The cause of the Cambrian explosion is not understood. Because it occurred shortly after marine animals evolved shells, some scientists have speculated that the changes observed in animal species may have allowed them to exploit new environments. Alternatively, others have suggested that the increase in diversity may be related to atmospheric oxygen levels. During this period, oxygen levels were increasing, and perhaps more complex body plans became possible only after the atmospheric oxygen surpassed a certain threshold. In addition, as atmospheric oxygen reached its present levels, an ozone (O_3) layer was produced that screens out ultraviolet radiation, thereby allowing complex life to live in shallow water and eventually on land. Another possible contributor to the Cambrian explosion was an "arms race" between predators and their prey. The ability of predators to capture prey and the ability of prey to avoid predators may have been a major factor that resulted in a diversification of animals into many different species.

Ordovician Period (490 to 443 mya) Like the Cambrian period, the climate of the early and middle parts of the Ordovician period was warm, and the atmosphere was moist. During this period, a diverse group of marine invertebrates, including trilobites and brachiopods, appeared in the fossil record (Figure 22.16). Marine communities consisted of invertebrates, algae, early jawless fishes (a type of early vertebrate), mollusks,

Figure 22.15 **The Cambrian explosion and the Burgess Shale.** **(a)** This photograph shows the original site in the Canadian Rockies discovered by Charles Walcott. Since its discovery, this site has been made into a quarry for the collection of fossils. **(b)** A fossil of an extinct arthropod, *Marrella*, that was found at this site.

and corals. Fossil evidence also suggests that early land plants and arthropods may have first invaded the land during this period.

Toward the end of the Ordovician period, the climate changed rather dramatically. Large glaciers formed, which drained the relatively shallow oceans, causing the water levels to drop. This resulted in a mass extinction in which as many as 60% of the existing marine invertebrates became extinct.

Silurian Period (443 to 417 mya) In contrast to the dramatic climate changes observed during the Ordovician period, the climate during the Silurian was relatively stable. The glaciers largely melted, which caused the ocean levels to rise. No new major types of invertebrate animals appeared during this period, but significant changes were observed among existing vertebrate and plant species. Many new types of fishes appeared in the fossil record. In addition, coral reefs made their first appearance during this period.

The Silurian marked a significant colonization by terrestrial plants and animals. For this to occur, certain species evolved adaptations that prevented them from drying out, such as an external cuticle. Ancestral relatives of spiders and centipedes became prevalent. The earliest fossils of **vascular plants**, which can transport water, sugar, and salts throughout the plant body, were observed in this period.

(a) Trilobite

(b) Brachiopod

Figure 22.16 Shelled, invertebrate fossils of the Ordovician period.

Devonian Period (417 to 354 mya) In the Devonian period, generally dry conditions occurred across much of the northern landmasses. However, the Southern Hemisphere was mostly covered by cool, temperate oceans.

The Devonian saw a major increase in the number of terrestrial species. At first, the vegetation consisted primarily of small plants, only a meter tall or less. Later, ferns, horsetails, and **seed plants**, such as gymnosperms, also emerged. By the end of the Devonian, the first trees and forests were formed. A major expansion of terrestrial animals also occurred. Insects first appeared in the fossil record, and other invertebrates became plentiful. In addition, the first **tetrapods**, vertebrates with four legs, are believed to have evolved in the Devonian. Early tetrapods included amphibians, which lived on land but required water in which to lay their eggs.

In the oceans, many types of invertebrates flourished, including brachiopods, echinoderms, and corals. This period is sometimes called the Age of Fishes, as many new types of fishes emerged. During a period of approximately 20 million years near the end of the Devonian period, a prolonged series of extinctions eliminated many marine species. The cause of this mass extinction is not well understood.

Carboniferous Period (354 to 290 mya) The term Carboniferous refers to the rich coal deposits found in rocks of this age. The Carboniferous had the ideal conditions for the subsequent formation of coal. It was a cooler period, and much of the land was covered by forest swamps. Coal was formed over many millions of years from compressed layers of rotting vegetation.

Plants and animals further diversified during the Carboniferous period. Very large plants and trees became prevalent. For example, tree ferns such as *Psaronius* grew to a height of 15 meters or more (Figure 22.17). The first flying insects emerged. Giant dragonflies with a wingspan of over 2 feet inhabited the forest swamps. Terrestrial vertebrates also became more diverse. Amphibians were very prevalent. One innovation that seemed particularly beneficial was the amniotic egg. In reptiles, the amniotic egg was covered with a leathery or hard shell. This prevented the desiccation of the embryo inside. This innovation was critical for the emergence of reptiles during this period.

Permian Period (290 to 248 mya) At the beginning of the Permian, continental drift had brought much of the total land together into a supercontinent known as Pangaea (see Figure 22.10). The interior regions of Pangaea were dry, with great seasonal fluctuations. The forests of fernlike plants were replaced with gymnosperms. Species resembling modern conifers first appeared in the fossil record. Amphibians were prevalent, but reptiles became the dominant vertebrate species.

At the end of the Permian period, the largest known mass extinction in the history of life on Earth occurred; 90–95% of marine species and a large proportion of terrestrial species were eliminated. The cause of the Permian extinction is the subject

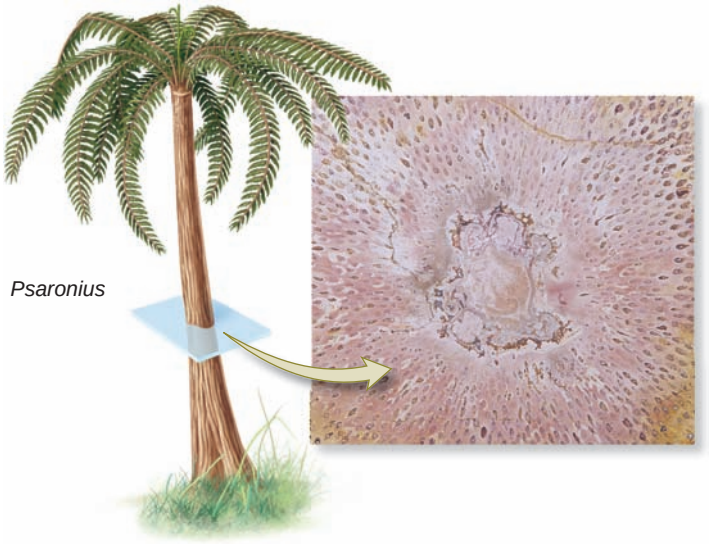

Figure 22.17 **A giant tree fern, *Psaronius*, from the Carboniferous period.** This genus became extinct during the Permian. The illustration is a re-creation based on fossil evidence. The inset shows a fossilized section of the trunk, also known as petrified wood.

of much research and controversy. One possibility is that glaciation destroyed the habitats of terrestrial species and lowered ocean levels, which would have created greater competition among marine species. Another hypothesis is that enormous volcanic eruptions in Siberia produced large ash clouds that abruptly changed the climate on Earth.

Phanerozoic Eon: The Mesozoic Era Saw the Rise and Fall of the Dinosaurs

The Permian extinction marks the division between the Paleozoic and Mesozoic eras. Mesozoic means "middle animals." It was a time period that saw great changes in animal and plant species. This era is sometimes called the Age of Dinosaurs, which flourished during this time. The climate during the Mesozoic era was consistently hot, and terrestrial environments were relatively dry. Little if any ice was found at either pole. The Mesozoic is divided into three periods, the Triassic, Jurassic, and Cretaceous.

Triassic Period (248 to 206 mya) Reptiles were plentiful in this period, including new groups such as crocodiles and turtles. The first dinosaurs emerged during the middle of the Triassic, as did the first true **mammals**, such as the small *Megazostrodon* (Figure 22.18). Gymnosperms were the dominant land plant. Volcanic eruptions near the end of the Triassic are thought to have caused global warming, resulting in mass extinctions that eliminated many marine and terrestrial species.

Jurassic Period (206 to 144 mya) Gymnosperms, such as conifers, continued to be the dominant vegetation. Mammals were not prevalent. Reptiles continued to be the dominant land vertebrate. These included dinosaurs, which were mostly terrestrial reptiles that shared certain anatomical features, such as an erect posture. Some dinosaurs attained enormous sizes, including the massive *Brachiosaurus* that reached a length of 25 m (80 ft) and weighed up to 100 tons! An early bird-like creature, *Archaeopteryx* (Figure 22.19), emerged in the Jurassic period.

Figure 22.18 ***Megazostrodon*, the first known mammal of the Triassic period.** The illustration is a re-creation based on fossilized skeletons. The *Megazostrodon* was 10 to 12 cm long.

Figure 22.19 **A fossil of the first bird-like animal, *Archaeopteryx*, which emerged in the Jurassic period.**

Cretaceous Period (144 to 65 mya) On land, dinosaurs continued to be the dominant animals. The earliest **flowering plants**, called angiosperms, which form seeds within a protective chamber, emerged and began to diversify.

The end of the Cretaceous witnessed another mass extinction, which brought an end to many previously successful groups of organisms. The dinosaurs and many other species abruptly died out. As with the Permian extinction, the cause of this mass extinction is still debated. One plausible hypothesis suggests that a large meteorite hit the region that is now the Yucatan

Peninsula of Mexico, lifting massive amounts of debris into the air and thereby blocking the sunlight from reaching the Earth's surface. Such a dense haze could have cooled the Earth's surface by 11–15°C (20–30°F). Evidence also points to strong volcanic eruptions as a contributing factor for this mass extinction.

Phanerozoic Eon: Mammals and Flowering Plants Diversified During the Cenozoic Era

The Cenozoic era spans the most recent 65 million years. It is divided into two periods, the Tertiary and Quaternary. In many parts of the world, tropical conditions were replaced by a colder, drier climate. During this time, mammals became the largest terrestrial animals, which is why the Cenozoic is sometimes called the Age of Mammals. However, the Cenozoic era also saw an amazing diversification of many types of organisms, including birds, fishes, insects, and flowering plants.

Tertiary Period (65 to 1.8 mya) On land, the mammals that survived from the Cretaceous period began to diversify rapidly during the early part of the Tertiary period. Angiosperms became the dominant land plant, and insects became important for their pollination. Fishes also diversified, and sharks became abundant.

Toward the end of the Tertiary period, about 7 million years ago, hominoids came into existence. **Hominoids** include modern humans, chimpanzees, gorillas, orangutans, and gibbons, plus all of their recent ancestors. The term **hominin** refers to a subset of hominoids, including modern humans, extinct human species (for example, of the *Homo* genus), and our immediate ancestors. In 2002, a fossil of the earliest known hominin, *Sahelanthropus tchadensis*, was discovered in Central Africa. This fossil was dated at between 6 and 7 million years old. Another early hominin genus, called *Australopithecus*, first emerged in Africa about 4 million years ago. Australopithecines walked upright and had a protruding jaw, prominent eyebrow ridges, and a small braincase.

Quaternary Period (1.8 mya to present) Periodic Ice Ages have been prevalent during the last 1.8 million years, covering much of Europe and North America. This period has witnessed the widespread extinction of many species of mammals, particularly larger species. Certain species of hominins became increasingly more like living humans. Near the beginning of the Quaternary period, fossils were discovered of *Homo habilis*, or handy man, so called because stone tools were found with the fossil remains. Fossils that are classified as *Homo sapiens*—modern humans—first appeared about 170,000 years ago. The evolution of hominins is discussed in more detail in Chapter 34.

Summary of Key Concepts

22.1 Origin of Life on Earth

- The first stage in the formation of life involved the synthesis of organic molecules to form a prebiotic soup. Possible scenarios of how this occurred are the reducing atmosphere, extraterrestrial, and deep-sea vent hypotheses. (Figures 22.2, 22.3)
- The second stage was the bonding of organic molecules to form polymers. This may have occurred on the surface of clay.
- The third stage in the evolution of the first living cells occurred when polymers became enclosed in structures called protobionts that separated them from the external environment. Examples include coacervates and liposomes. (Figure 22.4)
- The fourth stage that led to the first living cells was chemical selection in which molecules with functional properties, such as self-replication and other enzymatic functions, increased in number. (Figure 22.5)
- The precursors of living cells as well as the first living cells themselves are thought to have used RNA for both information storage and catalytic functions. This hypothetical early phase of life is termed the RNA world.
- Bartel and Szostak demonstrated that chemical selection for RNA molecules that can catalyze covalent bond formation is possible experimentally. (Figure 22.6)
- The RNA world was later superseded by the modern DNA/RNA/protein world.

22.2 Fossils

- Fossils, which are preserved remnants of past life-forms, are formed in sedimentary rock. Radioisotope dating is one way to estimate the age of a fossil. Fossils provide an extensive record of the history of life, though the record is incomplete and has biases. (Figures 22.7, 22.8, Table 22.1)

22.3 History of Life on Earth

- The geological time scale, which is divided into four eons and many eras and periods, charts the major events that occurred during the history of life on Earth. (Figure 22.9)
- The formation and extinction of species, as well as mass extinctions, are correlated with changes in temperature, atmosphere, and landmass locations, as well as floods, glaciation, volcanic eruptions, and meteorite impacts. (Figure 22.10)
- During the Archaean eon, bacteria and archaea arose. Organisms such as cyanobacteria became autotrophs and produced oxygen. Cyanobacteria were preserved in structures called stromatolites. (Figure 22.11)
- Eukaryotic cells arose during the Proterozoic eon. This origin involved a union between bacterial and archaeal cells that may have been symbiotic or endosymbiotic or both. The origin of mitochondria and chloroplasts was an endosymbiotic relationship. (Figure 22.12)
- Multicellular eukaryotes evolved during the Proterozoic eon and first emerged about 1.5 billion years ago. Multicellularity now occurs via cell division and the adherence of the resulting cells to each other. A multicellular organism can produce multiple cell types. (Figure 22.13)

- The first bilateral animal emerged toward the end of the Proterozoic eon. (Figure 22.14)
- The Phanerozoic eon is subdivided into the Paleozoic, Mesozoic, and Cenozoic eras. During the Paleozoic era, invertebrates greatly diversified, particularly during the Cambrian explosion, and the land became colonized by plants. Terrestrial vertebrates, including tetrapods, became more diverse. (Figures 22.15, 22.16, 22.17)
- Dinosaurs were prevalent during the Mesozoic era, particularly during the Jurassic period. Mammals and birds also emerged. (Figures 22.18, 22.19)
- During the Cenozoic era, mammals diversified, and flowering plants became the dominant plant species. The first hominoids emerged approximately 7 million years ago. Fossils classified as *Homo sapiens*, our species, appeared about 170,000 years ago.

Assess and Discuss

Test Yourself

1. The prebiotic soup was
   a. the assemblage of unicellular prokaryotes and eukaryotes that existed in the oceans of early Earth.
   b. the accumulation of organic molecules in the oceans of early Earth.
   c. the mixture of organic molecules that was found in the cytoplasm of the earliest cells on Earth.
   d. a pool of nucleic acids that contained the genetic information for the earliest organisms.
   e. none of the above.
2. Which of the following is not a characteristic of protobionts that was necessary for the evolution of living cells?
   a. a membrane-like boundary separating the external environment from an internal environment
   b. polymers capable of functioning in information storage
   c. polymers capable of enzymatic activity
   d. self-replication
   e. compartmentalization of metabolic activity
3. RNA is believed to be the first functional macromolecule in protobionts because it
   a. is easier to synthesize compared to other macromolecules.
   b. has the ability to store information, self-replicate, and perform enzymatic activity.
   c. is the simplest of the macromolecules commonly found in living cells.
   d. All of the above are correct.
   e. a and c only are correct.
4. The movement of landmasses that have changed their positions, shapes, and association with other landmasses is called
   a. glaciation.
   b. Pangaea.
   c. continental drift.
   d. biogeography.
   e. geological scale.
5. Paleontologists estimate the dates of fossils by
   a. the layer of rock in which the fossils are found.
   b. analysis of radioisotopes found in nearby rock.
   c. the complexity of the body plan of the organism.
   d. all of the above.
   e. a and b only.
6. The fossil record does not give us a complete picture of the history of life because
   a. not all past organisms have become fossilized.
   b. only organisms with hard skeletons can become fossilized.
   c. fossils of very small organisms have not been found.
   d. fossils of early organisms are located too deep in the crust of the Earth to be found.
   e. all of the above.
7. The endosymbiosis hypothesis explaining the evolution of eukaryotic cells is supported by
   a. DNA-sequencing analysis comparing bacterial genomes, mitochondrial genomes, and eukaryotic nuclear genomes.
   b. naturally occurring examples of endosymbiotic relationships between bacterial cells and eukaryotic cells.
   c. the presence of DNA in mitochondria and chloroplasts.
   d. all of the above.
   e. a and b only.
8. Which of the following explanations of the evolution of multicellularity in eukaryotes is seen in the development of complex, multicellular organisms today?
   a. endosymbiosis
   b. aggregation of cells to form a colony
   c. division of cells with the resulting cells sticking together
   d. multiple cell types aggregating to form a complex organism
   e. none of the above
9. The earliest fossils of vascular plants were formed during the _____ period.
   a. Ordovician
   b. Silurian
   c. Devonian
   d. Triassic
   e. Jurassic
10. The appearance of the first hominoids date to the _____ period.
    a. Triassic
    b. Jurassic
    c. Cretaceous
    d. Tertiary
    e. Quaternary

Conceptual Questions

1. What are the four stages that led to the origin of living cells?
2. How are the ages of fossils determined? In your answer, you should discuss which types of rocks are analyzed and explain the concepts of radioisotope dating and half-life.
3. What is meant by the Cambrian explosion? What is the significance of the Cambrian explosion with regard to modern animal species?

Collaborative Questions

1. Discuss possible hypotheses of how organic molecules were first formed.
2. Discuss the key features of a protobiont. What distinguishes a protobiont from a living cell?

Chapter Outline

An Introduction to Evolution

23

Selective breeding. The horses in this race have been bred for a particular trait, in this case, speed. Such a practice, called selective breeding, can dramatically change the traits of organisms over several generations.

Organic life beneath the shoreless waves
Was born and nurs'd in Ocean's pearly caves
First forms minute, unseen by spheric glass,
Move on the mud, or pierce the watery mass;
These, as successive generations bloom,
New powers acquire, and larger limbs assume;
Whence countless groups of vegetation spring,
And breathing realms of fin, and feet, and wing.

From The Temple of Nature *by Erasmus Darwin (1731–1802), grandfather of Charles Darwin. Published posthumously in 1803.*

The term **evolution** is used to describe a heritable change in one or more characteristics of a population from one generation to the next. Evolution can be viewed on a small scale (**microevolution**) as it relates to changes in a single gene or allele frequencies in a population over time, or it can be viewed on a larger scale (**macroevolution**) as it relates to the formation of new species or groups of related species.

It is helpful to begin our discussion of evolution with a definition of a species. As a working definition, biologists often define a **species** as a group of related organisms that share a distinctive form. Among species that reproduce sexually, such as plants and animals, members of the same species are capable of interbreeding in nature to produce viable and fertile offspring. The term **population** refers to all members of a species that live in the same area and have the opportunity to interbreed. Some of the emphasis in the study of evolution is on understanding how populations change over the course of many generations to produce new species.

In the first part of this chapter, we will examine the development of evolutionary thought and some of the basic tenets of evolution, particularly those proposed by Charles Darwin in the mid-1800s. Though the theory of evolution has been refined over the past 150 years or so, the fundamental principle of evolution remains unchanged and has provided a cornerstone for our understanding of biology. Theodosius Dobzhansky, an influential evolutionary scientist of the 1900s, once said, "Nothing in biology makes sense except in the light of evolution." The extraordinarily diverse and seemingly bizarre array of species on our planet can be explained within the context of evolution. As is the case with all scientific theories, evolution is called a theory because it is supported by a substantial body of evidence and because it explains a wide range of observations. The theory of evolution provides answers to many questions related to the diversity of life. In biology, theories such as this are viewed as scientific knowledge.

In the second part of this chapter, we will survey the extensive data that illustrate the processes by which evolution occurs. These data not only support the theory of evolution but also allow us to understand the interrelatedness of different species, whose similarities are often due to descent from a common ancestor. Much of the early evidence supporting evolution came from visual observations and comparisons of living and extinct species. More recently, advances in molecular genetics, particularly those related to DNA sequencing and genomics, have revolutionized the study of evolution. Scientists now have information that allows us to understand how evolution involves changes in the DNA of a given species. These changes affect both a species' genes and the proteins they encode. The term **molecular evolution** refers to the molecular changes in genetic material that underlie the phenotypic changes associated with evolution. A theme of this textbook, namely genomes and

proteomes, is rooted in an understanding of these changes. In the last section of this chapter, we consider some of the exciting new information that helps us to appreciate evolutionary change at the molecular level. In the following chapters of this unit, we will examine how such changes are acted upon by evolutionary factors in ways that alter the traits of a given species and may eventually lead to the formation of new species.

23.1 The Theory of Evolution

Undoubtedly, the question, "Where did we come from?" has been asked and debated by people for thousands of years. Many of the early ideas regarding the existence of living organisms were strongly influenced by religion and philosophy. Some of these ideas suggested that all forms of life have remained the same since their creation. In the 1600s, however, scholars in Europe began a revolution that created the basis of empirical and scientific thought. **Empirical thought** relies on observation to form an idea or hypothesis rather than trying to understand life from a nonphysical or spiritual point of view. The shift toward empirical thought encouraged scholars to look for the basic rationale behind a given process or phenomenon.

In the mid- to late-1600s, the first scientist to carry out a thorough study of the living world was an Englishman named John Ray, who developed an early classification system for plants and animals based on anatomy and physiology. He established the modern concept of a species, noting that organisms of one species do not interbreed with members of another, and used it as the basic unit of his classification system. Ray's ideas on classification were later expanded by the Swedish naturalist Carolus Linnaeus. How did their work contribute to the development of evolutionary theory? Neither Ray nor Linnaeus proposed that evolutionary change promotes the formation of new species. However, their systematic classification of plants and animals helped scholars of this period perceive the similarities and differences among living organisms.

Late in the 1700s, a small number of European scientists began to quietly suggest that life-forms are not fixed. A French zoologist, George Buffon, actually proposed that living things change through time. However, Buffon was careful to hide his views in a 44-volume natural history book series. He was a quiet pioneer in asserting that species can change over generations.

Around the same time, a French naturalist named Jean-Baptiste Lamarck suggested an intimate relationship between variation and evolution. By examining fossils, he realized that some species had remained the same over the millennia and others had changed. Lamarck hypothesized that species change over the course of many generations by adapting to new environments. He believed that living things evolved in a continuously upward direction, from dead matter, through simple to more complex forms, toward human "perfection." According to Lamarck, organisms altered their behavior in response to environmental change. He thought that behavioral changes modified traits and hypothesized that such modified traits were inherited by offspring. He called this idea the **inheritance of acquired characteristics**. For example, according to Lamarck's hypothesis, giraffes developed their elongated necks and front legs by feeding on high tree leaves. The exercise of stretching up to the leaves altered the neck and legs, and Lamarck presumed that these acquired characteristics were transmitted to offspring. However, further research has rejected Lamarck's idea that acquired traits can be inherited. Even so, Lamarck's work was important in promoting the idea of evolutionary change.

Interestingly, Erasmus Darwin, the grandfather of Charles Darwin, who was a contemporary of Buffon and Lamarck, was an early advocate of evolutionary change. He was a physician, a plant biologist, and also a poet (see poem at the beginning of the chapter). He was aware that modern species were different from similar types of fossilized organisms and also saw how plant and animal breeders used breeding practices to change the traits of domesticated species (see chapter-opening photo). He knew that offspring inherited features from their parents, and went so far as to say that life on Earth could have descended from a common ancestor.

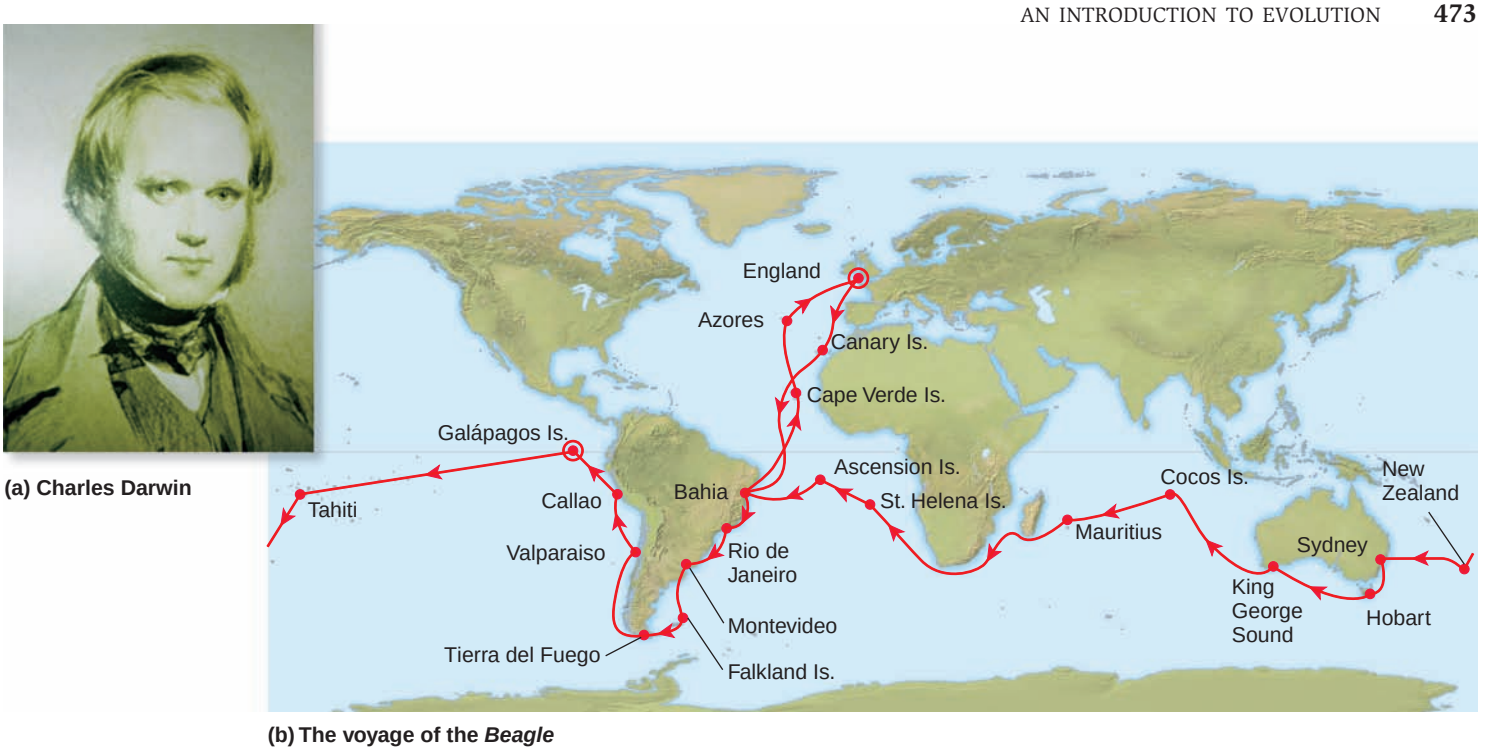
Overall, Charles Darwin's many scientific predecessors set the stage for the theory of evolution. With this historical introduction, we will now consider Darwin's observations and the tenets that provide the foundation for this theory.

Darwin Suggested That Species Are Derived from Pre-existing Species

Charles Darwin, a British naturalist born in 1809, played a key role in developing the theory that existing species have evolved from pre-existing species. Darwin's unique perspective and his ability to formulate evolutionary theory were shaped by several different fields of study, including ideas of his time about geological and biological processes.

Two main geological hypotheses predominated in the early 19th century. Catastrophism was first proposed by French zoologist and paleontologist Georges Cuvier to explain the age of the Earth. Cuvier suggested that the Earth was just 6,000 years old and that only catastrophic events had changed its geological structure. This idea fit well with religious teachings. Alternatively, uniformitarianism, proposed by Scottish geologist James Hutton and popularized by geologist Charles Lyell, suggested that changes in the Earth are directly caused by recurring events. For example, they suggested that geological processes such as erosion existed in the past and happened at the same gradual rate as they do now. For such slow geological processes to eventually lead to substantial changes in the Earth's characteristics, a great deal of time was required. Hutton and Lyell were the first to propose that the age of the Earth is well beyond 6,000 years. The ideas of Hutton and Lyell helped to shape Darwin's view of the world.

Darwin's thinking was also influenced by a paper published in 1798 called *Essay on the Principle of Population* by Thomas Malthus, an English economist. Malthus asserted that



(a) Charles Darwin

(b) The voyage of the *Beagle*

Figure 23.1 **Charles Darwin and the voyage of the *Beagle*, 1831–1836.** **(a)** A portrait of Charles Darwin (1809–1882) while in Ecuador. **(b)** Darwin's voyage on the *Beagle*, which took almost 5 years to circumnavigate the world.

the population size of humans can, at best, increase linearly due to increased land usage and improvements in agriculture, whereas our reproductive potential is exponential (for example, doubling with each generation). He argued that famine, war, and disease will limit population growth, especially among the poor. The relevant message from Malthus's work was that only a fraction of any population will survive and reproduce.

Darwin's ideas, however, were most influenced by his own experiences and observations. His work aboard the HMS *Beagle*, a survey ship, lasted from 1831 to 1836 and involved a careful examination of many different species (Figure 23.1). The main mission of the *Beagle* was to map the coastline of southern South America and take oceanographic measurements. Darwin's job was to record the weather, geological features, plants, animals, fossils, rocks, minerals, and indigenous people.

Though Darwin made many interesting observations on his journey, he was particularly struck by the distinctive traits of island species. For example, Darwin observed several species of finches found on the Galápagos Islands, a group of volcanic islands 600 miles from the coast of Ecuador. Though it is often assumed that Darwin's personal observations of these finches directly inspired his theory of evolution, this is not the case. Initially, Darwin thought the birds were various species of blackbirds, grosbeaks, and finches. Later, however, the bird specimens from the islands were given to the British ornithologist John Gould, who identified them as several new finch species. Gould's observations helped Darwin in the later formulation of his theory.

As seen in Table 23.1, the finches differed widely in the size and shape of their beaks and in their feeding habits. For example, the ground and vegetarian finches have sturdy, crushing beaks they use to crush various sizes of seeds or buds. The tree finches have grasping beaks they use to pick up insects from trees. The mangrove, woodpecker, warbler, and cactus finches have pointed, probing beaks. They use their beaks to search for insects in crevices. The cactus finches use their probing beaks to open cactus fruits and eat the seeds. One species, the woodpecker finch, even uses twigs or cactus spines to extract insect larvae from holes in dead tree branches. Darwin clearly saw the similarities among these species, yet he noted the differences that provided them with specialized feeding strategies. We now know these finches all evolved from a single species similar to the dull-colored grassquit finch (*Tiaris obscura*), commonly found along the Pacific Coast of South America. Once on the Galápagos Islands, the finches' ability to survive and reproduce in their new habitat depended, in part, on changes in the size and shape of their beaks over many generations. These specializations enabled succeeding generations to better obtain particular types of food.

With an understanding of geology and population growth, and his observations from his voyage on the *Beagle*, Darwin had formulated his theory of evolution by the mid-1840s. He had also catalogued and described all of the species he had collected on his *Beagle* voyage except for one type of barnacle. Some have speculated that Darwin may have felt that he should establish himself as an expert on one species before making generalizations about all of them. Therefore, he spent several additional years studying barnacles. During this time, the geologist Charles Lyell, who had greatly influenced Darwin's thinking, strongly encouraged Darwin to publish his theory of evolution. In 1856, Darwin began to write a long book to explain his ideas. In 1858, however, Alfred Wallace, a naturalist working in the East Indies, sent Darwin an unpublished manuscript to read prior to its publication. In it, Wallace proposed the same ideas

Table 23.1 A Comparison of Beak Type and Diet Among the Galápagos Finches Darwin Studied

Type of finch	Species		Type of beak	Diet
Ground finches	Large ground finch (*Geospiza magnirostris*)		Crushing	Seeds—Ground finches have crushing beaks to crush various sizes of seeds; large beaks can crush large seeds, whereas smaller beaks are better for crushing small seeds.
	Medium ground finch (*G. fortis*)			
	Small ground finch (*G. fuliginosa*)			
	Sharp-billed ground finch (*G. difficilis*)			
Vegetarian finch	Vegetarian finch (*Platyspiza crassirostris*)		Crushing	Buds—Vegetarian finches have crushing beaks to pull buds from branches.
Tree finches	Large tree finch (*Camarhynchus psittacula*)		Grasping	Insects—Tree finches have grasping beaks to pick insects from trees. Those with heavier beaks can also break apart wood in search of insects.
	Medium tree finch (*Camarhynchus pauper*)			
	Small tree finch (*Camarhynchus parvulus*)			
Tree finches	Mangrove finch (*Cactospiza heliobates*)		Probing	Insects—These finches have probing beaks to search for insects in crevices and then to pick them up. The woodpecker finch can also use a cactus spine for probing.
	Woodpecker finch (*Camarhynchus pallidus*)			
Warbler finch	Warbler finch (*Certhidea olivacea*)		Probing	
Cactus finches	Large cactus finch (*G. conirostris*)		Probing	Seeds—Cactus finches have probing beaks to open cactus fruits and take out seeds.
	Cactus finch (*G. scandens*)			

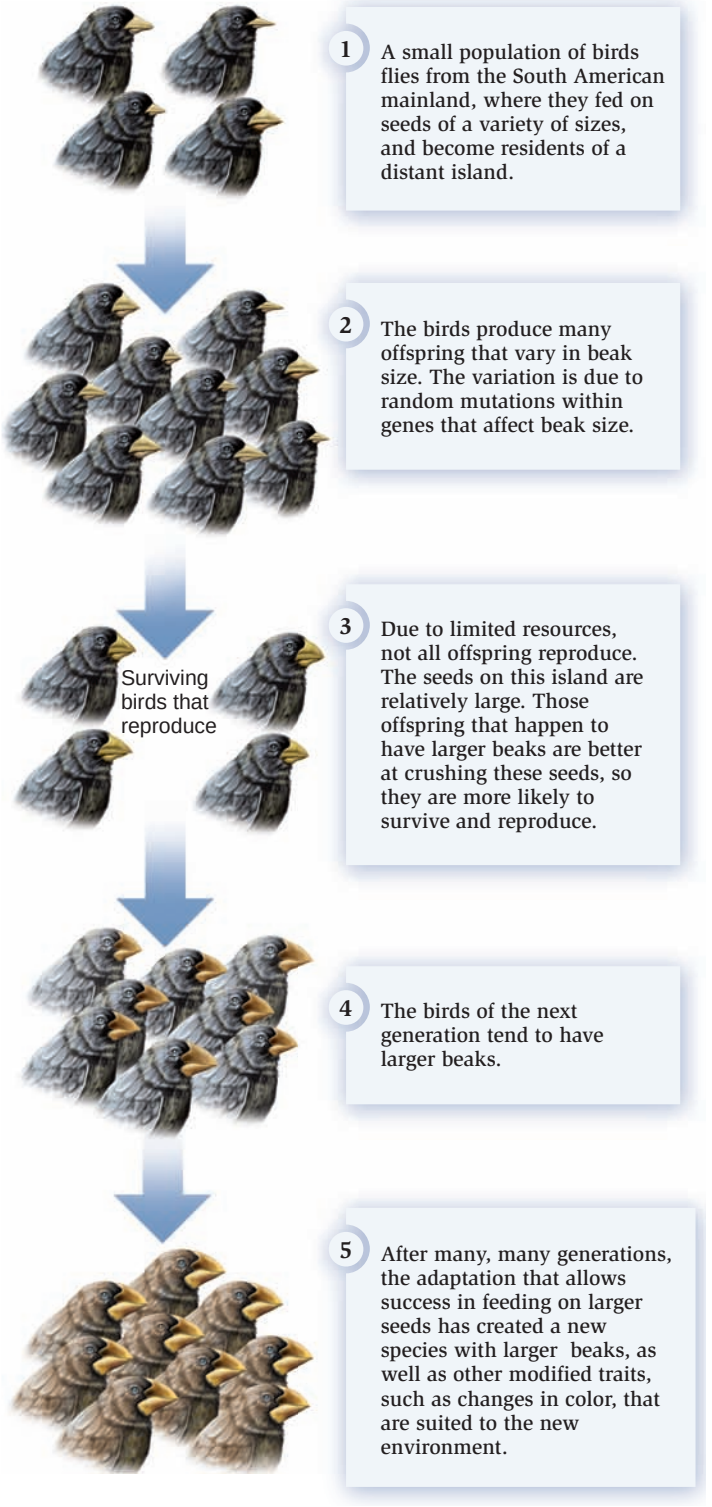


Figure 23.2 **Evolutionary adaptation to a new environment via natural selection.** The example shown here involves a species of finch adapting to a new environment on a distant island. The plants on this island produce larger seeds than do the plants on the mainland from which the birds originated. According to Darwin's theory of evolution by natural selection, the process of adaptation eventually leads to the formation of a new species with larger beaks that are better suited to crushing the large seeds.

Concept check: *The phrase "an organism evolves" is incorrect. Explain why.*

concerning evolution. In response to this, Darwin decided to use some of his own writings on this subject, and two papers, one by Darwin and one by Wallace, were published in the *Proceedings of the Linnaean Society of London*. These papers were not widely recognized. A year later, however, Darwin finished his book *The Origin of Species* (1859), which described his ideas in greater detail and included observational support. This book, which received high praise from many scientists and scorn from others, started a great debate concerning evolution. Although some of his ideas were incomplete because the genetic basis of traits was not understood at that time, Darwin's work remains one of the most important contributions to our understanding of biology.

Natural Selection Can Change Populations from Generation to Generation

As mentioned, evolution is a heritable change of one or more characteristics in a population from one generation to the next. Darwin hypothesized that existing life-forms on our planet result from the modification of pre-existing life-forms. He expressed this concept of evolution as "the theory of descent with modification through variation and natural selection." The term evolution refers to change. What factors bring about evolutionary change? According to Darwin's ideas, evolution may occur from generation to generation due to two interacting factors, genetic variation and natural selection:

1. Variation in traits may occur among individuals of a given species. The heritable traits are then passed from parents to offspring. The genetic basis for variation within a species was not understood at the time Darwin proposed his theory of evolution. We now know that such variation is due to different types of genetic changes such as random mutations in genes. Even though Darwin did not fully appreciate the genetic basis of variation, he and many other people before him observed that offspring resemble their parents more than they do unrelated individuals. Therefore, he assumed that some traits are passed from parent to offspring.
2. In each generation, many more offspring are usually produced than will survive and reproduce. Often times, resources in the environment are limiting for an organism's survival. During the process of **natural selection**, individuals with heritable traits that make them better suited to their native environment tend to flourish and reproduce, whereas other individuals are less likely to survive and reproduce. As a result of natural selection, certain traits that favor reproductive success become more prevalent in a population.

As an example, we can consider a population of finches that migrates from the South American mainland to a distant island (Figure 23.2). Variation exists in the beaks sizes among the migrating birds. Let's suppose the seeds produced on the distant island are larger than those produced on the mainland. Those birds with larger beaks would be better able to feed

on these larger seeds and therefore would be more likely to survive and pass on that trait to their offspring. What are the consequences of this selection process? In succeeding generations, the population will tend to have a greater proportion of finches with larger beaks. Alternatively, if a trait happens to be detrimental to an individual's ability to survive and reproduce, natural selection is likely to eliminate this type of variation. For example, if a finch in the same environment had a small beak, this bird would be less likely to acquire food, which would decrease its ability to survive and pass on this trait to its offspring. Natural selection may ultimately result in a new species with a combination of multiple traits that are quite different from those of the original species, such as finches with larger beaks and changes in coloration. In other words, the newer species has evolved from a pre-existing species. Now let's look at a scientific study involving change in a population over time.

Feature Investigation

The Grants Have Observed Natural Selection in Galápagos Finches

Since 1973, Peter Grant, Rosemary Grant, and their colleagues have studied natural selection in finches found on the Galápagos Islands. For over 30 years, the Grants have focused much of their work on one of the Galápagos Islands known as Daphne Major (Figure 23.3a). This small island (0.34 km^2) has a moderate degree of isolation (it is 8 km from the nearest island), an undisturbed habitat, and a resident population of *Geospiza fortis*, the medium ground finch (Figure 23.3b).

To study natural selection, the Grants have observed various traits in finches over the course of many years. One example is beak size. The medium ground finch has a relatively small crushing beak, allowing it to more easily feed on small, tender seeds (see Table 23.1). The Grants quantified beak size among the medium ground finches of Daphne Major by carefully measuring beak depth (a measurement of the beak from top to bottom, at its base) on individual birds (Figure 23.4). The small size of the island made it possible for them to measure a large percentage of birds and their offspring. During the course of their studies, they compared the beak sizes of parents and offspring by examining many broods over several years and found that the size of the beak was transmitted from parents to offspring, regardless of environmental conditions, indicating

(a) Daphne Major **(b) Medium ground finch**

Figure 23.3 **The Grants' investigation of natural selection in finches.** **(a)** Daphne Major, one of the Galápagos Islands. **(b)** One of the medium ground finches (*Geospiza fortis*) that populate this island.

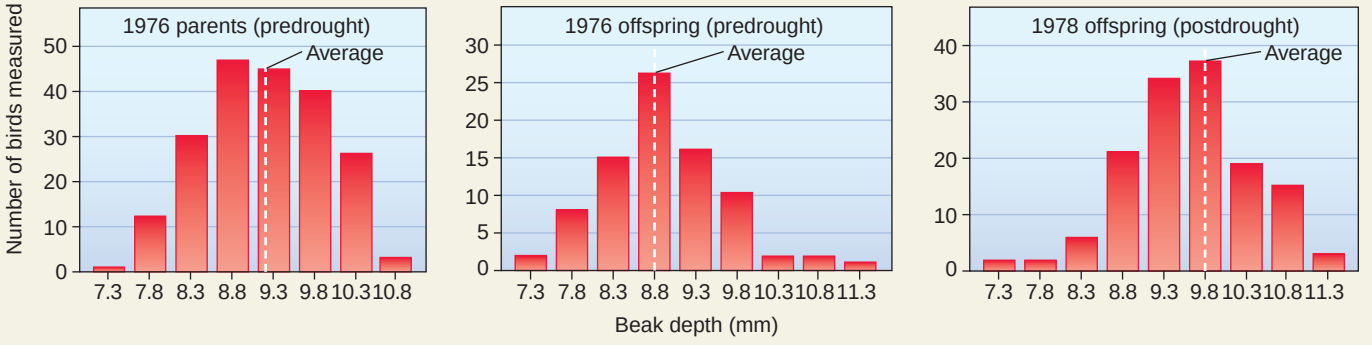
Figure 23.4 **The Grants and natural selection of beak size among the medium ground finch.**

HYPOTHESIS Dry conditions produce larger seeds and may result in larger beaks in succeeding generations of *Geospiza fortis* due to natural selection.

KEY MATERIALS A population of *G. fortis* on the Galápagos Island called Daphne Major.

		Experimental level	Conceptual level
1	In 1976, measure beak depth in parents and offspring of the species *G. fortis*.	Capture birds and measure beak depth. 	This is a way to measure a trait that may be subject to natural selection.
2	Repeat the procedure on offspring that were born in 1978 and had reached mature size. A drought had occurred in 1977 that caused plants on the island to produce mostly large dry seeds and relatively few small seeds.	Capture birds and measure beak depth. 	This is a way to measure a trait that may be subject to natural selection.

3 THE DATA



4 CONCLUSION Because a drought produced larger seeds, birds with larger beaks were more likely to survive and reproduce. The process of natural selection produced postdrought offspring that had larger beaks compared to predrought offspring.

5 SOURCE Grant, B. Rosemary, and Grant, Peter R. 2003. What Darwin's Finches Can Teach Us about the Evolutionary Origin and Regulation of Biodiversity. *Bioscience* 53:965–975.

that differences in beak sizes are due to genetic differences in the population. In other words, they found that beak size was a heritable trait.

By measuring many birds every year, the Grants were able to assemble a detailed portrait of natural selection in action. In the study shown in Figure 23.4, they measured beak depth from 1976 to 1978. In the wet year of 1976, the plants of Daphne Major produced an abundance of the small, tender seeds that these finches could easily eat. However, a severe drought occurred in 1977. During this year, the plants on Daphne Major tended to produce few of the smaller seeds, which the finches rapidly consumed. Therefore, the finches resorted to eating larger, drier seeds, which are harder to crush. As a result, birds with larger beaks were more likely to survive and reproduce because they were better at breaking open these large seeds. As shown in the data, the average beak depth of birds in the population increased substantially, from 8.8 mm in predrought offspring to 9.8 mm in postdrought offspring. How do we explain these results? According to evolutionary theory, birds with larger beaks were more likely to survive and pass this trait on to their offspring. Overall, these results illustrate the power of natural selection to alter the features of a trait—in this case, beak depth—in a given population.

Experimental Questions

1. What features of Daphne Major made it a suitable field site for studying the effects of natural selection?
2. Why is beak depth in finches a good trait for a study of natural selection? What environmental conditions were important to allow the Grants to collect information concerning natural selection?
3. What were the results of the Grants' study following the drought in 1977? What impact did these results have on the theory of evolution?

23.2 Observations of Evolutionary Change

As we have just seen, the Grants provided evidence for evolutionary change in a population of finches. Observations that support the theory of evolution have been gleaned from many sources (Table 23.2). Historically, the first evidence of biological evolution came from studies of the fossil record, the distribution of related species on our planet, selective breeding experiments, and the comparison of similar anatomical features in different species. More recently, additional observations that illustrate the process of evolution have been revealed at the molecular level. By comparing DNA sequences from many different species, evolutionary biologists have gained great insight into the relationship between the evolution of species and the associated changes in the genetic material. In this section, we will survey a variety of observations that show the process of evolutionary change.

Fossils Show Successive Evolutionary Change

As discussed in Chapter 22, the fossil record has provided biologists with evidence of the history of life on Earth. Today, scientists have access to a far more extensive fossil record than was available to Darwin or other scientists of his time. Even though the fossil record is still incomplete, the many fossils that have been discovered often provide detailed information regarding evolutionary change in a series of related organisms. When fossils are compared according to their age, from oldest to youngest, successive evolutionary change becomes apparent.

Table 23.2 Observations of Biological Evolution

Type of observation	Description
Fossil record	When fossils are compared according to their age, from oldest to youngest, successive evolutionary change becomes apparent.
Biogeography	Unique species found on islands and other remote areas have arisen because the species in these locations have evolved in isolation from the rest of the world.
Convergent evolution	Two different species from different lineages sometimes become anatomically similar because they occupy similar environments. This indicates that natural selection promotes adaptation to a given environment.
Selective breeding	The traits in domesticated species have been profoundly modified by selective breeding (also called artificial selection) in which breeders choose the parents that have desirable traits.
Homologies:*	
Anatomical	Evolutionarily related species may possess homologous structures that have been modified in ways that allowed them to be used differently by each species. In some cases, such structures are no longer needed and degenerate to vestigial structures.
Developmental	An analysis of embryonic development often reveals similar anatomical features that point to past evolutionary relationships.
Molecular	At the molecular level, certain characteristics are found in all living cells, suggesting that all living species are derived from a common ancestor. In addition, species that are closely related evolutionarily have DNA sequences that are more similar to each other than they are to those in distantly related organisms.

*Homology is a similarity that occurs due to descent from a common ancestor.

Let's consider a couple of examples in which paleontologists have observed evolutionary change. In 2005, fossils of *Tiktaalik roseae*, nicknamed fishapod, were discovered by Ted Daeschler, Neil Shubin, and Farish Jenkins. The discovery of fishapod illuminates one of several steps that led to the evolution of tetrapods, which are animals with four legs. *T. roseae* is called a **transitional form** because it displays an intermediate state between an ancestral form and the form of its descendants (Figure 23.5). In this case, the fishapod is a transitional form between fishes, which have fins for locomotion, and tetrapods, which are four-limbed animals. Unlike a true fish, *T. roseae* had a broad skull, a flexible neck, and eyes mounted on the top of its head like a crocodile. Its interlocking rib cage suggests it had primitive lungs. Perhaps the most surprising discovery was that its pectoral fins (those on the side of the body) revealed the beginnings of a primitive wrist and five finger-like bones. These appendages would have allowed *T. roseae* to support its body on shallow river bottoms and lift its head above the water to search for prey, and perhaps even move out of the water for short periods. During the Devonian period, 417–354 million years ago, this could have been an important advantage in the marshy floodplains of large rivers.

One of the best-studied examples of evolutionary change is that of the horse family, modern members of which include

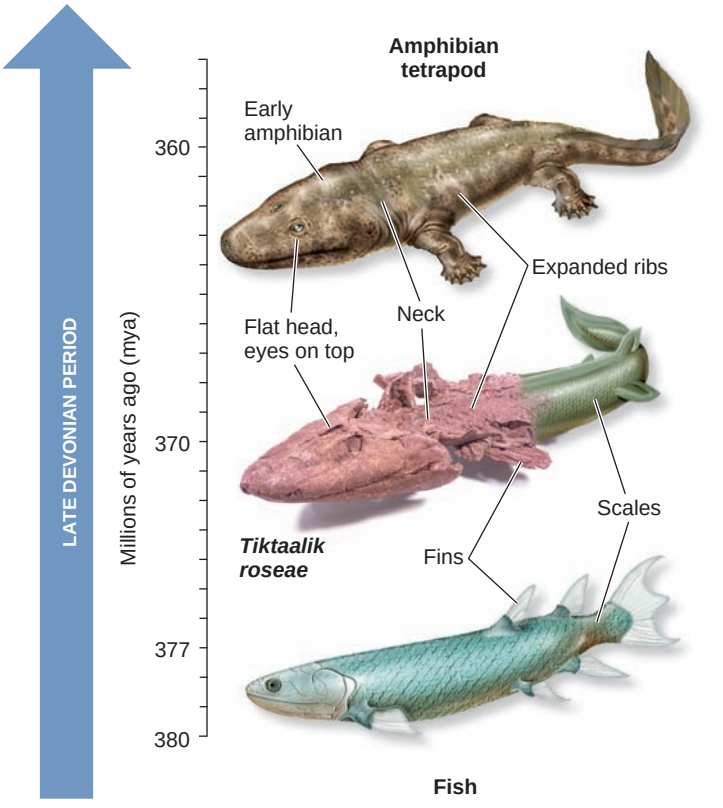


Figure 23.5 **Evolutionary change in the tetrapod lineage, showing a transitional form.** This figure shows two early tetrapod ancestors, a Devonian fish and the transitional form *Tiktaalik roseae*, as well as one of their descendants, an early amphibian. An analysis of the fossils shows that *T. roseae*, also known as a fishapod, had both fish and amphibian characteristics, so it was likely able to survive brief periods out of the water.

horses, zebras, and donkeys. These species, which are large, long-legged animals adapted to living in open grasslands, are the remaining descendants of a long lineage that produced many species that have subsequently become extinct since its origin approximately 55 million years ago. Examination of the horse lineage provides a particularly interesting case of how evolution involves adaptation to changing environments.

The earliest known fossils of the horse family revealed that the animals were small with short legs and broad feet (Figure 23.6). Early horses, such as *Hyracotherium*, lived in wooded habitats and are thought to have browsed on leaves and herbs. Between the time of these first members of the horse family and modern horses, the fossil record has revealed changes in size, foot anatomy, and tooth morphology among this group of related species. Early horses were the size of dogs, whereas modern horses typically weigh more than a half ton. *Hyracotherium* had four toes on its front feet and three on its hind feet. Instead of hooves, these toes were encased in fleshy pads. By comparison, the feet of modern horses have a single toe, enclosed in a tough, bony hoof. The fossil record shows an increase in the length of the central toe, the development of a bony hoof, and the loss of the other toes. Finally, the teeth of *Hyracotherium* were relatively small compared to those of modern horses. Over the course of millions of years, horse molars have increased in size and developed a complex pattern of ridges.

How do evolutionary biologists explain these changes in horse characteristics? The changes can be attributed to natural

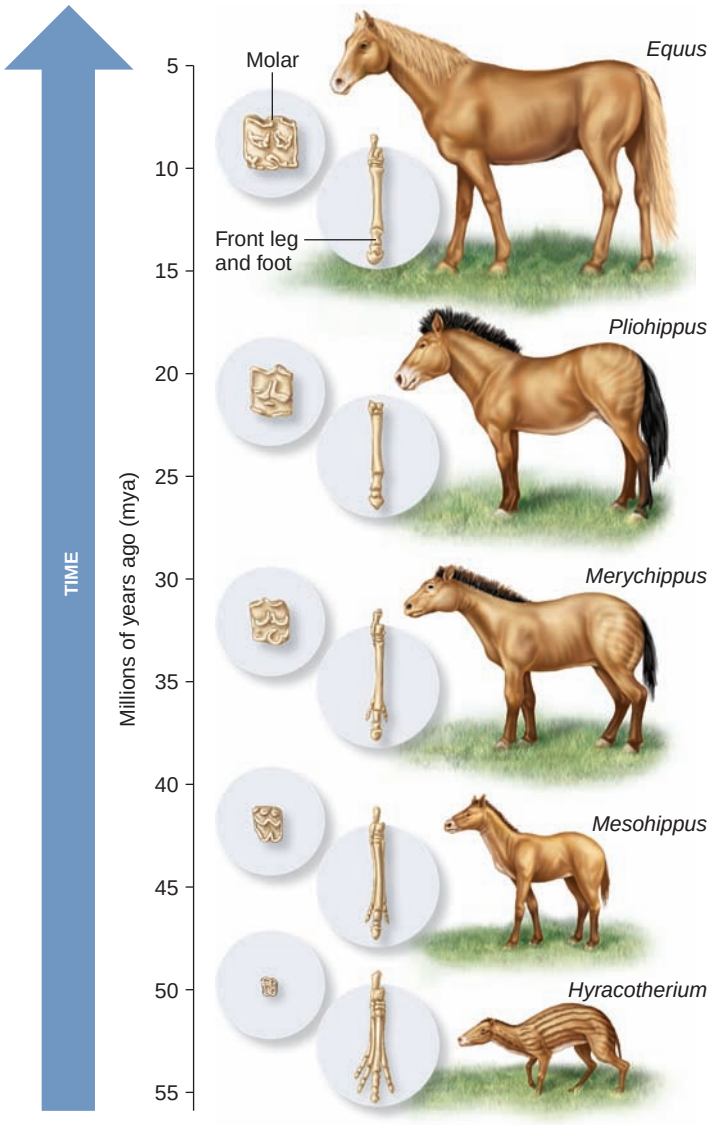

Figure 23.6 **Evolutionary changes that led to the modern horse.** Some major changes occurred in horses' body size, foot anatomy, and tooth morphology. These changes are hypothesized to be due to natural selection in a changing environment over the last 55 million years. Note: This figure is meant to emphasize changes that led to modern horses. The evolutionary pathway that produced modern horses involves several branches and is described in Chapter 26.

selection, which acted upon existing variation and resulted in adaptations to changes in global climates. Over North America, where much of horse evolution occurred, large areas of dense forests were replaced with grasslands. The increase in size and changes in foot structure enabled horses to escape predators more easily and travel greater distances in search of food. The changes seen in horses' teeth are consistent with a shift from eating more tender leaves to eating grasses and other vegetation that are more abrasive and require more chewing.

Biogeography Indicates That Species in a Given Area Have Evolved from Pre-existing Species

Biogeography is the study of the geographic distribution of extinct and living species. Patterns of past evolution are often found in the natural geographic distribution of related species. From such studies, scientists have discovered that isolated continents and island groups have evolved their own distinct plant and animal communities. As mentioned earlier, Darwin himself observed several species of finches found on the Galápagos Islands that had unique characteristics, such as beak shapes, when compared with similar finches found on the mainland. Scientists now hypothesize that these island species evolved from mainland birds that had migrated to the islands and then became adapted to a variety of new feeding habits (see Figure 23.2).

Around the world, islands, which are isolated from other large landmasses, provide numerous examples in which geography has played a key role in the evolution of new species. Islands often have many species of plants and animals that are **endemic**, which means they are naturally found only in a particular location. Most endemic island species have closely related relatives on nearby islands or the mainland. For example, consider the island fox (*Urocyon littoralis*), which lives on the Channel Islands located off the coast of southern California between Los Angeles and Santa Barbara (**Figure 23.7**). This type of fox is found nowhere else in the world. It weighs about 3–6 pounds and feeds largely on insects, mice, and fruits. The island fox evolved from the mainland gray fox (*Urocyon cinereoargenteus*), which is much larger, usually 7–11 pounds. During the last Ice Age, about 16,000–18,000 years ago, the Santa Barbara channel was frozen and narrow enough for ancestors of the mainland gray fox to cross over to the Channel Islands. When the Ice Age ended, the ice melted and sea levels rose, causing the foxes to be cut off from the mainland. Over the last 16,000–18,000 years, the population of foxes on the Channel Islands evolved into the smaller island fox, which is now considered a different species from the larger gray fox. The gray fox is still found on the mainland. The smaller size of the island fox is an example of island dwarfing, a phenomenon in which the size of large animals isolated on an island shrinks dramatically over many generations. It is an example of natural selection in which smaller size provides a survival and reproductive advantage probably because of limited food.

The evolution of major animal groups is also correlated with known changes in the distribution of landmasses on the Earth. The first mammals arose approximately 200 million years ago, when the area that is now Australia was still connected to the other continents. However, the first placental mammals, which have a long internal gestation and give birth to well-developed offspring, evolved much later after continental drift had separated Australia from the other continents (refer back to Figure 22.10). Except for a few species of bats and rodents that have migrated to Australia more recently, Australia lacks any of the larger, terrestrial placental mammals. How do biologists explain this observation? It is consistent with the idea that placental mammals first arose somewhere other than Australia, and that the barrier of a large ocean prevented most terrestrial placental mammals from migrating there. On the other hand, Australia has more than 100 species of kangaroos, koalas, and other marsupials, most of which are not found on any other continent. Marsupials are a group of mammal species in which young are born in a very immature condition and then develop further in the mother's abdominal pouch, which covers the mammary glands.

Figure 23.7 **The evolution of an endemic island species from a mainland species.** **(a)** The smaller island fox found on the Channel Islands evolved from **(b)** the gray fox found on the California mainland.

Concept check: *Explain how geography played a key role in the evolution of the island fox.*

Evolutionary theory is consistent with the idea that the existence of these unique Australian species is due to their having evolved in isolation from the rest of the world for millions of years.

Convergent Evolution Suggests Adaptation to the Environment

The process of natural selection is also evident in the study of plants and animals that have similar characteristics, even though they are not closely related evolutionarily. This similarity is the result of **convergent evolution**, in which two different species from different lineages have independently evolved similar characteristics because they occupy similar environments. For example, both the giant anteater (*Myrmecophaga tridactyla*), found in South America, and the echidna (*Tachyglossus aculeatus*), found in Australia, have a long snout and tongue. Both species independently evolved these adaptations that enable them to feed on ants (Figure 23.8a). The giant anteater is a placental mammal, whereas the echidna is an egg-laying mammal known as a monotreme, so they are not closely related evolutionarily.

Another example of convergent evolution involves aerial rootlets found in vines such as English ivy (*Hedera helix*) and wintercreeper (*Euonymus fortunei*) (Figure 23.8b). Based on differences in their structures, these aerial rootlets appear to have developed independently as an effective means to cling to the support on which a vine attaches itself.

A third example of convergent evolution is revealed by the molecular analysis of fishes that live in very cold water. Antifreeze proteins enable certain species of fishes to survive the subfreezing temperatures of Arctic and Antarctic waters by inhibiting the formation of ice crystals in body fluids. Researchers have determined that these fishes are an interesting case of convergent evolution (Figure 23.8c). Among different species of fishes, one of five different genes has independently evolved to produce antifreeze proteins. For example, in the sea raven (*Hemitripterus americanus*), the antifreeze protein is rich in the amino acid cysteine, and the secondary structure of the protein is in a β sheet conformation. In contrast, the antifreeze protein in the longhorn sculpin (*Trematomus nicolai*) is encoded by an entirely different gene. The antifreeze protein in this species is rich in the amino acid glutamine, and the secondary structure of the protein is largely composed of α helices.

The similar characteristics in the examples shown in Figure 23.8—for example, the snouts of the anteater and the echidna—are called **analogous structures** or **convergent traits**. They represent cases in which characteristics have arisen independently, two or more times, because different species have occupied similar types of environments on the Earth.

Selective Breeding Is a Human-Driven Form of Selection

The term **selective breeding** refers to programs and procedures designed to modify traits in domesticated species. This practice, also called **artificial selection**, is related to natural selection. In forming his theory of evolution, Charles Darwin was influenced by his observations of selective breeding by pigeon breeders. The primary difference between natural and artificial selection is how the parents are chosen. Natural selection occurs because of natural variation in reproductive success. Organisms that are able to survive and reproduce are more likely to pass their genes on to future generations. Environmental factors often determine which individuals will be successful parents. In artificial selection, the breeder chooses as parents those individuals that possess traits that are desirable from a human perspective.

The underlying phenomenon that makes selective breeding possible is genetic variation. Within a population, variation may exist in a trait of interest. For selective breeding to be successful, the underlying cause of the phenotypic variation is usually related to differences in **alleles**, variant forms of a particular gene, that determine the trait. The breeder will choose

(a) The long snouts and tongues of the giant anteater (left) and the echidna (right), allow them to feed on ants.

(b) The aerial rootlets of English ivy (left) and wintercreeper (right), allow them to climb up supports.

(c) The sea raven (left) and the longhorn sculpin (right) have antifreeze proteins that enable them to survive in frigid waters.

Figure 23.8 Examples of convergent evolution. All three pairs of organisms shown in this figure are not closely related evolutionarily but occupy similar environments, suggesting that natural selection promotes the formation of similar adaptations that are well suited to a particular environment.

Concept check: Can you think of another example in which two species that are not closely related have a similar adaptation?

parents with desirable phenotypic characteristics. For centuries, humans have employed selective breeding to obtain domesticated species with interesting or agriculturally useful characteristics. For example, many common breeds of dog are the result of selective breeding strategies (Figure 23.9). All dogs are members of the same species, *Canis lupus*, subspecies *familiaris*, so they can be interbred to produce offspring. Selective breeding can dramatically modify the traits in a species. When you compare certain breeds of dogs (for example, a greyhound and a dachshund), they hardly look like members of the same species! Recent work in 2007 by Nathan Sutter and colleagues indicates that the size of dogs may be determined by alleles in the *Igf1* gene that encodes a growth hormone called insulin-like growth factor 1. A particular allele of this gene was found to be common to all small breeds of dogs and nearly absent from very large breeds, suggesting that this allele is a major contributor to body size in small breeds of dogs.

Likewise, most of the food we eat—including products such as grains, fruits, vegetables, meat, milk, and juices—is obtained from species that have been profoundly modified by selective breeding strategies. For example, certain characteristics in the wild mustard plant (*Brassica oleracea*) have been modified by selective breeding to create several varieties of domesticated crops, including broccoli, Brussels sprouts, cabbage, and

(a) Bulldog

(b) Greyhound

(c) Dachshund

Figure 23.9 **Common breeds of dogs that have been obtained by selective breeding.** By selecting parents carrying the alleles that influence traits desirable to humans, dog breeders have produced breeds with distinctive features. All the dogs in this figure carry the same kinds of genes (for example, genes that affect their size, shape, and fur color). However, the alleles for many of these genes are different among these dogs, thereby allowing humans to select for or against them and produce breeds with strikingly different phenotypes.

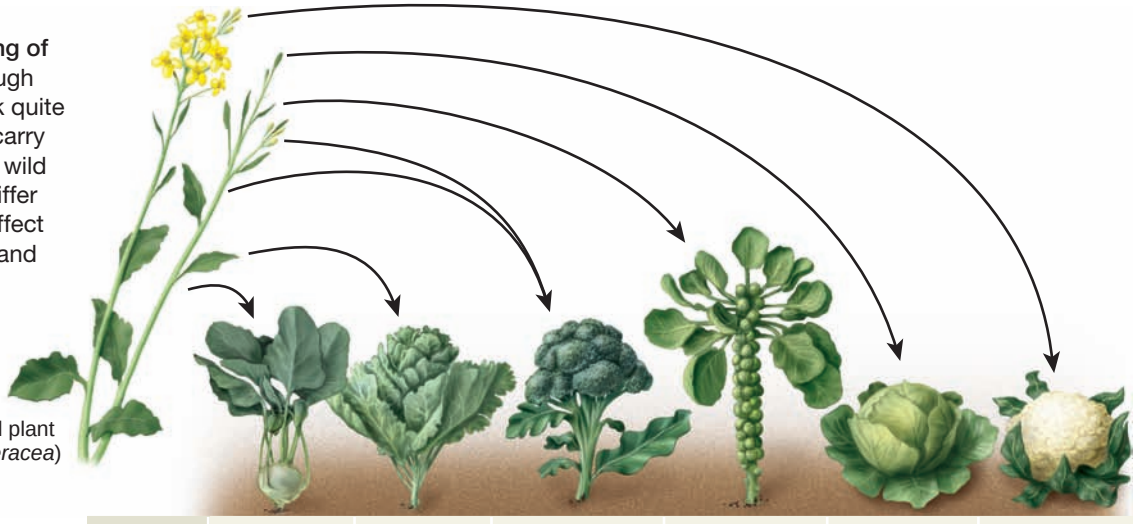
cauliflower (Figure 23.10). The wild mustard plant is native to Europe and Asia, and plant breeders began to modify its traits approximately 4,000 years ago. As seen here, certain traits in the domestic strains differ dramatically from those of the original wild species. These varieties are all members of the same species. They can interbreed to produce viable offspring. For example, in the grocery store you may have seen broccoflower, which is produced from a cross between broccoli and cauliflower.

As a final example, Figure 23.11 shows the results of an artificial selection experiment on corn begun at the University of Illinois Agricultural Experiment Station in 1896, several years before the rediscovery of Mendel's laws. This study began with 163 ears of corn with an oil content ranging from 4 to 6%. In each of 80 succeeding generations, corn plants were divided into two separate groups. In one group, members with the highest oil content in the kernels were chosen as parents of the next generation. In the other group, members with the lowest oil content were chosen. After many generations, the oil content in the first group rose to over 18%. In the other group, it dropped to less than 1%. These results show that selective breeding can modify a trait in a very directed manner.

A Comparison of Anatomical, Developmental, and Molecular Homologies Shows Evolution of Related Species from a Common Ancestor

Let's now consider other widespread observations of the process of evolution among living organisms. In biology, the term

Figure 23.10 **Crop plants developed by selective breeding of the wild mustard plant.** Although these six agricultural plants look quite different from each other, they carry many of the same alleles as the wild mustard plant. However, they differ from each other in alleles that affect the formation of stems, leaves, and flowers.



Wild mustard plant (*Brassica oleracea*)

Strain	Kohlrabi	Kale	Broccoli	Brussels sprouts	Cabbage	Cauliflower
Modified trait	Stem	Leaves	Flower buds and stem	Lateral leaf buds	Terminal leaf bud	Flower buds

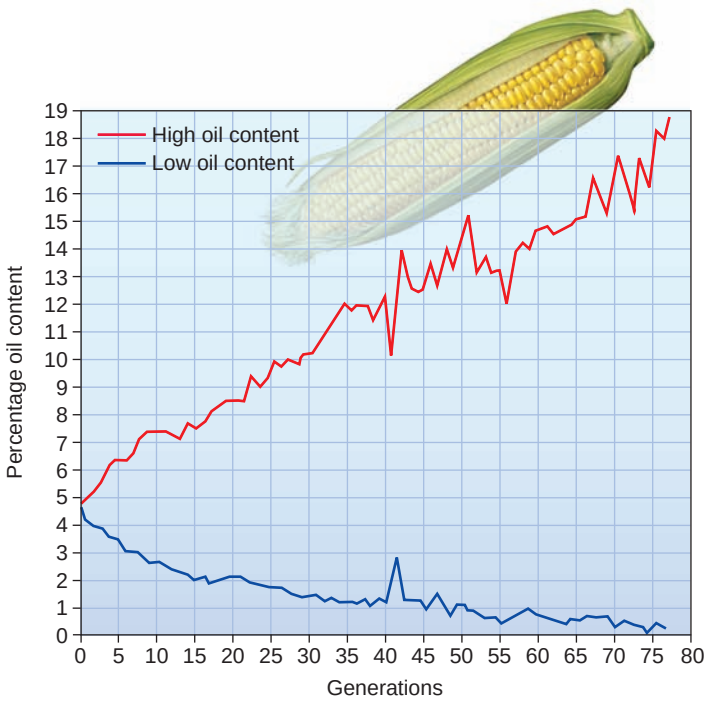


Figure 23.11 **Results of selective breeding for oil content in corn plants.** In this example, corn plants were selected for breeding based on high or low oil content of the kernels. Over the course of many generations, this had a major impact on the amount of corn oil (an agriculturally important product) made by the two groups of plants.

Concept check: *When comparing Figures 23.9, 23.10, and 23.11, what general effects of artificial selection do you observe?*

homology refers to a similarity that occurs due to descent from a common ancestor. Two species may have a similar trait because the trait was originally found in a common ancestor. As described next, such homologies may involve anatomical, developmental, or molecular features.

Anatomical Homologies As noted by Theodosius Dobzhansky, many observations regarding the features of living organisms simply cannot be understood in any meaningful scientific way except as a result of evolution. A comparison of vertebrate anatomy is a case in point. An examination of the limbs of modern vertebrate species reveals similarities that indicate the same set of bones has undergone evolutionary changes, becoming modified to perform different functions in different species. As seen in Figure 23.12, the forelimbs of vertebrates have a strikingly similar pattern of bone arrangements. These are termed **homologous structures**—structures that are similar to each other because they are derived from a common ancestor. The forearm has developed different functions among various vertebrates, including grasping, walking, flying, swimming, and climbing. The theory of evolution explains how these animals have descended from a common ancestor and how natural selection has resulted in modifications to the original set of bones in ways that ultimately allowed them to be used for several different purposes.

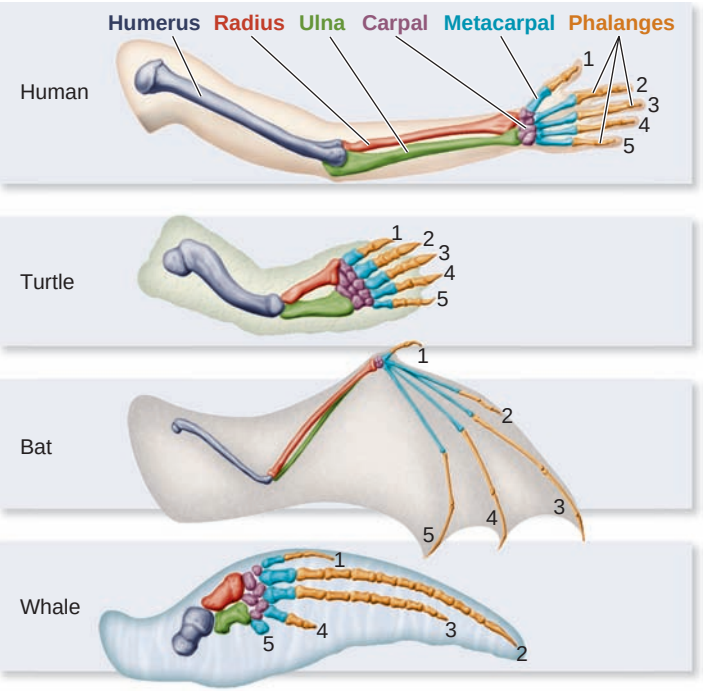

Figure 23.12 **An example of anatomical homology: homologous structures found in vertebrates.** The same set of bones is found in the human arm, turtle arm, bat wing, and whale flipper, although their relative sizes and shapes have been modified in ways that allow them to perform different functions. This homology suggests that all of these animals evolved from a common ancestor.

Another result of evolution is the phenomenon of **vestigial structures**, which are anatomical features that have no current function but resemble structures of their presumed ancestors (Table 23.3). An interesting case is found in humans. People have a complete set of muscles for moving their ears, even though most people are unable to do so. By comparison, many modern mammals can move their ears, and presumably this was an important trait in a distant human ancestor. Why would organisms have structures that are no longer useful? Within the context of evolutionary theory, vestigial structures are evolutionary relics. Organisms having vestigial structures share a common ancestry with organisms in which the structure is

Table 23.3 Examples of Vestigial Structures in Animals

Organism	Vestigial structure(s)
Humans	Tail bone and muscles to wiggle ears in adult
Boa constrictors	Skeletal remnants of hip and hind leg bones
Whales	Skeletal remnants of a pelvis
Manatees	Fingernails on the flippers
Hornbills and cuckoos	Fibrous cords that were derived from the common carotid arteries. In certain families of birds, both of the common carotid arteries are nonfunctional, fibrous cords. Their vascular function has been assumed by other vessels.

functional. Natural selection maintains functional structures in a population of individuals. However, if a species changes its lifestyle so that the structure loses its purpose, the selection that would normally keep the structure in a functional condition is no longer present. When this occurs, the structure may degenerate over the course of many generations due to the accumulation of mutations that limit its size and shape. Natural selection may eventually eliminate such traits due to the inefficiency and cost of producing unused structures.

Developmental Homologies Another example of homology is the way that animals undergo embryonic development. Species that differ substantially at the adult stage often bear striking similarities during early stages of embryonic development. These temporary similarities are called developmental homologies. In addition, evolutionary history is revealed during development in certain organisms, such as vertebrates. For example, if we consider human development, several features are seen in the embryo that are not present at birth. Human embryos possess rudimentary gill ridges like a fish embryo, even though human embryos receive oxygen via the umbilical cord. The presence of gill ridges indicates that humans evolved from an aquatic species that had gill slits. A second observation is that every human embryo has a bony tail. It is difficult to see the advantage of such a structure *in utero*, but easier to understand its presence assuming that an ancestor of the human lineage possessed a tail. These observations, and many others, illustrate that closely related species share similar developmental pathways.

Molecular Homologies Our last examples of homology due to evolution involve molecular studies. When scientists examine the features of organisms at the molecular level, similarities called **molecular homologies** are found. For example, all living species use DNA to store information. RNA molecules such as mRNA, tRNA, and rRNA are used to access that information, and proteins are the functional products of most genes. Furthermore, certain biochemical pathways are found in all or nearly all species, although minor changes in the structure and function of proteins involved in these pathways have occurred. For example, all species that use oxygen, which constitutes the great majority of species on our planet, have similar proteins that together make up an electron transport chain and an ATP synthase. In addition, nearly all living organisms can break down glucose via a metabolic pathway that is described in Chapter 7. How do we explain these types of observations? Taken together, they indicate that such molecular phenomena arose very early in the origin of life and have been passed to all or nearly all modern forms.

The most compelling observation at the molecular level indicating that modern life-forms are derived from a common ancestor is revealed by analyzing genetic sequences and finding genetic homologies. The same type of gene is often found in diverse organisms. Furthermore, the degree to which a genetic sequence from different species is similar reflects the evolutionary relatedness of those species. As an example, let's consider the *p53* gene, which encodes the p53 protein that plays a role in preventing cancer (see Chapter 14, Figure 14.15). Figure 23.13 shows a short amino acid sequence that makes up part of

	Short amino acid sequence within the p53 protein	Percentages of amino acids in the whole p53 protein that are identical to human p53
Human (*Homo sapiens*)	Val Pro Ser Gln Lys Thr Tyr Gln Gly Ser Tyr Gly Phe Arg Leu Gly Phe Leu His Ser Gly Thr	100

Figure 23.13 **An example of genetic homology: a comparison of a short amino acid sequence within the p53 protein from nine different animals.** This figure compares a short region of the p53 protein, which plays a role in preventing cancer. Amino acids are represented by three-letter abbreviations. The orange-colored amino acids in the sequences are identical to those in the human sequence. The numbers in the right column indicate the percentage of amino acids within the whole p53 protein that is identical with the human p53 protein, which is 393 amino acids in length. For example, 95% of the amino acids, or 373 of 393, are identical between the p53 sequence found in humans and in Rhesus monkeys.

Concept check: In the sequence shown in this figure, how many amino acid differences are there between the following pairs: Rhesus and green monkeys, Congo puffer fish and European flounder, and Rhesus monkey and Congo puffer fish? What do these differences tell you about the evolutionary relationships among these four species?

the p53 protein from a variety of species, including five mammals, one bird, and three fish. The top sequence is the human p53 sequence, and the right column describes the percentages of amino acids within the entire sequence that are identical to the entire human sequence. Amino acids in the other species that are identical to humans are highlighted in orange. The sequences from the two monkeys are the most similar to humans, followed by the other two mammalian species (rabbit and dog). The three fish sequences are the least similar to the human sequence, but the fish sequences tend to be similar to each other. Taken together, the data shown in Figure 23.13 illustrate two critical points regarding gene evolution. First, specific genes are found in a diverse array of species such as mammals, birds, and fishes. Second, the sequences of closely related species tend to be more similar to each other than they are to distantly related species. The mechanisms for this second observation are discussed in the next section.

23.3 The Molecular Processes That Underlie Evolution

Historically, the study of evolution was based on a comparison of the anatomies of extinct and modern species to identify similarities between related species. However, the advent of molecular approaches for analyzing DNA sequences has revolutionized the field of evolutionary biology. Now we can analyze how changes in the genetic material are associated with changes in phenotype. In this section, we will examine some of the molecular changes in the genetic material that are associated with evolution.

Homologous Genes Are Derived from a Common Ancestral Gene

When two or more genes are derived from the same ancestral gene, they are called **homologous genes**. The analysis of homologous genes reveals details of evolutionary change at the molecular level. How do homologous genes arise? As an example, let's consider a gene in two different species of bacteria that encodes a transport protein involved in the uptake of metal ions into bacterial cells. Homologous genes that are in different species are termed **orthologs**. Millions of years ago, these two species had a common ancestor (Figure 23.14). Over time, the common ancestor diverged into additional species, eventually evolving into *Escherichia coli*, *Clostridium acetylbutylicum*, and many other species. Since this divergence, the metal transporter gene has accumulated mutations that altered its sequence, though the similarity between the *E. coli* and the *C. acetylbutylicum* genes remains striking. In this case, the two sequences are similar because they were derived from the same ancestral gene, but they are not identical due to the independent accumulation of different random mutations.

Gene Duplications Create Gene Families

Demonstrations of evolutionary change can also be found within a single species. Two or more homologous genes found within a single species are termed **paralogs** of each other. Rare gene duplication events can produce multiple copies of a gene and ultimately lead to the formation of a gene family. A **gene family** consists of two or more copies of paralogous genes within the genome of a single species. A well-studied example of a gene family is the globin gene family found in humans and many other animal species. The globin genes encode polypeptides that are subunits of proteins that function in oxygen binding. One such protein is hemoglobin, which is found in red blood cells and carries oxygen throughout the body. The globin gene family is composed of 14 genes that are hypothesized to be derived from a single ancestral globin gene. According to an evolutionary analysis, the ancestral globin gene first duplicated between 500 to 600 million years ago. Since that

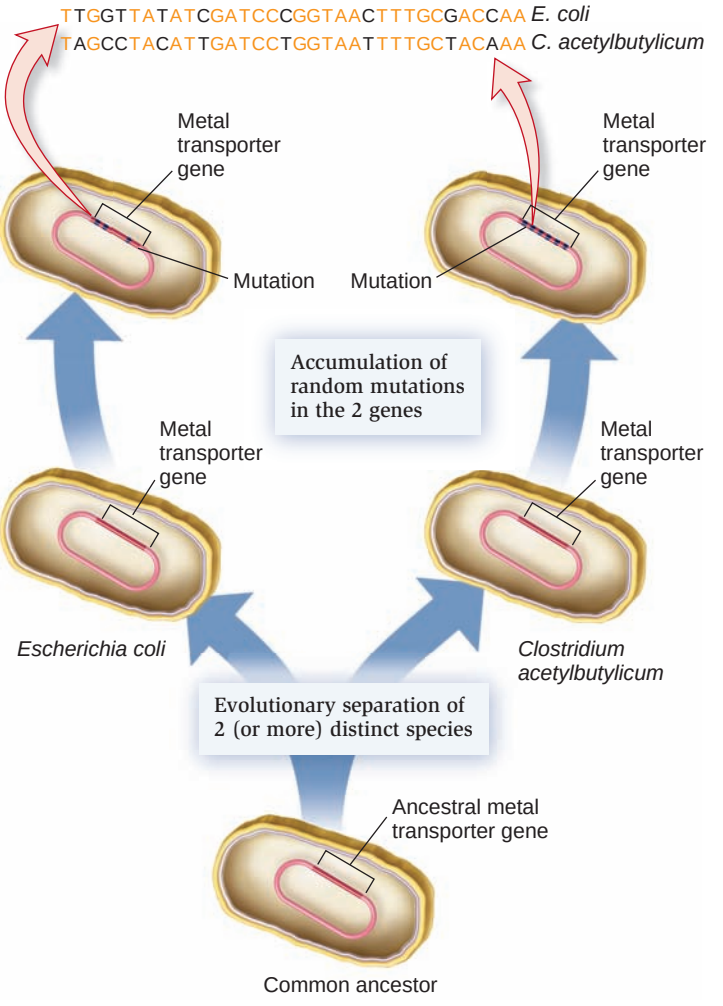

Figure 23.14 The evolution of orthologs, homologous genes from different species. After the two species diverged from each other, the genes accumulated random mutations that resulted in similar, but not identical, gene sequences called orthologs. These orthologs in *E. coli* and *C. acetylbutylicum* encode metal transporters. Only one of the two DNA strands is shown from each of the genes. Bases that are identical between the two genes are shown in orange.

