the specific technique to quantify bone mineral density in the cross-sectional x-ray computed-tomography (CT) images. Originally, QCT was restricted to measurement of trabecular bone mineral density in single transverse CT slices at the lumbar midvertebral levels and the distal forearm (Rüegsegger *et al.,* 1976; Genant *et al.,* 1982), but with the advent of multidetector row spiral CT

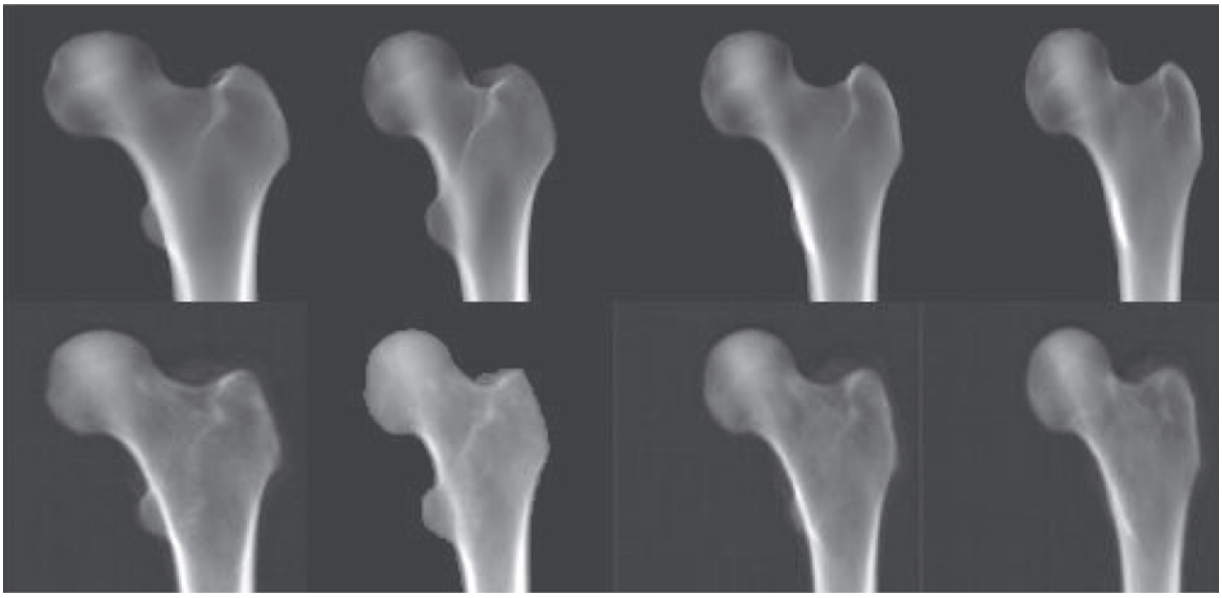

FIGURE 7 VXA of the proximal femur. (*Top*) 2D projections of 3D personalized results obtained form the statistical atlas based on measured DXA projections. (*Bottom*) Corresponding measured DXA projection. Results for four excised femora are shown (Ahmad *et al*., 2007).

technology, newer, fully three-dimensional QCT techniques (vQCT) have now been developed that encompass the entire object of interest (Lang *et al.,* 1999, 2002; Kang *et al.,* 2003; Mastmeyer *et al.,* 2006) (see Figs. 1 and 2). The term peripheral QCT (pQCT) was, and still is, sometimes used to refer specifically to dedicated peripheral scanners (Rüegsegger *et al.,* 1976). However, pQCT measurements can also be performed on clinical whole-body CT scanners, and therefore the term pQCT covers all peripheral QCT measurements.

Volumetric QCT of Spine and Femur

Whereas trabecular bone, in particular at the spine, is metabolically more active and may therefore serve as an early indicator of treatment success, cortical bone, in particular at the hip, may be more important to estimate fracture risk (Bousson *et al.,* 2006). Therefore the unique ability of QCT to separately analyze BMD of the trabecular and cortical compartments was advocated from the beginning as an advantage over projectional methods such as DXA. State-of-the-art spiral CT provides almost isotropic spatial resolution offering new opportunities for the 3D assessment of the cortex (Fig. 8). While the spatial resolution is not high enough to give accurate results of cortical thickness below values of approximately 1.0 to 1.5 mm, even below these values a 10% to 20% change of thickness can still be measured accurately, as shown by Prevrhal *et al.* (1999). In general, it is easier to measure cortical thickness in the femur than in the spine where thicknesses of as thin as 200 to 500 μm are encountered frequently, especially in the elderly.

The partial volume artifact caused by the limited spatial resolution also leads to an underestimation of cortical BMD on the order of 10% to 30%. Some analysis programs use empirical correction factors based on phantom measurements, but it should be cautioned that these correction factors vary among different scanner types. In particular in multicenter trials, the use of such factors seems to be questionable. The assessment of the cortex also highlights the importance of selecting adequate scan protocols. Slice thickness, reconstruction kernel, and reconstructed field of view are important parameters in order to optimize measurements of the cortex. In addition to the cortex, vQCT is a sophisticated tool to determine geometrical parameters of mechanical relevance such as cross-sectional moments of inertia.

At the spine, the cross-sectional area of the vertebral bodies is a macrostructural parameter of interest because it is likely that larger vertebrae can sustain loads better than smaller ones, albeit bigger individuals with larger cross sections also bear greater loads. Periosteal apposition, which may occur at the spine and the femur, has the potential to offset the increase in fragility caused by loss of bone mass by increasing cross-sectional area. A cross-sectional vQCT study by Riggs and coworkers showed that women not only start out with smaller vertebrae and lose bone mass faster, but also increase cross-sectional area slower than men (Riggs *et al.,* 2004). Although the magnitude of the changes reported by vQCT are inconsistent with DXA findings (Duan *et al.,* 2003), the study indicates that spinal cross-sectional area measurement with vQCT may provide additional predictive power for fracture risk.

Because the geometry of the proximal femur is much more complex than that of a vertebral body, macrostructural

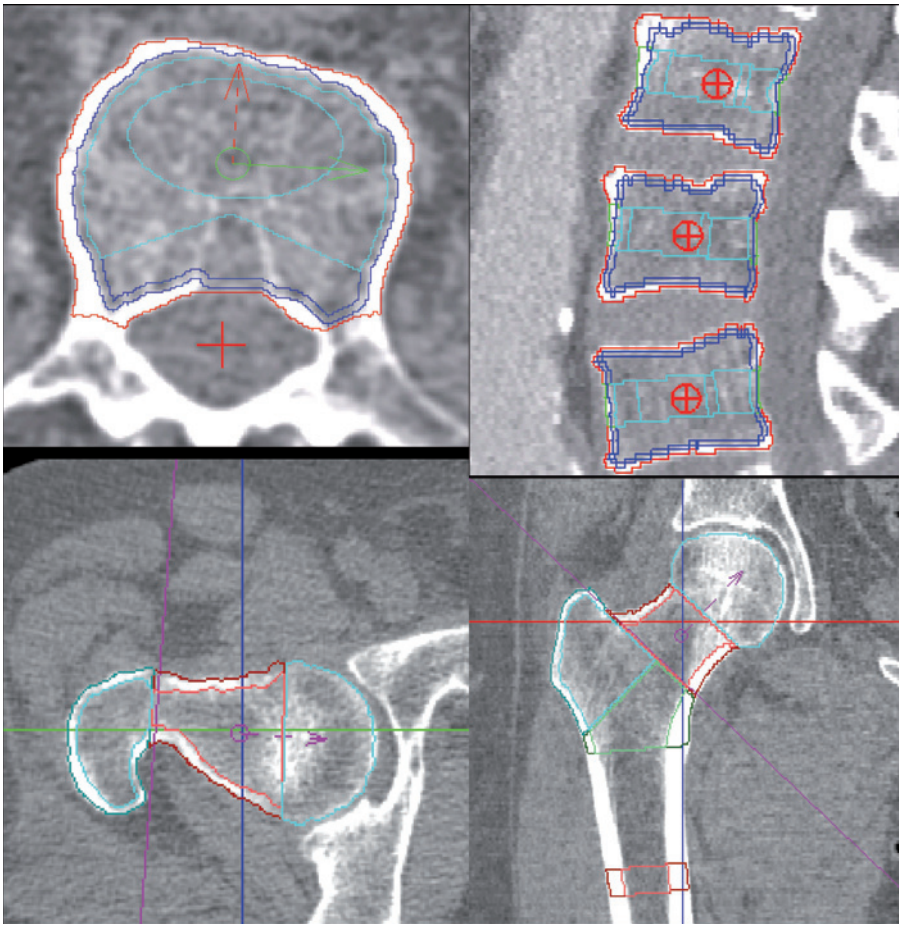

FIGURE 8 Advanced 3D QCT at spine and hip (slice thickness, 1 mm; in-plane resolution, 300 μm) to analyze regional BMD and geometry such as cortical thickness; left axial, right coronal MPRs of 3D datasets (Kang *et al.*, 2003; Mastmeyer *et al.*, 2006). (See plate section)

parameters of interest include cross-sectional areas at the neck and greater trochanter, hip axis length, and simple mechanical measures such as cross-sectional moment of inertia (a measure of how bone is radially distributed) and section moduli at various cross sections along the femoral neck axis. As in the spine, periosteal apposition causes the cross-sectional areas of the femoral neck and shaft to expand with age (Riggs *et al.*, 2004). The large Osteoporotic Fractures in Men Study (MrOS) study confirmed this and also found cortical thinning with age. However, whereas the neck seemed to exhibit net cortical bone loss, periosteal expansion seemed to offset cortical thinning in the shaft to maintain cortical cross-sectional area (Marshall *et al.*, 2006). This study also showed ethnic differences with higher femoral neck and lumbar spine volumetric BMD but lower cross-sectional areas in African Americans, which might contribute to some of the ethnic difference in hip and vertebral fracture epidemiology.

Lang and colleagues showed in a specimen study that these parameters explain femoral strength partially independently of BMD (Lang *et al.*, 1997). Interestingly, Cheng and colleagues found in a retrospective vQCT study of Chinese elderly women that fracture cases had larger femoral necks than nonfractured controls, which was interpreted as an adaptation to their lower femoral neck BMD (Cheng *et al.*, 2007). Volumetric QCT measurement was also employed to investigate bone loss during space flight. In the 14 crew members of the International Space Station, vQCT demonstrated that total femur integral BMC, but not integral volumetric BMD or trabecular BMD, recovered to its preflight value, 12 months after flight lasting 4 to 7 months. Recovery of bone mass involved increasing both bone density and bone size. Incomplete recovery of BMD in the hip in the year after long-duration spaceflight was observed. As shown by an increase in the minimum femoral neck cross-sectional area and integral tissue volume, the proximal femur appears to adapt to resumption of load bearing by periosteal apposition (Lang *et al.*, 2004).

Treatment effects on cortical volume using vQCT were reported from the PaTH study, investigating parathyroid hormone (PTH) and Alendronate treatment alone or in combination. The study found that femoral cortical volume increased with one-year treatment with PTH followed by one year with Alendronate (Black *et al.*, 2003,

2005). Similar results on cortical bone were observed in another PTH study (Greenspan *et al.,* 2007). The potential relevance of other geometrical parameters for the determination of bone strength has been shown in *in vitro* studies measuring bone failure loads. In the spine the endplate area (Biggemann *et al.,* 1988; Brinckmann *et al.,* 1989), cross-sectional area (Mosekilde *et al.,* 1989), or vertebral surface area (Eriksson *et al.,* 1989) improved the correlation of BMD with failure loads. In the femoral neck cross-sectional area, neck axis length (Lang *et al.,* 1997) and cortical thickness were identified as independent predictors of failure load.

Peripheral QCT

With respect to bone architecture pQCT has predominantly been used to assess the cortex of the distal and mid radius. At the ultradistal site in some studies cortical parameters were more successful than total or trabecular BMD, e.g., for fracture prediction (Grampp *et al.,* 1997), age-related bone loss (Hernandez *et al.,* 1997), or monitoring treatment (Ruegsegger *et al.,* 1995; Prince *et al.,* 2006). At the ultradistal site other treatment studies (Dambacher *et al.,* 1997; Fujita *et al.,* 2000; Merki-Feld *et al.,* 2003) showed better effects for trabecular or total BMD. Although this discrepancy may be explained in part by the particular pharmaceutical intervention, it is more likely that partial volume artifacts and differences in image-processing techniques, such as the selection of thresholds, have a large impact.

These effects probably also explain some of the controversial findings on differential age-related bone loss in cortical and trabecular bone. In cross-sectional studies of healthy women some authors reported higher trabecular, than cortical, losses (Boonen *et al.,* 1997; Nijs *et al.,* 1998; Qin *et al.,* 2000), whereas others showed comparable losses (Grampp *et al.,* 1995; Gatti *et al.,* 1996; Hasegawa *et al.,* 1997). If cortical parameters are of interest, then a more proximal site toward the shaft should be used because here the cortex is thicker and can more accurately be quantified. Such a location has indeed been used in several studies (Vico *et al.,* 1992; Nijs *et al.,* 1998; Schneider *et al.,* 1999; Tsurusaki *et al.,* 2000; Neu *et al.,* 2001; Clowes *et al.,* 2005; Rittweger *et al.,* 2005; Russo *et al.,* 2006). In *in vitro* studies a high association of geometry-based parameters with bone failure loads (Louis *et al.,* 1995; Augat *et al.,* 1996, 1998; Lochmuller *et al.,* 2002; Muller *et al.,* 2003) has been demonstrated. Moment of inertia, section modulus or moment of resistance, and stress-strain index (SSI) (density-weighted section modulus) demonstrated the strongest correlations with failure load.

In the radius, cortical thickness of the shaft significantly contributes to strength. However, studies that directly compared parameters failed to provide clear evidence that geometry-based parameters perform significantly better than measurement of bone mass (BMC) alone (Spadaro *et al.,* 1994; Augat *et al.,* 1996; Lochmuller *et al.,* 2002; Muller *et al.,* 2003; Ashe *et al.,* 2006). The combination of multiple pQCT parameters, however, tended to improve the prediction of failure loads versus single variables, but the multiple regression coefficients were generally not significantly higher than those obtained by DXA alone (Lochmuller *et al.,* 2002; Muller *et al.,* 2003) because most of these *in-vitro* studies did not adjust appropriately for bone size.

In the forearm, the scan location that best predicts mechanical competence of the radius has not yet been identified. Some studies found higher correlation coefficients for measurements at the shaft compared with measurements at the distal end of the bone, whereas others reported similar correlations for both sites (Lochmüller *et al.,* 2002; Müller *et al.,* 2003). Compression tests of the ultradistal region revealed the highest correlations between ultimate strength and BMC ($r = 0.83$ to 0.87). The loads to produce distal radius fractures by simulating a fall on to the outstretched hand (Myers *et al.,* 1993, 1994) have been accurately predicted by density measurements and geometric measurements. The most accurate predictors of fracture strength were BMC at the ultradistal site ($r = 0.94$) (Spadaro *et al.,* 1994), area of cortical bone at the shaft site ($r = 0.84$ to 0.89) (Myers *et al.,* 1993; Spadaro *et al.,* 1994), and combinations of BMD with moments of inertia ($r = 0.93$) (Augat *et al.,* 1996). In *in-vitro* studies, BMC instead of BMD was often the more important variable, but it must be considered that larger bones can withstand larger loads than smaller bones. At comparable BMD smaller bones thus would contain less BMC. However, big bone/little bone confounders have been rarely accounted for *in vitro*.

In *in-vivo* studies the SSI showed a similar dependence on the measurement site as in *in-vitro* studies discussed earlier. Nijs and coworkers found in a cross-sectional study that SSI at the proximal radius was almost as diagnostically sensitive to prevalent vertebral fracture as trabecular and total BMD at the ultradistal radius (ROC = 0.72 vs. 0.75). However, the SSI showed a much weaker diagnostic power at the ultradistal site (Nijs *et al.,* 1998). Augat and coworkers measured the 4% ultradistal site in hip fracture cases and controls and found that SSI ranked behind all other pQCT parameters, although none of them had a significant odd's ratio (Augat *et al.,* 1998). In another study, at the same site, geometrical parameters such as cross-sectional moment of inertia and cortical area discriminated less well than trabecular BMC and BMD between patients with and without Colles fractures (Schneider *et al.,* 2001). In patients receiving alendronate treatment, the bone strength index that is similar to the SSI showed a borderline significant ($P = 0.04$) increase of 4.7% versus baseline compared with a highly significant increase of 6.8% in total BMD after 24 months (Schneider *et al.,* 1999).

High-Resolution Computed Tomography (hrCT)

With appropriate acquisition and tomographic reconstruction protocols modern whole-body CT scanners for measurements of the axial skeleton achieve almost isotropic spatial resolution of approximately 0.5 mm. Dedicated single-slice pQCT scanners have improved in-plane resolution by about a factor of 2 to 3 but use slice thicknesses of 1 to 2 mm, although some pQCT research scanners also provide 0.5-mm-thick slices (Gordon *et al.*, 1996). Given typical trabecular dimensions (100 to- 400 μm) and trabecular spaces (200 to 2000 μm), this resolution is still insufficient for an accurate determination of standard stereological parameters. This is illustrated in Figure 9 where high-resolution CT images were simulated from a stack of 21 sagittal grindings ($9 \times 7\,mm^2$) of a trabecular network from a human calcaneus. The thickness of each grinding was 5 μm and the distance between two adjacent grindings was 51 μm owing to preparation requirements. All grindings were digitized, resulting in a stack of binary images (pixel area: $12 \times 12\,\mu m^2$). Additional slices obtained by interpolation between adjacent binary images were added to simulate a slice thickness of 12 μm. Thus, the final dataset consisted of isotropic voxels.

The images of the stack were averaged along the direction indicated in Figure 9. The first row of simulated images

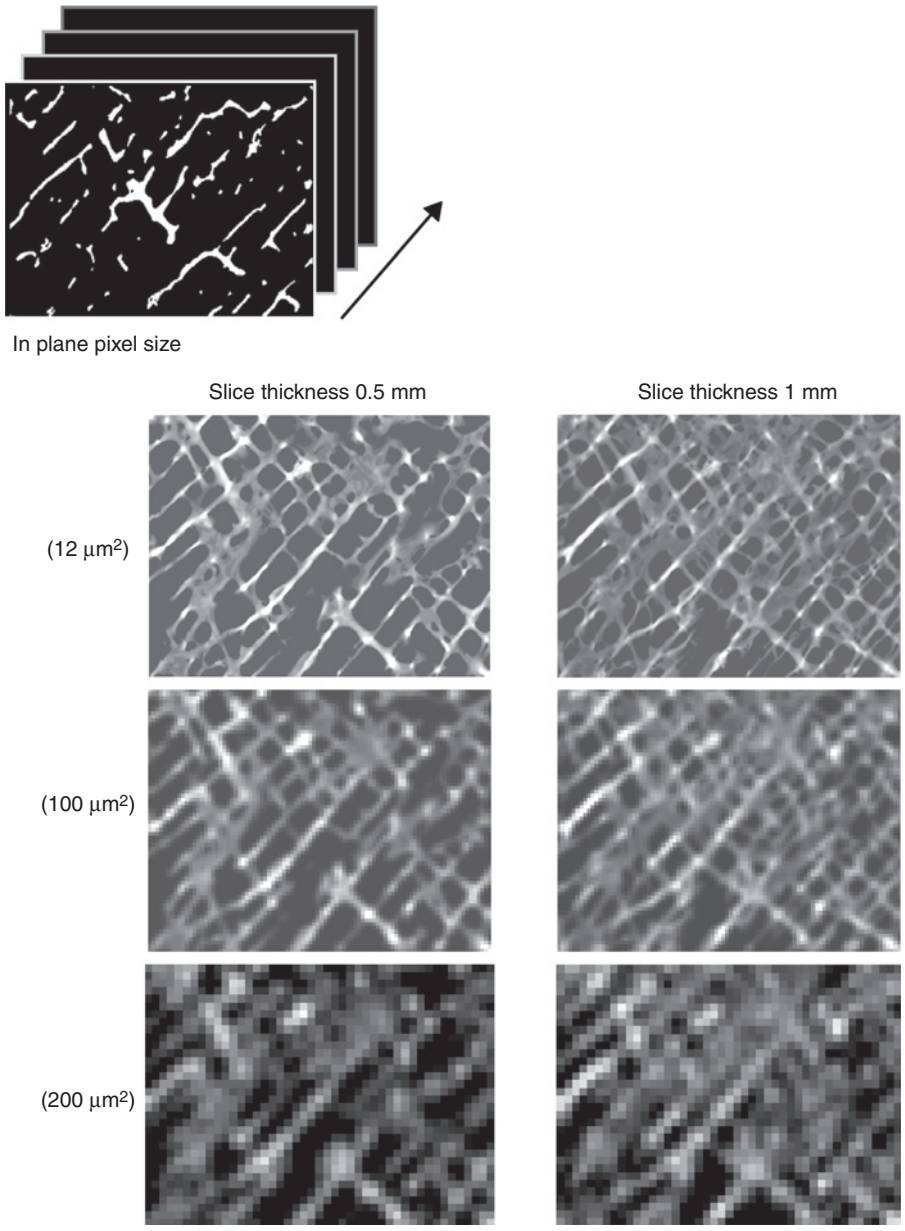

FIGURE 9 Effect of slice thickness and in-plane pixel size on trabecular structure. Simulation of radiographic and hrCT images based on a stack of stained grindings. (*Top*) Stack of grindings. (*Bottom*) Simulated radiographic and hrCT images (Engelke *et al.*, 2001).

shows two radiographic type images. One resulted by averaging half the stack and the other by averaging all images of the stack (see Fig. 9). Thus, a total slice thickness of 0.51 mm and of 1.02 mm was simulated, respectively. The in-plane pixel area in these radiographic-type images is unchanged at $12 \times 12\,\mu m^2$. There are still artificial discontinuities in the gray-value variations. They would be avoided by averaging more images. The second and third rows show simulated hrCT images with pixel sizes of 100 μm and 200 μm. The images were blurred with a Gaussian filter to give a more realistic impression of what can be expected *in vivo*.

The simulations demonstrate that in hrCT images only the dominant structures are preserved; details of the trabecular network cannot be extracted. The texture in the CT-like and in the radiographic-like images is similar and a major deterioration of the network will be noticeable in the hrCT images. However, a determination of parameters typically used in histomorphometry is problematic. It is evident that parameters like Tb.Th, Tb.Sp, or Tb.N change drastically with resolution. In order to indicate that structural parameters measured in hrCT and hrMRI images differ significantly from those measured by histomorphometry of thin section, it is recommended to call them apparent trabecular thickness, etc., and to use the prefix "app" such as appTb.Th, appTb.Sp, or appTb.N.

Laib and coworkers compared different structure extraction and morphometric evaluation techniques to measure stereological parameters in high-resolution images. They proposed to first extract the skeleton of the structure and then to apply a network model independent 3D technique to calculate appTb.N. The assumption of a plate- or rod-like trabecular structure is no longer necessary. appTb.Th and appTb.Sp can finally be calculated from densitometric bone volume fraction and appTb.N. Traditional histomorphometric analysis methods based on bone surface and volume ratios and assuming a plate model performed less well (Laib *et al.,* 1999). The 3D techniques also resulted in a number of new parameters to quantify the trabecular network, like ridge number density (Laib *et al.,* 1997) and the structure model index (SMI) (Hildebrand *et al.,* 1997). The SMI is based on a differential analysis of the triangulated bone surface. The SMI value is 0 for an ideal plate structure and 3 for an ideal rod structure, independent of the physical dimensions. For a structure with plates and rods of equal thickness the value lies between 0 and 3, depending on the volume ratio of rods and plates. Parameters quantifying network connectivity, such as Euler number, node-to-terminus strut count, or terminus-to-terminus strut count, have also been used (Cortet *et al.,* 2002).

In several publications, approaches of measuring structural parameters in binarized images (Klotz *et al.,* 1986; Durand *et al.,* 1991; Ito *et al.,* 1995) were replaced by textural or statistical descriptors to characterize the trabecular architecture without requiring segmentation to separate bone from marrow and other soft tissue. The mathematical principles used to describe texture in hrCT as well as in high-resolution MRI images (see section below) are often similar to those used for texture analysis of 2D radiographs (see section above).