Concept check: Why do these orthologs have similar gene sequences? Why aren't they identical?

time, additional duplication events and chromosomal rearrangements have produced the current number of 14 genes on three different human chromosomes (refer back to Figure 21.8).

What is the advantage of a gene family? Even though all of the globin polypeptides are subunits of proteins that play a role in oxygen binding, the accumulation of changes in the various family members has created globins that are more specialized in their function. For example, myoglobin is better at binding and storing oxygen in muscle cells, whereas the hemoglobins are better at binding and transporting oxygen via the red blood cells. Also, different globin genes are expressed during different stages of human development. The epsilon (ε)- and zeta (ζ)-globin genes are expressed very early in embryonic life, while the gamma (γ)-globin genes exhibit maximal expression during the second and third trimesters of gestation. Following birth, the γ-globin gene is turned off and the β-globin gene is turned on. These differences in the expression of the globin genes reflect the differences in the oxygen transport needs of humans during the embryonic, fetal, and postpartum stages of life.

What is the evolutionary significance of the globin gene family regarding adaptation? On land, egg cells and small embryos are very susceptible to drying out if they are not protected in some way. Species such as birds and reptiles lay eggs with a protective shell around them. Most mammals, however, have become adapted to a terrestrial environment by evolving internal gestation. The ability to develop young internally has been an important factor in the survival and proliferation of mammals. The embryonic and fetal forms of hemoglobin allow the embryo and fetus to capture oxygen from the bloodstream of the mother.

Genomes & Proteomes Connection

New Genes in Eukaryotes Have Evolved via Exon Shuffling

Thus far, we have considered how evolutionary change results in the formation of related genes, which are described as orthologs and paralogs. Evolutionary mechanisms are also revealed when exons, the parts of genes that encode protein domains, are compared within a single species. Many proteins, particularly those found in eukaryotic species, have a modular structure composed of two or more domains with different functions. For example, certain transcription factors have discrete domains involved with hormone binding, dimerization, and DNA binding. The glucocorticoid receptor discussed in Chapter 13 has a domain that binds the hormone, a second domain that facilitates protein dimerization, and a third domain that allows the glucocorticoid receptor to bind to glucocorticoid response elements (GREs) next to genes. By comparing the modular structure of eukaryotic proteins with the genes that encode them, geneticists have discovered that each domain tends to be encoded by one exon or by a series of two or more adjacent exons.

During the evolution of eukaryotic species, many new genes have been produced by a type of mutation known as **exon shuffling**. During this process, an exon and part of the flanking noncoding introns from one gene are inserted into another gene, thereby producing a new gene that encodes a protein with an additional domain (Figure 23.15). This process may also involve the duplication and rearrangement of exons. Exon shuffling results in novel genes that express proteins with diverse functional modules. Such proteins may alter traits in the organism and therefore be subjected to natural selection.

Exon shuffling may occur by more than one mechanism. One possibility is that a double crossover could promote the insertion of an exon into another gene (Figure 23.15). This is called nonhomologous recombination because the two regions involved in the crossover are not homologous to each other. Alternatively, transposable elements, described in Chapter 21, may promote the movement of exons into other genes.

Horizontal Gene Transfer Also Contributes to the Evolution of Species

At the molecular level, the type of evolutionary change depicted in Figures 23.13 through 23.15 is called **vertical evolution**. In these cases, new species arise from pre-existing species by the accumulation of genetic changes, such as gene mutations, gene duplications, and exon shuffling. Vertical evolution involves genetic changes in a series of ancestors that form a lineage. In addition to vertical evolution, species accumulate genetic changes by **horizontal gene transfer**—a process in which an organism incorporates genetic material from another organism without being the offspring of that organism. Horizontal gene transfer can involve the exchange of genetic material between members of the same species or different species.

How does horizontal gene transfer occur? Figure 23.16 illustrates one possible mechanism for horizontal gene transfer. In this example, a eukaryotic cell has engulfed a bacterial cell by endocytosis. During the degradation of the bacterium in an endocytic vesicle, a bacterial gene happens to escape to the nucleus of the cell, where it is inserted into one of the chromosomes. In this way, a gene has been transferred from a bacterial species to a eukaryotic species. By analyzing gene sequences among many different species, researchers have discovered that horizontal gene transfer is a common phenomenon. This process can occur from prokaryotes to eukaryotes, from eukaryotes to prokaryotes, between different species of prokaryotes, and between different species of eukaryotes. Therefore, when we view evolution, it is not simply a matter of one species evolving into one or more new species via the accumulation of random mutations. It also involves the horizontal transfer of genes among different species, enabling those species to acquire new traits that foster the evolutionary process.

Gene transfer among bacterial species is relatively widespread. As discussed in Chapter 18, bacterial species may carry out three natural mechanisms of gene transfer known as

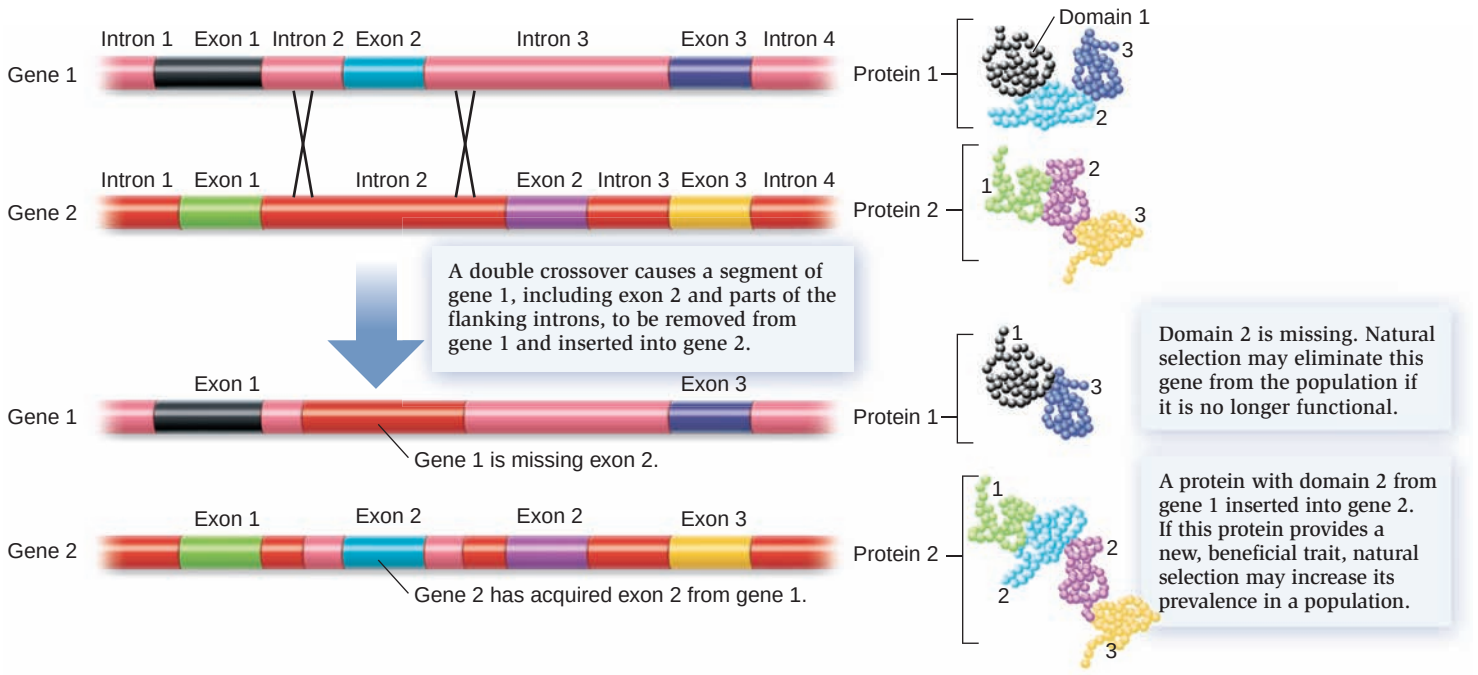

Figure 23.15 **The process of exon shuffling.** In this example, a segment of one gene containing an exon and part of the flanking introns has been inserted into another gene. A rare, abnormal crossing-over event called nonhomologous recombination may cause this to happen. Exon shuffling results in proteins that have new combinations of domains and new combinations of functions.

Concept check: *What is the evolutionary advantage of exon shuffling?*

conjugation, transformation, and transduction. By analyzing the genomes of bacterial species, scientists have determined that many genes within a given bacterial genome are derived from horizontal gene transfer. Genome studies have suggested that as much as 20–30% of the variation in the genetic composition of modern prokaryotic species can be attributed to this process. For example, in *E. coli* and *Salmonella typhimurium*, roughly 17% of their genes have been acquired via horizontal gene transfer during the past 100 million years. The roles of these acquired genes are quite varied, though they commonly involve functions that are beneficial for survival and reproduction. These include genes that confer antibiotic resistance, the ability to degrade toxic compounds, and pathogenicity (the ability to cause disease).

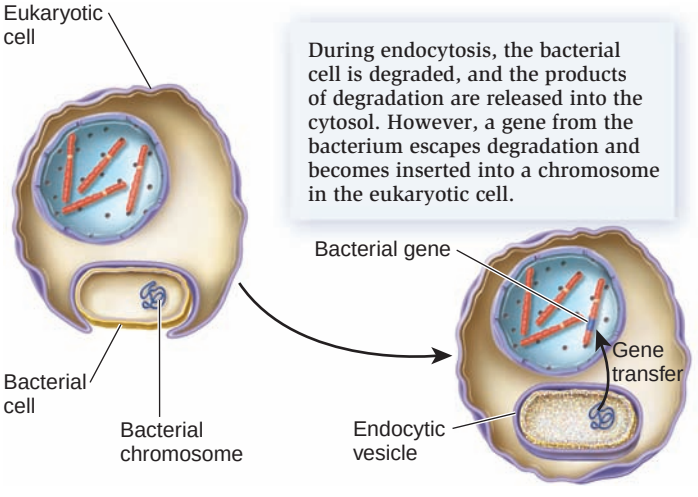

Figure 23.16 **Horizontal gene transfer from a bacterium to a eukaryote.** In this example, a bacterium is engulfed by a eukaryotic cell, and a bacterial gene is transferred to one of the eukaryotic chromosomes.

Evolution at the Genomic Level Involves Changes in Chromosome Structure and Number

Thus far, we have considered several ways that a species might acquire new genetic variation. These include random mutations within pre-existing genes, gene duplications to create gene families, exon shuffling, and horizontal gene transfer. Evolution also occurs at the genomic level, involving changes in chromosome structure and number. When comparing the chromosomes of closely related species, changes in chromosome structure and/or number are common.

As an example, Figure 23.17 compares the banding patterns of the three largest chromosomes in humans and the corresponding chromosomes in chimpanzees, gorillas, and orangutans. (Refer back to Chapter 15, Figure 15.1 for a description of chromosome banding.) The banding patterns are strikingly similar because these species are closely related evolutionarily. Even so, you can see some interesting differences. Humans have one large chromosome 2, but this chromosome is divided into two separate chromosomes in the other three species. This explains why human cells have 23 pairs of chromosomes, whereas ape

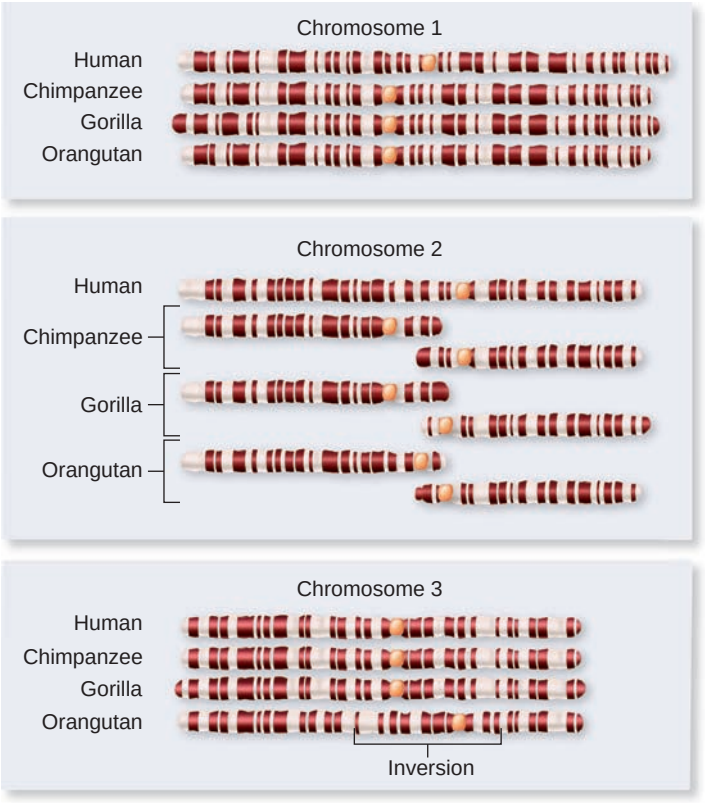

Figure 23.17 **An example of genomic evolution.** This figure is a comparison of banding patterns among the three largest human chromosomes and the corresponding chromosomes in the chimpanzee, gorilla, and orangutan. It is a schematic drawing of Giemsa-stained chromosomes. The differences between these chromosomes illustrate the changes that have occurred during the evolution of these related species.

Concept check: *Describe two changes in chromosome structure that have occurred among these chromosomes.*

cells have 24. The fusion of the two smaller chromosomes during the development of the human lineage may have caused this difference in chromosome number. Another interesting change in chromosome structure is seen in chromosome 3. The banding patterns among humans, chimpanzees, and gorillas are very similar, but the orangutan has a large inversion that flips the arrangement of bands in the centromeric region. As discussed in Chapter 25, changes in chromosome structure and number may affect the ability of two organisms to breed with one another. In this way, such changes have been important in the establishment of new species.

Summary of Key Concepts

23.1 The Theory of Evolution

- Biological evolution is a heritable change in one or more characteristics of a population or species from one generation to the next.
- Charles Darwin proposed the theory of evolution based on his understanding of geology and population growth and his observations of species in their natural settings. His voyage on the *Beagle*, during which he studied many species including finches on the Galápagos Islands, was particularly influential. (Figure 23.1, Table 23.1)
- Darwin expressed his theory of evolution as descent with modification through variation and natural selection. As a result of natural selection, genetic variation changes from generation to generation to produce populations of organisms with traits (adaptations) that promote greater reproductive success. (Figure 23.2)
- The Grants' research on finches showed how changes in beak size in response to changes in the food supply are driven by natural selection. (Figures 23.3, 23.4)

23.2 Observations of Evolutionary Change

- Observations of evolution include the fossil record, biogeography, convergent evolution, selective breeding, and homologies. (Table 23.2)
- Fossils show successive evolutionary change over long periods of time. The fossil record often reveals transitional forms that link past ancestors to modern species. (Figures 23.5, 23.6)
- Biogeography, the geographic distribution of species, provides information on how certain species are evolutionarily related to each other. Often, when populations become isolated, they evolve into new species. (Figure 23.7)
- Convergent evolution involves independent adaptations that result in analogous structures because organisms have evolved in similar environments. (Figure 23.8)
- Selective breeding, also known as artificial selection, illustrates how changes in genetic variation over the course of many generations can dramatically change the traits of organisms. (Figures 23.9, 23.10, 23.11)
- Homologous structures are similar to each other because they are derived from a common ancestral structure. The set of bones in the forearms of vertebrates is one example. (Figure 23.12)
- Vestigial structures are found in species because they are derived from structures that were once functional, but have degenerated because they no longer have use in a modern species. (Table 23.3)
- Homologies can also be seen during embryonic development and at the molecular level in gene and protein sequences. (Figure 23.13)

23.3 The Molecular Processes That Underlie Evolution

- Molecular evolution refers to the molecular changes in the genetic material that underlie the phenotypic changes associated with evolution.
- Homologous genes are derived from the same ancestral gene. They accumulate random mutations that make their sequences somewhat different. Orthologs are homologous genes in different species. (Figure 23.14)

- Paralogs are homologous genes in the same species that are produced by gene duplication events. Paralogs constitute a gene family. An example is the globin gene family that promoted the evolutionary adaptation of internal gestation.
- Exon shuffling is a form of mutation in which exons are inserted into genes and thereby create proteins with additional functional domains. (Figure 23.15)
- Another mechanism that produces genetic variation is horizontal gene transfer in which genetic material is transferred between different species. Such genetic changes are subject to natural selection. (Figure 23.16)
- Evolution is also associated with changes in chromosome structure and chromosome number. (Figure 23.17)

Assess and Discuss

Test Yourself

1. A change in one or more characteristics of a population that is heritable and occurs from one generation to the next is called
   a. natural selection.
   b. sexual selection.
   c. population genetics.
   d. evolution.
   e. inheritance of acquired characteristics.
2. Lamarck's vision of evolution differed from Darwin's in that Lamarck believed
   a. living things evolved in an upward direction.
   b. behavioral changes modified heritable traits.
   c. genetic differences among individuals in the population allowed for evolution.
   d. a and b only.
   e. none of the above.
3. Which of the following scientists influenced Darwin's views on the nature of population growth?
   a. Cuvier c. Lyell e. Wallace
   b. Malthus d. Hutton
4. An evolutionary change in which an organism's characteristics change in ways that make it better suited to its environment is
   a. natural selection. d. evolution.
   b. an adaptation. e. both a and c.
   c. an acquired characteristic.
5. Vestigial structures are anatomical structures
   a. that have more than one function.
   b. that were functional in an ancestor but no longer have a useful function.
   c. that look similar in different species but have different functions.
   d. that have the same function in different species but have very different appearances.
   e. of the body wall.
6. Which of the following is an example of a developmental homology seen in human embryonic development and other vertebrate species that are not mammals?
   a. gill ridges c. tail e. all of the above
   b. umbilical cord d. both a and c
7. Two or more homologous genes found within a particular species are called
   a. homozygous. c. paralogs. e. duplicates.
   b. orthologs. d. alleles.
8. The phenomenon of exon shuffling
   a. creates new gene products by changing the pattern of intron removal in pre-mRNA.
   b. creates new genes by inserting exons and flanking introns into a different gene sequence, thereby introducing a new domain in the gene product.
   c. deletes one or more bases in a single gene.
   d. rearranges the introns in a particular gene, creating new gene products.
   e. both a and d.
9. Horizontal gene transfer
   a. is a process in which an organism incorporates genetic material from another organism without being the offspring of that organism.
   b. can involve the exchange of genetic material among individuals of the same species.
   c. can involve the exchange of genetic material among individuals of different species.
   d. can be all of the above.
   e. can be a and b only.
10. Genetic variation can occur as a result of
    a. random mutations in genes.
    b. exon shuffling.
    c. gene duplication.
    d. horizontal gene transfer.
    e. all of the above.

Conceptual Questions

1. Evolution that results in adaptation is rooted in two phenomena: genetic variation and natural selection. In a very concise way (three sentences or less), describe how genetic variation and natural selection can bring about evolution.
2. What is convergent evolution? How does it support the theory of evolution?
3. What are homologous structures? Explain how the homologous forelimbs of vertebrates support the theory of evolution.

Collaborative Questions

1. The term natural selection is sometimes confused with the term evolution. Discuss the meanings of these two terms. Explain how the terms are different and how they are related to each other.
2. Make a list of the observations made by biologists that support the theory of evolution. Which of the observations on your list do you find the most convincing and the least convincing?

Population Genetics

24

Chapter Outline

Colorful African cichlids. Color is a factor that influences the choice of mates in populations of cichlids.

Kimbareta, age 19, lives in the Democratic Republic of Congo (formerly Zaire) with his parents, one brother, and two sisters. Kimbareta has sickle-cell disease, which causes his red blood cells to occasionally form a sickle shape. The sickled cells may block the flow of blood through his vessels. This results in tissue and organ damage along with painful episodes involving his arms, legs, chest, and abdomen. In some people with this disease, stroke may even occur. Sickle-cell disease is an inherited disease with a recessive pattern of inheritance. It is caused by a mutation in a gene that encodes β-globin, a subunit of hemoglobin that carries oxygen in the red blood cells.

Many different recessive diseases have been identified by geneticists. Most of them are very rare. However, in the village where Kimbareta lives, sickle-cell disease is surprisingly common. Nearly 2% of the inhabitants have sickle-cell disease, which is similar to other places in the country. How can we explain such a high occurrence of a serious inherited disease? If natural selection tends to eliminate detrimental genetic variation, as we saw in Chapter 23, why does the sickle-cell allele persist in this population? As we will see later, biologists have discovered that the effect of the allele in heterozygotes is the underlying factor. Heterozygotes who carry one copy of the sickle-cell allele and one copy of the more common (non-disease-causing) allele have an increased resistance to malaria.

Population genetics is the study of genes and genotypes in a population. A **population** is a group of individuals of the same species that occupy the same environment. For sexually reproducing species, members of a given population can interbreed with one another. The central issue in population genetics is genetic variation—its extent within populations, why it exists, how it is maintained, and how it changes over the course of many generations. Population genetics helps us to understand how underlying genetic variation is related to phenotypic variation. These include issues such as mate preference (see chapter-opening photo) and the prevalence of certain disease-causing alleles, such as the sickle-cell allele, in human populations.

Population genetics emerged as a branch of genetics in the 1920s and 1930s. Its mathematical foundations were developed by theoreticians who extended the principles of Darwin and Mendel by deriving equations to explain the occurrence of genotypes within populations. These foundations can be largely attributed to British evolutionary biologists J. B. S. Haldane and Ronald Fisher, and American geneticist Sewall Wright. As we will see, several researchers who analyzed the genetic composition of natural and experimental populations provided support for their mathematical theories. More recently, population geneticists have used techniques to probe genetic variation at the molecular level. In addition, the staggering improvements in computer technology have aided population geneticists in the analysis of data and the testing of genetic hypotheses.

We will begin this chapter by exploring the extent of genetic variation that occurs in populations and how such variation is subject to change. In many cases, genetic changes are associated with evolutionary adaptations, which are characteristics of a species that have evolved over a long period of time by the process of natural selection. In this chapter, we will examine the various mechanisms that promote genetic change, including natural selection, genetic drift, migration, and nonrandom mating.

24.1 Genes in Populations

Population genetics is an extension of our understanding of Darwin's theory of natural selection, Mendel's laws of inheritance, and newer studies in molecular genetics. All of the alleles for every gene in a given population make up the **gene pool**. Each member of the population receives its genes from its parents, which, in turn, are members of the gene pool. Individuals that reproduce contribute to the gene pool of the next generation. Population geneticists study the genetic variation within the gene pool and how such variation changes from one generation to the next. The emphasis is often on understanding the variation in alleles among members of a population. In this section, we will examine some of the general features of populations and gene pools.

Populations Are Dynamic Units

As mentioned, a population is a group of individuals of the same species that occupy the same environment and can interbreed with one another. Certain species occupy a wide geographic range and are divided into discrete populations due to geographic isolation. For example, distinct populations of a given species may be located on different sides of a mountain.

Populations change from one generation to the next. How might populations become different? Populations may change in size and geographic location. As the size and locations of a population change, their genetic composition generally changes as well. Some of the genetic changes involve adaptation, in which a population becomes better suited to its environment, making it more likely to survive and reproduce. For example, a population of mammals may move from a warmer to a colder geographic location. Over the course of many generations, natural selection may change the population such that the fur of the animals is thicker and provides better insulation against the colder temperatures.

Genomes & Proteomes Connection

Genes Are Usually Polymorphic

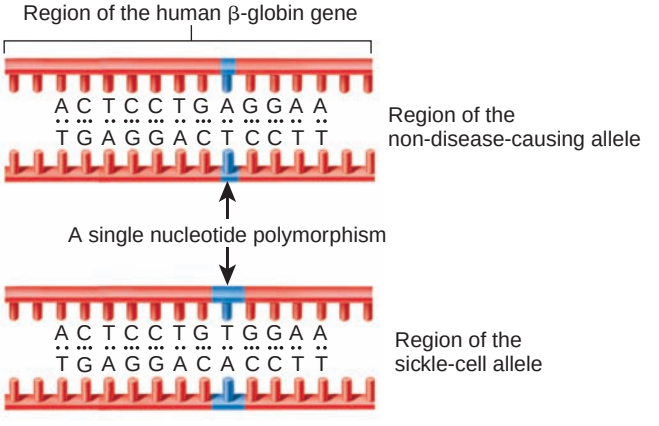
The term **polymorphism** (from the Greek, meaning many forms) refers to the phenomenon that a trait displays variation within a population. Populations that are polymorphic for a trait have more than one phenotype for that trait. Figure 24.1 illustrates a striking example of polymorphism in the elder-flowered orchid (*Dactylorhiza sambucina*). Throughout the range of this species in Europe, both yellow- and red-flowered individuals are prevalent.

Polymorphism in a trait is usually due to two or more alleles of a gene that influence the trait. Geneticists also use the term polymorphism to describe the variation in genes; this is sometimes called genetic or gene polymorphism. A gene that commonly exists as two or more alleles in a population is a

Figure 24.1 An example of polymorphism: the two color variations found in the orchid *Dactylorhiza sambucina*.

polymorphic gene. To be considered polymorphic, a gene must exist in at least two alleles, and each allele must occur at a frequency that is greater than 1%. By comparison, a **monomorphic gene** exists predominantly as a single allele in a population. When 99% or more of the alleles of a given gene are identical in a population, the gene is considered to be monomorphic.

What types of molecular changes cause genes to be polymorphic? A polymorphism may involve various types of changes such as a deletion of a significant region of the gene, a duplication of a region, or a change in a single nucleotide. This last phenomenon is called a **single-nucleotide polymorphism** (**SNP**). SNPs ("snips") are the smallest type of genetic change that can occur within a given gene, and also the most common. For example, the sickle-cell allele discussed at the beginning of the chapter involves a single nucleotide change in a gene that encodes β-globin, a subunit of the oxygen-carrying protein called hemoglobin. The non-disease-causing allele and sickle-cell allele represent a single-nucleotide polymorphism of the β-globin gene:



Relative to the non-disease-causing allele, this is a single-nucleotide substitution of an A (in the top strand) to a T (in the sickle-cell allele).

SNPs represent 90% of all the variation in human DNA sequences that occurs among different people. In human populations, a gene that is 2,000–3,000 bp in length will, on average, contain 10 different SNPs. Likewise, SNPs with a frequency of 1% or more are found very frequently among genes of nearly all species. Polymorphism is the norm for relatively large, healthy populations of nearly all species, as evidenced by the occurrence of SNPs within most genes.

Why do we care about SNPs? One reason is their importance in human health. By analyzing SNPs in human genes, researchers have determined that these small variations in DNA sequences can affect the function of the proteins encoded by the genes. These effects on the proteome, in turn, may influence how humans develop diseases, such as heart disease, diabetes, and sickle-cell disease. Variations in SNPs in the human population are also associated with how people respond to viruses, drugs, and vaccines. The analysis of SNPs may be instrumental in the current and future development of **personalized medicine**—a medical practice in which information about a patient's genotype is used to tailor their medical care. For example, an analysis of a person's SNPs may be used to select between different types of medication or customize their dosage. In addition, SNP analysis may reveal that a person has a high predisposition to the development of a particular disease, such as heart disease. Such information may be used to initiate preventative measures to minimize the chances of developing the disease.

Population Genetics Is Concerned with Allele and Genotype Frequencies

To analyze genetic variation in populations, one approach is to consider the frequency of alleles in a quantitative way. Two fundamental calculations are central to population genetics: **allele frequencies** and **genotype frequencies**. Allele and genotype frequencies are defined as follows:

$$\text{Allele frequency} = \frac{\text{Number of copies of a specific allele in a population}}{\text{Total number of all alleles for that gene in a population}}$$

$$\text{Genotype frequency} = \frac{\text{Number of individuals with a particular genotype in a population}}{\text{Total number of individuals in a population}}$$

Although allele and genotype frequencies are related, make sure you keep in mind a clear distinction between them. As an example, let's consider a population of 100 four-o'clock plants (*Mirabilis jalapa*) with the following genotypes:

49 red-flowered plants with the genotype C^RC^R

42 pink-flowered plants with the genotype C^RC^W

9 white-flowered plants with the genotype C^WC^W

When calculating an allele frequency for a diploid species, remember that homozygous individuals have two copies of an allele, whereas heterozygotes have only one. For example, in tallying the C^W allele, each of the 42 heterozygotes has one copy of the C^W allele, and each white-flowered plant has two copies. Therefore, the allele frequency for C^W (the white color allele) equals

$$\text{Frequency of } C^W = \frac{(C^RC^W) + 2(C^WC^W)}{2(C^RC^R) + 2(C^RC^W) + 2(C^WC^W)}$$

$$\text{Frequency of } C^W = \frac{42 + (2)(9)}{(2)(49) + (2)(42) + (2)(9)}$$

$$= \frac{60}{200} = 0.3, \text{ or } 30\%$$

This result tells us that the allele frequency of C^W is 0.3. In other words, 30% of the alleles for this gene in the population are the C^W allele.

Let's now calculate the genotype frequency of C^WC^W homozygotes (white-flowered plants).

$$\text{Frequency of } C^WC^W = \frac{9}{49 + 42 + 9}$$

$$= \frac{9}{100} = 0.09, \text{ or } 9\%$$

We see that 9% of the individuals in this population have white flowers.

Allele and genotype frequencies always sum to less than or equal to one (that is, less than or equal to 100%). If a gene is monomorphic, the allele frequency for the single allele will equal or be close to a value of 1.0. For polymorphic genes, if we add up the frequencies for all the alleles in the population, we should obtain a value of 1.0. In our four-o'clock example, the allele frequency of C^W equals 0.3. Therefore, we can calculate the frequency of the other allele, C^R, as equal to $1.0 - 0.3 = 0.7$, because they must add up to 1.0.

The Hardy-Weinberg Equation Relates Allele and Genotype Frequencies in a Population

In 1908, Godfrey Harold Hardy, an English mathematician, and Wilhelm Weinberg, a German physician, independently derived a simple mathematical expression called the Hardy-Weinberg equation that describes the relationship between allele and genotype frequencies when a population is not evolving. Let's examine the Hardy-Weinberg equation using the population of four-o'clock plants that we just considered. If the allele frequency of C^R is denoted by the symbol p and the allele frequency of C^W by q, then

$$p + q = 1$$

For example, if $p = 0.7$, then q must be 0.3. In other words, if the allele frequency of C^R equals 70%, the remaining 30% of alleles must be C^W, because together they equal 100%.

For a gene that exists in two alleles, the **Hardy-Weinberg equation** states that

$$p^2 + 2pq + q^2 = 1$$

If we apply this equation to our flower color gene, then

p^2 = the genotype frequency of C^RC^R homozygotes

$2pq$ = the genotype frequency of C^RC^W heterozygotes

q^2 = the genotype frequency of C^WC^W homozygotes

If $p = 0.7$ and $q = 0.3$, then

Frequency of $C^RC^R = p^2 = (0.7)^2 = 0.49$

Frequency of $C^RC^W = 2pq = 2(0.7)(0.3) = 0.42$

Frequency of $C^WC^W = q^2 = (0.3)^2 = 0.09$

In other words, if the allele frequency of C^R is 70% and the allele frequency of C^W is 30%, the expected genotype frequency of C^RC^R is 49%, C^RC^W is 42%, and C^WC^W is 9%.

To see the relationship between allele frequencies and genotypes in a population, Figure 24.2 considers the relationship between allele frequencies and the way that gametes combine to produce genotypes. To be valid, the Hardy-Weinberg equation carries the assumption that two gametes combine randomly with each other to produce offspring. In a population, the frequency of a gamete carrying a particular allele is equal to the allele frequency in that population. For example, if the allele frequency of C^R equals 0.7, the frequency of a gamete carrying the C^R allele also equals 0.7. The frequency of producing a C^RC^R homozygote with red flowers is $0.7 \times 0.7 = 0.49$, or 49%. The probability of inheriting both C^W alleles, which produces white flowers, is $0.3 \times 0.3 = 0.09$, or 9%. In our Punnett square, two different gamete combinations can produce heterozygotes with pink flowers (Figure 24.2). An offspring could inherit the C^R allele from the pollen and C^W from the egg, or C^R from the egg and C^W from the pollen. Therefore, the frequency of heterozygotes is $pq + pq$, which equals $2pq$. In our example, this is $2(0.7)(0.3) = 0.42$, or 42%. Note that the frequencies total 100%.

The Hardy-Weinberg equation predicts that allele and genotype frequencies will remain the same, generation after generation, but only when a population is in equilibrium. To be in equilibrium, evolutionary mechanisms that can change allele and genotype frequencies are not acting on a population. For this to occur, the following conditions must be met:

- No new mutations occur.
- No natural selection occurs; that is, no survival or reproductive advantage exists for any of the genotypes.
- The population is so large that allele frequencies do not change due to random chance.
- No migration occurs between different populations.

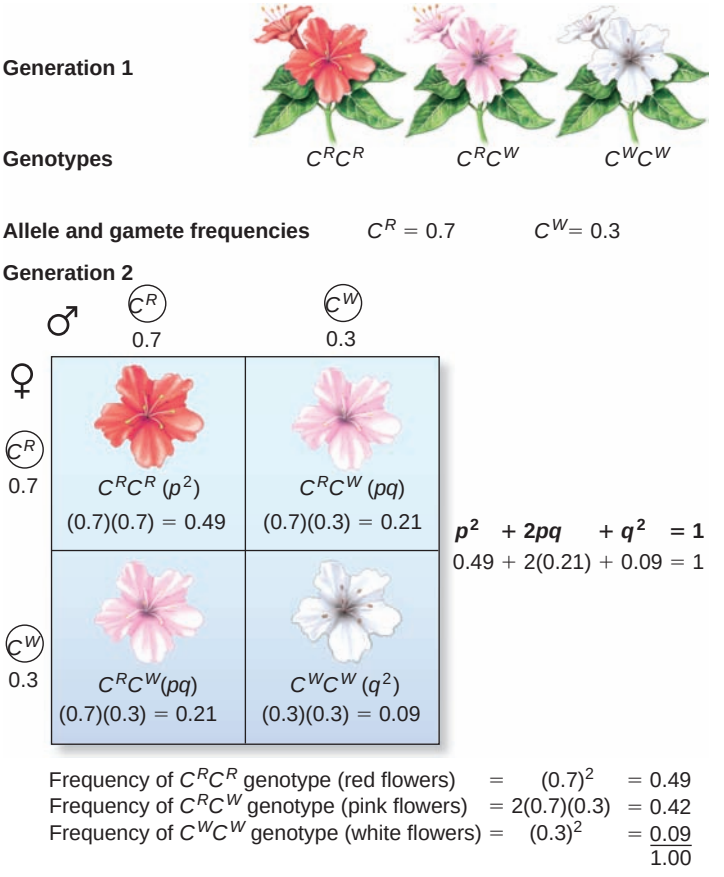


Figure 24.2 Calculating allele and genotype frequencies with the Hardy-Weinberg equation. A population of four-o'clock plants has allele and gamete frequencies of 0.7 for the C^R allele and 0.3 for the C^W allele. Knowing the allele frequencies allows us to calculate the genotype frequencies in the population.

Concept check: What would be the frequency of pink flowers in a population where the allele frequency of C^R is 0.4 and the population is in Hardy-Weinberg equilibrium? Assume that C^R and C^W are the only two alleles.

- Random mating occurs; that is, the members of the population mate with each other without regard to their phenotypes and genotypes.

In reality, no population satisfies the Hardy-Weinberg equilibrium completely. Nevertheless, in large natural populations with little migration and negligible natural selection, the Hardy-Weinberg equilibrium may be nearly approximated for certain genes. Alternatively, researchers may experimentally examine allele and genotype frequencies for one or more genes in a given species and discover they are not in Hardy-Weinberg equilibrium. In such cases, we would say that the population is in disequilibrium—in other words, evolutionary mechanisms are affecting the population. Disequilibrium indicates that evolution is occurring. Conservation biologists and wildlife managers may wish to identify the reason(s) why disequilibrium has occurred because this may impact the future survival of the species. Next, we will examine the mechanisms that cause such evolutionary change.

Microevolution Involves Changes in Allele Frequencies from One Generation to the Next

The term **microevolution** is used to describe changes in a population's gene pool, such as changes in allele frequencies, from generation to generation. What causes microevolution to happen? Such change is rooted in two related phenomena (Table 24.1). First, the introduction of new genetic variation into a population is one essential aspect of microevolution. As discussed in Chapter 23, genetic variation can originate by a variety of molecular mechanisms. New alleles of preexisting genes can arise by random mutation, and new genes can be introduced into a population by gene duplication, exon shuffling, and horizontal gene transfer. Such mutations, albeit rare, provide a continuous source of new variation to populations. In 1926, the Russian geneticist Sergei Chetverikov was the first to suggest that random mutations are the raw material for evolution. However, due to their low rate of occurrence, mutations by themselves do not act as a major factor in dictating the allele frequencies in a population.

Table 24.1 Factors That Govern Microevolution

Sources of new genetic variation*	
New mutations within genes that create new alleles	Random mutations within pre-existing genes introduce new alleles into populations, but at a very low rate. New mutations may be beneficial, neutral, or deleterious. For alleles to rise to a significant percentage in a population, evolutionary mechanisms, such as natural selection, genetic drift, and migration, must operate on them.
Gene duplication**	Abnormal crossover events and transposable elements may increase the number of copies of a gene. Over time, the additional copies can accumulate random mutations and create a gene family.
Exon shuffling***	Abnormal crossover events and transposable elements may promote gene rearrangements in which one or more exons from one gene are inserted into another gene. The protein encoded by such a gene may display a novel function that is acted upon by evolutionary mechanisms.
Horizontal gene transfer***	Genes from one species may be introduced into another species. The transferred gene may be acted upon by evolutionary mechanisms.
Evolutionary mechanisms that alter the frequencies of existing genetic variation	
Natural selection	The process in which individuals that possess certain traits are more likely to survive and reproduce than individuals without those traits. Over the course of many generations, beneficial traits that are heritable become more common and detrimental traits become less common.
Genetic drift	This is a change in genetic variation from generation to generation due to random chance. Allele frequencies may change as a matter of chance from one generation to the next. Genetic drift has a greater impact in a small population.
Migration	Migration can occur between two different populations that have different allele frequencies. The introduction of migrants into a recipient population may change the allele frequencies of that population.
Nonrandom mating	The phenomenon in which individuals select mates based on their phenotypes or genetic lineage. This can alter the relative proportion of homozygotes and heterozygotes that is predicted by the Hardy-Weinberg equation, but it will not change allele frequencies.

* These are examples that affect single genes. Other events, such as crossing over, independent assortment, and changes in chromosome structure and number, may alter the genetic variation among many genes.

** Described in Chapter 21. See Figures 21.7 and 21.8.

*** Described in Chapter 23. See Figures 23.16 and 23.17.

The second phenomenon that is required for evolution to happen is one or more mechanisms that alter the prevalence of a given allele or genotype in a population. These mechanisms are natural selection, genetic drift, migration, and nonrandom mating (Table 24.1). Over the course of many generations, these mechanisms may promote widespread genetic changes in a population. In the remainder of this chapter, we will examine how natural selection, genetic drift, migration, and nonrandom mating can affect the type of genetic variation that occurs when a gene exists as two alleles in a population.

24.2 Natural Selection

Recall from Chapter 23 that **natural selection** is the process in which beneficial traits that are heritable become more common in successive generations. In contrast, detrimental traits that are heritable become less common. Natural selection occurs because some individuals possess more favorable phenotypes compared to others. The phenotypes, in turn, are controlled by the individuals' genotypes. Keep in mind that natural selection itself is not evolution. Rather, natural selection is a key mechanism that causes evolution to happen. Over time, natural selection results in **adaptations**—changes in populations of living organisms that promote their survival and reproduction in a particular environment. In this section, we will examine various ways that natural selection produces adaptations.

Natural Selection Favors Individuals with Greater Reproductive Success

Reproductive success is the likelihood of an individual contributing fertile offspring to the next generation. Natural selection occurs because some individuals in a population have greater reproductive success compared to other individuals. Those individuals having heritable traits that favor reproductive success are more likely to pass those traits to their offspring.

Reproductive success is commonly attributed to two categories of traits. First, certain characteristics make organisms better adapted to their environment and more likely to survive to reproductive age. Such organisms have a greater chance to reproduce and pass their favorable traits to offspring of the next generation. Therefore, natural selection favors individuals with characteristics that provide a survival advantage. Second,

reproductive success may involve traits that are directly associated with reproduction, such as the ability to find a mate and the ability to produce viable gametes and offspring. Traits that enhance the ability of individuals to reproduce, such as brightly colored plumage in male birds, are often subject to natural selection.

As we discussed in Chapter 23, Charles Darwin and Alfred Wallace independently proposed the theory of evolution by natural selection. A modern description of the principles of natural selection can relate our knowledge of molecular genetics to the process of evolution:

1. Within a population, allelic variation arises from random mutations that cause differences in DNA sequences. A mutation that creates a new allele may alter the amino acid sequence of the encoded protein. This, in turn, may alter the function of the protein.
2. Some alleles encode proteins that enhance an individual's survival or reproductive capability compared to other members of the population. For example, an allele may produce a protein that is more efficient at a higher temperature, conferring on the individual a greater probability of survival in a hot climate.
3. Individuals with beneficial alleles are more likely to survive and contribute their alleles to the gene pool of the next generation.
4. Over the course of many generations, allele frequencies of many different genes may change through natural selection, thereby significantly altering the characteristics of a population. The net result of natural selection is a population that is better adapted to its environment and more successful at reproduction.

Fitness Is a Quantitative Measure of Reproductive Success

As mentioned earlier, Haldane, Fisher, and Wright developed mathematical relationships to explain the phenomenon of natural selection. To begin our quantitative discussion of natural selection, we need to consider the concept of **fitness**, which is the relative likelihood that a genotype will contribute to the gene pool of the next generation as compared with other genotypes. Although this property often correlates with physical fitness, the two ideas should not be confused. Fitness is a measure of reproductive success. An extremely fertile individual may have a higher fitness than a less fertile individual that appears more physically fit.

To examine fitness, let's consider an example of a hypothetical gene existing in *A* and *a* alleles. We can assign fitness values to each of the three possible genotypes according to their relative reproductive success. For example, let's suppose the average reproductive successes of the three genotypes are

AA produces 5 offspring
Aa produces 4 offspring
aa produces 1 offspring

By convention, the genotype with the highest reproductive success is given a fitness value of 1.0. Fitness values are denoted by the variable *w*. The fitness values of the other genotypes are assigned values relative to this 1.0 value.

Fitness of *AA*: $w_{AA} = 1.0$

Fitness of *Aa*: $w_{Aa} = 4/5 = 0.8$

Fitness of *aa*: $w_{aa} = 1/5 = 0.2$

Variation in fitness occurs because certain genotypes result in individuals that have a greater reproductive success compared to other genotypes.

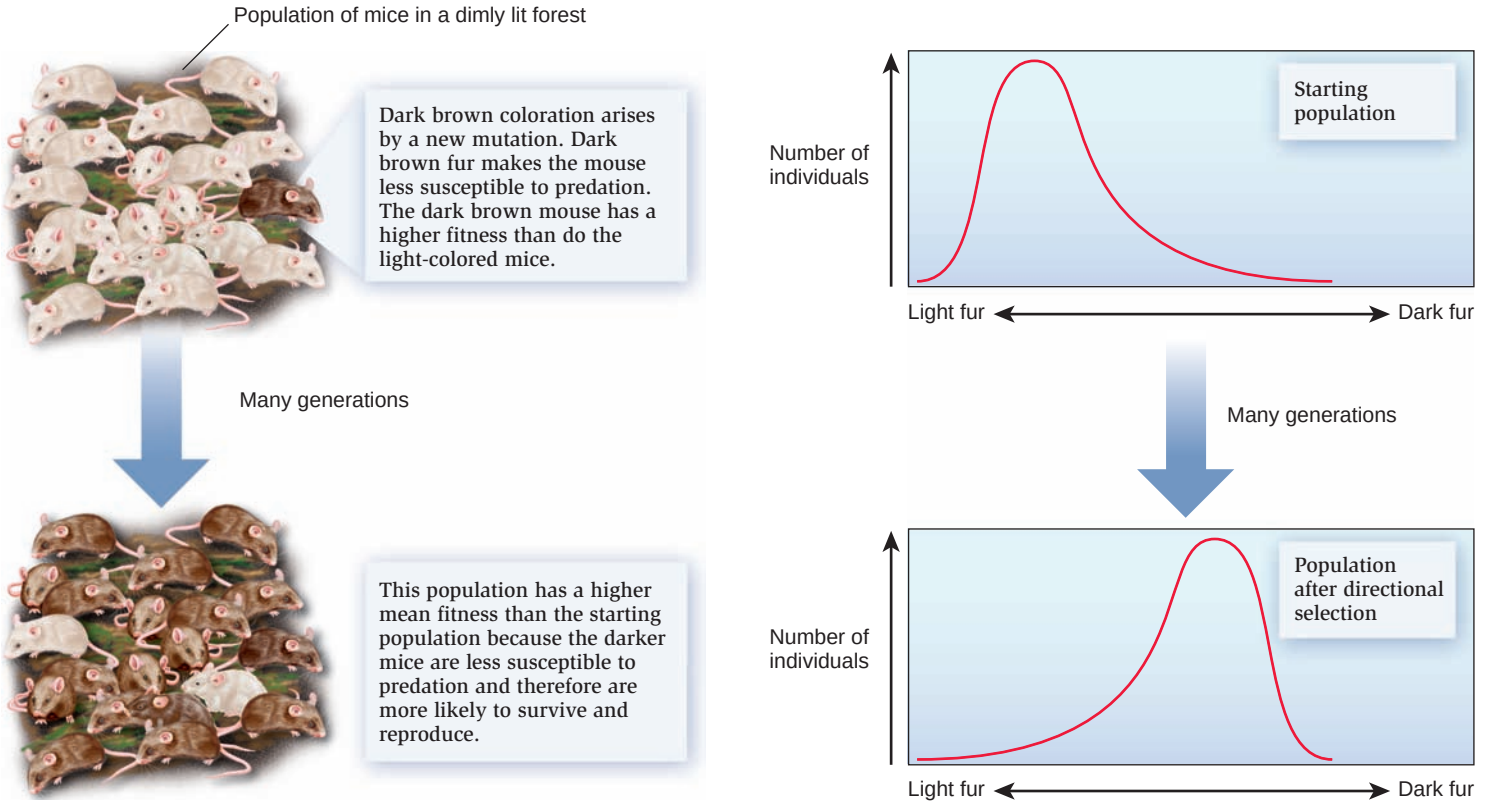
Likewise, the effects of natural selection can be viewed at the level of a population. The average reproductive success of members of a population is called the **mean fitness of the population**. Over many generations, as individuals with higher fitness values become more prevalent, natural selection also increases the mean fitness of the population. In this way, the process of natural selection results in a population of organisms that is well adapted to its native environment and likely to be successful at reproduction.

Natural Selection Can Follow Different Patterns

By studying species in their native environments, population geneticists have discovered that natural selection can occur in several ways. In most of the examples described next, natural selection leads to adaptations such that certain members of a species are more likely to survive to reproductive age.

Directional Selection During **directional selection**, individuals at one extreme of a phenotypic range have greater reproductive success in a particular environment. Different phenomena may initiate the process of directional selection. One way that directional selection may arise is that a new allele may be introduced into a population by mutation, and the new allele may confer a higher fitness in individuals that carry it (Figure 24.3). What are the long-term effects of such directional selection? If the homozygote carrying the favored allele has the highest fitness value, directional selection may cause this favored allele to eventually become predominant in the population, perhaps even leading to a monomorphic gene.

Another reason for directional selection is that a population may be exposed to a prolonged change in its living environment. Under the new environmental conditions, the relative fitness values may change to favor one genotype, and this will promote the elimination of other genotypes. As an example, let's suppose a population of finches on a mainland already has genetic variation that affects beak size (refer back to Figure 23.2). A small number of birds migrate to an island where the seeds are generally larger than they are on the mainland. In this new environment, birds with larger beaks would have a higher fitness because they would be better able to crack open the larger seeds and thereby survive to reproduce. Over the course of many generations, directional selection would



(a) An example of directional selection

(b) Graphical representation of directional selection

Figure 24.3 **Directional selection.** This pattern of natural selection selects for one extreme of a phenotype that confers the highest fitness in the population's environment. **(a)** In this example, a mutation causing darker fur arises in a population of mice. This new genotype confers higher fitness, because mice with dark fur can evade predators and are more likely to survive and reproduce. Over many generations, directional selection will favor the prevalence of darker individuals. **(b)** These graphs show the change in fur color phenotypes in this mouse population before and after directional selection.

Concept check: *Let's suppose the climate on an island abruptly changed such that the average temperature was 10° higher. The climate change is permanent. How would directional selection affect the genetic diversity in a population of mice on the island (1) over the short run and (2) over the long run?*

produce a population of birds carrying alleles that promote larger beak size.

Stabilizing Selection A type of natural selection called **stabilizing selection** favors the survival of individuals with intermediate phenotypes and selects against those with extreme phenotypes. Stabilizing selection tends to decrease genetic diversity. An example of stabilizing selection involves clutch size (number of eggs laid) in birds, which was first studied by British biologist David Lack in 1947. Under stabilizing selection, birds that lay too many or too few eggs per nest have lower fitness values than do those that lay an intermediate number of eggs. When a bird lays too many eggs, many offspring will die due to inadequate parental care and food. In addition, the strain on the parents themselves may decrease their likelihood of survival and therefore their ability to produce more offspring. Having too few offspring, however, does not contribute many individuals to the next generation. Therefore, the most successful parents are those that produce an intermediate clutch size. In the 1980s, Swedish evolutionary biologist Lars Gustafsson and his colleagues examined the phenomenon of stabilizing selection in the collared flycatcher (*Ficedula albicollis*) on the island of Gotland south of Sweden. They discovered that Lack's hypothesis concerning an optimal clutch size appears to be true for this species (Figure 24.4).

Diversifying Selection **Diversifying selection** (also known as disruptive selection) favors the survival of two or more different genotypes that produce different phenotypes. In diversifying selection, the fitness values of a particular genotype are higher in one environment and lower in a different environment, whereas the fitness values of the other genotype vary in an opposite manner. Diversifying selection is likely to occur in populations that occupy heterogeneous environments, so some members of the species will be more likely to survive in each type of environmental condition.

An example of diversifying selection involves colonial bentgrass (*Agrostis capillaris*) (Figure 24.5). In certain locations where this grass is found, such as South Wales, isolated places occur where the soil is contaminated with high levels of heavy metals due to mining. The relatively recent metal contamination has selected for the proliferation of mutant strains of

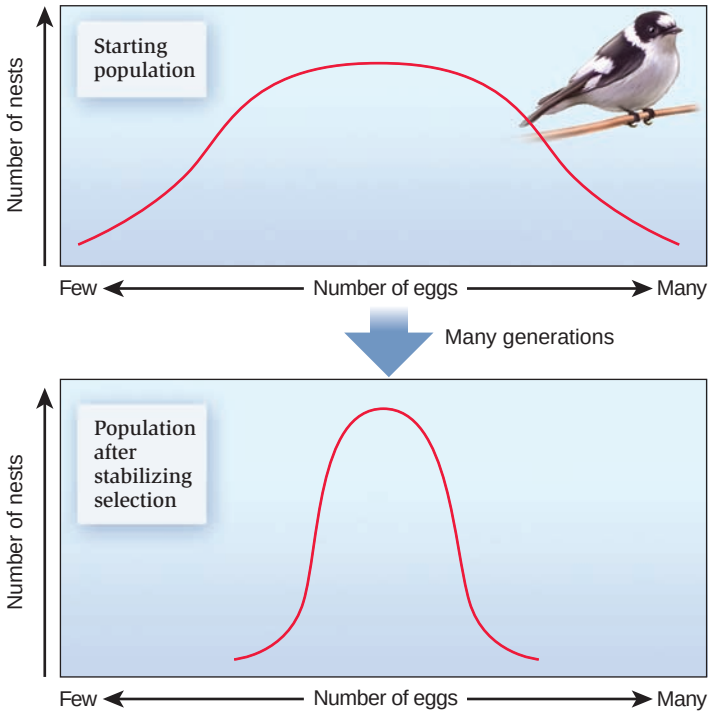


Figure 24.4 **Stabilizing selection.** In this pattern of natural selection, the extremes of a phenotypic distribution are selected against. Those individuals with intermediate traits have the highest fitness. These graphs show the results of stabilizing selection on clutch size in a population of collared flycatchers (*Ficedula albicollis*). This process results in a population with less diversity and more uniform traits.

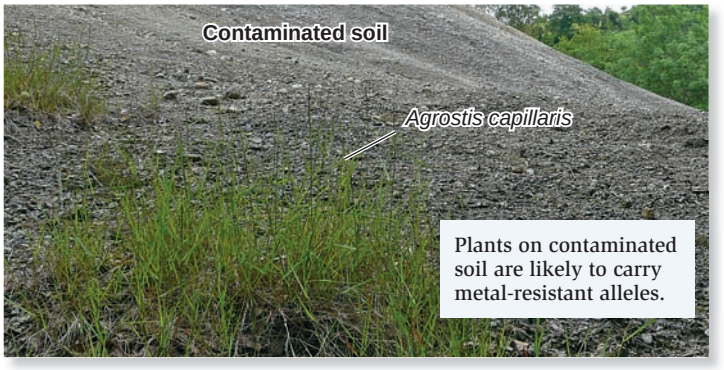
Concept check: Why does stabilizing selection decrease genetic diversity?



(a) Growth of *Agrostis capillaris* on contaminated soil

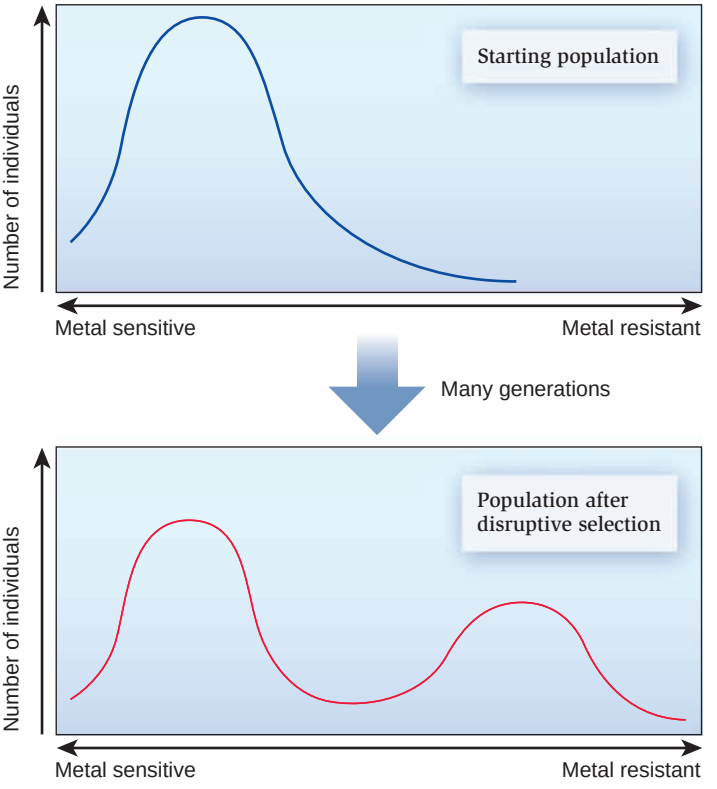
Figure 24.5 **Diversifying selection.** This pattern of natural selection selects for two different phenotypes, each of which is most fit in a particular environment. **(a)** In this example, random mutations have resulted in metal-resistant alleles in colonial bentgrass (*Agrostis capillaris*) that allow it to grow on soil contaminated with high levels of heavy metals such as copper. In uncontaminated soils, the grass does not show metal tolerance. Because both metal-resistant and metal-sensitive alleles are maintained in the population, this situation is an example of diversifying selection due to heterogeneous environments. **(b)** These graphs show the change in phenotypes in this bentgrass population before and after diversifying selection.

A. capillaris that are tolerant of the heavy metals (Figure 24.5a). Such genetic changes enable these mutant strains to grow on contaminated soil but tend to inhibit their growth on normal, noncontaminated soil. These metal-resistant plants often grow on contaminated sites that are close to plants that grow on uncontaminated land and do not show metal tolerance.

Balancing Selection Contrary to a popular misconception, natural selection does not always cause the elimination of "weaker" or less-fit alleles. **Balancing selection** is a type of natural selection that maintains genetic diversity in a population. Over many generations, balancing selection can create a situation known as a **balanced polymorphism**, in which two or more alleles are kept in balance and therefore are maintained in a population over many generations.

How can balancing selection maintain a polymorphism? Population geneticists have identified two common ways that balancing selection can occur. First, for genetic variation involving a single gene, balancing selection can favor the heterozygote over either corresponding homozygote. This situation is called **heterozygote advantage**. Heterozygote advantage can sometimes explain the persistence of alleles that are deleterious in a homozygous condition.

A classic example of heterozygote advantage involves the H^S allele of the human β-globin gene. A homozygous H^SH^S individual has sickle-cell disease, such as Kimbareta, discussed at the beginning of the chapter. This disease leads to the sickling of the red blood cells. The H^SH^S homozygote has a lower fitness than a homozygote with two copies of the more

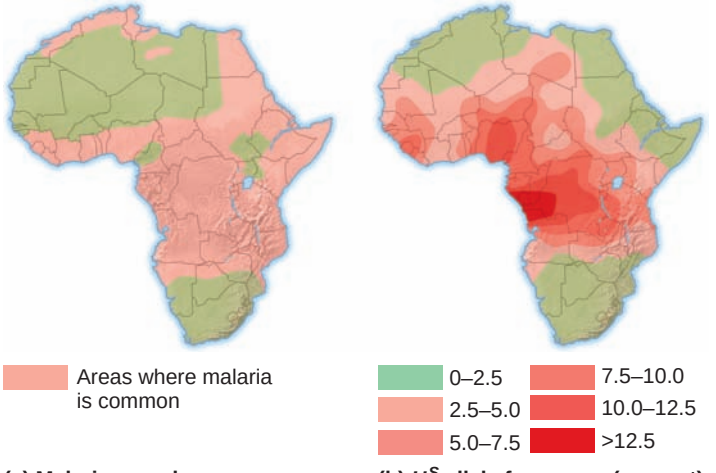


(b) Graphical representation of disruptive selection

common β-globin allele, H^AH^A. Heterozygotes, H^AH^S, do not typically show symptoms of sickle-cell disease but they have an increased resistance to malaria. Compared with H^AH^A homozygotes, heterozygotes have the highest fitness because they have a 10–15% better chance of survival if infected by the malarial parasite *Plasmodium falciparum*. Therefore, the H^S allele is maintained in populations where malaria is prevalent, such as the Democratic Republic of Congo, even though the allele is detrimental in the homozygous state (Figure 24.6). This balanced polymorphism results in a higher mean fitness of the population. In areas where malaria is endemic, a population composed of all H^AH^A individuals would have a lower mean fitness.

Negative frequency-dependent selection is a second way that natural selection can produce a balanced polymorphism. In this pattern of natural selection, the fitness of a genotype decreases when its frequency becomes higher. In other words, rare individuals have a higher fitness, and common individuals have a lower fitness. Therefore, rare individuals are more likely to reproduce, whereas common individuals are less likely, thereby producing a balanced polymorphism in which no genotype becomes too rare or too common.

Negative frequency-dependent selection is thought to maintain polymorphisms among species that are preyed upon by predators. Research has shown that certain predators form a mental "search image" for their prey, which is usually based on the common type of prey in an area. A prey that exhibits a rare polymorphism that affects its appearance is less likely to be recognized by the predator. For example, a prey that is a different color than most other members of its species may not be readily recognized by the predator. Such rarer organisms will be subjected to a lower rate of predation. This type of selection maintains polymorphism among certain prey.



(a) Malaria prevalence **(b) H^S allele frequency (percent)**

Figure 24.6 Balancing selection and heterozygote advantage. **(a)** The geographic prevalence of malaria in Africa. **(b)** The frequency of the H^S allele of the β-globin gene in the same area. In the homozygous condition, the H^S allele causes sickle-cell disease. This allele is maintained in human populations in areas where malaria is prevalent, because the heterozygote (H^AH^S) has a higher fitness than either of the corresponding homozygotes (H^AH^A or H^SH^S).

Concept check: If malaria was eradicated, what would you expect to happen to the frequencies of the H^A and H^S alleles over the long run?

24.3 Sexual Selection

Thus far we have largely focused on examples of natural selection that produce adaptations for survival in particular environments. Now let's turn our attention to a form of natural selection, called **sexual selection**, that is directed at certain traits of sexually reproducing species that make it more likely for individuals to find or choose a mate and/or engage in successful mating. Darwin originally described sexual selection as "the advantage that certain individuals have over others of the same sex and species solely with respect to reproduction." In this section, we will explore how sexual selection can alter traits that play a key role in reproduction.

Sexual Selection Is a Type of Natural Selection That Directly Promotes Reproductive Success

In many species of animals, sexual selection affects male characteristics more intensely than female characteristics. Unlike females, which tend to be fairly uniform in their reproductive success, male success tends to be more variable, with some males mating with many females and others not mating at all. Sexual selection results in the evolution of traits, called secondary sex characteristics, that favor reproductive success. The result of this process is sometimes a significant difference between the appearances of the two sexes within a species, a situation called sexual dimorphism.

Sexual selection operates in one of two ways. In **intrasexual selection**, members of one sex directly compete with each other for the opportunity to mate with individuals of the opposite sex. Examples of traits that result from intrasexual selection in animals include horns in male sheep, antlers in male moose, and the enlarged claw of male fiddler crabs (Figure 24.7a). In fiddler crabs (*Uca paradussumieri*), males enter the burrows of females that are ready to mate. If another male attempts to enter the burrow, the male already inside the burrow stands in the burrow shaft and blocks the entrance with his enlarged claw. Males with the largest claws are more likely to be successful at this behavior and more likely to pass their genes to future generations.

Now let's consider an example of **intersexual selection**, namely, mate choice. This type of sexual selection often results in showy characteristics in males. Figure 24.7b shows a classic example that involves the Indian peafowl (*Pavo cristatus*), the national bird of India. Male peacocks have long and brightly colored tail feathers, which they fan out as a mating behavior. Females select among males based on feather color and pattern as well as the physical prowess of the display.

(a) Intrasexual selection

(b) Intersexual selection

(c) Sexual selection balanced by predation

Figure 24.7 **Examples of the results of sexual selection, a type of natural selection.** **(a)** An example of intrasexual selection. The enlarged claw of the male fiddler crab is used in direct male-to-male competition. In this photograph, a male inside a burrow is extending its claw out of the burrow to prevent another male from entering. **(b)** An example of intersexual selection. Female peahens choose male peacocks based on the males' colorful and long tail feathers and the robustness of their display. **(c)** Male guppies (on the right) are brightly colored to attract a female (on the left), but brightly colored males are less common where predation is high.

Concept check: *Male birds of many species have loud and elaborate courtship songs. Is this likely to be the result of intersexual or intrasexual selection? Explain.*

A less obvious type of intersexual selection is cryptic female choice, in which the female reproductive system can influence the relative success of sperm. As an example of cryptic female choice, the female genital tract of certain animals selects for sperm that tend to be genetically unrelated to the female. Sperm from males closely related to the female, such as brothers or cousins, are less successful than are sperm from genetically unrelated males. The selection for sperm may occur over the journey through the reproductive tract. The egg itself may even have mechanisms to prevent fertilization by genetically related sperm. Cryptic female choice occurs in species in which females may mate with more than one male, such as many species of reptiles and ducks. A similar mechanism is found in many plant species in which pollen from genetically related plants, perhaps from the same flower, is unsuccessful at fertilization, whereas pollen from unrelated plants is successful. One possible advantage of cryptic female choice is that it inhibits inbreeding, which is described later in this chapter. At the population level, cryptic female choice may promote genetic diversity by favoring interbreeding among genetically unrelated individuals.

Sexual selection is sometimes a combination of both intrasexual and intersexual selection. During breeding season, male elk (*Cervus elaphus*) become aggressive and bugle loudly to challenge other male elk. Males spar with their antlers, which usually turns into a pushing match to determine which elk is stronger. Female elk then choose the strongest bulls as their mates.

Sexual selection can explain the existence of traits that could decrease an individual's chances of survival but increase their chances of reproducing. For example, the male guppy (*Poecilia reticulata*) is brightly colored compared to the female (Figure 24.7c). In nature, females prefer brightly colored males. However, brightly colored males are more likely to be seen and eaten by predators. In places with few predators, the males tend to be brightly colored. In contrast, where predators are abundant, brightly colored males are less plentiful because they are subject to predation. In this case, the relative abundance of brightly and dully colored males depends on the balance between sexual selection, which favors bright coloring, and escape from predation, which favors dull coloring.

Many animals have secondary sexual characteristics, and evolutionary biologists generally agree that sexual selection is responsible for such traits. But why should males compete, and why should females be choosy? Researchers have proposed various hypotheses to explain the underlying mechanisms. One possible reason is related to the different roles that males and females play in the nurturing of offspring. In some species, the female is the primary caregiver, whereas the male plays a minor role. In such species, mating behavior may influence the fitness of both males and females. Males increase their fitness by mating with multiple females. This increases their likelihood of passing their genes on to the next generation. By comparison, females may produce relatively few offspring, and their reproductive success may not be limited by the number of available males. Females will have higher fitness if they choose males that are good defenders of their territory and have alleles that confer a survival advantage to their offspring. One measure of alleles that confer higher fitness is age. Males that live to an older age are more likely to carry beneficial alleles. Many research studies involving female choice have shown that females tend to select traits that are more likely to be well developed in older

males than in immature males. For example, in certain species of birds, females tend to choose males with a larger repertoire of songs, which is more likely to occur in older males.

Sexual selection is governed by the same processes involved in the evolution of traits that are not directly related to sex. The result of sexual selection can be directional, stabilizing, diversifying, or balancing selection. For example, the evolution of the large and brightly colored tail of the male peacock reflects directional selection. Next, we will consider an example in which sexual selection may be diversifying.

Feature Investigation

Seehausen and van Alphen Found That Male Coloration in African Cichlids Is Subject to Female Choice

Cichlids are tropical freshwater fish that are popular among aquarium enthusiasts. The Cichlidae family is composed of more than 3,000 species that vary with regard to body shape, coloration, behavior, and feeding habits, making it one of the largest and most diverse vertebrate families. By far the greatest diversity of these fish is found in Lake Victoria, Lake Malawi, and Lake Tanganyika in East Africa, where more than 1,800 species are found.

Cichlids have complex mating behavior, and females play an important role in choosing males with particular characteristics. In 1998, population geneticists Ole Seehausen and Jacques van Alphen investigated the effect of male coloration of two species of cichlids on female choice. In some locations, *Pundamilia pundamilia* and *Pundamilia nyererei* do not readily interbreed and behave like two distinct biological species, whereas in other places, they behave like a single interbreeding species with two color morphs. They can interbreed to produce viable offspring, and both inhabit Lake Victoria. Males of both species have blackish underparts and blackish vertical bars on their sides (Figure 24.8a). *P. pundamilia* males are grayish white on top and on the sides, and they have a metallic blue and red dorsal fin, which is the uppermost fin. *P. nyererei* males are red-orange on top and yellow on their sides.

Seehausen and van Alphen hypothesized that females choose males for mates based, in part, on the males' coloration. The researchers took advantage of the observation that colors are obscured under orange monochromatic light. As seen in Figure 24.8b, males of both species look similar under these conditions. In their study, a female of one species was placed in an aquarium that contained one male of each species within an enclosure (Figure 24.9). The males were within glass enclosures to avoid direct competition with each other, which would have likely affected female choice. The goal of the experiment was to determine which of the two males a female would prefer. Courtship between a male and female begins when a male swims toward a female and exhibits a lateral display (that is, shows the side of his body to the female). If the female is interested, she will approach the male, and then the male will display a quivering motion. Such courtship behavior was examined under normal light and under orange monochromatic light.

As seen in the data, Seehausen and van Alphen found that the females' preference for males was dramatically different depending on the illumination conditions. Under normal light, *P. pundamilia* females preferred *P. pundamilia* males, and *P. nyererei* females preferred *P. nyererei* males. However, such mating preference was lost when colors were masked by artificial light. If the light conditions in their native habitats are similar to the normal light used in this experiment, female choice would be expected to separate cichlids into two populations, with *P. pundamilia* females mating with *P. pundamilia* males and *P. nyererei* females mating with *P. nyererei* males. In this case, sexual selection appears to have followed a diversifying mechanism in which certain females prefer males with one color pattern, while other females prefer males with a different color pattern. A possible outcome of such sexual selection is that it can separate one large population into smaller populations that selectively breed with each other and eventually become distinct species. We will discuss the topic of species formation in more depth in Chapter 25.

(a) Males of two species in normal light **(b) Males of two species in artificial light**

Figure 24.8 **Male coloration in African cichlids.** **(a)** Two males (*Pundamilia pundamilia*, top, and *Pundamilia nyererei*, bottom) under normal illumination. **(b)** The same species under orange monochromatic light, which obscures their color differences.

Experimental Questions

1. What hypothesis is tested in the Seehausen and van Alphen experiment?
2. Describe the experimental design for this study, illustrated in Figure 24.9. What was the purpose of conducting the experiment under the two different light conditions?
3. What were the results of the experiment in Figure 24.9?

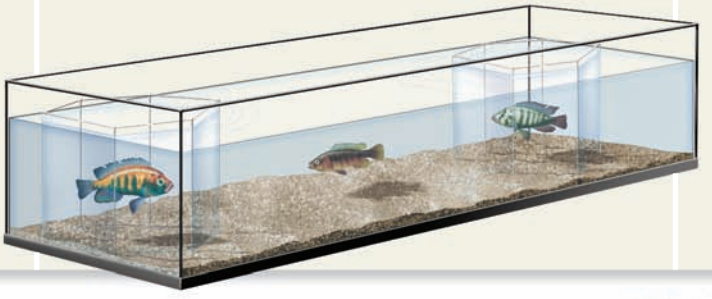
Figure 24.9 A study by Seehausen and van Alphen involving the effects of male coloration on female choice in African cichlids.

HYPOTHESIS Female African cichlids choose mates based on the males' coloration.

KEY MATERIALS Two species of cichlid, *Pundamilia pundamilia* and *Pundamilia nyererei*, were chosen. The males differ with regard to their coloration. A total of 8 males and 8 females (4 males and 4 females from each species) were tested.

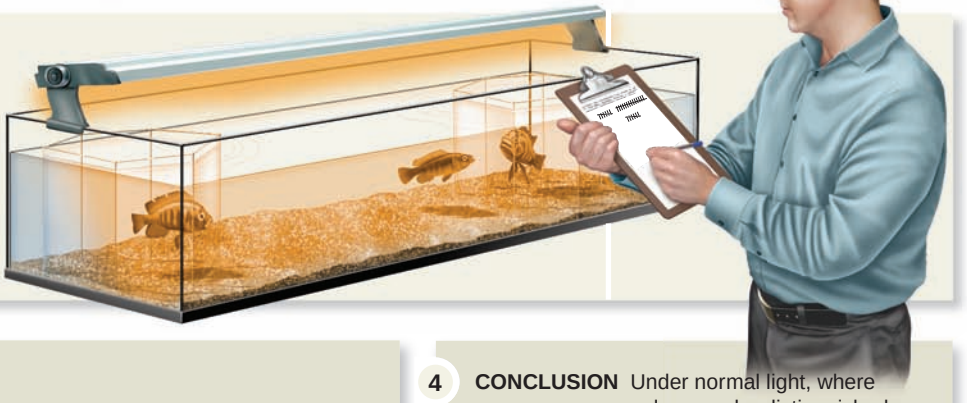
Experimental level | **Conceptual level**

1 Place 1 female and 2 males in an aquarium. Each male is within a separate glass enclosure. The enclosures contain 1 male from each species.



This is a method to evaluate sexual selection via female choice in 2 species of cichlid.

2 Observe potential courtship behavior for 1 hour. If a male exhibited lateral display (a courtship invitation) and then the female approached the enclosure that contained the male, this was scored as a positive encounter. This protocol was performed under normal light and under orange monochromatic light.



3 **THE DATA**

Female	Male	Light condition	Percentage of positive encounters*
P. pundamilia	*P. pundamilia*	Normal	16
P. pundamilia	*P. nyererei*	Normal	2
P. nyererei	*P. nyererei*	Normal	16
P. nyererei	*P. pundamilia*	Normal	5
P. pundamilia	*P. pundamilia*	Monochromatic	20
P. pundamilia	*P. nyererei*	Monochromatic	18
P. nyererei	*P. nyererei*	Monochromatic	13
P. nyererei	*P. pundamilia*	Monochromatic	18

*A positive encounter occurred when a male's lateral display was followed by the female approaching the male.

4 **CONCLUSION** Under normal light, where colors can be distinguished, *P. pundamilia* females prefer *P. pundamilia* males, and *P. nyererei* females prefer *P. nyererei* males.

24.4 Genetic Drift

Thus far, we have focused on natural selection as a mechanism that fosters genetic change. Let's now turn our attention to a second important way the gene pool of a population can change. In the 1930s, Sewall Wright played a large role in developing the concept of **genetic drift** (also called random genetic drift), which refers to changes in allele frequencies due to random chance. The term genetic drift is derived from the observation that allele frequencies may "drift" randomly from generation to generation as a matter of chance.

Changes in allele frequencies due to genetic drift happen regardless of the fitness of individuals that carry those alleles. For example, an individual with a high fitness value may, as a matter of bad luck, not encounter a member of the opposite sex. Likewise, random chance can influence which alleles happen to be found in the gametes that fuse with each other in a

successful fertilization. In this section, we will examine how genetic drift can alter allele frequencies in populations.

Genetic Drift Has a Greater Impact in Small Populations

What are the effects of genetic drift? Over the long run, genetic drift favors either the elimination or the fixation of an allele, that is, when its frequency reaches 0% or 100% in a population, respectively. However, the number of generations it takes for an allele to be lost or fixed greatly depends on the population size. Figure 24.10 illustrates the potential consequences of genetic drift in one large (N = 1,000) and two small (N = 10) populations. This simulation involves the frequency of hypothetical B and b alleles of a gene for fur color in a population of mice—B is the black allele, and b is the white allele.

At the beginning of this hypothetical simulation, which runs for 50 generations, all of these populations had identical allele frequencies: B = 0.5 and b = 0.5. In the small populations, the allele frequencies fluctuated substantially from generation to generation. Eventually, in one population, the b allele was eliminated, while in another, it was fixed at 100%. These small populations would then consist of only black mice or white mice, respectively. At this point, the gene has become monomorphic and cannot change any further. By comparison, the frequencies of B and b in the large population fluctuated much less. As discussed in Chapter 16, the relative effect of random chance, also termed random sampling error, is much smaller when the sample size is large. Nevertheless, genetic drift will eventually lead to allele loss or fixation even in large populations, but this will take many more generations to occur than it does in small populations.

In nature, genetic drift may rapidly alter allele frequencies when the population size dramatically decreases. Two common examples of this phenomenon are the bottleneck effect and the founder effect, which are described next.

Bottleneck Effect A population can be reduced dramatically in size by events such as earthquakes, floods, drought, and human destruction of habitat. These occurrences may eliminate most members of the population without regard to their genetic composition. When allele frequencies of the resulting population change due to genetic drift, this is called the **bottleneck effect**. Such changes may happen for two reasons. First, the surviving members may have allele frequencies that differ from those of the original population that was much larger. Second, as we saw in Figure 24.10, genetic drift acts more quickly to reduce genetic variation when the population size is small. In extreme cases, alleles may even be eliminated. Eventually, the bottlenecked population may regain its original size. However, the new population is likely to have less genetic variation than the original one.

A hypothetical example of the bottleneck effect is shown with a population of frogs in Figure 24.11. In this example, a starting population of frogs is found in three phenotypes: yellow, dark green, and striped. Due to a bottleneck caused by a drought, the dark green variety is lost from the population.

As a real-life example, the African cheetah has lost nearly all of its genetic variation. This was likely caused by a bottleneck effect. An analysis of the current population by population geneticists has suggested that a severe population bottleneck occurred in this species approximately 10,000–12,000 years ago, reducing it to near extinction. The species eventually rebounded in numbers, but the bottleneck apparently reduced its genetic variation to very low levels. The modern species is monomorphic for many of its genes.

Founder Effect Another common phenomenon in which genetic drift may have a rapid impact is the **founder effect**. This occurs when a small group of individuals separates from a larger population and establishes a colony in a new location. For example, a few individuals may migrate from a large continental population and become the founders of an island

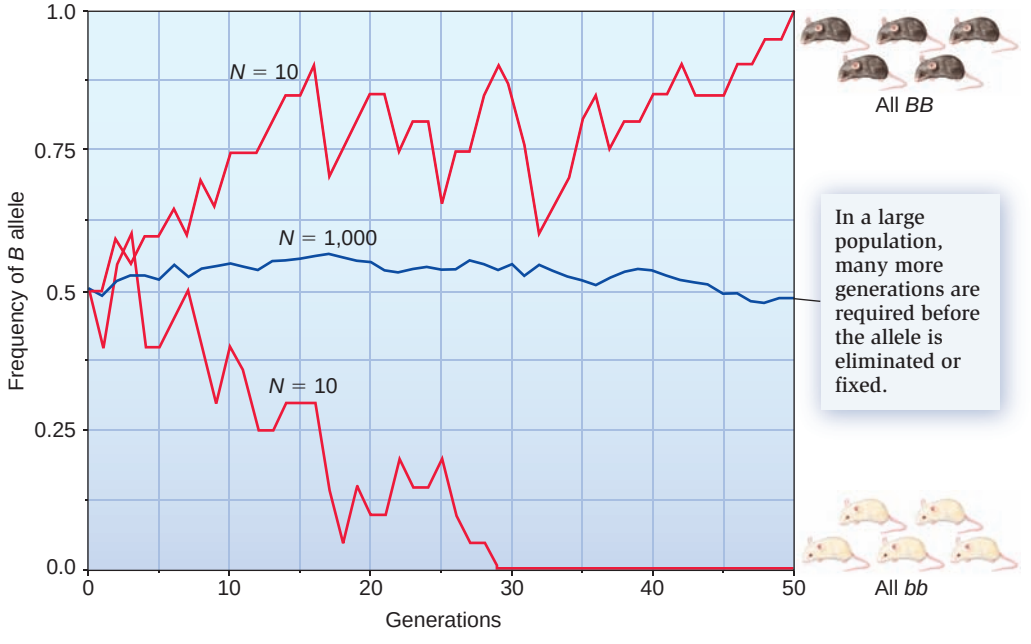

Figure 24.10 Genetic drift and population size. This graph shows three hypothetical simulations of genetic drift and their effects on small and large populations of black (B allele) and white (b allele) mice. In all cases, the starting allele frequencies are B = 0.5 and b = 0.5. The red lines illustrate two populations of mice in which N = 10; the blue line shows a population in which N = 1,000. Genetic drift eventually leads to either the elimination or fixation of alleles.

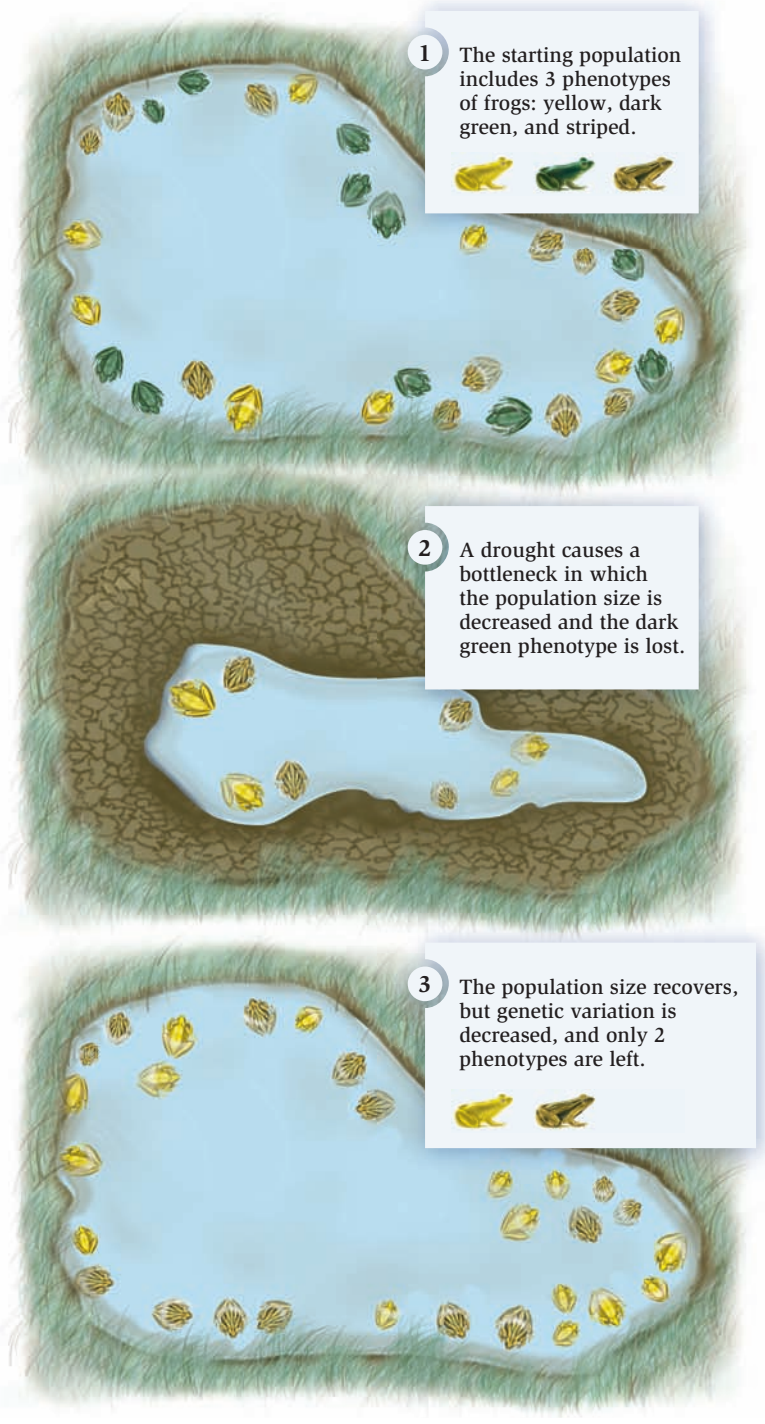

Figure 24.11 **A hypothetical example of the bottleneck effect.** This example involves a population of frogs in which a drought dramatically reduced population size, resulting in a bottleneck. The bottleneck reduced the genetic diversity in the population.