Textural parameters still based on binary images used for instance the trabecular fragmentation index (length of the trabecular network divided by the number of discontinuities) (Chevalier *et al.,* 1992), a run-length analysis (Ito *et al.,* 1995), a parameter reflecting trabecular hole area, analogous to star volume (Gordon *et al.,* 1996, 1998; Showalter *et al.,* 2006), and co-occurrence texture measures (Showalter *et al.,* 2006). Newer approaches prefer gray-level analyses and use, for example, Minkowsky functionals (Saparin *et al.,* 2006) or Gabor wavelets (Xiang *et al.,* 2007) to quantify trabecular topology.

HrCT of the Spine

In the past, hrCT applications of the spine have often yielded ambiguous results because either a segmentation step was used for binarization during the analysis or because CT scanners providing slice thicknesses below 1 or 1.5 mm were not available at that time. CT reconstruction parameters such as the reconstruction kernel, a parameter that can be chosen to balance spatial resolution versus noise in the tomographic image, or the reconstructed field of view (FOV), were often not optimized. For example, Laval-Jeantet and colleagues (Chevalier *et al.,* 1992) used 1.5-mm thin spinal CT images but a larger-than- necessary FOV. Their trabecular fragmentation index separated women with spinal fracture from those without but not as well as BMD. In another *in-vivo* study, Ito and coworkers used CT of the spine with 2-mm slice thickness. Trabecular separation significantly increased with age in women 50 years of age or older, whereas women with vertebral fractures had significantly lower BMD and significantly higher trabecular separation (Ito *et al.,* 1995; Ito *et al.,* 1997). Trabecular separation was a better discriminator than BMD in 60- to 69-year-old but not in 50- to 59-year-old women. Gordon and coworkers showed that trabecular hole area discriminated vertebral fractures even after adjustment for BMD (Gordon *et al.,* 1998).

Some *in-vitro* studies using QCT of bone specimens (Jiang *et al.,* 1998; Link *et al.,* 1998; Bauer *et al.,* 2004) or whole excised bones (Link *et al.,* 2004; Bauer *et al.,* 2006; Saparin *et al.,* 2006) also indicate the potential to improve fracture discrimination by using structural parameters. However, even with identical acquisition protocols *in-vitro* scans typically have better image quality than *in-vivo* scans because the signal-to-noise ratio is increased considerably owing to the smaller size of the samples and removed soft tissue (Bauer *et al.,* 2007). Thus, there should be some caution generalizing results of structure analysis techniques in hrCT images from *in vitro* to *in vivo* studies.

If the structural analysis is based on binary images, then segmentation is the most crucial step (Dufresne 1998; Cendre *et al.,* 2000; Engelke *et al.,* 2001; Elmoutaouakkil *et al.,* 2002), and it is advisable to evaluate accuracy with the help of high-resolution data, e.g., taken from μCT scans which can be sub-sampled to the resolution of the hrCT image (Engelke *et al.,* 1996; Elmoutaouakkil *et al.,* 2002). In order to avoid segmentation and its problems, the application of gray-level analysis methods such as those mentioned above seems to be very promising. *In-vivo* studies using these methods in CT or MRI have not been published yet. Interestingly, the two most recent *in vivo* studies applying trabecular structure analysis of vertebral bodies using hrCT images have applied rather simplistic global thresholds to segment trabecular bone (Ito *et al.,* 2005; Graeff *et al.,* 2007), but both used 0.5-mm slice thickness and 0.2-mm in-plane voxel size and applied a volumetric analysis by using several slices per vertebra.

In Ito's cross-sectional study (Fig. 10), vertebral trabecular structure parameters measured with hrCT better distinguished between fractured cases and non-fractured controls than BMD measurements with DXA, but not better than with site-matched BMD as measured by vQCT (Ito *et al.,* 2005). Glüer and colleagues (Graeff *et al.,* 2007) carried out a longitudinal study using teriparatide and claimed that structural changes under treatment, in particular, those for appBV/TV and appTb.N, were partly independent of BMD.

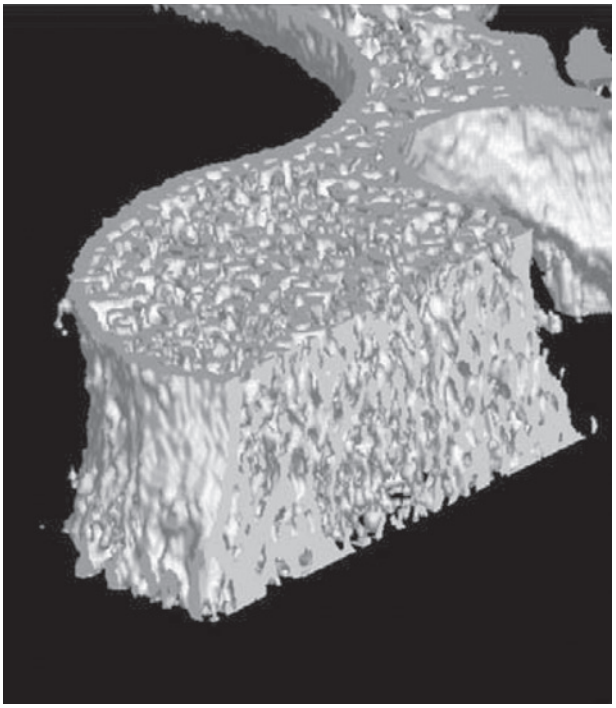

FIGURE 10 High-resolution *in vivo* CT image of the spine. The 3D rendering reveals the connectedness of the trabecular network but also reveals that stereological parameters cannot be determined accurately. Courtesy of Masako Ito.

However, it is not entirely clear whether the decoupling of BMD and appBV/TV may at least in part be caused by the segmentation process. With a fixed threshold a slight increase in mineralization from just below to just above the threshold may overproportionally increase the appBV/TV. If treatment effects do not substantially affect mineralization, as seems to be the case with teriparatide, then appBV/TV changes should approximate site-matched BMD changes.

HrCT of the Forearm

Because the assessment of trabecular structure *in vivo* is difficult, special-purpose peripheral CT scanners have been developed to assess the distal forearm, where trabecular thickness ranges from 60 to 150 μm and trabecular separation ranges from 300 to 1000 μm. The trabecular dimensions are similar to the spine, but owing to the much smaller cross section of the forearm compared with the central body, the absorption decreases significantly and, therefore, the spatial resolution can be increased without a radiation dose penalty. On the contrary, because the forearm tissue is less radiation sensitive than that at the spine for forearm hrCT the effective dose is typically well below 100 μSv.

The first to pursue hrCT successfully at the distal forearm were Rüegsegger and colleagues, who built a thin-slice high-resolution laboratory pQCT scanner for *in vivo* applications with an isotropic voxel size of $(170\,\mu m)^3$ (Durand *et al.,* 1992), which was successfully decreased further to below $(100\,\mu m)^3$. Müller reported a high *in vivo* reproducibility of about 1% achieved by careful registration of the acquired three-dimensional datasets (Muller *et al.,* 1996). When *in vitro* pQCT structure measurements of iliac crest biopsies were compared with μCT, the correlation of various three-dimensional structural parameters between the two systems was $r^2 > 0.9$, despite the lower resolution of the high-resolution pQCT system. For a very precise analysis an isotropic spatial resolution of approximately 10 μm was required. Up to about a resolution of 100 to 150 μm, changes of these parameters could be described by a linear relation. Therefore a dedicated segmentation threshold can be obtained for pQCT by calibrating the pQCT bone volume fraction to the μCT bone volume fraction. That is, appropriate calibration techniques can restore an accurate value of BV/TV (Müller *et al.,* 1996). A similar study of cadaveric specimens of the calcaneus that were scanned with hrCT at a slice thickness of 1 mm and histomorphometry showed that, at this resolution, correlations for BV/TV, Tb.N, and Tb.Sp dropped to $r = 0.7$ to 0.9 and were even lower for the Euler number and the number of nodes (Cortet *et al.,* 2004). Thus, the calibration approach suggested by Müller would not work for standard pQCT or hrCT of the spine.

The laboratory efforts of the Swiss group cumulated in the XtremeCT, a commercially available *in-vivo* pQCT scanner for the forearm and the tibia (Boutroy *et al.,* 2005).

As proposed by Laib *et al.* (1999), histomorphometric parameters are determined from a measurement of bone volume fraction and apparent trabecular number. The spatial registration of baseline and follow-up scans with a very small accuracy error (lower than 100 μm) is a critical step in the analysis of follow-up scans in order to detect longitudinal changes of bone structure within a given subject. Thus during these scans, even slight motions of the forearm must be avoided, which is not an easy task, given a scan time of several minutes. Currently, a 2D slice-by-slice based area matching between baseline and follow-up scans is used for XtremeCT scans. A full 3D registration may reduce motion artifacts and may improve precision, but will expand the time required for image processing.

The first indication that peripheral trabecular structure assessment is indeed useful to differentiate women with an osteoporotic fracture history from controls better than DXA at hip or spine came from Boutroy and colleagues (2005). Apart from trabecular, cortical, and total BMD, apparent trabecular spacing significantly discriminated osteopenic women with and without a variety of different prior fractures. In a second age-matched case control study of 101 women of the OFELY study, radial DXA BMD_a-adjusted differences between cases with fragility fractures at various sites and controls remained borderline ($P = 0.06$) significant for trabecular BMD, appBV/TV, and appTb.Sp as measured by XtremeCT. BMD_a adjusted ORs ranged from 1.32 to 1.5 (Sornay-Rendu *et al.*, 2007). At the tibia, adjusted ORs for cortical thickness and appTb.Th also ranged from 1.80 to 2.09 after adjusting for BMD_a as measured by DXA of the hip. Khosla *et al.* (2006a, b) examined age- and sex-related bone loss cross-sectionally and speculated as to the different patterns of bone loss in men and women.

Microcomputed Tomography (μCT)

Since the pioneering work for the use of μCT in medicine by using either x-ray tubes (Elliott *et al.*, 1984; Feldkamp *et al.*, 1989; Kuhn *et al.*, 1989) or synchrotron radiation (Engelke *et al.*, 1987; Flannery *et al.*, 1987; Engelke *et al.*, 1989), μCT has greatly matured technically and is now widely used in various medical areas such a vessel and tumor research. Most of the initial work on μCT was dedicated to the investigation of trabecular bone architecture. As will be discussed in this section, this a still a major focus today but other areas in bone research such as fracture healing (Ibiwoye *et al.*, 2004; Gauthier *et al.*, 2005; Shefelbine *et al.*, 2005), tissue engineering (Jaecques *et al.*, 2004; Van Cleynenbreugel *et al.*, 2006; Peyrin *et al.*, 2007), bone implants and scaffolds (Hiu-Yan *et al.*, 2005; De Smet *et al.*, 2006; Otsuki *et al.*, 2006; Cowan *et al.*, 2007; Jones *et al.*, 2007; Stoppie *et al.*, 2007), or oral applications (Van Oosterwyck *et al.*, 2000; Verdonschot *et al.*, 2001; Butz *et al.*, 2006; Cheung *et al.*, 2006; Nomoto *et al.*, 2006; Takada *et al.*, 2006) are increasingly benefiting from μCT. Unfortunately, a description of these applications is beyond the scope of this review, but the cited literature, although far from being complete, may provide a stimulating entry point for further research.

A broad range of commercial and research scanners for 3D μCT is available today. Scanners using x-ray sources offer spatial resolution from about 10 μm to 100 μm, whereas synchrotron radiation (SR) is still the method of choice for higher spatial resolutions. Several commercial devices integrate sophisticated software for the analysis of bone structure including finite-element modeling (see section below). Most earlier μCT studies aimed at technical improvements of the equipment, at the development of new 3D analysis methods for the quantification of trabecular structure (Odgaard *et al.*, 1993; Hildebrand *et al.*, 1997, 1997), and at the characterization (Müller *et al.*, 1996; Ding *et al.*, 1999) and establishment of μCT as a valuable research tool (Bonse *et al.*, 1996; Borah *et al.*, 2001; Dalstra *et al.*, 2001). After this period, in particular, in conjunction with the introduction of genetically engineered laboratory animals like mice and rats, many studies started to focus on medical questions.

For example, iliac crest bone biopsy specimens were analyzed from women participating in a placebo-controlled risedronate trial. After one year, in the control group, BV/TV decreased by 20% and Tb.N decreased by 14% compared with baseline. Tb.Sp increased by 13% and marrow star volume by 86%. In the same period, lumbar spine BMD_a as measured by DXA decreased by only 3.3%. In the risedronate-treated group the architectural parameters did not significantly change during the same period (Dufresne *et al.*, 2003). In another study of paired biopsies taken before and after treatment with human PTH, μCT showed increased 3D connectivity density and confirmed the preservation of 2D histomorphometric BV/TV, Tb.N, and Tb.Th (Dempster *et al.*, 2001). Similar results for PTH were reported recently in a third biopsy study. After 19 months of PTH treatment compared with placebo, BV/TV increased by 44%, Tb.N by 12%, Tb.Th by 16%, and connectivity density by 25%. Tb.Sp decreased by 10% and SMI by 50%, demonstrating the usefulness of 3D parameters obtainable from μCT (Fox *et al.*, 2005). In a study in ovariectomized baboons, bisphosphonates preserved the microarchitecture in thoracic vertebrae (Hordon *et al.*, 2006).

As it is rather difficult to obtain human bone biopsies, studies investigating drug and disease effects are typically performed during the preclinical phase using laboratory animals. In an investigation of rat tibiae 16 weeks after ovariectomy (OVX), BV/TV decreased by 69% and Tb.Th by 30% compared with a sham-operated control group. Tb.Sp increased by 100% and SMI by 48%. This showed that with estrogen deficiency the trabecular network consisted of more rod-shaped trabeculae (Yang *et al.*, 2003). Treatment of OVX

rats with residronate maintained the plate-like trabecular structure and network connectivity (Ito *et al.,* 2005). A study with either cathepsin K- or rolipram-treated OVX BALB/c mice showed that, compared with the sham-operated control group, in both treatment arms a decrease of BV/TV and deterioration of trabecular structure were prevented (Xiang *et al.,* 2007). Another study with ovariectomized rats showed that PTH and elcatonin (ECT), a synthetic derivative of eel calcitonin, preserved bone architecture by different means. After 12 weeks of treatment BV/TV was greater in the ECT and PTH groups than in the OVX group. The number of nodes per volume (N.Nd/TV) and Tb.N were significantly greater in the ECT group, whereas Tb.Th was greater in the PTH group (Washimi *et al.,* 2007). 3D μCT has also been used to quantify trabecular architecture in osteoarthritis (Ding *et al.,* 2003; Patel *et al.,* 2003; Batiste *et al.,* 2004a, 2004b; Wachsmuth *et al.,* 2004; Chappard *et al.,* 2006).

In contrast to hrCT and hrMRI techniques, the aim of μCT is to measure structural parameters accurately. The question of what spatial resolution is required to do so has been discussed in several publications in which 3D μCT was compared with standard 2D histomorphometry of thin sections. Using histomorphometry as a gold standard may be questionable if just one or two slices are extracted from the volume assessed by μCT, because there may be considerable variations of 2D slice-based structural parameters within the 3D volume analyzed by μCT (Engelke *et al.,* 1996). Nevertheless, the comparison of μCT and histomorphometry allows characterizing some potential weakness in using μCT for structural analysis.

One study comparing the two techniques in human bone biopsies found that BV/TV was slightly overestimated by 3% in μCT. However, Tb.Th was overestimated by almost 50%. The discrepancy of Tb.Sp was smaller (25%) but depended on the absolute value of Tb.Sp (Chappard *et al.,* 2005). For μCT a voxel size of $(14\,\mu m)^3$ and a dual-threshold segmentation was used. A discrepancy of 50% for Tb.Th seems to be very high at this voxel size; however, it must be cautioned that most studies only give voxel sizes in the reconstructed μCT dataset and not a true spatial resolution that, for example, can been determined with the help of the modulation transfer function. Without knowledge of the acquisition parameters, such as detector pixel size and magnification factor, it is impossible to judge the true spatial resolution from the reported image voxel size. Indeed, the voxel size in the μCT dataset can be selected during the tomographic reconstruction and can easily be decreased below the true spatial resolution of the tomographic scanner. A study comparing voxel sizes of $(21\,\mu m)^3$, $(50\,\mu m)^3$, and $(110\,\mu m)^3$ showed that subsampling data during tomographic reconstruction in order to improve spatial resolution does not give the same results as scanning with higher resolution (Kim *et al.,* 2004). Unfortunately the true spatial resolution of a given scanner and scan acquisition protocol is rarely known and therefore just the voxel size is reported. Also this is often advantageous from a marketing perspective.

In contrast to Chappard's results a different study also comparing 2D histomorphometry and 3D μCT found only a 22% overestimation of Tb.Th by μCT. BV/TV was overestimated by 4% and Tb.N by 5%; Tb.Sp was underestimated by 10% (Fox *et al.,* 2005). The good agreement for BV/TV with histomorphometry was confirmed in a third study with μCT by using a voxel size of $(20\,\mu m)^3$ (Thomsen *et al.,* 2005). As the correlation of results between μCT and histomorphometry is high, e.g., $r = 0.95$ for BV/TV, $r = 0.75$ for Tb.Th, and $r = 0.81$ for Tb.Sp (Chappard *et al.,* 2005), some authors argue that with linear correction factors μCT is a substitute for histomorphometry when determining trabecular structure (Thomsen *et al.,* 2005). However, caution should be exercised if Tb.Th is determined directly in μCT images instead of being indirectly derived from a measurement of Tb.N and BV/TV. Direct measurements are very sensitive to the segmentation algorithm (Lublinsky *et al.,* 2007).

For the comparisons between histomorphometry and μCT discussed earlier human or bovine bone biopsies were used. To our knowledge, a comparison in excised bones of mice and rats has not been published so far. The imaging and image processing of those bones pose new challenges for μCT because dimensions are smaller compared with human bone biopsies. A typical voxel size of (20 to $30\,\mu m^3$) resolution may be acceptable for connectivity determinations of human trabeculae, but is insufficient for accurate measurement in rats or mice where the trabecular widths average about 50 μm and trabecular separations average 150 μm or less (Kinney *et al.,* 1995).

As an example, Figure 11 shows the 3D segmentation of a mouse knee (Wachsmuth *et al.,* 2004). Owing to partial volume artifacts, the results are still not perfect in small pores in the trabeculae, in sclerotized regions and for thinner trabeculae, which has significant impact in particular on the accuracy of Tb.Th. A further significant increase in spatial resolution down to 1 μm can be achieved by using Synchrotron radiation (SR) (Peyrin *et al.,* 1998, 2001; Martin-Badosa *et al.,* 2003; Ito, 2005). Compared with μCT systems equipped with x-ray tubes, SR offers magnitudes higher x-ray intensity and monochromatic radiation, among other advantages. Higher intensity can be used to increase spatial resolution or signal-to-noise ratio or to decrease scan times or a combination of the three parameters. With spatial resolution better than 10 μm, the investigation of cortical porosity and of the Haversian system becomes feasible (Bousson *et al.,* 2004; Matsumoto *et al.,* 2006; Schneider *et al.,* 2007). Spatial resolution between 1 and 10 μm can also be achieved with micro-focus x-ray tubes, but then scan times are in the order of several hours. Nevertheless, such systems have also been used for the investigation of cortical bone beyond cortical thickness and volume (Cooper *et al.,* 2003, 2004; Basillais *et al.,* 2007; Cooper *et al.,* 2007).

The use of monochromatic synchrotron radiation avoids beam-hardening artifacts of the tomographic reconstruction, which pose a major obstacle for the determination

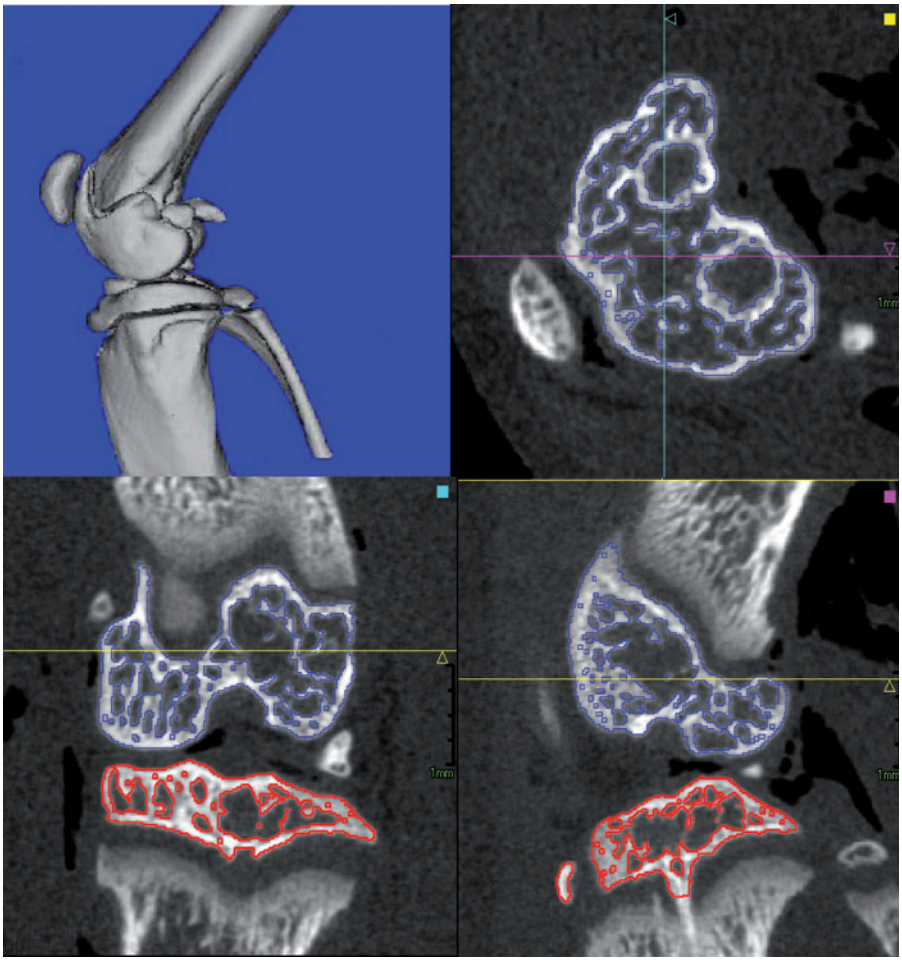

FIGURE 11 μCT dataset with $(11\,\mu m)^3$ voxel size of a knee joint of a 30-day-old CBA mouse. A 3D segmentation of the subchondral bone is shown in axial, coronal, and sagittal multiplanar reconstructions using advanced multistep gradient-based segmentation algorithms (Wachsmuth *et al*., 2004). (See plate section)

of bone mineral density in μCT. Techniques for x-ray-tube-equipped μCT scanners have been reported (Mulder *et al.,* 2006; Schweizer *et al.,* 2007), but the calibration of CT values to BMD remains a challenge if a polychromatic x-ray spectrum is used, whereas monochromatic radiation can easily be obtained from synchrotrons. Therefore, a number of studies have employed SR to measure local mineralization or the Ca/P ratio in μCT images (Nuzzo *et al.,* 2002a, 2002b; Martin-Badosa *et al.,* 2003; Borah *et al.,* 2006; Matsumoto *et al.,* 2006; Tzaphlidou *et al.,* 2006).

Another avenue to use the high intensity of SR has been pioneered by Kinney and coworkers, who first reported serial measurements in rats *in vivo*. In order to limit the radiation exposure only one leg fixed in a stretched out position was scanned (Kinney *et al.,* 1995). Meanwhile the development of x-ray-tube-based μCT scanners for *in vivo* investigations of small anesthetized laboratory animals has gained considerable attention and a number of *in vivo* studies to monitor the bone-protective effects of zoledronic acid and 17-alpha ethinylestradiol in rats (Gasser *et al.,* 2005), bone architecture alterations in hind-limb-unloaded rats (David *et al.,* 2003), bone loss in OVX rats (Waarsing *et al.,* 2004; Boyd *et al.,* 2006), subchondral bone adaptations in a rodent model of osteoarthritis (OA) (McErlain *et al.,* 2007), or age-related changes of trabecular microarchitecture in rabbits (Voor *et al.,* 2007) have been reported. In order to position the analysis volumes reproducibly a 3D registration of baseline and follow-up scans has been suggested (Boyd *et al.,* 2006). Waarsing reported an *in vivo* precision of 3% for BV/TV and of better than 1% for Tb.Th (Waarsing *et al.,* 2004). Voor obtained values of about 2% for BV/TV, Tb.Sp, and Tb.Th (Voor *et al.,* 2007).