Concept check: *How does the bottleneck effect undermine the efforts of conservation biologists who are trying to save species nearing extinction?*

population. The founder effect differs from a bottleneck in that it occurs in a new location, although both effects are related to a reduction in the size of a population. The founder effect has two important consequences. First, the founding population, which is relatively small, is expected to have less genetic variation than the larger original population from which it was derived. Second, as a matter of chance, the allele frequencies in the founding population may differ markedly from those of the original population.

Population geneticists have studied many examples in which isolated populations were founded via colonization by members of another population. For example, in the 1960s, American geneticist Victor McKusick studied allele frequencies in the Old Order Amish of Lancaster County, Pennsylvania. At that time, this was a group of about 8,000 people, descended from just three couples that immigrated to the U.S. in 1770. Among this population of 8,000, a genetic disease known as the Ellis–van Creveld syndrome (a recessive form of dwarfism) was found at a frequency of 0.07, or 7%. By comparison, this disorder is extremely rare in other human populations, even the population from which the founding members had originated. The high frequency in the Lancaster County population is a chance occurrence due to the founder effect.

The Neutral Theory of Evolution Proposes That Genetic Drift Also Plays an Important Role in Promoting Genetic Change

In 1968, Japanese evolutionary biologist Motoo Kimura proposed that much of the genetic variation seen in natural populations is the result of genetic drift rather than natural selection. Genetic drift is a random process that does not preferentially select for any particular allele—it can alter the frequencies of both beneficial and deleterious alleles. Much of the time, genetic drift promotes **neutral variation**, which does not affect reproductive success. According to Kimura's **neutral theory of evolution**, most genetic variation is due to the accumulation of neutral mutations that have attained high frequencies in a population via genetic drift.

Neutral mutations are not subject to natural selection because they do not affect reproductive success. For example, a new mutation within a structural gene that changes a glycine codon from GGG to GGC would not affect the amino acid sequence of the encoded protein. Both genotypes are equal in fitness. However, such new mutations can spread throughout a population due to genetic drift (Figure 24.12). This theory has been called **non-Darwinian evolution** and also "survival of the luckiest." Kimura agreed with Darwin that natural selection is responsible for adaptive changes in a species during evolution. The long neck of the giraffe is the result of natural selection. His main idea is that much of the variation in DNA sequences is explained by neutral variation rather than adaptive variation.

The sequencing of genomes from many species is consistent with the neutral theory of evolution. When we examine changes of the coding sequence within structural genes, we find that nucleotide substitutions are more prevalent in the third base of a codon than in the first or second base. Mutations in the third base are often neutral; that is, they do not change the amino acid sequence of the protein (refer back to Table 12.1). In contrast, random mutations at the first or second base are

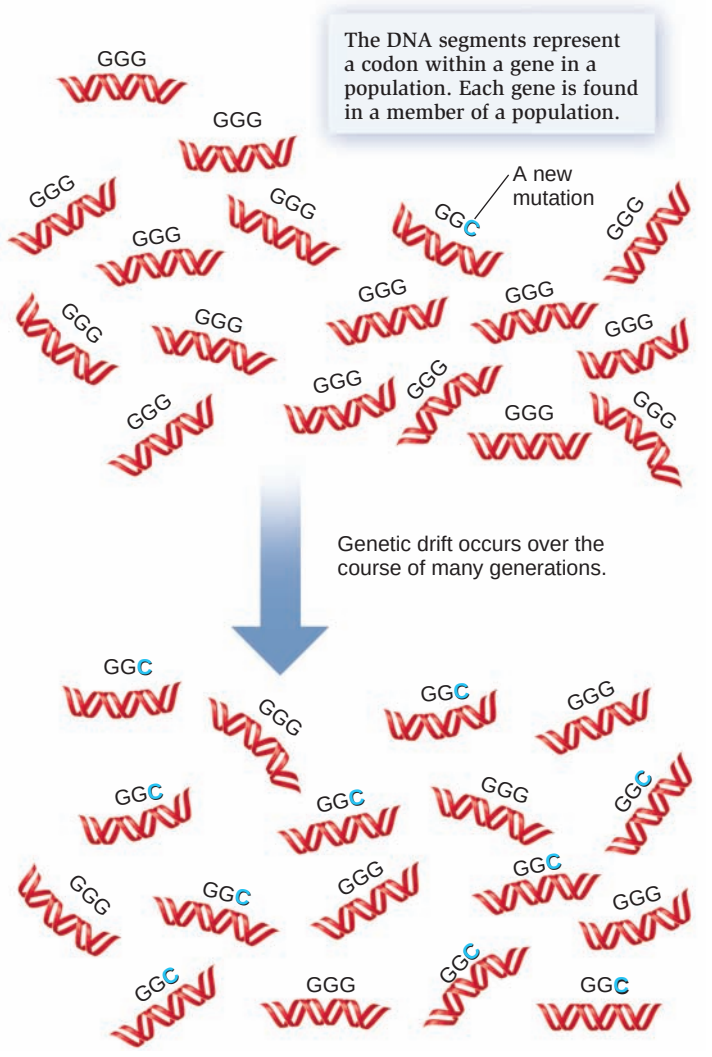

Figure 24.12 **Neutral evolution in a population.** In this example, a mutation within a gene changes a glycine codon from GGG to GGC, which does not affect the amino acid sequence of the encoded protein. Each gene shown represents a copy of the gene in a member of a population. Over the course of many generations, genetic drift may cause this neutral allele to become prevalent in the population, perhaps even monomorphic.

Concept check: Describe two other examples of genetic changes that might be neutral.

more likely to be harmful than beneficial and tend to be eliminated from a population.

24.5 Migration and Nonrandom Mating

Thus far, we have considered how natural selection and genetic drift are key mechanisms that cause evolution to happen. In addition, migration between neighboring populations and nonrandom mating may have an impact on genetic variation and the relative proportions of genotypes. In this section, we will explore how these mechanisms work.

Migration Between Two Populations Tends to Increase Genetic Variation

Earlier in this chapter, we considered how migration to a new location by a relatively small group can result in a founding population with an altered genetic composition due to genetic drift. In addition, migration between two different established populations can alter allele frequencies. As an example, let's consider two populations of a particular species of deer that are separated by a mountain range running north and south (Figure 24.13). On rare occasions, a few deer from the western population may travel through a narrow pass between the mountains and become members of the eastern population. If the two populations are different with regard to genetic variation, this migration will alter the frequencies of certain alleles in the eastern population. Of course, this migration could occur in the opposite direction as well and would then affect the western population. This movement of alleles into or out of a population, called **gene flow**, occurs whenever individuals migrate between populations having different allele frequencies.

In nature, individuals commonly migrate in both directions. What are the consequences of bidirectional migration? First, migration tends to reduce differences in allele frequencies between neighboring populations. Population geneticists can evaluate the extent of migration between two populations by

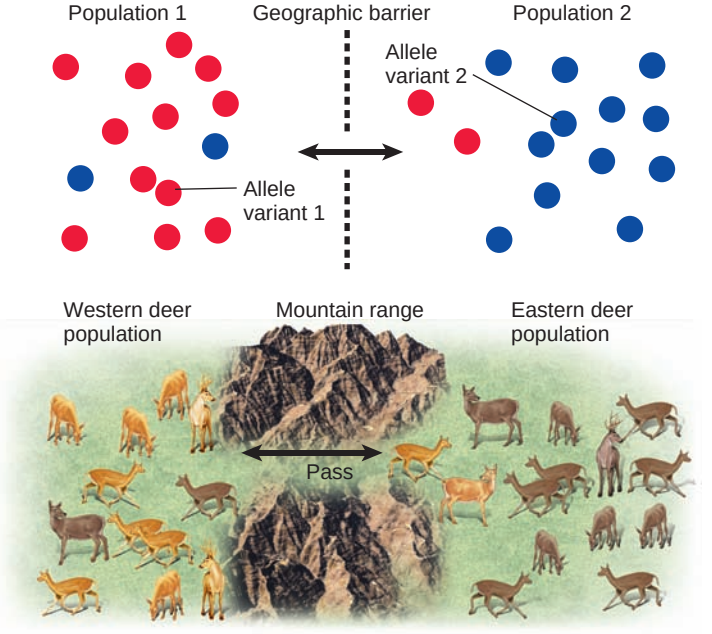

Figure 24.13 **Migration and gene flow.** In this example, two populations of a deer species are separated by a mountain range. On rare occasions, a few deer from the one population travel through a narrow pass and become members of the other population. If the two populations differ in regard to genetic variation, this migration will alter the frequencies of alleles in the populations.

Concept check: How does gene flow affect the genetic compositions of populations?

analyzing the similarities and differences between their allele frequencies. Populations that frequently mix their gene pools via migration tend to have similar allele frequencies, whereas the allele frequencies of isolated populations are more disparate, due to the effects of natural selection and genetic drift. Second, migration tends to increase genetic diversity within populations. As discussed earlier in this chapter, new mutations are relatively rare events. Therefore, a new mutation may arise in only one population, and migration may then introduce this new allele into a neighboring population.

Nonrandom Mating Affects the Relative Proportion of Homozygotes and Heterozygotes in a Population

As mentioned earlier in this chapter, one of the conditions required to establish the Hardy-Weinberg equilibrium is random mating, which means that individuals choose their mates irrespective of their genotypes or phenotypes. In many species, including human populations, this condition is violated. Such **nonrandom mating** takes different forms. Assortative mating occurs when individuals with similar phenotypes are more likely to mate. If the similar phenotypes are due to similar genotypes, assortative mating tends to increase the proportion of homozygotes and decrease the proportion of heterozygotes in the population. The opposite situation, where dissimilar phenotypes mate preferentially, causes heterozygosity to increase.

Another form of nonrandom mating involves the choice of mates based on their genetic history rather than their phenotypes. Individuals may choose a mate that is part of the same genetic lineage. The mating of two genetically related individuals, such as cousins, is called **inbreeding**. This sometimes occurs in human societies and is more likely to take place in nature when population size becomes very small.

In the absence of other evolutionary factors, nonrandom mating does not affect allele frequencies in a population. However, it will disrupt the balance of genotypes that is predicted by the Hardy-Weinberg equilibrium. As an example, let's consider a human pedigree involving a mating between cousins (Figure 24.14). Individuals III-2 and III-3 are cousins and have produced the daughter labeled IV-1. She is said to be inbred, because her parents are genetically related. The parents of an inbred individual have one or more common ancestors. In the pedigree of Figure 24.14, I-2 is the grandfather of both III-2 and III-3.

Inbreeding increases the relative proportions of homozygotes and decreases the likelihood of heterozygotes in a population. Why does this happen? An inbred individual has a higher chance of being homozygous for any given gene because the same allele for that gene could be inherited twice from a common ancestor. For example, let's suppose that individual I-2 is a heterozygote, *Cc*. The *c* allele could pass from I-2 to II-2 to III-2 and finally to IV-1 (see red lines in Figure 24.14). Likewise, the *c* allele could pass from I-2 to II-3 to III-3 and then to IV-1. Therefore, IV-1 has a chance of being homozygous because she inherited both copies of the *c* allele from a common ancestor to both of her parents. Inbreeding does not favor any particular allele—it does not favor *c* over *C*—but it does increase the likelihood that an individual will be homozygous for any given gene.

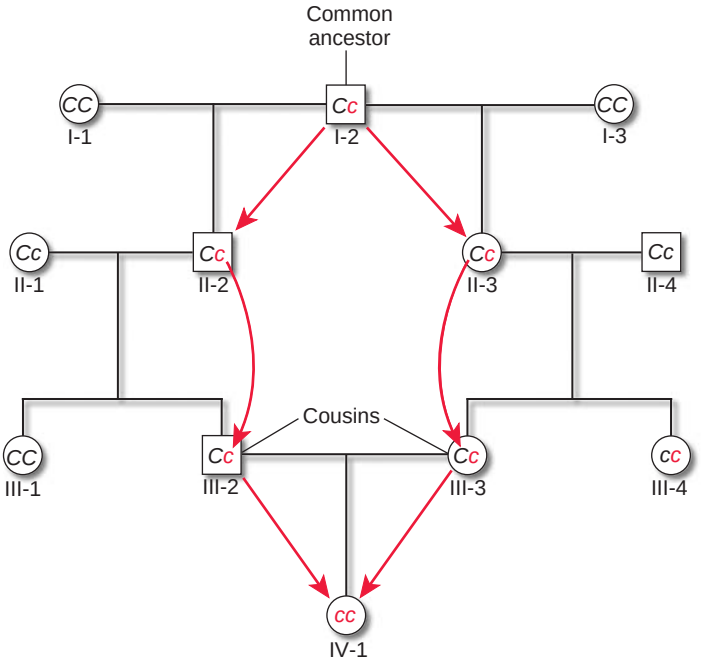

Figure 24.14 **A human pedigree containing inbreeding.** The parents of individual IV-1 are genetically related (cousins), and therefore, individual IV-1 is inbred. Inbreeding increases the likelihood that an individual will be homozygous for any given gene. The red arrows show how IV-1 could become homozygous by inheriting the same allele (*c*) from the common ancestor (I-2) to both of her parents.

Concept check: Although inbreeding by itself does not affect allele frequencies, how might inbreeding indirectly affect allele frequencies over the course of many generations if natural selection was also occurring?

Although inbreeding by itself does not affect allele frequencies, it may have negative consequences with regard to recessive alleles. Rare recessive alleles that are harmful in the homozygous condition are found in all populations. Such alleles do not usually pose a problem because heterozygotes carrying a rare recessive allele are also rare, making it very unlikely that two such heterozygotes will mate with each other. However, when inbreeding is practiced, homozygous offspring are more likely to be produced. For example, rare recessive diseases in humans are more frequent when inbreeding occurs.

In natural populations, inbreeding will lower the mean fitness of the population if homozygous offspring have lower fitness values. This can be a serious problem as natural populations become smaller due to human habitat destruction. As the population shrinks, inbreeding becomes more likely because individuals have fewer potential mates from which to choose. The inbreeding, in turn, produces homozygotes that are less fit, thereby decreasing the reproductive success of the population. This phenomenon is called **inbreeding depression**. Conservation biologists sometimes try to circumvent this problem

by introducing individuals from one population into another. For example, the endangered Florida panther (*Puma concolor coryi*) suffers from inbreeding-related defects, which include poor sperm quality and quantity, and morphological abnormalities. To alleviate these effects, panthers from Texas have been introduced into the Florida population of panthers.

Summary of Key Concepts

24.1 Genes in Populations

- Population genetics is the study of genes and genotypes in a population, with a focus on understanding genetic variation. A population is a group of individuals of the same species that occupy the same environment and can interbreed with one another. All of the genes in a population constitute a gene pool.
- Polymorphism, which is very common in nearly all populations, refers to a phenotype or genotype that is found in two or more forms in a population. A monomorphic gene exists predominantly (>99%) as a single allele in a population. (Figure 24.1)
- An allele frequency is the number of copies of a specific allele divided by the total number of all alleles in a population. A genotype frequency is the number of individuals with a given genotype divided by the total number of individuals in a population.
- The Hardy-Weinberg equation ($p^2 + 2pq + q^2 = 1$) describes the allele and genotype frequencies in a population that is not evolving. It predicts an equilibrium if no new mutations are formed, no natural selection occurs, the population size is very large, the populations do not migrate, and mating is random. (Figure 24.2)
- Microevolution involves changes in a population's gene pool from one generation to the next.
- Sources of new genetic variation include random gene mutations, gene duplications, exon shuffling, and horizontal gene transfer. Natural selection, genetic drift, migration, and nonrandom mating may alter allele and genotype frequencies and cause a population to evolve. (Table 24.1)

24.2 Natural Selection

- Natural selection favors individuals with greater reproductive success. A measure of reproductive success is fitness, the contribution of a genotype to the genetic composition of the next generation as compared to the contributions of other genotypes.
- Directional selection favors one extreme of a phenotypic distribution. (Figure 24.3)
- Stabilizing selection favors an intermediate phenotype. (Figure 24.4)
- Diversifying selection favors two or more phenotypes. An example is when a population occupies a diverse environment. (Figure 24.5)
- Balancing selection maintains genetic polymorphism in a population. Examples include heterozygote advantage and negative frequency-dependent selection. (Figure 24.6)

24.3 Sexual Selection

- Sexual selection is a form of natural selection in which individuals possessing certain traits are more likely than others to find or choose a mate and/or engage in successful mating. Intrasexual and intersexual selection can lead to traits described as secondary sex characteristics. (Figure 24.7)
- Seehausen and van Alphen discovered that female cichlids' choice of mates is influenced by male coloration. This is an example of sexual selection. (Figures 24.8, 24.9)

24.4 Genetic Drift

- Genetic drift involves changes in allele frequencies due to random chance. It occurs more rapidly in small populations and leads to either the elimination or the fixation of alleles. (Figure 24.10)
- The bottleneck effect is a form of genetic drift in which a population size is dramatically reduced and then rebounds. During the bottleneck, genetic variation may be lost from a population. (Figure 24.11)
- The founder effect occurs when a small population moves to a new geographic location and genetic drift alters the genetic composition of that population.
- The neutral theory of evolution by Kimura indicates that much of the genetic variation observed in populations is due to the accumulation of neutral genetic changes. (Figure 24.12)

24.5 Migration and Nonrandom Mating

- Gene flow occurs when individuals migrate between populations with different allele frequencies. It reduces differences in allele frequencies between neighboring populations and enhances genetic diversity in populations. (Figure 24.13)
- Inbreeding is a type of nonrandom mating in which genetically related individuals mate with each other. This tends to increase the proportion of homozygotes relative to heterozygotes. When homozygotes have lower fitness, this phenomenon is called inbreeding depression. (Figure 24.14)

Assess and Discuss

Test Yourself

1. Population geneticists are interested in the genetic variation in populations. The most common type of genetic change that can cause polymorphism in a population is
   a. a deletion of a gene sequence.
   b. a duplication of a region of a gene.
   c. a rearrangement of a gene sequence.
   d. a single-nucleotide substitution.
   e. an inversion of a segment of a chromosome.
2. The Hardy-Weinberg equation characterizes the genotype frequencies and allele frequencies
   a. of a population that is experiencing selection for mating success.
   b. of a population that is extremely small.

c. of a population that is very large and not evolving.
d. of a community of species that is not evolving.
e. of a community of species that is experiencing selection.

3. Considering the Hardy-Weinberg equation, what portion of the equation would be used to calculate the frequency of individuals that do not exhibit a disease but are carriers of a recessive genetic disorder?
   a. q
   b. p^2
   c. $2pq$
   d. q^2
   e. both b and d

4. By itself, which of the following is not likely to have a major impact on allele frequencies?
   a. natural selection
   b. genetic drift
   c. mutation
   d. inbreeding
   e. both c and d

5. Which of the following statements is correct regarding mutations?
   a. Mutations are not important in evolution.
   b. Mutations provide the source for genetic variation, but other evolutionary factors are more important in determining allele frequencies in a population.
   c. Mutations occur at such a high rate that they promote major changes in the gene pool from one generation to the next.
   d. Mutations are insignificant when considering evolution of a large population.
   e. Mutations are of greater importance in larger populations than in smaller populations.

6. In a population of fish, body coloration varies from a light shade, almost white, to a very dark shade of green. If changes in the environment resulted in decreased predation of individuals with the lightest coloration, this would be an example of _____ selection.
   a. diversifying
   b. stabilizing
   c. directional
   d. sexual
   e. artificial

7. Considering the same population of fish described in question 6, if the stream environment included several areas of sandy, light-colored bottom areas and a lot of dark-colored vegetation, both the light- and dark-colored fish would have selective advantage and increased survival. This type of scenario could explain the occurrence of
   a. genetic drift.
   b. diversifying selection.
   c. mutation.
   d. stabilizing selection.
   e. sexual selection.

8. The microevolutionary factor most sensitive to population size is
   a. mutation.
   b. migration.
   c. selection.
   d. genetic drift.
   e. all of the above.

9. The neutral theory of evolution differs from Darwinian evolution in that
   a. neutral theory states that natural selection does not exist.
   b. neutral theory states that most of the genetic variation in a population is due to neutral mutations, which do not affect reproductive success.
   c. neutral variation alters survival and reproductive success.
   d. neutral mutations are not affected by population size.
   e. both b and c.

10. Populations that experience inbreeding may also experience
    a. a decrease in fitness due to an increased frequency of recessive genetic diseases.
    b. an increase in fitness due to increases in heterozygosity.
    c. very little genetic drift.
    d. no apparent change.
    e. increased mutation rates.

Conceptual Questions

1. The percentage of individuals exhibiting a recessive disease in a population is 0.04, which is 4%. Based on a Hardy-Weinberg equilibrium, what percentage of individuals would be expected to be heterozygous carriers?
2. Describe the four patterns of natural selection that lead to environmental adaptation. You should also discuss sexual selection.
3. Explain how the founder effect is related to genetic drift.

Collaborative Questions

1. Antibiotics are commonly used to combat bacterial and fungal infections. During the past several decades, however, antibiotic-resistant strains of microorganisms have become alarmingly prevalent. This has undermined the ability of physicians to treat many types of infectious disease. Discuss how the following processes that alter allele frequencies may have contributed to the emergence of antibiotic-resistant strains:
   a. random mutation
   b. genetic drift
   c. natural selection
2. Discuss the similarities and differences among directional, disruptive, balancing, and stabilizing selection.

Origin of Species and Macroevolution

25

Chapter Outline

Two different species of zebras. Grey zebra (*Equus grevyi*) is shown on the left and Grant's zebra (*E. quagga* subspecies *boehmi*), which has fewer and thicker stripes, is shown on the right. This chapter will examine how different species come into existence.

The origin of living organisms has been described by philosophers as the great "mystery of mysteries." Perhaps that is why so many different views have been put forth to explain the existence of living species. At the time of Aristotle (4th century B.C.E.), most people believed that some living organisms could come into being by spontaneous generation, which is the idea that nonliving materials could give rise to living organisms. For example, it was commonly believed that worms and frogs could arise from mud, and mice could come from grain. By comparison, many religious teachings contend that species were divinely made and have remained the same since their creation. In contrast to these ideas, the work of Charles Darwin provided the scientific theory of evolution by descent with modification. This theory helps us to understand the diversity of life, and in particular, it presents a logical explanation for how new species can evolve from pre-existing species.

This chapter provides an exciting way to build on the information that we have considered in previous chapters. In Chapter 22, we examined how the first primitive cells in an RNA world could have evolved into prokaryotic cells and eventually eukaryotes. Chapter 23 surveyed the tenets on which the theory of evolution is built, and in Chapter 24, we viewed evolution on a small scale as it relates to a single gene. In this chapter, we will consider evolution on a larger scale, as it relates to the formation of new species. **Macroevolution** refers to evolutionary changes that create new species and groups that include many new species. It concerns the diversity of organisms established over long periods of time through the evolution and extinction of many species.

To biologists, the concept of a **species** has come to mean a group of related organisms that maintains a distinctive set of attributes in nature. Members of the same species share an evolutionary history, which makes them more genetically similar to each other than they are to members of a different species. You may already have an intuitive sense of this concept. It is obvious that giraffes and mice are different species. However, as we will learn in the first section of this chapter, the distinction between different, closely related species is often blurred in natural environments. It may not be easy to definitively distinguish two species, as the chapter-opening photo illustrates. Species identification has several practical uses. For example, it allows biologists to plan for the preservation and conservation of endangered species. In addition, it is often important for a physician to identify the correct bacterial species that is causing a disease in a patient so the proper medication can be prescribed.

In this chapter, we will also focus on the mechanisms that promote the formation of new species, a phenomenon called **speciation**. Such macroevolution typically occurs by the accumulation of microevolutionary changes, those that occur in single genes (see Chapter 24). We will also consider how macroevolution can happen at a fast or slow pace and explore how variations in the genes that control development are important in the evolution of new species.

25.1 Identification of Species

How many different species are on Earth? The number is astounding. A study done by biologist E. O. Wilson and colleagues in 1990 estimated the known number of species at approximately 1.4 million. Currently, about 1.75 million species

have been identified. However, a vast number of species have yet to be established. This is particularly true among prokaryotic organisms, which are difficult to categorize into distinct species. Common estimates of the total number of species range from 5 to 50 million!

When studying natural populations, evolutionary biologists are often confronted with situations where some differences between two populations are apparent, but it is difficult to decide whether the two populations truly represent separate species. When two or more geographically restricted groups of the same species display one or more traits that are somewhat different but not enough to warrant their placement into different species, biologists sometimes classify such groups as **subspecies**. Similarly, many bacterial species are subdivided into **ecotypes**. Each ecotype is a genetically distinct population adapted to its local environment. In this section, we will consider the different characteristics that biologists examine when deciding if two groups of organisms constitute different species.

Each Species Is Established Using Characteristics and Histories That Distinguish It from Other Species

As mentioned, a species is a group of organisms that maintains a distinctive set of attributes in nature. In the case of sexually reproducing species, members of one species usually cannot successfully interbreed with members of other species. Members of the same species share an evolutionary history that is distinct from other species. While this may seem like a reasonable way to characterize a given species, biologists would agree that the identification of many species is a difficult undertaking. What criteria do we use to distinguish species? How many differences must exist between two populations to classify them as different species? Such questions are often difficult to answer.

The characteristics that a biologist uses to identify a species will depend, in large part, on the species in question. For example, the traits used to distinguish insect species would be quite different from those used to identify different bacterial species. The relatively high level of horizontal gene transfer among bacteria presents special challenges in the grouping of bacterial species. Among bacteria, it is sometimes very difficult and perhaps arbitrary to divide closely related organisms into separate species.

The most commonly used characteristics to identify species are morphological traits, the ability to interbreed, molecular features, ecological factors, and evolutionary relationships. A comparison of these concepts will help you to appreciate the various approaches that biologists use to identify the bewildering array of species on our planet.

Morphological Traits One way to establish that a population constitutes a unique species is based on their physical characteristics. Organisms are classified as the same species if their anatomical traits appear to be very similar. Likewise, microorganisms can be classified according to morphological traits at the cellular level. By comparing many different morphological traits, biologists may be able decide that certain populations constitute a unique species.

Although an analysis of morphological traits is a common way for biologists to establish that a particular group constitutes a species, this approach has drawbacks. First, researchers may have difficulty deciding how many traits to consider. In addition, quantitative traits that vary in a continuous way among members of the same species, such as size and weight, are not easy to analyze. Another drawback is that the degree of dissimilarity that distinguishes different species may not show a simple relationship; the members of the same species sometimes look very different, and conversely, members of different species sometimes look remarkably similar to each other. For example, Figure 25.1a shows two different frogs of the species *Dendrobates tinctorius*, commonly called the dyeing poison frog. This species exists in many different-colored morphs, which are individuals of the same species that have noticeably dissimilar appearances. In contrast, Figure 25.1b shows two different species of frogs, the Northern leopard frog (*Rana pipiens*) and the Southern leopard frog (*Rana utricularia*), which look fairly similar.

(a) Frogs of the same species

(b) Frogs of different species

Figure 25.1 Difficulties of using morphological traits to identify species. In some cases, members of the same species can appear quite different; in other cases, members of different species can look very similar. **(a)** Two frogs of the same species, the dyeing poison frog (*Dendrobates tinctorius*). **(b)** Two different species of frog, the Northern leopard frog (*Rana pipiens*, left) and the Southern leopard frog (*Rana utricularia*, right).

Concept check: Can you think of another example of two different species that look very similar?

Reproductive Isolation Why would biologists describe two species, such as the Northern leopard frog and Southern leopard frog, as being different if they are morphologically similar? One reason is that biologists have discovered that they are unable to breed with each other in nature. Therefore, a second way to identify a species is by the ability to interbreed. In the late 1920s, geneticist Theodosius Dobzhansky proposed that each species is reproductively isolated from other species. Such **reproductive isolation** prevents one species from successfully interbreeding with other species. In 1942, evolutionary biologist Ernst Mayr expanded on the ideas of Dobzhansky to provide a reproductive definition of a species. According to Mayr, a key feature of sexually reproducing species is that, in nature, the members of one species have the potential to interbreed with one another to produce viable, fertile offspring but cannot successfully interbreed with members of other species. As discussed later in this section, reproductive isolation among species of plants and animals can occur by an amazing variety of different mechanisms.

Reproductive isolation has been used to distinguish many plant and animal species, especially those that look alike but do not interbreed. Even so, it suffers from four main problems. First, in nature, it may be difficult to determine if two populations are reproductively isolated, particularly if they are populations with nonoverlapping geographic ranges. Second, biologists have noted many cases in which two different species can interbreed in nature yet consistently maintain themselves as separate species. For example, different species of yucca plants, such as *Yucca pallida* and *Yucca constricta*, do interbreed in nature yet typically maintain populations with distinct characteristics. For this reason, they are viewed as distinct species. A third drawback of reproductive isolation is that it does not apply to asexual species such as bacteria. Likewise, some species of plants and fungi reproduce only asexually. Finally, a fourth drawback is that it cannot be applied to extinct species. For these reasons, reproductive isolation has been primarily used to distinguish closely related species of modern animals and plants that reproduce sexually.

Molecular Features Molecular features are now commonly used to determine if two different populations are different species. Evolutionary biologists often compare DNA sequences within genes, gene order along chromosomes, chromosome structure, and chromosome number as features to identify similarities and differences among different populations. DNA sequence differences are often used to compare populations. For example, researchers may compare the DNA sequence of the *16S* rRNA gene between different bacterial populations as a way to decide if the two populations represent different species. When the sequences are very similar, such populations would probably be judged as the same species. However, it may be difficult to draw the line when separating groups into different species. Is a 2% difference in their genome sequences sufficient to warrant placement into two different species, or do we need a 5% difference?

Ecological Factors A variety of factors related to an organism's habitat can be used to distinguish one species from another. For example, certain species of warblers can be distinguished by the habitat in which they forage for food. Some species search the ground for food, others forage in bushes or small trees, and some species primarily forage in tall trees. Such habitat differences can be used to distinguish different species that look morphologically similar.

Many bacterial species have been categorized as distinct species based on ecological factors. Bacterial cells of the same species are likely to use the same types of resources (such as sugars and vitamins) and grow under the same types of conditions (such as temperature and pH). However, a drawback of this approach is that different groups of bacteria sometimes display very similar growth characteristics, and even the same species may show great variation in the growth conditions it will tolerate.

Evolutionary Relationships In Chapter 26, we will examine the methods that are used to produce evolutionary trees that describe the relationships between ancestral species and modern species. In some cases, such relationships are based on an analysis of the fossil record. For example, in Chapter 26, we will consider how the fossil record was used to construct a tree that describes the ancestors that led to modern horse species. Alternatively, another way to establish evolutionary relationships is by the analysis of DNA sequences. Researchers can obtain samples of cells from different individuals and compare the genes within those cells to see how similar or different they are.

Species Concepts Thus far, we have considered multiple ways to identify species. The most commonly used characteristics to distinguish species are morphological traits, the ability to interbreed, molecular features, ecological factors, and evolutionary relationships.

A **species concept** is a way to define the concept of a species and/or provide an approach to distinguish one species from another. In 1942, Ernst Mayr proposed one of the first species concepts called the **biological species concept**. According to this idea, a species is a group of individuals whose members have the potential to interbreed with one another in nature to produce viable, fertile offspring but cannot successfully interbreed with members of other species. The biological species concept emphasizes reproductive isolation as the most important criterion for delimiting species.

Since 1942, over 20 different species concepts have been proposed by a variety of evolutionary biologists. Another example is the **evolutionary lineage concept** proposed by American paleontologist George Gaylord Simpson in 1961. A **lineage** is a series of species that forms a line of descent, with each new species the direct result of speciation from an immediate ancestral species. According to Gaylord, species should be defined based on the separate evolution of lineages. A third example is the **ecological species concept**, described by American evolutionary biologist Leigh Van Valen in 1976. According to this viewpoint, each species occupies an ecological niche, which is the unique set of habitat resources that a species requires, as well as its influence on the environment and other species.

Most evolutionary biologists would agree that different methods are needed to distinguish the vast array of species on Earth. Even so, some evolutionary biologists have questioned whether it is valid to have many different species concepts. In

1998, Kevin de Queiroz suggested that there is only a single general species concept, which concurs with Simpson's evolutionary lineage concept, and includes all previous concepts. According to de Queiroz's **general lineage concept**, each species is a population of an independently evolving lineage. Each species has evolved from a specific series of ancestors and, as a consequence, forms a group of organisms with a particular set of characteristics. Multiple criteria are used to determine if a population is part of an independent evolutionary lineage, and thus a species, which is distinct from others. Typically, researchers will use analyses of morphology, reproductive isolation, DNA sequences, and ecology to determine if a population or group of populations is distinct from others. Because of its generality, the general lineage concept has received significant support.

Reproductive Isolating Mechanisms Help to Maintain the Distinctiveness of Each Species

Thus far we have considered various ways to identify different species. In our discussion, you may have realized that the identification of a species is not always a simple matter. With regard to plants and animals, the phenomenon of reproductive isolation has played a major role in the way that biologists study plant and animal species, partly because it identifies a possible mechanism for the process of forming new species. For this reason, much research has been done to try to understand **reproductive isolating mechanisms**, the mechanisms that prevent interbreeding between different species. Why do reproductive isolating mechanisms occur? Populations do not intentionally erect these reproductive barriers. Rather, reproductive isolating mechanisms are a consequence of genetic changes that occur usually because a species becomes adapted to its own particular environment. The view of evolutionary biologists is that reproductive isolation typically evolves as a by-product of genetic divergence. Over time, as a species evolves its own unique characteristics, some of those traits are likely to prevent breeding with other species.

Reproductive isolating mechanisms fall into two categories: **prezygotic isolating mechanisms** prevent the formation of a zygote, whereas **postzygotic isolating mechanisms** block the development of a viable and fertile individual after fertilization has taken place. Figure 25.2 summarizes some of the more common ways that reproductive isolating mechanisms prevent reproduction between different species. When two species do produce offspring, such an offspring is called an **interspecies hybrid**.

Prezygotic Isolating Mechanisms We will consider five types of prezygotic isolating mechanisms. One obvious way to prevent interbreeding is for members of different species to never come in contact with each other. This phenomenon, called habitat isolation, may involve a geographic barrier to interbreeding. For example, a large body of water may separate two different plant species that live on nearby islands.

A second prezygotic isolating mechanism is temporal isolation, in which species happen to reproduce at different times of the day or year. In the northeastern U.S., for example, the two most abundant field crickets, *Gryllus veletis* and *Gryllus*

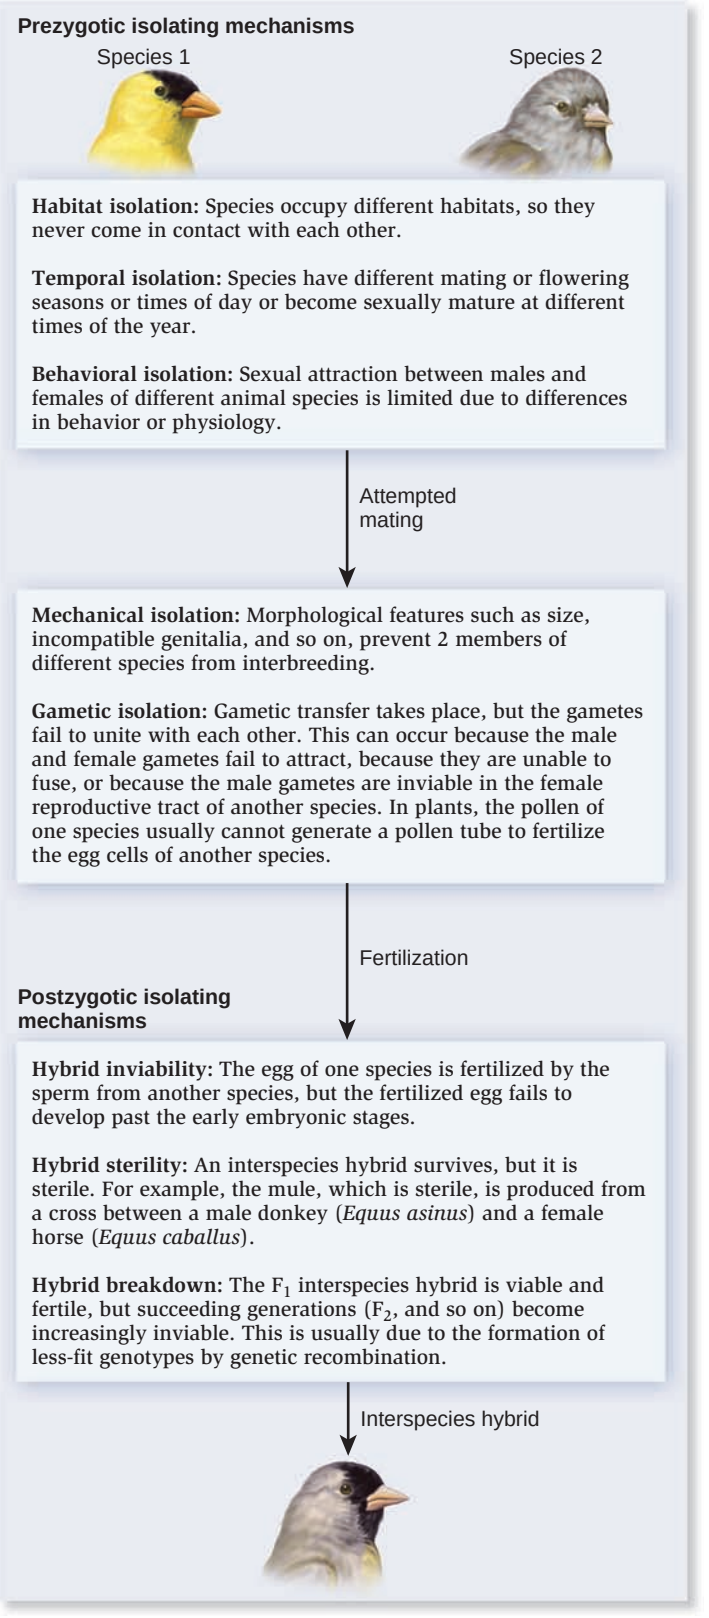

Figure 25.2 **Reproductive isolating mechanisms.** These mechanisms prevent successful breeding between different species. They can occur prior to fertilization (prezygotic) or after fertilization (postzygotic).

(a) Spring field cricket (*Gryllus veletis*)

(b) Fall field cricket (*Gryllus pennsylvanicus*)

Figure 25.3 An example of temporal isolation.
Interbreeding between these two species of crickets does not usually occur because *Gryllus veletis* matures in the spring, whereas *Gryllus pennsylvanicus* matures in the fall.

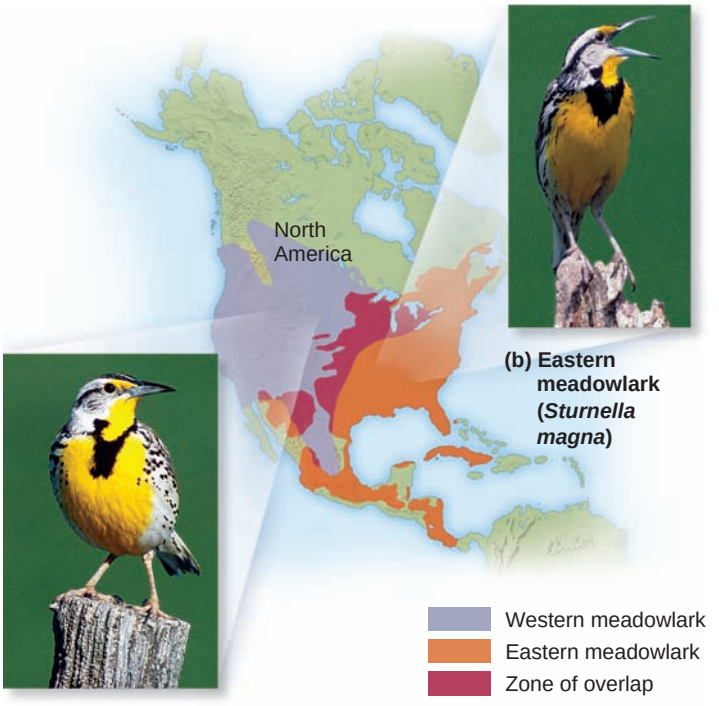
Concept check: *Is this an example of a prezygotic or a postzygotic isolating mechanism?*

pennsylvanicus (spring and fall field crickets, respectively), do not differ in song or habitat and are morphologically very similar (Figure 25.3). How do the two species maintain reproductive isolation? *G. veletis* matures in the spring, whereas *G. pennsylvanicus* matures in the fall. This minimizes interbreeding between the two species.

In the case of animals, mating behavior and anatomy often play key roles in promoting reproductive isolation. An example of the third type of prezygotic isolation, behavioral isolation, is found between the western meadowlark (*Sturnella neglecta*) and eastern meadowlark (*Sturnella magna*). Both species are nearly identical in shape, coloration, and habitat, and their ranges overlap in the central U.S. (Figure 25.4). For many years, they were thought to be the same species. When biologists discovered that the western meadowlark is a separate species, it was given the species name *S. neglecta* to reflect the long delay in its recognition. In the zone of overlap, very little interspecies mating takes place between western and eastern meadowlarks, largely due to differences in their songs. The song of the western meadowlark is a long series of flutelike gurgling notes that go down the scale. By comparison, the eastern meadowlark's song is a simple series of whistles, typically about four or five notes. These differences in songs enable meadowlarks to recognize potential mates as members of their own species.

A fourth type of prezygotic isolation, called mechanical isolation, occurs when morphological features such as size or incompatible genitalia prevent two species from interbreeding. For example, male dragonflies use a pair of special appendages to grasp females during copulation. When a male tries to mate with a female of a different species, his grasping appendages do not fit her body shape.

A fifth type of prezygotic isolating mechanism can occur when two species attempt to interbreed, but the gametes fail to unite in a successful fertilization event. This phenomenon, called gametic isolation, is widespread among plant and animal species. In aquatic animals that release sperm and egg cells into the water, gametic isolation is important to prevent interspecies hybrids. For example, closely related species of sea urchins



(a) Western meadowlark (*Sturnella neglecta*)

Figure 25.4 An example of behavioral isolation.
(a) The western meadowlark (*Sturnella neglecta*) and **(b)** eastern meadowlark (*Sturnella magna*) are very similar in appearance. The red region in this map shows where the two species' ranges overlap. However, very little interspecies mating takes place due to differences in their songs.

may release sperm and eggs into the water at the same time. Researchers have discovered that sea urchin sperm have a protein on their surface called bindin, which mediates sperm–egg attachment and membrane fusion. The structure of bindin is significantly different among different sea urchin species and thereby ensures that fertilization occurs only between sperm and egg cells of the same species.

In flowering plants, gametic isolation is commonly associated with pollination. As discussed in Chapter 39, plant fertilization is initiated when a pollen grain lands on the stigma of a flower and sprouts a pollen tube that ultimately reaches an egg cell (look ahead to Figure 39.4). When pollen is released from a plant, it could be transferred to the stigma of many different plant species. In most cases, when a pollen grain lands on the stigma of a different species, it either fails to generate a pollen tube or the tube does not grow properly and reach the egg cell.

Postzygotic Isolating Mechanisms Let's now turn to postzygotic mechanisms of reproductive isolation. The first such mechanism is hybrid inviability, in which an egg of one species is fertilized by a sperm from another species, but the fertilized egg cannot develop past the early embryonic stages.

A second mechanism is hybrid sterility, in which an interspecies hybrid may be viable but sterile. A classic example of hybrid sterility is the mule, which is produced by a mating between a male donkey (*Equus asinus*) and a female horse

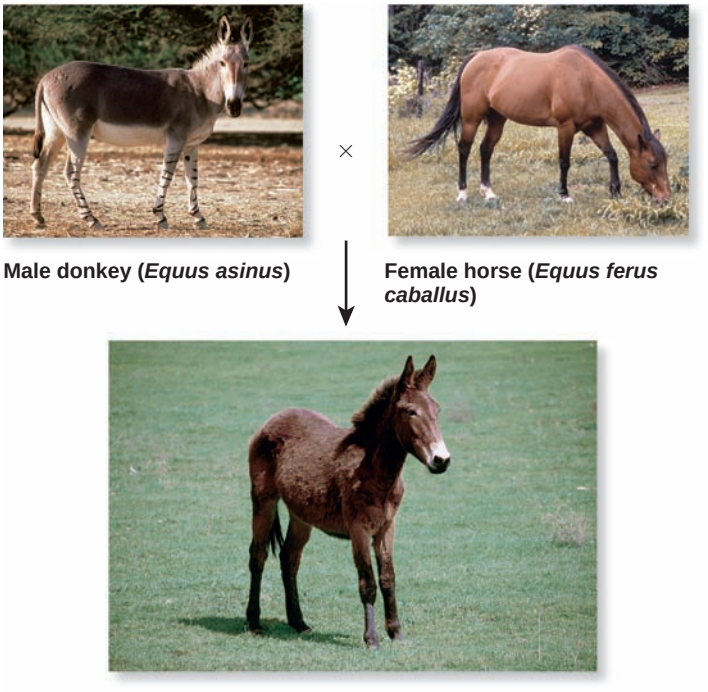


Figure 25.5 **An example of hybrid sterility.** When a male donkey (*Equus asinus*) mates with a female horse (*Equus ferus caballus*), their offspring is a mule, which is usually sterile.

Concept check: *Is this an example of a prezygotic or a postzygotic isolating mechanism?*

(*Equus ferus caballus*) (Figure 25.5). All male mules and most female mules are sterile. Why are mules usually sterile? Two reasons explain the sterility. Because the horse has 32 chromosomes per set and a donkey has 31, a mule inherits 63 chromosomes (32 + 31). Due to the uneven number, all of the chromosomes cannot pair evenly. Also, the chromosomes of the horse and donkey have structural differences, which either prevent them from pairing correctly or lead to chromosomal abnormalities if crossing over occurs during meiosis. For these reasons, mules usually produce inviable gametes. Note that the mule has no species name because it is not considered a species due to this sterility.

Finally, interspecies hybrids may be viable and fertile, but the subsequent generation(s) may harbor genetic abnormalities that are detrimental. This third mechanism, called hybrid breakdown, can be caused by changes in chromosome structure. The chromosomes of closely related species may have structural differences from each other, such as inversions. In hybrids, a crossover may occur in the region that is inverted in one species but not the other. This will produce gametes with too little or too much genetic material. Such hybrids would often have offspring with developmental abnormalities.

Postzygotic isolating mechanisms tend to be uncommon in nature compared to prezygotic mechanisms. Why are postzygotic mechanisms rare? One explanation is that they are more costly in terms of energy and resources used. For example, a female mammal would use a large amount of energy to produce an offspring that is sterile. Evolutionary biologists hypothesize that natural selection has favored prezygotic isolating mechanisms because they do not waste a lot of energy.

25.2 Mechanisms of Speciation

Speciation, the formation of a new species, is caused by genetic changes in a particular group that make it different from the species from which it was derived. As discussed in Chapter 24, random mutations in genes can be acted upon by natural selection and other evolutionary mechanisms to alter the genetic composition of a population. New species commonly evolve in this manner. In addition, interspecies matings, changes in chromosome number, and horizontal gene transfer may also cause new species to arise. In all of these cases, the underlying cause of speciation is the accumulation of genetic changes that ultimately promote enough differences so that we judge a population to constitute a unique species.

Even though genetic changes account for the phenotypic differences observed among living organisms, such changes do not fully explain the existence of many distinct species on our planet. Why does life often diversify into the more or less discrete populations that we recognize as species? Two main explanations have been proposed:

1. In some cases, speciation may occur due to abrupt events, such as changes in chromosome number, which can cause reproductive isolation.
2. More commonly, species arise as a consequence of adaptation to different ecological niches. For sexually reproducing organisms, reproductive isolation is typically a by-product of that adaptation.

Depending on the species involved, one or both factors may play a dominant role in the formation of new species. In this section, we will consider how reproductive isolating mechanisms and adaptation to particular environments are critical aspects of the speciation process.

Geographic and Habitat Isolation Can Promote Allopatric Speciation

Cladogenesis is the splitting or diverging of a population into two or more species. In the case of sexually reproducing organisms, the process of cladogenesis requires that gene flow becomes interrupted between two or more populations, limiting or eliminating reproduction between members of different populations. **Allopatric speciation** (from the Greek *allos*, meaning other, and the Latin *patria*, meaning homeland) is the most prevalent way for cladogenesis to occur. This form of speciation occurs when some members of a species occupy a habitat that is isolated from other members. Typically, this isolation may involve a geographic barrier such as a large area of land or a large body of water.

In some cases, geographic separation may be caused by slow, geological events that eventually produce quite large geographic barriers. For example, a mountain range may emerge and split one species that occupies the lowland regions, or a creeping glacier may divide a population. Figure 25.6 shows an interesting example in which geological separation promoted

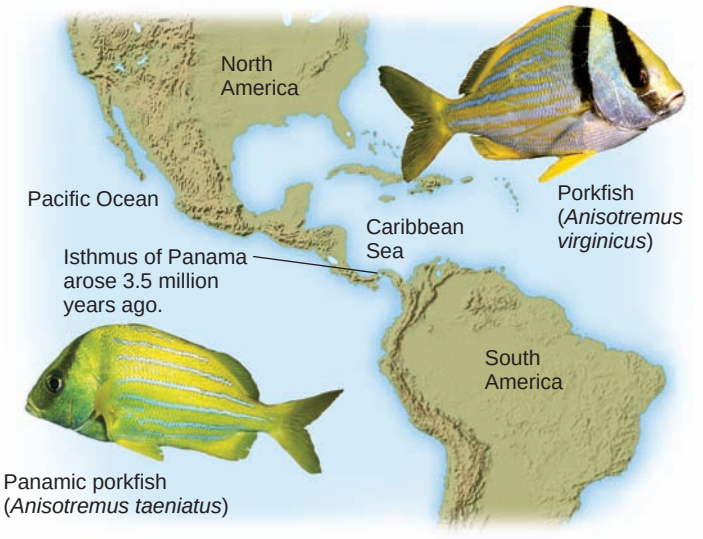

Figure 25.6 **An example of allopatric speciation.** An ancestral fish population was split into two by the formation of the Isthmus of Panama about 3.5 million years ago. Since that time, different genetic changes occurred in the two populations because of their geographic isolation. These changes eventually led to the formation of different species: the Panamic porkfish (*Anisotremus taeniatus*) is found in the Pacific Ocean, whereas the porkfish (*Anisotremus virginicus*) is found in the Caribbean Sea.

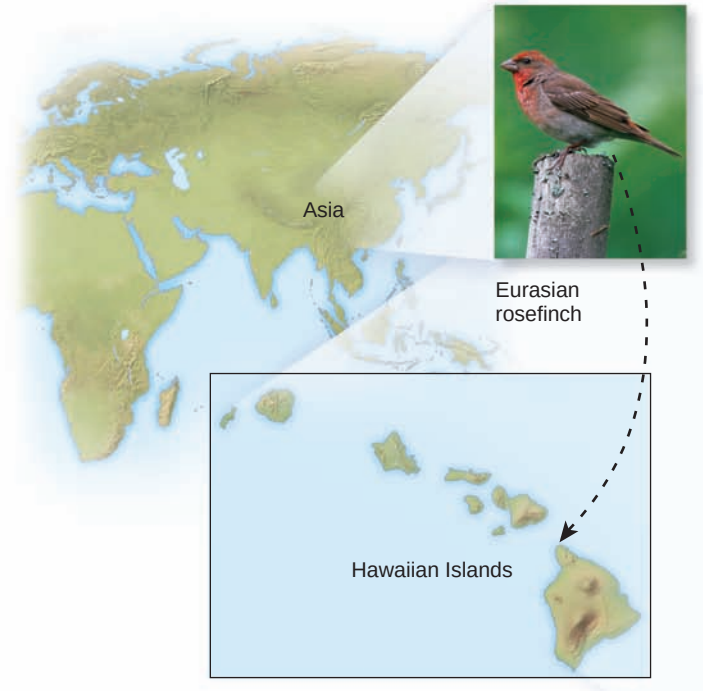
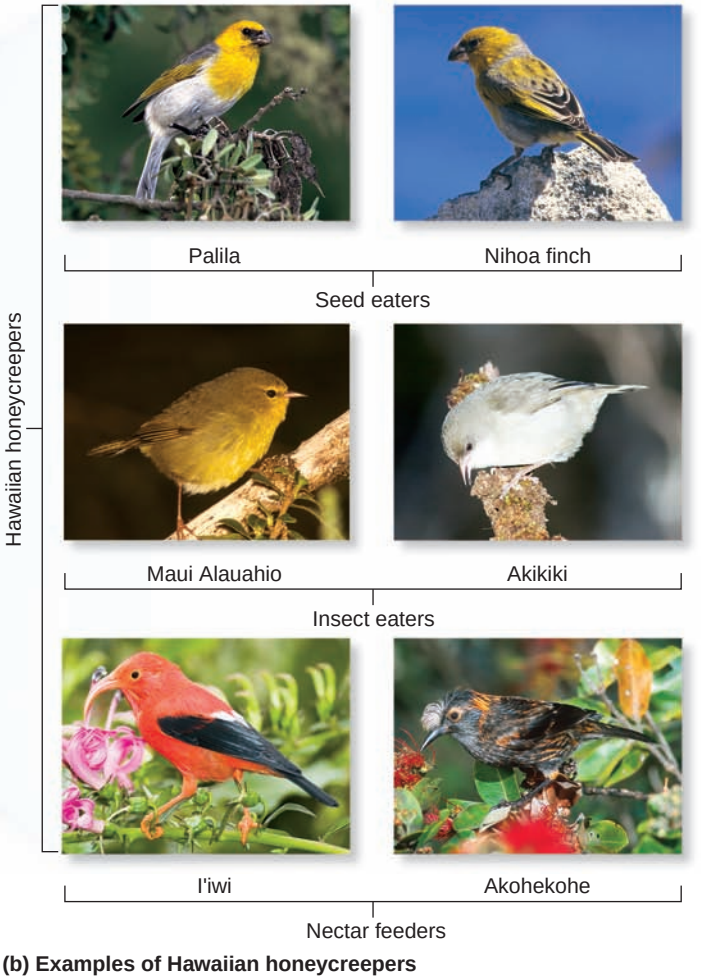
speciation. A fish called the Panamic porkfish (*Anisotremus taeniatus*) is found in the Pacific Ocean, whereas the porkfish (*Anisotremus virginicus*) is found in the Caribbean Sea. These two species were derived from an ancestral species whose population was split by the formation of the Isthmus of Panama about 3.5 million years ago. Before that event, the waters of the Pacific Ocean and Caribbean Sea mixed freely. Since the formation of the isthmus, the two populations have been geographically isolated and have evolved into distinct species.

Allopatric speciation can also occur when a small population moves to a new location that is geographically isolated from the main population. For example, a storm may force a small group of birds from a mainland to a distant island. In this case, migration between the island and the mainland population is an infrequent event. In a relatively short period of time, the founding population on the island may evolve into a new species. How does speciation occur rapidly? Because the environment on the island may differ significantly from the mainland environment, natural selection may rapidly alter the genetic composition of the population, leading to adaptation to the new environment. This scenario is thought to be responsible for the speciation of honeycreepers that occurred on the Hawaiian Islands (Figure 25.7).



(a) Migration of ancestor to the Hawaiian Islands



(b) Examples of Hawaiian honeycreepers

Figure 25.7 **An example of adaptive radiation.** **(a)** The honeycreepers' ancestor is believed to be related to a Eurasian rosefinch that arrived on the Hawaiian Islands approximately 3–7 million years ago. Since that time, at least 54 different species of honeycreepers (*Drepanidinae*) have evolved on the islands. **(b)** Adaptations to feeding have produced honeycreeper species with notable differences in beak morphology.

Concept check: *Explain why so many different species of honeycreepers evolved on the Hawaiian Islands.*

The Hawaiian Islands are a showcase of allopatric speciation. The islands' extreme isolation coupled with their phenomenal array of ecological niches has enabled a small number of founding species to evolve into a vast assortment of different species. Biologists have investigated several examples of **adaptive radiation**, in which a single ancestral species has evolved into a wide array of descendant species that differ greatly in their habitat, form, or behavior. For example, approximately 1,000 species of *Drosophila* are found dispersed throughout the Hawaiian Islands. Evolutionary studies suggest that these were derived from a single colonization by one species of fruit fly!

As shown in Figure 25.7, an example of adaptive radiation is seen with a family of birds called honeycreepers (*Drepanidinae*). Researchers estimate that the honeycreepers' ancestor arrived in Hawaii 3–7 million years ago. This ancestor was a single species of finch, possibly a Eurasian rosefinch (genus *Carpodacus*) or, less likely, the North American house finch (*Carpodacus mexicanus*). At least 54 different species of honeycreepers, many of which are now extinct, have evolved from this founding event to fill available niches in the islands' habitats. Seed eaters developed stouter, stronger bills for cracking tough husks. Insect-eating honeycreepers developed thin, warbler-like bills for picking insects from foliage or strong, hooked bills to root out wood-boring insects. Nectar-feeding honeycreepers evolved curved bills for extracting nectar from the flowers of Hawaii's endemic plants.

Before ending our discussion of allopatric speciation, let's consider a common situation in which geographic separation is not complete. The zones where two populations can interbreed are known as **hybrid zones**. Figure 25.8 shows a hybrid zone along a mountain pass that connects two deer populations. For speciation to occur, the amount of gene flow within hybrid zones must become very limited. But how does this happen? As the two populations accumulate different genetic changes, this may decrease the ability of individuals from different populations

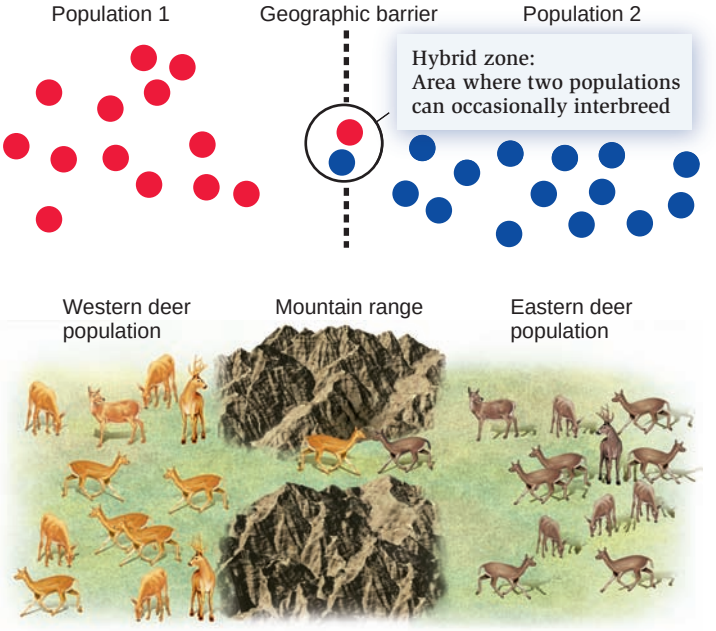


Figure 25.8 **Hybrid zones.** Two populations of deer are separated by a mountain range. A hybrid zone exists in a mountain pass where occasional interbreeding may occur.

to mate with each other in the hybrid zone. For example, natural selection in the western deer population may favor an increase in body size that is not favored in the eastern population. Over time, as this size difference between members of the two populations becomes greater, breeding in the hybrid zone may decrease. Larger individuals may not interbreed easily with smaller individuals due to mechanical isolation. Alternatively, larger individuals may prefer larger individuals as mates, while smaller individuals may also prefer each other. Once gene flow through the hybrid zone is greatly diminished, the two populations are reproductively isolated. Over the course of many generations, such populations may evolve into distinct species.

Feature Investigation

Podos Found That an Adaptation to Feeding May Have Promoted Reproductive Isolation in Finches

In 2001, American evolutionary biologist Jeffrey Podos analyzed the songs of Darwin's finches on the Galápagos Islands to determine how environmental adaptation may contribute to reproductive isolation. As in honeycreepers, the differences in beak sizes and shapes among the various species of finches are adaptations to different feeding strategies. Podos hypothesized that changes in beak morphology could also impact the songs that the birds produce, thereby having the potential to affect mate choice. The components of the vocal tract of birds, including the trachea, larynx, and beak, work collectively to produce a bird's song. Birds actively modify the shape of their vocal tracts during singing, and beak movements are normally very rapid and precise.

Podos focused on two aspects of a bird's song. The first feature is the frequency range, which is a measure of the minimum and maximum frequencies in a bird's song. The second feature is the trill rate. A trill is a series of notes or group of notes repeated in succession. Figure 25.9 shows a graphical depiction of the songs of Darwin's finches. As you can see, the song patterns of these finches are quite different from each other.

To quantitatively study the relationship between beak size and song, Podos first captured male finches on one of the Galápagos Islands (Santa Cruz) and measured their beak sizes (Figure 25.10). The birds were banded and then released into the wild. The banding provided a way to identify the birds whose beaks had already been measured. After release, the songs of the banded birds were recorded on a tape recorder, and their range of frequencies and trill rate were analyzed. Podos then compared the data for the Galápagos finches to a large body of data that had been collected on many other bird species. This comparison was used to evaluate whether beak size, in this case, beak depth—the measurement of the beak from top to bottom, at its base—constrained either the frequency range and/or the trill rate of the finches.

Figure 25.9 **Differences in the songs of Galápagos finches.** These spectrograms depict the frequency of each bird's song over time, measured in kilohertz (kHz). The songs are produced in a series of trills that have a particular pattern and occur at regular intervals. Notice the differences in frequency and trill rate between different species of birds.

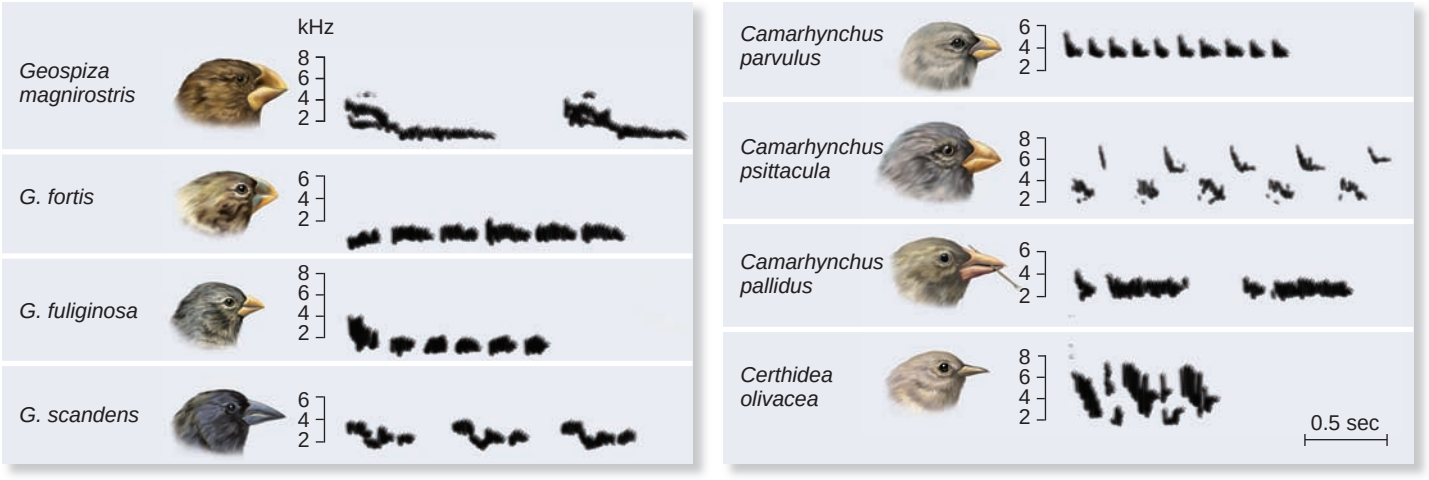

Figure 25.10 **Study by Podos investigating the effects of beak depth on song among different species of Galápagos finches.**

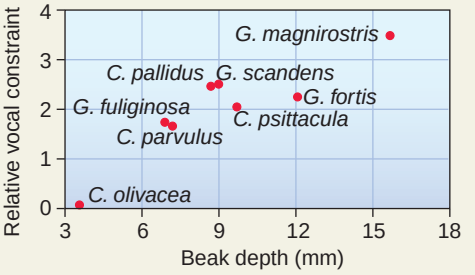
HYPOTHESIS Changes in beak morphology that are an adaptation to feeding may also affect the songs of Galápagos finches and thereby lead to reproductive isolation between species.

KEY MATERIALS This study was conducted on finch populations of the Galápagos Island of Santa Cruz.

	Experimental level	Conceptual level
1 Capture male finches and measure their beak depth. Beak depth is measured at the base of beak, from top to bottom.		This is a measurement of phenotypic variation in beak size.
2 Band the birds and release them back into the wild.		Banding allows identification of birds with known beak depths.
3 Record the bird's songs on a tape recorder.		This is a measurement of phenotypic variation in song.
4 Analyze the songs with regard to frequency range and trill rate.		The frequency range is the value between high and low frequencies. The trill rate is the number of repeats per unit time.

5 THE DATA

The data for the Galápagos finches were compared to a large body of data that had been collected on many other bird species. The relative constraint on vocal performance is higher if a bird has a more narrow frequency range and/or a slower trill rate. These constraints were analyzed with regard to each bird's beak depth.



6 CONCLUSION Larger beak size, which is an adaptation to cracking open large, hard seeds, constrains vocal performance. This may affect mating song patterns and thereby promote reproductive isolation and, in turn, speciation.

7 SOURCE Podos, Jeffrey. 2001. Correlated evolution of morphology and vocal signal structure in Darwin's finches. *Nature* 409:185–188.

The results of this comparison are shown in the data of Figure 25.10. As seen here, the relative constraint on vocal performance became higher as the beak depth became larger. This means that birds with larger beaks had a more narrow frequency range and/or a slower trill rate. Podos proposed that as jaws and beaks become adapted for strength to crack open larger, harder seeds, they will be less able to perform the rapid movements associated with certain types of songs. In contrast, the finches with smaller beaks that were adapted to probe for insects or eat smaller seeds had less constraint on their vocal performance. From the perspective of evolution, the changes observed in song patterns for the Galápagos finches could have played an important role in promoting reproductive isolation, because song pattern is an important factor in mate selection in birds. Therefore, a by-product of beak adaptation for feeding is that it also appears to have affected song pattern, possibly promoting reproductive isolation. In this way, populations of finches would have evolved into distinct species.

Experimental Questions

1. What did Podos hypothesize regarding the effects of beak size on a bird's song? How could changes in beak size and shape lead to reproductive isolation among the finches?
2. How did Podos test the hypothesis that beak morphology caused changes in the birds' songs?
3. Did the results of Podos's study support his original hypothesis? Explain. What is meant by the phrase "by-product of adaptation," and how does it apply to this particular study?

Sympatric Speciation Occurs When Populations Are in Direct Contact

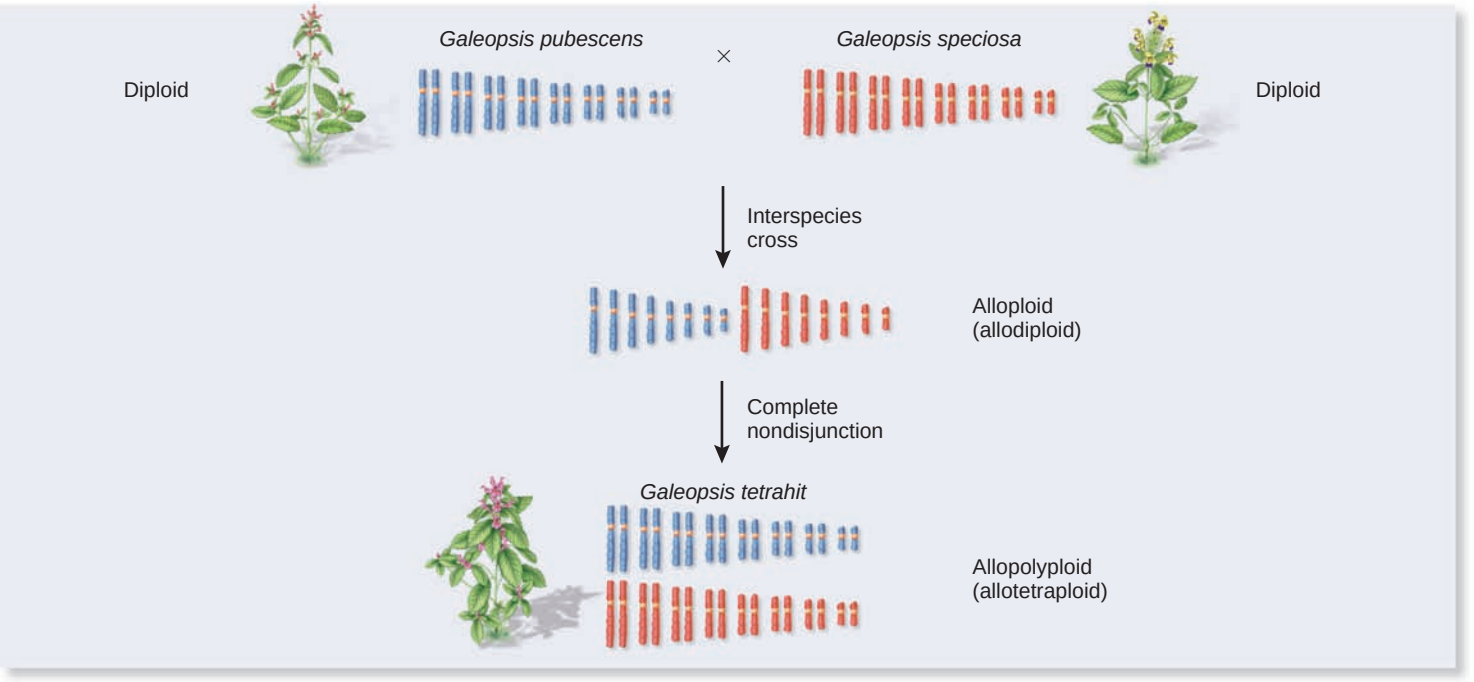
Sympatric speciation (from the Greek *sym*, meaning together) occurs when members of a species that are within the same range diverge into two or more different species even though there are no physical barriers to interbreeding. Although sympatric speciation is believed to be much less common than allopatric speciation, particularly in animals, evolutionary biologists have discovered several ways in which it can occur. These include polyploidy, adaptation to local environments, and sexual selection.

Polyploidy A type of genetic change that can cause immediate reproductive isolation is **polyploidy**, in which an organism has more than two sets of chromosomes. Plants tend to be more tolerant of changes in chromosome number than animals. For example, many crops and decorative species of plants are polyploid. How does polyploidy occur? One mechanism is complete nondisjunction of chromosomes, which can increase the number of chromosome sets in a given species (autopolyploidy). Such changes can result in an abrupt sympatric speciation. For example, nondisjunction could produce a tetraploid plant with four sets of chromosomes from a species that was diploid with two sets. A cross between a tetraploid and a diploid produces a triploid offspring with three sets of chromosomes. Triploid offspring are usually sterile because an odd number of chromosomes cannot be evenly segregated during meiosis. This hybrid sterility causes reproductive isolation between the tetraploid and diploid species.

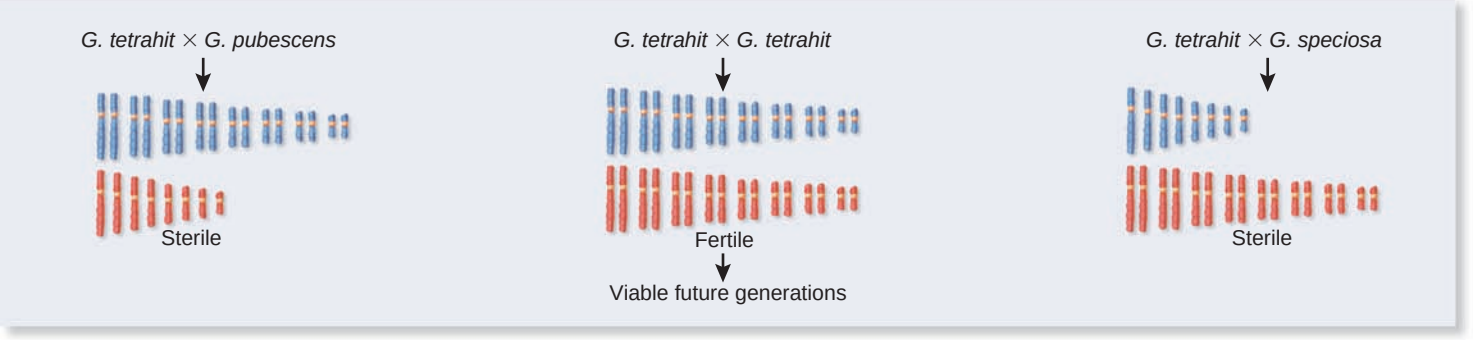
Another mechanism that leads to polyploidy is interspecies breeding. An **alloploid** organism contains at least one set of chromosomes from two or more different species. This term refers to the occurrence of chromosome sets (ploidy) from the genomes of different (allo-) species. When two different species interbreed, this may produce an allodiploid that has only one set of chromosomes from each species. Species that are close evolutionary relatives are most likely to breed and

produce allodiploid offspring. For example, closely related species of grasses may interbreed to produce allodiploids. An organism containing two or more complete sets of chromosomes from two or more different species is called an allopolyploid. An allopolyploid can be the result of interspecies breeding between species that are already polyploid, or it can occur as a result of nondisjunction in an allodiploid organism. For example, complete nondisjunction in an allodiploid could produce an allotetraploid, which is an allopolyploid with two complete sets of chromosomes from two species for a total of four sets.

The formation of an allopolyploid can also abruptly lead to reproductive isolation and thereby promote speciation. As an example, let's consider the origin of a natural species of a plant called the common hemp nettle, *Galeopsis tetrahit*. This species is thought to be an allotetraploid derived from two diploid species, *Galeopsis pubescens* and *Galeopsis speciosa* (Figure 25.11a). These two diploid species contain 16 chromosomes each ($2n = 16$), while *G. tetrahit* contains 32 chromosomes. Though the origin of *G. tetrahit* is not completely certain, research suggests it may have originated from an interspecies cross between *G. pubescens* and *G. speciosa*, which initially



(a) Possible formation of *G. tetrahit*



(b) Outcome of breeding among *G. tetrahit*, *G. pubescens*, and *G. speciosa*

Figure 25.11 **Polyploidy and sympatric speciation.** **(a)** *Galeopsis tetrahit* may have arisen by an interspecies cross between *G. pubescens* and *G. speciosa*, which was followed by a subsequent nondisjunction event. **(b)** Polyploidy may have caused reproductive isolation between these three natural species of hemp nettle. If *G. tetrahit* is mated with either of the other two species, the resulting offspring would be monoploid for one chromosome set and diploid for the other set, making them sterile. Therefore, *G. tetrahit* is reproductively isolated from the diploid species, making it a new species.

Concept check: *Suppose that G. tetrahit was crossed to G. pubescens to produce an interspecies hybrid as shown at the bottom of this figure. If this interspecies hybrid was crossed to G. tetrahit, how many chromosomes do you think an offspring would have? The answer you give should be a range, not a single number.*

produced an allodiploid with 16 chromosomes (one set from each species). The allodiploid then underwent complete nondisjunction to become an allotetraploid carrying four sets of chromosomes—two from each species.

How do these genetic changes cause reproductive isolation? The allotetraploid, *G. tetrahit*, is fertile, because all of its chromosomes occur in homologous pairs that can segregate evenly during meiosis. However, a cross between an allotetraploid and a diploid, *G. pubescens* or *G. speciosa*, produces an offspring that is monoploid for one chromosome set and diploid for the other set (Figure 25.11b). The chromosomes of the monoploid set cannot be evenly segregated during meiosis. These offspring are expected to be sterile, because they will produce gametes that have incomplete sets of chromosomes. This hybrid sterility causes the allotetraploid to be reproductively isolated from both diploid species. Therefore, this process could have led to the formation of a new species, *G. tetrahit*, by sympatric speciation.

Polyploidy is so frequent in plants that it is a major mechanism of their speciation. In ferns and flowering plants, about 40–70% of the species are polyploid. By comparison, polyploidy can occur in animals, but it is much less common. For example, less than 1% of reptiles and amphibians have been identified that are polyploids derived from diploid ancestors.

Adaptation to Local Environments In some cases, a geographic area may have variation so that some members of a population may diverge and occupy different local environments that are continuous with each other. An early example of this type of sympatric speciation was described by Jeffrey Feder, Guy Bush, and colleagues. They studied the North American apple maggot fly (*Rhagoletis pomenella*). This fly originally fed on native hawthorn trees. However, the introduction of apple trees approximately 200 years ago provided a new local environment for this species. The apple-feeding populations of this species develop more rapidly because apples mature more quickly than hawthorn fruit. The result is partial temporal isolation, which is an example of prezygotic reproductive isolation. Although the two populations—those that feed on apple trees and those that feed on hawthorn trees—are considered subspecies, evolutionary biologists speculate they may eventually become distinct species due to reproductive isolation and the accumulation of independent mutations in the two populations.

Sara Via and colleagues have studied the beginnings of sympatric speciation in pea aphids (*Acyrthosiphon pisum*), a small, plant-eating insect. Pea aphids in the same geographic area can be found on both alfalfa (*Medicago sativa*) and red clover (*Trifolium pratenae*) (Figure 25.12). Although pea aphids on these two host plants look identical, they show significant genetic differences and are highly ecologically specialized. Pea aphids that are found on alfalfa exhibit a lower fitness when transferred to red clover, whereas pea aphids found on red clover exhibit a lower fitness when transferred to alfalfa. The same traits involved in this host specialization cause these two groups of pea aphids to be substantially reproductively isolated. Taken together, the observations of the North American apple maggot fly, pea aphids, and other insect species suggest

Figure 25.12 **Pea aphids, a possible example of sympatric speciation in progress.** Some pea aphids prefer alfalfa, whereas others prefer red clover. These two populations may be in the process of sympatric speciation.

Concept check: *How may host preference eventually lead to speciation?*

that diversifying selection (described in Chapter 24) may occur because some members evolve to feed on a different host. This may be an important mechanism of sympatric speciation among insects.

A third example in which sympatric speciation may be occurring due to local environment adaptation involves metal tolerance in colonial bentgrass (*Agrostis capillarus*), which was discussed in Chapter 24 (refer back to Figure 24.5). Along metal mines in south Wales, the soil is contaminated with high levels of heavy metals such as copper. On these sites, natural selection has promoted the spread of plants carrying alleles that confer resistance to the heavy metals. Although these alleles enable *A. capillarus* to grow on contaminated soil, they inhibit growth on normal, uncontaminated soil. Therefore, along metal mines, metal tolerance is advantageous, but in adjacent pastures, it is a disadvantage. Any gene flow between the mine and pasture populations would introduce less favored alleles into either population. In recent years, the metal-tolerant plants are starting to show a change in their flowering season, which will minimize interbreeding. Over time, if this process continues, the metal-tolerant population may no longer breed with the original metal-sensitive species because their flowering periods do not overlap.

Sexual Selection Another mechanism that may promote sympatric speciation is sexual selection. As discussed in

Chapter 24, one type of sexual selection is mate choice (refer back to Figures 24.8 and 24.9). Ole Seehausen and Jacques van Alphen found that male coloration in African cichlids is subject to female choice. *Pundamilia pundamilia* females preferred *P. pundamilia* males, and *P. nyererei* females preferred *P. nyererei* males. In this case, sexual selection appears to have followed a diversifying mechanism in which certain females prefer males with one color pattern, while other females prefer males with a different color pattern. A possible outcome of such sexual selection is that it can separate one large sympatric population into smaller populations that eventually become distinct species because they selectively breed among themselves.

25.3 The Pace of Speciation

Throughout the history of life on Earth, the rate of evolutionary change and speciation has not been constant. Even Darwin himself suggested that evolution can be fast or slow. Figure 25.13 illustrates contrasting views concerning the rate of evolutionary change. These ideas are not mutually exclusive but represent two different ways to consider the tempo of evolution. The concept of **gradualism** suggests that each new species evolves continuously over long spans of time (Figure 25.13a). The principal idea is that large phenotypic differences that produce new species are due to the accumulation of many small genetic changes. By comparison, the concept of **punctuated equilibria**, advocated in the 1970s by American paleontologists and evolutionary biologists Niles Eldredge and Stephen Jay Gould, suggests that the tempo of evolution is more sporadic (Figure 25.13b). According to this hypothesis, species exist relatively unchanged for many generations. During this equilibrium period, genetic changes are likely to accumulate, particularly neutral changes, but genetic changes that significantly alter phenotype do not substantially change the overall composition of a population. These long periods of equilibrium are punctuated by relatively short periods (that is, on a geological timescale) during which the frequencies of certain phenotypes in a population do substantially change at a far more rapid rate.

A rapid rate of evolution could commonly occur via allopatric speciation in which a small group migrates away from a larger population to a new environment in which different alleles provide better adaptation to the surroundings. By natural selection, the small population may rapidly evolve into a new species. In addition, events such as polyploidy may abruptly create individuals with new phenotypic traits. On an evolutionary timescale, these types of events can be rather rapid, because a few genetic changes can have a major impact on phenotype.

In conjunction with genetic changes, species may also be subjected to sudden environmental shifts that quickly drive the gene pool in a particular direction via natural selection. For example, a species may be subjected to a relatively sudden environmental event that has a major impact on survival. The climate may change, or a new predator may infiltrate the geographic range of the species. Natural selection may lead to a rapid evolution of the gene pool by favoring those alleles that allow members of the population to survive the climatic change or to have phenotypic characteristics that allow them to avoid the predator.

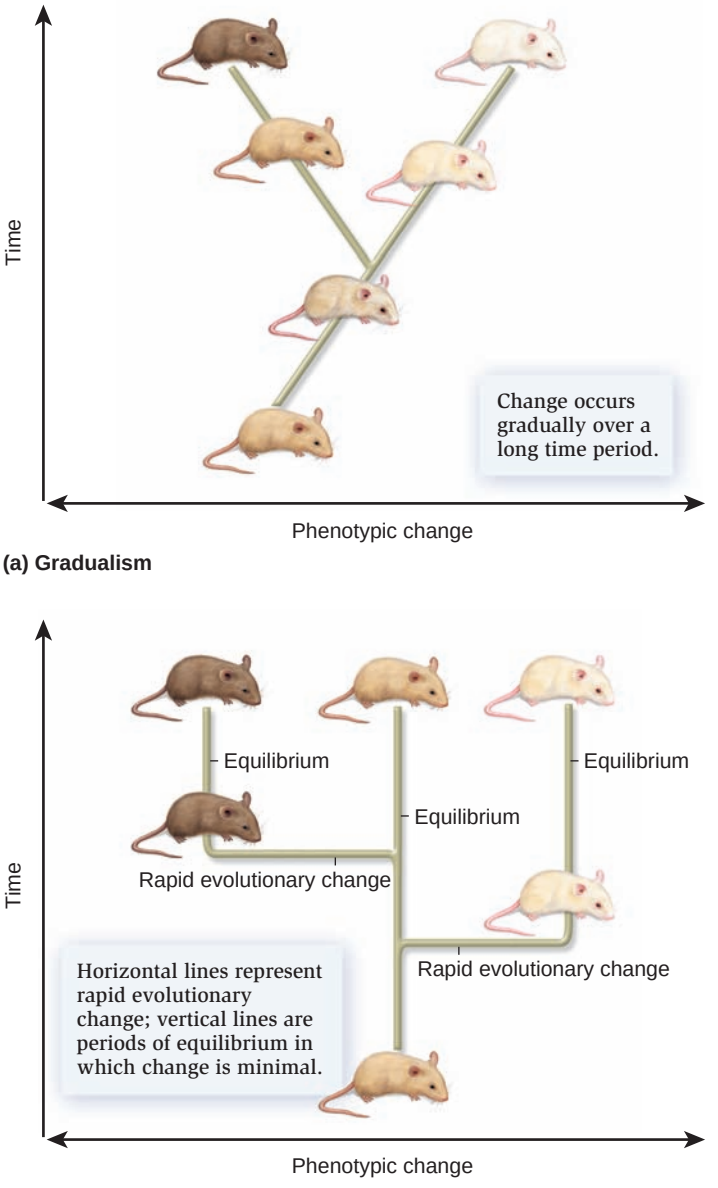


Figure 25.13 **A comparison of gradualism and punctuated equilibrium.** **(a)** During gradualism, the phenotypic characteristics of a species gradually change due to the accumulation of small genetic changes. **(b)** During punctuated equilibrium, long periods of equilibrium in which species exist essentially unchanged are punctuated by relatively short periods of evolutionary change during which phenotypic characteristics may change rapidly.

Which viewpoint is correct, punctuated equilibrium or gradualism? Both have merit. The occurrence of punctuated equilibrium is often supported by the fossil record. New species seem to arise rather suddenly in a layer of rocks, persist relatively unchanged for a very long period of time, and then

become extinct. In such cases, scientists think that the transition period during which a previous species evolved into a new species was so short that few, if any, of the transitional members were preserved as fossils. Even so, these rapid periods of change were probably followed by long periods of equilibrium that likely involved the additional accumulation of many small genetic changes, consistent with gradualism.

Finally, another issue associated with the speed of speciation is generation time. Species of large animals with long generation times tend to evolve much more slowly than do microbial species with short generations. Many new species of bacteria will come into existence during our lifetime, while new species of large animals tend to arise on a much longer timescale. This is an important consideration for people because bacteria have great environmental impact. They are decomposers of organic materials and pollutants in the environment, and they play a role in many diseases of plants and animals, including humans.

25.4 Evo-Devo: Evolutionary Developmental Biology

As we have learned, the origin of new species involves genetic changes that lead to adaptations to environmental niches and/or to reproductive isolating mechanisms that prevent closely related species from interbreeding. These genetic changes result in morphological and physiological differences that distinguish one species from another. In recent years, many evolutionary biologists have begun to investigate how genetic variation produces species and groups of species with novel shapes and forms. The underlying reasons for such changes are often rooted in the developmental pathways that control an organism's morphology.

Evolutionary developmental biology (referred to as **evo-devo**) is an exciting and relatively new field of biology that compares the development of different organisms in an attempt to understand ancestral relationships between organisms and the developmental mechanisms that bring about evolutionary change. During the past few decades, developmental geneticists have gained a better understanding of biological development at the molecular level. Much of this work has involved the discovery of genes that control development in experimental organisms. As more and more organisms have been analyzed, researchers have become interested in the similarities and differences that occur between closely related and distantly related species. The field of evolutionary developmental biology has arisen in response to this trend.

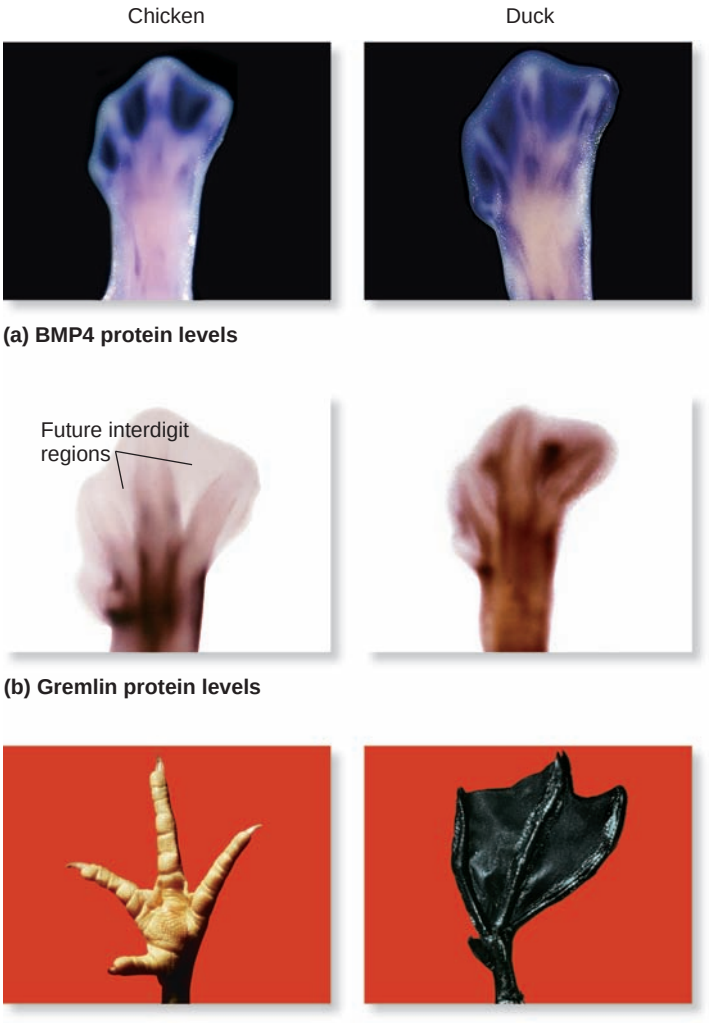
How do new morphological forms come into being? For example, how does a nonwebbed foot evolve into a webbed foot? How does a new organ, such as an eye, come into existence? As we will learn, such novelty arises through genetic changes, also called genetic innovations. Certain types of genetic innovations have been so advantageous that they have resulted in groups of new species. For example, the innovation of feathered forearms resulted in the evolution of many different species of birds. In this section, we will learn that proteins that control developmental changes, such as cell-signaling proteins and transcription factors, often play a key role in promoting the morphological changes that occur during evolution.

The Spatial Expression of Genes That Affect Development Can Have a Dramatic Effect on Phenotype

In Chapter 19, we considered the role of genetics in the development of plants and animals. As we learned, genes that play a role in development may influence cell division, cell migration, cell differentiation, and cell death. The interplay among these four processes produces an organism with a specific body pattern, a process called **pattern formation**. As you might imagine, developmental genes are very important to the phenotypes of individuals. They affect traits such as the shape of a bird's beak, the length of a giraffe's neck, and the size of a plant's flower. In recent years, the study of development has indicated that developmental genes are key players in the evolution of many types of traits. Changes in such genes affect traits that can be acted on by natural selection. Furthermore, variation in the expression of such genes may be commonly involved in the acquisition of new traits that promote speciation.

As an example, let's compare the formation of a chicken's foot with that of a duck. Developmental biologists have discovered that the morphological differences between a nonwebbed and a webbed foot are due to the differential expression of two different cell-signaling proteins called bone morphogenetic protein 4 (BMP4) and gremlin. The *BMP4* gene is expressed throughout the developing limb; this is shown in Figure 25.14a, in which the BMP4 protein is stained purple. The BMP4 protein causes cells to undergo apoptosis and die. The gremlin protein, which is stained brown in Figure 25.14b, inhibits the function of BMP4 and thereby allows cells to survive. In the developing chicken limb, the *Gremlin* gene is expressed throughout the limb, except in the regions between each digit. Therefore, in these regions, the cells die, and a chicken develops a nonwebbed foot (Figure 25.14c). By comparison, in the duck, *Gremlin* is expressed throughout the entire limb, including the interdigit regions, and as a result, the duck develops a webbed foot. Interestingly, researchers have been able to introduce gremlin protein into the interdigit regions of developing chicken limbs. This produces a chicken with webbed feet!

How are these observations related to evolution? During the evolution of birds, genetic variation arose such that some individuals expressed the *Gremlin* gene in the regions between each digit, while others did not. This variation determined whether or not a bird's feet were webbed. In terrestrial settings, having nonwebbed feet is an advantage because they enable the individual to hold onto perches, run along the ground, and snatch prey. Therefore, natural selection would favor nonwebbed feet in terrestrial environments. This process explains the occurrence of nonwebbed feet in chickens, hawks, crows, and many



(a) BMP4 protein levels

(b) Gremlin protein levels

(c) Comparison of a chicken foot and a duck foot

Figure 25.14 The role of cell-signaling proteins in the morphology of birds' feet. This figure shows how changes in developmental gene expression can produce certain traits. **(a)** Expression of the *BMP4* gene in the developing limbs. BMP4 protein is stained purple here and is expressed throughout the limb. **(b)** Expression of the *Gremlin* gene in the developing limbs. Gremlin protein is stained brown here. Note that *Gremlin* is not expressed in the interdigit regions of the chicken but is expressed in these regions of the duck. Gremlin inhibits BMP4, which causes programmed cell death. **(c)** Because BMP4 is not inhibited in the interdigit regions in the chicken, the cells in this region die, and the foot is not webbed. By comparison, inhibition of BMP4 in the interdigit regions in the duck results in a webbed foot.

Concept check: *What would you expect to happen to the morphology of the feet of ducks if the Gremlin gene was underexpressed?*

other terrestrial birds. In aquatic environments, webbed feet are an advantage because they act as paddles for swimming, so genetic variation that produced webbed feet would have been promoted by natural selection. Over time, this gave rise to the webbed feet now found in a wide variety of aquatic birds, including ducks, geese, and penguins.

The *Hox* Genes Have Been Important in the Evolution of a Variety of Body Plans Found in Different Species of Animals

The study of developmental genes has revealed interesting trends among large groups of species. *Hox* genes, which are discussed in Chapter 19, are found in all animals, indicating they have originated very early in animal evolution. Developmental biologists have hypothesized that variation in the *Hox* genes may have spawned the formation of many new body plans. As shown in Figure 25.15, the number and arrangement of *Hox* genes varies considerably among different types of animals. Sponges, the simplest of animals, have at least one *Hox* gene, whereas insects typically have nine or more. In most cases, multiple *Hox* genes occur in a cluster in which the genes are close to each other along a chromosome. In mammals, *Hox* gene clusters have been duplicated twice during the course of evolution to form four clusters, all slightly different, containing a total of 38 genes.

Researchers propose that increases in the number of *Hox* genes have been instrumental in the evolution of many animal species with greater complexity in body structure. To understand how, let's first consider *Hox* gene function. All *Hox* genes encode transcription factors that act as master control proteins to direct the formation of particular regions of the body. Each *Hox* gene controls a hierarchy of many regulatory genes that regulate the expression of genes encoding proteins that ultimately affect the morphology of the organism. The evolution of complex body plans is associated with an increase not only in the number of regulatory genes—as evidenced by the increase in *Hox* gene complexity during evolution—but also in genes that encode proteins that directly affect an organism's form and function.

How would an increase in *Hox* genes enable more complex body forms to evolve? Part of the answer lies in the spatial expression of the *Hox* genes. Different *Hox* genes are expressed in different regions of the body along the anteroposterior axis (refer back to Figure 19.16). Therefore, an increase in the number of *Hox* genes allows each of these master control genes to become more specialized in the region that it controls. In fruit flies, one segment in the middle of the body can be controlled by a particular *Hox* gene and form wings and legs, while a segment in the head region can be controlled by a different *Hox* gene and develop antennae. Therefore, research suggests that one way for new, more complex body forms to evolve is by increasing the number of *Hox* genes, thereby making it possible to form many specialized parts of the body that are organized along a body axis.

Three lines of evidence support the idea that *Hox* gene number has been instrumental in the evolution and speciation of animals with different body patterns. First, as discussed in Chapter 19, *Hox* genes are known to control the fate of regions along the anteroposterior axis. Second, as described in Figure 25.15, a general trend is observed in which animals with a more complex body structure tend to have more *Hox* genes and *Hox* clusters in their genomes compared with the genomes of

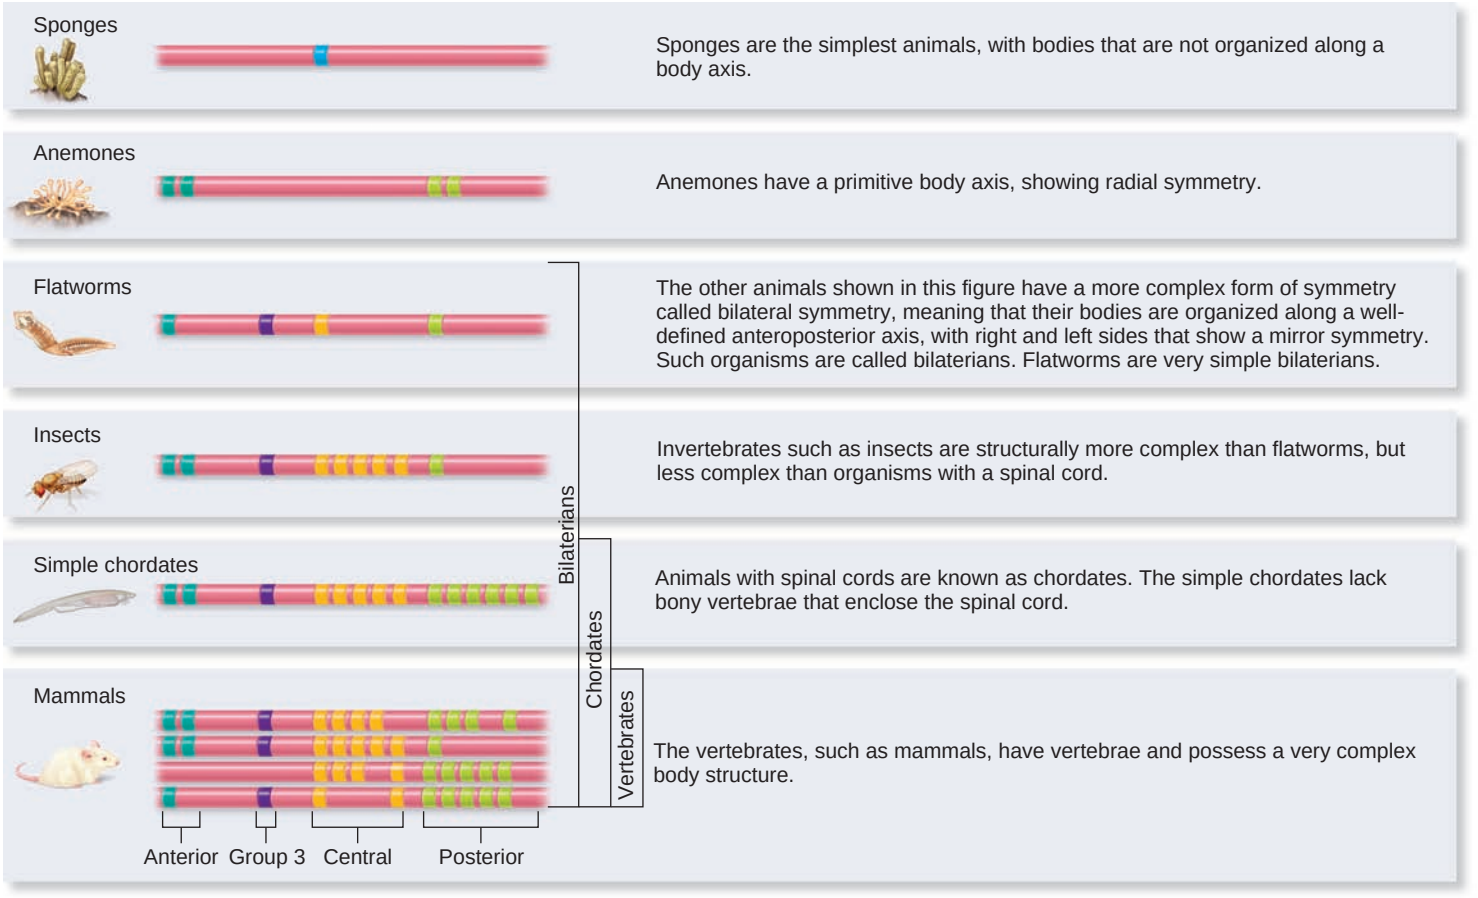


Figure 25.15 ***Hox* gene number and body complexity in different types of animals.** Researchers speculate that the duplication of *Hox* genes and *Hox* gene clusters played a key role in the evolution of more complex body plans in animals. A correlation is observed between increasing numbers of *Hox* genes and increasing complexity of body structure. The *Hox* genes are divided into four groups, called anterior, group 3, central, and posterior, based on their relative similarities. Each group is represented by a different color in this figure.

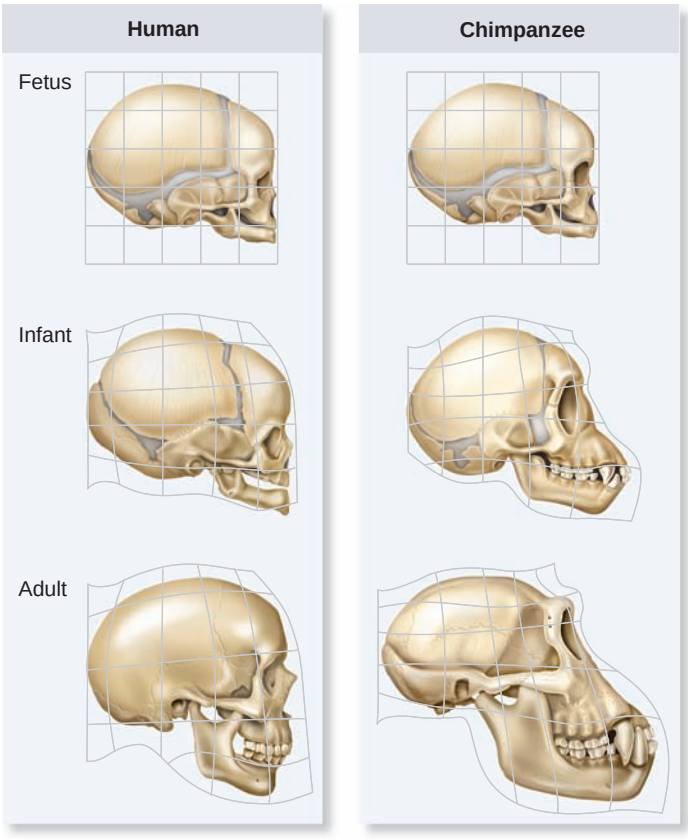
Concept check: What is the relationship between the total number of Hox genes in an animal species and its morphological complexity?

simpler animals. Third, a comparison of *Hox* gene evolution and animal evolution bears striking parallels. Researchers can analyze *Hox* gene sequences among modern species and make estimates regarding the timing of past events. Using this type of approach, geneticists can estimate when the first *Hox* gene arose by gene innovation. The date is difficult to pinpoint but is well over 600 million years ago. The single *Hox* gene found in the sponge has descended from this primordial *Hox* gene. In addition, gene duplications of this primordial gene produced clusters of *Hox* genes in other species. Clusters such as those found in modern insects were likely to be present approximately 600 million years ago. A duplication of that cluster is estimated to have occurred around 520 million years ago.

Interestingly, these estimates of *Hox* gene origins correlate with major diversification events in the history of animals. As described in Chapter 22, the Cambrian period, which occurred from 543 to 490 million years ago, saw a great diversification of animal species. This diversification occurred after the *Hox* cluster was formed and was possibly undergoing its first duplication to create two *Hox* clusters. Also, approximately 420 million years ago, a second duplication produced species with four *Hox* clusters. This event preceded the proliferation of tetrapods—vertebrates with four limbs—that occurred during the Devonian period, approximately 417–354 million years ago. Modern tetrapods have four *Hox* clusters. This second duplication may have been a critical event that led to the evolution of complex terrestrial vertebrates with four limbs, such as amphibians, reptiles, and mammals.

Developmental Genes That Affect Growth Rates Can Have a Dramatic Effect on Phenotype and Lead to the Formation of New Species

In Figure 25.14, we saw how differences in the spatial expression of the *Gremlin* gene affected whether a bird species has nonwebbed or webbed feet. Another way that genetic variation can influence morphology is by controlling the relative growth rates of different parts of the body during development. The



(a) The effects of different growth rates of the jaw and cranium on head morphology in the human and chimpanzee

(b) Paedomorphosis in Cope's giant salamander

Figure 25.16 Effects of growth rate on development. **(a)** Heterochrony refers to the phenomenon in which one region of the body grows faster than another among different species. The phenomenon explains why the skulls of adult chimpanzees and humans have different shapes even though their fetal shapes are quite similar. **(b)** Paedomorphosis occurs when an adult species retains characteristics that are juvenile traits in another related species. Cope's giant salamander reproduces at the tadpole stage.

term **heterochrony** refers to evolutionary changes in the rate or timing of developmental events. The speeding up or slowing down of growth appears to be a common occurrence in evolution and can lead to different species with striking morphological differences.

As an example, Figure 25.16a compares the progressive growth of human and chimpanzee skulls. At the fetal stage, the size and shape of the skulls look fairly similar. However, after this stage, the relative growth rates of certain regions become markedly different, thereby affecting the shape and size of the adult skull. In the chimpanzee, the jaw region grows faster, giving the adult chimpanzee a much larger and longer jaw. In the human, the jaw grows more slowly, and the region of the skull that surrounds the brain, which is called the cranium, grows slightly faster. Therefore, adult humans have smaller jaws but a larger cranium.

Changes in growth rates can also affect the developmental stage at which one species reproduces. This can occur in two ways. One possibility is that the parts of the body associated with reproduction develop faster than the rest of the body. Alternatively, reproduction may occur at the same absolute age, but the development of nonreproductive body parts is slowed down. In either case, the morphological result is the same—reproduction is observed at an earlier stage in one species than it is in another. In such cases, the sexually mature organism may retain traits typical of the juvenile stage of the organism's ancestor, a condition called **paedomorphosis** (from the Greek *paedo*, meaning young or juvenile, and *morph*, meaning the form of an organism). It is particularly common among salamanders. Even though paedomorphic species have certain juvenile features as adults, they have the ability to reproduce successfully. For example, Cope's giant salamander (*Dicamptodon copei*) becomes mature and reproduces in the aquatic form, without changing into a terrestrial adult as do other salamander species (Figure 25.16b). The adult form of Cope's giant salamander has gills and a large paddle-shaped tail, features that resemble those of the larval (tadpole) stage of other salamander species. Such a change in morphology was likely to have been a contributing factor to the formation of this species or an ancestral species to Cope's giant salamander.

Genomes & Proteomes Connection

The Study of the *Pax6* Gene Indicates That Different Types of Eyes Evolved from a Simpler Form

Thus far in this section, we have focused on the roles of particular genes as they influence the development of species with novel shapes and forms. Explaining how a complex organ comes into existence is another major challenge for evolutionary biologists. While it is relatively easy to comprehend how a limb

could undergo evolutionary modifications to become a wing, flipper, or arm, it is more difficult to understand how a body structure, such as a limb, comes into being in the first place. In his book *The Origin of Species*, Charles Darwin addressed this question and admitted that the evolution and development of a complex organ such as the eye was difficult to understand. As noted by Darwin, the eyes of vertebrate species are exceedingly complex, being able to adjust focus, let in different amounts of light, and detect a spectrum of colors. Darwin speculated that such complex eyes must have evolved from a simpler structure through the process of descent with modification. With amazing insight, he suggested that a very simple eye would be composed of two cell types, a photoreceptor cell and an adjacent pigment cell. The photoreceptor cell, which is a type of nerve cell, is able to absorb light and respond to it. The function of the pigment cell is to stop the light from reaching one side of the photoreceptor cell. This primitive, two-cell arrangement would allow an organism to sense both light and the direction from which the light comes.

A primitive eye would provide an additional way for an organism to sense its environment, possibly allowing it to avoid predators or locate food. Vision is nearly universal among animals, which indicates a strong selective advantage for better eyesight. Over time, eyes could become more complex by enhancing the ability to absorb different amounts and wavelengths of light and also by refinements in structures such as the addition of lenses that focus the incoming light.

Since the time of Darwin, many evolutionary biologists have wrestled with the question of eye evolution. From an anatomical point of view, researchers have discovered many different types of eyes. For example, the eyes of fruit flies, squid, and humans are quite different from each other. This observation led evolutionary biologists such as Luitfried von Salvini-Plawen and Ernst Mayr to propose that eyes may have independently arisen multiple times during evolution. Based solely on morphology, such a hypothesis seemed reasonable and for many years was accepted by the scientific community.

The situation took a dramatic turn when geneticists began to study eye development. Researchers identified a master control gene, *Pax6*[1]. The protein encoded by the *Pax6* gene is a transcription factor that controls the expression of many other genes, including those involved in the development of the eye in both rodents and humans. In mice and rats, a mutation in the *Pax6* gene results in small eyes. A mutation in the human *Pax6* gene causes an eye disorder called aniridia, in which the iris and other structures of the eye do not develop properly. Similarly, *Drosophila* has a gene named *eyeless* that also causes a defect in eye development when mutant. The *eyeless* and *Pax6* genes are homologous; they were derived from the same ancestral gene.

In 1995, Swiss geneticist Walter Gehring and his colleagues were able to show experimentally that the expression of the *eyeless* gene in parts of *Drosophila* where it is normally inactive could promote the formation of additional eyes. For example, using genetic engineering techniques, they were able to express the *eyeless* gene in the region where antennae should form. As seen in Figure 25.17a, this resulted in the formation of an eye where antennae are normally found! Remarkably, the expression of the mouse *Pax6* gene in *Drosophila* can also cause the formation of eyes in unusual places. For example, Figure 25.17b shows the formation of an eye on the leg of *Drosophila*.

Note that when the mouse *Pax6* master control gene switches on eye formation in *Drosophila*, the eye produced is a *Drosophila* eye, not a mouse eye. Why does this occur? It happens because the *Pax6* master control gene activates genes from the *Drosophila* genome. In *Drosophila*, the *Pax6* homolog called *eyeless* switches on a cascade involving several hundred genes required for eye morphogenesis. In more primitive eyes, the *Pax6* gene would be expected to control a cascade of fewer genes.

Since the discovery of the *Pax6* and *eyeless* genes, homologs of this gene have been discovered in many different species. In all cases where it has been tested, this gene is involved with eye development. Gehring and colleagues have hypothesized that the eyes from many different species may have evolved from a common ancestral form consisting of, as proposed by Darwin, one photoreceptor cell and one pigment cell (Figure 25.18). As mentioned, such a very simple eye can accomplish a rudimentary form of vision by detecting light and its direction. Eyes such as these are still found in modern species, such as the larvae of certain types of mollusks. Over time, simple eyes evolved into more complex types of eyes by modifications that resulted in the addition of more types of cells, such as lens cells and muscle cells. Alternatively, other researchers argue that

(a) Abnormal expression of the *Drosophila eyeless* gene in the antenna region

(b) Abnormal expression of the mouse *Pax6* gene in a fruit fly leg

Figure 25.17 **Formation of additional eyes in *Drosophila* due to the abnormal expression of a master control gene for eye morphogenesis.** **(a)** When the *Drosophila eyeless* gene is expressed in the antenna region, eyes are formed where antennae should be located. **(b)** When the mouse *Pax6* gene is expressed in the leg region of *Drosophila*, a small eye is formed there.

Concept check: *What do you think would happen if the Drosophila eyeless gene was expressed at the tip of a mouse's tail?*

[1] Pax is an acronym for paired box. The protein encoded by this gene contains a domain called a paired box.

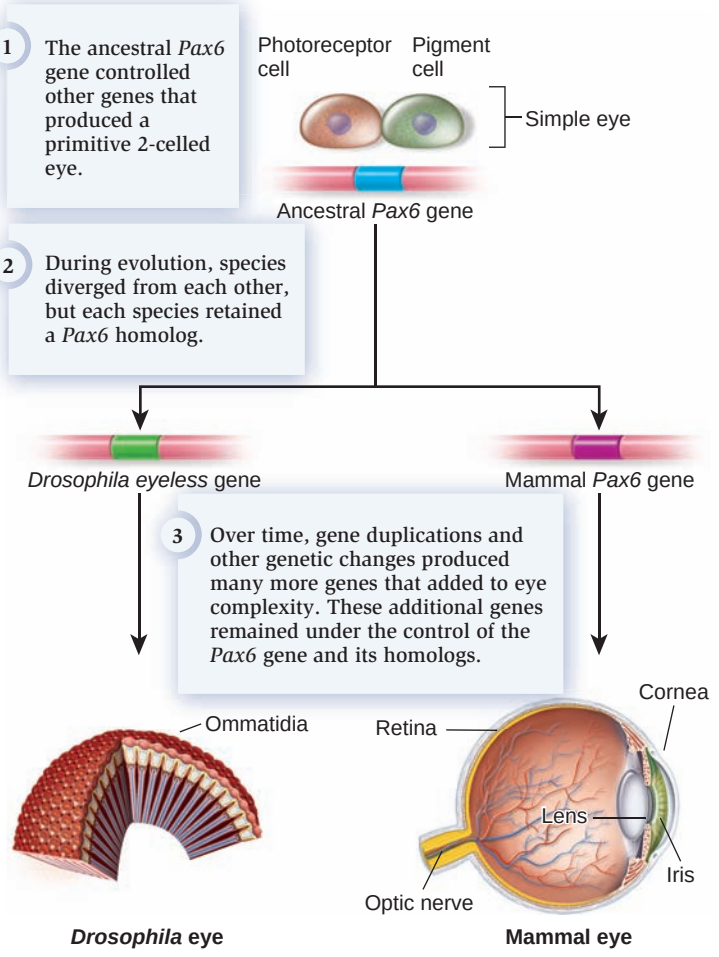


Figure 25.18 **Genetic control of eye evolution.** In this diagram, genetic changes, under control of the ancestral *Pax6* gene, led to the evolution of different types of eyes.

Pax6 may control only certain features of eye development and that different types of eyes may have evolved independently. Future research will be needed to resolve this controversy.

Summary of Key Concepts

25.1 Identification of Species

- A species is a group of organisms that maintains a distinctive set of attributes in nature. Speciation is the process whereby new species are formed. Macroevolution refers to the evolutionary changes that create new species and groups of species.
- Different characteristics are used to identify species, including morphological traits, reproductive isolation, molecular features, ecological factors, and evolutionary relationships. (Figure 25.1)
- Researchers have identified many reproductive isolating mechanisms that prevent two different species from breeding with each other. (Figure 25.2)
- Prezygotic isolating mechanisms include habitat isolation, temporal isolation, behavioral isolation, mechanical isolation, and gametic isolation. (Figures 25.3, 25.4)
- Postzygotic isolating mechanisms include hybrid inviability, hybrid sterility, and hybrid breakdown. (Figure 25.5)

25.2 Mechanisms of Speciation

- Allopatric speciation occurs when a population becomes isolated from other populations and evolves into one or more new species. When speciation occurs multiple times due to the migration of populations into new environments, the evolutionary process is called adaptive radiation. If populations are incompletely separated, occasional interbreeding may occur in hybrid zones. (Figures 25.6, 25.7, 27.8)
- Podos discovered that changes in beak depth, associated with evolutionary changes involved with feeding, may also promote reproductive isolation by altering the song pattern of finches. (Figures 25.9, 25.10)
- Sympatric speciation involves the formation of different species that are not geographically isolated from one another. Polyploidy, adaptation to local environments, and sexual selection are mechanisms that can promote sympatric speciation. (Figures 25.11, 25.12)

25.3 The Pace of Speciation

- The pace of evolution may seem relatively constant or it may vary. Gradualism involves gradual evolution due to many small genetic changes, whereas punctuated equilibrium is a pattern of evolution in which new species arise more rapidly and then remain unchanged for long periods of time. (Figure 25.13)

25.4 Evo-Devo: Evolutionary Developmental Biology

- Evolutionary developmental biology compares the development of different species with the goal of understanding ancestral relationships and the mechanisms that bring about evolutionary change. These changes often involve variation in the expression of cell-signaling proteins and transcription factors.
- The spatial expression of genes that affect development can change phenotypes dramatically, as shown by the expression of the *BMP4* and *Gremlin* genes in birds with nonwebbed or webbed feet. (Figure 25.14)
- The evolution and duplication of *Hox* genes played an important role in producing groups of animals with specific body plans that are organized along an anteroposterior axis. (Figure 25.15)
- A difference in the relative growth rates of body parts among different species is called heterochrony. Paedomorphosis occurs when an adult species retains characteristics that are juvenile traits in another related species. (Figure 25.16)
- The *Pax6* gene and its homolog in other species are master control genes that control eye development in animals. (Figures 25.17, 25.18)

Assess and Discuss

Test Yourself

1. Macroevolution refers to the evolutionary changes that
   a. occur in multicellular organisms.
   b. create new species and groups of species.
   c. occur over long periods of time.
   d. cause changes in allele frequencies.
   e. occur in large mammals.
2. The biological species concept classifies a species based on
   a. morphological characteristics.
   b. reproductive isolation.
   c. the niche the organism occupies in the environment.
   d. genetic relationships between an organism and its ancestors.
   e. both a and b.
3. Which of the following would be considered an example of a postzygotic isolating mechanism?
   a. incompatible genitalia
   b. different mating seasons
   c. incompatible gametes
   d. mountain range separating two populations
   e. fertilized egg fails to develop normally
4. Hybrid breakdown occurs when species hybrids
   a. do not develop past the early embryonic stages.
   b. have a reduced life span.
   c. are infertile.
   d. are fertile but produce offspring with reduced viability and fertility.
   e. produce offspring that express the traits of only one of the original species.
5. The evolution of one species into two or more species is
   a. gradualism.
   b. punctuated equilibrium.
   c. cladogenesis.
   d. horizontal gene transfer.
   e. microevolution.
6. A large number of honeycreeper species on the Hawaiian Islands is an example of
   a. adaptive radiation.
   b. genetic drift.
   c. stabilizing selection.
   d. horizontal gene transfer.
   e. microevolution.
7. A major mechanism of speciation in plants but not animals is
   a. adaptation to new environments.
   b. polyploidy.
   c. hybrid breakdown.
   d. genetic changes that alter the organism's niche.
   e. both a and d.
8. The concept of punctuated equilibrium suggests that
   a. the rate of evolution is constant, with short time periods of no evolutionary change.
   b. evolution occurs gradually over time.
   c. small genetic changes accumulate over time to allow for phenotypic change and speciation.
   d. long periods of little evolutionary change are interrupted by short periods of major evolutionary change.
   e. both b and c.
9. Researchers suggest that an increase in the number of *Hox* genes
   a. would lead to reproductive isolation in all cases.
   b. could explain the evolution of color vision.
   c. allows for the evolution of more complex body forms in animals.
   d. results in the decrease in the number of body segments in insects.
   e. does all of the above.
10. The observation that the mammalian *Pax6* gene and the *Drosophila eyeless* gene are homologous genes that promote the formation of different types of eyes suggests that
    a. *Drosophila* eyes are more complex.
    b. mammalian eyes are more complex.
    c. eyes arose once during evolution.
    d. eyes arose at least twice during evolution.
    e. eye development is a simple process.

Conceptual Questions

1. What is the key difference between prezygotic isolating mechanisms and postzygotic isolating mechanisms? Give an example of each. Which type is more costly from the perspective of energy?
2. What are the key differences between gradualism and punctuated equilibrium? How are genetic changes related to these two models?
3. Describe one example in which genes that control development may have played an important role in the evolution of different species.

Collaborative Questions

1. What is a species? Discuss how geographic isolation can lead to speciation. Explain how reproductive isolation plays a role.
2. Discuss the type of speciation (allopatric or sympatric) that is most likely to occur under each of the following conditions:
   a. A pregnant female rat is transported by an ocean liner to a new continent.
   b. A meadow containing several species of grasses is exposed to a pesticide that promotes nondisjunction.
   c. In a very large lake containing several species of fishes, the water level gradually falls over the course of several years. Eventually, the large lake becomes subdivided into smaller lakes, some of which are connected by narrow streams.

Taxonomy and Systematics

26

Chapter Outline

A new species, the African forest elephant. In 2001, biologists decided that this is a unique species of elephant, now named *Loxodonta cyclotis*.

Until recently, biologists classified elephants into only two species—the African savanna elephant (*Loxodonta africana*) and the Asian elephant (*Elephas maximus*). However, by analyzing the DNA of African elephants, researchers revised this classification, and proposed a third species, now called the African forest elephant (*Loxodonta cyclotis*) (see chapter-opening photo). How was this new species identified? This surprising finding was made somewhat by accident in 2001. A DNA identification system was set up to trace ivory poachers. By studying the DNA, researchers decided that Africa has two distinctly different *Loxodonta* elephant species. The African forest elephant is found in the forests of central and western Africa. The African savanna elephant, which is larger and has longer tusks, lives on large, dry grasslands. One consequence of this discovery is that it will have an impact on conservation efforts, which had previously been based on a single species of African elephants.

The rules for the classification of newly described species, such as the African forest elephant, are governed by the discipline of taxonomy (from the Greek *taxis*, meaning order, and *nomos*, meaning law). **Taxonomy** is the science of describing, naming, and classifying **extant** organisms, which still exist today, as well as extinct organisms. Taxonomy results in the ordered division of species into groups based on similarities and dissimilarities in their characteristics. This task has been ongoing for over 300 years. As discussed in Chapter 23, the naturalist John Ray made the first attempt to broadly classify all known forms of life. Ray's ideas were later extended by naturalist Carolus Linnaeus in the mid-1700s, which is considered by some as the official birth of taxonomy.

Systematics is the study of biological diversity and the evolutionary relationships among organisms, both extant and extinct. In the 1950s, German entomologist Willi Hennig began classifying organisms in a new way. Hennig proposed that evolutionary relationships should be inferred from new features shared by descendants of a common ancestor. Since that time, biologists have applied systematics to the field of taxonomy. Researchers now try to place new species into taxonomic groups based on evolutionary relationships with other species. In addition, previously established taxonomic groups are revised as new data shed light on evolutionary relationships. As in any scientific discipline, taxonomy should be viewed as a work in progress.

In this chapter, we will begin with a discussion of taxonomy and the concept of taxonomic groups. We will then examine how biologists use systematics to determine evolutionary relationships among organisms, looking in particular at how these relationships are portrayed in diagrams called **phylogenetic trees**. We will explore how analyses of morphological data and molecular genetic data are used to understand the evolutionary history of life on earth.

26.1 Taxonomy

A hierarchy is a system of organization that involves successive levels. In biology, every species is placed into several different nested groups within a hierarchy. For example, a leopard and a fruit fly are both classified as animals, though they differ in many traits. By comparison, leopards and lions are placed together into a group with a smaller number of species called felines (more formally named Felidae), which are predatory cats. The felines are a subset of the animal group, which has

species that share many similar traits. The species that are placed together into small taxonomic groups are likely to share many of the same characteristics. In this section, we will consider how biologists use a hierarchy to group similar species.

Living Organisms Are Now Subdivided into Three Domains of Life

Modern taxonomy places species into progressively smaller hierarchical groups. Each group at any level is called a **taxon** (plural, taxa). The taxonomic group called the **kingdom** was originally the highest and most inclusive. Linnaeus had classified all life into two kingdoms, plants and animals. In 1969, American ecologist Robert Whittaker proposed a five-kingdom system in which all life was classified into the kingdoms Monera, Protista, Fungi, Plantae, and Animalia. (Monera included all prokaryotic organisms.) However, as biologists began to learn more about the evolutionary relationships among these groups, they found that these groupings did not correctly reflect the relationships among them.

In the late 1970s, based on information in the sequences of genes, American biologist Carl Woese proposed the idea of creating a category called a **domain**. Under this system, all forms of life are grouped within three domains: **Bacteria**, **Archaea**, and **Eukarya** (Figure 26.1). The kingdom Monera was split into two domains, Bacteria and Archaea, due to major differences between these two types of prokaryotes. The terms Bacteria and Archaea are capitalized when referring to the domains. Alternatively, these terms can also refer to prokaryotic cells and species, in which case they are not capitalized. A single bacterial cell is called a bacterium, and a single archaeal cell is an archaeon.

The domain Eukarya formerly consisted of four kingdoms called **Protista**, **Fungi**, **Plantae**, and **Animalia**. However, researchers later discovered that Protista is not a separate kingdom but instead is a very broad collection of organisms. Taxonomists now place eukaryotes into seven groups called supergroups. In the taxonomy of eukaryotes, a **supergroup** lies between a domain and a kingdom (Figure 26.1). Kingdom Plantae is within the supergroup called Land plants and algal relatives, and kingdoms Fungi and Animalia are within the supergroup Opisthokonta. Table 26.1 compares a variety of molecular and cellular characteristics among Bacteria, Archaea, and Eukarya.

Table 26.1 Distinguishing Cellular and Molecular Features of Domains Bacteria, Archaea, and Eukarya*

Characteristic	Bacteria	Archaea	Eukarya
Chromosomes	Usually circular	Circular	Usually linear
Nucleosome structure	No	No	Yes
Chromosome segregation	Binary fission	Binary fission	Mitosis/ meiosis
Introns in genes	Rarely	Rarely	Commonly
Ribosomes	70S	70S	80S
Initiator tRNA	Formylmethionine	Methionine	Methionine
Operons	Yes	Yes	No
Capping of mRNA	No	No	Yes
RNA polymerases	One	Several	Three
Promoters of structural genes	–35 and –10 sequences	TATA box	TATA box
Cell compartmentalization	No	No	Yes
Membrane lipids	Ester-linked	Ether-linked	Ester-linked

*The descriptions in this table are meant to represent the general features of most species in each domain. Some exceptions are observed. For example, certain bacterial species have linear chromosomes.

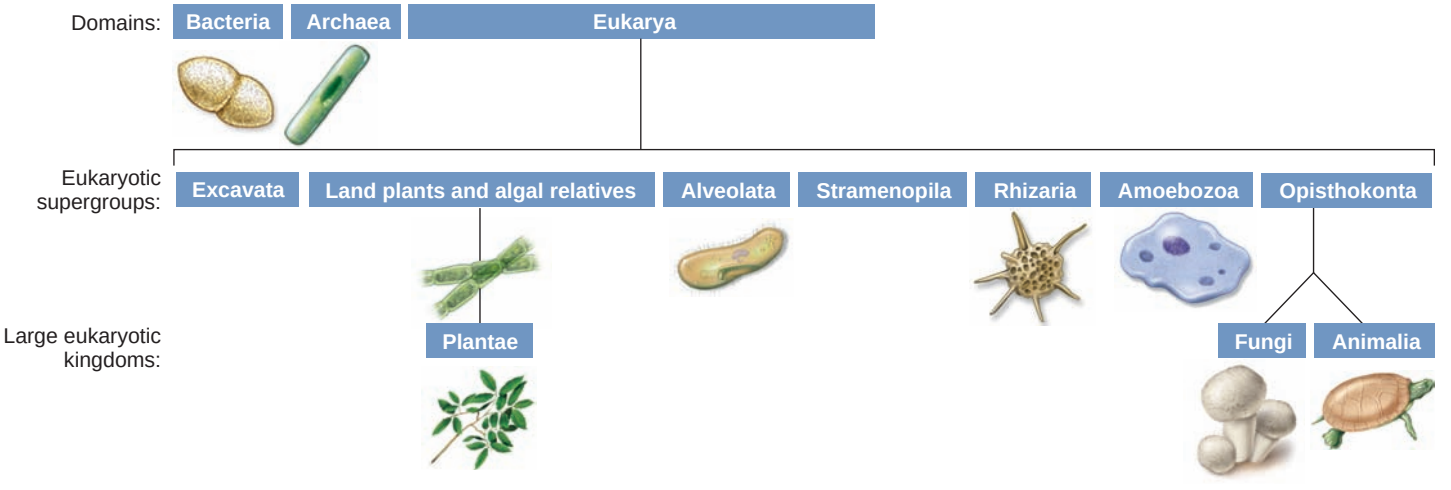

Figure 26.1 **A classification system for living and extinct organisms.** All organisms can be grouped into three large domains: Bacteria, Archaea, or Eukarya. Eukaryotes are divided into seven supergroups. As discussed in Chapter 28, the division of eukaryotes into supergroups is under current investigation and should be viewed as work in progress.

Every Species Is Placed into a Taxonomic Hierarchy

Why is it important to categorize species into groups? The three domains of life contain millions of different species. Subdividing them into progressively smaller groups makes it easier for biologists to appreciate the relationships among such a large number of species.

As mentioned, the broadest taxon is the domain, which is divided into supergroups among eukaryotes. Below the domain and supergroup is the kingdom, which is divided into **phyla** (singular, phylum). Each phylum is divided into **classes**, then **orders**, **families**, and **genera** (singular, genus). Each of these taxa contains progressively fewer species that are more similar to each other than they are to the members of the taxa above them in the hierarchy. For example, the taxon Animalia, which is at the kingdom level, has a larger number of fairly diverse species than does the class Mammalia, which contains fewer species that are relatively similar to each other.

To further understand taxonomy, let's consider the classification of a species such as the gray wolf (*Canis lupus*) (Figure 26.2). The gray wolf is placed in the domain Eukarya, the supergroup Opisthokonta, and then within the kingdom Animalia, which includes over 1 million species of all animals. Next, the gray wolf is classified in the phylum Chordata. The 50,000 species of animals in this group all have four common features at some stage of their development. These are a notochord (a cartilaginous rod that runs along the back of all chordates at some point in their life cycle), a tubular nerve or spinal cord located above the notochord, gill slits or arches, and a post-anal tail. Examples of animals in the phylum Chordata include fishes, reptiles, and mammals.

The gray wolf is in the class Mammalia, which includes all 5,000 species of mammals. Two distinguishing features of animals in this group are hair and mammary glands. The mammary glands produce milk, which nourishes the young, and hair helps insulate the body to maintain a warm, constant body temperature. There are 26 orders of mammals; the order that includes the gray wolf is called Carnivora and has about 270 species. The gray wolf is placed in the family Canidae, which is a relatively small family of 34 species, including different species of wolves, jackals, foxes, wild dogs, and the coyote and domestic dog. All species in the family Canidae are doglike animals. The smallest grouping that contains the gray wolf is the genus *Canis*, which includes four species of jackals, the coyote, two types of wolves, and the domestic dog. The domestic dog (*Canis lupus familiaris*) is a subspecies of the gray wolf.

Binomial Nomenclature Is Used to Name Species

As originally advocated by Linnaeus, **binomial nomenclature** is the standard method for naming species. The scientific name of every species has two names, its genus name and its unique specific epithet. An example is the gray wolf, *Canus lupis*. The

Taxonomic group	Gray wolf found in	Number of species
Domain	Eukarya	~4–10 million
Supergroup	Opisthokonta	>1 million
Kingdom	Animalia	>1 million
Phylum	Chordata	~50,000
Class	Mammalia	~5,000
Order	Carnivora	~270
Family	Canidae	34
Genus	*Canis*	7
Species	*lupus*	1

Figure 26.2 A taxonomic classification of the gray wolf (*Canis lupus*).

Concept check: Which group is broader, a phylum or a family?

genus name is always capitalized, but the specific epithet is not. Both names are italicized. After the first mention, the genus name is abbreviated to a single letter. For example, we would write that *Canis lupus* is the gray wolf, and in subsequent sentences, the species would be referred to as *C. lupus*.

When naming a new species, genus names are always nouns or treated as nouns, whereas species epithets may be either nouns or adjectives. The names often have a Latin or Greek origin and refer to characteristics of the species or to features of its habitat. For example, the genus name of the newly discovered African forest elephant, *Loxodonta*, is from the Greek *loxo*, meaning slanting, and *odonta*, meaning tooth. The species epithet *cyclotis* refers to the observation that the ears of this species are rounder compared to those of *L. africana*. However, sometimes the choice of name for a species can be lighthearted. For example, there is a beetle named *Agra vation* and a spider named *Draculoides bramstokeri*.

The rules for naming animal species, such as *Canis lupus* and *Loxodonta africana*, have been established by the International Commission on Zoological Nomenclature (ICZN). The ICZN provides and regulates a uniform system of nomenclature to ensure that every animal has a unique and universally accepted scientific name. Who is allowed to identify and name a new species? As long as ICZN rules are followed, new animal species can be named by anyone, not only by scientists. The rules for naming plants are described in the International Code of Botanical Nomenclature (ICBN), and the naming of prokaryotes is overseen by the International Committee on Systematics of Prokaryotes (ICSP).

26.2 Phylogenetic Trees

As mentioned, systematics is the study of biological diversity and evolutionary relationships. By studying the similarities and differences among species, biologists can gain information about **phylogeny**, which is the evolutionary history of a species or group of species. To propose a phylogeny, biologists use the tools of systematics. Evolutionary relationships are used to construct taxonomic groups. For example, the classification of the gray wolf described in Figure 26.2 is based on systematics. Therefore, one use of systematics is to place species into taxa and to understand the evolutionary relationships among different taxa.

In this section, we will consider the features of diagrams or trees that describe the evolutionary relationships among various species, both living and extinct. As you will learn, such trees are usually based on morphological or genetic data.

A Phylogenetic Tree Is a Hypothesis That Depicts the Evolutionary Relationships Among Species

A phylogenetic tree is a diagram that describes the evolutionary relationships among various species, based on the information available to and gathered by systematists. Phylogenetic trees should be viewed as hypotheses that are proposed, tested, and later refined as additional data become available. Let's look at what information a phylogenetic tree contains and the form in which it is presented. Figure 26.3 shows a hypothetical phylogenetic tree of the relationships among various bird species, in which the species are labeled A through K. The vertical axis represents time, with the oldest species at the bottom.

New species can be formed by **anagenesis**, in which a single species evolves into a different species, or more commonly by **cladogenesis**, in which a species diverges into two or more species. The branch points or **nodes** in a phylogenetic tree illustrate times when cladogenesis has occurred. For example, approximately 12 million years ago, species A diverged into species A and species B. Figure 26.3 also shows anagenesis in which species C evolved into species G. The tips of branches may represent species that became extinct in the past, such as species B and E, or living species, such as F, I, G, J, H, and K, which are at the top of the tree. Species A and D are also extinct but gave rise to species that are still in existence.

By studying the branch points of a phylogenetic tree, researchers can group species according to common ancestry. A **clade** consists of a common ancestral species and all of its descendant species. For example, the group highlighted in light green in Figure 26.3 is a clade derived from the common ancestral species labeled D. Likewise, the entire tree forms a clade, with species A as a common ancestor. Therefore, smaller and more recent clades are nested within larger clades that have older common ancestors.

What is the relationship between a clade and taxonomy? The relationship depends on how far back we go to identify a common ancestor. For broader taxa, such as a kingdom, the common ancestor existed a very long time ago, on the order of hundreds of millions or even billions of years ago. For smaller taxa, such as a family or genus, the common ancestor occurred much more recently, on the order of millions or tens of millions of years ago. This concept is shown in a very schematic way in Figure 26.4. This small, hypothetical kingdom is a clade that contains 64 living species. (Actual kingdoms are obviously larger and exceedingly more complex.) The diagram emphasizes the taxa that contain the species designated number 43. The common ancestor that gave rise to this kingdom of organisms existed approximately 1 billion years ago. Over time, more recent species arose that subsequently became the common ancestors to the phylum, class, order, family, and genus that contain species number 43.

One goal of modern systematics is to create taxonomic groups that reflect evolutionary relationships. Systematics attempts to organize species into clades, which means that each group includes an ancestral species and all of its descendants. A **monophyletic group** is a taxon that is a clade. Ideally, every taxon, whether it is a kingdom, phylum, class, order, family, or genus, should be a monophyletic group.

How does research in systematics impact taxonomy? As researchers gather new information, they sometimes discover that some of the current taxonomic groups are not monophyletic. Figure 26.5 compares a monophyletic group with those that are not. A **paraphyletic group** contains a common ancestor

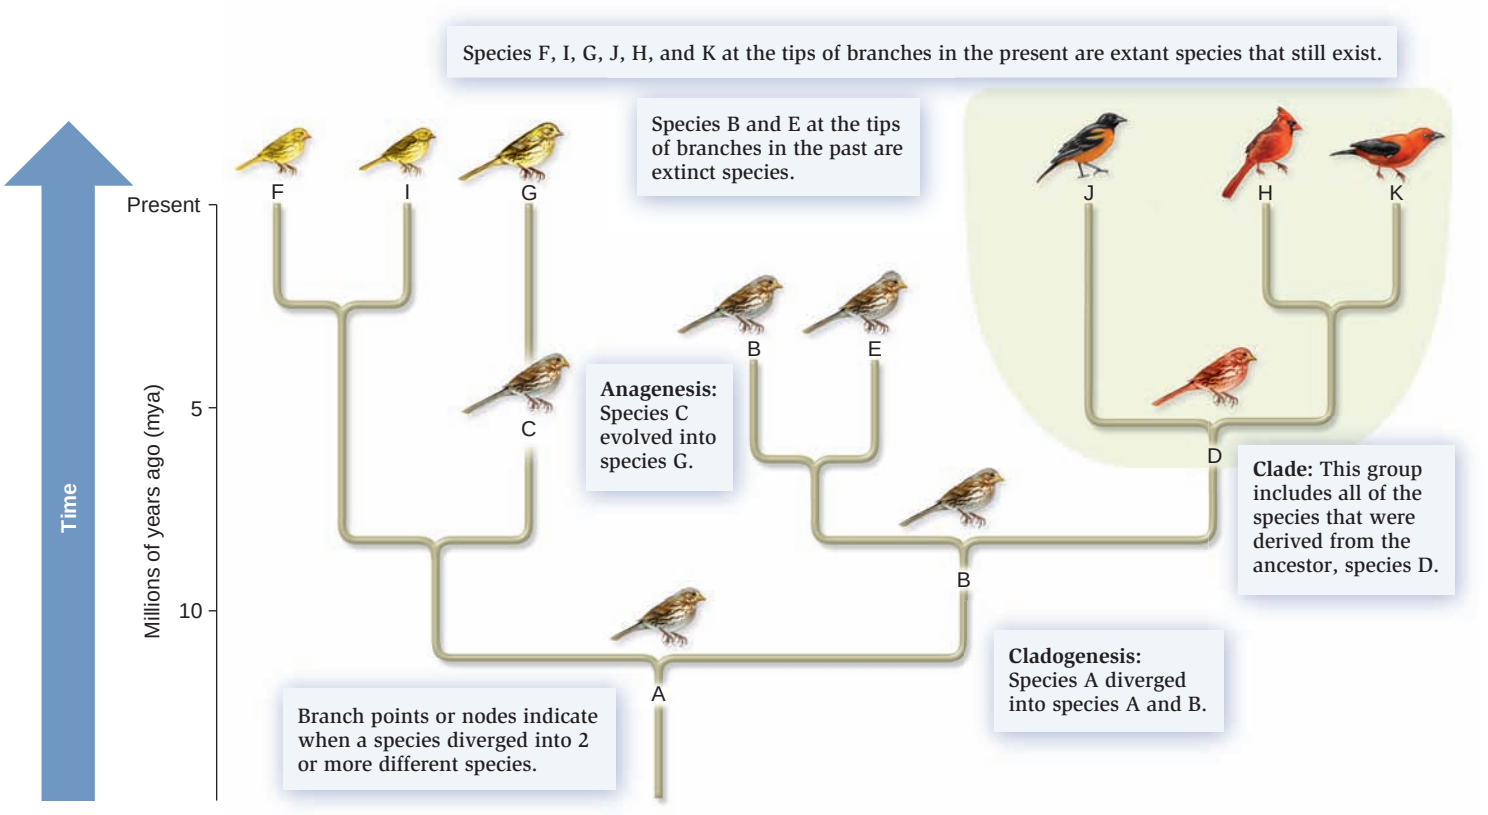

Figure 26.3 **How to read a phylogenetic tree.** This hypothetical tree shows the proposed relationships between various bird species. Species are placed into clades, groups of organisms containing an ancestral organism and all of its descendants.

Concept check: *Can two different species have more than one common ancestor?*

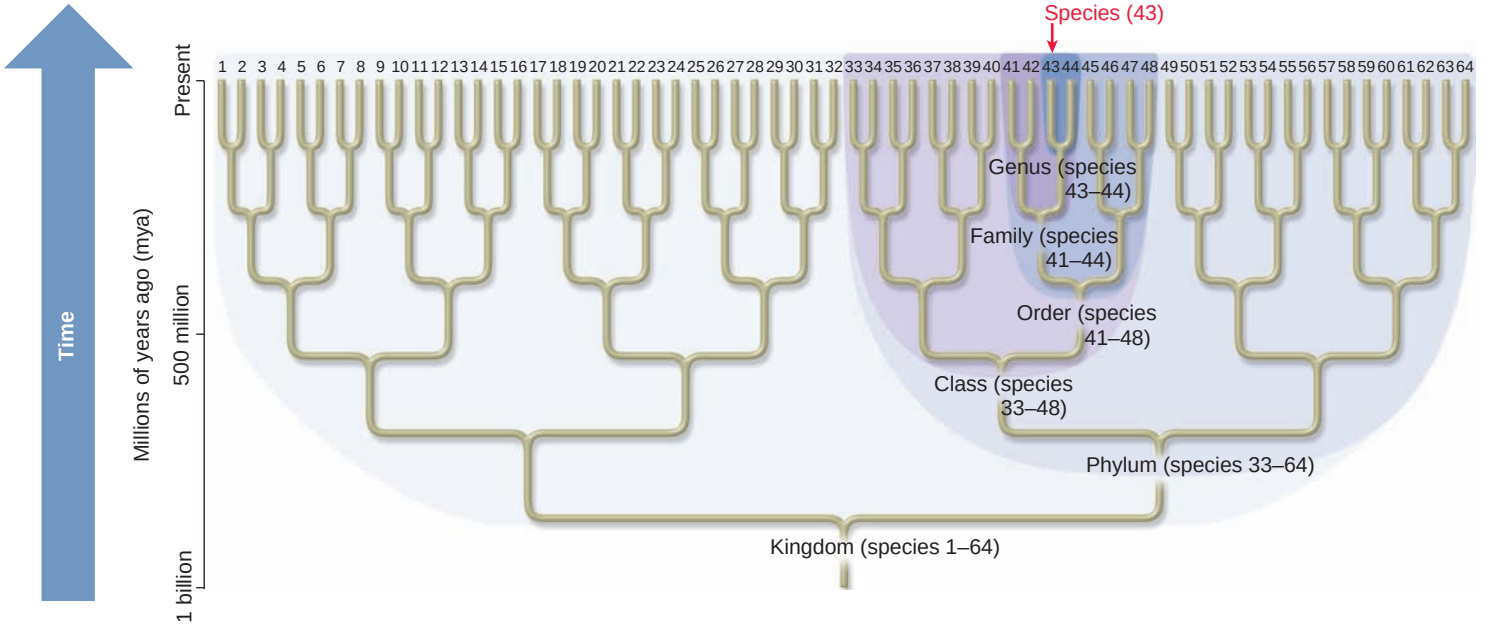

Figure 26.4 **Schematic relationship between a phylogenetic tree and taxonomy, when taxonomy is correctly based on evolutionary relationships.** The shaded areas highlight the kingdom, phylum, class, order, family, and genus for species number 43. All of the taxa are clades. Broader taxa, such as phyla and classes, are derived from more-ancient common ancestors. Smaller taxa, such as families and genera, are derived from more-recent common ancestors. These smaller taxa are subsets of the broader taxa.

Concept check: *Which taxon would have a more-recent common ancestor, a phylum or an order?*

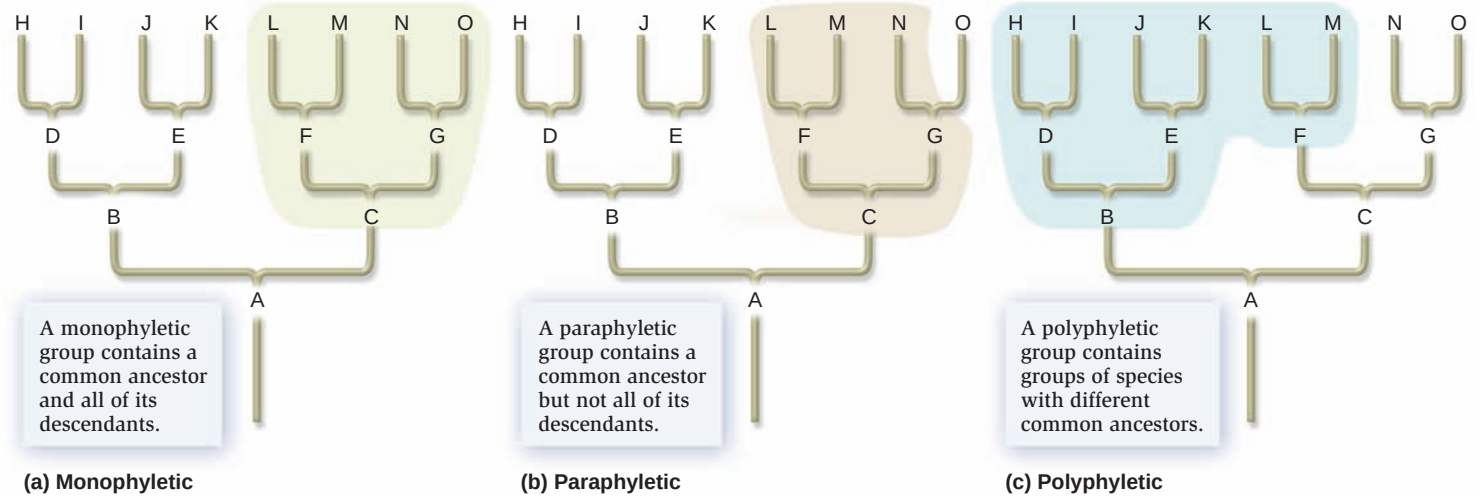

Figure 26.5 A comparison of monophyletic, paraphyletic, and polyphyletic taxonomic groups.

and some, but not all, of its descendants (Figure 26.5b). In contrast, a **polyphyletic group** consists of members of several evolutionary lines and does not include the most recent common ancestor of the included lineages (Figure 26.5c).

Over time, as we learn more about evolutionary relationships, taxonomic groups are being reorganized in an attempt to recognize only monophyletic groups in taxonomy. For example, traditional classification schemes once separated birds and reptiles into separate classes (Figure 26.6a). In this scheme, the reptile class (officially named Reptilia) contained orders that included turtles, lizards and snakes, and crocodiles. Research has indicated that the reptile taxon is paraphyletic, because birds were excluded from the group. One way that this group can be made monophyletic is by including birds as a class within the reptile clade and elevating the other groups to a class status (Figure 26.6b).

The Study of Systematics Is Usually Based on Morphological or Genetic Homology

As discussed in Chapter 23, the term **homology** refers to similarities among various species that occur because the species are derived from a common ancestor. Such features are said to be homologous. For example, the arm of a human, the wing of a bat, and the flipper of a whale are homologous structures (refer back to Figure 23.12). Similarly, genes found in different species are homologous if they have been derived from the same ancestral gene (refer back to Figure 23.13).

In systematics, researchers identify homologous features that are shared by some species but not by others, which allows them to group species based on their shared similarities. Researchers usually study homology at the level of morphological traits or at the level of genes. In addition, the data they gather are viewed in light of geographic data. Many organisms do not migrate extremely long distances. Species that are closely related evolutionarily are relatively likely to inhabit neighboring or overlapping geographic regions, though many exceptions are known to occur.

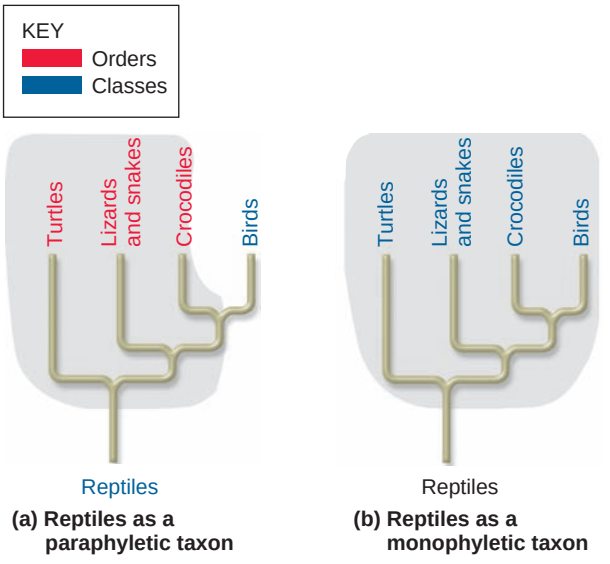

Figure 26.6 An example of a taxon that is not monophyletic. (a) The class of reptiles as a paraphyletic taxon. (b) The group can be made monophyletic if birds and the other orders were classified as classes within the reptile clade.

Morphological Analysis The first studies in systematics focused on morphological features of extinct and living species. Morphological traits continue to be widely used in systematic studies, particularly in those studies pertaining to extinct species and those involving groups that have not been extensively studied at the molecular level. To establish evolutionary relationships based on morphological homology, many traits have to be analyzed to identify similarities and differences.

By studying morphological features of extinct species in the fossil record, paleontologists can propose phylogenetic trees that chart the evolutionary lineages of species, including those that still exist. In this approach, the trees are based on morphological features that change over the course of many generations. As an example, Figure 26.7 depicts a current hypothesis of the

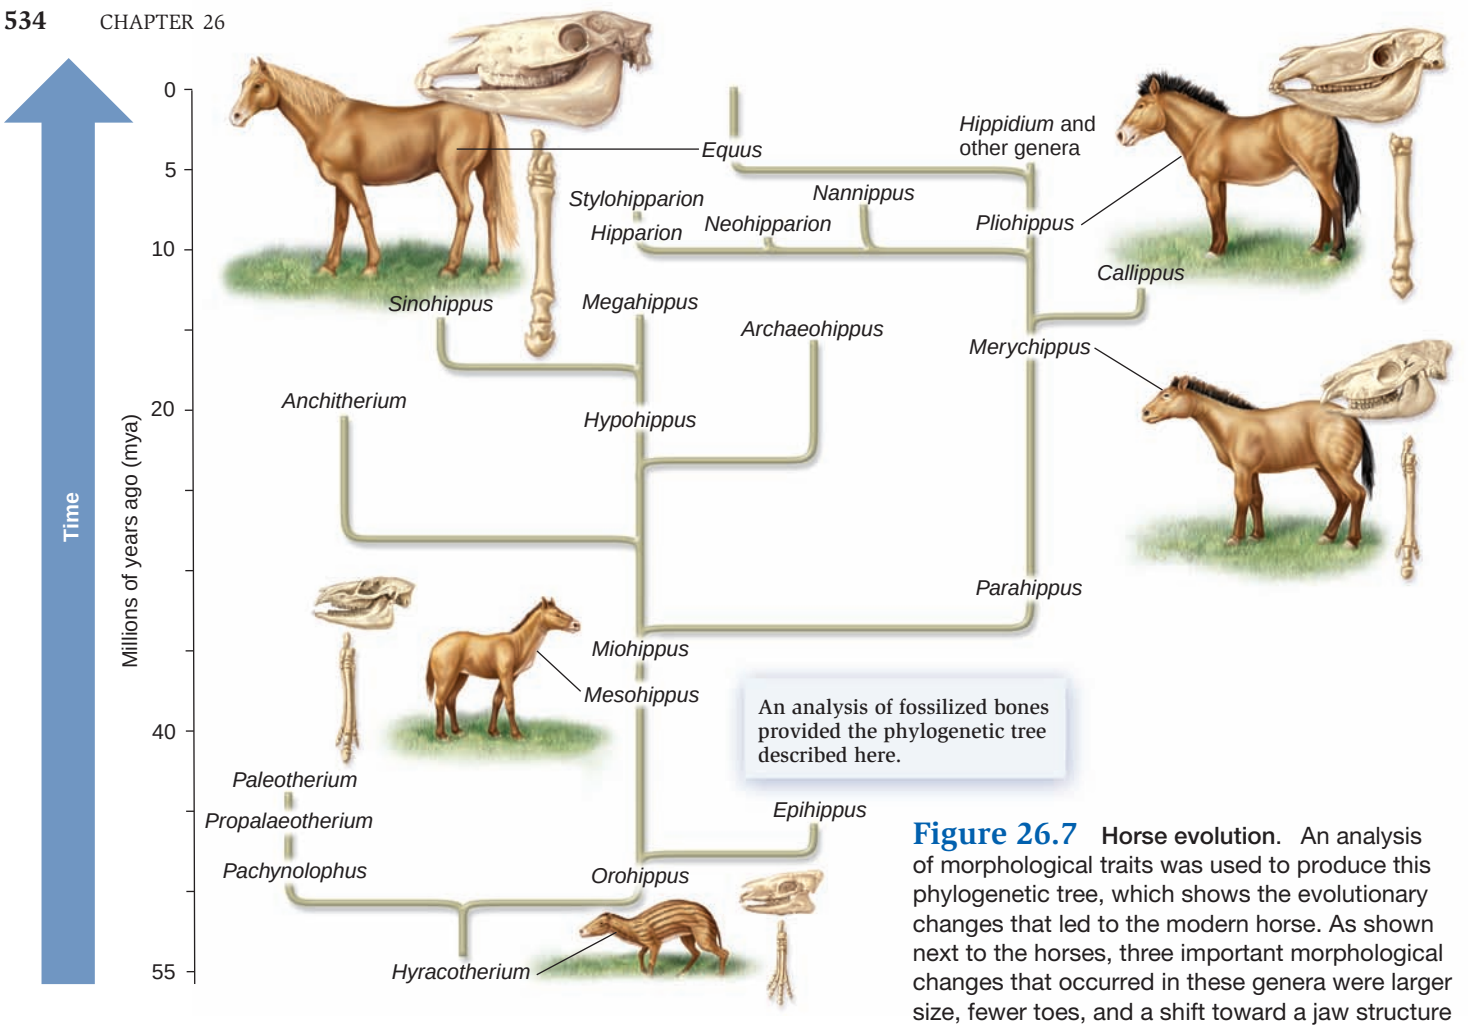

Figure 26.7 **Horse evolution.** An analysis of morphological traits was used to produce this phylogenetic tree, which shows the evolutionary changes that led to the modern horse. As shown next to the horses, three important morphological changes that occurred in these genera were larger size, fewer toes, and a shift toward a jaw structure suited for grazing.

evolutionary changes that led to the development of the modern horse. This figure shows representative species from various genera. Many morphological features were used to propose this tree. Because hard parts of the body are more commonly preserved in the fossil record, this tree is largely based on the analysis of skeletal changes in foot structure, lengths and shapes of various leg bones, skull shape and size, and jaw and tooth morphology. Over an evolutionary time scale, the accumulation of many genetic changes has had a dramatic impact on species' characteristics. In the genera depicted in this figure, a variety of morphological changes occurred, such as an increase in size, a reduction in the number of toes, and modifications in the jaw and teeth that were suitable for grazing on fibrous grasses.

Similar morphological features may occasionally confound an evolutionary analysis. As described in Chapter 23, convergent evolution can result in analogous structures, characteristics that arise independently in different lineages because different species have evolved in similar environments. For example, the giant anteater and the echidna have similar structures, such as long snouts and tongues, that enable these animals to feed on ants (refer back to Figure 23.8a). These traits are not derived from a common ancestor. Rather, they arose twice independently during evolution due to adaptation to similar environments. In systematics, the use of analogous structures can cause errors if a researcher assumes that a particular trait arose only once and that all species having the trait are derived from a common ancestor.

Molecular Systematics The field of **molecular systematics** involves the analysis of genetic data, such as DNA and amino acid sequences, to identify and study genetic homologies and propose phylogenetic trees. In 1963, Austrian biologist Emile Zuckerkandl and American chemist Linus Pauling were the first to suggest that molecular data could be used to establish evolutionary relationships. How can a comparison of genetic sequences help to establish evolutionary relationships? As discussed later in this chapter, DNA sequences change over the course of many generations due to the accumulation of mutations. Therefore, when comparing homologous sequences in different organisms, DNA sequences from closely related organisms are more similar to each other than they are to sequences from distantly related species.

26.3 Cladistics

Cladistics is the classification of species based on evolutionary relationships. A cladistic approach discriminates among

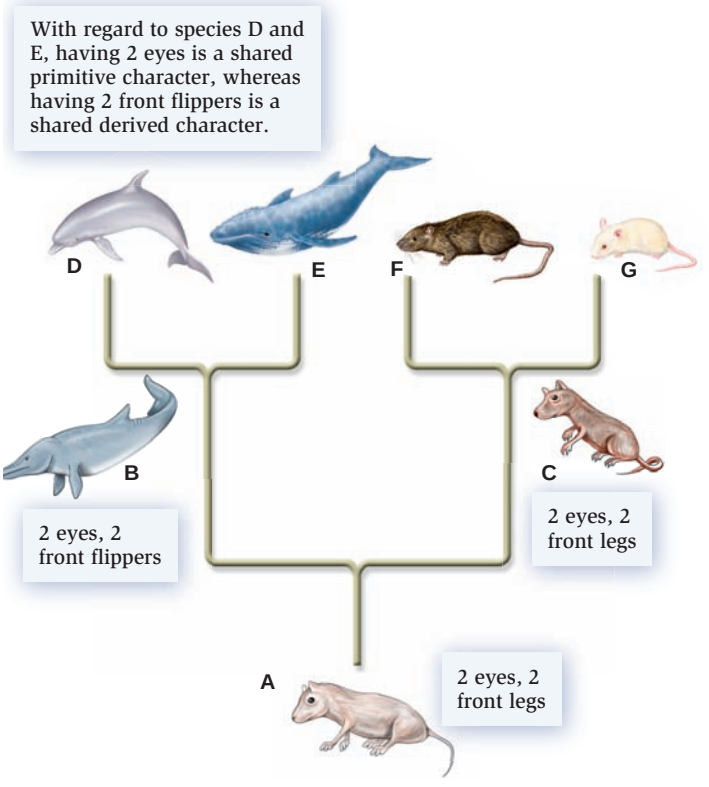

Figure 26.8 A comparison of shared primitive characters and shared derived characters.

possible phylogenetic trees by considering the possible pathways of evolutionary changes and then choosing the tree based on characteristics that are shared or not shared among various species. Cladistics is a commonly used method for the evaluation of phylogenetic trees, which are known as **cladograms**. In this section, we will consider the cladistic approach and other methods that are used to evaluate phylogenetic trees.

Species Differ with Regard to Primitive and Derived Characters

A cladistic approach compares homologous traits, also called **characters**, which may exist in two or more **character states**. For example, among different species, a front limb, which is a character, may exist in different character states such as a wing, an arm, or a flipper. The various character states are either shared or not shared by different species.

To understand the cladistic approach, let's take a look at a simplified phylogeny (Figure 26.8). We can place the extant species that currently exist into two groups: D and E, and F and G. The most recent common ancestor to D and E is B, whereas species C is the most recent common ancestor to F and G. With these ideas in mind, let's focus on the front limbs (flippers versus legs) and eyes. A character that is shared by two or more different taxa and inherited from ancestors older than their last common ancestor is called a **shared primitive character**, or **symplesiomorphy**. Such traits are viewed as being older traits—ones that occurred earlier in evolution. With regard to species D, E, F, and G, having two eyes is a shared primitive character. It originated prior to species B and C.

By comparison, a **shared derived character**, or **synapomorphy**, is a character that is shared by two or more species or taxa and has originated in their most recent common ancestor. With regard to species D and E, having two front flippers is a shared derived character that originated in species B, their most recent common ancestor (Figure 26.8). Compared to shared primitive characters, shared derived characters are more recent traits on an evolutionary timescale. For example, among mammals, only some species have flippers, such as whales and dolphins. In this case, flippers were derived from the two front limbs of an ancestral species. The word "derived" indicates that evolution involves the modification of traits in pre-existing species. In other words, populations of organisms with new traits are derived from changes in pre-existing populations. The basis of the cladistic approach is to analyze many shared derived characters among groups of species to deduce the pathway that gave rise to those species.

Note that the terms primitive and derived do not indicate the complexity of a character. For example, the flippers of a dolphin do not appear more complex than the front limbs of ancestral species A (Figure 26.8), which were limbs with individual toes. Derived characters can be similar in complexity, less complex, or more complex than primitive characters.

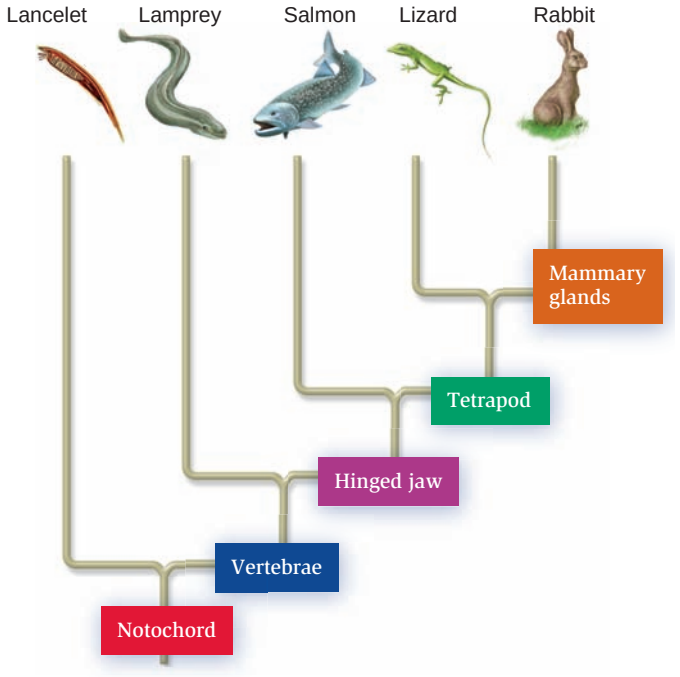
A Cladistic Approach Is Used to Determine If a Phylogenetic Tree Is a Reasonable Hypothesis

To understand how shared derived characters can be used to propose a phylogenetic tree, Figure 26.9a compares several traits among five species of animals. The proposed cladogram shown in Figure 26.9b is consistent with the distribution of shared derived characters among these species. A branch point is where two species differ in a character. The oldest common ancestor, which would now be extinct, had a notochord and gave rise to all five species. Vertebrae are a shared derived character of the lamprey, salmon, lizard, and rabbit, but not the lancelet, which is an invertebrate. By comparison, a hinged jaw is a shared derived character of the salmon, lizard, and rabbit, but not of the lamprey or lancelet.

In a cladogram, an **ingroup** is the group whose evolutionary relationships we wish to understand. By comparison, an **outgroup** is a species or group of species that is assumed to have diverged before the species in the ingroup. An outgroup will lack one or more shared derived characters that are found in the ingroup. A designated outgroup can be closely related or more distantly related to the ingroup. In the tree shown in Figure 26.9, if the salmon, lizard, and rabbit are an ingroup, an outgroup would be the lamprey. The lamprey has a notochord and vertebrae but lacks a character shared by the ingroup, namely, a hinged jaw. Thus, for the ingroup, the notochord and vertebrae are shared primitive traits, whereas the hinged jaw is a shared derived trait that is not found in the outgroup.