MAGNETIC RESONANCE IMAGING

MRI depicts trabecular bone as a negative image by virtue of the strong signal generated by the abundant fat and water protons in the surrounding marrow tissue, whereas bone mineral lacks free protons and generates no MR signal. Similar to CT, MRI can be used to determine geometrical measures such as the cross-sectional area of the femoral neck (Hong *et al.,* 2000; Arokoski *et al.,* 2002; Hogler *et al.,* 2003; McKay *et al.,* 2004; Manske *et al.,* 2006) or cortical

thickness (Saha *et al.,* 2004). Another avenue to employ MRI that has been explored even earlier (Davis *et al.,* 1986) is the use of susceptibility differences between trabecular bone and the surrounding bone marrow that affect the marrow signal intensity by using, for example, gradient echo or asymmetric spin echo sequences. The susceptibility differences cause local inhomogeneities in the main magnetic field which result in changes in the apparent relaxation time T_2*. Similar to a BMD measurement typically T_2* is analyzed in a larger ROI or VOI. The use of the macroscopic measurement of the relaxation rate $1/T_2$* for diagnostic purposes, its correlation with BMD and with bone structure, has been summarized in a number of review articles (Genant *et al.,* 1996; Link, 2008).

In the context discussed in this review, however, the more interesting application of MRI is the determination of trabecular architecture either *in vivo* by using methods of high-resolution MRI (hrMRI) or *in vitro* by using micro MR (μMR) technology. Both techniques have received considerable attention as research and potential clinical tools over the past decade. Although scan times with MR are much longer than with CT and BMD cannot be quantified and the analysis and the interpretation of MR images is more complicated than for CT, MR is a highly interesting approach because of the lack of ionizing radiation, which is a fundamental limitation to achieve higher spatial resolution in *in-vivo* investigations using CT.

Both spin-echo (Jara *et al.,* 1993; Magland *et al.,* 2006) and gradient-echo sequences (Majumdar *et al.,* 1995) can be used to generate hrMRI images. The appearance of the trabecular network on these images is affected by many factors beyond spatial resolution, including the field strength and specific pulse sequence used, the echo time, the signal-to-noise achieved, and the marrow compositional changes (Majumdar *et al.,* 1995; De Bisschop *et al.,* 1996; Newitt *et al.,* 1996; Selby *et al.,* 1996; Fransson *et al.,* 1999; Banerjee *et al.,* 2005; Techawiboonwong *et al.,* 2005). For example, fast 3D spin-echo approaches are preferable to gradient echoes because they are less sensitive to local T_2* differences between bone and marrow. As a consequence, overestimation of trabecular dimension is more pronounced in gradient-echo images (Boutry *et al.,* 2004), especially when the echo-time TE is increased. In contrast, gradient echo sequences are advocated for their higher signal-to-noise characteristics allowing for shorter scan times, which is an important factor for *in vivo* imaging (Majumdar *et al.,* 1995).

High-Resolution Magnetic Resonance Imaging (hrMRI)

With hrMRI using standard 1.5-Tesla (T) clinical MR scanners, an in-plane spatial resolution of approximately 0.3 mm can be achieved, which is approximately twice as high as for hrCT, whereas the slice thicknesses of 0.5 mm is comparable in both methods. In a direct comparison of cadaver specimens between hrMRI and hrCT with contact radiographs (Fig. 12), apparent histomorphometric parameters derived from hrMRI better predicted the values

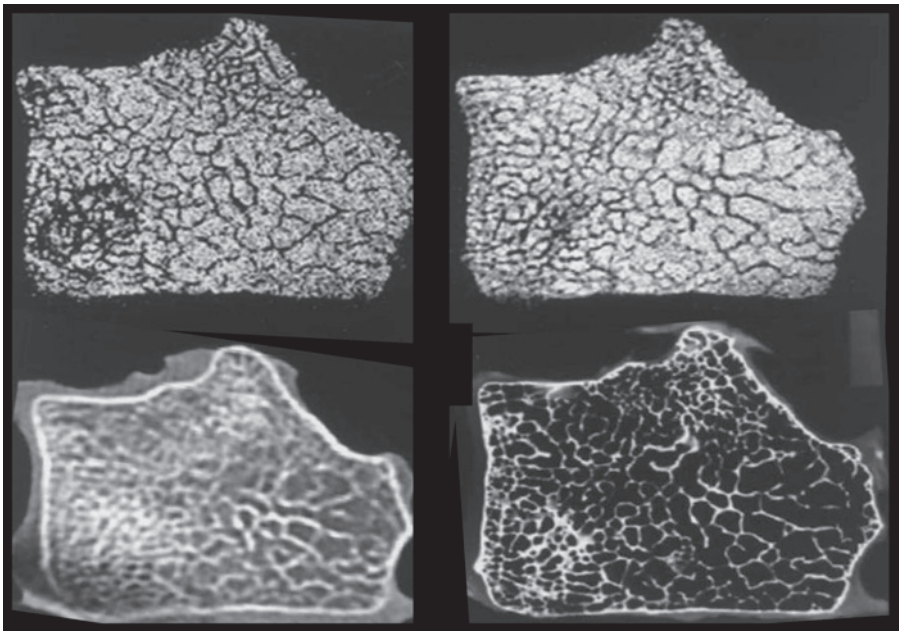

FIGURE 12 Comparison of trabecular structure of a calcaneus specimen imaged with hrMRI, hrCT, and microradiography. (*Top*) 3D hrMRI spin-echo sequence; in-plane pixel size, 150 μm; slice thickness, 300 μm (*Left*) and 900 μm (*Right*). (*Bottom*) Left hrCT plane pixel size, 250 μm; slice thickness, 1000; right contact radiograph of a 1-mm-thick section cut from the calcaneus; slice of plane pixel size, 5 μm (Link *et al*., 2003).

obtained from the radiographs than those obtained from hrCT (Link *et al.,* 2003). However, for contact radiographs a slice thickness of 1 mm was chosen to match the hrCT and hrMRI protocols used in the study. Thin sections to accurately determine histomorphometric parameters were not produced.

Nevertheless, in hrMRI as in hrCT the spatial resolution is still insufficient for an accurate measurement of histomorphometric parameters, and the same limitations as discussed in the section on hrCT above apply. This is also the reason why in hrMRI most work has been done in the appendicular skeleton, namely in the distal forearm and the calcaneus where a higher spatial resolution can be obtained than in the spine or hip. Similar to hrCT considerable resolution dependence was observed for 2D and 3D stereological parameters using hrMRI (Majumdar *et al.,* 1996; Kothari *et al.,* 1998). In a study comparing the analysis of histomorphometric parameters from hrMRI with thin sections, correlations were highest for BV/TV and Tb.Th with r^2 values of about 0.5. The image segmentation parameters used for a binarization had a significant impact on the correlations (Vieth *et al.,* 2001) confirming results from a similar study (Engelke *et al.,* 2001). The effect of thresholding technique and section thickness in hrMRI was also confirmed in another study of femoral specimen. Depending on image-processing technique, correlations between hrMRI and hrCT results varied considerably (Issever *et al.,* 2002; Link *et al.,* 2003).

In order to reduce the effect of partial volume artifacts a number of advanced preprocessing techniques, such as distance transforms (Laib *et al.,* 2002; Saha *et al.,* 2004), subvoxel processing (Hwang *et al.,* 2002), autocorrelation (Hwang *et al.,* 1997; Wald *et al.,* 2007), or adaptive thresholds (Gordon *et al.,* 1997; Vasilic *et al.,* 2005), have been suggested. As an alternative to histomorphometric analysis, several methods to analyze network topology (Gomberg *et al.,* 2000; Boutry *et al.,* 2003; Gomberg *et al.,* 2003; Tabor 2005), 3D morphology (Boehm *et al.,* 2003), anisotropy (Harrigan *et al.,* 1984; Rotter *et al.,* 2001), fractals (Zaia *et al.,* 2006), parameters describing the fuzziness of the network (Carballido-Gamio *et al.,* 2006), or other textural parameters, have also been introduced to hrMRI (Herlidou *et al.,* 2004; Pothuaud *et al.,* 2004; Mueller *et al.,* 2006; Krug *et al.,* 2007).

Several studies obtaining stereological as well as textural parameters from hrMRI images have been carried out to characterize trabecular architecture in various subject groups. For instance, in early studies representative axial sections of the distal radius from normal and osteoporotic subjects clearly depicted the loss of the integrity of the trabecular network with the development of osteoporosis (Majumdar *et al.,* 1994) (Fig. 13), sagittal sections of the calcaneus demonstrated age-related changes (Majumdar *et al.,* 1997; Ouyang *et al.,* 1997) and regional variations of trabecular parameters (Lin *et al.,* 1998). Images of the calcaneus of normal subjects showed that the orientation of the trabeculae also is significantly different in various anatomic regions. Ellipses representing the mean intercept length (MIL) were used to map the degree of anisotropy (DA) of trabecular structure (Majumdar *et al.,* 1994). DA was calculated as the ratio between the maximal and the minimal radius of the MIL ellipsoid.

The use of special-purpose RF coils at the appendicular skeleton can partially offset the problem of limited spatial resolution. Wehrli and colleagues (Jara *et al.,* 1993) and Glüer and colleagues (Kühn *et al.,* 1997; Stampa *et al.,* 2002) have utilized clinical imagers at 1.5 Tesla with coil designs optimized for the phalanges, a convenient anatomical site suitable for obtaining high signal-to-noise images *in vivo* with spatial resolution of $150 \times 150 \times 280\,\mu m^3$. Stampa used these phalangeal images to derive quantitative three-dimensional parameters for defining trabecular rods and plates (Stampa *et al.,* 2002). Others, including Link (Link *et al.,* 1998, 2002), Majumdar (Majumdar *et al.,* 1999; Laib *et al.,* 2002), and Wehrli (Wehrli *et al.,* 2001) have shown the ability to discriminate spine and/or hip fractures by using trabecular structure or textural parameters in vivo.

After 24 months of testosterone treatment in hypogonadal men, in addition to BMD of the spine (+7.4%)

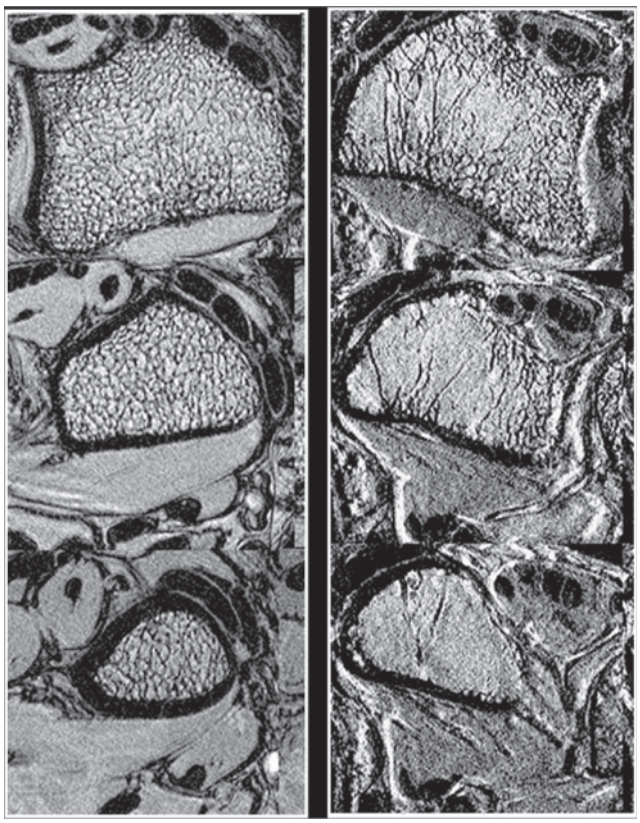

FIGURE 13 hrMRI (~$150 \times 150 \times 500\,\mu m$) of the distal radius of a young woman (*Left*) and an elderly osteoporotic woman (*Right*); axial gradient echo technique. Courtesy of Sharmila Majumdar.

and of the total hip (+7.5%), two advanced architectural parameters assessed by hrMRI significantly changed: the surface-to-curve ratio (+11%) and the topological erosion index (−7.5%) (Benito *et al.,* 2005). In another study with salmon calcitonin, hrMRI imaging at the distal radius but not at the ultradistal radius revealed significant improvement or preservation of appBV/TV, appTb.N, and appTb.Sp in the treated group compared with significant deterioration in the placebo control group (Chesnut *et al.,* 2005). However, in both studies it remained unclear whether results in the structural parameters were adjusted for BMD. A few studies have also indicated a role for monitoring trabecular architecture after heart and kidney transplantations (Link *et al.,* 2000; Link, 2002; Link *et al.,* 2002) and in renal osteodystrophy (Wehrli *et al.,* 2004).

In parallel to the *in-vivo* studies listed earlier, a number of *in-vitro* studies using whole bones or trabecular cubes from the distal radius (Gordon *et al.,* 1998; Link *et al.,* 2004; Hudelmaier *et al.,* 2005), lumbar vertebrae (Link *et al.,* 1998; Majumdar *et al.,* 1998; Beuf *et al.,* 2001; Pothuaud *et al.,* 2002), calcaneus (Majumdar *et al.,* 1998; Link *et al.,* 2004), or proximal femur (Link *et al.,* 1998; Majumdar *et al.,* 1998; Link *et al.,* 2003) addressed a variety of topics. For example, studies confirmed *in-vivo* results of differences of trabecular architecture between gender (Hudelmaier *et al.,* 2005) and among anatomical locations (Majumdar *et al.,* 1998). Majumdar also found good correlation between hrMRI and microscopic optical images for appTb.Sp and appTb.N, but not for appTb.Th (Majumdar *et al.,* 1998). In another study of bone cubes extracted from the vertebrae, traditional morphometric measures of bone structure (appBV/TV; appTb.N, appTb.Sp), including appTb.Th, correlated highly ($0.8 < r < 0.92$) with age, BMD, and stress values (Beuf *et al.,* 2001). In a study comparing hrMRI with hrCT texture parameters derived from femur and spine specimens, both techniques correlated equally poorly with maximum compressive strength (spine: $r^2 = 0.3$ to 0.6; femur $r^2 = 0.1$ to 0.2). For hrMRI, texture measures combined with BMD significantly increased r^2, whereas improvement was less significant for hrCT (Link *et al.,* 1998).

Studies investigating the prediction of biomechanical parameters from trabecular structure show a large range in terms of absolute correlations but agree that trabecular structure can improve the prediction of biomechanical parameters over just using BMD (Gordon *et al.,* 1998; Pothuaud *et al.,* 2002; Link *et al.,* 2003; Hudelmaier *et al.,* 2005). For example, in forearm cadavers, Gordon found that BMD as measured by pQCT explained 50% of the variability with load. Indices relating to the size of the marrow spaces either measured by hrMRI or pQCT explained an additional 25% to 30% (Gordon *et al.,* 1998). In contrast, in a study of bone cubes from vertebral bodies, appBV/TV was found to be a much strong predictor of the mechanical properties, accounting for 89% to 94% of the variability of the elastic moduli and for 69% to 86% of the variability of the ultimate stresses. The inclusion of topological parameters increased these values to 96% to 98% for the variability of the elastic moduli (Pothuaud *et al.,* 2002). The correlations are stronger here because cubes, not whole bones, were used, eliminating the big bone/little bone confounding effect.

Most of the development of hrMRI and the majority of *in vivo* studies, including all those cited earlier, have been carried out on clinical 1.5 T imagers. Recently some initial work has been reported from a small compact 1.0 T device (Handa *et al.,* 2007; Iita *et al.,* 2007) as well as from new clinical 3 T devices. At 1.0 T studies have concentrated on the determination of BV/TV (Kose *et al.,* 2004; Tomiha *et al.,* 2005) and it still needs to be proven that, despite limitations in spatial resolution and signal-to-noise, trabecular structure can also be quantified.

The introduction of new high-field MR scanners to clinical use has triggered the extension of the work of hrMRI to the central skeleton. At higher field strength, either the scan time can be reduced, or the signal-to-noise ratio can be increased, or a combination of both can be achieved. New challenges are increases in susceptibility artifacts that may partially be offset by new acquisition sequences (Banerjee *et al.,* 2005). One study showed that structural parameters measured at 3 T better discriminated spinal fractures than the same parameters measured at 1.5 T (Phan *et al.,* 2006), but susceptibly and partial volume artifacts were still present with 3 T, causing an overestimation of 50% for appBV/TV and by 100% for appTb.Th. appTb.Sp was still underestimated whereas appTb.N was largely unaffected (Sell *et al.,* 2005), confirming Laib's approach to use Tb.N as a starting point when calculating histomorphometric parameters (see section 4.3) (Laib *et al.,* 1999).

First *in-vivo* studies at 3 T have demonstrated the possibilities of the characterization of trabecular architecture in the trochanter of the femur (Krug *et al.,* 2005) as well as improved spatial resolution in the wrist (Ludescher *et al.,* 2005). New imaging sequences and segmentation techniques for trabecular bone are also being developed (Vasilic *et al.,* 2005; Magland *et al.,* 2006).

Micro Magnetic Resonance Imaging

In the literature, hrMRI techniques described in the previous section are often termed μMRI or MR microscopy. However, for a better differentiation we prefer and suggest reserving the term μMRI to techniques with a spatial resolution of better than 100 μm and MR microscopy to techniques with a spatial resolution of better than 1 μm. Similar to μCT, μMRI applications are restricted to *in vitro* specimen work and to *in vivo* investigations of small animals. Obviously, with higher spatial resolution, histomorphometric parameters can be determined more accurately,

but the main advantage of MRI versus CT, the absence of radiation, is only important for *in vivo* animal and not for specimen work. Also for μMRI different acquisition protocols and image-processing algorithms are used than for hrMRI. Thus, with respect to the imaging of bone architecture, μMRI has only limited value in improving hrMRI techniques. So, not surprisingly, a rather limited number of studies have been published over the past decade and many of the results, in particular, the relation of bone architecture to bone strength, could have been obtained from μCT studies as well.

In μMRI, special-purpose, small-bore, high-field magnets have been employed to obtain very high resolution and to optimize the relation of signal-to-field strength. Early approaches of μMRI in bone showed good in-plane resolutions, but at a slice thickness of 250 μm, partial volume artifacts were still obvious (Kapadia *et al.,* 1993). Wehrli and colleagues obtained 78-μm isotopic voxels of human and bovine bone cubes using three-dimensional imaging at 9.4 Tesla, and derived anisotropy ellipsoids from the analysis of mean intercept length. They also found good correlation between MR-derived parameters and standard histomorphometric measures (Chung *et al.,* 1993, 1995a, 1995b). Timonen and coworkers investigated the connectivity of the trabecular network in rat femora at 7 Tesla (Timonen *et al.,* 2001). At 8.6 Tesla, BV/TV determined in human bone cubes with μMRI no longer differed significantly from BV/TV ($r^2 = 0.81$) determined from optical imaging of the stained cube surfaces (Hipp *et al.,* 1996).

A comparison of μMRI data obtained at 8.5 Tesla and a voxel size of 66 μm^3 with μCT data obtained at a voxel size of 10 μm^3 showed that network connectivity, orientation, and anisotropy as determined by μMRI were accurate. However, BV/TV and morphometric parameters were still biased relative to their values from the μCT data, although there was a significant correlation between the two modalities (Last *et al.,* 2005). In contrast, in another study carried out at 4.7 T in the rat femur, correlations between μMRI (in-plane voxel size 23 μm^2; slice thickness, 39 μm) and histomorphometry of decalcified 5-μm sections were only moderate ($r^2 \approx 0.5$), but the authors pointed out that the decalcification had potentially distorted the sections (Hopper *et al.,* 2004).

In two *in-vitro* studies in OVX rats μMRI was successfully used to show drug-related effects on trabecular structure. In the first study, it was shown that ERT prevented ovariectomy-induced losses in trabecular BV/TV and structure (Kapadia *et al.,* 1998). In the second study carried out at 9.4 T using an isotropic voxel size of 46 μm^3, it was shown that in a group of rats given alendronate for 2 months starting 2 months after OVX, BV/TV was maintained midway between non-OVX and nontreated (intact) animals. Treatment with prostaglandin E_2 instead of alendronate returned BV/TV to levels observed in intact levels (Takahashi *et al.,* 1999). In hind limp suspended mice imaged at 11.7 Tesla, BV/TV (−53%), Tb.Th (−19%), Tb.Sp (+114%), and Tb.N (−43%) changed significantly compared with a control group (Gardner *et al.,* 2001).

In vivo μMRI measurements of the femoral bone structure of C57Bl/6 mice at 11.7 T have been reported recently. Trabecular and cortical bone properties have been compared with histomorphometry. An optimal correlation with histomorphometry was obtained with gradient-echo sequences. Increases of percent area of marrow and decreases of percent area of trabecular bone and of cortical bone thickness from the epiphyseal growth plate to the diaphysis correlated with the histomorphometric data (Weber *et al.,* 2005).

MULTIMODALITY IMAGING

The assessment of bone structure is not only important in osteoporosis. Another application is the investigation in rheumatoid and osteoarthritis (Pelletier 2004; Schett *et al.,* 2005). A few studies using hrMRI (Beuf *et al.,* 2002; Blumenkrantz *et al.,* 2004; Lahm *et al.,* 2006), μCT (Patel *et al.,* 2003; Botter *et al.,* 2006; Chappard *et al.,* 2006; McErlain *et al.,* 2007), and μMRI (Lammentausta *et al.,* 2007) techniques have been reported. Rheumatoid arthritis (RA) and OA are complicated diseases. In OA, cartilage, synovial membrane, and subchondral bone are involved. Thus, a combination of CT and MRI techniques may simultaneously assess cartilage and subchondral bone (Batiste *et al.,* 2004; Wachsmuth *et al.,* 2004). For example, in Figure 14, μCT and μMR images of male Lewis rats demonstrate the potential of multimodality imaging. μCT is preferable to μMRI for the determination of bone structure, whereas μMRI can depict cartilage and other soft tissue. Figure 15 shows the registration of the two datasets so that a local correlation of bone structure and cartilage defects can be performed more accurately.

Finite-Element Modeling

Finite-element modeling (FEM) is a computer-based simulation of the strains and stresses induced by mechanical loading of an object and is widely used in engineering. The object is described as a connected set of simply shaped elements that are ascribed elastic properties. Bone biomechanics research with this tool was pioneered by Lotz and Hayes (Lotz *et al.,* 1991a, 1991b) and Faulkner (Faulkner *et al.,* 1991). One of its goals is to better predict load conditions that lead to fracture and thus to improve fracture prediction. Currently, the models are typically derived from volumetric QCT scans, and element elastic properties are computed from bone density at the position of the elements (Fig. 16) (Lang *et al.,* 1997; Keyak *et al.,* 2000). Finite-element models integrate mechanically all of the anisotropic, inhomogeneous, and complex geometry of the bone structure examined.