	Lancelet	Lamprey	Salmon	Lizard	Rabbit
Notochord	Yes	Yes	Yes	Yes	Yes
Vertebrae	No	Yes	Yes	Yes	Yes
Hinged jaw	No	No	Yes	Yes	Yes
Tetrapod	No	No	No	Yes	Yes
Mammary glands	No	No	No	No	Yes

(a) Characteristics among species



(b) Cladogram based on morphological traits

Figure 26.9 **Using shared primitive characters and shared derived characters to propose a phylogenetic tree.** **(a)** A comparison of characteristics among these species. **(b)** This phylogenetic tree illustrates both shared primitive and shared derived characters in a cladogram of five animal species.

Concept check: *What shared derived character is common to the salmon, lizard, and rabbit, but not the lamprey?*

Likewise, the concept of shared derived characters can apply to molecular data, such as a gene sequence. Let's consider an example to illustrate this idea. Our example involves molecular data obtained from seven different hypothetical plant species called A–G. In these species, a homologous region of DNA was sequenced as shown here:

```
   12345678910
A: GATAGTACCC
B: GATAGTTCCC
C: GATAGTTCCG
D: GGTATTACCC
E: GGTATAACCC
F: GGTAGTACCA
G: GGTAGTACCC
```

The cladogram of Figure 26.10 is a hypothesis of how these DNA sequences arose. In this case, a mutation that changes the sequence of nucleotides is comparable to a modification of a character. For example, let's designate species D as an outgroup and species A, B, C, F, and G as the ingroup. In this case, a G (guanine) at the fifth position is a shared derived character. The genetic sequence carrying this G is derived from an older primitive sequence.

Now that we have an understanding of shared primitive and derived characters, let's consider the steps a researcher would follow to propose a cladogram using a cladistics approach.

1. **Choose the species in whose evolutionary relationships you are interested.** In a simple cladogram, such as those described in this chapter, individual species are compared to each other. In more complex cladograms, species may be grouped into larger taxa (for example, families) and compared with each other. If such grouping is done, the results will not be reliable if the groups are not clades.
2. **Choose characters for comparing the species selected in step 1.** As mentioned, a character is a general feature of an organism and may come in different versions called character states. For example, a front limb is a character in mammals, which could exist in different character states such as a wing, an arm, or a flipper.
3. **Determine the polarity of character states.** In other words, determine if a character state came first and is primitive or came later and is a derived character. This information may be available by examining the fossil record, for example, but is usually done by comparing the ingroup with the outgroup. For a character with two character states, an assumption is made that a character state shared by the outgroup and ingroup is primitive. A character state shared only by members of the ingroup is derived.
4. **Analyze cladograms based on the following principles:**
   - All species (or higher taxa) are placed on tips in a phylogenetic tree, not at branch points.
   - Each cladogram branch point should have a list of one or more shared derived characters that are common to all species above the branch point unless the character is later modified.
   - All shared derived characters appear together only once in a cladogram unless they arose independently during evolution more than once.
5. **Among many possible options, choose the cladogram that provides the simplest explanation for the data.** A common approach is to use a computer program that generates many possible cladograms. Analyzing the data and choosing the cladogram with the fewest number of character changes is a key aspect of this process. As described later, different theoretical approaches, such as the principle of parsimony, can be followed to achieve this goal.
6. **Provide a root to the phylogenetic tree by choosing a noncontroversial outgroup.** In this textbook, most

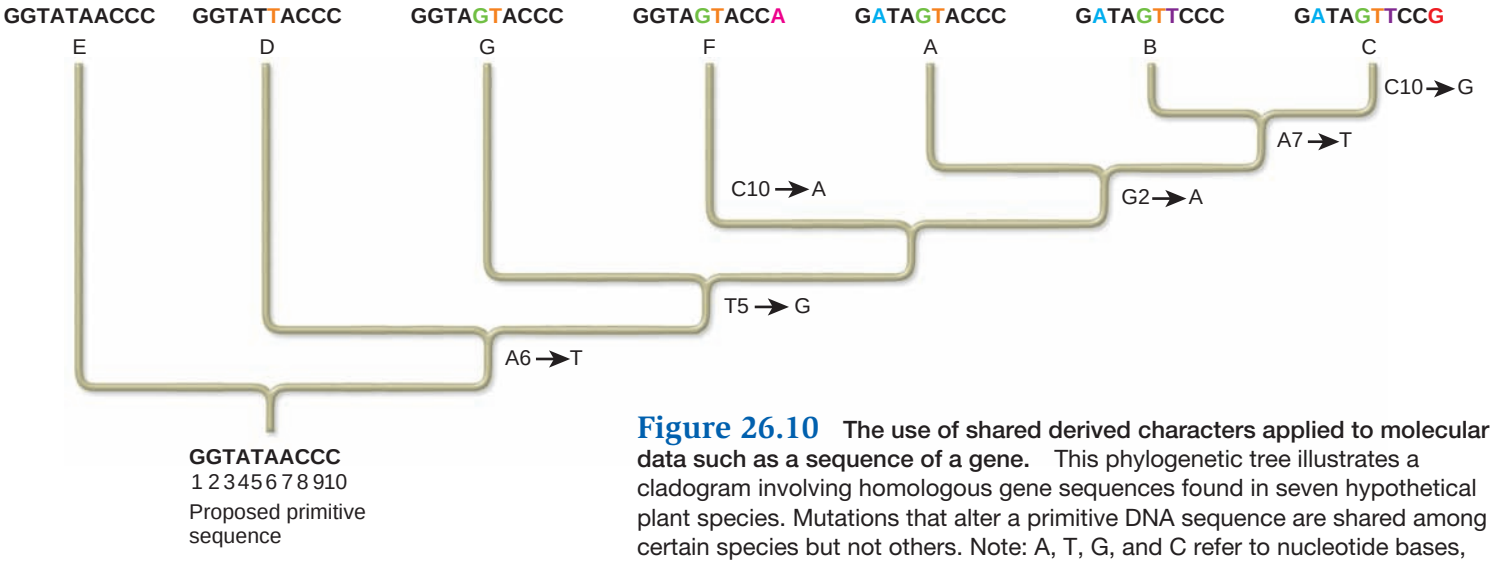


Figure 26.10 **The use of shared derived characters applied to molecular data such as a sequence of a gene.** This phylogenetic tree illustrates a cladogram involving homologous gene sequences found in seven hypothetical plant species. Mutations that alter a primitive DNA sequence are shared among certain species but not others. Note: A, T, G, and C refer to nucleotide bases, and the numbers refer to the position of the base in the nucleotide sequences. For example, A6 refers to an adenine at the sixth position.

Concept check: *What nucleotide change is a shared derived character for species A, B, and C, but not for species G?*

phylogenetic trees are rooted, which means that a single node at the bottom of the tree corresponds to a common ancestor for all of the species or groups of species in the tree. A method for rooting trees is the use of a noncontroversial outgroup. Such an outgroup typically shares morphological traits and/or DNA sequence similarities with the members of the ingroup to allow a comparison between the ingroup and outgroup. Even so, the outgroup must be noncontroversial in that it shows enough distinctive differences with the ingroup to be considered a clear outgroup.

The Principle of Parsimony Can Help Researchers Choose from Among Possible Phylogenetic Trees

One approach for choosing among possible phylogenetic trees is to assume that the best hypothesis is the one that requires the smallest number of evolutionary changes. This concept, called the **principle of parsimony**, states that the preferred hypothesis is the one that is the simplest for all the characters and their states. For example, if two species possess a tail, we would initially assume that a tail arose once during evolution and that both species have descended from a common ancestor with a tail. Such a hypothesis is simpler, and more likely to be correct, than assuming that tails arose twice during evolution and that the tails in the two species are not due to descent from a common ancestor.

The principle of parsimony can also be applied to gene sequence data. Let's consider a hypothetical example involving molecular data from four taxa (A–D), where A is presumed to be the outgroup.

```
   12345
A: GTACA (outgroup)
B: GACAG
C: GTCAA
D: GACCG
```

Given that B, C and D are the ingroup, three hypotheses for phylogenetic trees are shown in Figure 26.11, although more are possible. Tree 1 requires seven mutations, and tree 2 requires six, whereas tree 3 requires only five. Therefore, tree 3 requires the smallest number of mutations and is considered the most parsimonious. Based on the principle of parsimony, it would be the hypothesis that is the most likely to accurately reflect the evolutionary history of the taxon (or ingroup) in question. In practice, when researchers have multiple sequences that are longer than the ones shown here, computer programs are used to find the most parsimonious tree.

Maximum Likelihood and Bayesian Methods Are Also Used to Discriminate Among Possible Phylogenetic Trees

In addition to the principle of parsimony, evolutionary biologists also apply other approaches, such as maximum likelihood and Bayesian methods, when proposing and evaluating phylogenetic trees. These methods involve the use of an evolutionary model—a set of assumptions about how evolution is likely to happen. For example, mutations affecting the third base in a codon are often neutral because they don't affect the amino acid sequence of the encoded protein and therefore don't affect the fitness of an organism. As discussed in Chapter 24, such neutral

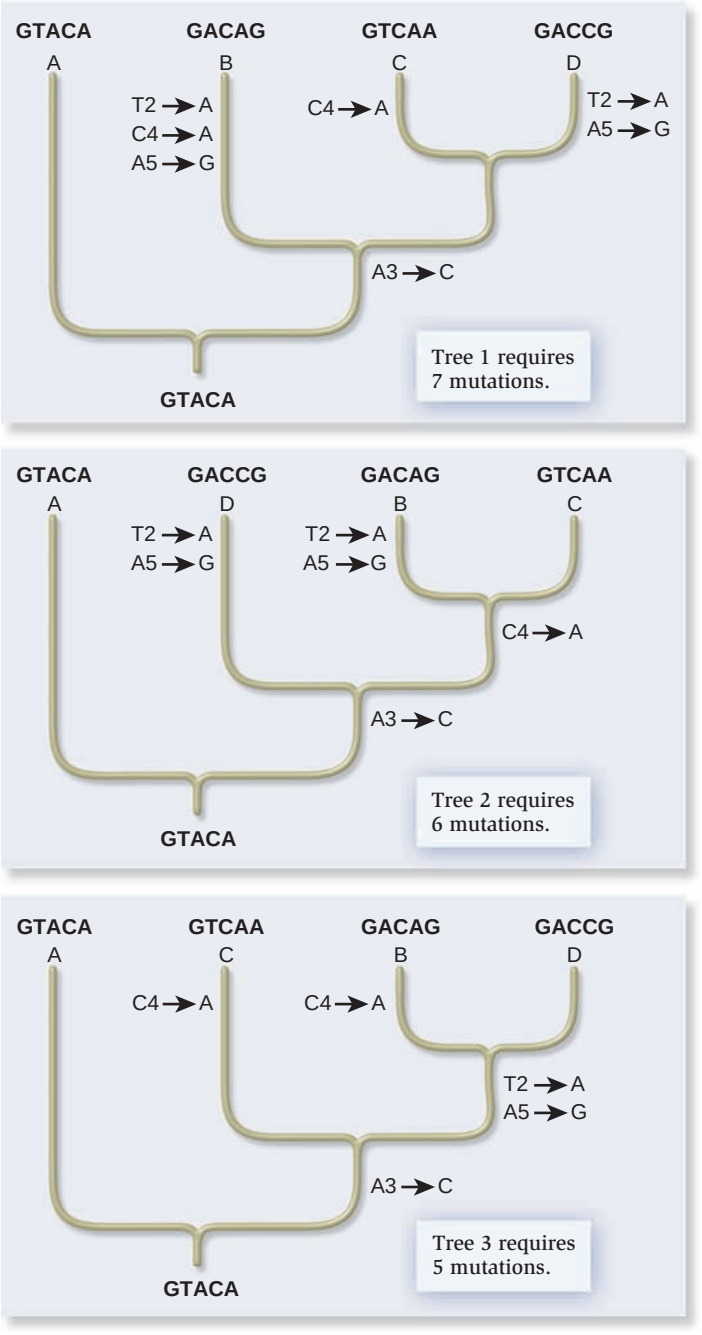

Figure 26.11 **Using the principle of parsimony and molecular genetic data to choose a phylogenetic tree.** These are three possible phylogenetic trees for the evolution of a short DNA sequence, but many more are possible. Changes in nucleotide sequence are shown along each tree. For example, T2 → A means that the second base, a T, was changed to an A. According to the principle of parsimony, tree number 3 is the more likely choice because it requires only five mutations.

mutations are more likely to become prevalent in a population compared to mutations in the first or second base. Therefore, one possible assumption of an evolutionary model is that neutral mutations are more likely than nonneutral mutations.

According to an approach called **maximum likelihood**, researchers ask the question: What is the probability that an evolutionary model and a proposed phylogenetic tree would give rise to the observed data? The rationale is that a phylogenetic tree that gives a higher probability of producing the observed data is preferred to any trees that give a lower probability. By comparison, **Bayesian methods** ask the question: What is the probability that a particular phylogenetic tree is correct given the observed data and a particular evolutionary model? Though the computational strategies of maximum likelihood and Bayesian methods are different (and beyond the scope of this textbook), the goal of both approaches is to identify one or more trees that are most likely to be correct based on an evolutionary model and the available data.

26.4 Molecular Clocks

As we have seen, researchers employ various methods to propose a phylogeny that describes the evolutionary relationships among various species. Researchers are interested not only in the most likely pathway of evolution, but also the timing of evolutionary change. How can researchers determine when different species diverged from each other in the past? As shown in Figure 26.7, the fossil record can sometimes help researchers apply a timescale to a phylogeny. Another way to infer the timing of past events is by analyzing genetic sequences. As discussed in Chapter 24, the neutral theory of evolution proposes that most genetic variation that exists in populations is due to the accumulation of neutral mutations, meaning that such genetic variation is not acted upon by natural selection. The reasoning behind this concept is that favorable mutations are likely to be very rare, and detrimental mutations are likely to be eliminated from a population by natural selection. A large body of evidence supports the idea that much of the genetic variation observed in living species is due to the accumulation of neutral mutations. From an evolutionary point of view, if neutral mutations occur at a relatively constant rate, they can act as a **molecular clock** on which to measure evolutionary time. In this section, we will consider the concept of a molecular clock and its application in phylogenetic trees.

The Timing of Past Events May Be Inferred from Molecular Clock Data

Figure 26.12 illustrates the concept of a molecular clock. The graph's y-axis is a measure of the number of nucleotide differences in a homologous gene between different pairs of species. The x-axis plots the amount of time that has elapsed since each pair of species shared a common ancestor. As discussed in the boxes in this diagram, the number of nucleotide differences is lower when two species shared a common ancestor in the more recent past than it is in pairs that shared a more distant common ancestor. The explanation for this phenomenon is that the gene sequences of various species accumulate independent mutations after they have diverged from each other. A

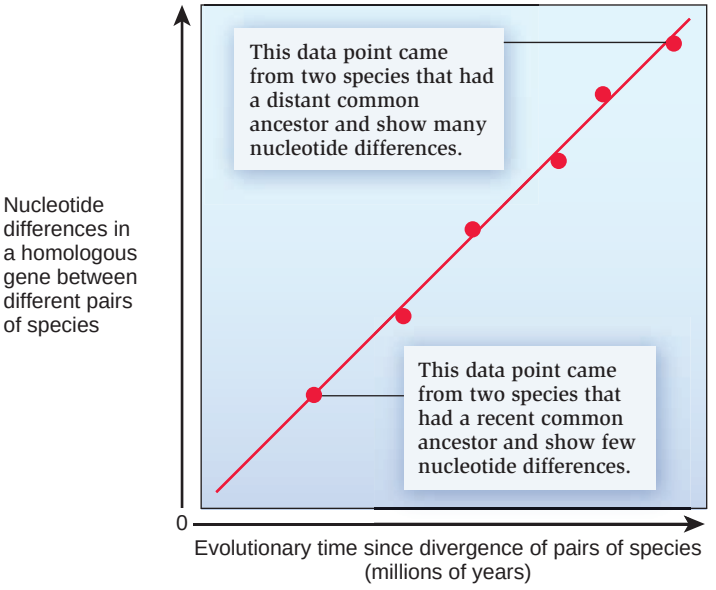

Figure 26.12 **A molecular clock.** According to the concept of a molecular clock, neutral mutations accumulate at a relatively constant rate over evolutionary time. When comparing homologous genes between species, those species that diverged more recently tend to have fewer differences than do those whose common ancestor occurred in the very distant past.

Concept check: *When comparing the sequences of a homologous gene in four different species, one pair of species shows a 1% difference, whereas the other pair shows a 3% difference. Which pair diverged longer ago from their common ancestor?*

longer period of time since their divergence allows for a greater accumulation of mutations, which makes their sequences more different.

Figure 26.12 suggests a linear relationship between the number of nucleotide changes and the time of divergence. For example, a linear relationship predicts that a pair of species that has 20 nucleotide differences in a given gene sequence would have a common ancestor that is roughly twice as old as that of a pair showing 10 nucleotide differences. While actual data sometimes show a relatively linear relationship over a defined time period, evolutionary biologists do not think that molecular clocks are perfectly linear over very long periods of time. Several factors can contribute to nonlinearity of molecular clocks. These include differences in the generation times of the species being analyzed and variation in mutation rates between different species.

To obtain reliable data, researchers must calibrate their molecular clocks. How much time does it take to accumulate a certain percentage of nucleotide changes? To perform such a calibration, researchers must have information regarding the date when two species diverged from a common ancestor. Such information could come from the fossil record, for instance. The genetic differences between those species are then divided by the amount of time since their last common ancestor to calculate a rate of change. For example, research suggests that humans and chimpanzees diverged from a common ancestor approximately 6 million years ago. The percentage of nucleotide differences between mitochondrial DNA of humans and chimpanzees is 12%. From these data, the molecular clock for changes in mitochondrial DNA sequences of primates is calibrated at roughly 2% nucleotide changes per million years.

Different Genes Are Analyzed to Study Phylogeny

For evolutionary comparisons, the DNA sequences of many genes have been obtained from a wide range of sources. Many different genes have been used to propose phylogenetic trees. For example, the gene that encodes an RNA found in the small ribosomal subunit (SSU rRNA) has been commonly used in evolutionary studies. As noted in Chapter 12, the gene for SSU rRNA is found in the genomes of all living organisms. Therefore, its function must have been established at an early stage in the evolution of life on this planet, and its sequence has changed fairly slowly. Furthermore, SSU rRNA is a rather large molecule, so it contains a large amount of sequence information. This gene has been sequenced from thousands of different species. Slowly changing genes such as the gene that encodes SSU rRNA are useful for evaluating distant evolutionary relationships, such as comparing higher taxa. For example, SSU rRNA data can be used to place eukaryotic species into their proper phyla or orders.

Other genes have changed more rapidly during evolution because of a greater tolerance of neutral mutations. For example, the mitochondrial genome and DNA sequences within introns can more easily incur neutral mutations (compared to the coding sequences of genes), and so their sequences change frequently during evolution. More rapidly changing DNA sequences have been used to study recent evolutionary relationships, particularly among eukaryotic species such as large animals that have long generation times and tend to evolve more slowly. In these cases, slowly evolving genes may not be very useful for establishing evolutionary relationships because two closely related species are likely to have identical or nearly identical DNA sequences for such genes.

Figure 26.13 shows a simplified phylogeny of closely related species of primates. This tree was proposed by comparing DNA sequence changes in the gene for cytochrome oxidase subunit II, a protein located in the mitochondrial inner membrane that is involved in cellular respiration. This gene tends to change fairly rapidly on an evolutionary timescale. The vertical scale represents time, and the branch points that are labeled with letters represent common ancestors. Let's take a look at three branch points (labeled A, D, and E) and relate them to the accumulation of neutral mutations.

Ancestor A: This ancestor diverged into two species that ultimately gave rise to siamangs and the other five species. Since this divergence, there has been a long time (approximately 23 million years) for the siamang genome to accumulate a relatively high

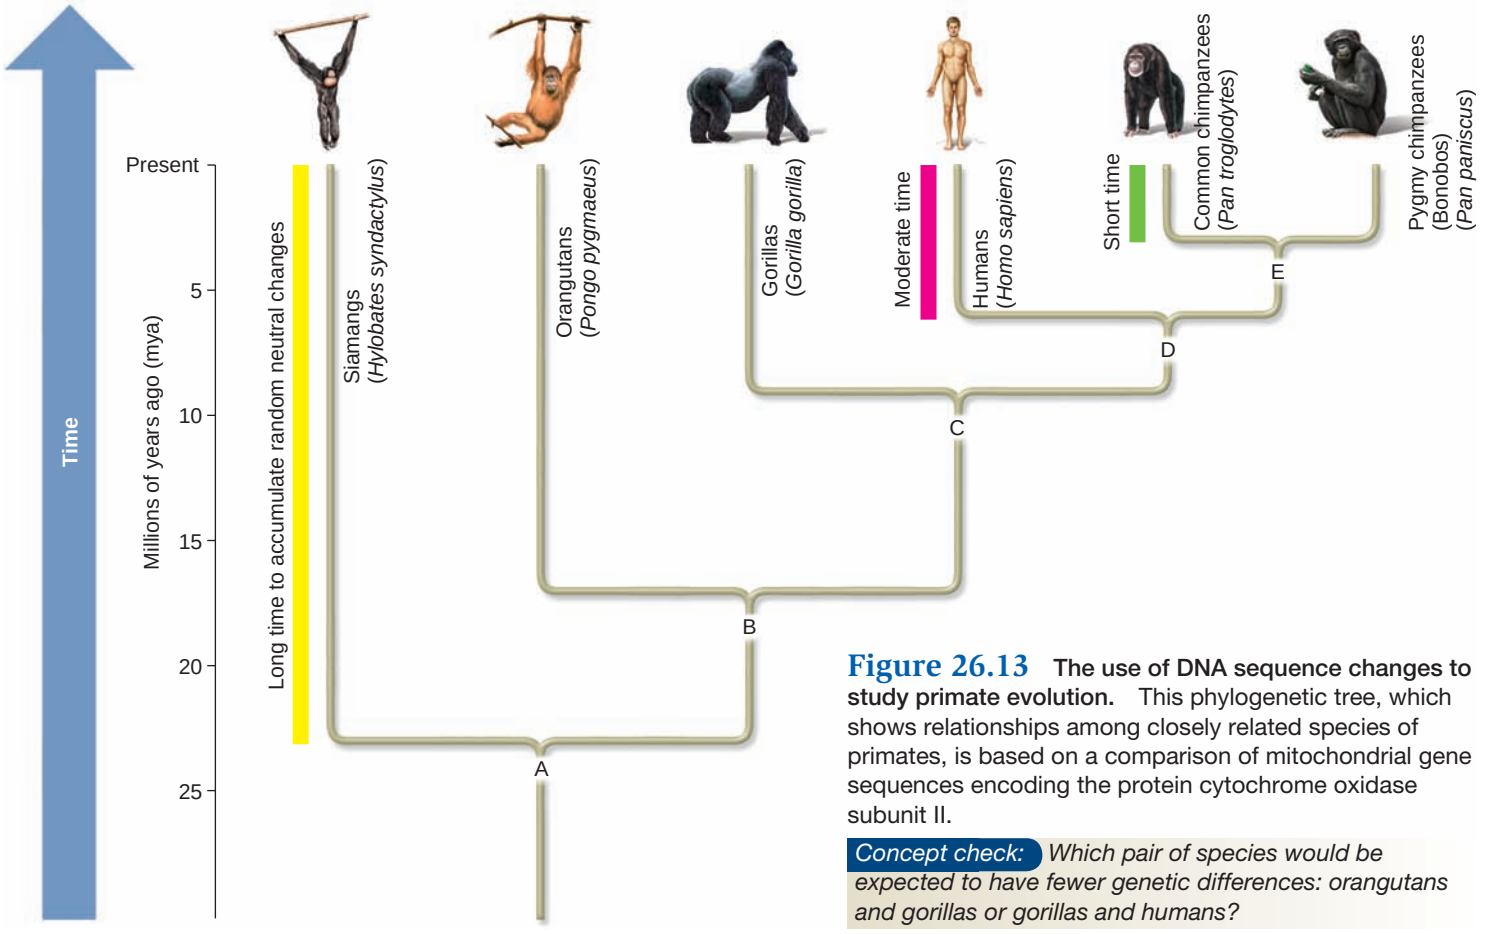

Figure 26.13 **The use of DNA sequence changes to study primate evolution.** This phylogenetic tree, which shows relationships among closely related species of primates, is based on a comparison of mitochondrial gene sequences encoding the protein cytochrome oxidase subunit II.

Concept check: *Which pair of species would be expected to have fewer genetic differences: orangutans and gorillas or gorillas and humans?*

number of random neutral changes that would be different from the random changes that have occurred in the genomes of the other five species (see the yellow bar in Figure 26.13). Therefore, the gene in the siamangs is fairly different from the genes in the other five species.

Ancestor D: This ancestor diverged into two species that eventually gave rise to humans and chimpanzees. This divergence occurred a moderate time ago, approximately 6 million years ago, as illustrated by the red bar. The differences in gene sequences between humans and chimpanzees are relatively moderate.

Ancestor E: This ancestor diverged into two species of chimpanzees. Since the divergence of species E into two species, approximately 3 million years ago, the time for the molecular clock to "tick" (that is, accumulate random mutations) is relatively short, as depicted by the green bar in Figure 26.13. Therefore, the two existing species of chimpanzees have fewer differences in their gene sequences compared to other primates.

Feature Investigation

Cooper and Colleagues Compared DNA from Extinct Flightless Birds and Existing Species to Propose a New Phylogenetic Tree

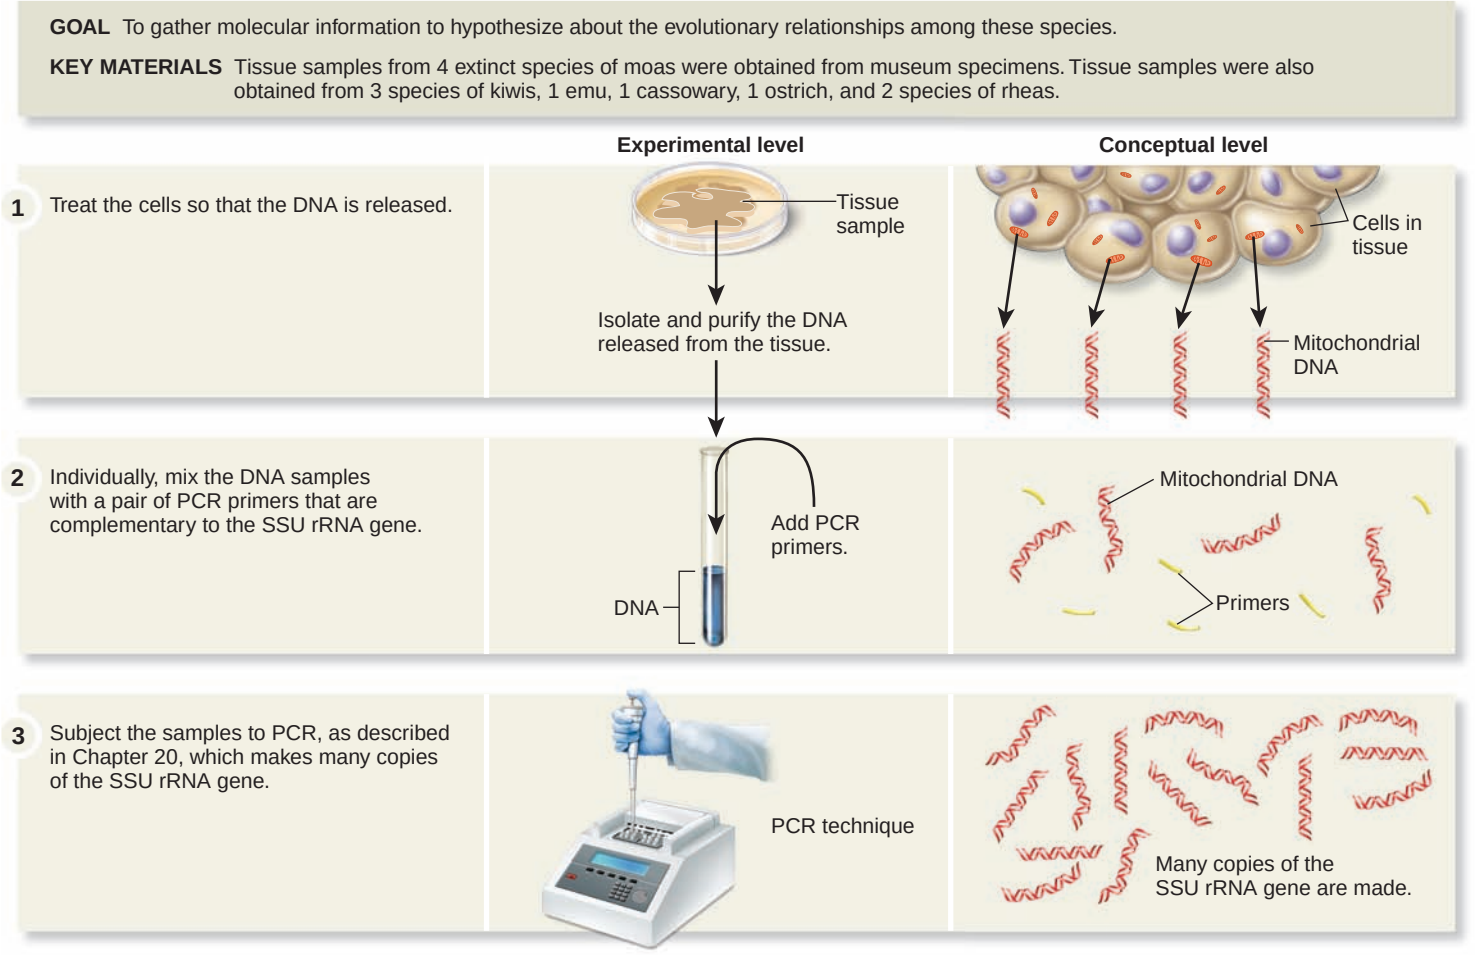
Genetic sequence information is primarily used for studying relationships among existing species. Sometimes DNA can be obtained from extinct organisms as well. Starting with small tissue samples from extinct species, scientists have discovered that it is occasionally possible to obtain DNA sequence information. This is called ancient DNA analysis or molecular paleontology. Since the mid-1980s, some researchers have become excited about the information derived from sequencing DNA of extinct specimens. Debate has centered on how long DNA can remain intact after an organism has died. Over time, the structure of DNA is degraded by hydrolysis and the loss of purines. Nevertheless, under certain conditions (cold temperature, low oxygen, and so on), DNA samples may be stable for as long as 50,000–100,000 years. In most studies involving extinct specimens, the ancient DNA is extracted from bone, dried muscle, or preserved skin. In recent years, this approach has been used to study evolutionary relationships between living and extinct species.

As shown in Figure 26.14, Alan Cooper, Cécile Mourer-Chauviré, Geoffrey Chambers, Arndt von Haeseler, Allan Wilson, and Svante Pääbo investigated the evolutionary relationships among some extinct and living species of flightless birds. This is an example of discovery-based science. The researchers gathered data with the goal of investigating the evolutionary relationships among certain species. The kiwis and moas are two groups of flightless birds that existed in New Zealand during the Pleistocene. Species of kiwis still exist, but the moas are now extinct. Eleven known species of moas formerly existed. In this study, the researchers investigated the phylogenetic relationships between four extinct species of moas, which were available as museum samples; three species of New Zealand kiwis; and other living species of flightless birds, including the emu and the cassowary (both found in Australia and/or New Guinea), the ostrich (found in Africa and formerly Asia), and two rheas (found in South America).

Samples from the various species were subjected to PCR to amplify a region of the mitochondrial SSU rRNA gene. This provided enough DNA for sequencing. The data in Figure 26.14 illustrate a comparison of the sequences of a continuous region of the SSU rRNA gene from these species. The first line shows the DNA sequence for one of the four extinct moa species. Below it are the sequences of several of the other species they analyzed. When the other sequences are identical to the first sequence, a dot is placed in the corresponding position. When the sequences are different, the changed nucleotide base (A, T, G, or C) is placed there. In a few regions, the genes are different lengths. In these cases, a dash is placed to indicate missing nucleotides.

As you can see from the large number of dots, the gene sequences among these flightless birds are very similar, though some differences occur. If you look carefully at the data, you will notice that the sequence from the kiwi (a New Zealand species) is actually more similar to the sequence from the ostrich (an African species) than it is to that of the moa, which was once found in New Zealand. Likewise, the kiwi is more similar to the emu and cassowary (found in Australia and New Guinea) than to the moa. How were these results interpreted? The researchers concluded that the kiwis are more closely related to African and Australian flightless birds than they are to the moas. From these results, they proposed that New Zealand was colonized twice by ancestors of flightless birds. As shown in Figure 26.15, the researchers proposed a new phylogenetic tree that illustrates the revised relationships among these living and extinct species.

Figure 26.14 DNA analysis of phylogenetic relationships among living and extinct flightless birds by Cooper and colleagues.



4	Subject the amplified DNA fragments to DNA sequencing, as described in Chapter 20.	Sequence the amplified DNA.	The amplification of the SSU rRNA gene allows it to be subjected to DNA sequencing.
5	Align the DNA sequences to each other, using computer techniques described in Chapter 21.	 Align sequences, using computer programs.	Align sequences to compare the degree of similarity.

Experimental Questions

1. What is molecular paleontology? What was the purpose of the study conducted by Cooper and colleagues?
2. What birds were examined in the Cooper study, and what are their geographic distributions? Why were the different species selected for this study?
3. What results did Cooper and colleagues obtain by comparing these DNA sequences? How did the results of this study impact the proposed phylogeny of flightless birds?

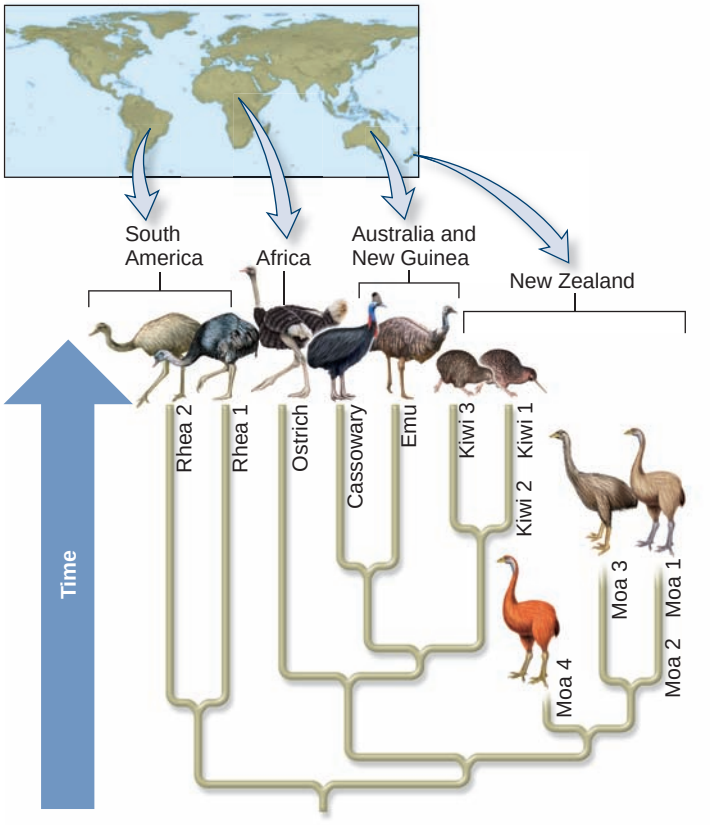

Figure 26.15 **A revised phylogenetic tree of flightless birds.** This tree is based on a comparison of DNA sequences from extinct and living birds as described in Figure 26.14.

Concept check: *With regard to geography, why are the results in this figure surprising?*

26.5 Horizontal Gene Transfer

Thus far, we have considered various ways to propose phylogenetic trees, which describe the relationships between ancestors and their descendents. The type of evolution depicted in previous figures, which involves changes in groups of species due to descent from a common ancestor, is called vertical evolution. Since the time of Darwin, vertical evolution has been the traditional way that biologists view the evolutionary process. However, over the past couple of decades researchers have come to realize that evolution is not so simple. In addition to vertical evolution, horizontal gene transfer has also played a significant role in the phylogeny of living species.

As discussed in Chapter 23, **horizontal gene transfer** is used to describe any process in which an organism incorporates genetic material from another organism without being the offspring of that organism. As discussed next, this phenomenon has reshaped the way that biologists view the evolution of species.

Genomes & Proteomes Connection

Due to Horizontal Gene Transfer, the "Tree of Life" Is Really a "Web of Life"

Horizontal gene transfer has played a major role in the evolution of many species. As discussed in Chapter 18, bacteria can transfer genes via conjugation, transformation, and transduction. The transferred genes may encode proteins that provide a survival advantage such as resistance to antibiotics or the ability to metabolize an organic molecule in the environment. Horizontal gene transfer is also fairly common among certain unicellular eukaryotes. However, its relative frequency and importance in the evolution of multicellular eukaryotes remains difficult to evaluate.

Scientists have debated the role of horizontal gene transfer in the earliest stages of evolution, prior to the emergence of the two prokaryotic domains. The traditional viewpoint was that the three domains of life—Bacteria, Archaea, and Eukarya—arose from a single type of prokaryotic (or pre-prokaryotic) cell called the universal ancestor. However, genomic research has suggested that horizontal gene transfer may have been particularly common during the early stages of evolution on Earth, when all species were unicellular. Horizontal gene transfer may have been so prevalent that the universal ancestor may have actually been an ancestral community of cell lineages that evolved as a whole. If that were the case, the tree of life cannot be traced back to a single prokaryotic ancestor.

Figure 26.16 illustrates a schematic scenario for the evolution of life on Earth that includes the roles of both vertical evolution and horizontal gene transfer. This has been described as a "web of life" rather than a "tree of life." Instead of a universal ancestor, a web of life began with a community of primitive cells that transferred genetic material in a horizontal fashion. Horizontal gene transfer was also prevalent during the early evolution of bacteria and archaea, and when eukaryotes first emerged as unicellular species. In living bacteria and archaea, it remains a prominent way to foster evolutionary change. By comparison, the region of the diagram that contains most eukaryotic species has a more treelike structure. Researchers have speculated that multicellularity and sexual reproduction have presented barriers to horizontal gene transfer in most eukaryotes. For a gene to be transmitted to eukaryotic offspring, it would have to be transferred into a eukaryotic cell that is a gamete or a cell that gives rise to gametes. Horizontal gene transfer has become less common in eukaryotes, though it does occur occasionally.

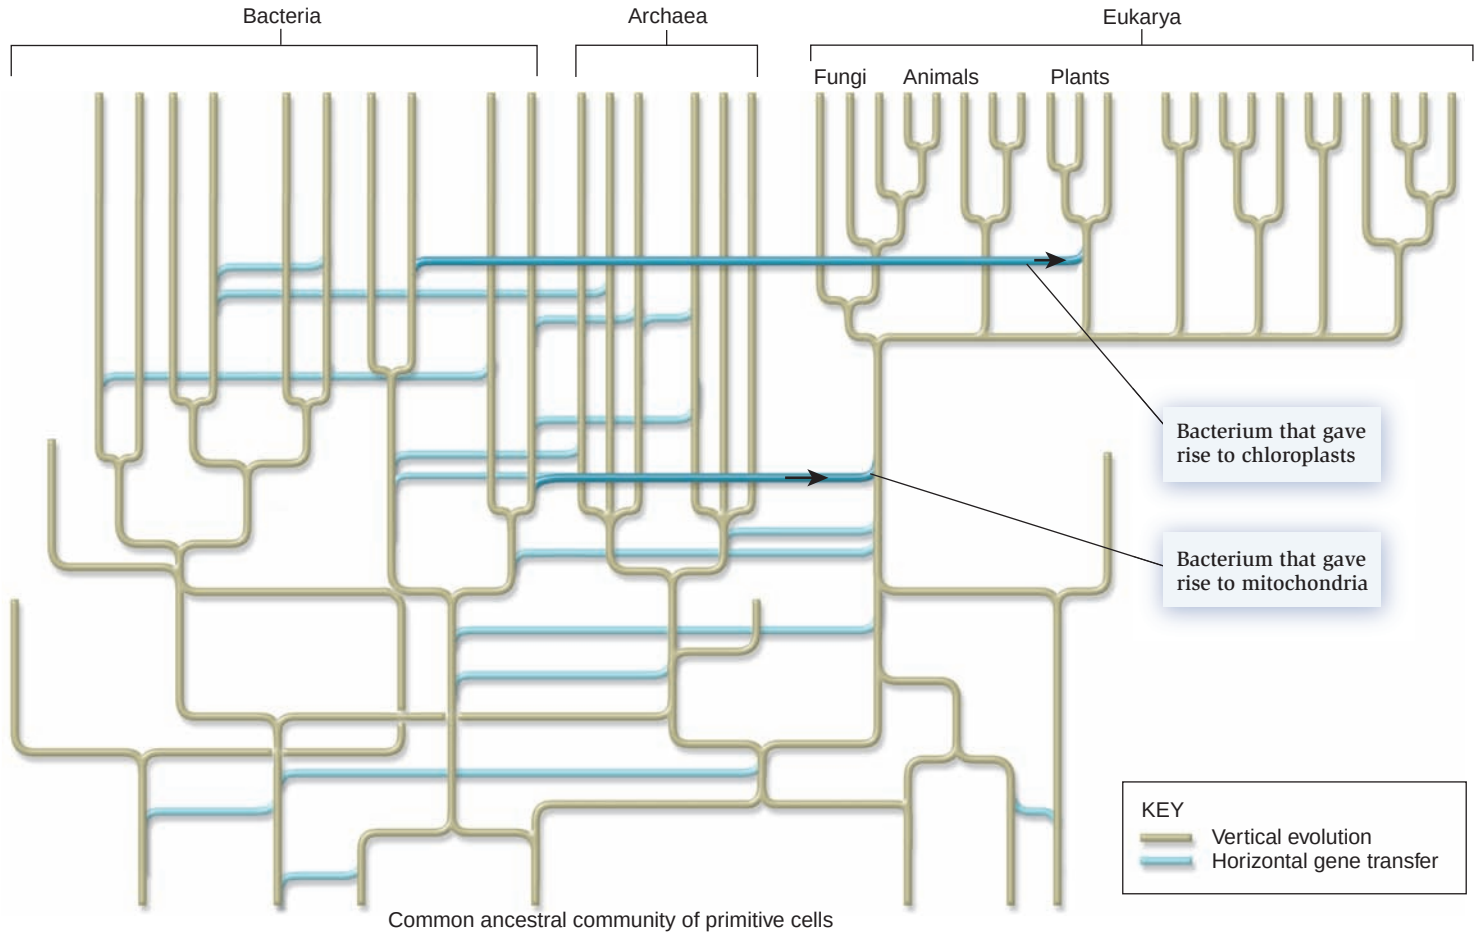

Figure 26.16 **A web of life.** This phylogenetic tree shows not only the vertical evolution of life on Earth but also the contribution of horizontal gene transfer. In this scenario, horizontal gene transfer was prevalent during the early stages of evolution, when all organisms were unicellular, and continues to be a prominent factor in the speciation of Bacteria and Archaea. Note: This tree is meant to be schematic. Also, while the introduction of chloroplasts into the eukaryotic domain is shown as a single event, such events have occurred multiple times and by different mechanisms, as discussed in Unit V.

Concept check: *How does the phenomenon of horizontal gene transfer muddle the concept of monophyletic groups?*

Summary of Key Concepts

26.1 Taxonomy

- Taxonomy is the field of biology that is concerned with the theory, practice, and rules of classifying living and extinct organisms and viruses.
- Taxonomy places all living organisms into progressively smaller hierarchical groups called taxa. The broadest groups are the three domains, called Bacteria, Archaea, and Eukarya, followed by supergroups, kingdoms, phyla, classes, orders, families, genera, and species. (Figures 26.1, 26.2, Table 26.1)
- Binomial nomenclature provides each species with a scientific name that refers to its genus and species epithet.

26.2 Phylogenetic Trees

- Systematics is the study of biological diversity and evolutionary relationships. The evolutionary history of a species is its phylogeny.
- A phylogenetic tree is a hypothesis that describes the phylogeny of particular species. A monophyletic group or clade includes all of the species that are derived from a common ancestor. (Figure 26.3)
- The hierarchy of taxonomy is related to the process of descent with modification and the timing of common ancestors. Smaller taxa, such as families and genera, are derived from more recent common ancestors than are broader taxa such as kingdoms and phyla. (Figure 26.4)
- Molecular systematics, which involves the analysis of genetic sequences, has led to major revisions in taxonomy. Ideally, all taxa should be monophyletic, consisting of the most recent common ancestor and all of its descendants, though previously established taxa sometimes turn out to be paraphyletic or polyphyletic. (Figures 26.5, 26.6)
- Both morphological and genetic data are used to propose phylogenetic trees. (Figure 26.7)

26.3 Cladistics

- In the cladistic approach to proposing a phylogenetic tree, also called a cladogram, species are grouped together according to shared derived characters. (Figure 26.8)
- An ingroup is the group of interest, whereas an outgroup is a species or group of species that lacks one or more shared

derived characters (synapomorphies). A comparison of the ingroup and outgroup is used to determine which character states are derived or primitive. (Figures 26.9, 26.10)

- The cladistic approach can produce many possible cladograms. The most likely phylogenetic tree is chosen by a variety of methods, including the analysis of fossils, the principle of parsimony, maximum likelihood, and Bayesian methods. (Figure 26.11)

26.4 Molecular Clocks

- Assuming that neutral mutations occur at a relatively constant rate, genetic data can act as a molecular clock on which to measure evolutionary time. (Figure 26.12)
- Slowly changing genes are used to analyze broader taxa, whereas rapidly changing genes are used to analyze more closely related species such as eukaryotes with long generation times. (Figure 26.13)
- Cooper and colleagues analyzed DNA sequences from extinct and living flightless birds and proposed a phylogeny in which New Zealand was colonized twice, once by moas and later by kiwis. (Figures 26.14, 26.15)

26.5 Horizontal Gene Transfer

- Due to horizontal gene transfer, the tree of life may more accurately be described as a web of life. (Figure 26.16)

Assess and Discuss

Test Yourself

1. The study of biological diversity based on evolutionary relationships is
   a. paleontology. c. systematics. e. both a and b.
   b. evolution. d. ontogeny.
2. Which of the following is the correct order of the taxa used to classify organisms?
   a. kingdom, domain, phylum, class, order, family, genus, species
   b. domain, kingdom, class, phylum, order, family, genus, species
   c. domain, kingdom, phylum, class, family, order, genus, species
   d. domain, kingdom, phylum, class, order, family, genus, species
   e. kingdom, domain, phylum, order, class, family, species, genus
3. When considering organisms within the same taxon, which level includes organisms with the greatest similarity?
   a. kingdom c. order e. genus
   b. class d. family
4. Which of the following characteristics is not shared by prokaryotes and eukaryotes?
   a. DNA is the genetic material.
   b. Messenger RNA encodes the information to produce proteins.
   c. All cells are surrounded by a plasma membrane.
   d. The cytoplasm is compartmentalized into organelles.
   e. both a and d
5. The branch points or nodes in a phylogenetic tree depict which of the following?
   a. anagenesis d. a and b only
   b. cladogenesis e. b and c only
   c. horizontal gene transfer
6. The evolutionary history of a species is its
   a. ontogeny. c. evolution. e. embryology.
   b. taxonomy. d. phylogeny.
7. A taxon composed of all species derived from a common ancestor is referred to as
   a. a phylum.
   b. a monophyletic group or clade.
   c. a genus.
   d. an outgroup.
   e. all of the above.
8. The goal of modern taxonomy is to
   a. classify all organisms based on morphological similarities.
   b. classify all organisms in monophyletic groups.
   c. classify all organisms based solely on genetic similarities.
   d. determine the evolutionary relationships between similar species.
   e. none of the above
9. The concept that the preferred hypothesis is the one that is the simplest is
   a. phenetics. d. maximum likelihood.
   b. cladistics. e. both b and d.
   c. the principle of parsimony.
10. Research indicates that horizontal gene transfer is less prevalent in eukaryotes because of
    a. the presence of organelles. d. all of the above.
    b. multicellularity. e. b and c only.
    c. sexual reproduction.

Conceptual Questions

1. Explain how species' names follow a binomial nomenclature. Give an example.
2. What are some advantages and potential pitfalls of morphological analysis with regard to phylogenetic trees?
3. What is a molecular clock? How is it used in depicting phylogenetic trees?

Collaborative Questions

1. Discuss how taxonomy is useful. Make a list of some practical applications that are derived from taxonomy.
2. Discuss systematics and how it is used to propose a phylogenetic tree. What are some pros and cons of the principle of parsimony, maximum likelihood, and Bayesian methods for proposing the correct tree?

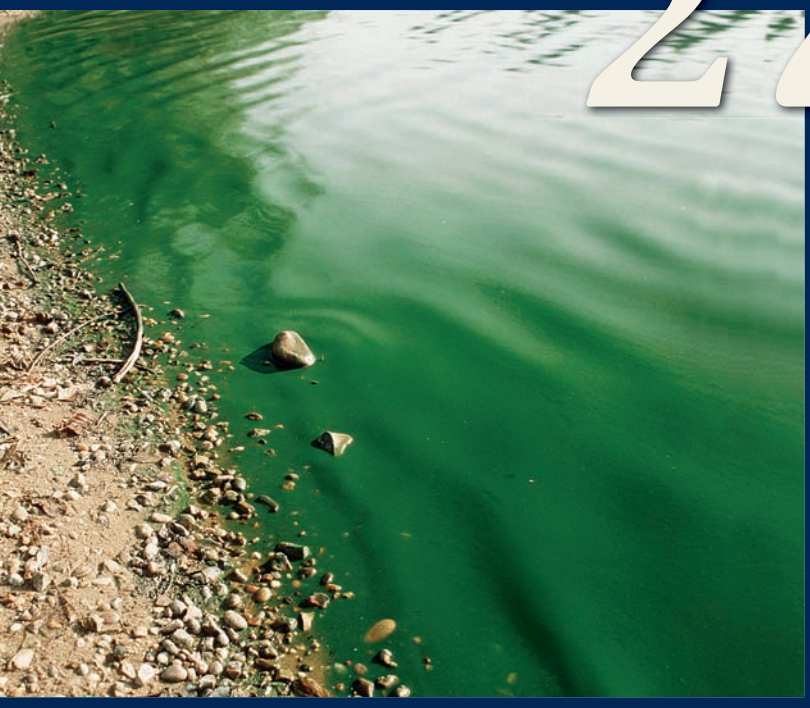
Bacteria and Archaea

27



Cyanobacterial bloom. A visible cyanobacterial bloom gives a pea-soup appearance to this lake water.

Among Earth's life-forms, the domains Bacteria and Archaea are distinct from domain Eukarya in several ways. These organisms have the simplest cell structure and include the smallest known cells. Bacteria and archaea are also the most abundant organisms on Earth. About half of Earth's total biomass consists of an estimated 10^{30} individuals; just a pinch of garden soil can contain 2 billion prokaryotic cells, and about a million occur in 1 ml of seawater. Bacteria and archaea live in nearly every conceivable habitat, including extremely hot or salty waters that support no other life, and they are also Earth's most ancient organisms, having originated more than 3.5 billion years ago. Their great age and varied habitats have resulted in very high diversity. Today, many millions of species of bacteria and archaea collectively display more diverse metabolic processes than occur in any other group of organisms. Many of these metabolic processes are important on a global scale, influencing Earth's climate, atmosphere, soils, water quality, and human health and technology. In this chapter, we will survey the diversity, structure, reproduction, metabolism, and ecology of bacteria and archaea. This survey will illustrate major principles of diversity, including descent with modification and horizontal gene transfer.

Chapter Outline

27.1 Diversity and Evolution

As we have noted, one of the prominent features of bacteria and archaea is their astounding diversity. In the past, microbiologists studied diversity by isolating these organisms from nature and growing cultures in the laboratory. Such cultures allowed microbiologists to observe variation in cell structure and metabolism, major features used to classify bacteria and archaea. Today, microbiologists also use molecular techniques to detect diverse bacteria and archaea in nature. By using these new techniques, they have discovered that bacteria and archaea are vastly more diverse than previously realized, and many new species have been discovered.

Though much remains to be learned about the diversity of Earth's microorganisms, extensive molecular analysis has supported the concept that prokaryotic microbes can be classified into two major domains of life: the **Archaea** and **Bacteria** (also called Eubacteria) (Figure 27.1). The terms prokaryote and prokaryotic are often used to refer to archaeal and bacterial cells because these organisms lack nuclei with porous envelopes and other cellular features typical of eukaryotes (see Chapter 4). As we noted in Chapter 26, in the 1970s, microbiologist Carl Woese and associates proposed splitting the kingdom Monera, which had included all prokaryotes, into these two domains, based on comparisons of ribosomal RNA sequences from diverse microorganisms. In this section, we will first survey the major kingdoms and phyla of the domains Archaea and Bacteria and then explore how horizontal gene transfer—the transfer of genes between different species—has influenced their evolution.

Domain Archaea Includes Inhabitants of Extremely Harsh Environments

Organisms classified in the domain Archaea, commonly known as archaea, display some unique characteristics. First, archaea possess a number of features in common with the eukaryotic nucleus and cytoplasm, suggesting common ancestry. For example, histone proteins are typically associated with

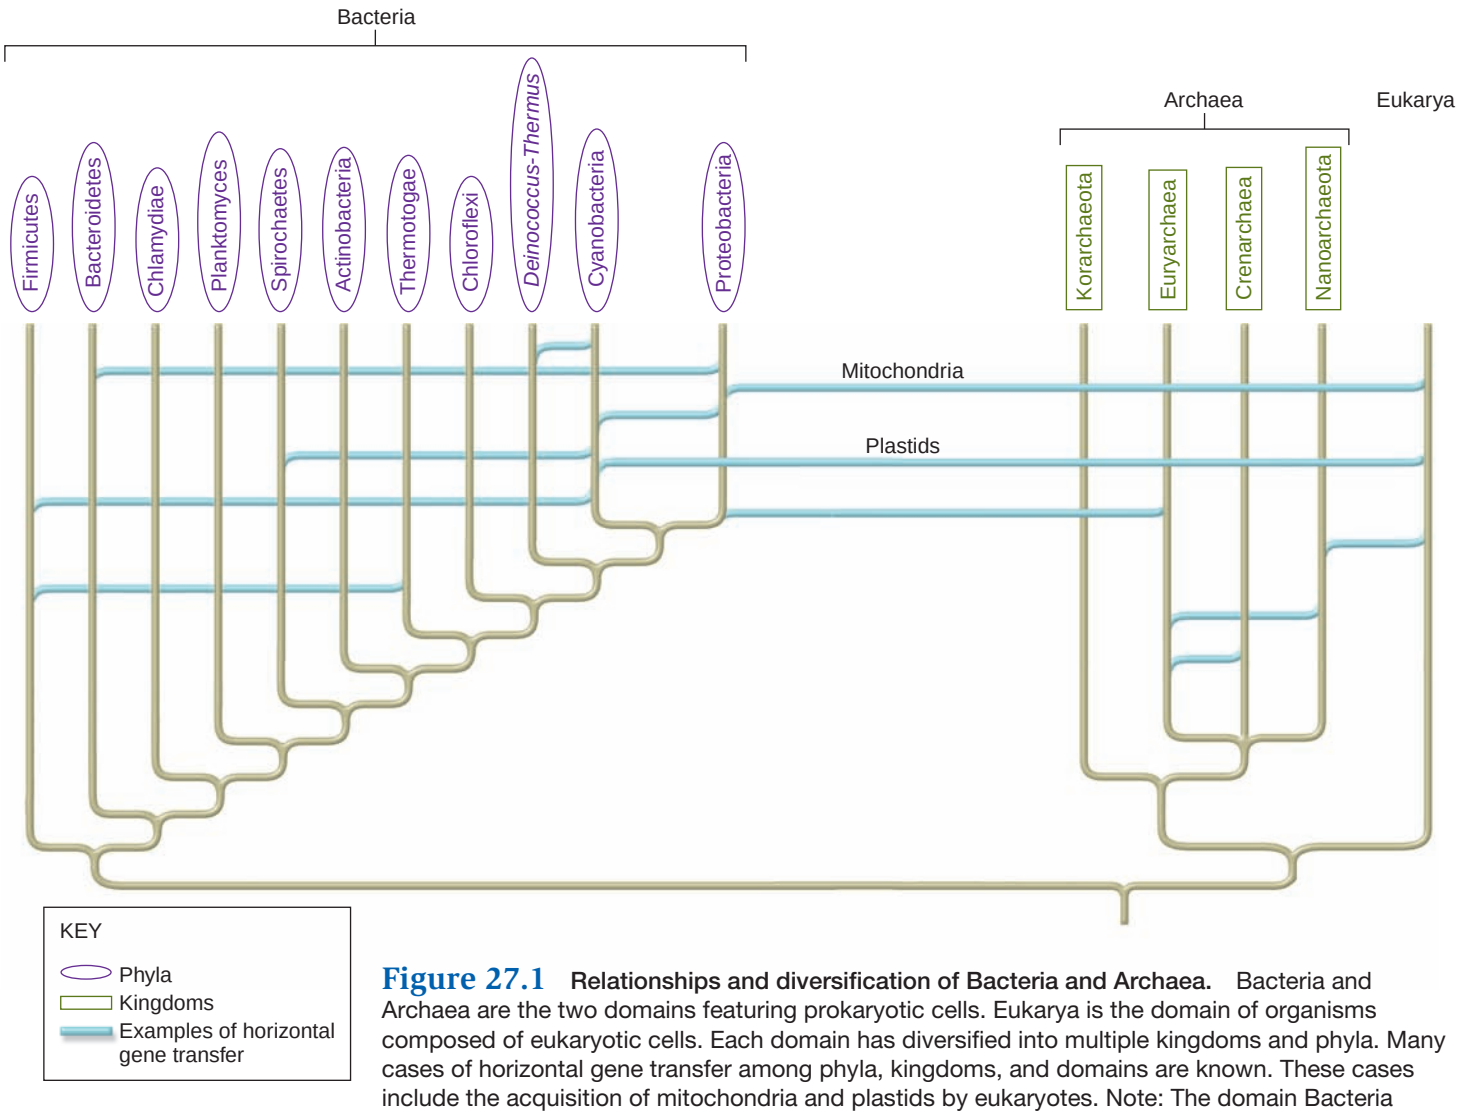


Figure 27.1 **Relationships and diversification of Bacteria and Archaea.** Bacteria and Archaea are the two domains featuring prokaryotic cells. Eukarya is the domain of organisms composed of eukaryotic cells. Each domain has diversified into multiple kingdoms and phyla. Many cases of horizontal gene transfer among phyla, kingdoms, and domains are known. These cases include the acquisition of mitochondria and plastids by eukaryotes. Note: The domain Bacteria includes about 50 phyla, but for simplicity, only 11 are shown in this figure.

the DNA of both archaea and eukaryotes, but they are absent from most bacteria. A distinctive feature of archaea is their membrane lipids, which are formed with ether linkages (in contrast, ester linkages characterize the membrane lipids of bacteria and eukaryotes). Ether-linked membranes are resistant to damage by heat and other extreme conditions, which helps explain why many archaea are able to grow in extremely harsh environments.

Though many archaea occur in soils and surface ocean waters of moderate conditions, diverse archaea occupy habitats of very high salt content, acidity, methane levels, or temperatures that would kill most bacteria and eukaryotes. Organisms that occur primarily in extreme habitats are known as **extremophiles**. One example is the methane producer *Methanopyrus*, which grows best at deep-sea thermal vent sites where the temperature is 98°C. At this temperature, the proteins of most organisms would denature, but those of *Methanopyrus* are resistant to such damage. *Methanopyrus* is so closely adapted to its extremely hot environment that it will not grow when the temperature is less than 84°C. Such archaea are known as **hyperthermophiles**. Some archaea prefer habitats having both high temperatures and extremely low pH. For example, microbiologist Thomas Brock discovered the archaeal genus *Sulfolobus* in samples taken from sulfur hot springs having a pH of 3 or lower.

Extreme **halophiles** (from the Greek, meaning salt lovers) occupy evaporation ponds used to produce salt from seawater, often growing so abundantly that they color the ponds red (Figure 27.2). Halophiles are often red because their plasma membranes contain large amounts of rhodopsins, proteins combined with the light-sensitive red pigment known as retinal. (Similar rhodopsins play important roles in eukaryote light sensing, and they are essential for animal vision.) In bacteria and archaea, rhodopsin functions as a proton pump, a protein that can move protons and other ions across the plasma membrane (see Chapter 5).

The domain Archaea includes several kingdoms: Korarchaeota, Euryarchaeota, Crenarchaeota, and Nanoarchaeota. Korarchaeota is primarily known from DNA sequences found in samples from hot springs. Euryarchaeota includes methane producers, extreme halophiles, and some hyperthermophiles. Crenarchaeota includes organisms that grow in extremely hot

Figure 27.2 Hypersaline waters colored red by numerous halophilic archaea.

Concept check: What material explains the red color of the water in this figure?

or cold habitats and also some that are widespread in aquatic and terrestrial habitats. Nanoarchaeota includes the hyperthermophile *Nanoarchaeum equitans*, which appears to be a parasite of the thermal vent crenarchaeote *Ignicoccus*. Molecular biologist Elizabeth Waters and associates sequenced the exceptionally small genome of *N. equitans* and determined that it represents an early branching archaeal lineage.

Domain Bacteria Includes Proteobacteria, Cyanobacteria, and Many Other Phyla

Molecular studies suggest the existence of 50 or so bacterial phyla. However, the structural and metabolic features of about half of these are unknown. Though some members of domain Bacteria live in extreme environments, many more favor moderate conditions. Many bacteria form symbiotic associations with eukaryotes and are thus of concern in medicine and agriculture. The characteristics of 11 prominent bacterial phyla are briefly summarized in Table 27.1. Among these, the Proteobacteria and the Cyanobacteria are particularly diverse and relevant to eukaryotic cell evolution, global ecology, and human affairs.

Table 27.1 Representative Bacterial Phyla

Phyla	Characteristics
Firmicutes	Diverse Gram-positive bacteria, some of which produce endospores.
Bacteroidetes	Includes representatives of diverse metabolism types; some are common in the human intestinal tract, and others are primarily aquatic.
Chlamydiae	Notably tiny, obligate intracellular parasites. Some cause eye disease in newborns or sexually transmitted diseases.
Planktomycetes	Reproduce by budding; cell walls lack peptidoglycan; cytoplasm contains nucleus-like bodies.
Spirochaetes	Motile bacteria having distinctive corkscrew shapes, with flagella held close to the body. They include the pathogens *Treponema pallidum*, the agent of syphilis, and *Borrelia burgdorferi*, which causes Lyme disease.
Actinobacteria 	Gram-positive bacteria producing branched filaments; many form spores. *Mycobacterium tuberculosis*, the agent of tuberculosis in humans, is an example. Actinobacteria are notable antibiotic producers; over 500 different antibiotics are known from this group. The pharmaceutical industry produces antibiotics from large-scale cultures of the actinobacterium *Streptomyces*. Some fix nitrogen in association with plants.
Thermotogae	Hyperthermophiles.
Chloroflexi	Known as the green nonsulfur bacteria; conduct photosynthesis without releasing oxygen (anoxygenic photosynthesis).
Deinococcus-Thermus 	Extremophiles. The genus *Deinococcus* is known for high resistance to ionizing radiation, and the genus *Thermus* inhabits hot springs. *Thermus aquaticus* has been used in commercial production of Taq polymerase enzyme used in the polymerase chain reaction (PCR), an important procedure in molecular biology laboratories.
Cyanobacteria 	The oxygen-producing photosynthetic bacteria (some are also capable of anoxygenic photosynthesis). Photosynthetic pigments include chlorophyll *a* and phycobilins, which often give cells a blue-green pigmentation. Occur as unicells, colonies, unbranched filaments, and branched filaments. Many of the filamentous species produce specialized cells: dormant akinetes and heterocysts (heterocytes) in which nitrogen fixation occurs. In waters having excess nutrients, cyanobacteria produce blooms and may release toxins harmful to the health of humans and wild and domesticated animals.
Proteobacteria 	A very large group of Gram-negative bacteria, collectively having high metabolic diversity. Includes many species important in medicine, agriculture, and industry. *Myxococcus xanthus* is a Gram-negative bacterium that is able to glide across surfaces, forming swarms of thousands of cells. This behavior aids feeding by concentrating digestive enzymes secreted by the bacteria. When food is scarce, the swarms form tree-shaped structures from which tough spores disperse. By this means, cells move to new, food-rich places.

Proteobacteria Though Proteobacteria share molecular and cell-wall features, this phylum displays amazing diversity of form and metabolism. Genera of this phylum are classified into five major subgroups: alpha (α), beta (β), gamma (γ), delta (δ), and epsilon (ε). As we saw in Chapter 22, the ancestry of mitochondria can be traced to the α-proteobacteria, which also include several genera noted for mutually beneficial relationships with animals and plants. For example, *Rhizobium* and related genera of α-proteobacteria form nutritionally beneficial associations with the roots of legume plants such as beans and peas and are thus agriculturally important (see Chapter 37). Another α-proteobacterium, *Agrobacterium tumifaciens*, causes destructive cancer-like galls to develop on susceptible plants, including grapes and ornamental crops (Figure 27.3). *Agrobacterium tumifaciens* induces gall formation by injecting DNA into plant cells, a property that has led to the use of the bacterium in the production of transgenic plants (see Chapter 20).

The genus *Nitrosomonas*, a soil inhabitant important in the global nitrogen cycle, represents the β-proteobacteria. *Neisseria gonorrhoeae*, the agent of the sexually transmitted disease gonorrhea, is a member of the γ-proteobacteria. *Vibrio cholerae*, another γ-proteobacterium, causes cholera epidemics when drinking water becomes contaminated with animal waste during floods and other natural disasters. The γ-proteobacteria *Salmonella enterica* and *Escherichia coli* strain O157:H7 also cause human disease, and food and water are widely tested for their presence. The δ-proteobacteria include the colony-forming myxobacteria and predatory bdellovibrios, which drill their way through the cell walls of other bacteria in order to consume them. *Helicobacter pylori*, which causes stomach ulcers, belongs to the ε-proteobacteria.

Cyanobacteria The phylum Cyanobacteria contains photosynthetic bacteria that are abundant in fresh waters, oceans, and wetlands and on the surfaces of arid soils. Cyanobacteria are named for the typical blue-green (cyan) coloration of their cells. Blue-green pigmentation results from the presence of accessory phycobilin pigments that help chlorophyll absorb light energy. Cyanobacteria are the only prokaryotes that generate oxygen as a product of photosynthesis. Ancient cyanobacteria produced Earth's first oxygen-rich atmosphere, which allowed the rise of eukaryotes. The chloroplasts of eukaryotic algae and plants arose from cyanobacteria.

Cyanobacteria display the greatest structural diversity found among bacterial phyla (Figure 27.4). Some occur as single cells called unicells (Figure 27.4a); others form colonies of cells held together by a thick gluey substance called mucilage (Figure 27.4b). Many cyanobacteria form filaments of cells that are attached end-to-end (Figure 27.4c,d). Some of the filamentous cyanobacteria produce specialized cells and display intercellular chemical communication, the hallmarks of multicellular organisms. Many cyanobacteria that grow in conditions of high light intensity produce protective brown sunscreen compounds at their surfaces (Figure 27.4d).

Figure 27.3 ***Agrobacterium tumifaciens*** **infection.** This bacterium causes cancer-like tumors to grow on plants.

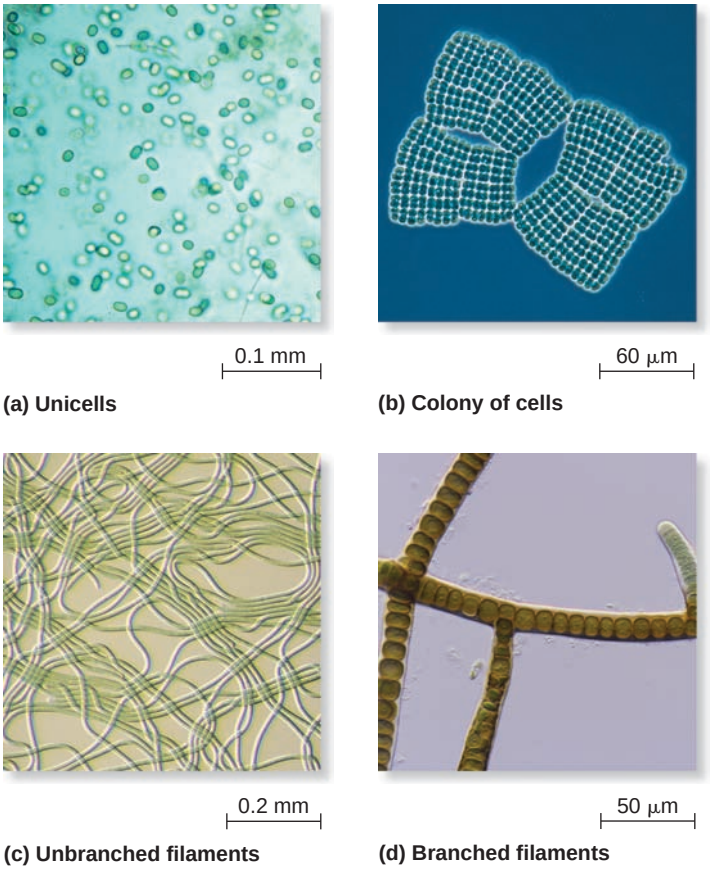

Figure 27.4 **Major types of microbial cell aggregations found in the phylum Cyanobacteria.** **(a)** The genus *Chroococcus* occurs as unicells. **(b)** The genus *Merismopedia* is a flat colony of cells held together by mucilage. **(c)** The genus *Oscillatoria* is an unbranched filament. **(d)** The genus *Stigonema* is a branched filament having a mucilage sheath; the brown color is caused by sunscreen compounds that protect the cells from damage by ultraviolet radiation.

Cyanobacteria play essential ecological roles by producing organic carbon and fixed nitrogen (see Section 27.4). However, several kinds of cyanobacteria, notably the genera *Microcystis*, *Anabaena*, and *Cylindrospermopsis*, form nuisance growths in freshwater lakes during the warm season. Such growths, known as blooms, give the water a pea-soup appearance (see chapter-opening photo). Blooms develop when natural waters receive excess fertilizer from sewage discharges or agricultural runoff. Such blooms are becoming more common every year and are of serious concern because they may produce toxins in amounts sufficient to harm the health of humans and other animals. Consequently, it would be best for people or pets not to swim in or consume water that has a visible cyanobacterial bloom.

Now that we have learned something about the diversity of Archaea and Bacteria, we consider the evolutionary effects of gene exchanges within and between these domains.

Horizontal Gene Transfer Influences the Evolution of Bacteria and Archaea

Horizontal gene transfer, also known as lateral gene transfer, is the process in which an organism receives genetic material from another organism without being the offspring of that organism. This process contrasts with vertical gene transfer from parent to progeny and is increasingly recognized as an important evolutionary mechanism. Horizontal gene transfer affects the evolutionary process by increasing genetic diversity.

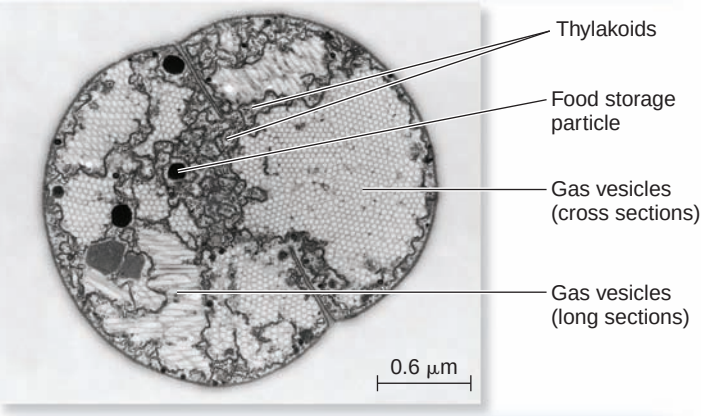
Horizontal gene transfer is common among bacteria and archaea, and it can result in large genetic changes. For example, at least 17% of the genes present in the common human gut inhabitant *E. coli* came from other bacteria. Study of nearly 200 genomes has revealed that about 80% of prokaryotic genes have been involved in horizontal transfer at some point in their history. Genes also move among the bacterial, archaeal, and eukaryotic domains. For example, about a third of the genes present in the archaeon *Methanosarcina mazei* originally came from bacteria. Viruses are probably important gene transfer vectors.

Phylogenetic trees displaying our current understanding of relationships (see Figure 27.1) reveal several important concepts. Bacteria and Archaea probably evolved from a common ancestor, and the eukaryotic nucleus and cytoplasm likely arose in an ancient archaeal organism. In addition, mitochondria and plastids originated from proteobacteria and cyanobacteria by endosymbiosis (see Chapter 22). In these cases, endosymbiosis resulted in the transfer of many genes from bacteria to eukaryotes. The next section surveys ways in which bacteria and archaea vary in structure and locomotion.

27.2 Structure and Motility

Bacteria and archaea have several features in common, including small size, rapid growth, and simpler cellular structure than eukaryotes. Some basic features of prokaryotic cell structure are described in Chapter 4 (refer back to Figure 4.4). With few exceptions, bacteria and archaea are 1–5 µm in diameter and

Thylakoids provide a greater surface area for chlorophyll and other molecules involved in photosynthesis.



The gas vesicles buoy this photosynthetic organism to the lighted water surface, where it often forms conspicuous scums.

Figure 27.5 **Photosynthetic thylakoid membranes and numerous gas vesicles found in a cell of the cyanobacterial genus *Microcystis*.**

Concept check: *Do you think this cell would tend to float or sink?*

are thus known as microorganisms or microbes. (By contrast, most plant and animal cells are between 10 and 100 µm in diameter.) Small cell size limits the amount of materials that can be stored within cells but allows faster cell division. When nutrients are sufficient, many microorganisms can divide many times within a single day. This explains how bacteria can spoil food rapidly and why bacterial infections can spread quickly within the human body. Despite these common features, prokaryotes differ in many ways. In this section, we explore variation in cell structure and shape, in surface and cell-wall features, and in movement.

Bacteria and Archaea Have More Complex Cellular Structure Than Previously Thought

Prokaryotic cells are much simpler than eukaryotic cells. Even so, many prokaryotes display a surprising complexity of cellular structures resulting from adaptive evolution. For example, cyanobacteria and other photosynthetic bacteria are able to use light energy to produce organic compounds and typically contain large numbers of intracellular tubules known as thylakoids (Figure 27.5). The extensive membrane surface of the thylakoids bears large amounts of chlorophyll and other components of the photosynthetic apparatus. Thylakoids therefore enable photosynthetic bacteria and chloroplasts that evolved from them to take maximum advantage of light energy in their environments.

Cyanobacteria and some other bacteria that live in aquatic habitats use cytoplasmic structures known as **gas vesicles** to adjust their buoyancy. This process allows them to move up or down in the water, an advantage in finding nutrients and avoiding harmful conditions. Gas vesicles are hollow cylinders

whose water-tight surfaces are made of protein (Figure 27.5). These vesicles do not actually contain gas concentrations different from the rest of the cell, but their density is lower than that of the surrounding cytoplasm, helping bacteria to float. Gas vesicles can repeatedly collapse and reassemble, depending on the cell's solute content. When sugars and other solutes are abundant in the cytoplasm, the high osmotic pressure collapses the vesicles, and heavy particles of stored food are produced within cells. Cells in which the gas vesicles have collapsed and which contain heavy food particles tend to sink. Sinking removes bacteria from damaging radiation at the water's surface and allows them to harvest inorganic minerals from deeper water. When organic solutes and food storages are used up during cell metabolism, the gas vesicles reassemble, providing flotation to the surface and allowing photosynthesis to resume. The presence of gas vesicles explains why cyanobacteria often form buoyant scums at the surfaces of ponds and lakes (see chapter-opening photo).

Earlier described, thylakoids develop in some bacterial cells by ingrowth of the plasma membrane. In other bacteria, plasma membrane ingrowth has generated additional intriguing adaptations—magnetosomes and nucleus-like bodies—that are sometimes described as bacterial organelles. Magnetosomes are tiny crystals of an iron mineral known as magnetite, each surrounded by a membrane. These structures occur in the bacterium *Magnetospirillum* and related genera (Figure 27.6). In each cell, about 15 to 20 magnetosomes occur in a row, together acting as a compass needle that responds to the Earth's magnetic field. This helps the bacteria to orient themselves in space and thereby locate the submerged, low-oxygen habitats they prefer. Microbiologists Arash Komeili, Grant Jensen, and their colleagues used rapid freezing techniques and a special type of transmission electron microscope to observe the development of magnetosomes. They found that the process begins with ingrowth of the plasma membrane to form a row of spherical vesicles. If *Magnetospirillum* cells are grown in media having low iron levels, the vesicles remain empty. But if iron is available, a magnetite crystal forms within each vesicle. The investigators also observed that fibrils of an actin-like protein known as MamK keep the magnetosomes aligned in a row.

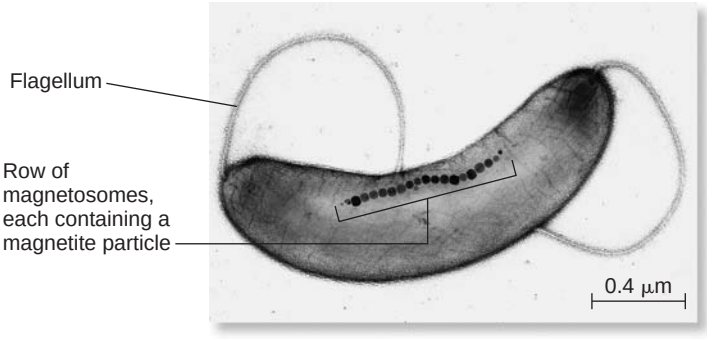


Figure 27.6 **Magnetosomes found in the spirillum *Magnetospirillum magnetotacticum*.** An internal row of iron-rich magnetite crystals, each enclosed by a membrane, functions like a compass needle, allowing this bacterium to detect the Earth's magnetic field. This feature allows *M. magnetotacticum* to orient itself in space and thereby locate its preferred habitat, low-oxygen subsurface waters. Cells use their flagellum to move from less-favorable to more-attractive locations.

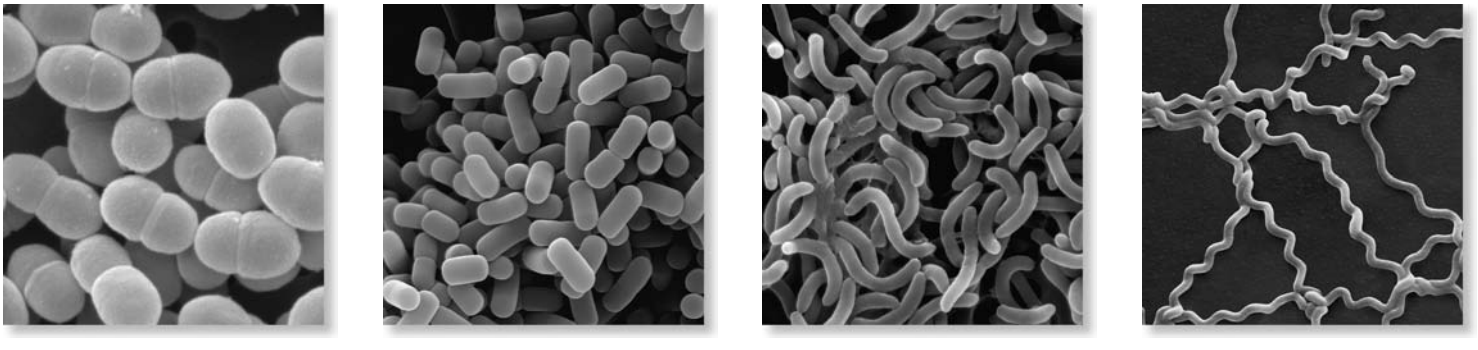
(Recall from Chapter 4 that actin is a major cytoskeletal protein of eukaryotes.) Mutant bacteria lacking a functional form of this protein produce magnetosomes, but they do not remain aligned in a row. Instead, magnetosomes scatter around mutant cells, disrupting their ability to detect a magnetic field.

Plasma membrane invaginations also produce nucleus-like bodies in *Gemmata obscuriglobus* and other members of the bacterial phylum Planktomycetes. In *G. obscuriglobus*, an envelope composed of a double membrane encloses all cellular DNA and some ribosomes. Although this bacterial envelope lacks the nuclear pores characteristic of the eukaryotic nuclear envelope, it likely plays a similar adaptive role in isolating DNA from other cellular influences.

Bacteria and Archaea Vary in Cell Shape and Arrangement

Microbial cells occur in five major shapes (Figure 27.7): spheres (**cocci**), rods (**bacilli**), comma-shaped cells (**vibrios**), and spiral-shaped cells that are either flexible (**spirochaetes**) or rigid



(a) Sphere-shaped cocci (*Lactococcus lactis*) **(b) Rod-shaped bacilli (*Lactobacillus plantarum*)** **(c) Comma-shaped vibrios (*Vibrio cholerae*)** **(d) Spiral-shaped spirochaetes (*Leptospira jaundice*)**

Figure 27.7 **Major types of microbial cell shapes.** Scanning electron microscopic views.