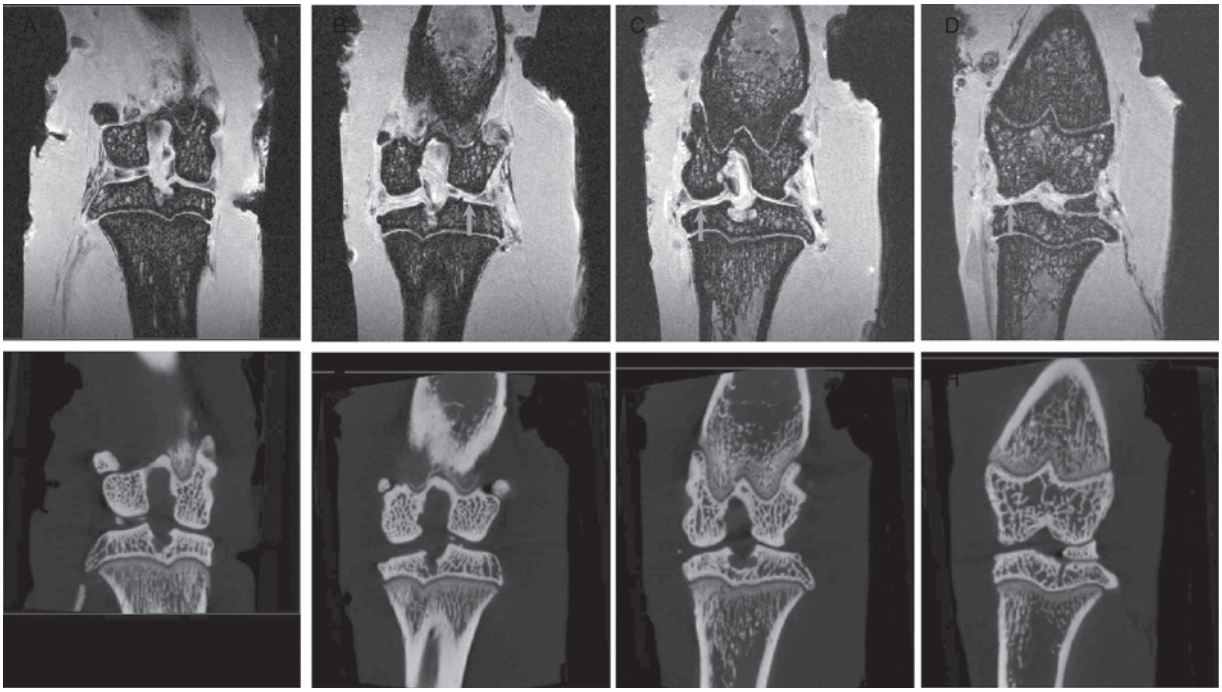

FIGURE 14 μMRI (*Top*) and μCT (*Button*) data for male Lewis rat knees with severed cruciate ligament and removed medial menisci. **A** and **E**, nonoperated contralateral knee; **B–D** and **F–G**, operated knee. In the μCT images the medial subchondral bone shows a higher degree of sclerotization and the trabeculae appear to be thickened compared with the nonoperated knee. In the μMRI images (gradient-echo sequence) the medial cartilage is more homogeneous in the nonoperated knee (Wachsmuth *et al*., 2004).

Finite-element analysis potentially integrates density and geometry and may better account for regional variations than the separation of a bone into subvolumes. Several *in vitro* studies have shown QCT-based finite-element analysis to be a strong predictor of whole-bone strength, with some (Cody *et al.,* 1999; Crawford *et al.,* 2003), though not all (Keyak *et al.,* 1998; Buckley *et al.,* 2007), studies reporting stronger correlations for FEM than for DXA- or QCT-based measures. However, it still has to be demonstrated that FEM provides additional advantages to a combination of densitometric and geometrical QCT parameters. For the hip, it has been shown that such a combination of densitometric and geometric parameters that can be extracted easily and rapidly from a QCT dataset is a better predictor of failure load than single parameters alone (Bousson *et al.,* 2006).

At the spine, Keaveny, Hayes and colleagues found that in healthy subjects the cortical shell does not transfer much of the load (Silva *et al.,* 1997). It has been claimed that voxel-based finite-element model-derived estimates of strength are better predictors of *in vitro* vertebral compressive strength than clinical measures of bone density derived from QCT with or without bone size (Crawford *et al.,* 2003). However, this advantage of FEM may not pertain if more sophisticated parameters than just midvertebral trabecular BMD and bone size are measured. Recently, these parameters have been made available (Mastmeyer *et al.,* 2006) but a comparison with FEM has not been performed. A pilot study in 20 randomly selected postmenopausal women treated with PTH for one year indicates that about half the overall increase in vertebral strength can be attributed to an average increase in bone density, and the remaining effect is due to alterations in the distribution of bone density within the vertebra (Black *et al.,* 2005). Although imaging resolution for FEM is not critical in cross-sectional studies using clinical CT scanners, longitudinal studies that seek to track more subtle changes in stiffness over time should account for the small but highly significant effects of voxel size (Crawford *et al.,* 2003).

In the femur, FEM so far has mostly been used for the optimization of endoprostheses; vQCT-based applications for fracture prediction are still rare. One study of the hip in 51 women aged 74 years (Ciarelli *et al.,* 2000) showed different risk factors for hip fracture during single-limb stance and falls, which agrees with epidemiological findings of different risk factors for cervical and trochanteric fractures. In the *in-vitro* arm of the European femur fracture study with finite-element analysis and QCT (EFFECT), QCT parameters predicted fracture load in fall and stance configurations as well as FEM (Engelke *et al.,* 2006).

With the vast increases of computer power during the past decade and the availability of μCT data, the application of FEM at spatial resolutions that allow modeling of individual trabeculae, which is computationally much more demanding than just using voxels containing average gray values, has become feasible (Fig. 17). Although 2D simulation studies indicate that the amount and thickness of trabeculae strongly determine overall bone strength (Silva *et al.,* 1997), full 3D models were first developed

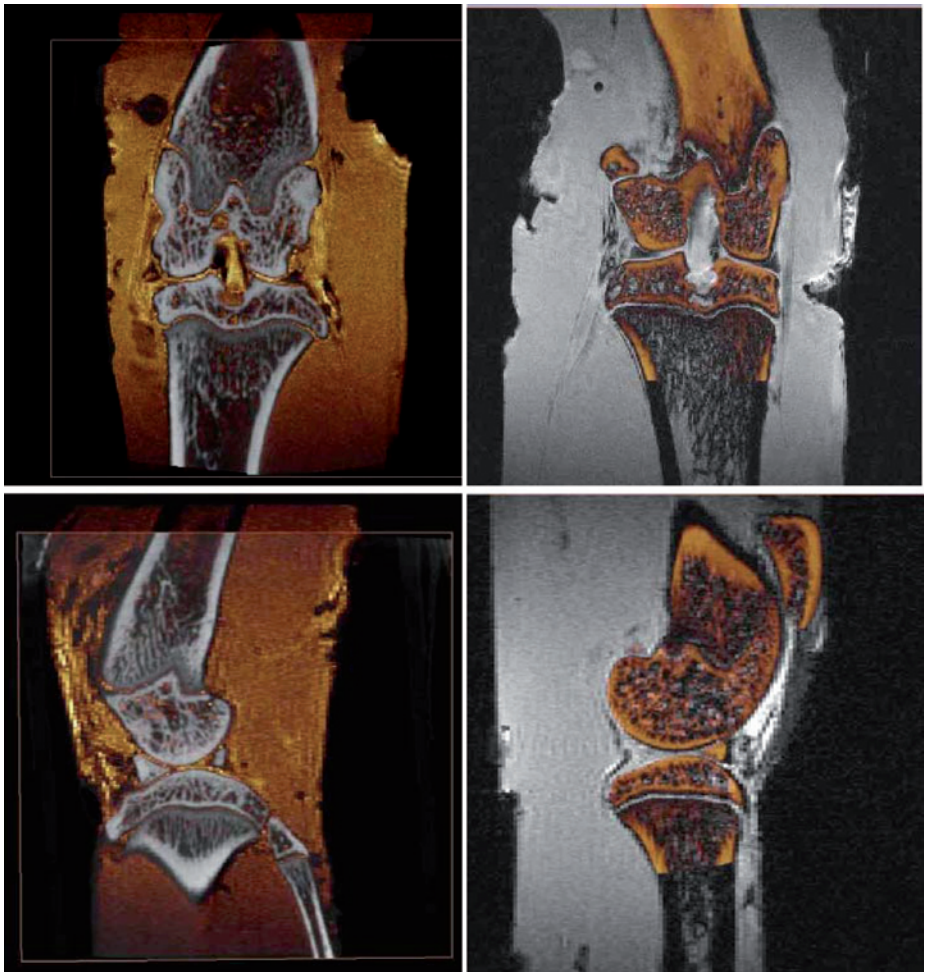

FIGURE 15 Registration of μMRI and μCT datasets from Fig. 14. In the two images on the left the μCT part is gray and the μMRI part is colored; in the two images on the right the color coding is inverted. (See plate section)

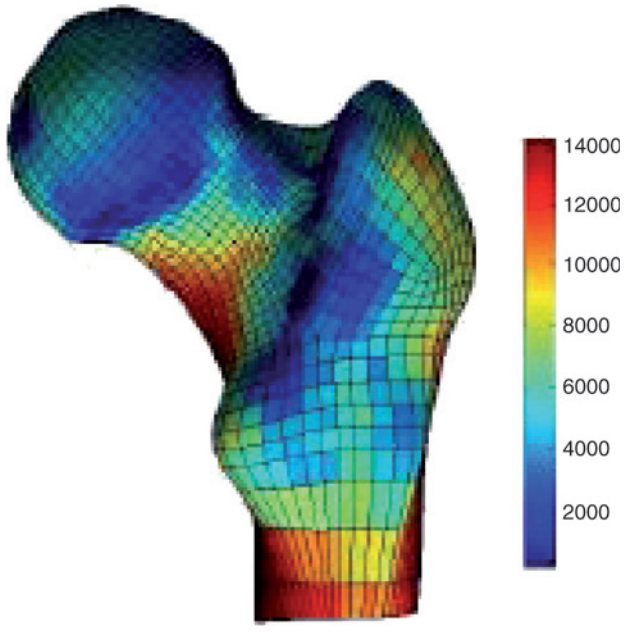

FIGURE 16 Distribution of Young's modulus computed from BMD in the elements of the mesh using vQCT data. Courtesy of David Mitton. (See plate section)

by van Rietbergen *et al.* (1995). Prediction of overall bone strength recorded during mechanical testing of small samples of trabecular bone with such models are indeed better than with macroscopic bone density measurements (Ulrich *et al.,* 1997; Crawford *et al.,* 2003).

μCT scanning has only recently reached the resolution to allow conversion of the gray values of the individual pixels to elastic moduli to further improve the accuracy of fracture load prediction (Homminga *et al.,* 2001, 2002). Using this improved technique, Homminga and colleagues showed that, although osteoporotic vertebrae can withstand daily load patterns comparably to normal bone, loading as occurs during forward bending caused much higher stresses in the osteoporotic vertebra (Homminga *et al.,* 2004). μFEM based on μCT data has been used to estimate distal radius failure loads (Pistoia *et al.,* 2002), to calculate load transfer from the biomaterial structure of bone scaffolds (Lacroix *et al.,* 2006), to determine regional variations and age-related changes in mechanical parameters of trabecular bone in the vertebrae (Gong *et al.,* 2007), or to predict mechanical properties of fracture callus during fracture healing (Shefelbine *et al.,* 2005).

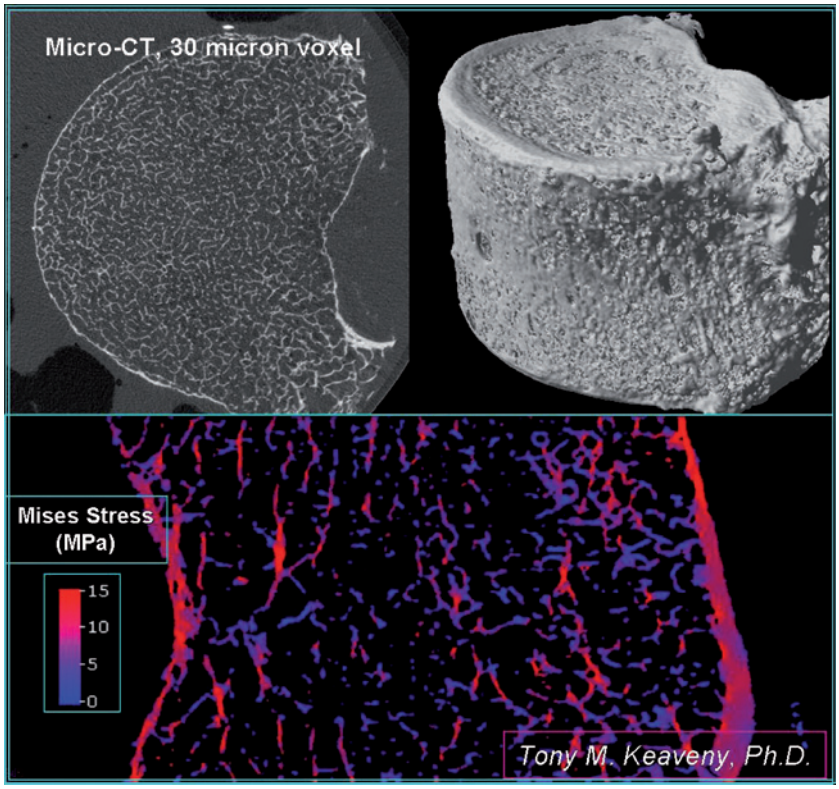

FIGURE 17 Micro CT of vertebral body at 30-μm resolution and generation of micro finite-element model at the trabecular level. Courtesy of Tony Keaveny. (See plate section)

FEM has also been applied to magnetic resonance images. Newitt and coworkers have reported promising results on the application of micro finite-element analyses based on hrMR images of the distal radius *in vivo* (Newitt *et al.,* 2002). In another study structure parameters determined in high-resolution MR images of the proximal femur specimen correlated significantly with bone strength, with the highest correlations obtained by combining DXA BMD and structure measures (Link *et al.,* 2003). The femoral neck trabecular microstructure significantly correlated with biomechanical properties, and its combination with BMD further improved the prediction of bone quality (Jiang *et al.,* 2005).