(**spirilli**; see Figure 27.6). Cytoskeletal proteins similar to those present in eukaryotic cells control these cell shapes. For example, helical strands of the actin-like protein known as MreB are responsible for the rod shape of bacilli. If MreB is not produced, bacilli become spherical in shape. In addition, these differently shaped cells can occur in several types of arrangements. Some microorganisms occur only as single cells or pairs of cells resulting from recent division (Figure 27.7a). Others occur as cell aggregates or are attached end-to-end to form filaments.

Slimy Mucilage Often Coats Microbial Surfaces

Many microorganisms produce a coat of slimy mucilage, sometimes called a glycocalyx, that is found outside the cell wall and coats the cell and nearby surfaces. Mucilage, which varies in consistency and thickness, is composed of polysaccharides, protein, or both. It is secreted from cells and serves a variety of functions. One example is the mucilage coat (known as a capsule) that helps some disease bacteria evade the defense system of their host. You may recall that Frederick Griffith discovered the transfer of genetic material while experimenting with capsule-producing pathogenic strains and capsuleless nonpathogenic strains of the bacterium *Streptococcus pneumoniae* (refer back to Figure 11.1). The immune system cells of mice are able to destroy this bacterium only if it lacks a capsule.

Mucilage also holds together the cells of colonial microorganisms (see Figure 27.4b), helps aquatic species to float in water, binds mineral nutrients, and repels predators. Slime sheaths (see Figure 27.4d) often coat bacterial filaments, where they may help to prevent drying.

Mucilage is also critical to the formation of biofilms, which are environmentally and medically important. **Biofilms** are aggregations of microorganisms that secrete adhesive mucilage, thereby gluing themselves to surfaces. They help microbes to remain in favorable locations for growth; otherwise body or environmental fluids would wash them away. A process known as **quorum sensing** fosters biofilm formation. During quorum sensing, individual microbes secrete small molecules having the potential to influence the behavior of nearby microbes. If enough individuals are present (a quorum), the concentration of signaling molecules builds to a level that causes collective behavior. In the case of biofilms, populations of microbes respond to chemical signals by moving to a common location and producing mucilage.

From a human standpoint, biofilms have both beneficial and harmful consequences. In aquatic and terrestrial environments, they help to stabilize and enrich sand and soil surfaces. Microbial biofilms can also be important in the formation of mineral deposits. For example, in 2006, microbiologist Frank Reith and colleagues reported that biofilms formed by a bacterium that precipitates gold from solution help to form gold grains and nuggets. Biofilms that form on the surfaces of animal tissues, however, can be harmful. Dental plaque is an example of a harmful biofilm (Figure 27.8); if allowed to remain, the bacterial community secretes acids that can damage tooth enamel. Biofilms may also develop in industrial pipelines, where the attached microbes can contribute to corrosion by secreting enzymes that chemically degrade metal surfaces.

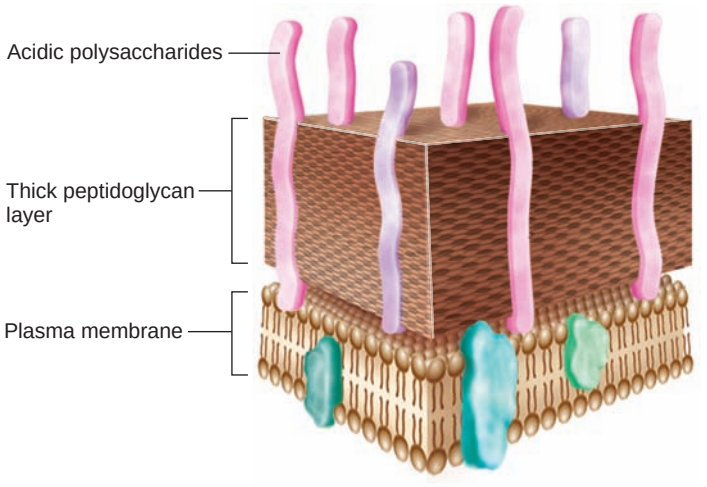
Figure 27.8 **A biofilm composed of a community of microorganisms glued by mucilage to a surface.** This SEM shows dental plaque.

Bacteria and Archaea Differ in Cell-Wall Structure

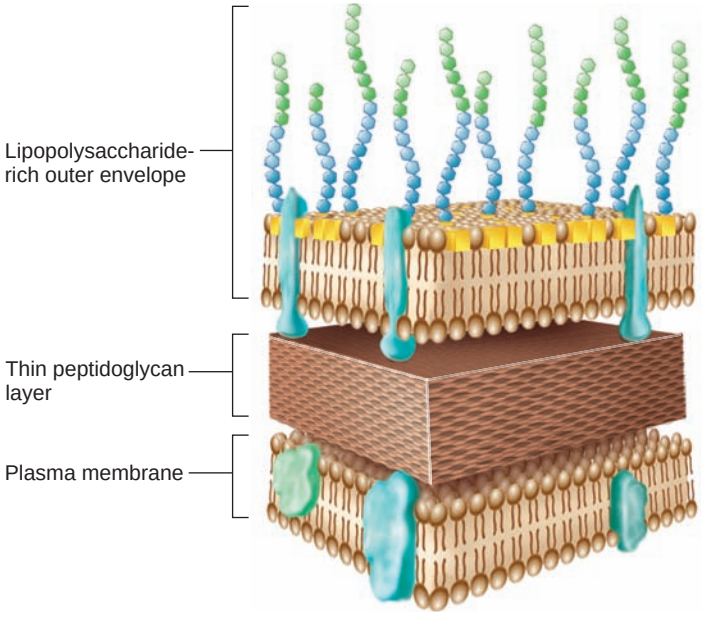
Whether coated with mucilage or not, most prokaryotes possess a rigid cell wall outside the plasma membrane. Cell walls maintain cell shape and help protect against attack by viruses or predatory bacteria. Cell walls also help microbes avoid lysing in hypotonic conditions, when the solute concentration is higher inside the cell than outside. The structure and composition of cell walls vary in ways that can be important in medical and other contexts.

The cell walls of most archaea and certain bacteria are composed of protein or glycoprotein. In contrast, the polymer known as **peptidoglycan** is lacking from archaea but is an important component of most bacterial cell walls. Peptidoglycan is composed of carbohydrates that are cross-linked by peptides. Bacterial cell walls occur in two major forms that differ in their amount of peptidoglycan, staining properties, and response to antibiotics. These are called Gram-positive and Gram-negative walls, for the Gram stain used to identify them. The Gram-positive cell wall features a relatively thick peptidoglycan layer (Figure 27.9a). The Gram-negative cell wall has relatively less wall peptidoglycan and is enclosed by a thin, outer envelope whose outer leaflet is rich in **lipopolysaccharides** (Figure 27.9b). This outer layer envelope is a lipid bilayer but is distinct from the plasma membrane.

Lipopolysaccharides and peptidoglycan affect bacterial responses to antibiotics and sometimes disease symptoms. For example, part of the peptidoglycan covering of *Bordetella*

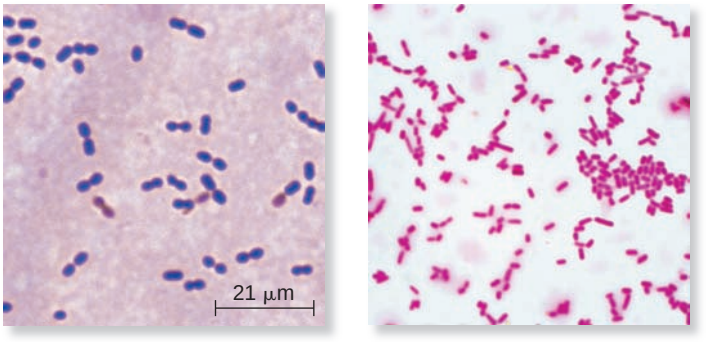


(a) Gram-positive: thick peptidoglycan layer, no outer envelope



(b) Gram-negative: thinner peptidoglycan layer, with outer envelope

Figure 27.9 **Cell-wall structure of Gram-positive and Gram-negative bacteria.** **(a)** The structure of the cell wall of Gram-positive bacteria. **(b)** The structure of the cell wall and lipopolysaccharide envelope typical of Gram-negative bacteria.



(a) Gram-positive bacteria **(b) Gram-negative bacteria**

Figure 27.10 **Gram-positive and Gram-negative bacteria.** **(a)** *Streptococcus pneumoniae* stains positive (purple) with the Gram stain. **(b)** *Escherichia coli* stains negative (pink) when the Gram stain procedure is applied.

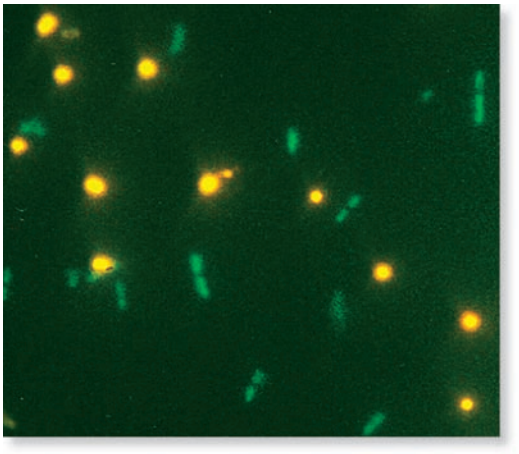


Figure 27.11 **A commercial fluorescent stain used to distinguish Gram-positive and Gram-negative bacteria.** This preparation shows green-fluorescent cells of the Gram-negative bacterium *E. coli* mixed with yellow-fluorescent cells of the Gram-positive bacterium *Staphylococcus aureus*.

Concept check: *For ecological studies, what would be the advantages and disadvantages of this fluorescence staining procedure as compared to the classical Gram stain process?*

pertussis is responsible for the extensive tissue damage associated with whooping cough. Microbiologists use the Gram stain to identify these two major types of bacterial cell walls.

The Gram Stain In the late 1800s, the Danish physician Hans Christian Gram developed the **Gram stain** procedure to more easily detect and distinguish bacteria. The Gram stain remains a useful tool to identify bacteria and predict their responses to antibiotics. To perform a Gram stain, a microbiologist starts by smearing bacteria onto a glass slide and heating it briefly to aid cell attachment. The microbiologist then floods the slide with crystal violet, a purple dye, followed by an iodine solution. The iodine binds the purple dye, forming an insoluble complex. Next, the microbiologist adds alcohol. The alcohol is able to remove the purple dye complex from thin peptidoglycan walls, but not dye bound in cell walls with thick peptidoglycan layers. Finally, safranin, a pink stain, is applied. At the end of the procedure, some bacteria will remain purple; these are known as Gram-positive bacteria (Figure 27.10a). Other types of bacteria will lose the purple stain at the alcohol step but retain the final pink stain; these are known as Gram-negative bacteria (Figure 27.10b). If a fluorescence microscope is available, a single-step fluorescent stain can be used to distinguish Gram-positive from Gram-negative bacteria (Figure 27.11). A closer look at Gram-positive and Gram-negative bacteria will reveal how these staining differences are useful.

Gram-Positive Bacteria Gram-positive bacteria occur in the phyla Firmicutes and Actinobacteria (see Figure 27.1 and

Table 27.1). Gram-positive bacteria typically have thick peptidoglycan cell walls lacking a lipopolysaccharide envelope. Such bacteria are typically vulnerable to penicillin and related antibiotics, because these antibiotics interfere with peptidoglycan synthesis. An example of a Gram-positive bacterium is *S. pneumoniae* (see Figure 27.10a). Streptococci of various types cause strep throat, streptococcal pneumonia, streptococcal meningitis (an infection of the spinal fluid), and eye infections. Streptococci also include the infamous "flesh-eating" bacteria that cause necrotizing fasciitis, a disease whose progression is notoriously difficult to control. The entire DNA sequence of *S. pneumoniae* has been determined, revealing the presence of many genes conferring the ability to break down several types of molecules in human tissues for use as food. The presence of these genes explains why streptococci can cause such varying disease symptoms. *Staphylococcus aureus* is another medically important Gram-positive bacterium, which is commonly found on human skin.

Gram-Negative Bacteria Gram-negative bacteria have thin peptidoglycan cell walls enclosed by a lipopolysaccharide envelope. Diverse phyla of bacteria display Gram-negative staining. *E. coli* is an example of a Gram-negative bacterium that normally lives in the human lower intestine (see Figure 27.10b). The outer lipopolysaccharide envelope enables Gram-negative bacteria to resist the effects of penicillin and chemically similar antibiotics. (Infections caused by Gram-negative bacteria would be treated with different antibiotics.) However, the outer envelope impedes the secretion of proteins from bacterial cells into the environment, a process that allows cells to communicate with each other and plays other roles. Gram-negative bacteria have adapted by evolving five or more types of protein systems that function in secretion, known as types I–V secretion systems.

Microbes Display Diverse Types of Motility Structures

Many microorganisms have structures at the cell surface or within cells that enable them to change position in their environment. Motility allows microbes to respond to chemical signals emitted from other cells during quorum sensing and mating and to move to favorable conditions within gradients of light, gases, or nutrients. For example, we have already learned that cyanobacteria use gas buoyancy vesicles for motility (see Figure 27.5). In addition, microbes move by twitching, gliding, or swimming by means of flagella.

Prokaryotic **flagella** (singular, flagellum) differ from eukaryotic flagella in several ways. For example, prokaryotic flagella lack an internal cytoskeleton of microtubules, the motor protein dynein, and a plasma membrane covering, all features that characterize eukaryotic flagella (see Chapter 4). Unlike eukaryotic flagella, prokaryotic flagella do not repeatedly bend and straighten. Instead, prokaryotic flagella spin, propelled by molecular machines composed of a filament, hook, and motor that work together somewhat like a boat's outboard motor and propeller (Figure 27.12). Lying outside the cell, the long, stiff, curved filament, which is composed of the protein flagellin, acts as a propeller. The hook links the filament with the motor that contains a set of protein rings at the cell surface. Hydrogen ions (protons), which have been pumped out of the cytoplasm, usually via the electron transport system, diffuse back into the cell through channel proteins within the motor. This proton movement powers the turning of the hook and filament.

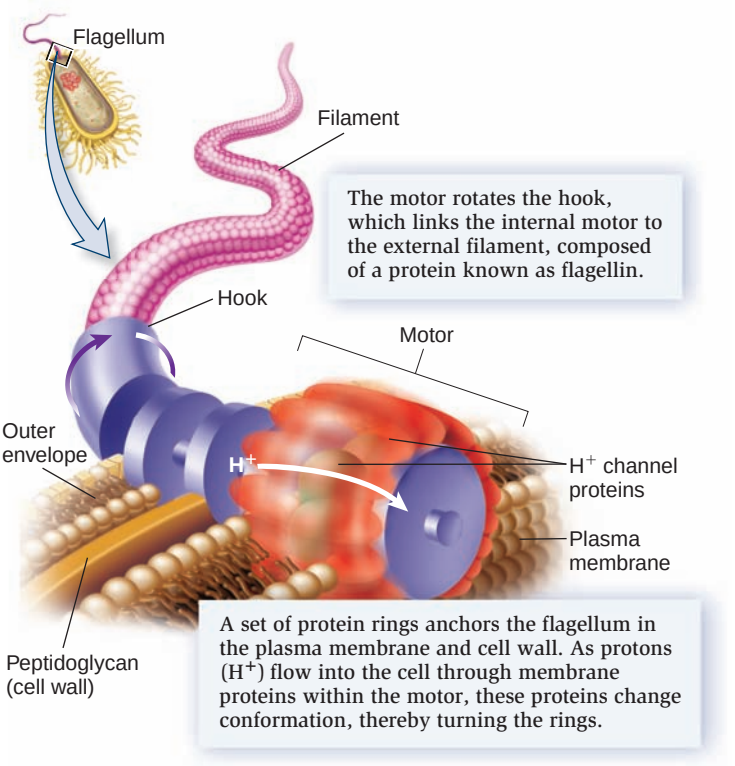

Figure 27.12 **Diagram of a prokaryotic flagellum, showing a filament, hook, and motor.**

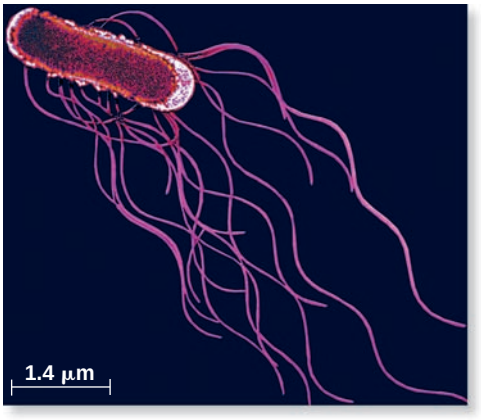
Concept check: *Does the filament move more like the arms of a human swimmer or the shaft of a boat propeller?*

Prokaryotic species differ in the number and location of flagella, which may occur singly or in clumps at one pole of a bacterial cell or may emerge from around the cell (Figure 27.13). Differences in flagellar number and location cause microorganisms to exhibit different modes of swimming. For example, spirochaete flagella are located outside the peptidoglycan cell wall but within the confines of an outer membrane that holds them close to the cell. Rotation of these flagella causes spirochaetes to display characteristic bending, flexing, and twirling motions.

Some prokaryotes twitch or glide across surfaces, using threadlike cell surface structures known as **pili** (singular, pilus) (Figure 27.14). *Myxococcus xanthus* cells, for example, move by alternately extending and retracting pili from one pole or the other. This process allows directional movement toward food materials. If nutrients are low, cells of these bacteria glide together to form tiny treelike colonies, which are part of a reproductive process. As we will see, pili can also play important roles in bacterial reproduction and disease processes.

(a) Bacteria with a single short flagellum



(b) Bacterium with multiple long flagella

Figure 27.13 **Differences in the number and location of flagella.** Depending on the species, microbial cells can produce one or more flagella at the poles or numerous flagella around the periphery. **(a)** *Vibrio parahaemoliticus*, a bacterium that causes seafood poisoning, has a single short flagellum. **(b)** *Salmonella enterica*, another bacterium that causes food poisoning, has many flagella distributed around the cell periphery.

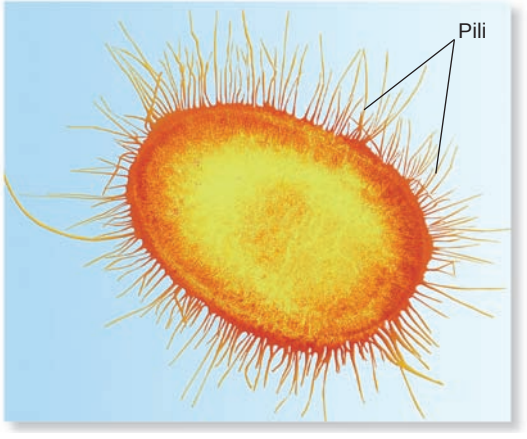


Figure 27.14 **Pili extending from the surface of *Proteus mirabilis*.**

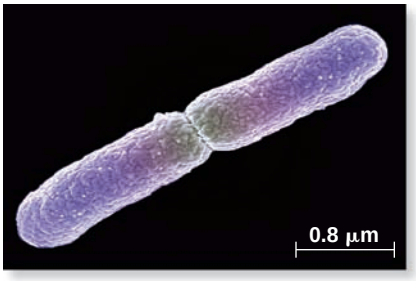
Concept check: *What type of motion does this cell likely use?*

27.3 Reproduction

Bacteria and archaea enlarge their populations by means of cell division. In addition, some microbes produce tough cells that can withstand deleterious conditions for long periods in a dormant condition. Although bacteria and archaea lack meiosis and other features typical of eukaryotic sexual reproduction, they are able to obtain additional genes by a variety of methods.

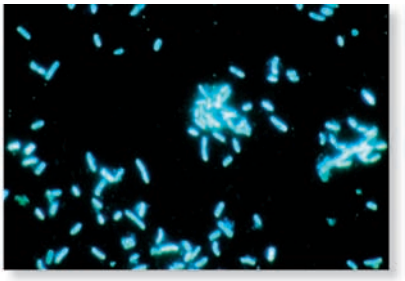
Populations of Bacteria and Archaea Increase by Binary Fission

The cells of bacteria and archaea divide by splitting in two, a process known as **binary fission** (Figure 27.15a; also refer back to Figure 18.14). Binary fission requires a protein known as FtsZ, which is related to the tubulin protein that makes up eukaryotic microtubules. FtsZ squeezes dividing cells into two progeny cells; if this protein is not functional, bacterial cells cannot complete binary fission, and the cells become very long. When sufficient nutrients are available, an entire population of



(a) Bacterium undergoing binary fission

(b) Colonies developed from single cells



(c) Bacteria stained with fluorescent DNA-binding dye

Figure 27.15 **Binary fission and counting microbes.** **(a)** Division of a bacterial cell as viewed by scanning electron microscopy. **(b)** When samples are spread onto the surfaces of laboratory dishes containing nutrients, single cells of bacteria or archaea may divide repeatedly to form visible colonies, which can be easily counted. The number of colonies is an estimate of the number of culturable cells in the original sample. **(c)** If a fluorescence microscope is available, cells can be counted directly by applying a fluorescent stain that binds to cell DNA. Each cell glows brightly when illuminated with ultraviolet light.

Concept check: *Which procedure would you choose to count bacteria in a sample that is known to include many species that have not as yet been cultured?*

identical cells can be produced from a single parental cell by repeated binary fission. This growth process allows microbes to become very numerous in water, food, or animal tissues, potentially causing harm.

Binary fission is the basis of a widely used method for detecting and counting bacteria in food, water samples, or patient fluids. Microbiologists who study the spread of disease need to quantify bacterial cells in samples taken from the environment. Medical technicians often need to count bacteria in body fluid samples to assess the likelihood of infection. However, because bacterial cells are small and often unpigmented, they are difficult to count directly. One way that microbiologists count bacteria is to place a measured volume of sample into plastic dishes filled with a semisolid nutrient medium. Bacteria in the sample undergo repeated binary fission to form colonies of cells visible to the unaided eye (Figure 27.15b). Because each colony represents a single cell that was present in the original sample, the number of colonies in the dish reflects the number of living bacteria in the original sample.

Another way to detect and count bacteria is to treat samples with a stain that binds bacterial DNA, causing cells to glow brightly when illuminated with ultraviolet light. The glowing bacteria can be viewed and counted by the use of a fluorescence microscope (Figure 27.15c). The fluorescence method must be used when the microbes of interest cannot be cultured in the laboratory. Microorganisms can also be stained with fluorescent reagents that bind to specific DNA sequences, allowing microbiologists to detect and count bacteria and archaea of precise genetic types. This procedure, known as fluorescence *in situ* hybridization (FISH), is a powerful technique for finding particular types of microorganisms in mixed populations.

Some Bacteria Survive Harsh Conditions as Akinetes or Endospores

Some bacteria produce thick-walled cells known as akinetes or endospores that are able to survive unfavorable conditions in a dormant state. Akinetes and endospores develop when bacteria have experienced stress, such as low nutrients or unfavorable temperatures. Such cells are able to germinate into metabolically active cells when conditions improve again. For example, aquatic filamentous cyanobacteria often produce large, food-filled **akinetes** when winter approaches (Figure 27.16a). Akinetes are able to survive winter at the bottoms of lakes, and they produce new filaments in spring when they are carried by water currents to the brightly lit surface.

Endospores (Figure 27.16b) are cells having tough protein coats that are produced inside bacterial cells and then released when the enclosing cell dies and breaks down. Endospores can remain alive, though in a dormant state, for perhaps hundreds of years.

The ability to produce endospores allows some Gram-positive bacteria to cause serious diseases. For example, *Bacillus anthracis* causes the disease anthrax, a potential agent in bioterrorism and germ warfare. Most cases of human anthrax result when endospores of *B. anthracis* enter wounds, causing

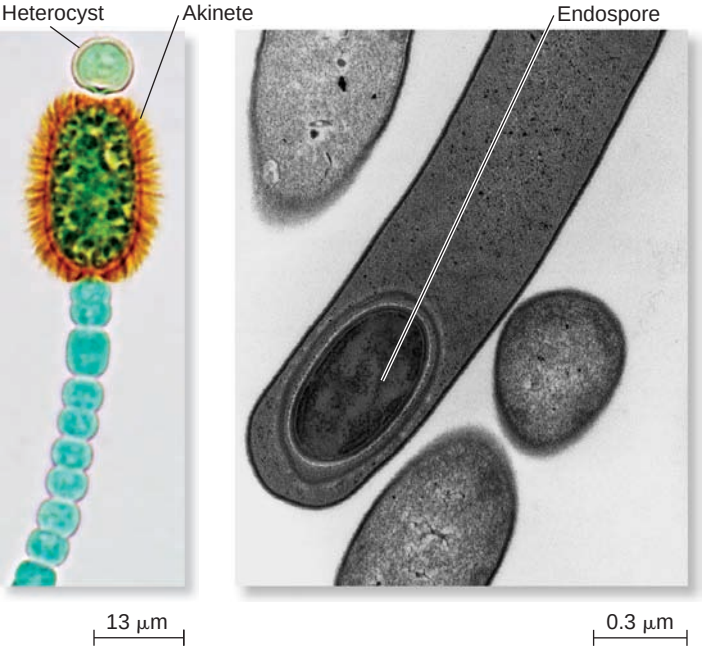


Figure 27.16 **Specialized cells capable of dormancy.** **(a)** Akinetes are thick-walled, food-filled cells produced by some cyanobacteria. They are able to resist stressful conditions and generate new populations when conditions improve. As discussed later, the heterocyst is a specialized cell in which nitrogen fixation occurs. **(b)** An endospore with a resistant wall develops within the cytoplasm of the pathogen *Clostridium difficile.*

Concept check: How do endospores influence the ability of some bacteria to cause disease?

skin infections that are relatively easily cured by antibiotic treatment. But sometimes the endospores are inhaled, or they are consumed in undercooked, contaminated meat, potentially causing more serious illness or death. *Clostridium botulinum* can contaminate improperly canned food that has not been heated to temperatures high enough to destroy its tough endospores. When the endospores germinate and bacterial cells grow in the food, they produce a deadly toxin, as well as NH_3 and CO_2 gas, which causes the can lids to bulge. If humans consume the food, the toxin causes botulism, a severe type of food poisoning that can lead to respiratory and muscular paralysis. The botulism toxin has been recently marketed commercially as Botox, which is injected into the skin, where it paralyzes facial muscles, thereby reducing the appearance of wrinkles. *Clostridium tetani* produces a nerve toxin that causes lockjaw, also known as tetanus, when bacterial cells or endospores from soil enter wounds. The ability of the genera *Bacillus* and *Clostridium* to produce resistant endospores helps to explain their widespread presence in nature and their impact on humans.

Bacteria and Archaea Obtain Genetic Material by Transduction, Transformation, and Conjugation

In Chapter 18, you were introduced to the varied ways in which microorganisms can acquire genetic material from other cells.

In this chapter, we have noted the ecological and evolutionary impacts of horizontal gene transfer. DNA may enter cells by means of viral vectors in the process known as **transduction**. Microbes are able to take up DNA directly from their environments in the process known as **transformation**. Some bacteria transmit DNA during a mating process known as **conjugation**. Pili (see Figure 27.14) help mating cells attach to each other, allowing conjugation to proceed in Gram-negative bacteria. Such gene exchange processes have contributed to the diversity of microbial nutrition and metabolism, our next topic.

27.4 Nutrition and Metabolism

All living cells require energy and a source of carbon to build their organic molecules. Bacteria and archaea use a wide variety of strategies to obtain energy and carbon for growth (Table 27.2). Together, bacteria and archaea display more diverse types of metabolism than other groups of organisms. Microbes can be classified according to their energy source, carbon source, response to oxygen, and presence of specialized metabolic processes.

Bacteria and Archaea Display Diverse Types of Nutrition and Responses to Oxygen

Cyanobacteria and some other bacteria are **autotrophs** (from the Greek, meaning self-feeders), organisms that are able to produce all or most of their own organic compounds from inorganic sources. Autotrophic microorganisms fall into two categories: photoautotrophs and chemoautotrophs. **Photoautotrophs** are able to use light as a source of energy for the synthesis of organic compounds from CO_2 and H_2O or H_2S. **Chemoautotrophs** are able to use energy obtained by chemical modifications of inorganic compounds to synthesize organic compounds. Such chemical modifications include nitrification (the conversion of ammonia to nitrate) and the oxidation of sulfur, iron, or hydrogen.

Heterotrophs (from the Greek, meaning other feeders) are organisms that require at least one organic compound, and often more. Some microorganisms are **photoheterotrophs**, meaning that they are able to use light energy to generate ATP, but they must take in organic compounds from their environment. **Chemoheterotrophs** must obtain organic molecules for both energy and as a carbon source. Among the many types of bacterial chemoheterotrophs is the Gram-positive *Propionibacterium acnes*, which causes acne, affecting up to 80% of adolescents in the U.S. The genome sequence of *P. acnes* has revealed numerous genes that allow it to break down skin cells and consume the products.

Table 27.2 Major Types of Bacteria and Archaea Based on Energy and Carbon Source

Type	Energy source	Carbon source	Example
Autotroph			
Photoautotroph	Light	CO_2	Cyanobacteria
Chemoautotroph	Inorganic compounds	CO_2	*Sulfolobus*
Heterotroph			
Photoheterotroph	Light	Organic compounds	Chloroflexi
Chemoheterotroph	Organic compounds	Organic compounds	Many

Microorganisms differ in their need for oxygen. **Obligate aerobes** require O_2. **Facultative anaerobes** can use O_2 in aerobic respiration, obtain energy via anaerobic fermentation, or use inorganic chemical reactions to obtain energy. One fascinating example of a facultative anaerobe is *Thiomargarita namibiensis*, a giant bacterium about 1 mm in diameter that lives in marine waters off the Namibian coast of Africa. This heterotroph obtains its energy in two ways: by oxidizing sulfide with oxygen when this is available or, when oxygen is low or unavailable, by oxidizing sulfide with nitrate. In either case, the cells convert sulfide to elemental sulfur, which is stored within the cells as large globules.

In contrast to obligate aerobes, **obligate anaerobes**, such as the bacterial genus *Clostridium*, are poisoned by O_2. People suffering from gas gangrene (caused by *Clostridium perfringens* and related species) are usually treated by placement in a chamber having a high oxygen content (called a hyperbaric chamber), which kills the organisms and deactivates the toxins. **Aerotolerant anaerobes** do not use O_2, but they are not poisoned by it either. These organisms obtain their energy by fermentation or anaerobic respiration, which uses electron acceptors other than oxygen in electron transport processes. Anaerobic metabolic processes include denitrification (the conversion of nitrate into N_2 gas) and the reduction of manganese, iron, and sulfate, which are all important in the Earth's mineral cycles.

Bacteria Play Important Roles as Nitrogen Fixers

Many cyanobacteria and some other microbes are known as **diazotrophs** (from the Greek, meaning dinitrogen feeders) because they conduct a specialized metabolic process called **nitrogen fixation**. The removal of nitrogen from the gaseous phase is called fixation. During nitrogen fixation, the enzyme nitrogenase converts inert atmospheric gas (N_2) into ammonia (NH_3). Plants and eukaryotic algae can use ammonia (though not N_2) to produce proteins and other essential nitrogen-containing molecules. As a result, many plants have developed close relationships with diazotrophs, which provide ammonia to the plant partner. For example, nitrogen-fixing cyanobacteria typically live in leaf cavities of water ferns that float in rice paddies. The fern partner and the rice crop both take up ammonia produced by the diazotrophs. This natural fertilizer allows the rice plants to produce more protein. Many types of heterotrophic soil bacteria also fix nitrogen. Examples include *Rhizobium* and its relatives, which live within the roots of legumes (see Chapter 37).

Oxygen binds to nitrogenase, irreversibly disabling it. Thus, most diazotrophs are able to conduct nitrogen fixation only in

low-oxygen habitats. Many cyanobacteria accomplish nitrogen fixation in specialized cells known as **heterocysts** (or heterocytes) (Figure 27.16a). Heterocysts display many adaptations that reduce nitrogenase exposure to oxygen. These adaptations include thick walls, which reduce inward oxygen diffusion; absence of oxygen-producing photosystems; and increased respiration, which consumes oxygen.

Genomes & Proteomes Connection

Gene Expression Studies Revealed How Cyanobacteria Fix Nitrogen in Hot Springs

The microbial communities of hot springs in Yellowstone National Park and other thermal areas around the world have long fascinated microbiologists interested in the occurrence of life at high temperatures. Thermal pools characteristically display beautiful, multicolored microbial mats (Figure 27.17). Such mats are composed of diverse photoautotrophs, including many types of cyanobacteria, along with chemoautotrophs, photoheterotrophs, and chemoheterotrophs. However, in particular Yellowstone thermal pools where temperatures range from 50 to 70°C, single-celled cyanobacteria of the genus *Synechococcus* are the only photoautotrophic organisms present. Heterocyst-producing cyanobacteria are absent from such hot waters, and few heterotrophic diazotrophs tolerate such temperatures, yet nitrogen fixation occurs in these pools. It was not clear which organisms could fix nitrogen until genomic information provided an essential clue.

Anne-Soisig Steunou, Arthur Grossman, and associates sequenced the genomes of *Synechococcus* cultures obtained from these hot springs and discovered that *nif* (nitrogen fixation) genes were present. They also determined that *Synechococcus nif* genes were expressed in parts of the microbial mat having temperatures near 60°C. These results indicated that *Synechococcus* conducts nitrogen fixation in the mats, producing fixed nitrogen and other compounds used by other community members. But the investigators wondered how this single-celled bacterium managed to fix nitrogen without the oxygen arising from photosynthesis disabling the functioning of nitrogenase. They tracked the expression of *Synechococcus* genes over a 24-hour period and found that after nightfall the expression of a photosynthesis gene (*psaB*) fell dramatically, whereas expression of nitrogen fixation genes (*nifH*, *nifD*, and *nifK*) increased (Figure 27.18). They concluded that *Synechococcus* turns on nitrogen fixation at dusk, when oxygen production from photosynthesis drops. But nitrogen fixation is an energy-intensive process, so how does *Synechococcus* fuel it? Steunou and colleagues used differential gene expression analyses to establish that *Synechococcus* uses fermentation, an anaerobic metabolic pathway, to supply the ATP needed for nitrogen fixation. This study not only illustrates important features of microbial metabolism, but also the essential ecological roles played by bacteria and archaea, a topic that we will explore in more detail next.

Figure 27.17 A thermal pool in Yellowstone National Park. Brightly colored mats at the pool edge are microbial communities that include thermophilic cyanobacteria.

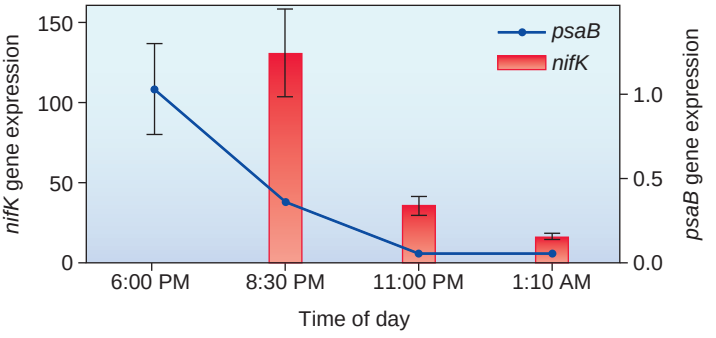

Figure 27.18 Daily changes in photosynthesis and nitrogen fixation gene expression in *Synechococcus* cultures isolated from thermal pools.

Concept check: At what time of the day does the photosynthesis gene psaB reach its lowest level of expression, and when does the nitrogen fixation gene nifK reach its highest expression level?

27.5 Ecological Roles and Biotechnology Applications

Bacteria and archaea play many key ecological roles, including the production and cycling of carbon. Earth's carbon cycle depends on microorganisms that produce and degrade organic compounds, including methane. Bacteria also play fascinating roles as symbionts living in close associations with eukaryotes, as we have seen in the case of nitrogen-fixing bacteria that partner with plants. In this section, we focus on these diverse ecological roles and also provide examples of ways that humans use the metabolic capabilities of bacteria and archaea in biotechnology.

Bacteria and Archaea Play Important Roles in Earth's Carbon Cycle

The Earth's carbon cycle is the sum of all the chemical changes that occur among compounds that contain carbon. (See Chapter 59 for a detailed discussion of the carbon cycle.) Bacteria and archaea are important in producing and degrading organic compounds. For example, cyanobacteria and other autotrophic bacteria are important **producers**. These bacteria, together with algae and plants, synthesize the organic compounds used by other organisms for food. **Decomposers**, also known as saprobes, include heterotrophic microorganisms (as well as fungi and animals). These organisms break down dead organisms and organic matter, releasing minerals for uptake by living things.

Bacteria and archaea also influence Earth's carbon cycle by producing and consuming methane (CH_4). Methane—the major component of natural gas—is a powerful greenhouse gas, as are CO_2 and H_2O vapor. Atmospheric methane has the potential to alter the Earth's climate, and in recent years, the level of methane has been increasing in Earth's atmosphere as the result of human activities. Several groups of anaerobic archaea known as the **methanogens** convert CO_2, methyl groups, or acetate to methane and release it from their cells. Methanogens live in swampy wetlands, in deep-sea habitats, or in the digestive systems of ungulate animals, such as cattle. Marsh gas produced in wetlands is largely composed of methane, and large quantities of methane produced long ago are trapped in deep-sea and subsurface Arctic deposits. Microbes also play a role in limiting atmospheric methane. The balance of methane in Earth's atmosphere is maintained by the activities of prokaryotes known as **methanotrophs**, which consume methane. In the absence of methanotrophs, Earth's atmosphere would be much richer in the greenhouse gas methane, which would substantially increase global temperatures.

Many Bacteria Live in Symbiotic Associations with Other Prokaryotes or Eukaryotes

An organism that lives in close association with one or more other organisms is said to occur in **symbiosis** (from the Greek, meaning life together with). If symbiotic associations are beneficial to both partners, the association is known as a **mutualism**. If one partner benefits at the expense of the other, the association is known as a **parasitism**. There are numerous examples of mutualistic and parasitic bacteria. Many mutualistic bacteria live in symbioses of two or a few other bacterial species that supply each other with essential nutrients, a type of association known as a **syntrophy**. For example, certain deep-sea archaea are able to metabolize the plentiful methane present in such anaerobic conditions only by partnering with bacteria that reduce sulfate. Other microbes occur in larger communities known as **consortia**, in which metabolite exchange occurs. The marine worm *Olavius algarvensis*, for example, has no mouth, gut, or anus, and depends on a consortium of several types of bacteria that live within the worm, providing it with food and recycling its wastes.

Mutualistic Partnerships with Eukaryotes Bacteria are involved in many mutually beneficial symbioses in which they provide eukaryotes with minerals or vitamins or other valuable services. For example, the common green seaweed *Ulva* does not display its typical lettuce-leaf shape unless bacterial partners belonging to the phylum Bacteroidetes are present. The bacteria produce a compound that induces normal seaweed development. Bioluminescent bacteria form symbiotic relationships with squid and other marine animals. In deep-sea thermal vent communities, sulfur-oxidizing bacteria live within the tissues of tube worms and mussels, supplying these animals with carbon compounds used as food. Bacteriologist Cameron Curry and his associates have documented a complex land association involving four partners: ants, fungi that the ants cultivate for food, parasitic fungi that attack the food fungi, and mutualistic Actinobacteria, which produce antibiotics. These antibiotics control the growth of the fungal parasite, preventing it from destroying the ants' fungal food supply. The ants rear the useful bacteria in cavities on their body surfaces; glands near these cavities supply the bacteria with nutrients. Humans, too, harbor symbiotic microbes.

The Human Microbiome On human skin and in our digestive and reproductive systems many types of microbes exist that are known collectively as the human **microbiome**. An estimated 10–100 trillion microbes live in the typical human colon! These microbes provide services using traits that humans do not possess, and the diverse types of metabolism present in the microbiome have co-evolved with human metabolism. For this reason, humans and other multicellular organisms, together with their microbiomes, are considered to function and evolve as superorganisms. Recent research has revealed that human gut microbiome communities contain hundreds of prokaryotic species, dominated by the bacterial phyla Firmicutes and Bacteroidetes, and that extensive horizontal gene transfer has occurred among gut microbial species. Studies also reveal that gut microbiomes differ among healthy people, and between healthy people and those having different types of medical conditions. An ongoing Human Microbiome Project seeks to understand the relationship between human metabolism and the microbiome, with the goal of opening new opportunities to improve human health.

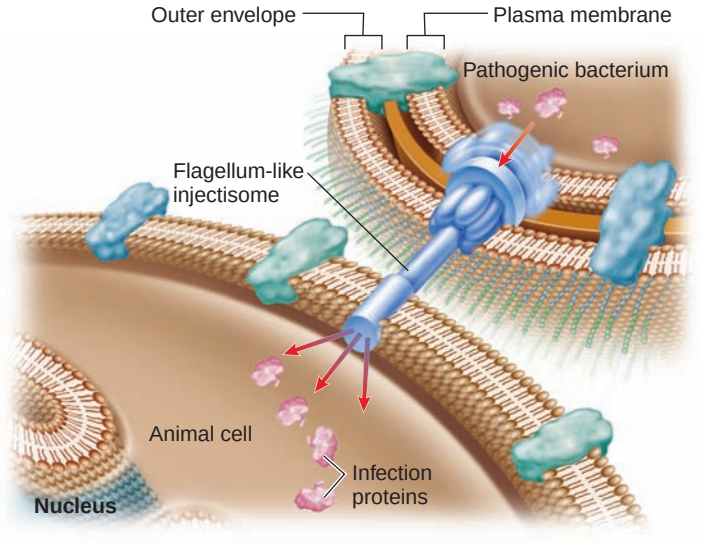
Parasitic and Pathogenic Microbes **Parasites** are organisms that obtain organic compounds from living hosts. If parasitic microbes cause disease symptoms in their hosts, the microorganisms are known as **pathogens**. Cholera, leprosy, tetanus, pneumonia, whooping cough, diphtheria, Lyme disease, scarlet fever, rheumatic fever, typhoid fever, bacterial dysentery, and tooth decay are among the many examples of human diseases caused by bacterial pathogens. Bacteria also cause many plant diseases of importance in agriculture, including blights, soft rots, and wilts. How do microbiologists determine which bacteria cause these diseases? The pioneering research of the Nobel Prize–winning German physician Robert Koch provides the answer.

In the mid- to late 1800s, Koch established a series of four steps to determine whether a particular organism causes a specific disease. First, the presence of the suspected pathogen must correlate with occurrence of symptoms. Second, the pathogen must be isolated from an infected host and grown in pure culture if possible. Third, cells from the pure culture should cause disease when inoculated into a healthy host. Fourth and finally, one should be able to isolate the same pathogen from the second-infected host. Using these steps, known as **Koch's postulates**, Koch discovered the bacterial causes of anthrax, cholera, and tuberculosis. Subsequent investigators have used Koch's postulates to establish the causes of many other infectious diseases.

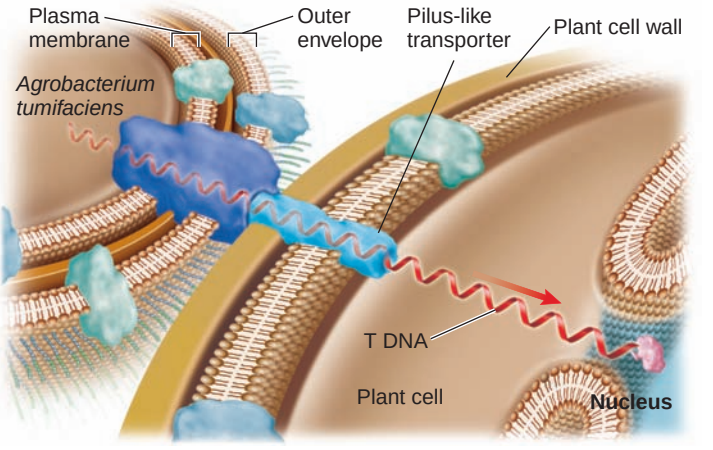
How Pathogenic Bacteria Attack Cells Modern research is providing new information about how bacteria attack cells. Such knowledge aids in developing strategies for disease prevention and treatment. Many pathogenic bacteria attack cells by binding to the target cell surfaces and injecting substances that help them utilize cell components. During their evolution, some pathogenic bacteria have developed needle-like systems, made of components also found in flagella, that inject infection proteins into animal or plant cells as part of the infection process. Such structures are known as type III secretion systems, also called injectisomes (Figure 27.19a). Examples of bacteria whose injectisomes allow them to attack human cells are *Yersinia pestis* (the agent of bubonic plague), *Salmonella enterica* (which causes salmonellosis), and *Burkholderia pseudomallei* (the cause of melioidosis, a deadly disease of emerging concern in some parts of the world). These bacteria also induce the host cell to form a plasma membrane pocket that encloses the bacterial cell, bringing it into the host cell. Once within a host cell, pathogenic bacteria use the cell's resources to reproduce and spread to nearby tissues.

Some other bacterial pathogens use a type IV secretion system to deliver toxins or to transform DNA into cells (Figure 27.19b). Examples of such bacteria that cause human disease include *Helicobacter pylori*, *Legionella pneumophila*, and *Bordetella pertussis*. The plant pathogen *Agrobacterium tumifaciens* uses a type IV secretion system to transfer DNA (T DNA) into plant cells. The bacterial T DNA encodes an enzyme that affects normal plant growth, with the result that cancer-like tumors develop (see Figure 27.3). Type IV systems evolved from pili and other components of bacterial mating. The type IV attack system is an example of descent with modification, the evolutionary process by which organisms acquire new features. Some experts propose that type III and IV secretion systems may be useful in human gene therapy, to deliver DNA to target cells.

Antibiotic-Resistant Pathogens Antibiotics are compounds widely used to treat diseases caused by bacterial pathogens. Such compounds work because they inhibit processes that occur in bacteria, but not eukaryotes. However, the overuse of antibiotics can favor the growth and proliferation of resistant bacteria, a serious health problem. For example, some strains



(a) Type III secretion system



(b) Type IV secretion system

Figure 27.19 **Attack systems of pathogenic bacteria.**
(a) The type III secretion system functions like a syringe to inject proteins into host cells, thereby starting a disease process.
(b) The type IV secretion system forms a channel through which DNA can be transmitted from a pathogen to a host cell, in this case from the bacterium *Agrobacterium tumifaciens* into a plant cell.

Concept check: *How does the type IV secretion system illustrate the evolutionary concept of descent with modification?*

of *Staphylococcus aureus*, which causes "staph" infections, have developed resistance to methicillin (an antibiotic related to penicillin). Such strains, known as MRSA (methicillin-resistant *Staphylococcus aureus*), have been much in the news. Livestock are often fed antibiotics to reduce the effects of minor bacterial infections or to prevent infections from spreading, thereby increasing the production profit margin. Unfortunately, this activity, as well as the improper use of antibiotics by patients, promotes the evolution of antibiotic-resistant bacterial strains. Antibiotics select against vulnerable strains, allowing resistant strains to thrive, and antibiotic resistance can spread rapidly in bacterial populations by means of horizontal gene transfer. When humans become infected by antibiotic-resistant strains, antibiotic

treatments are not effective, and cases have occurred in which patients' infections were resistant to all known antibiotics.

Some Bacteria Are Useful in Industrial and Other Applications

Several industries have harnessed the metabolic capabilities of microbes obtained from nature. The food industry uses bacteria to produce chemical changes in food that improve consistency or flavor—to make dairy products, including cheese and yogurt. Cheese makers add pure cultures of certain bacteria to milk. The bacteria consume milk sugar (lactose) and produce lactic acid, which aids in curdling the milk.

The chemical industry produces materials such as vinegar, amino acids, enzymes, vitamins, insulin, vaccines, antibiotics, and other useful pharmaceuticals by growing particular bacteria in giant vats. For example, bacteria produce the antibiotics streptomycin, tetracycline, kanamycin, gentamycin, bacitracin, polymyxin-B, and neomycin.

The ability of microorganisms to live in harsh environments and break down organic compounds makes them very useful in treating wastewater, industrial discharges, and harmful substances such as explosives, pesticides, and oil spills. This process is known as bioremediation. *Geobacter sulfurreducens*, for example, is used to precipitate metals such as uranium from contaminated water, thereby purifying it. This bacterium uses metal ions and elemental sulfur in an electron transport process to oxidize acetate to CO_2, thereby producing ATP needed for its growth and reproduction. Taking advantage of this observation, engineers drip acetate into the groundwater at contaminated sites, thereby enriching the population of *G. sulfurreducens* to 85% of the microbial community, which more efficiently precipitates uranium.

In addition to food production and waste treatment, bacteria are also used in agriculture. Several species of *Bacillus*, particularly *B. thuringiensis*, produce crystalline proteins known as Bt-toxins. These toxins kill insects that ingest them, but are harmless to many non-insect species that have been tested. Tent caterpillars, potato beetles, gypsy moths, mosquitoes, and black flies are among the pests that can be controlled by Bt-toxin. For this reason, genes involved in Bt-toxin production have been engineered into some crop plants, such as corn, to limit pests, thereby increasing crop yields. *Deinococcus radiodurans* is another example of a bacterial species whose unusual ecological properties may prove useful to humans, as described next.

Feature Investigation

The Daly Experiments Revealed How Mn^{2+} Helps *Deinococcus radiodurans* Avoid Radiation Damage

The bacterial phylum known as *Deinococcus-Thermus* includes *Deinococcus radiodurans*, which is unusually resistant to chemical mutagens and ionizing radiation (see Table 27.1). This bacterium can survive brief radiation doses greater than 10,000 Gray (Gy). (One Gy = the absorption of one joule of radiation energy by one kg of matter.) *Deinococcus radiodurans* can survive continuous radiation levels as high as 50 Gy/hour. (By contrast, a radiation dose of 5 Gy is lethal to humans.) Radiation resistance evolved as an adaptation that aids *Deinococcus* survival in its natural habitats, which include nuclear waste sites, hot springs, and deserts. Like ionizing radiation, drying and solar radiation cause chromosome breakage, and *Deinococcus* has acquired very effective methods for repairing damaged DNA. M. J. Daly and associates were interested in learning more about how *D. radiodurans* survives treatment with high radiation, with the hope that such information might lead to better ways of treating victims of radiation sickness.

As the result of a series of experiments, Daly and colleagues learned that radiation-resistant bacteria tended to have higher levels of manganese—Mn^{2+}—ions than do radiation-sensitive bacteria. From these observations, Daly and associates hypothesized that *D. radiodurans* might protect itself by accumulating Mn^{2+} to high levels. In experiments reported in 2004 and described in Figure 27.20, they first grew *D. radiodurans* in basic culture media containing three different levels of manganese ion (50, 100, or 250 nM Mn^{2+}). As they grew, the bacteria took up Mn^{2+} from the media. Researchers then inoculated bacteria from each type of medium into separate sectors of laboratory dishes containing media to which high, medium, or low levels of Mn^{2+} had been added. Next, they exposed some of the dishes to 50 Gy/hour of radiation, leaving the medium concentration as a nonirradiated control. After a period of growth, irradiated bacteria grown in dishes containing high Mn^{2+} levels grew as well as the control, but irradiated bacteria grown in dishes containing low Mn^{2+} levels did not grow as well. Irradiated bacteria that had been grown beforehand with high Mn^{2+} levels fared particularly well.

This experiment revealed that *D. radiodurans* cells that had accumulated high levels of Mn^{2+} were better able to grow in the presence of ionizing radiation. Manganese seems to confer resistance to such damage, possibly by preventing damage to proteins that repair DNA.

Experimental Questions

1. What feature of *Deinococcus radiodurans* attracted the attention of researchers?
2. What hypothesis did Daly and associates develop to explain radiation resistance in *D. radiodurans*?
3. As shown in Figure 27.20, bacterial cells were grown in media having various levels of manganese ion, which they absorbed. Later, some of these bacteria were exposed to high levels of ionizing radiation, whereas control bacteria were not exposed. What results of this experiment support the hypothesis that cellular manganese plays a role in radiation resistance?

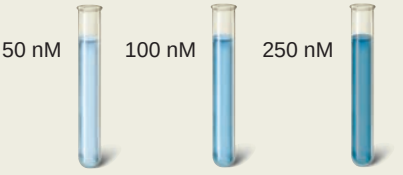
Figure 27.20 Manganese helps *Deinococcus radiodurans* avoid radiation damage.

HYPOTHESIS High levels of intracellular Mn^{2+}, also called Mn(II), help to protect *Deinococcus radiodurans* from the effects of ionizing radiation.

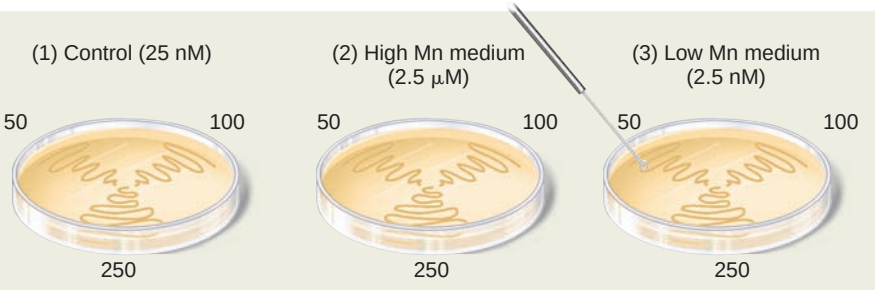
KEY MATERIALS *Deinococcus radiodurans.*

Experimental level

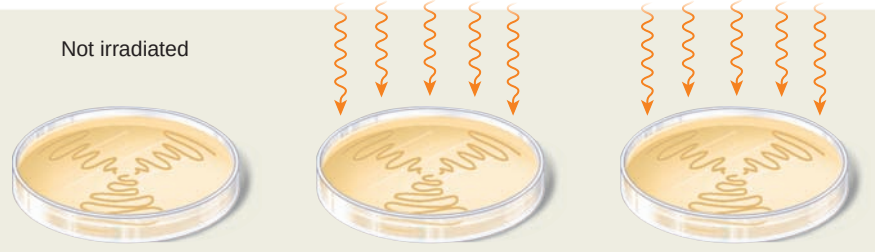
1 Cultivate *Deinococcus radiodurans* in media having different Mn^{2+} content (50 nM, 100 nM, 250 nM).



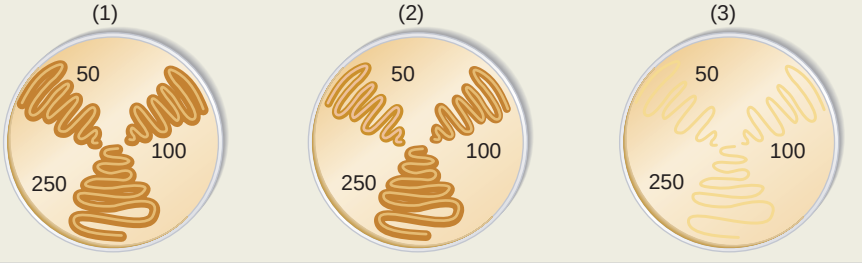
2 Inoculate the bacteria onto the surfaces of media differing in Mn^{2+} content.



3 Expose media plates to 50 Gy/hour of ionizing radiation.



4 Compare bacterial growth to control plates not irradiated.



5 THE DATA

Results from step 4: Even when exposed to ionizing radiation, *D. radiodurans* grew well when high levels of Mn^{2+} were present in its environment (compare plates 2 and 1). The higher the level of Mn^{2+} accumulated by cells, the better the growth after ionizing radiation (plate 2). When environmental levels of Mn^{2+} are low, cells are more readily damaged by ionizing radiation (compare plates 2 and 3).

6 CONCLUSION This experiment revealed that *D. radiodurans* cells that had accumulated high levels of Mn^{2+} were better able to grow in the presence of ionizing radiation. Manganese seems to confer resistance to such damage, possibly by preventing damage to proteins that repair DNA.

Summary of Key Concepts

27.1 Diversity and Evolution

- Domains of life include Bacteria, Archaea, and Eukarya (known informally as bacteria, archaea, and eukaryotes). (Figure 27.1)
- Many representatives of the domain Archaea occur in extremely hot, salty, or acidic habitats. Ether-linked membranes are among the features of archaea that enable their survival in extreme habitats. (Figure 27.2)
- The domain Bacteria includes 50 or more phyla, including Proteobacteria and Cyanobacteria, which are particularly diverse and of great evolutionary and ecological importance. (Table 27.1)
- Mitochondria arose from a proteobacterial ancestor, and many modern proteobacteria occur in close relationships with animals or plants. (Figure 27.3)
- Algal and plant plastids arose from a cyanobacterial ancestor. Modern cyanobacteria play important ecological roles, including the production of harmful blooms in overfertilized waters. (Figure 27.4)
- Widespread horizontal DNA transfer has occurred among bacteria and archaea. Horizontal DNA transfer allows microorganisms to evolve rapidly.

27.2 Structure and Motility

- Bacteria and archaea are composed of prokaryotic cells that are smaller and simpler than those of eukaryotes. Even so, structures such as thylakoids, gas vesicles, magnetosomes, and nucleus-like bodies are examples of bacterial cell structure complexity. (Figures 27.5, 27.6)
- Cells of bacteria and archaea vary in shape. Major cell shape types are spherical cocci, rod-shaped bacilli, comma-shaped vibrios, and coiled spirochaetes and spirilli. Some cyanobacteria display specialized cells and intercellular communication, the hallmarks of multicellular organisms. (Figure 27.7)
- Many microbes occur within a coating of slimy mucilage, which may play a role in diseases or aid in the development of biofilms. Biofilm development is influenced by quorum sensing, a process in which group activity is coordinated by chemical communication. (Figure 27.8)
- Most prokaryotic cells possess a protective cell wall. Archaea and some bacteria have walls composed of proteins, but most bacterial cell walls contain peptidoglycan, which is composed of carbohydrates cross-linked by peptides. (Figure 27.9)
- Gram-positive bacterial cells have walls rich in peptidoglycan, whereas Gram-negative cells have less peptidoglycan in their walls and are enclosed by a lipopolysaccharide envelope. Gram-positive bacteria can be distinguished from Gram-negative bacteria by use of the Gram stain and other staining procedures. (Figures 27.10, 27.11)
- Motility enables microbes to change positions within their environment, which aids in locating favorable conditions for growth. Some microbes adjust their buoyancy in water by means of intracellular gas vesicles, whereas others swim by means of flagella or twitch or glide by the action of threadlike pili. (Figures 27.12, 27.13, 27.14)

27.3 Reproduction

- Populations of bacteria and archaea enlarge by binary fission, a simple type of cell division that provides a means by which culturable microbes can be counted. (Figure 27.15)
- Some bacteria are able to survive harsh conditions as dormant akinetes or endospores. (Figure 27.16)
- Many microorganisms obtain new DNA sequences directly from their environment (transformation), by means of viral vectors (transduction), or by a mating process (conjugation).

27.4 Nutrition and Metabolism

- Bacteria and archaea can be grouped according to nutritional type, response to oxygen, or presence of distinctive metabolic features. Major nutritional types are photoautotrophs, chemoautotrophs, photoheterotrophs, and chemoheterotrophs. (Table 27.2)
- Obligate aerobes require oxygen, whereas facultative aerobes are able to live with or without oxygen by using different processes for obtaining energy. Obligate anaerobes are poisoned by oxygen; aerotolerant anaerobes do not use oxygen but are not poisoned by it. Both obtain their energy by anaerobic respiration.
- Nitrogen fixation is an example of a distinctive metabolism displayed only by certain microorganisms. A number of plants display symbiotic associations with bacteria that fix nitrogen, called diazotrophs; many of these associations are ecologically or agriculturally important. (Figures 27.17, 27.18)

27.5 Ecological Roles and Biotechnology Applications

- Bacteria and archaea play key roles in Earth's carbon cycle as producers, decomposers, symbionts, or pathogens.
- Methane-producing methanogens and methane-using methanotrophs are important in the carbon cycle, and they influence the Earth's climate.
- Parasitic bacteria obtain organic compounds from living hosts, and if disease symptoms result, such bacteria are known as pathogens.
- Bacteria attack eukaryotic cells by means of flagella-like type III secretion systems or type IV secretion systems, which evolved from pili and other mating components. (Figure 27.19)
- Many bacteria and archaea are useful in industrial and other applications; others are used to make food products or antibiotics or to clean up polluted environments. The cellular adaptations of bacteria that are extremely resistant to ionizing radiation may suggest new ways to treat radiation sickness in humans. (Figure 27.20)

Assess and Discuss

Test Yourself

1. Which of the following features is common to prokaryotic cells?
   a. a nucleus, featuring a nuclear envelope with pores
   b. mitochondria
   c. plasma membranes
   d. mitotic spindle
   e. none of the above
2. The bacterial phylum that typically produces oxygen gas as the result of photosynthesis is
   a. the proteobacteria.
   b. the cyanobacteria.
   c. the Gram-positive bacteria.
   d. all of the listed choices.
   e. none of the listed choices.
3. The Gram stain is a procedure that microbiologists use to
   a. determine if a bacterial strain is a pathogen.
   b. determine if a bacterial sample can break down oil.
   c. infer the structure of a bacterial cell wall and bacterial response to antibiotics.
   d. count bacteria in medical or environmental samples.
   e. do all of the above.
4. Place the following steps in the correct order, according to Koch's postulates:
   I. Determine if pure cultures of bacteria cause disease symptoms when introduced to a healthy host.
   II. Determine if disease symptoms correlate with presence of a suspected pathogen.
   III. Isolate the suspected pathogen and grow it in pure culture, free of other possible pathogens.
   IV. Attempt to isolate pathogen from second-infected hosts.
   a. II, III, IV, I
   b. II, IV, III, I
   c. III, II, I, IV
   d. II, III, I, IV
   e. I, II, III, IV
5. Cyanobacteria play what ecological role?
   a. producers
   b. consumers
   c. decomposers
   d. parasites
   e. none of the listed choices
6. Bacterial structures that are produced by pathogenic bacteria for use in attacking host cells include
   a. type III and IV secretion systems.
   b. magnetosomes.
   c. gas vesicles.
   d. thylakoids.
   e. none of the above.
7. The structures that enable some Gram-positive bacteria to remain dormant for extremely long periods of time are known as
   a. akinetes.
   b. endospores.
   c. biofilms.
   d. lipopolysaccharide envelopes.
   e. pili.
8. By means of what process do populations of bacteria or archaea increase their size?
   a. mitosis
   b. meiosis
   c. conjugation
   d. transduction
   e. none of the listed choices
9. By what means do bacterial cells acquire new DNA?
   a. by conjugation, the mating of two cells of the same bacterial species
   b. by transduction, the injection of viral DNA into bacterial cells
   c. by transformation, the uptake of DNA from the environment
   d. all of the above
   e. none of the above
10. How do various types of bacteria move?
    a. by the use of flagella, composed of a filament, hook, and motor
    b. by means of pili, which help cells twitch or glide along a surface
    c. by using gas vesicles to regulate buoyancy in water bodies
    d. all of the above
    e. none of the above

Conceptual Questions

1. Explain why many microbial populations grow more rapidly than do eukaryotes and how bacterial population growth influences the rate of food spoilage or infection.
2. Why does the overuse of antibiotics in medicine and agriculture result in widespread antibiotic resistance?
3. What organisms are responsible for the blue-green blooms that often occur in warm weather on lake surfaces? Think carefully; the answer is not just "cyanobacteria," as you might first guess.

Collaborative Questions

1. How would you go about cataloging the phyla of bacteria and archaea that occur in a particular place?
2. How would you go about developing a bacterial product that could be sold for remediation of a site contaminated with materials that are harmful to humans?

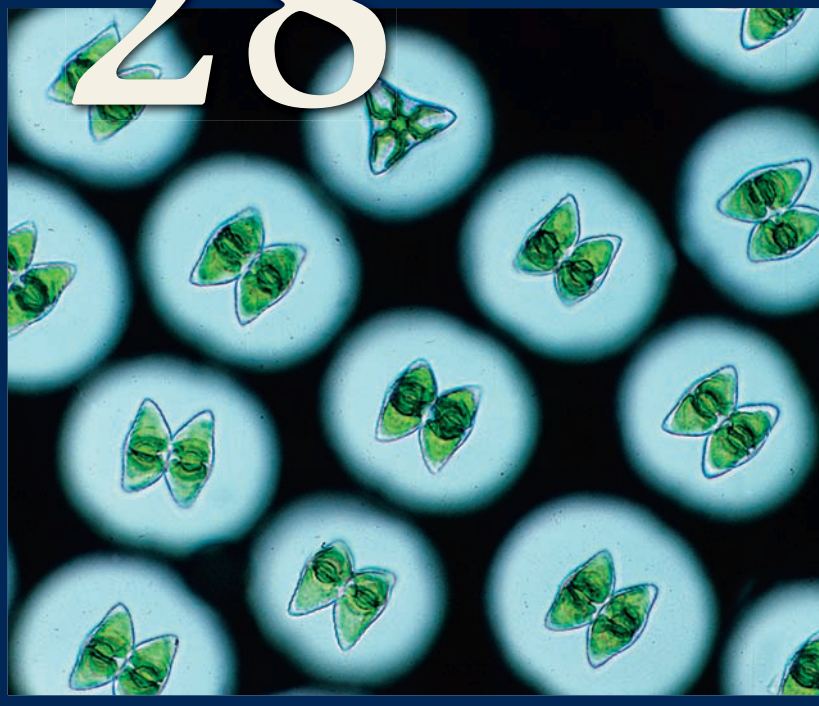
Chapter Outline

Protists

28



Protists such as these green algal cells produce much of the Earth's oxygen. Each of the cells in this population is surrounded by a halo of protective mucilage.

Protists are eukaryotes that live in moist habitats and are mostly microscopic in size. Despite their small size, protists have a greater impact on global ecology and human affairs than most people realize. For example, the photosynthetic protists known as algae generate at least half of the oxygen in the Earth's atmosphere and produce organic compounds that feed marine and freshwater animals. The oil that fuels our cars and industry is derived from pressure-cooked algae that accumulated on the ocean floor over millions of years. Today, algae are being engineered into systems for cleaning pollutants from water or air and for producing biofuels.

Protists also include some parasites that cause serious human illnesses. For example, in 1993, the waterborne protist *Cryptosporidium parvum* sickened 400,000 people in Milwaukee, Wisconsin, costing $96 million in medical expenses and lost work time. The related protist *Plasmodium falciparum*, which is carried by mosquitoes in many warm regions of the world, causes the disease malaria. Every year, nearly 500 million people become ill with malaria, and more than 2 million die of this disease. As we will see, sequencing the genomes of these and other protist species has suggested new ways of battling such deadly pathogens.

In this chapter, we will survey protist diversity, including structural, nutritional, and ecological variations. We begin by exploring ways of informally naming protists by their ecological roles, habitat, and motility. We then will focus on the defining features, classification, and evolutionary importance of the major protist phyla. Next, the nutritional modes and defensive adaptations of protists are discussed, and we conclude by looking at the reproductive adaptations that allow protists to exploit and thrive in a variety of environments.

28.1 An Introduction to Protists

Protists are eukaryotes that are not classified in the plant, animal, or fungal kingdoms. The term protist comes from the Greek word *protos*, meaning first, reflecting the observation that protists were Earth's first eukaryotes. Protists display two common characteristics: They are most abundant in moist habitats, and most of them are microscopic in size. Protists are often informally labeled according to their ecological roles, habitats, or type of motility.

Protists Can Be Informally Labeled According to Their Diverse Ecological Roles

Protists are often labeled according to their ecological roles, which occur in three major types: algae, protozoa, and fungus-like protists. The term **algae** (from the Latin, meaning seaweeds) applies to protists that are generally photoautotrophic, meaning that most can produce organic compounds by means of photosynthesis. In addition to organic compounds that can be used as food by heterotrophic organisms, photosynthetic algae produce oxygen, which is also needed by most heterotrophs. Despite the general feature of photosynthesis, algae do not form a monophyletic group descended from a single common ancestor.

The term **protozoa** (from the Greek, meaning first life) is commonly used to describe diverse heterotrophic protists. Protozoa feed by absorbing small organic molecules or by ingesting

Figure 28.1 **A heterotrophic protozoan feeding on photosynthetic algae.** The ciliate shown here has consumed several oil-rich, golden-pigmented, glass-walled algal cells known as diatoms. The algal cells were ingested by the process of phagocytosis, and their organic components will be digested as food. Diatom cells that have avoided capture glide nearby.

Concept check: *Why are diatoms good food for protozoans such as this?*

prey. For example, the protozoa known as ciliates consume smaller cells such as the single-celled photosynthetic algae known as diatoms (Figure 28.1). Like the algae, the protozoa do not form a monophyletic group.

Several types of heterotrophic **fungus-like protists** have bodies, nutrition, or reproduction similar to the true fungi. For example, fungus-like protists often have threadlike, filamentous bodies and absorb nutrients from their environment, as do the true fungi (see Chapter 31). However, fungus-like protists are not actually related to fungi; their similar features represent cases of convergent evolution (see Chapter 23). Water molds, some of which cause diseases of fish, and *Phytophthora infestans*, which causes diseases of many crops and wild plants, are examples of fungus-like protists. Various types of slime molds, some of which can be observed on decaying wood in forests, are also fungus-like though not closely related to water molds and *Phytophthora*. These examples illustrate that the terms algae, protozoa, and fungus-like protists, while very useful in describing ecological roles, lack taxonomic or evolutionary meaning.

Protists Can Be Informally Labeled According to Their Diverse Habitats

Although protists occupy nearly every type of moist habitat, they are particularly common and diverse in oceans, lakes, wetlands, and rivers. Even extreme aquatic environments such as Antarctic ice and acidic hot springs serve as habitats for some protists. In such places, protists may swim or float in open water or live attached to surfaces such as rocks or beach sand. These different habitats influence protist structure and size.

Swimming or floating protists are members of an informal group of organisms known as plankton, a group that also includes bacteria, viruses, and small animals. The photosynthetic protists in plankton are called **phytoplankton** (plantlike plankton). Planktonic protists are necessarily quite small in size; otherwise they would readily sink to the bottom. Staying afloat is particularly important for phytoplankton, which need light for photosynthesis. For this reason, planktonic protists occur primarily as single cells, colonies of cells held together with mucilage, or short filaments of cells linked end to end (Figure 28.2a–c).

Many protists live within **periphyton**, communities of microorganisms attached by mucilage to underwater surfaces such as rocks, sand, and plants. Because sinking is not a problem for attached protists, these often produce multicellular bodies, such as branched filaments (Figure 28.2d). Photosynthetic protists large enough to see with the unaided eye are known as **macroalgae**, or seaweeds. Although the bodies of some macroalgae are very large single cells (Figure 28.2e), most macroalgae are multicellular, often producing large and complex bodies. Macroalgae usually grow attached to underwater surfaces such as rocks, sand, docks, ship hulls, or offshore oil platforms. Seaweeds require sunlight and carbon dioxide for photosynthesis and growth, so most of them grow along coastal shorelines, fairly near the water surface.

Protists Can Be Informally Labeled According to Their Type of Motility

Microscopic protists have evolved diverse ways to propel themselves in moist environments. Swimming by means of flagella, cilia, amoeboid movement, and gliding are major types of protist movements.

Many types of photosynthetic and heterotrophic protists are able to swim because they produce one or a few eukaryotic flagella, cellular extensions whose movement is based on interactions between microtubules and the motor protein dynein (refer back to Figure 4.13). Eukaryotic flagella rapidly bend and straighten, thereby pulling or pushing cells through water. Protists that use flagella to move in water are commonly known as **flagellates** (Figure 28.2a). Flagellates are typically composed of one or only a few cells and are small—usually from 2–20 μm long—because flagellar motion is not powerful enough to keep larger bodies from sinking. Some flagellate protists are sedentary, living attached to underwater surfaces. These protists use flagella to collect bacteria and other small particles for food. Macroalgae and other immobile protists often produce small, flagellate reproductive cells that allow these protists to mate and disperse to new habitats.

An alternate type of protist motility relies on **cilia**, tiny hairlike extensions on the outsides of cells, mentioned earlier as occurring on the surfaces of some protozoa. Cilia are structurally similar to eukaryotic flagella but are shorter and more abundant on cells (Figure 28.3). Protists that move by means of cilia are **ciliates**. Having many cilia allows ciliates to achieve larger sizes than flagellates yet still remain buoyant in water.

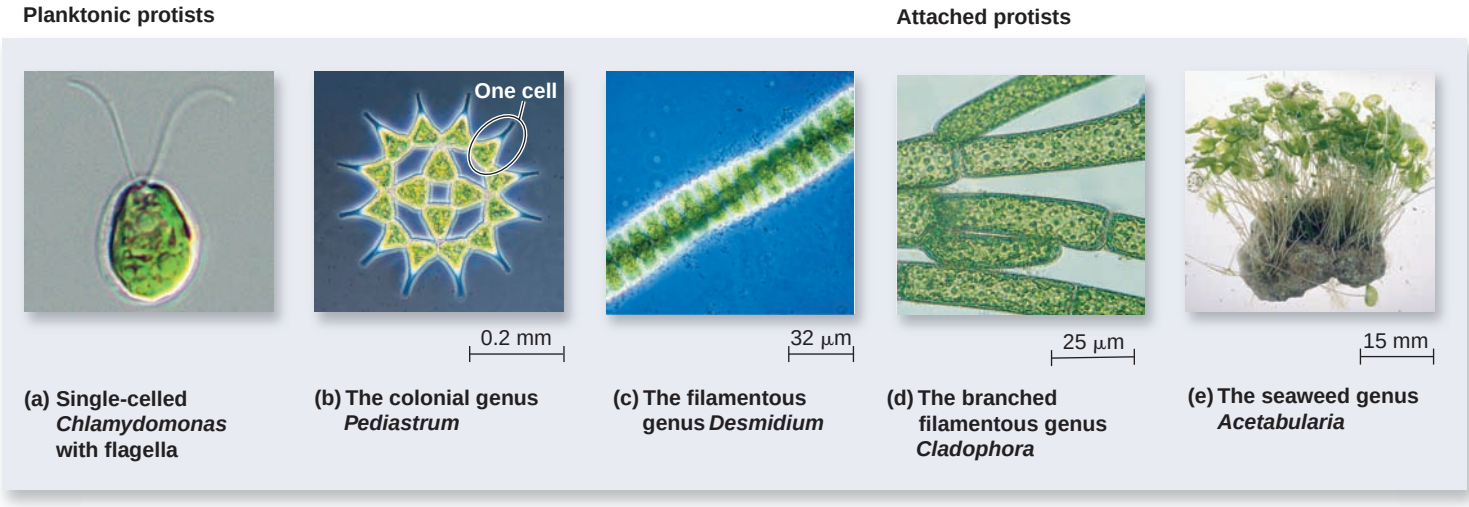


Figure 28.2 **The diversity of algal body types reflects their habitats.** **(a)** The single-celled flagellate genus *Chlamydomonas* occurs in the phytoplankton of lakes. **(b)** The colonial genus *Pediastrum* is composed of several cells arranged in a lacy star shape that helps to keep this alga afloat in water. **(c)** The filamentous genus *Desmidium* occurs as a twisted row of cells. **(d)** The branched filamentous genus *Cladophora* that grows attached to nearshore surfaces is large enough to see with the unaided eye. **(e)** The relatively large seaweed genus *Acetabularia* lives on rocks and coral rubble in shallow tropical oceans.

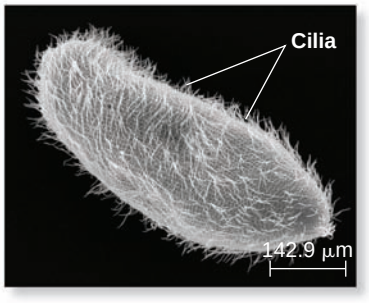

Figure 28.3 **A member of the ciliate genus *Paramecium*, showing numerous cilia on the cell surface.**

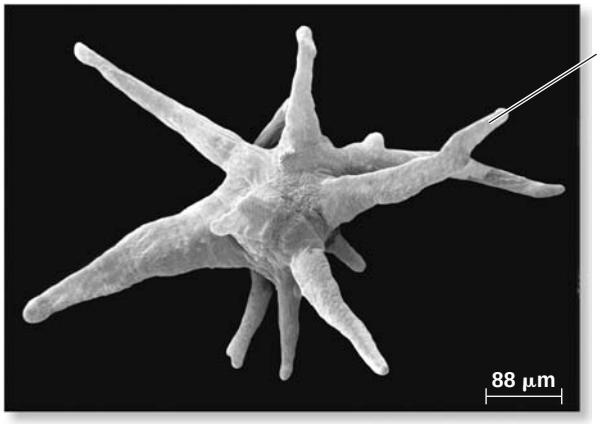

Figure 28.4 **A member of the amoebozoan genus *Pelomyxa*, showing pseudopodia.**

A third type of motility is amoeboid movement. This kind of motion involves extending protist cytoplasm into lobes, known as pseudopodia (from the Greek, meaning false feet). Once these pseudopodia move toward a food source or other stimulus, the rest of the cytoplasm flows after them, thereby changing the shape of the entire organism as it creeps along. Protist cells that move by pseudopodia are described as **amoebae** (Figure 28.4).

Finally, many diatoms, the malarial parasite *Plasmodium falciparum*, and some other protists glide along surfaces in a snail-like fashion by secreting protein or carbohydrate slime. With the exception of ciliates, motility classification does not correspond with the phylogenetic classification of protists, our next topic.

28.2 Evolution and Relationships

At one time, protists were classified into a single kingdom. However, modern phylogenetic analyses based on comparative analysis of DNA sequences and cellular features reveal that protists do not form a monophyletic group. The relationships of some protists are uncertain or disputed, and new protist species are continuously being discovered. As a result, concepts of protist evolution and relationships have been changing as new information becomes available.

Even so, molecular and cellular data reveal that many protist phyla can be classified within several eukaryotic **supergroups** that each display distinctive features (Figure 28.5). All of the supergroups shown include phyla of protists; some, in fact, contain only protist phyla. The supergroup Opisthokonta includes the multicellular animal and fungal kingdoms and related protists, while another supergroup includes the multicellular plant kingdom and the protists most closely related to it. The study of such protists helps to reveal how multicellularity originated in animals, fungi, and plants.

In this section, we survey the eukaryotic supergroups, focusing on the defining features and evolutionary importance of the major protist phyla. We will also examine ways in which protists are important ecologically or in human affairs.

A Feeding Groove Characterizes Many Protists Classified in the Excavata

The protist supergroup known as the Excavata originated very early among eukaryotes, so this supergroup is important in understanding the early evolution of eukaryotes. The Excavata is named for a feeding groove "excavated" into the cells of many representatives, such as the genus *Jakoba* (phylum Metamonada) (Figure 28.6). The feeding groove is an important adaptation that allows these organisms (informally called excavates) to ingest small particles of food in their aquatic habitats. Once food particles are collected within the feeding groove, they are then taken into cells by a type of endocytosis known as **phagocytosis** (from the Greek, meaning cellular eating). During phagocytosis, a vesicle of plasma membrane surrounds each food particle and pinches off within the cytoplasm. Enzymes within these food vesicles break the food particles down into small molecules that, upon their release into the cytoplasm, can be used for energy. Phagocytosis is also the basis for an important evolutionary process known as endosymbiosis.

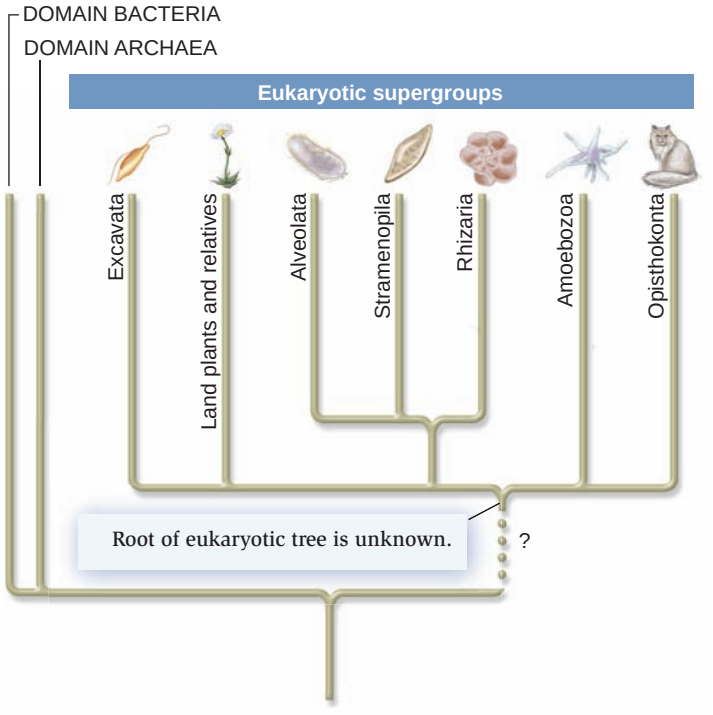

Figure 28.5 **A phylogenetic tree showing the major eukaryotic supergroups.** Each of the supergroups shown here includes some phyla of protists. The position of the root of the eukaryotic tree is uncertain, as are the branching patterns of supergroups and many phyla. Many more branches exist than are shown here.

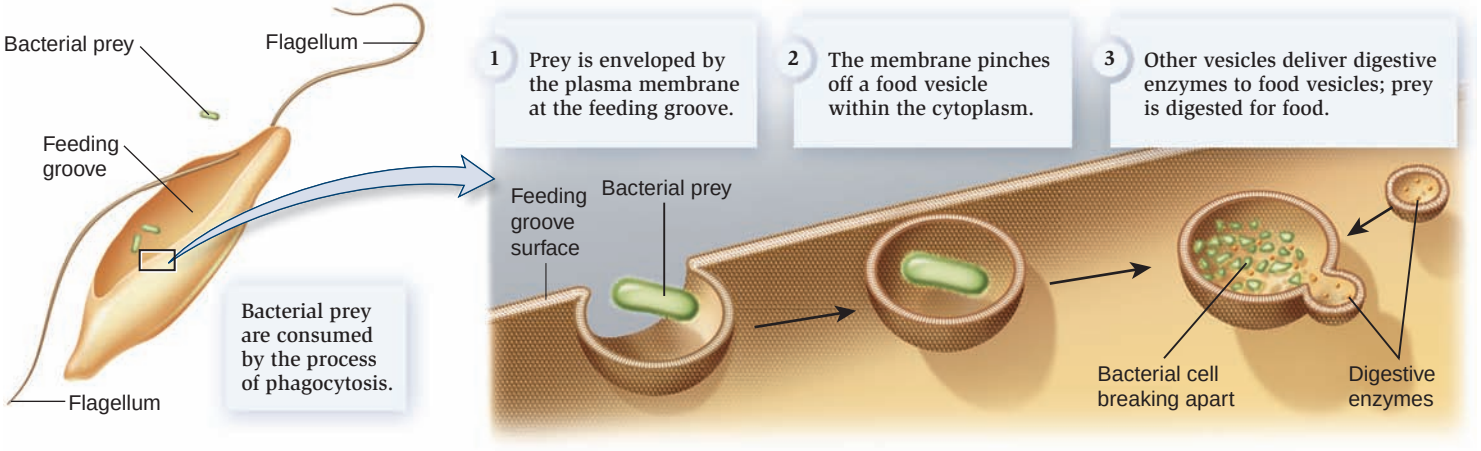
Endosymbiosis is a symbiotic association in which a smaller species known as the **endosymbiont** lives within the body of a larger species known as the **host**. Phagocytosis provides a way for protist cells that function as hosts to take in prokaryotic or eukaryotic cells that function as endosymbionts. Such endosymbiotic cells confer valuable traits and are not digested. Endosymbiosis has played a particularly important role in protist evolution. For example, early in protist history, endosymbiotic bacterial cells gave rise to mitochondria, the organelle that is the major site of ATP synthesis in most eukaryotic cells (see Chapter 7). Consequently, most protists possess mitochondria, though these may be highly modified in some species, including certain modern protists that can be linked with Excavata.

Some excavate protists have become parasitic within animals, including human hosts. In addition to feeding by phagocytosis, parasitic species attack host cells and absorb food molecules released from them. For example, *Trichomonas vaginalis* causes a sexually transmitted infection of the human genitourinary tract. In this location, *T. vaginalis* consumes bacteria and host epithelial and red blood cells by phagocytosis, as well



(a) Excavate *Jakoba* with feeding groove

(b) The process of phagocytosis in excavates

(b) *Giardia lamblia*

Figure 28.7 Parasitic members of the supergroup Excavata. (a) *Trichomonas vaginalis*. (b) *Giardia lamblia*. These specialized flagellates absorb nutrients from living cells of their hosts.

Concept check: How do these two parasitic protists differ in the process of transmission from one human host to another?

as carbohydrates and proteins released from damaged host cells. More than 170 million cases are estimated to occur each year around the globe, and infections can predispose humans to other diseases. *T. vaginalis* has an undulating membrane and flagella that allow it to move over mucus-coated skin (Figure 28.7a).

Giardia lamblia, another type of excavate protist, contains two active nuclei and produces eight flagella (Figure 28.7b). *G. lamblia* causes giardiasis, an intestinal infection that can result from drinking untreated water or from unsanitary conditions in day-care centers. Flagellate cells attach to the epithelium of the small intestine, causing disease and also producing infectious stages (cysts) that are transmitted in feces. *T. vaginalis* and *G. lamblia* were once thought to lack mitochondria, but they are now known to possess structures that are highly modified mitochondria.

Genomes & Proteomes Connection

Genome Sequences Reveal the Different Evolutionary Pathways of *Trichomonas vaginalis* and *Giardia lamblia*

In 2007, genome sequences were reported for two excavate-related parasites, *Trichomonas vaginalis* and *Giardia lamblia*. A comparison of their genomic features reveals similarities and differences in the evolution of parasitic lifestyles. One common feature is that horizontal gene transfer from bacterial or archaeal donors has powerfully affected both genomes. About 100 *G. lamblia* genes are likely to have originated via horizontal gene transfer. In *T. vaginalis*, more than 150 cases of likely horizontal gene transfer were identified, with most transferred genes encoding metabolic enzymes such as those involved in carbohydrate or protein metabolism. Another similarity between *T. vaginalis* and *G. lamblia* revealed by comparative genomics is an absence of the cytoskeletal protein myosin, which is present in most eukaryotic cells.

Despite these similarities, the genome sequences of *T. vaginalis* and *G. lamblia* reveal some dramatic differences. The *G. lamblia* genome is quite compact, only 11.7 megabases (MB) in size, with relatively simple metabolic pathways and machinery for DNA replication, transcription, and RNA processing. In contrast, the *T. vaginalis* genome is a surprisingly large 160 MB in size. *T. vaginalis* has a core set of about 60,000 protein-coding genes, one of the greatest coding capacities known among eukaryotes. The additional genes provide an expanded capacity for biochemical degradation. Because most trichomonads inhabit animal intestine, the genomic data suggest that the large genome size of *T. vaginalis* is related to its ecological transition to a new habitat, the urogenital tract.

Euglenoids The excavate protists known as euglenoids possess unique, interlocking ribbon-like protein strips just beneath their plasma membranes (Figure 28.8a). These strips make the surfaces of some euglenoids so flexible that they can crawl through mud. Many euglenoids are colorless and heterotrophic, but *Euglena* and some other genera possess green plastids and are photosynthetic. Plastids are organelles found in plant and algal cells that are distinguished by their synthetic abilities and were acquired via endosymbiosis. Many euglenoids possess a light-sensing system that includes a conspicuous red structure known as an eyespot, or stigma, and light-detecting molecules located in a swollen region at the base of a flagellum. Most euglenoids produce conspicuous storage carbohydrate particles that occur in the cytoplasm. Euglenoids are particularly abundant and ecologically significant in wetlands.

Kinetoplastids The heterotrophic excavate protists known as kinetoplastids are named for a large mass of DNA known as a kinetoplast that occurs in their single large mitochondrion (Figure 28.8b). These protists lack plastids, but they do possess an unusual modified peroxisome that contains glycolytic enzymes; in most eukaryotes, glycolysis occurs in the cytosol. Some kinetoplastids, including *Leishmania* (Figure 28.8b) and *Trypanosoma brucei*, the causative agent of sleeping sickness, are serious pathogens of humans and other animals (Figure 28.8c).

Land Plants and Related Algae Share Similar Genetic Features

The supergroup that includes land plants also encompasses several algal phyla (Figure 28.9). The land plants, also known as the

kingdom Plantae (described more fully in Chapters 29 and 30), evolved from green algal ancestors. Together, plants and some closely related green algae, called streptophyte algae, form a clade, while most green algae are classified in the phylum Chlorophyta. The red algae, classified in the phylum Rhodophyta, are also regarded as close relatives of green algae and land plants. Recent molecular sequence data and some similarities in cell structure link the plants and green and red algae to two additional algal phyla, the Haptophyta and the Cryptophyta.

Green Algae Diverse structural types of green algae (see Figure 28.2) occur in fresh waters, the ocean, and on land. Most of the green algae are photosynthetic, and their cells contain the same types of plastids and photosynthetic pigments as are present in land plants. Some green algae are responsible for harmful algal growths, but others are useful as food for aquatic animals, model laboratory research systems, or even possible sources of renewable oil supplies. Many green algae possess flagella or the ability to produce them during the development of reproductive cells.

Red Algae Most species of the protists known as red algae are multicellular marine macroalgae (Figure 28.10). The red

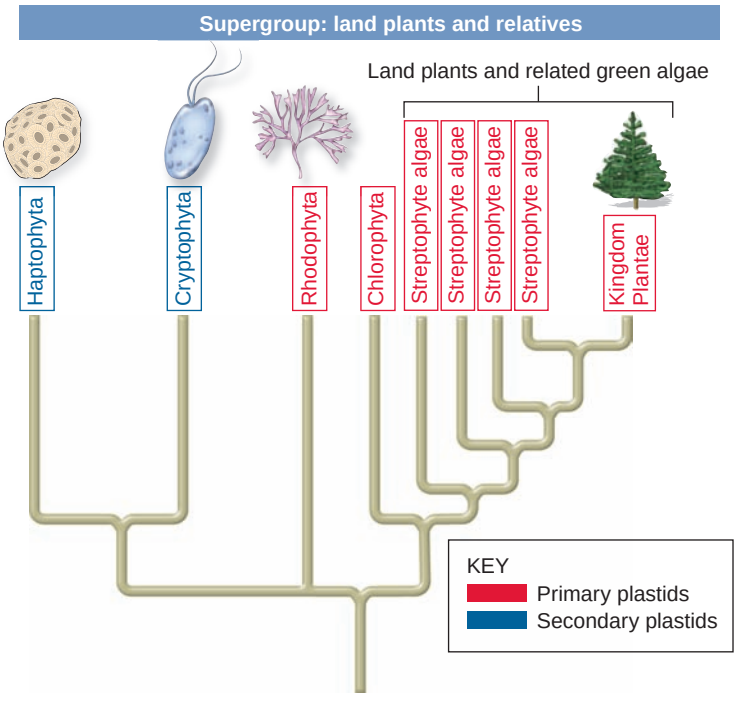

Figure 28.9 A phylogenetic tree of the supergroup that includes land plants and their close protist relatives.

appearance of these algae is caused by the presence of distinctive photosynthetic pigments that are absent from green algae or land plants. Red algae characteristically lack flagella, and this feature has strongly influenced the evolution of this group, resulting in unusually complex life cycles (described in Section 28.4). These life cycles are important to humans because we cultivate red algae in ocean waters for production of food or industrial and scientific materials. For example, the sushi wrappers called nori are composed of the sheetlike red algal genus *Porphyra*, which is grown in ocean farms. Knowledge of *Porphyra*'s life cycle was critical to the economic development of this important seaweed crop. Red algae are grown or harvested for other commercially valuable products, such as carrageenan. Carrageenan is a complex red algal cell-wall polysaccharide that has numerous applications in the food industry; for example, you may have seen it listed in the ingredients for

ice cream or chocolate milk, where it is used to keep chocolate particles evenly suspended.

Primary Plastids and Primary Endosymbiosis The plastids of red algae resemble those of green algae and land plants (and differ from most other algae) in having an enclosing envelope composed of two membranes (Figure 28.11). Such plastids, known as **primary plastids**, are thought to have originated via a process known as **primary endosymbiosis**. During primary endosymbiosis, heterotrophic host cells captured cyanobacterial cells via phagocytosis but did not digest them. These endosymbiotic cyanobacteria provided host cells with photosynthetic capacity and other useful biochemical pathways and eventually evolved into primary plastids (Figure 28.12a). Endosymbiotic acquisitions of plastids and mitochondria resulted in massive horizontal gene transfer from the endosymbiont to the

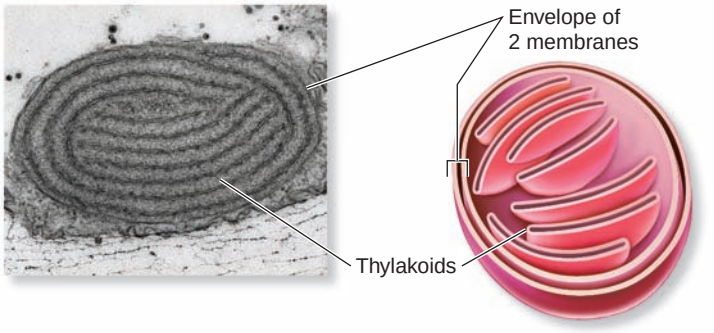

Figure 28.11 **A primary plastid, showing an envelope composed of two membranes.** The plastid shown here is red, but primary plastids can also be green or blue-green in color.

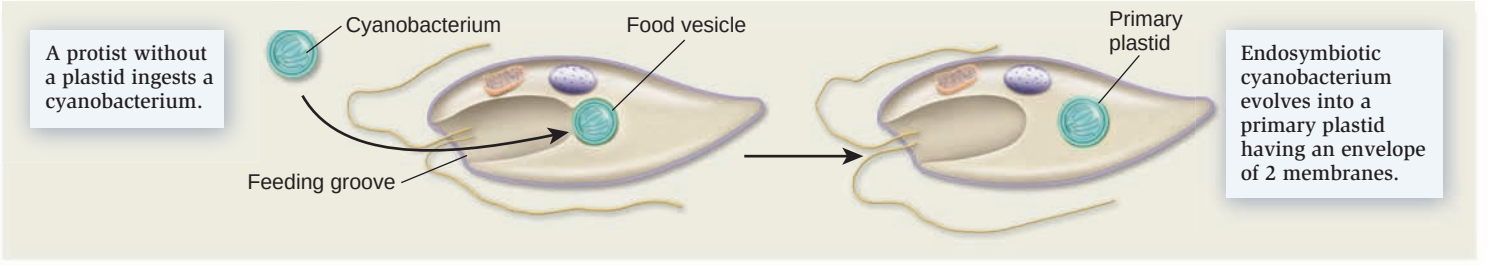
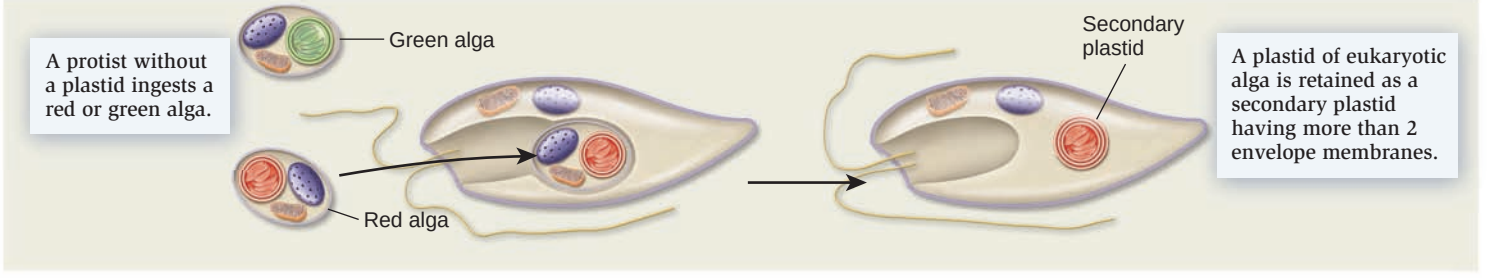
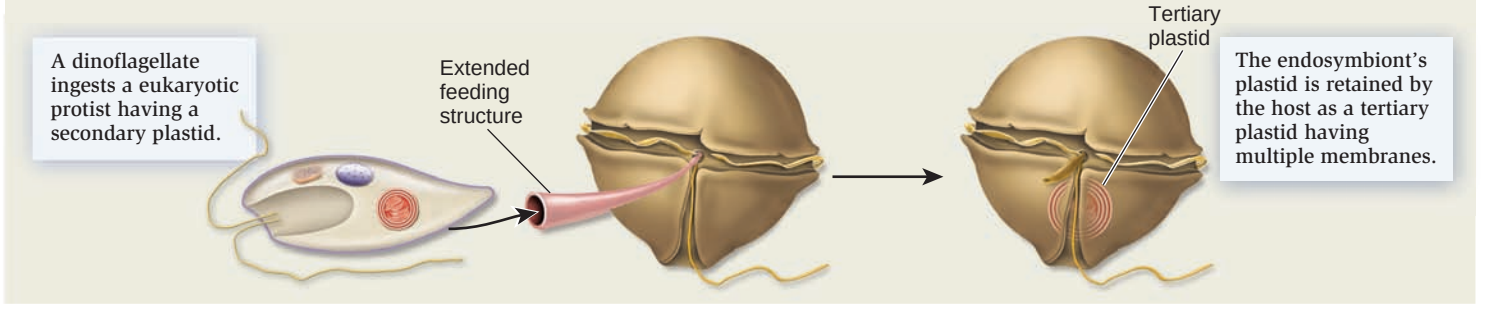


(a) Primary endosymbiosis



(b) Secondary endosymbiosis



(c) Tertiary endosymbiosis

Figure 28.12 **Primary, secondary, and tertiary endosymbiosis.** **(a)** Primary endosymbiosis involves the acquisition of a cyanobacterial endosymbiont by a host cell without a plastid. During the evolution of a primary plastid, the bacterial cell wall is lost, and most endosymbiont genes are transferred to the host nucleus. **(b)** Secondary endosymbiosis involves the acquisition by a host cell of a eukaryotic endosymbiont that contains one or more primary plastids. During the evolution of a secondary plastid, most components of the endosymbiont cell are lost, but a plastid is often retained within an envelope of endoplasmic reticulum. **(c)** Tertiary endosymbiosis involves the acquisition by a host cell of a eukaryotic endosymbiont that possesses secondary plastids.

host nucleus. As a result of such gene transfer, many of the proteins needed by plastids and mitochondria are synthesized in the host cytoplasm and then targeted to these organelles. All cells of plants, green algae, and red algae contain one or more plastids, and most of these organisms are photosynthetic. However, some species (or some of the cells within the multicellular bodies of photosynthetic species) are heterotrophic because photosynthetic pigments are not produced in the plastids.

Cryptomonads and Haptophytes Some gene sequence data and cellular features indicate that plants, green algae, and red algae may be closely related to two additional algal groups, the cryptomonads and the haptophytes (see Figure 28.9). Cryptomonads are unicellular flagellates, most of which contain red, blue-green, or brown plastids and are photosynthetic (Figure 28.13a). Occurring in marine and fresh waters, cryptomonads are excellent sources of the fatty-acid-rich food essential to aquatic animals.

Haptophytes are primarily unicellular marine photosynthesizers, some having flagella and others not. Some haptophytes are known as the coccolithophorids because they produce a covering of intricate white calcium carbonate discs known as coccoliths (Figure 28.13b). Coccolithophorids often form massive ocean growths that are visible from space and play important roles in Earth's climate by reflecting sunlight and producing compounds that foster cloud formation. In some places, coccoliths produced by huge populations of ancient coccolithophorids accumulated on the ocean floor, together with the calcium carbonate remains of other protists, for millions of years. These deposits were later raised above sea level, forming massive limestone formations or chalk cliffs such as those visible at Dover, on the southern coast of England (Figure 28.13c).

Secondary Plastids and Secondary Endosymbiosis In contrast to the primary plastids of plants and green and red algae, the plastids of cryptomonads and haptophytes are derived from a photosynthetic eukaryote, likely a red alga. Such plastids are known as **secondary plastids** because they originate by the process of **secondary endosymbiosis** (see Figure 28.12b). Secondary endosymbiosis occurs when a eukaryotic host cell ingests and retains another type of eukaryotic cell that already has one or more primary plastids, such as a red or green alga. Such eukaryotic endosymbionts are often enclosed by endoplasmic reticulum (ER), explaining why secondary plastids typically have envelopes of more than two membranes. Although most of the endosymbiont's cellular components are digested away over time, its plastids are retained, providing the host cell with photosynthetic capacity and other biochemical capabilities.

Cryptomonad plastids are unusual because they retain a highly reduced form of the captured red algal nucleus, known as a nucleomorph (Figure 28.14). Located within the enclosing ER, but outside the two inner plastid membranes, the nucleomorph contains a small amount of DNA that encodes materials needed by the cryptomonad plastid that are not provided by host cells. Evolutionary biologists are intrigued by cryptomonad nucleomorphs because they reflect an intermediate stage in the origin of plastids by secondary endosymbiosis. Haptophyte plastids arose by secondary endosymbiosis involving a red alga, and euglenoid plastids arose by secondary endosymbiosis involving a green alga, but neither haptophytes nor euglenoids have retained the endosymbiont nucleus as a nucleomorph.

Membrane Sacs Lie at the Cell Periphery of Protists Classified in Alveolata

The three supergroups Alveolata, Stramenopila, and Rhizaria seem to form a cluster in recent phylogenetic studies (Figure 28.15). Turning first to Alveolata, we see that it includes three important phyla: (1) the Ciliophora, or ciliates; (2) the Apicomplexa, a medically important group of parasites; and

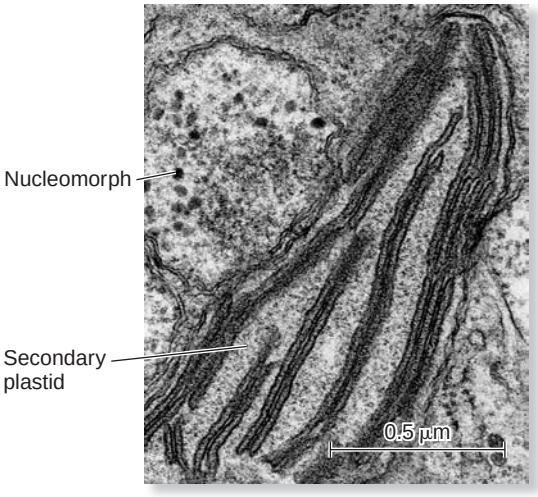

Figure 28.14 **A nucleomorph within the secondary plastid of a cryptomonad.**

Concept check: *What function does the nucleomorph serve?*

(3) the Dinozoa, informally known as dinoflagellates. Ciliates are notable for a complex mating behavior known as conjugation (see Section 28.4). Apicomplexans include the malarial agent *Plasmodium falciparum* (see Section 28.4), the related protist *Cryptosporidium parvum*, and other serious pathogens of humans and other animals. Dinoflagellates are recognized for the mutually beneficial relationships that some establish with reef-building corals and the harmful blooms (red tides) that other species produce (see Section 28.3). The Alveolata is named for saclike membranous vesicles known as alveoli that are present at the cell periphery in all of these phyla, illustrated here by dinoflagellates (Figure 28.16a).

The alveoli of some dinoflagellates seem empty, so the cell surface appears smooth (Figure 28.16b). By contrast, the alveoli

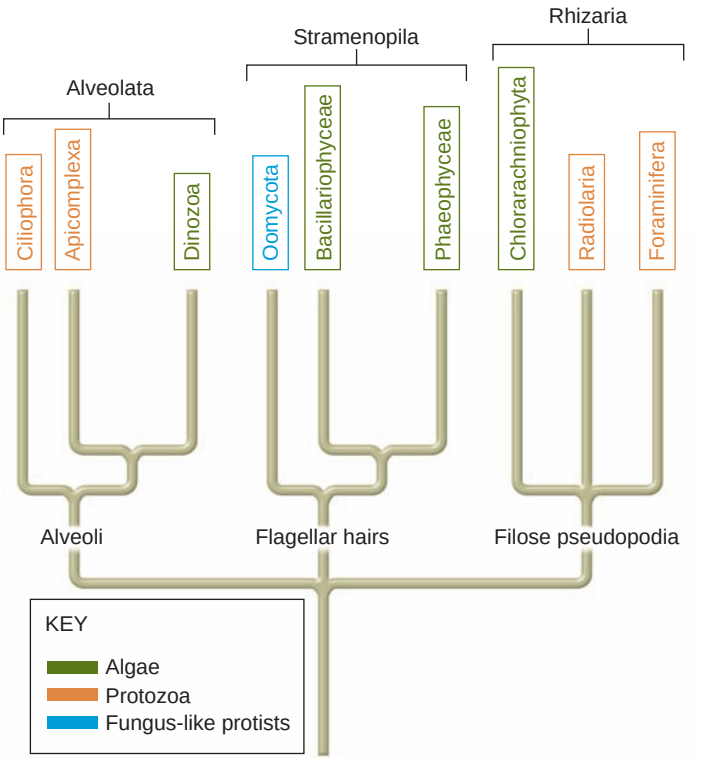

Figure 28.15 **A phylogenetic tree illustrating close relationship among the supergroups Alveolata, Stramenopila, and Rhizaria.**

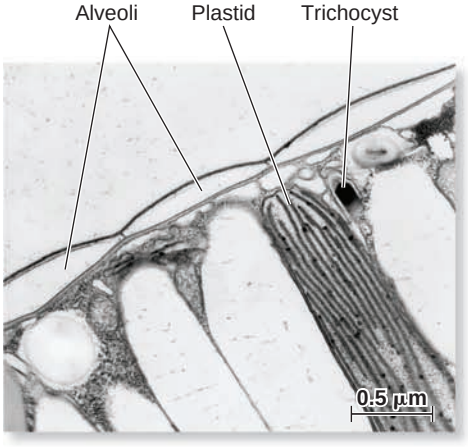
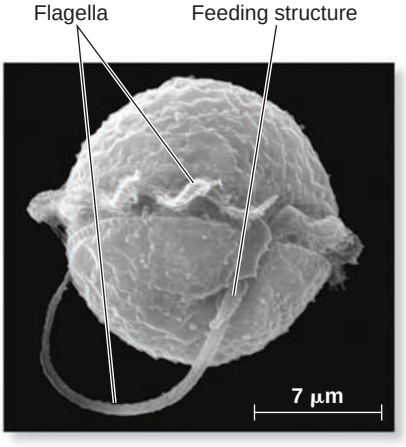
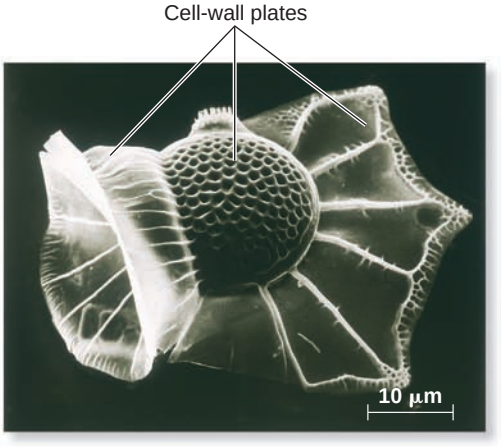
of many dinoflagellates contain plates of cellulose, which form an armor-like enclosure (Figure 28.16c). These plates are often modified in ways that provide adaptive advantage, such as protection from predators or increased ability to float.



(a) Cross section through characteristic alveoli



(b) A freshwater dinoflagellate with empty alveoli



(c) A marine dinoflagellate with cell-wall plate alveoli

Figure 28.16 **Dinoflagellates of the supergroup Alveolata and their characteristic alveoli.** **(a)** Sac-shaped membranous vesicles known as alveoli lie beneath the plasma membrane of a dinoflagellate, along with defensive projectiles, called trichocysts, ready for discharge. **(b)** The surface of the freshwater dinoflagellate *Peridiniopsis berolinensis* appears smooth because the alveoli seem empty. Dinoflagellates have two types of flagella. One flagellum coils around a cellular groove; as it moves, this flagellum causes the cell to spin. A second flagellum extends from the cell, acting as a rudder to determine the direction of movement. **(c)** The alveoli of the marine dinoflagellate genus *Ornithocercus* contain cellulose cell-wall plates.

Concept check: *Why do parts of the cell wall of Ornithocercus resemble sails?*

About half of dinoflagellate species are heterotrophic and half possess photosynthetic plastids of diverse types that originated by secondary or even tertiary endosymbiosis; therefore, these are known as secondary or tertiary plastids. **Tertiary plastids** were obtained by **tertiary endosymbiosis**—the acquisition by hosts of plastids from cells that possessed secondary plastids (see Figure 28.12c). Species having tertiary plastids have received genes by horizontal transfer from diverse genomes.

Flagellar Hairs Distinguish Stramenopila

The supergroup Stramenopila (informally known as the stramenopiles) encompasses a wide range of algae, protozoa, and fungus-like protists that usually produce flagellate cells at some point in their lives (see Figure 28.15). The Stramenopila (from the Greek *stramen*, meaning straw, and *pila*, meaning hair) is named for distinctive strawlike hairs that occur on the surfaces of flagella (Figure 28.17). These flagellar hairs function something like oars to greatly increase swimming efficiency. Stramenopiles are also informally known as heterokonts (from the Greek, meaning different flagella), because the two flagella often present on swimming cells have slightly different structures.

Stramenopiles include diverse heterotrophic protists as well as many groups of algae having golden- or brown-colored plastids. The plastids of stramenopile algae originated from red algae

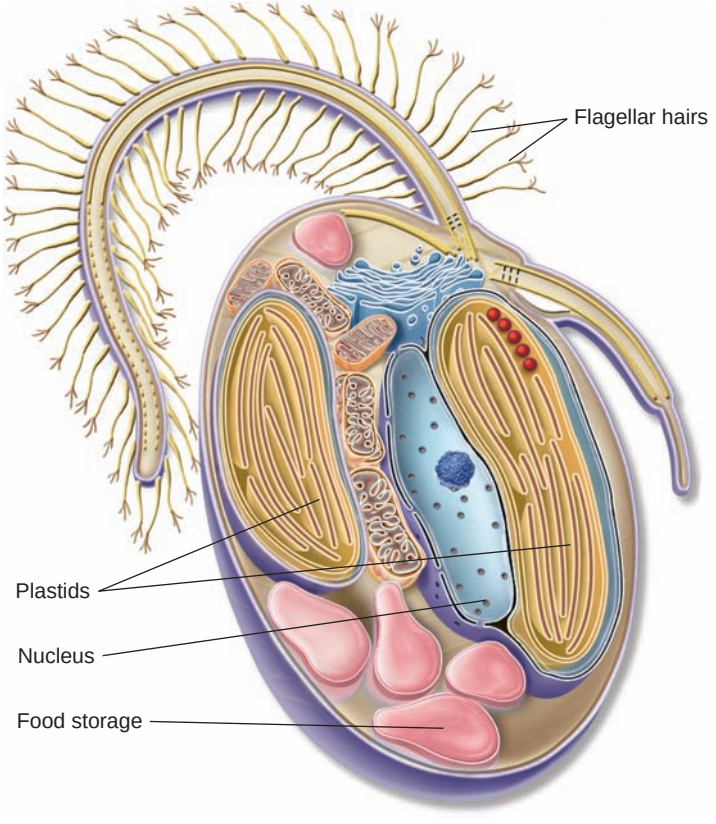


Figure 28.17 Diagram of a flagellate stramenopile cell, showing characteristic flagellar hairs.

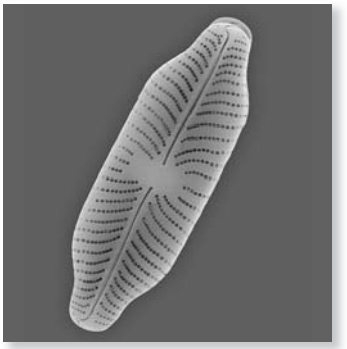
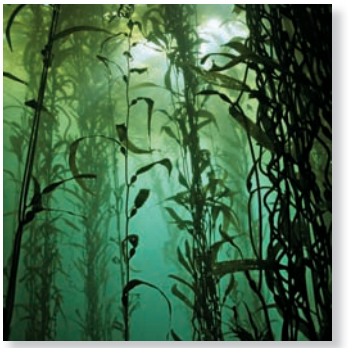
Concept check: *How do the flagellar hairs aid cell motion?*



(a) Diatom



(b) Kelp forest

Figure 28.18 Stramenopiles include diatoms and giant kelps. **(a)** SEM of a diatom cell wall, showing elaborate ornamentation of the silicate structure. **(b)** Forests of giant kelps occur along many ocean shores, providing habitat for diverse organisms.

Concept check: *In what ways are kelp forests economically important?*

by secondary endosymbiosis. Stramenopiles include diatoms (Bacillariophyceae), whose glass cell walls are elaborately ornamented with pores, lines, and other intricate features (Figure 28.18a). Recent genome sequencing projects have focused on the processes by which diatoms produce such detailed silicate structures, which may prove useful in industrial microfabrication applications. Vast accumulations of the glass walls of ancient diatoms, known as diatomite or diatomaceous earth, are mined for use in reflective paint and other industrial products.

Diverse brown algae (Phaeophyceae) are sources of industrial products such as polysaccharide emulsifiers known as alginates. The brown algae known as giant kelps are ecologically important because they form extensive forests in cold and temperate coastal oceans (Figure 28.18b). Kelp forests are essential nurseries for fish and shellfish. The reproductive processes of kelps are described in Section 28.4.

Spiky Cytoplasmic Extensions Are Present on the Cells of Many Protists Classified in Rhizaria

Several groups of flagellates and amoebae that have thin, hair-like extensions of their cytoplasm, known as filose pseudopodia, are classified into the supergroup Rhizaria (from the Greek *rhiza*, meaning root) (see Figure 28.15). Rhizaria includes the phylum Chlorarachniophyta, whose spider-shaped cells possess secondary plastids obtained from endosymbiotic green algae. Other examples of Rhizaria are the Radiolaria (Figure 28.19a) and Foraminifera (Figure 28.19b), two phyla of ocean plankton that produce exquisite mineral shells. Fossil shells of foraminiferans are widely used to infer past climatic conditions.

Amoebozoa Includes Many Types of Amoebae with Pseudopodia

The supergroup Amoebozoa includes many types of amoebae that move by extension of pseudopodia (see Figure 28.4). One example is the human parasite *Entamoeba histolytica*, which

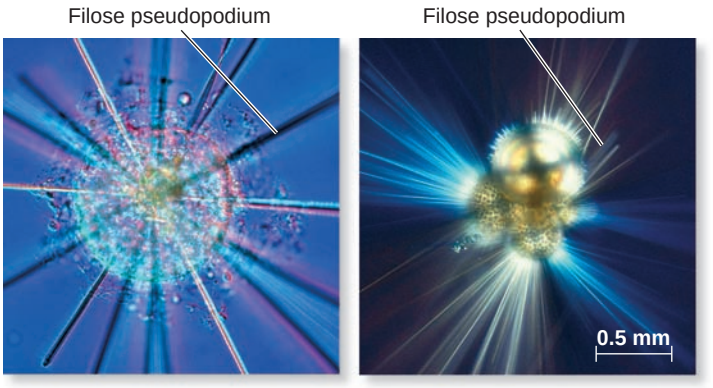


Figure 28.19 **Representatives of supergroup Rhizaria.** **(a)** A radiolarian, *Acanthoplegma* spp., showing long filose pseudopodia. **(b)** A foraminiferan, showing calcium carbonate shell with long filose pseudopodia extending from pores in the shell.

causes a severe form of intestinal illness. Several types of protists known as slime molds are also classified in this supergroup. For example, the phylum Dictyostelia includes the slime mold *Dictyostelium discoideum*, widely used as a model laboratory system for understanding communication among cells.

A Single Flagellum Occurs on Swimming Cells of Opisthokonta

The supergroup Opisthokonta includes the animal and fungal kingdoms and related protists (Figure 28.20). This supergroup is named for the presence of a single posterior flagellum on swimming cells. Closely related to the animal kingdom are the protists known as choanoflagellates (formally, the Choanomonada). These single-celled or colonial protists feature a distinctive collar surrounding the single flagellum (Figure 28.21). The collar is made of cytoplasmic extensions that filter bacterial food from water currents generated by flagellar motion.

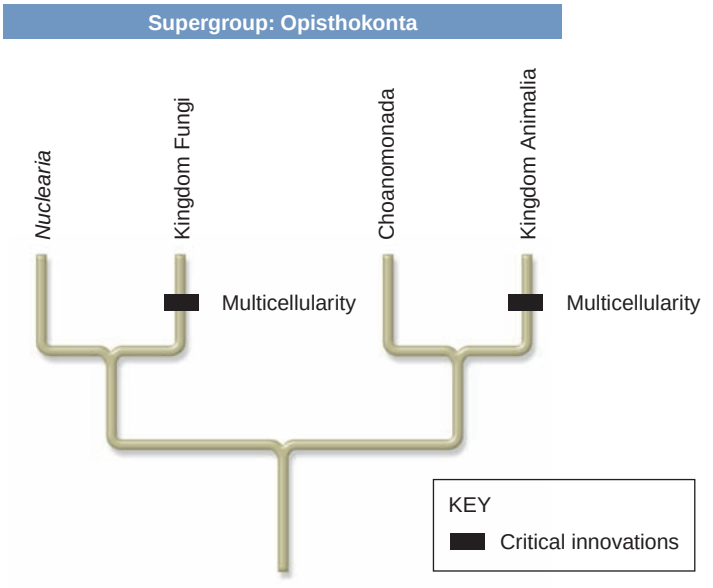

Figure 28.20 **A phylogenetic tree of the supergroup Opisthokonta.** This supergroup includes protist phyla as well as the kingdoms Fungi and Animalia. Notice that a critical innovation of these kingdoms is multicellularity.

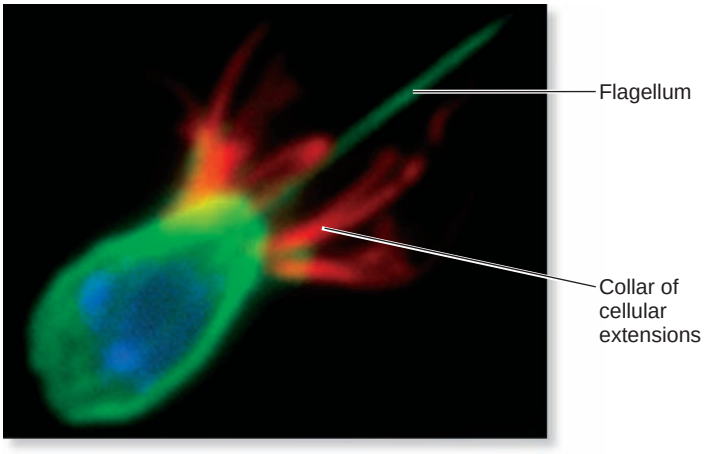

Figure 28.21 **A choanoflagellate of the supergroup Opisthokonta.** This cell has been stained with fluorescent dyes specific for DNA (blue) and the proteins actin (red) and tubulin (green). The single flagellum is stained green because it is rich in tubulin. A collar of cellular extensions that are rich in actin surrounds the flagellum.

Concept check: *What features of the ancient choanoflagellate ancestors of animals were important in the evolution of multicellularity, and what function do such features serve in modern choanoflagellates?*

Evolutionary biologists interested in the origin of animals study choanoflagellates for molecular clues to this important event in our evolutionary history. In 2008, evolutionary biologist Nicole King and associates reported a genome sequence for the choanoflagellate *Monosiga brevicollis* and identified several genes that are present only in choanoflagellates and animals. Some of the shared genes encode cell adhesion and extracellular matrix proteins that help choanoflagellates attach to surfaces and were also essential to the evolution of multicellularity in animals.

The preceding survey of protist diversity, summarized in Table 28.1, illustrates the enormous evolutionary and ecological importance of protists. Next, we consider the diverse ways in which protists have become adapted to their environments.

28.3 Nutritional and Defensive Adaptations

Wherever you look in moist places, you will find protists playing diverse and important ecological roles. In this section, we will survey protist nutritional and defensive adaptations, which help to explain their ecological roles.

Table 28.1 Eukaryotic Supergroups and Examples of Constituent Kingdoms, Phyla, Classes, or Species

Supergroup	KINGDOMS, **Phyla,** classes, or *species*	Distinguishing features
EXCAVATA	**Metamonada** *Giardia lamblia* *Trichomonas vaginalis*	Unicellular flagellates, often with feeding groove
	Kinetoplastea (kinetoplastids) *Trypanosoma brucei* **Euglenida** (euglenoids)	Secondary plastids (when present) derived from endosymbiotic green algae
LAND PLANTS AND ALGAL RELATIVES	**Rhodophyta** (red algae) **Chlorophyta** (green algae) KINGDOM PLANTAE and close green algal relatives	Land plants, green algae, and red algae have primary plastids derived from cyanobacteria; such plastids have two envelope membranes
	Cryptophyta (cryptomonads) **Haptophyta** (haptophytes, including coccolithophorids)	Haptophytes and most cryptomonads possess secondary plastids derived from red algae; such plastids have more than two envelope membranes. Some experts classify cryptomonads and haptophytes with alveolates, stramenopiles, and rhizaria.
ALVEOLATA	**Ciliophora** (ciliates) **Apicomplexa** (apicomplexans) *Plasmodium falciparum* *Cryptosporidium parvum* **Dinozoa** (dinoflagellates) *Pfiesteria shumwayae*	Peripheral membrane sacs (alveoli); Apicomplexa sometimes have secondary plastids derived from red algae; some Dinozoa have secondary plastids derived from red algae, some have secondary plastids derived from green algae, and some have tertiary plastids derived from diatoms, haptophytes, or cryptomonads
STRAMENOPILA	Bacillariophyceae (diatoms) Phaeophyceae (brown algae) *Phytophthora infestans* (fungus-like)	Strawlike flagellar hairs; secondary plastids (when present) derived from red algae; fucoxanthin accessory pigment common in autotrophic forms
RHIZARIA	**Chlorarachniophyta** **Radiolaria** **Foraminifera**	Thin, cytoplasmic projections; secondary plastids (when present) derived from endosymbiotic green algae
AMOEBOZOA	*Entamoeba histolytica* **Dictyostelia** (a slime mold phylum) *Dictyostelium discoideum*	Amoeboid movement by pseudopodia
OPISTHOKONTA	*Nuclearia* spp. KINGDOM FUNGI **Choanomonada** (choanoflagellates) KINGDOM ANIMALIA	Swimming cells possess a single posterior flagellum

Protists Display Four Basic Types of Nutrition

Protist nutrition occurs in four basic types: phagotrophy, osmotrophy, photoautotrophy, and mixotrophy. Heterotrophic protists that feed by ingesting particles, or phagocytosis, are known as **phagotrophs**, whereas those relying on osmotrophy (uptake of small organic molecules) are **osmotrophs**. As mentioned earlier, photosynthetic protists are **photoautotrophs**, organisms that can make their own organic nutrients by harvesting light energy. **Mixotrophs** are able to use photoautotrophy as well as phagotrophy or osmotrophy to obtain organic nutrients. The genus *Dinobryon* (Figure 28.22), a photosynthetic stramenopile that lives in the phytoplankton of freshwater lakes, is an example of a mixotroph. These protists may switch back and forth between photoautotrophy and heterotrophy, depending on conditions in their environment. If sufficient light, carbon dioxide, and other minerals are available, *Dinobryon* cells produce their own organic food. If any of these resources limits photosynthesis, or organic food is especially abundant, *Dinobryon* cells can function as heterotrophs, consuming enormous numbers of bacteria. Mixotrophs thus have remarkable nutritional flexibility.

Heterotrophic protists that feed on nonliving organic material function as decomposers, essential in breaking down wastes and releasing minerals for use by other organisms. Heterotrophic

Figure 28.22 **A mixotrophic protist.** The genus *Dinobryon* is a colonial flagellate that occurs in the phytoplankton of freshwater lakes. The photosynthetic cells have golden photosynthetic plastids and also capture and consume bacterial cells.

protists that feed on the living cells of other organisms are parasites that may cause disease in other organisms. *Trichomonas vaginalis*, *Giardia lamblia*, *Entamoeba histolytica*, and *Phytophthora infestans* are examples of pathogenic protists that have previously been described in this chapter. Humans view such protists as pests when they harm us or our agricultural animals and crops, but pathogenic protists also play important roles in nature by controlling the population growth of other organisms.

Algal Protists Vary in Photosynthetic Pigments and Food Storage Molecules

As we have earlier noted, algae display a surprising diversity of coloration: gold, brown, red, blue-green, and green. Why do so many pigmentation types occur? The answer is related to light availability in these protists' watery environment.

If you dive more than a few feet into lakes or the ocean, your aquatic world will appear intensely blue-green. This occurs because water absorbs the longer red to yellow wavelengths of light to a greater degree than it does the shorter blue and green wavelengths. Little red light penetrates far into natural waters, depriving chlorophyll *a*, the photosynthetic pigment generally present in photosynthetic eukaryotes, of much of the light it would ordinarily absorb. Photosynthetic protists living in water have evolved photosynthetic systems that capture more of the available blue-green light. Macroalgae may be colored red, gold, or brown, in addition to green, because they produce diverse accessory pigments that can absorb more of the light available underwater and transfer the energy to chlorophyll *a* for photosynthesis. For example, the red accessory pigment phycoerythrin is abundant in plastids of red algae, and golden fucoxanthin enriches the color of golden and brown algae (compare Figures 28.10 and 28.18b). Carotene and lutein play similar accessory pigment roles in green algae and were inherited by their land plant descendants, today playing important roles in animal nutrition.

Photosynthetic protists also vary in the types of molecules that serve as food storage. Starch stored in the plastids of green algae, the cytoplasmic polysaccharides of euglenoids, and oil droplets in diatom cells are examples. Algae use such food storage materials for energy when light or minerals are too low to allow photosynthesis. These food storage materials explain why algae are both useful sources of renewable energy and desirable food sources for heterotrophs (see Figure 28.1).

Protists Defend Themselves in Diverse Ways

Protists use a wide variety of defensive adaptations to ward off attack. Major types of defenses are slimy, tough, or spiny cell coverings; sharp projectiles that can be explosively shot from cells; light flashes; and toxic compounds.

Many protists have cell coverings such as slimy mucilages (see chapter-opening photo) or cell walls that provide protection from attack by herbivores or pathogens. Cell walls may also aid in preventing osmotic damage or enhance flotation in water (see Figure 28.16c). Rigid cellulose walls are common in brown and green algae, whereas slimy polysaccharide polymers form a protective matrix around red algal cells. Calcium carbonate forms a stony coat for many protist cells, including foraminifera, haptophytes, and some marine macroalgae (see Figures 28.10a and 28.13b). As noted earlier, ornate glassy coatings of silica protect diatoms, while metallic iron and manganese crystals armor other protists.

Some protist defenses reduce predation by herbivores. Several types of protist cells contain compressed protein structures known as trichocysts (see Figure 28.16a). Upon attack, trichocysts rapidly elongate into spear-shaped projectiles that are shot from these cells, thereby discouraging herbivores from feeding. Some species of ocean dinoflagellates emit flashes of blue light when disturbed, explaining why ocean waters teeming with these protists display bioluminescence. The light flashes may deter herbivores by startling them, but when ingested, the dinoflagellates make the herbivores also glow, revealing them to hungry fishes. Light flashes benefit dinoflagellates by helping to reduce populations of herbivores that consume the algae.

Various protist species produce **toxins**, compounds that inhibit animal physiology and may function to deter small herbivores. Dinoflagellates are probably the most important protist toxin producers; they synthesize several types of toxins that affect humans and other animals. Why does this happen? Under natural conditions, small populations of dinoflagellates produce low amounts of toxin that do not harm large organisms. Dinoflagellate toxins become dangerous to humans when people contaminate natural waters with excess mineral nutrients such as nitrogen and phosphorus from untreated sewage, industrial discharges, or fertilizer that washes from agricultural fields. The excess nutrients fuel the development of harmful algal blooms, which then produce sufficient toxin to affect birds, aquatic mammals, fishes, and humans. Toxins can concentrate in organisms. Humans who ingest shellfish that have accumulated dinoflagellate toxins can suffer poisoning.

In the early 1990s, ecologist JoAnn Burkholder and colleagues reported that the toxic dinoflagellate *Pfiesteria* had caused major fish kills in the overly fertile waters of the Chesapeake Bay. These investigators observed that the dinoflagellate could live by consuming algal cells but also could produce a toxin that damages fish skin, allowing the dinoflagellates to consume fish flesh. These biologists also discovered that *Pfiesteria*-associated toxin caused amnesia and other nervous system conditions in fishers and scientists who were exposed to it, though the cellular basis of the effect on humans was unclear. The discovery of *Pfiesteria* excited the media, which dubbed it a "killer alga" and focused attention on nutrient pollution of Chesapeake Bay, the fundamental cause of *Pfiesteria*'s excessive growth and fish kills. Because of this organism's importance to the fishing industry and human health, teams of aquatic ecologists have continued to study the genus *Pfiesteria* and its toxin, as described next.

Feature Investigation

Burkholder and Colleagues Demonstrated That Strains of the Dinoflagellate Genus *Pfiesteria* Are Toxic to Mammalian Cells

A team of investigators led by JoAnn Burkholder performed an experiment to determine whether or not two strains of *Pfisteria shumwayae* were toxic to mammalian cells (Figure 28.23). Although one of these strains (CCMP 1024C) was thought to be toxic to fishes and people, other work suggested that a different strain (CCMP 2089) did not produce toxin, a difference that might have resulted from variation in growth conditions. Neither strain had been tested for its impact on mammalian cells. The experiment was conducted in a biohazard containment facility, for the safety of the investigators.

In the first step of the experiment, the team provided both *Pfiesteria* strains with two forms of food—cryptomonad algal cells or juvenile fish—because the impact of food type on toxicity was unclear. In a second step, the dinoflagellates grown in step 1 were transferred to tanks with fish to elicit maximal toxin production, before treating mammalian cell cultures with the dinoflagellates. Dinoflagellates were not added to a control tank of fish. Toxin was detected, and fish deaths occurred in all of the tanks except the control. In a third step, samples from the step 2 treatments were added to mammalian cell cultures, and investigators determined the relative levels of toxicity to the mammalian cells. They found that both strains of *P. shumwayae* were toxic to mammalian cells and that both types of food supported the growth of toxin-producing dinoflagellates.

Figure 28.23 **Burkholder and colleagues demonstrated that some strains of *Pfiesteria shumwayae* are toxic to fish and mammalian cells.**

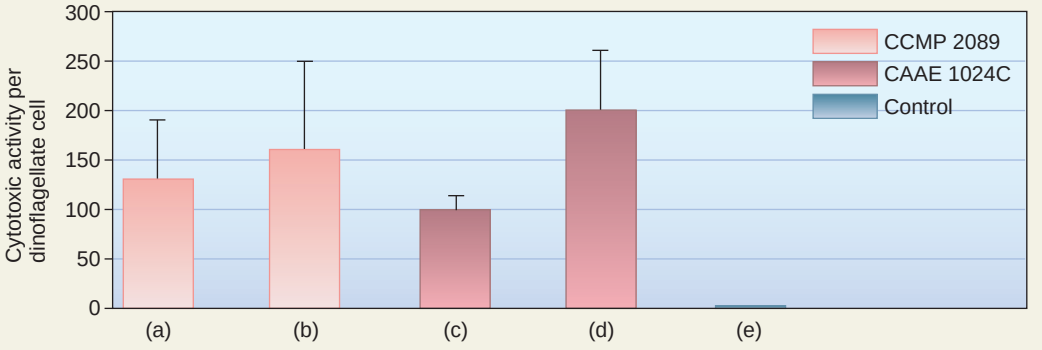
GOAL To determine the toxicity of two *Pfiesteria shumwayae* strains, grown on different food types, to mammalian cells.

KEY MATERIALS
1) *P. shumwayae* strain CCMP 2089
2) *P. shumwayae* strain CAAE 1024C
3) *Cryptomonas* sp.—algal food for dinoflagellates
4) Juvenile tilapia (*Oreochromis* spp.)—fish food for dinoflagellates
5) Mammalian pituitary cell line

	Experimental level	Conceptual level
1 Grow strains CCMP 2089 and CAAE 1024C with algal food in culture flasks, or with fish as food in tanks. Use a biohazard containment facility to prevent toxins from harming scientists.		Food source, algae or juvenile fish, might affect the amount of toxin produced by dinoflagellates. The 2 dinoflagellate strains might differ in toxin production response.
2 Transfer dinoflagellates grown under step 1 conditions to new tanks containing juvenile fish.		Grow with fish to elicit maximal toxin production.
3 Expose mammalian pituitary cells to dinoflagellates from treatments a–d and control water from tank e in step 2.		Determine toxicity of dinoflagellates to mammalian cells.

4 THE DATA

Results from step 3:



5 CONCLUSION Both strains of *P. shumwayae* were toxic to mammalian cells, and both types of food supported the growth of toxic dinoflagellates.

6 SOURCE Burkholder, J.M., et al. 2005. Demonstration of toxicity to fish and to mammalian cells by *Pfiesteria* species: Comparison of assay methods and strains. *Proceedings of the National Academy of Sciences of the United States of America* 102:3471–3476.

Experimental Questions

1. Why did the Burkholder team test two different strains of *Pfiesteria shumwayae*?
2. Why did the Burkholder team grow *Pfiesteria shumwayae* with algae or fish as food?
3. Why did the Burkholder team use a biohazard containment system?

28.4 Reproductive Adaptations

Diverse reproductive adaptations allow protists to thrive in an amazing variety of environments, including the bodies of hosts in the cases of parasitic protists. These adaptations include specialized asexual reproductive cells, tough-walled dormant cells that allow protists to survive periods of environmental stress, and several types of sexual life cycles.

Protist Populations Increase by Means of Asexual Reproduction

All protists are able to reproduce asexually by mitotic cell divisions of parental cells to produce progeny. When resources are plentiful, repeated mitotic divisions of single-celled protists will generate large protist populations. By contrast, multicellular protists often generate specialized asexual cells that help disperse the organisms in their environment.

Many protists produce unicellular **cysts** as the result of asexual (and in some cases, sexual) reproduction (Figure 28.24). Cysts often have thick, protective walls and can remain dormant through periods of unfavorable climate or low food availability. Dinoflagellates commonly produce cysts that can be transported in ship ballast water from one port to another,

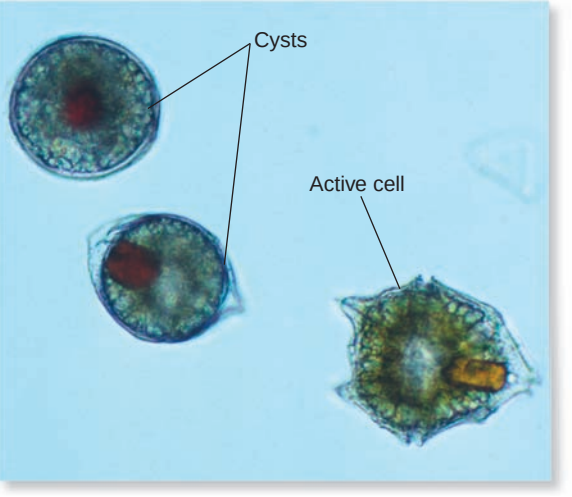


Figure 28.24 Protistan cysts. The round cells are dormant, tough-walled cysts of the dinoflagellate *Peridinium limbatum*. The pointed cell is an actively growing cell of the same species. As cysts develop, the outer cellulose plates present on actively growing cells are cast off.

Concept check: How can cysts be involved in the spread of harmful algae and disease-causing parasitic protists?

a problem that has caused harmful dinoflagellate blooms to appear in harbors around the world. Ship captains can help to prevent such ecological disasters by heating ballast water before it is discharged from ships.

Many protozoan pathogens spread from one host to another via cysts. For example, the apicomplexan pathogen *Cryptosporidium parvum* infects humans via waterborne cysts. *Entamoeba histolytica* is a pathogen that infects people who consume food or water that is contaminated with its cysts. Once inside the human digestive system, *E. histolytica* attacks intestinal cells, causing amoebic dysentery, a worldwide problem.

Sexual Reproduction Provides Multiple Benefits to Protists

Eukaryotic sexual reproduction, featuring gametes, zygotes, and meiosis, first arose among protists. Sexual reproduction has not been observed in some protist phyla but is common in others. Sexual reproduction is generally adaptive because it produces diverse genotypes, thereby increasing the potential for faster evolutionary response to environmental change. Many protists reap additional ecological benefits from sexual reproduction, illustrated by several types of sexual life cycles.

Zygotic Life Cycles Most unicellular protists that reproduce sexually display what is known as a **zygotic life cycle** (Figure 28.25). In this type of life cycle, haploid cells develop into gametes. Some protists produce nonmotile eggs and smaller flagellate sperm. However, many other protists have gametes that look similar to each other structurally but have distinctive biochemical features and hence are known as + and − mating types. Gametes fuse to produce thick-walled diploid zygotes, which give this type of life cycle its name. Such zygotes often have tough cell walls and can survive stressful conditions, much like cysts. When conditions permit, the zygote divides by meiosis to produce haploid cells that increase in number via mitotic cell divisions.

Sporic Life Cycles Many multicellular green and brown seaweeds display a **sporic life cycle**, which is also known as alternation of generations (Figure 28.26). Giant kelps and some other protists having sporic life cycles produce two types of multicellular organisms: a haploid gametophyte generation that produces gametes (sperm or eggs) and a diploid sporophyte generation that produces spores by the process of meiosis (Figure 28.26a). This type of life cycle takes its name from the characteristic production of spores as the result of meiosis. Each of the two types of multicellular organisms can adapt to distinct habitats or seasonal conditions, thus allowing protists to occupy more types of environments for longer periods.

Many red seaweeds display a variation of the sporic life cycle that involves alternation of three distinct multicellular generations (Figure 28.26b). This unique type of sexual life cycle has evolved due to the lack of flagella on red algal sperm. Because these sperm are unable to swim to eggs, fertilization occurs only when sperm carried by ocean currents happen to drift close to

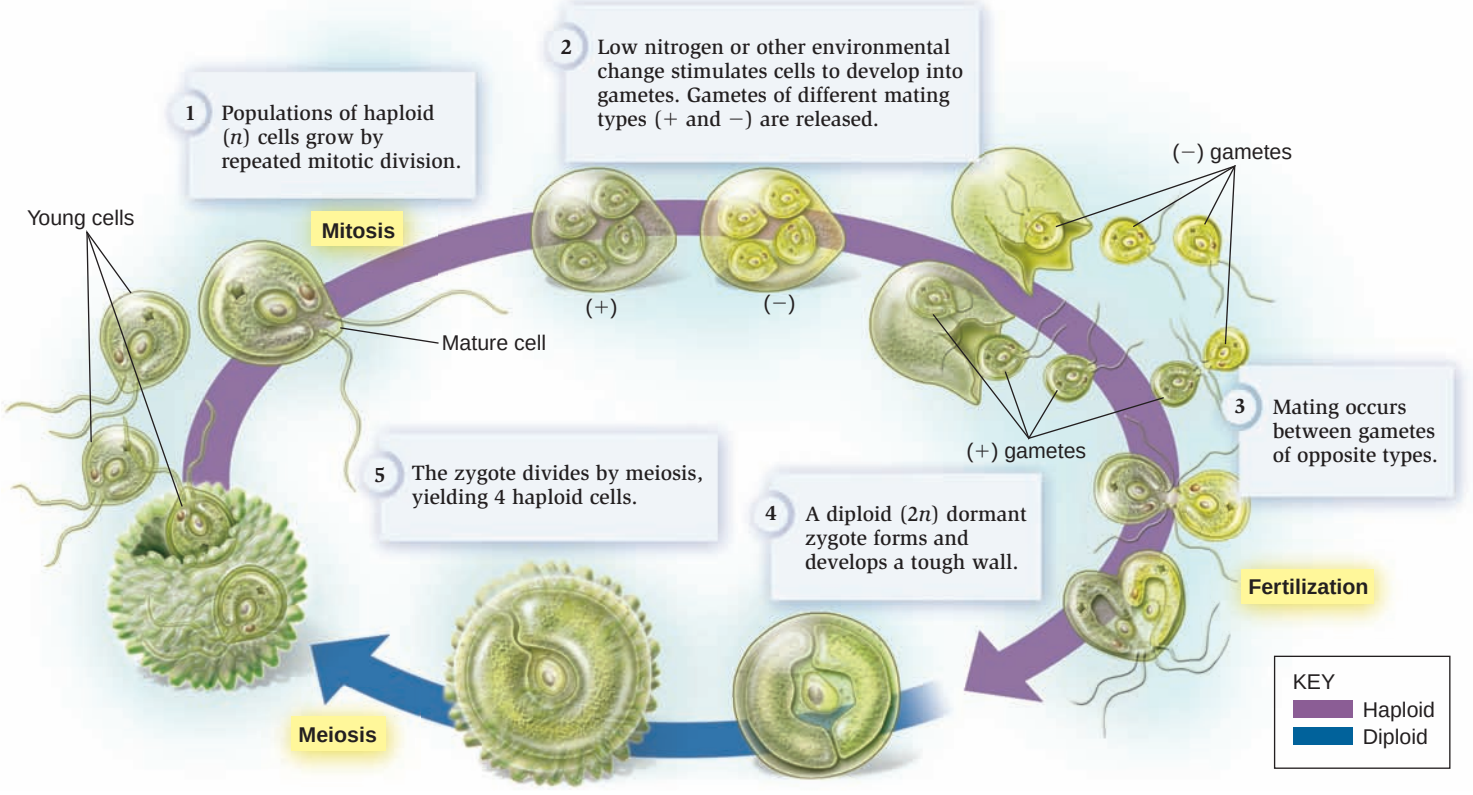

Figure 28.25 **Zygotic life cycle, illustrated by the unicellular flagellate genus *Chlamydomonas*.** In *Chlamydomonas*, most cells are haploid; only the zygote is diploid.

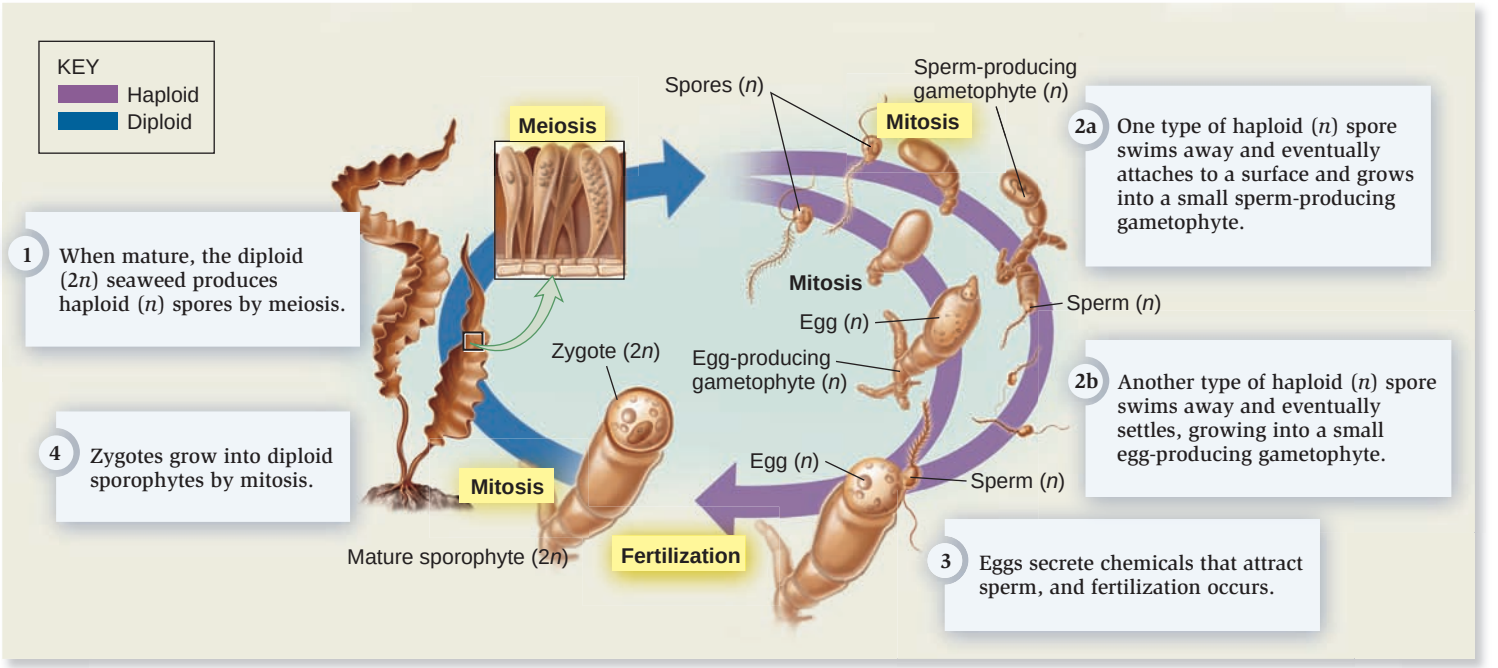
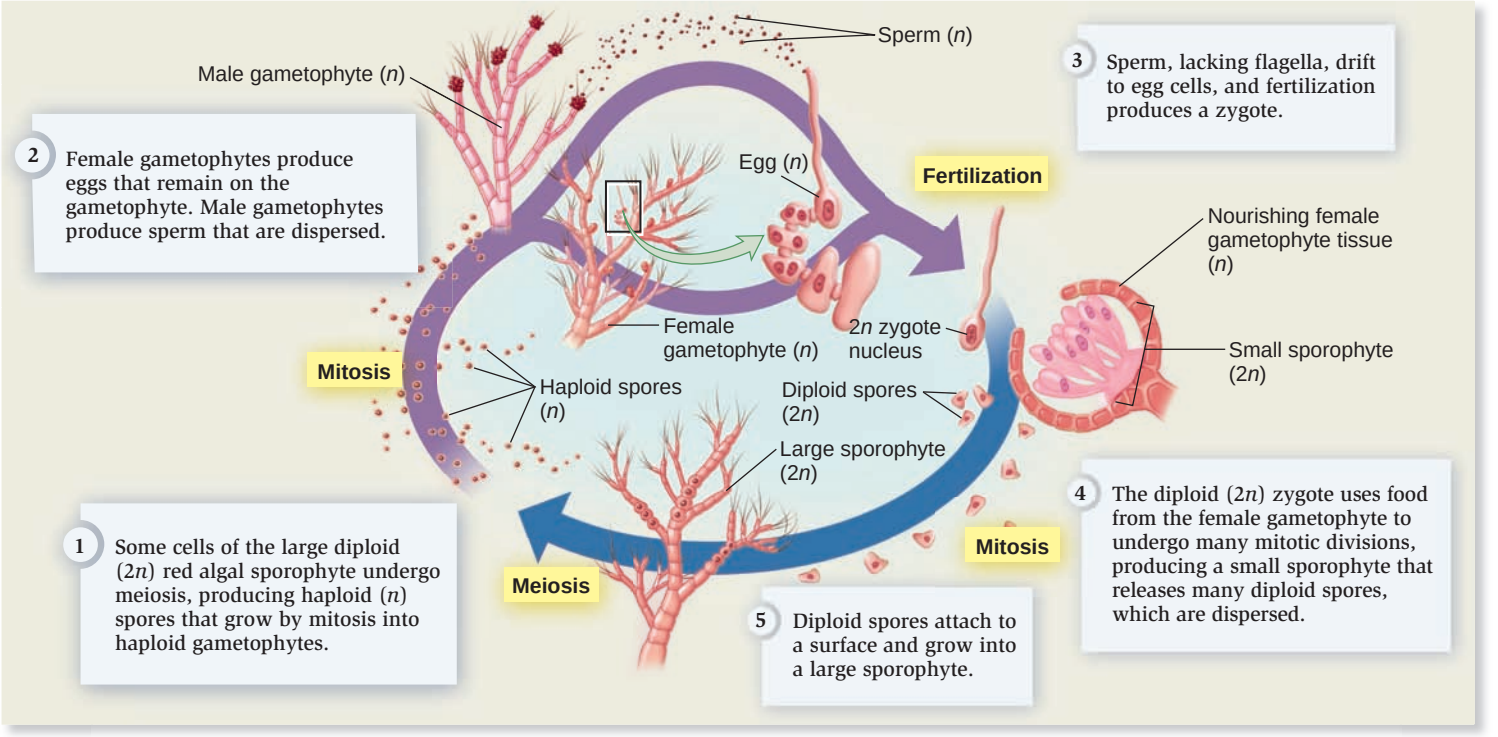


(a) *Laminaria* life cycle—alternation of 2 generations



(b) *Polysiphonia* life cycle—alternation of 3 generations

Figure 28.26 **Sporic life cycles.** **(a)** Sporic life cycle with two alternating generations, illustrated by the brown seaweed *Laminaria*. **(b)** Sporic life cycle involving three alternating generations, illustrated by the red seaweed *Polysiphonia*.

eggs. As a consequence, fertilization can be rare. Many red algae therefore make millions of spores that are produced by two distinct sporophyte generations. A small sporophyte produces diploid spores, while a larger sporophyte produces haploid spores.

Gametic Life Cycle and the Problem of Diatom Size Diatoms are one of the relatively few types of protists known to display a **gametic life cycle** (Figure 28.27). In gametic life cycles, all cells except the gametes are diploid, and gametes are produced by meiosis. Sexual reproduction in diatoms not only increases their genetic variability, but it also has another major benefit related to cell size.

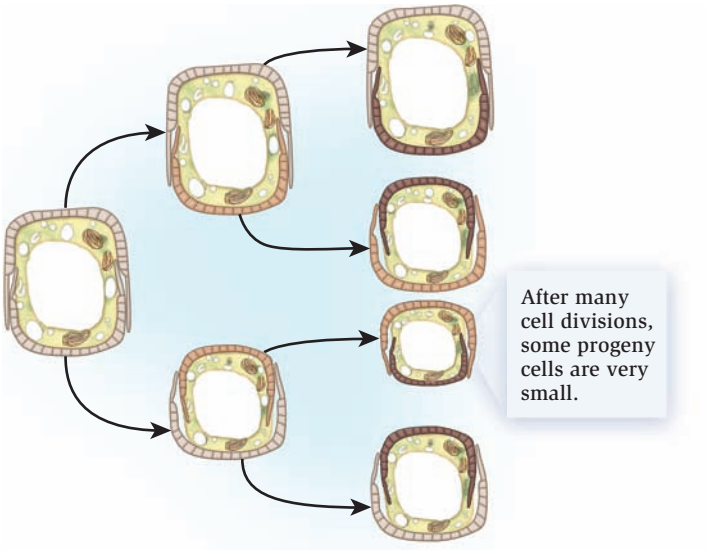
In many diatoms, one daughter cell arising from mitosis is smaller than the other, and it is also smaller than the parent

cell. This happens because diatom cell walls are composed of two overlapping halves, much like two-part round glass laboratory dishes having lids that overlap bottoms. After each mitotic division, each daughter cell receives one-half of the parent cell wall. The daughter cell that inherits a larger, overlapping parental "lid" then produces a new "bottom" that fits inside. This daughter cell will be the same size as its parent. However, the daughter cell that inherits the parental "bottom" uses this wall half as its lid and produces a new, even smaller "bottom." This cell will be smaller than its sibling or parent. Consequently, after many such mitotic divisions, the average cell size of diatom populations often declines over time (Figure 28.27a). If diatom cells become too small, they cannot survive.

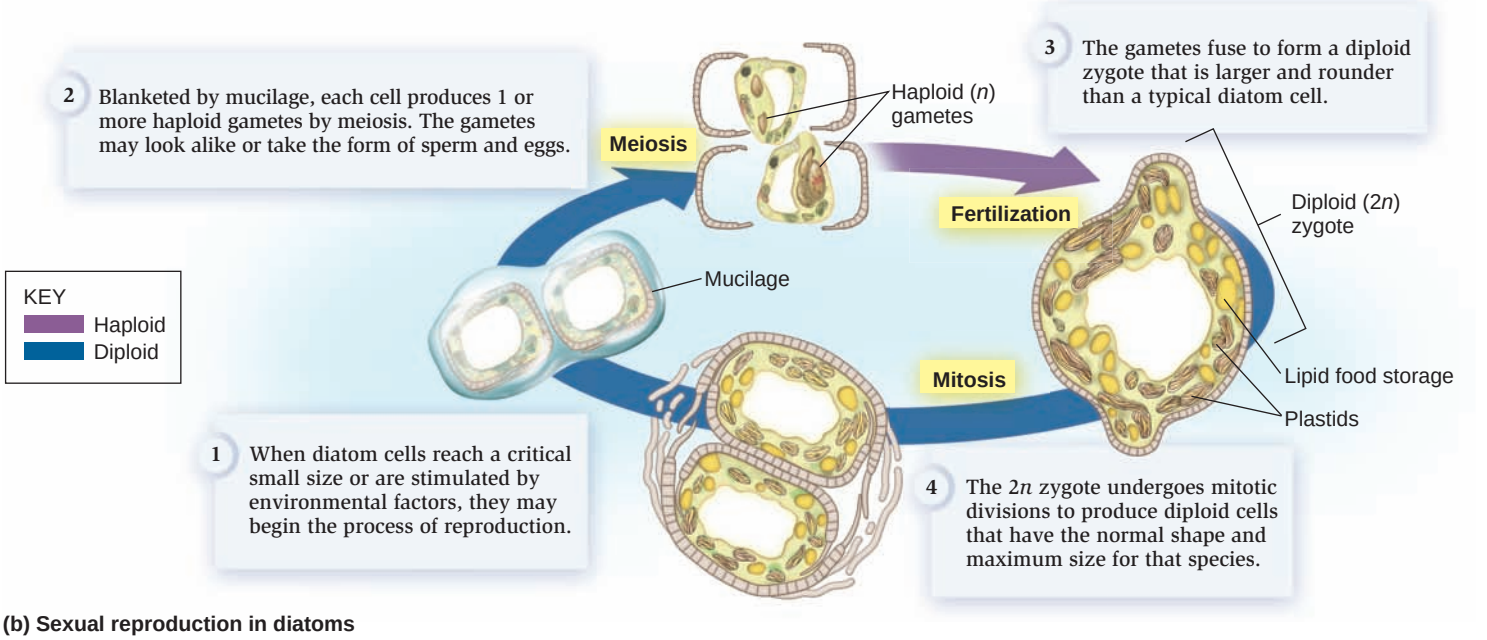
Sexual reproduction helps solve this problem by allowing diatom species to recover maximal cell size. Diatom cells mate within a blanket of mucilage, each partner undergoing meiotic divisions to produce gametes. The large, spherical diatom zygotes that result from fertilization (Figure 28.27b) later undergo a series of mitotic divisions to produce new diatom cells having the maximal size for the species.

Ciliate Sexual Reproduction Among protists, ciliates have one of the most complex sexual processes known. Ciliates are unusual in having two types of nuclei: one or more smaller micronuclei and a single large macronucleus. Micronuclei, which are diploid, do not transcribe genes during cell growth; their role is to transmit the genome to the next generation during sexual reproduction. Macronuclei, which have many copies of the genome, a condition known as polyploidy, serve as the source of information for cell function, Macronuclei divide when ciliates reproduce asexually by mitosis (Figure 28.28a).

Sexual reproduction in ciliates involves a process known as conjugation (Figure 28.28b).

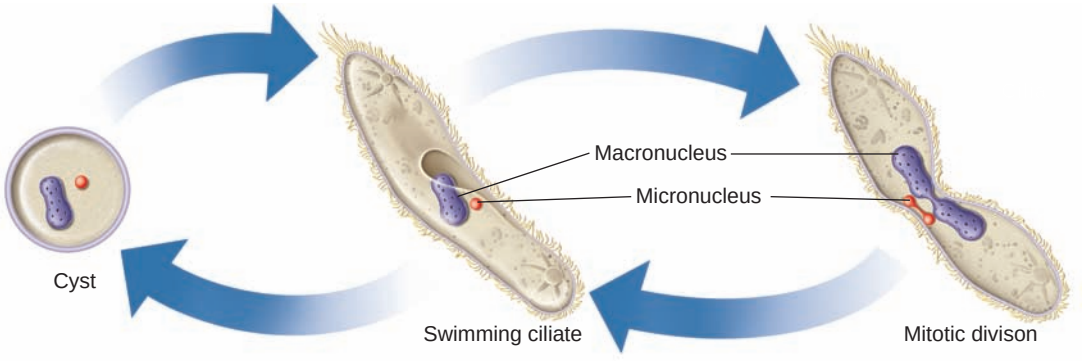


(a) Asexual reproduction in diatoms

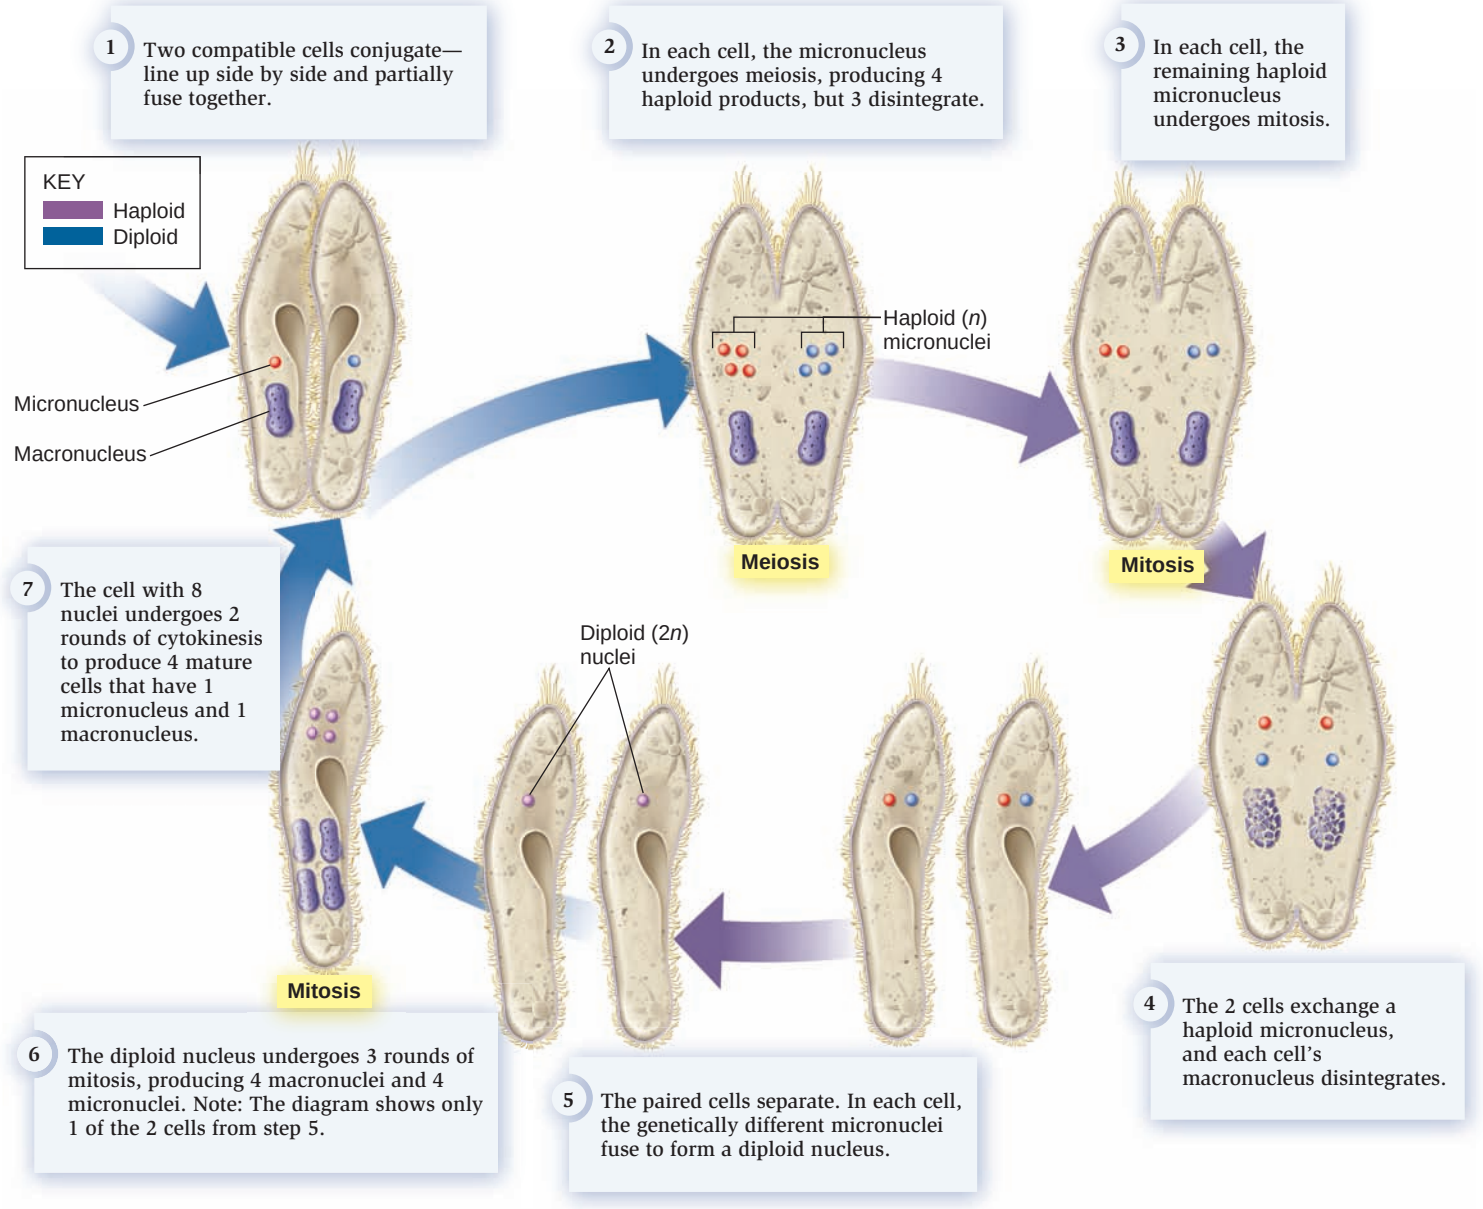


(b) Sexual reproduction in diatoms

Figure 28.27 Gametic life cycle, as illustrated by diatoms. **(a)** Diatom asexual reproduction involves repeated mitotic division. Because a new bottom cell-wall piece is always synthesized, asexual reproduction may eventually cause the mean cell size to decline in a diatom population. **(b)** Small cell size may trigger sexual reproduction, which regenerates maximal cell size.