SUMMARY

For many years the assessment of 3D bone architecture has been an important aim in bone research in order to better understand disease etiology, to facilitate bone strength determination, to improve fracture risk prediction, and to more effectively assess aging and treatment mechanisms. Many studies have indeed shown that changes in bone quality and structural characteristics lead to changes in bone biomechanical competence or individual risk of fracture independently of BMD.

From a clinical perspective, two directions seem to be most relevant. The first is the quantitative characterization *in vivo* of bone macro- and microstructure in humans as information complimentary to BMD. The second is the *in-vivo* investigation of mice and rats that should include bone structure and density. Fueled by the introduction of genetically engineered mice and rat models, most progress has been made in the field of μCT. *In-vivo* investigations of anesthetized animals with spatial resolution down to 50 μm are almost routine procedures today. Obviously, this greatly facilitates preclinical research. By using 3D analysis algorithms to analyze trabecular structure it has been demonstrated that, in μCT, standard parameters such as Tb.N, BV/TV, and Tb.Sp can be measured reproducibly and with adequate accuracy despite remaining partial volume artifacts. However, acceptable limits of radiation exposure that eventually define maximum achievable image quality in terms of noise and spatial resolution still have to be determined for small animals. The measurement of BMD with μCT by using polychromatic radiation emitted from x-ray tubes also still has to be validated.

μCT has also been used successfully for *in vitro* characterization of bone structure. Spatial resolution below 10 μm, which is required to investigate cortical bone structure, is still the domain of synchrotron radiation, although the first such x-ray tube-based scanners have recently become available. While μMRI techniques have not found widespread use for the determination of bone architecture

they may become more relevant in order to bypass limitations of spatial resolution owing to radiation exposure in *in-vivo* μCT. For *in-vitro* applications, the domain of μMRI may be limited to soft tissue imaging such as cartilage, however, multimodality applications of μCT and μMRI, in particular for Osteoarthritis, show promising potential.

With respect to *in-vivo* imaging of bone structure in humans, volumetric QCT has significantly improved our capability to determine BMD in dedicated regions of interest, to assess bone geometry and, with some limitations, cortical thickness. Finite-element modeling has shown the potential to integrate BMD and geometry, although it still has to be shown that FEM is superior to a multivariate model of BMD and geometrical parameters directly measured with CT for fracture prediction. The extension of DXA into a more volumetric technique may open new avenues to obtain volumetric BMD information with DXA equipment.

With respect to trabecular structure, however, despite more than ten years of development and impressive technological advances of the equipment, little progress has been made with hrCT or hrMRI. Only a few clinical and pharmaceutical studies have been reported, and even these have been supervised and analyzed by highly skilled researchers at those few sites involved in the development of these techniques. Obviously, the use of these techniques, in particular, the acquisition in hrMRI and image processing in hrMRI and hrCT is still very challenging in the context of multicenter, multinational clinical trials and far too complicated for routine clinical work.

One reason is that the spatial resolution of hrCT and hrMRI is not adequate to measure stereological parameters accurately, and apparent Tb.N, Tb.Sp, and Tb.Th are not independent from the selected image acquisition and processing techniques. This may explain their limited success as additional predictors for fracture discrimination or for health and disease or treatment assessments, which are substantially independent of BMD. Also typically, these structural parameters correlate highly with BV/TV and as a consequence are highly correlated to site-matched BMD. A huge variety of alternate parameters characterizing texture has been introduced but their meaning as well as their relevance often remains obscure, in particular, because two studies have rarely used the same set of parameters. Interestingly, the performance of texture parameters applied to radiographs also seems to be promising.

For theoretical reasons, parameters describing geometry and structure are expected to provide a more accurate prediction of structural strength than a global BMD measurement because they consider the spatial distribution of bone material and the bone architecture rather than bone mass alone. However, the distribution of available bone mass is thought to be subject to an optimization process that provides adequate mechanical strength and is influenced by mechanical stimuli (Huiskes, 2000). Therefore, the strength of the relationships between mechanical competence might be similar for geometric and bone mass measurements.

Of course it has been demonstrated that trabecular networks with different SMI, that is with different structure, still may have identical BMD (Muller *et al.,* 1997), thus BMD and bone strength may be decoupled. However, during normal aging, at least in the spine, decrease of BMD and structural deterioration of the trabecular network seem to occur in parallel. This supports the hypothesis by Huiskes and may explain why structural parameters in many studies have added only a minor value to BMD in improving fracture discrimination (Chevalier *et al.,* 1992; Ito *et al.,* 1995; Gordon *et al.,* 1998; Link *et al.,* 1998; Majumdar *et al.,* 1999; Wehrli *et al.,* 2001; Link, 2002), although structural parameters remained significant after BMD adjustment. Under pharmaceutical treatment this may change, at least it is known that BMD increases do not fully account for fracture reduction. Often this has been explained with systematic errors of DXA, but μCT studies have shown differential effects on structure under different treatment options. Of course, it is speculative that under pharmaceutical treatment, structure and density may be decoupled but it definitely provides further motivation to improve hrCT and hrMRI techniques and to include BMD measurements in μCT analyses. For the forearm and tibia, an advanced high-resolution pQCT scanner with integrated software for structural analysis that offers a spatial resolution of about 100 μm has recently become available commercially, and several studies are currently evaluating the potential of this device; however, for the spine and femur, the most important fracture sites, technical challenges are still waiting to be solved.

Vico, L., Prallet, B., Chappard, D., Pallot-Prades, B., Pupier, R., and Alexandre, C. (1992). Contributions of chronological age, age at menarche and menopause and of anthropometric parameters to axial and peripheral bone densities. *Osteoporos Int.* **2**(3), 153–158.

Vieth, V., Link, T. M., Lotter, A., Persigehl, T., Newitt, D., Heindel, W., and Majumdar, S. (2001). Does the trabecular bone structure depicted by high-resolution MRI of the calcaneus reflect the true bone structure? *Invest. Radiol.* **36**(4), 210–217.

Voor, M. J., Yang, S., Burden, R. L., and Waddell, S. W. (2007). In vivo micro-CT scanning of a rabbit distal femur: Repeatability and reproducibility. *J. Biomech*.

Waarsing, J. H., Day, J. S., van der Linden, J. C., Ederveen, A. G., Spanjers, C., De Clerck, N., Sasov, A., Verhaar, J. A., and Weinans, H. (2004). Detecting and tracking local changes in the tibiae of individual rats: a novel method to analyse longitudinal in vivo micro-CT data. *Bone* **34**(1), 163–169.

Wachsmuth, L., and Engelke, K. (2004). High-resolution imaging of osteoarthritis using microcomputed tomography. *Methods Mol. Med.* **101**, 231–248.

Wachter, N. J., Augat, P., Hoellen, I. P., Krischak, G. D., Sarkar, M. R., Mentzel, M., Kinzl, L., and Claes, L. (2001). Predictive value of Singh index and bone mineral density measured by quantitative computed tomography in determining the local cancellous bone quality of the proximal femur. *Clin. Biomech. (Bristol, Avon),* **16**(3) 257–262.

Wald, M. J., Vasilic, B., Saha, P. K., and Wehrli, F. W. (2007). Spatial autocorrelation and mean intercept length analysis of trabecular bone anisotropy applied to in vivo magnetic resonance imaging. *Med. Phys.* **34**(3), 1110–2220.

Ward, K. A., Cotton, J., and Adams, J. E. (2003). A technical and clinical evaluation of digital x-ray radiogrammetry. *Osteoporos Int.* **14**(5), 389–395.

Washimi, Y., Ito, M., Morishima, Y., Taguma, K., Ojima, Y., Uzawa, T., and Hori, M. (2007). Effect of combined humanPTH(1–34) and calcitonin treatment in ovariectomized rats. *Bone*.

Weber, M. H., Sharp, J. C., Latta, P., Sramek, M., Hassard, H. T., and Orr, F. W. (2005). Magnetic resonance imaging of trabecular and cortical bone in mice: comparison of high resolution in vivo and ex vivo MR images with corresponding histology. *Eur. J. Radiol.* **53**(1), 96–102.

Wehrli, F. W., Gomberg, B. R., Saha, P. K., Song, H. K., Hwang, S. N., and Snyder, P. J. (2001). Digital topological analysis of in vivo magnetic resonance microimages of trabecular bone reveals structural implications of osteoporosis. *J. Bone Miner. Res.* **16**(8), 1520–1531.

Wehrli, F. W., Hwang, S. N., Song, H. K., and Gomberg, B. R. (2001). Visualization and analysis of trabecular bone architecture in the limited spatial resolution regime of in vivo micro-MRI. *Adv. Exp. Med. Biol.* **496**, 153–164.

Wehrli, F. W., Leonard, M. B., Saha, P. K., and Gomberg, B. R. (2004). Quantitative high-resolution magnetic resonance imaging reveals structural implications of renal osteodystrophy on trabecular and cortical bone. *J. Magn. Reson. Imaging,* **20**(1), 83–89.

Wilkie, J. R., Giger, M. L., Chinander, M. R., Vokes, T. J., Li, H., Dixon, L., and Jaros, V. (2004). Comparison of radiographic texture analysis from computed radiography and bone densitometry systems. *Med. Phys.* **31**(4), 882–891.

Wu, C., van Kuijk, C., Li, J., Jiang, Y., Chan, M., Countryman, P., and Genant, H. K. (2000). Comparison of digitized images with original radiography for semiquantitative assessment of osteoporotic fractures. *Osteoporos Int.* **11**(1), 25–30.

Xiang, A., Kanematsu, M., Kumar, S., Yamashita, D., Kaise, T., Kikkawa, H., Asano, S., and Kinoshita, M. (2007). Changes in micro-CT 3D bone parameters reflect effects of a potent cathepsin K inhibitor (SB-553484) on bone resorption and cortical bone formation in ovariectomized mice. *Bone* **40**(5), 1231–1237.

Xiang, Y., Yingling, V. R., Malique, R., Li, C. Y., Schaffler, M. B., and Raphan, T. (2007). Comparative assessment of bone mass and structure using texture-based and histomorphometric analyses. *Bone* **40**(2), 544–552.

Yang, J., Pham, S. M., and Crabbe, D. L. (2003). High-resolution Micro-CT evaluation of mid- to long-term effects of estrogen deficiency on rat trabecular bone. *Acad. Radiol.* **10**(10), 1153–1158.

Yoshikawa, T., Turner, C. H., Peacock, M., Slemenda, C. W., Weaver, C. M., Teegarden, D., Markwardt, P., and Burr, D. B. (1994). Geometric structure of the femoral neck measured using dual-energy x-ray absorptiometry. *J. Bone Miner. Res.* **9**(7), 1053–1064.

Zaia, A., Eleonori, R., Maponi, P., Rossi, R., and Murri, R. (2006). MR imaging and osteoporosis: fractal lacunarity analysis of trabecular bone. *IEEE Trans. Inf. Technol. Biomed.* **10**(3), 484–489.