(a) Asexual reproduction by mitosis and cysts



(b) Sexual reproduction by conjugation

Figure 28.28 **Ciliate reproduction.** **(a)** The asexual reproduction process in ciliates. **(b)** The sexual reproduction process in the ciliate *Paramecium caudatum*, which involves conjugation.

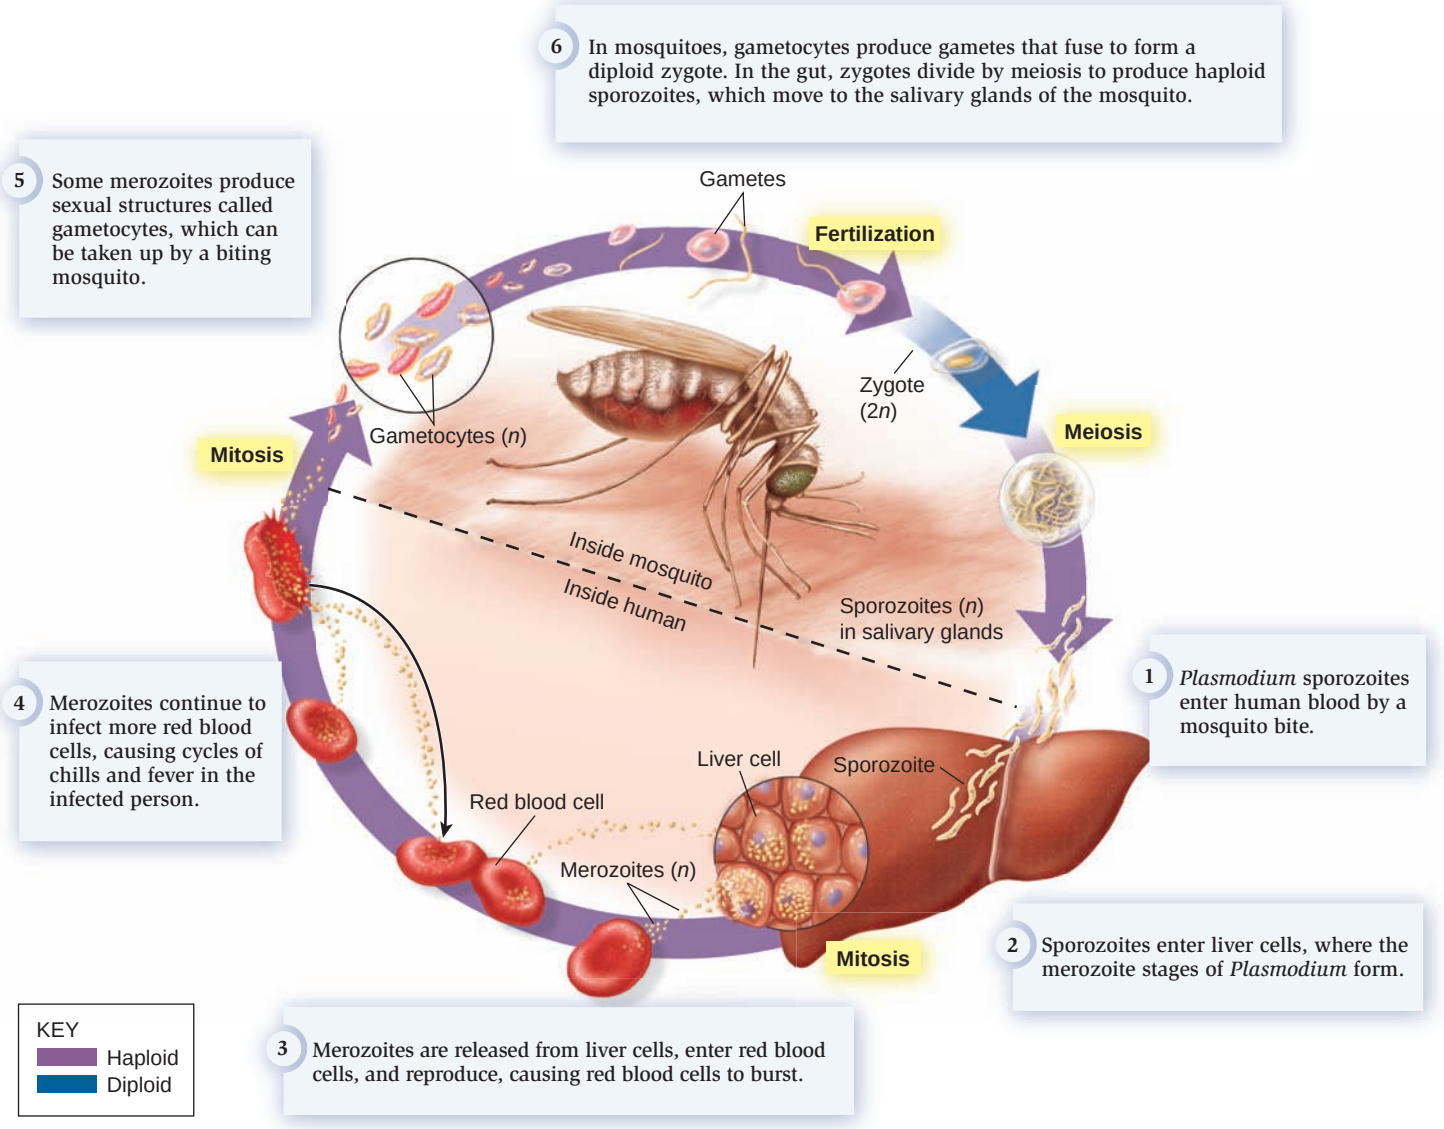


Figure 28.29 **Diagram of the life cycle of *Plasmodium falciparum*, the agent of malaria.** This life cycle requires two alternate hosts, humans and *Anopheles* mosquitoes.

Concept check: *In which of the hosts does sexual mating of P. falciparum gametes occur?*

Parasitic Protists May Use Alternate Hosts for Different Life Stages

Parasitic protists are notable for often using more than one host organism, in which different life stages occur. The malarial parasite genus *Plasmodium* is a prominent example. About 40% of humans live in tropical regions of the world where malaria occurs, and as noted earlier, millions of infections and human deaths result each year. Malaria is particularly deadly for young children; in Africa alone, more than 1 million children die each year from malaria. In addition to humans, the malarial parasite's alternate host is the mosquito classified in the genus *Anopheles*. Though insecticides can be used to control mosquito populations and though antimalarial drugs exist, malarial parasites can develop drug resistance. Experts are concerned that cases may double in the next 20 years.

When a mosquito bites a human, *Plasmodium* enters the bloodstream as a life stage known as a sporozoite (Figure 28.29). The sporozoites eventually reach the victim's liver and enter the liver cells. Following several cycles of cell division, a life stage known as the merozoite develops and is released from liver cells. Merozoites have protein complexes at their front ends, or apices, that allow them to invade human red blood cells. (The presence of these apical complexes gives rise to the phylum name Apicomplexa.) The merozoites consume the hemoglobin in red blood cells. While living within red blood cells, they form rings, which can be visualized by staining and the use of a microscope, allowing diagnosis. Merozoites reproduce asexually, generating large numbers of new merozoites that synchronously break out of red blood cells at intervals of 48 or 72 hours. These merozoite reproduction cycles correspond to cycles of chills and fever experienced by the infected person.

Some merozoites produce sexual structures—gametocytes—which are transmitted to a female mosquito as she bites.

Within the mosquito's body, the gametocytes produce gametes and fertilization occurs, yielding a zygote, the only diploid cell in *Plasmodium*'s life cycle. Within the mosquito gut, the zygote undergoes meiosis, generating structures filled with many sporozoites, the stage that can be transmitted to a new human host. Sporozoites move to the mosquito's salivary glands, where they remain until injected into a human host when the mosquito feeds.

In recent years, genomic information that has added to our knowledge of these life stages is helping medical scientists to develop new ways to prevent or treat malaria. In the case of *P. falciparum*, genomic data have already highlighted potential new pharmaceutical approaches. About 550 (some 10%) of the nuclear-encoded proteins are likely imported into a nonphotosynthetic plastid known as an apicoplast, where they are needed for fatty-acid metabolism and other processes. *P. falciparum* and some other apicomplexan protists possess plastids because they are descended from algal ancestors that had photosynthetic plastids. Because plastids are not present in mammalian cells, enzymes in apicoplast pathways are possible targets for development of drug therapy. Mammals also lack calcium-dependent protein kinases (CDPKs), enzymes that are essential to *P. falciparum*'s sexual development, offering another potential drug target.

Summary of Key Concepts

28.1 An Introduction to Protists

- Protists are eukaryotes that are abundant in moist habitats, and most are microscopic in size.
- Protists are often informally labeled according to their ecological roles: Algae are mostly photosynthetic protists; protozoa are heterotrophic protists that are often mobile; and fungus-like protists resemble true fungi. (Figure 28.1)
- Protists are particularly diverse in aquatic habitats, occurring as small floating or swimming phytoplankton, attached members of the periphyton, and more complex macroalgae (seaweeds). (Figure 28.2)
- Microscopic protists propel themselves by means of flagella (flagellates), cilia (ciliates), pseudopodia (amoebae), or by gliding across surfaces. (Figures 28.3, 28.4)

28.2 Evolution and Relationships

- Modern phylogenetic analysis has revealed that protists do not form a monophyletic group; instead, many can be classified into several eukaryotic supergroups. (Figure 28.5)
- The supergroup Excavata includes flagellate protists characterized by a feeding groove, the kinetoplastids and euglenoids, some of which are photosynthetic. (Figures 28.6, 28.7, 28.8)
- Land plants are related to green algae and red algae (having primary plastids) and possibly haptophytes and cryptomonads (featuring secondary plastids). (Figures 28.9, 28.10, 28.11, 28.12, 28.13, 28.14)
- The supergroup Alveolata includes the ciliates, apicomplexans, and dinoflagellates, whose cells feature alveoli. Many dinoflagellates display secondary plastids, and some feature tertiary plastids. (Figures 28.15, 28.16)
- The supergroup Stramenopila includes diverse protists whose flagella have strawlike hairs that aid in swimming. Stramenopiles include diatoms, giant kelps, and other groups of algae, as well as some fungus-like protists. (Figures 28.17, 28.18)
- The supergroup Rhizaria consists of flagellates and amoebae with filose pseudopodia. Three prominent phyla are Chlorarachniophyta, with secondary green plastids; mineral-shelled Radiolaria; and Foraminifera, with calcium carbonate shells. (Figure 28.19)
- The supergroup Amoebozoa is composed of many types of amoebae and includes the parasite *Entamoeba histolytica* and slime molds such as *Dictyostelium discoideum*.
- The supergroup Opisthokonta includes organisms that produce swimming cells having a single posterior flagellum. It includes the fungal and animal kingdoms and choanoflagellate protists related to the ancestry of animals. (Figures 28.20, 28.21, Table 28.1)

28.3 Nutritional and Defensive Adaptations

- Protists display four basic types of nutrition: phagotrophs rely on particle feeding; osmotrophs absorb small organic molecules; photoautotrophs make their own organic food by using light energy; and mixotrophs use both autotrophy and heterotrophy to obtain nutrients. Heterotrophic protists may function as decomposers or parasites. (Figure 28.22)
- Protists possess defensive adaptations such as protective cell coverings, sharp projectiles, light flashes, and toxic compounds. Dinoflagellates are particularly important toxin producers, and aquatic ecologists found that populations of the unicellular dinoflagellate genus *Pfiesteria* kill fishes by using a toxin that can also harm human cells. (Figure 28.23)

28.4 Reproductive Adaptations

- Protist populations grow by means of asexual reproduction involving mitosis, and many persist through unfavorable conditions as tough-walled cysts. (Figure 28.24)
- Protists having zygotic life cycles often use tough-walled zygotes to survive unfavorable conditions. (Figure 28.25)
- Protists displaying sporic life cycles are able to occupy multiple habitats because they produce two or more alternating life stages having differing environmental preferences. (Figure 28.26)
- Diatoms, which have a gametic life cycle, use sexual reproduction to solve a cell size problem that originates from their unique mode of asexual cell division. (Figure 28.27)
- Ciliates display a unique type of sexual reproduction (conjugation) that involves the exchange of genetic material between a mating pair of cells. (Figure 28.28)
- Parasitic protists may have life cycles involving alternate hosts. One example is *Plasmodium*, the malarial agent, whose alternate hosts are humans and mosquitoes. (Figure 28.29)

Assess and Discuss

Test Yourself

1. If you were studying the evolution of animal-specific cell-to-cell signaling systems, from which of the following would you choose representative species to observe?
   a. Rhodophyta
   b. Excavata
   c. Choanomonada
   d. Radiolaria
   e. Chlorophyta
2. If you were studying the origin of land plant traits, which of the following groups would you study?
   a. green algae
   b. radiolarians
   c. choanoflagellates
   d. diatoms
   e. ciliates
3. Which informal ecological group of protists includes photoautotrophs?
   a. protozoa
   b. algae
   c. fungus-like protists
   d. ciliates
   e. all of the choices listed
4. How would you recognize a primary plastid? It would:
   a. have one envelope membrane.
   b. have two envelope membranes.
   c. have more than two envelope membranes.
   d. lack pigments.
   e. be golden brown in color.
5. What organisms have tertiary plastids?
   a. certain stramenopiles
   b. certain euglenoids
   c. certain cryptomonads
   d. certain opisthokonts
   e. certain dinoflagellates
6. What is unusual about mixotrophs?
   a. They have no plastids, but they occur mixed in communities with autotrophs.
   b. They have mixed heterotrophic and autotrophic nutrition.
   c. Their cells contain a mixture of red and green plastids.
   d. Their cells contain a mixture of haploid and diploid nuclei.
   e. They consume a mixed diet of algae.
7. What advantages do diatoms obtain from sexual reproduction?
   a. increased genetic variability
   b. increased ability of populations to respond to environmental change
   c. evolutionary potential
   d. regeneration of maximal cell size for the species
   e. all of the above
8. What are trichocysts?
   a. hairs on flagella
   b. membrane sacs beneath the cell surface
   c. tough-walled asexual cells
   d. spearlike defensive structures shot from cells under attack
   e. special types of survival cysts
9. How do accessory pigments benefit autotrophic protists?
   a. They provide camouflage, so herbivores cannot see algae.
   b. They absorb underwater light and transfer the energy to chlorophyll *a* for use in photosynthesis.
   c. They attract aquatic animals that carry gametes between seaweeds.
   d. They absorb UV light that would harm the photosynthetic apparatus.
   e. All of the above are correct.
10. What are the two alternate hosts of the malarial parasite *Plasmodium falciparum*?
    a. humans and ticks
    b. ticks and mosquitoes
    c. humans and *Anopheles* mosquitoes
    d. humans and all types of mosquitoes
    e. sporophytes and gametophytes

Conceptual Questions

1. Explain why protists are classified into multiple supergroups, rather than a single kingdom or phylum.
2. Why have molecular biologists sequenced the genomes of several parasitic protists?
3. Why are protistan cysts important to epidemiologists, biologists who study the spread of disease?

Collaborative Questions

1. Imagine you are studying an insect species and you discover that the insects are dying of a disease that results in the production of cysts of the type that protists often generate. Thinking that the cysts might have been produced by a parasitic protist that could be used as an insect control agent, how would you go about identifying the disease agent?
2. Imagine you are part of a marine biology team seeking to catalogue the organisms inhabiting a threatened coral reef. The team has found two new seaweeds (macroalgae), each of which occurs during a particular time of the year when the water temperature differs. You suspect that the two seaweeds might be different generations of the same species that have differing optimal temperature conditions. How would you go about testing your hypothesis?

Chapter Outline

Plants and the Conquest of Land

29

A temperate rain forest in Olympic National Park in Washington State, containing diverse plant phyla.

When thinking about plants, people envision lush green lawns, shady street trees, garden flowers, or leafy fields of valuable crops. On a broader scale, they might imagine dense rain forests (see chapter-opening photo), vast grassy plains, or tough desert vegetation. Shopping in the produce section of the local grocery store may remind us that plant photosynthesis is the basic source of our food. Just breathing crisp fresh air might bring to mind the role of plants as oxygen producers—the ultimate air fresheners. Do you start your day with a "wake-up" cup of coffee, tea, or hot chocolate? Then you may appreciate the plants that produce these and many other materials we use in daily life: medicines, cotton, linen, wood, bamboo, cork, and even the paper on which this textbook has been printed.

In addition to their importance to humans and modern ecosystems, plants have played dramatic roles in the Earth's past. Throughout their evolutionary history, diverse plants have influenced Earth's atmospheric chemistry, climate, and soils. Plants have also affected the evolution of many other groups of organisms, including humans. In this chapter, we will survey the diversity of modern plant phyla and their distinctive features. This chapter also explains how early plants adapted to land and how plants have continued to adapt to changing terrestrial environments. During this process, we will gain insight into descent with modification, one of the main principles of evolution and diversity.

29.1 Ancestry and Diversity of Modern Plants

Several hundred thousand modern species are formally classified into the kingdom Plantae, informally known as the plants or land plants (Figure 29.1). Plants are multicellular eukaryotic organisms composed of cells having plastids, and plants primarily live on land. Molecular and other evidence indicates that the plant kingdom evolved from green algal ancestors that lived in aquatic habitats such as lakes or ponds. **Plants** are distinguished from their modern algal relatives by the presence of traits that foster survival in terrestrial conditions, which are drier, sunnier, hotter, colder, and less physically supportive than aquatic habitats. In this section, we will examine the modern algae that are most closely related to plants and survey the diverse phyla of living land plants. This process reveals how plants gradually acquired diverse structural, biochemical, and reproductive adaptations that foster survival on land.

Modern Green Algae Are Closely Related to the Ancestors of Land Plants

Molecular, biochemical, and structural data indicate that the kingdom Plantae (plant kingdom) originated from a photosynthetic protist ancestor having a relatively complex body, a filament of cells with side branches. Such a body is characteristic of the modern green algal genera *Chara* and *Coleochaete* and their close relatives, the complex **charophyceans** (Figure 29.2a). All charophyceans have features in common with land plants, but complex charophyceans display several derived features shared with land plants. Examples of these shared features are a distinctive type of cytokinesis, intercellular connections known as plasmodesmata (see Chapter 10), and sexual reproduction by means of an egg and smaller sperm (see Figure 29.1). For this reason, *Chara* and *Coleochaete* are good sources of information

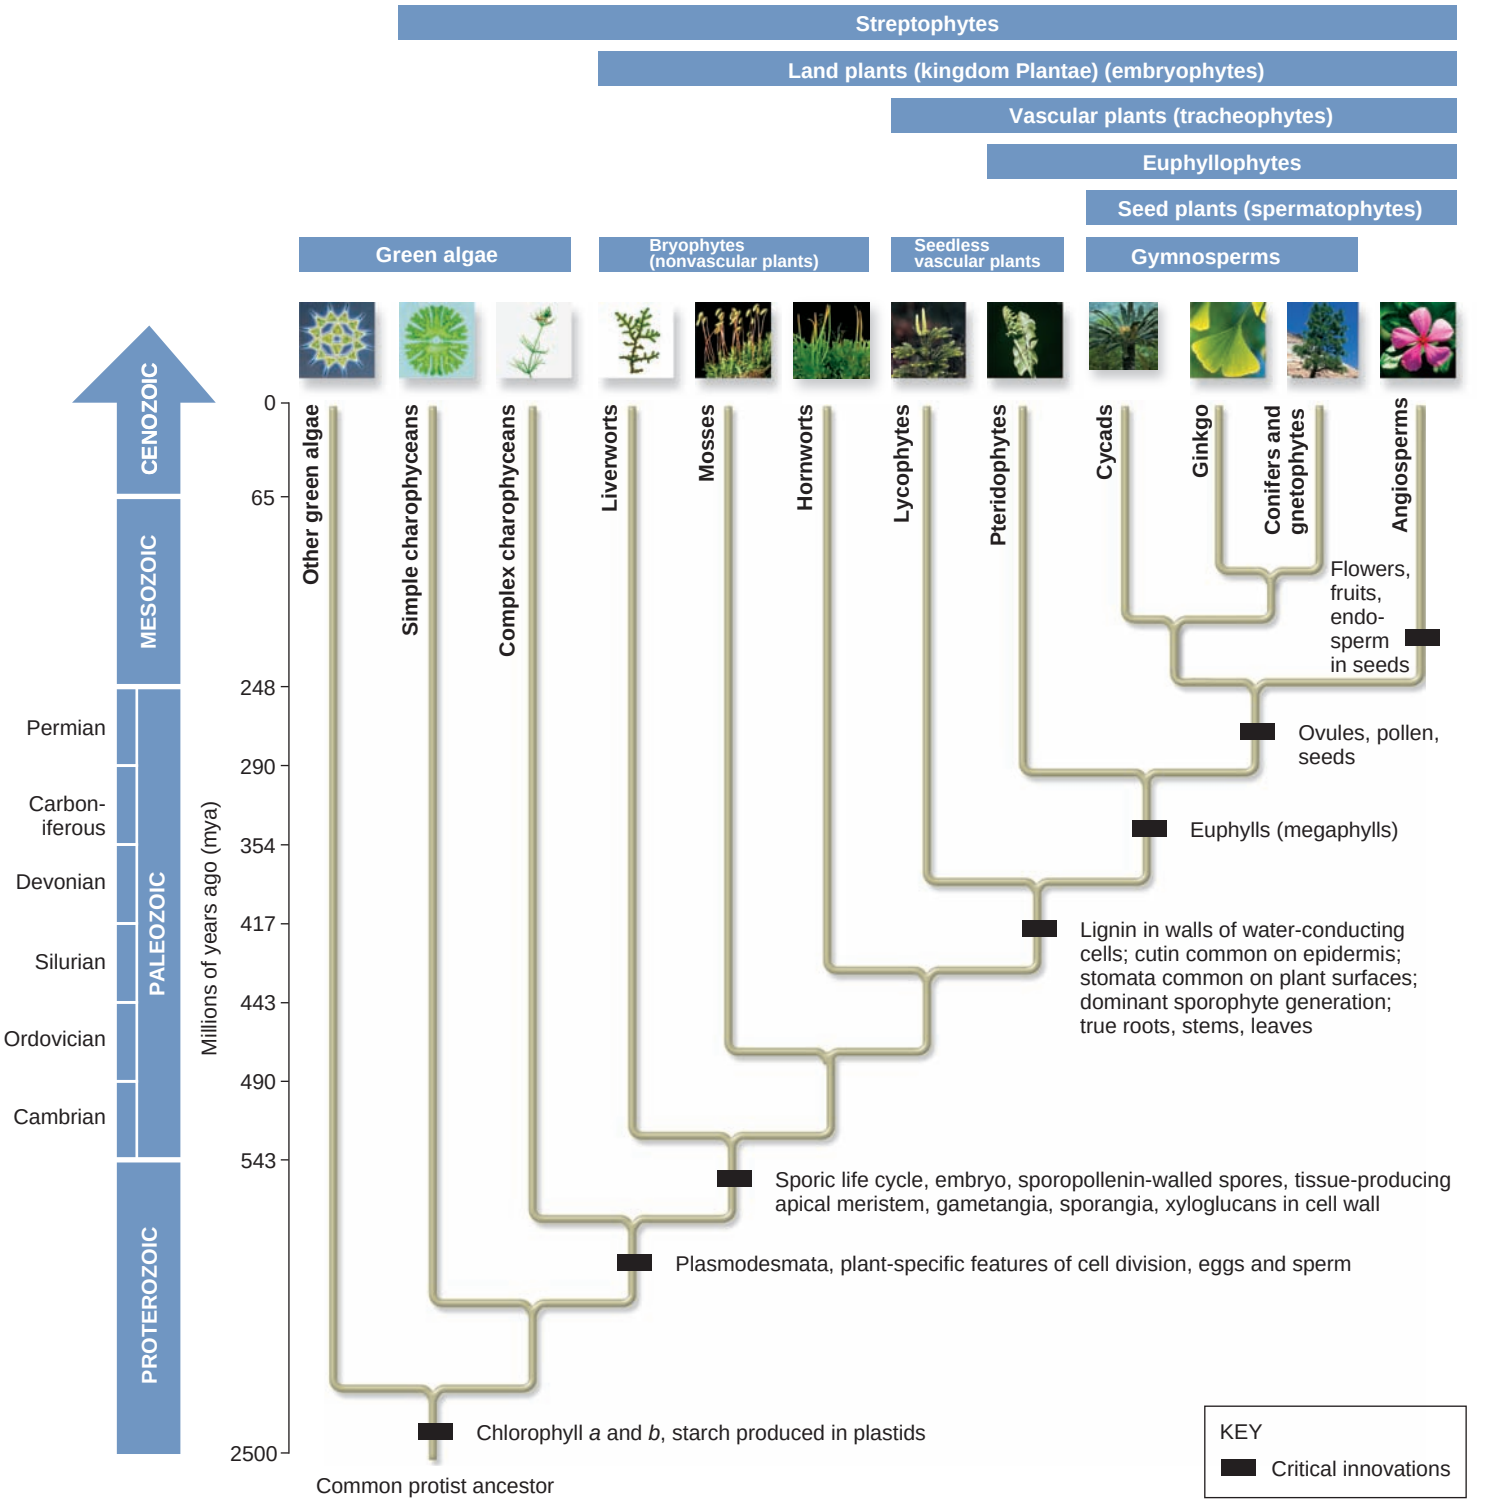

Figure 29.1 **Evolutionary relationships of the modern plant phyla.** Land plants gradually acquired diverse structural, biochemical, and reproductive adaptations, allowing them to better survive in terrestrial habitats.

about the ancestors of land plants. By contrast, the simpler charophyceans have less complex reproduction and bodies consisting of single cells or unbranched filaments. Examples include the beautiful desmids such as *Micrasterias radiosa* and the flagellate *Mesostigma viride* (Figure 29.2b). Study of both complex and simpler charophyceans helps to illustrate how traits of early plants arose in a sequence of evolutionary events.

By themselves the charophyceans do not form a monophyletic group, but together with land plants, they form a clade known as the streptophytes, which are related to other green algae (see Figure 29.1). Streptophytes and other green algae share distinctive characters such as cellulose-rich cell walls and green, starch-bearing chloroplasts that contain the accessory pigments chlorophyll *b* and β-carotene. Even so, the land plants

(b) Simple charophyceans: *Micrasterias radiosa* (left) and *Mesostigma viride* (right)

Figure 29.2 Charophycean green algal relatives of the land plants. Charophycean algae inhabit freshwater lakes and ponds, and they display structural, reproductive, biochemical, and molecular features in common with land plants. **(a)** Complex charophyceans with branched filaments share more traits with land plants than do simpler charophyceans illustrated in **(b)**.

display several common features that distinguish them from green algae, even their closest charophycean relatives.

Distinctive Features of the Land Plants

The features that distinguish land plants represent early adaptations to the land habitat. For example, the bodies of all land plants are primarily composed of three-dimensional tissues, defined as close associations of cells of the same type. Tissues provide land plants with an increased ability to avoid water loss at their surfaces. That's because bodies composed of tissues have lower surface area/volume ratios than do branched filaments. Land plant tissues arise from one or more actively dividing cells that occur at growing tips. Such localized regions of cell division are known as **apical meristems**. The tissue-producing apical meristems of land plants are able to produce relatively thick, robust bodies able to withstand drought and mechanical stress and to produce tissues and organs having specialized functions.

The land plants also have distinctive reproductive features. These include a life cycle involving alternation between two types of bodies; embryos that depend on maternal tissues during early development; reproductive cells whose tough walls allow dispersal through dry air; and specialized structures that generate, protect, and disperse reproductive cells. The following survey of modern plant phyla and their distinctive features illustrates how these and other fundamental plant features evolved.

Modern Land Plants Can Be Classified into Ten Phyla

Plant systematists use molecular and structural information from living and fossil plants to classify plants into phyla, also known as divisions. In this textbook, 10 phyla of living land plants are described: (1) the plants informally known as **liverworts** (formally called Hepatophyta), (2) **mosses** (Bryophyta), (3) **hornworts** (Anthocerophyta), (4) **lycophytes** (Lycopodiophyta), (5) **pteridophytes** (Pteridophyta), (6) **cycads** (Cycadophyta), (7) **ginkgos** (Ginkgophyta), (8) **conifers** (Coniferophyta), (9) **gnetophytes** (Gnetophyta), and (10) the **flowering plants**, also known as **angiosperms** (Anthophyta) (see Figure 29.1). Fossils reveal that additional plant phyla once lived but are now extinct.

Phylogenetic information suggests that the modern plant phyla arose in a particular sequence (see Figure 29.1). Liverworts diverged first, mosses diverged next, and hornworts seem to be closely related to the vascular plants. The vascular plants are distinguished by internal water and nutrient-conducting tissues that also provide structural support. Lycophytes are sister to all of the other modern vascular plants, pteridophytes arose next, and then seed plants. Our survey of these modern plant phyla reveals how plants acquired more adaptations to life on land.

Liverworts, Mosses, and Hornworts Are the Simplest Land Plants

Liverworts, mosses, and hornworts are Earth's simplest land plants (Figures 29.3, 29.4, and 29.5), and each forms a distinct, monophyletic group. There are about 6,500 species of modern liverworts, 12,000 or more species of mosses, and about 100 species of hornworts. Collectively, liverworts, mosses, and hornworts are known informally as the **bryophytes** (from the Greek *bryon,* meaning moss, and *phyton,* meaning plant). The bryophytes do not form a clade, but the term bryophyte is useful for expressing common structural, reproductive, and ecological features of liverworts, mosses, and hornworts. For example, the bryophytes are all relatively small in stature and are most common and diverse in moist habitats because they lack traits allowing them to grow tall or reproduce in dry places.

Because bryophytes diverged early in the evolutionary history of land plants (see Figure 29.1), they serve as models of the

Mature sporophytes generate spores, then release them. **(b)** A close-up of *M. polymorpha* showing surface cups that contain multicellular, frisbee-shaped asexual structures known as gemmae that are dispersed by wind and grow into new liverworts. **(c)** A species of liverwort having leaflike structures and so known as a leafy liverwort.

Concept check: *Why do you think liverworts produce their spores on raised structures?*

earliest terrestrial plants. Bryophytes display apical meristems that produce specialized tissues and other features that evolved early in the history of land plants, such as the sporic life cycle. A comparison of the life cycle of aquatic charophyceans with that of bryophytes reveals the bryophyte life cycle's adaptive value on land.

The charophycean algae display a **zygotic life cycle** in which the diploid generation consists of only one cell, the zygote (Figure 29.6a). Zygotic life cycles take their name from the observation that the zygote is the only cell that undergoes meiosis (see Figure 28.25). By contrast, sexual reproduction in bryophytes and all other plants follows what is called a **sporic life cycle**, in which there is an alternation of generations (see Figures 15.15c and 28.26). In the sporic life cycle, meiosis results in the formation of spores, which are reproductive cells that allow organisms to disperse in the environment (Figure 29.6b). **Alternation of generations** means that land plants produce two types of multicellular bodies that alternate in time. These two types of bodies are known as the diploid, spore-producing **sporophyte** generation and the haploid, gamete-producing **gametophyte** generation. Biologists think the plant life cycle originated by a delay in zygotic meiosis, with the result

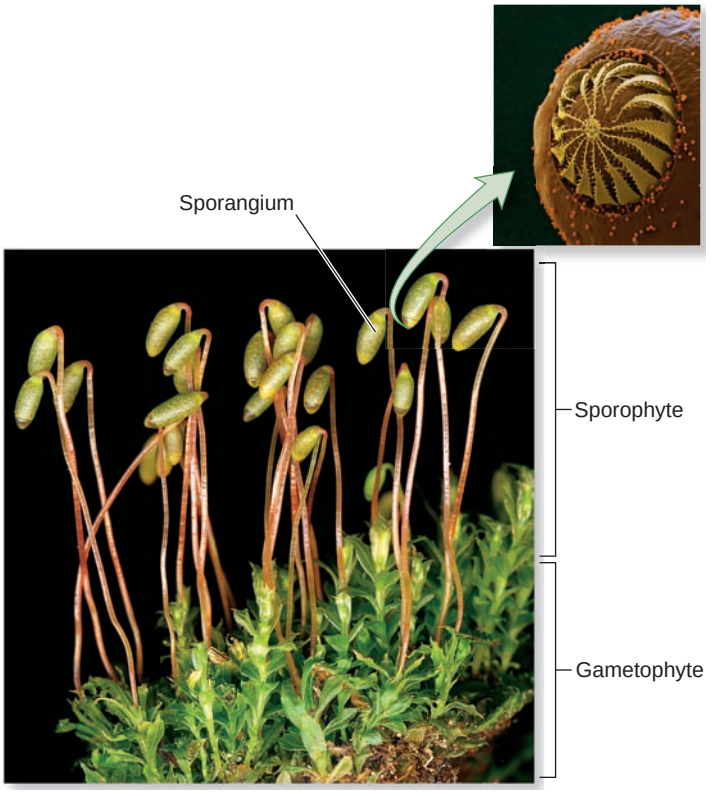

Figure 29.4 **Mosses.** The common moss genus *Mnium* has a leafy green gametophyte (multicellular body that generates gametes) and an unbranched, dependent sporophyte that bears a spore-producing sporangium at its tip. Inset: This SEM shows that the tips of moss sporangia are often specialized, so spores are sprinkled into the wind, rather than being released all at once.

Concept check: *Why might it be advantageous for a moss sporophyte to release spores gradually?*

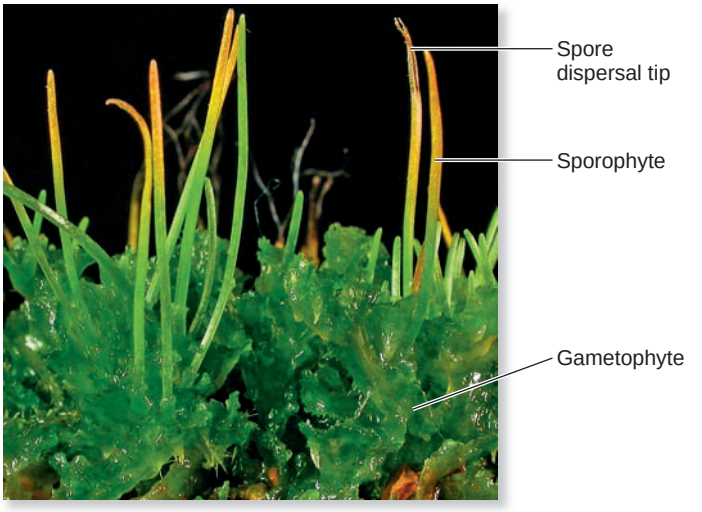

Figure 29.5 **Hornworts.** Sporophytes of hornworts generally grow up into the air, whereas the gametophytes grow close to the ground. Hornwort sporophytes become mature and open at the top, dispersing spores.

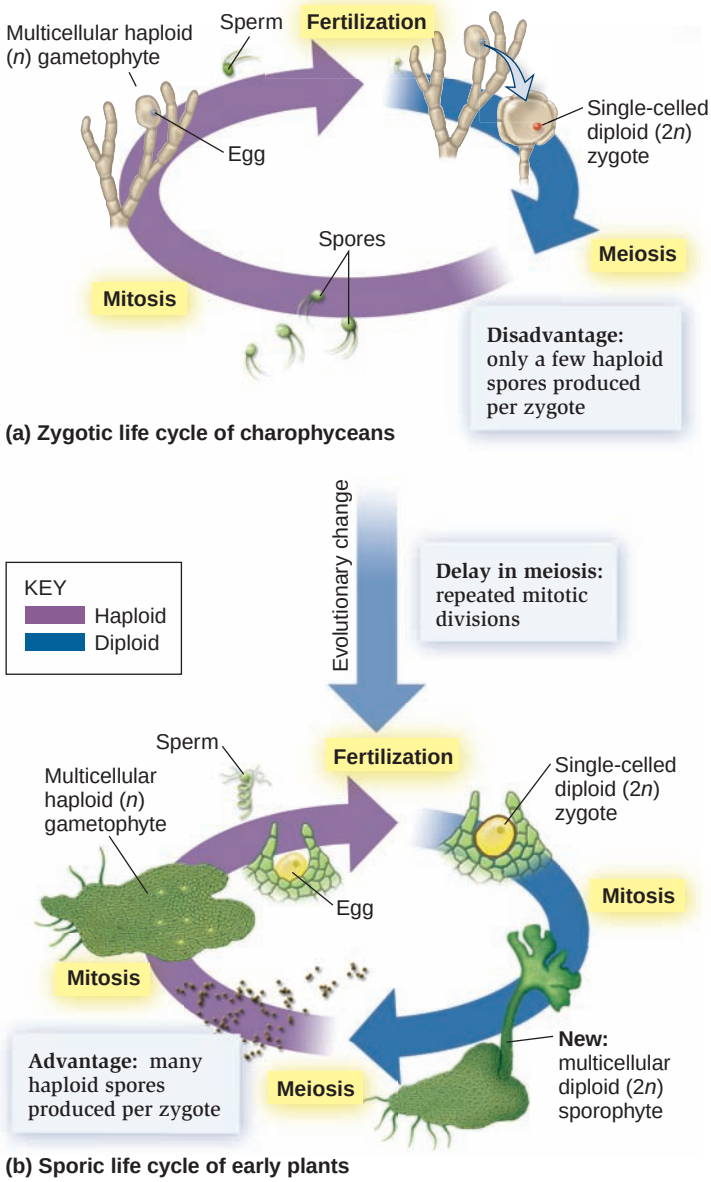

Figure 29.6 Origin of the plant life cycle.

that the diploid generation became multicellular before undergoing meiosis. For the earliest land plants, having a multicellular diploid generation provided several advantages in coping with terrestrial conditions. Can you guess what these advantages might be? A closer look at the process of sexual reproduction in bryophytes reveals the answer and also highlights ways in which bryophytes differ from other plants.

Bryophyte Reproduction Illustrates Early Plant Adaptations to Life on Land

As noted, bryophytes and other land plants display alternation of generations (Figure 29.7). On land, a multicellular diploid sporophyte generation is advantageous because it allows a single plant to disperse widely by using meiosis to produce numerous, genetically variable haploid spores. Each spore has the potential to grow into a gametophyte. In bryophytes, the gametophyte generation is generally green and photosynthetic and thus has a major function of organic food production. The more spores that sporophytes produce, the greater the numbers of gametophytes, helping bryophytes to spread in their environments and thereby increase in fitness. We next discuss how gametophytes and sporophytes function together during the life cycle of a bryophyte, starting with gamete production.

Gametophytes From an evolutionary and reproductive viewpoint, the role of plant gametophytes is to produce haploid gametes. Because the gametophyte cells are already haploid, meiosis is not involved in producing plant gametes. Instead, plant gametes are produced by mitosis; therefore, all gametes produced from a single gametophyte are genetically identical.

The gametophytes of bryophytes and many other land plants produce gametes in specialized structures known as **gametangia** (from the Greek, meaning gamete containers). Certain cells of gametangia develop into gametes, and other cells form an outer jacket of tissue. The gametangial jacket protects delicate gametes from drying out and from microbial attack while they develop. Flask-shaped gametangia that each enclose a single egg cell are known as **archegonia**; spherical or elongate gametangia that each produce many sperm are known as **antheridia** (Figure 29.7).

When the plant sperm are mature, if moist conditions exist, they are released from antheridia into films of water. Under the influence of sex-attractant molecules secreted from archegonia, the sperm swim toward the eggs, twisting their way down the tubular archegonial necks. The sperm then fuse with egg cells in the process of fertilization to form diploid zygotes, which grow into embryos. New sporophytes develop from embryos. Fertilization cannot occur in bryophytes unless water is present because the sperm are flagellate and need water to reach eggs. Conditions of uncertain moisture, common in the land habitat, can thus limit plant reproductive success. As we explain next, plant embryos and sporophytes are adaptive responses to this environmental challenge.

Sporophytes One reproductive advantage of the plant life cycle is that zygotes remain enclosed within gametophyte tissues, where they are sheltered and fed (a process described in more detail in Section 29.3). This critical innovation, known as **matrotrophy** (from the Latin, meaning mother, and the Greek, meaning food) gives zygotes a good start while they grow into embryos. Because all groups of land plants possess matrotrophic embryos, they are known as **embryophytes**. Sheltering and feeding embryos is particularly important when embryo production is limited by water availability, as is often the case for bryophytes.

Another reproductive advantage to plants of the sporic life cycle is that, when mature, specialized cells within multicellular sporophytes undergo meiosis to produce many genetically diverse spores. Meiosis occurs within enclosures known

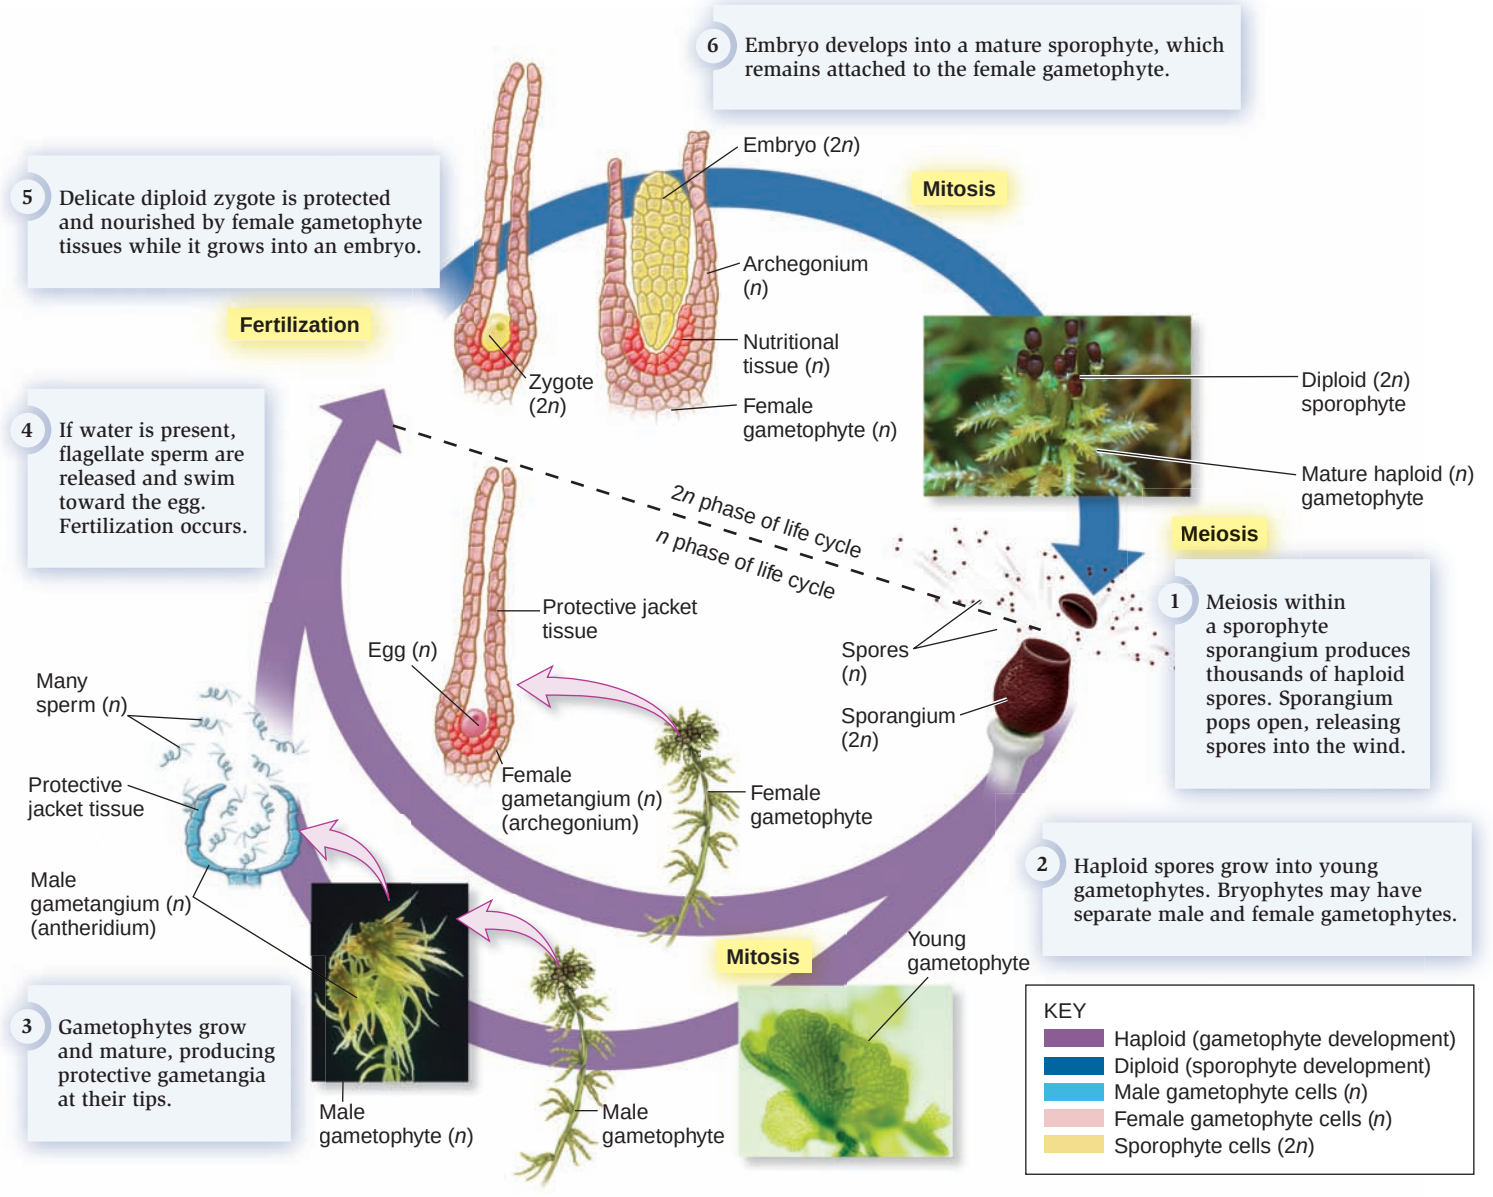

Figure 29.7 **The life cycle of the early diverging moss genus *Sphagnum*, illustrating reproductive adaptations that likely helped early plants to reproduce on land.** The life cycle of this organism is illustrated because among modern bryophytes, *Sphagnum* is the single most abundant and ecologically important genus.

as **sporangia** (from the Greek, meaning spore containers), whose tough cell walls protect developing spores from harmful UV radiation and microbial attack. Bryophyte sporangia open in specialized ways that foster dispersal of mature spores into the air, allowing spore transport by wind (see Figures 29.4 and 29.7). Dispersed spores have cell walls containing a tough material, known as **sporopollenin**, that helps to prevent cellular damage during transport in air. If spores reach habitats favorable for growth, their walls crack open, and new gametophytes develop by mitotic divisions, completing the life cycle.

Spore production is a measure of plant fitness, because plants can better disperse progeny throughout the environment when they produce more spores. The larger the diploid generation, the more spores a plant can produce. As a result, during plant evolution, the sporophyte generation has become larger and more complex (Figure 29.8).

Bryophytes Display Several Distinguishing Features

As we have seen, bryophytes share several fundamental adaptive traits: alternation of generations, tissue-producing apical meristems, protective gametangia and sporangia, and sporopollenin-walled spores. These same traits are shared with other land plants. Even so, several features distinguish bryophytes from other land plants. First, bryophyte gametophytes are more common in nature, larger, and longer-lived than bryophyte sporophytes. Green patches of moss that you might see in the woods are primarily gametophytes. In order to observe bryophyte sporophytes, you would have to look very closely, because this life stage is quite small and remains attached to gametophytes throughout its short lifetime (see Figures 29.4, 29.5, and 29.7). Plant biologists consider bryophyte gametophytes to be the dominant generation in their life cycle. By contrast, other plants have dominant sporophyte generations (Figure 29.8).

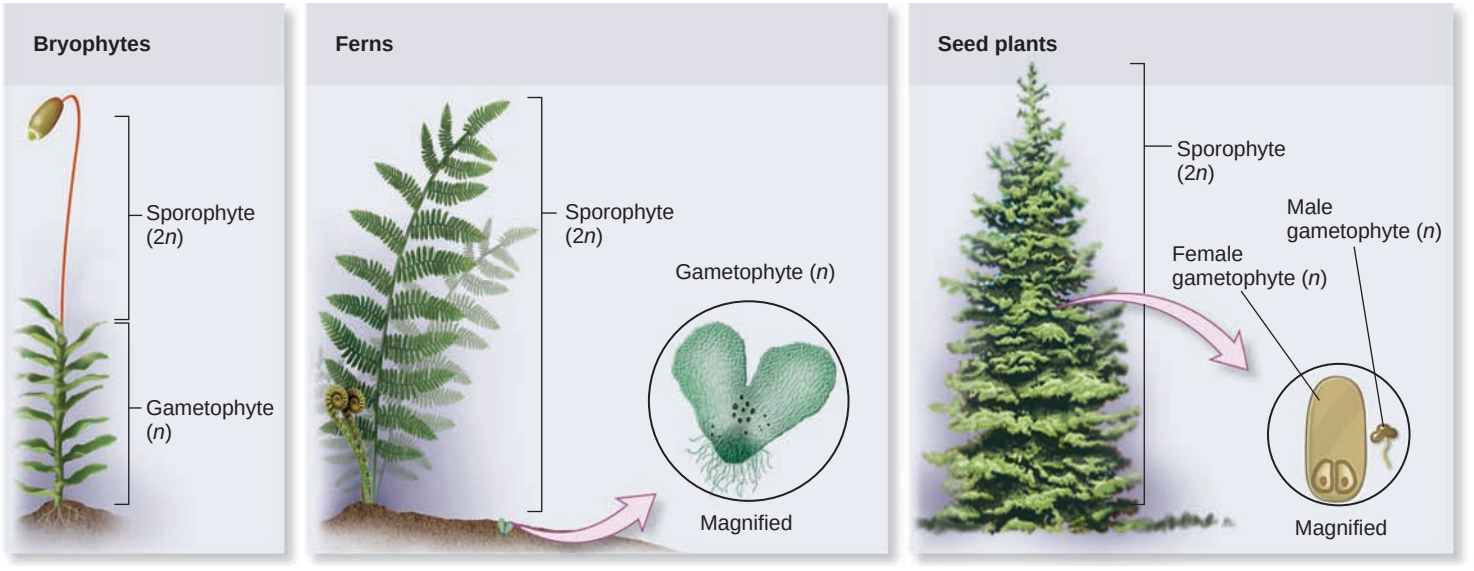

Figure 29.8 **Relative sizes of the sporophyte and gametophyte generations of bryophytes, ferns, and seed plants.**

Concept check: *What is the advantage to ferns and seed plants of having larger sporophytes than those of bryophytes?*

Bryophyte sporophytes are small; they remain attached to parental gametophytes, are unable to branch, and have short lifetimes. At their tips, bryophyte sporophytes produce only a single sporangium containing a limited number of spores. By contrast, the sporophytes of other land plants become independent, and because they can branch, they can continue to grow and produce sporangia on lateral branches, often for many years (Figure 29.8). In all land plants except bryophytes, the sporophyte generation is the dominant generation, meaning that it is larger, more complex, and longer-lived than the gametophyte.

Yet another distinguishing feature of bryophytes is that they lack tissues that both provide structural support and serve in conduction, known as **vascular tissues**. Although the gametophytes of some bryophytes display simple conducting tissues, these do not provide much structural support. Thus, bryophytes are informally known as **nonvascular plants**. As mentioned, other modern plant phyla are collectively and informally known as **vascular plants** because they produce vascular tissues that function in both conduction and support.

Lycophytes and Pteridophytes Are Vascular Plants That Do Not Produce Seeds

If you take a look outside, most of the plants in view are probably vascular plants. The presence of vascular tissue and the ability to branch allows most of these plants to grow much taller than bryophytes and to produce more spores. As a result, vascular plants are more prominent than bryophytes in most modern plant communities.

Vascular plants have been important to Earth's ecology for several hundreds of millions of years. Fossils tell us that the first vascular plants appeared later than the earliest bryophytes (see Section 29.2) and that several early vascular plant lineages once existed but became extinct. Molecular data indicate that the lycophytes are the oldest phylum of living vascular plants and that pteridophytes are the next oldest living plant phylum (see Figure 29.1). In the past, lycophytes were very diverse and included tall trees that contributed importantly to coal deposits, but the tree lycophytes became extinct, and now only about 1,000 relatively small species exist (Figure 29.9). Pteridophytes have diversified more recently, and there are about 12,000 species of modern pteridophytes, including horsetails, whisk ferns, and other ferns (Figure 29.10).

Because the lycophytes and pteridophytes diverged prior to the origin of seeds, they are informally known as seedless vascular plants. Together, lycophytes, pteridophytes, and

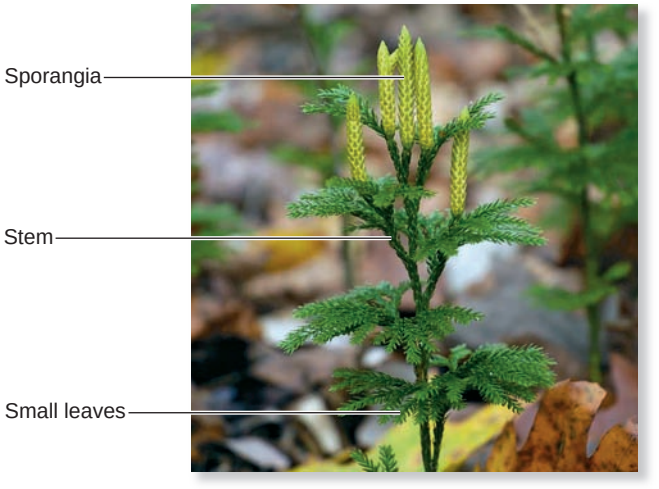

Figure 29.9 **An example of a lycophyte (*Lycopodium obscurum*).** The sporophyte stems bear many tiny leaves, and sporangia generally occur in club-shaped clusters. For this reason, lycophytes are informally known as club mosses or spike mosses, though they are not true mosses. The gametophytes of lycophytes are small structures that often occur underground, where they are better protected from drying.

(d) A later-diverging fern

Figure 29.10 **Pteridophyte diversity.** **(a)** The leafless, rootless green stems of the whisk fern (*Psilotum nudum*) branch by forking and bear many clusters of yellow sporangia that disperse spores via wind. The gametophyte of this plant is a tiny pale structure that lives underground in a partnership with fungi. **(b)** The giant horsetail (*Equisetum telmateia*) displays branches in whorls around the green stems. The leaves of this plant are tiny, light brown structures that encircle branches at intervals. This plant produces spores in cone-shaped structures, and the wind-dispersed spores grow into small green gametophytes. **(c)** The early-diverging fern *Botrychium lunaria*, showing a green photosynthetic leaf with leaflets and a modified leaf that bears many round sporangia. **(d)** The later-diverging fern *Blechnum capense*, viewed from above, showing a whorl of young leaves that are in the process of unrolling from the bases to the tips. The leaves have many leaflets. The stem of this fern grows parallel to the ground and thus is not shown. Most ferns produce spores in sporangia on the undersides of leaves.

seed-producing plants are known as the **tracheophytes**. The latter term takes its name from **tracheids**, a type of specialized vascular cell that conducts water and minerals and provides structural support. Vascular tissues occur in the major plant organs: stems, roots, and leaves.

Stems, Roots, and Leaves **Stems** are branching structures that contain vascular tissue and produce leaves and sporangia. Stems contain the specialized conducting tissues known as **phloem** and **xylem**, the latter of which contains tracheids. Together, such conducting tissues enable vascular plants to conduct organic compounds, water, and minerals throughout the plant body. The xylem also provides structural support, allowing vascular plants to grow taller than nonvascular plants. This support function arises from the presence of a compression and decay-resistant waterproofing material known as **lignin**, which occurs in the cell walls of tracheids and some other types of plant cells. Most vascular plants also produce **roots**—organs specialized for uptake of water and minerals from the soil—and **leaves**, which generally have a photosynthetic function.

Lycophyte roots and leaves differ from those of pteridophytes. For example, lycophyte roots fork at their tips, whereas roots of pteridophytes branch from the inside like the roots of seed plants (see Chapter 35). Lycophyte leaves are relatively small and possess only one unbranched vein, whereas pteridophyte leaves are larger and have branched veins, as do those of

seed plants (compare Figures 29.9 and 29.10d). The evolutionary origins of leaves are discussed in Section 29.4.

Adaptations That Foster Stable Internal Water Content In relatively dry habitats, lycophytes, pteridophytes, and other vascular plants are able to grow to larger sizes and remain metabolically active for longer periods than can bryophytes. Vascular plants have this advantage because they are better able to maintain stable internal water content by means of several adaptations. Such adaptations include a protective **waxy cuticle**, present on most surfaces of vascular plant sporophytes (Figure 29.11). The plant cuticle contains a polyester polymer known as cutin, which helps to prevent attack by pathogens, and wax, which helps to prevent desiccation (drying out). The surface tissue of vascular plant stems and leaves contains many **stomata** (singular, stomate or stoma), pores that are able to open and close (Figure 29.11). Stomata allow plants to take in the carbon dioxide needed for photosynthesis and release oxygen to the air, while conserving water. When the environment is moist, the pores open, allowing photosynthetic gas exchange to occur. But when the environment is very dry, the pores close, which reduces water loss from plants (more information about stomata can be found in Chapters 35 and 38). Though a cuticle and stomata occur in bryophytes, they are not so common as in vascular plants, and bryophytes easily become dry. In vascular plants, conducting tissues, a waxy cuticle, and stomata function together to maintain moisture homeostasis, allowing tracheophytes to exploit a wider spectrum of land habitats.

Life Cycle Lycophyte and pteridophyte gametophytes are small, delicate, and easily harmed by exposure to heat and drought. This explains why the gametophytes of lycophytes and pteridophytes are restricted to moist places, including underground, or why they have short lifetimes. Lycophyte and pteridophyte sperm are released from antheridia into water films within which they swim to eggs in archegonia (Figure 29.12). For this reason, lycophyte and pteridophyte reproduction is limited by dry conditions, as is the case for bryophytes. However, if fertilization occurs, lycophytes and pteridophytes can produce many more spores, because the spore-producing sporophyte generation grows to a much larger size than do bryophyte sporophytes. This fundamental difference has two explanations. First, vascular plant sporophytes are dependent upon maternal gametophytes for only a short time during early embryo development; they eventually become independent by developing a first leaf and roots able to harvest resources needed for photosynthesis (Figure 29.12). Second, the stems of vascular plant sporophytes are able to produce branches, forming relatively large adult plants having many leaves. Roots obtain large amounts of soil water and minerals, supporting the ability of leaves to generate abundant organic compounds by photosynthesis. Lycophytes and pteridophytes use such resources to produce large numbers of sporangia that eject multitudes of spores. You might have seen clusters of sporangia as dark brown dots or lines on the undersides of fern leaves. Dispersed by the wind, spores may land in a suitable place and grow into new gametophytes, completing the life cycle.

Figure 29.11 **A pteridophyte stem with tracheophyte adaptations for transporting and conserving water.** **(a)** This is a cross section through a stem of the pteridophyte *Psilotum nudum.* When viewed with fluorescence microscopy and illuminated with violet light, an internal core of xylem tracheids glows yellow, as does the surface cuticle. **(b)** Surface pores associated with specialized cells—the complexes known as stomata—allow for gas exchange between plant and atmosphere.

Genomes & Proteomes Connection

The Fern *Ceratopteris richardii* Is a Useful Model Genetic System in the Study of Plant Evolution

The fern *Ceratopteris richardii* is useful as a plant model genetic system, as is the flowering plant *Arabidopsis thaliana* (Figure 29.13). Comparisons of the genomes and proteomes of plants help to illuminate the genetic changes that occurred during plant evolution.

For example, in 2005, Mari Salmi, Stanley Roux, and associates reported the results of a study of the expression of nearly 4,000 genes during spore germination in *C. richardii*. They

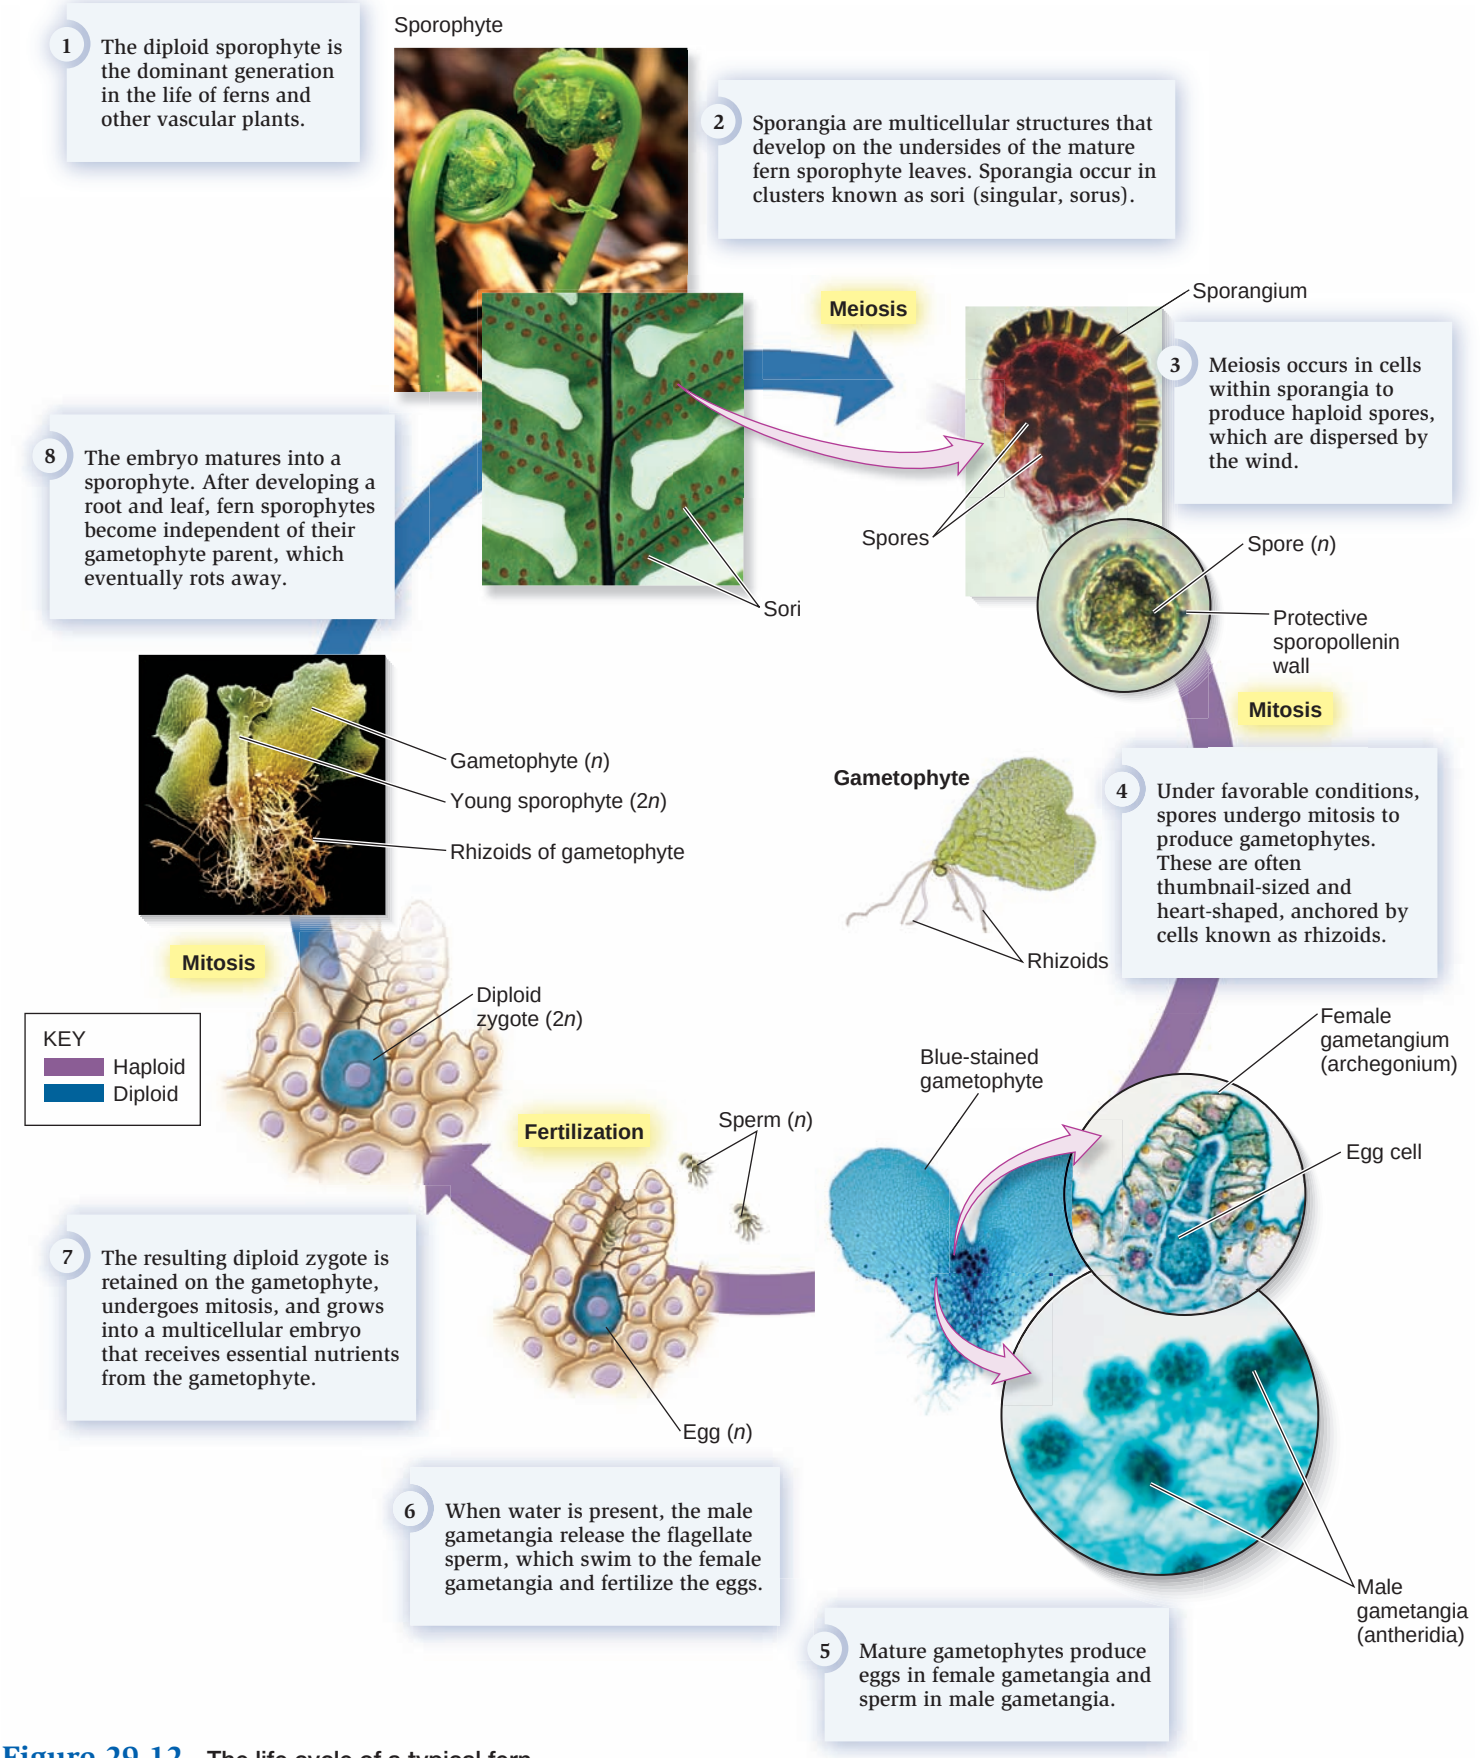

Figure 29.12 The life cycle of a typical fern.

Figure 29.13
A model genetic system, the fern *Ceratopteris richardii*. This fern is a model genetic system for the study of spore germination and other plant features.

identified genes expressed by both fern spores and germinating flowering plant seeds or pollen, a type of spore. One such gene is associated with the role of peroxisomes in making the cellular transition from dormancy to active metabolism, and others are related to cellular use of calcium ions and nitrous oxide (NO) as signaling molecules. In ferns, NO helps the long, thin cells known as rhizoids to perceive gravity, with the result that these elongate cells grow downward at their tips (see Figure 29.12). Such downward growth enables rhizoids to anchor gametophytes in a position that helps to keep gametangia and gametes from drying out. In this way, rhizoid growth fosters the production of embryos, thereby increasing plant fitness. Comparative genomic or proteomic studies suggest how the evolutionary process of descent with modification has generated the reproductive features of the seed plants upon which people greatly depend.

Gymnosperms and Angiosperms Are the Modern Seed Plants

Among the vascular plants, the seed plant phyla dominate most modern landscapes. The modern seed plant phyla commonly known as cycads, ginkgos, conifers, and gnetophytes are collectively known as gymnosperms (Figure 29.14 shows an example). **Gymnosperms** reproduce using both spores and seeds, as do the flowering plants, the angiosperms (Figure 29.15). For this reason, gymnosperms and angiosperms are known informally as the **seed plants**. **Seeds** are complex structures having specialized tissues that protectively enclose embryos and contain stores of carbohydrate, lipid, and protein. Embryos use such food stores to grow and develop. As explained in Section 29.4, the ability to produce seeds helps to free seed plants from the reproductive limitations experienced by the seedless plants, revealing why seed plants are the dominant plants on Earth today.

In addition to the modern seed plant phyla, several additional phyla once existed and left fossils but are now extinct. Collectively, all of the living and fossil seed plant phyla are formally known as **spermatophytes** (the prefix sperm in this case, from the Greek, meaning seed) (see Figure 29.1). Together with extinct seedless, woody plants, modern and fossil seed plants are known as **lignophytes**, a term that reflects the capacity to produce wood.

Wood is composed of xylem, a tissue whose cellulose-rich cell walls also contain lignin. Functioning something like superglue, lignin cements the fibrils of cellulose together, making wood exceptionally strong. Wood production enables plants to increase in girth and become tall. Though not all modern seed plants produce wood, many are trees or shrubs that produce

Figure 29.14 An example of a gymnosperm, the pine.

Concept check: What key characteristics of lignophytes are displayed in this image?

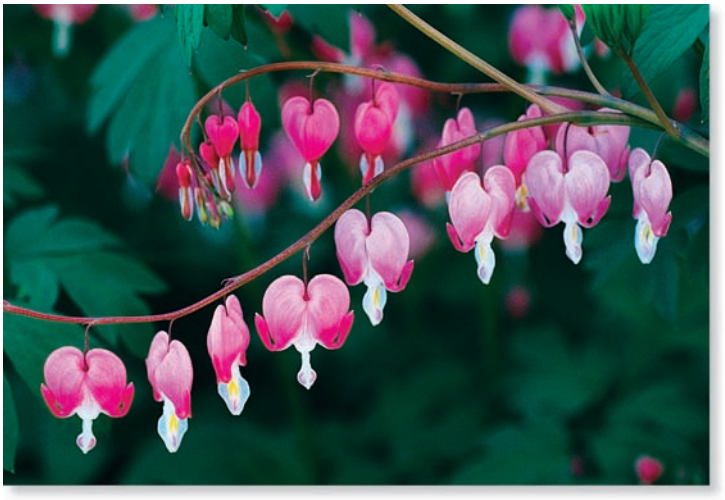

Figure 29.15 An example of an angiosperm, the bleeding heart plant (genus *Dicentra*).

considerable amounts of wood (described more completely in Chapters 30, 35, and 38).

The angiosperms are distinguished by the presence of flowers, fruits, and a specialized seed tissue known as endosperm. **Flowers** are short stems bearing organs that are specialized in ways that enhance seed production (Figure 29.15). **Fruits** are structures that develop from flower organs, enclose seeds, and foster seed dispersal in the environment. The term angiosperm comes from the Greek, meaning enclosed seeds, reflecting the observation that the flowering plants produce seeds within fruits. **Endosperm** is a nutritive seed tissue that increases the efficiency with which food is stored in the seeds of flowering plants (explained further in Section 29.4). Flowers, fruits, and endosperm are defining features of the angiosperms, and they are integral components of animal nutrition.

Though gymnosperms produce seeds and many are woody plants, they lack flowers, fruits, and endosperm. The term gymnosperm comes from the Greek, meaning naked seeds, reflecting the observation that gymnosperm seeds are not enclosed within fruits. Despite their lack of flowers, fruits, and seed endosperm, the modern gymnosperms are diverse and abundant in many places (see Chapter 30). The plant phyla we have just surveyed played significant roles in the past evolutionary history of plants, our next topic.

29.2 An Evolutionary History of Land Plants

A billion years ago, Earth's terrestrial surface was comparatively bare of life. Green or brown crusts of cyanobacteria most likely grew in moist places, but there would have been very little soil, no plants, and no animal life. The origin of the first land plants was essential to development of the first substantial soils, the evolution of modern plant communities, and the ability of animals to colonize land.

How can we know about events such as the origin and diversification of land plants? One line of information comes from comparing molecular and other features of modern plants. For example, the genome sequence of the moss *Physcomitrella patens*, first reported in 2007, reveals the presence of genes that aid heat and drought tolerance, which are especially useful in the terrestrial habitat. Plant fossils, the preserved remains of plants that lived in earlier times, provide another line of information (Figure 29.16). The distinctive plant materials sporopollenin, cutin, and lignin do not readily decay and therefore foster the fossilization of plant parts that contain these tough materials.

The study of fossils and the molecular, structural, and functional features of modern plants has revealed an amazing story—how plants conquered the land. This story can be conceptualized as three dramatic episodes: (1) the first land plants arise from ancestors shared with aquatic charophycean algae and begin to adapt to terrestrial habitats; (2) seedless plants transformed Earth's ecology; and (3) an ancient cataclysm led to the diversification of modern angiosperm lineages.

Figure 29.16 Fossil of *Pseudosalix handleyi*, an angiosperm.

Concept check: What biochemical components of plants favor the formation of fossils?

The First Plants Begin to Adapt to Terrestrial Habitats

Land plants inherited some traits from charophycean algae, as we have noted, but also acquired novel features in response to stresses present on land, but not in the water. For example, plant biologists Zoe Popper and Stephen Fry discovered that the cell walls of all land plants possess xyloglucan carbohydrates that cross-link cellulose microfibrils, but charophycean algae lack this feature. Cell-wall xyloglucans are among the new features that appeared as early plants began to adapt to land, possibly aiding in the development of more complex bodies. As previously mentioned, tissue-producing meristems, a sporic life cycle, tough-walled spores, and the sporophyte generation also appeared very early in plant history.

Seedless Plants Transformed Earth's Ecology

In addition to tough spores, other types of decay-resistant tissues evolved in early seedless plants, likely in response to attack by soil bacteria and fungi. When the plants died, some of their organic constituents were not completely degraded to carbon dioxide, but instead were buried in sediments that were eventually transformed into rock. Such fossil organic carbon can accumulate and remain buried for very long time periods, with the consequence that the amount of carbon dioxide in the atmosphere declined. Carbon dioxide is a greenhouse gas, meaning that an increase in its concentration warms the atmosphere, thereby influencing climate. Very early bryophyte-like land plants and later vascular plants influenced Earth's past climate by reducing the concentration of atmospheric carbon dioxide, and plants continue to do so today.

Ecological Effects of Ancient and Modern Bryophytes In 2004, plant evolutionary biologists Linda Graham, David Hanson, and colleagues determined the amount of decay-resistant tissue mass produced by several modern, early diverging

bryophytes and used these data to estimate the ecological impact of early nonvascular plants. The results suggested that nonvascular plants likely contributed organic substances to early soils, thereby helping to enrich them. The results also indicated that ancient nonvascular plants could have produced organic carbon that was buried before being recycled back to carbon dioxide. By this process, early plants could have thereby influenced climate. The investigators calculated that such effects on soil, atmospheric chemistry, and climate might have been significant because they could have occurred over large geographic areas and for millions of years before vascular plants became dominant.

Modern bryophytes likewise play important roles by storing CO_2 as decay-resistant organic compounds. Plants of the locally abundant modern moss genus *Sphagnum* contain so much decay-resistant body mass that in many places, dead moss has accumulated over thousands of years, forming deep peat deposits. By storing very large amounts of organic carbon for long periods, *Sphagnum* helps to keep Earth's climate steady. Under cooler than normal conditions, *Sphagnum* grows more slowly and thus absorbs less CO_2, allowing atmospheric CO_2 to rise a bit, warming the climate a little. As the climate warms, *Sphagnum* grows faster and sponges up more CO_2, storing it in peat deposits. Such a reduction in atmospheric CO_2 returns the climate to slightly cooler conditions. In this way, peat moss helps to keep the world's climate from changing dramatically.

Ecological Effects of Ancient Vascular Plants Vascular plants originated from extinct plants called protracheophytes, which had branched sporophytes and produced numerous sporangia. However, protracheophyte water-conducting cells lacked lignin and did not provide structural support. Vascular plant fossils first appear in rocks deposited 420–429 million years ago and rapidly became diverse and abundant. These fossils reveal that the earliest vascular plants had no leaves or roots, but they did have stems with a central core of lignin-coated water-conducting cells, a tough outer cuticle, and stomata, much like modern vascular plants (see Figure 29.11). These features suggest that early vascular plants had the ability to maintain a stable internal water level. Abundant lignin and cutin also fostered the ability of vascular plant bodies to resist decaying long enough to fossilize, explaining why vascular plants have left a more extensive fossil record than did the earliest bryophyte-like plants.

Fossils tell us that extensive forests dominated by tree-sized lycophytes, pteridophytes, and early lignophytes occurred in widespread swampy regions during the warm, moist Carboniferous period (354–290 million years ago) (Figure 29.17). For example, in 2007, paleobotanist William DiMichele and colleagues reported that they had found fossils of an entire coastal forest that was 297 million years old and covered an area of more than 1,000 hectares in what is now Illinois. Large trees related to modern lycophytes dominated this forest, but pteridophytes and representatives of extinct plant phyla were also present. The forest was well preserved because an earthquake had quickly dropped it below sea level into water low in oxygen. Under such conditions, decay microbes could not completely decompose the forest, which was then buried in sediments that later formed coal. Much of today's coal is similarly derived from the abundant remains of ancient plants, explaining why the Carboniferous is commonly known as the Coal Age. Carboniferous plants converted huge amounts of the atmospheric CO_2 into decay-resistant organic materials such as lignin. Long-term burial of these materials, compressed into coal, together with chemical interactions

Figure 29.17 **Reconstruction of a Carboniferous (Coal Age) forest.** This ancient forest was dominated by tree-sized lycophytes and pteridophytes, which later contributed to the formation of large coal deposits.

Concept check: *Why did giant dragonflies occur during this time, but not now?*

between soil and the roots of vascular plants, dramatically changed Earth's atmosphere and climate. The removal of large amounts of the greenhouse gas CO_2 from the atmosphere by plants had a cooling effect on the climate, which also became drier because cold air holds less moisture than warm air.

Mathematical models of ancient atmospheric chemistry, supported by measurements of natural carbon isotopes, led paleoclimatologist Robert Berner to propose that the Carboniferous proliferation of vascular plants was correlated with a dramatic decrease in atmospheric carbon dioxide, which reached the lowest known levels about 290 million years ago (Figure 29.18). During this period of very low CO_2, atmospheric oxygen levels rose to the highest known levels, because less O_2 was being used to break down organic carbon into CO_2. High atmospheric oxygen content has been invoked to explain the occurrence of giant Carboniferous dragonflies and other huge insects. The great Carboniferous decline in CO_2 level ultimately caused cool, dry conditions to prevail in the late Carboniferous and early Permian periods. As a result of this relatively abrupt global climate change, many of the tall seedless lycophytes and pteridophytes that had dominated earlier Carboniferous forests became extinct, as did organisms such as the giant dragonflies. Cooler, drier conditions favored extensive diversification of the first seed plants, the gymnosperms. Compared to seedless plants, seed plants were better at reproducing in cooler, drier habitats (as we will see in Section 29.4). As a result, seed plants came to dominate Earth's terrestrial communities, as they continue to do.

An Ancient Cataclysm Marked the Rise of Angiosperms

Diverse phyla of gymnosperms dominated Earth's vegetation through the Mesozoic era (248–65 million years ago), which is sometimes called the Age of Dinosaurs. In addition, fossils provide evidence that early flowering plants were present in the early Mesozoic and perhaps before that. Likewise, fossils indicate that early mammals existed in the Mesozoic. Gymnosperms and early angiosperms were probably major sources of food for such early mammals as well as herbivorous dinosaurs. For example, Ruth Stockey and colleagues found many fossils of a new type of angiosperm, named *Cobbania*, which grew in wetlands that are now the Dinosaur Park Formation in Alberta, Canada. These plant fossils occurred with a skeleton of the dinosaur *Ornithomimus* that may have fed on the plant when alive (Figure 29.19).

One fateful day about 65 million years ago, disaster struck from the sky, causing a dramatic change in the types of plants and animals that dominated terrestrial ecosystems.

That day, at least one large meteorite crashed into the Earth near the present-day Yucatán Peninsula in Mexico. This episode is known as the **K/T event** because it marks the end of the Cretaceous (sometimes spelled with a K) period and the beginning of the Tertiary (T) period. The impact, together with substantial volcanic activity that also occurred at this time, is thought to have produced huge amounts of ash, smoke, and haze that dimmed the sun's light long enough to kill many of the world's

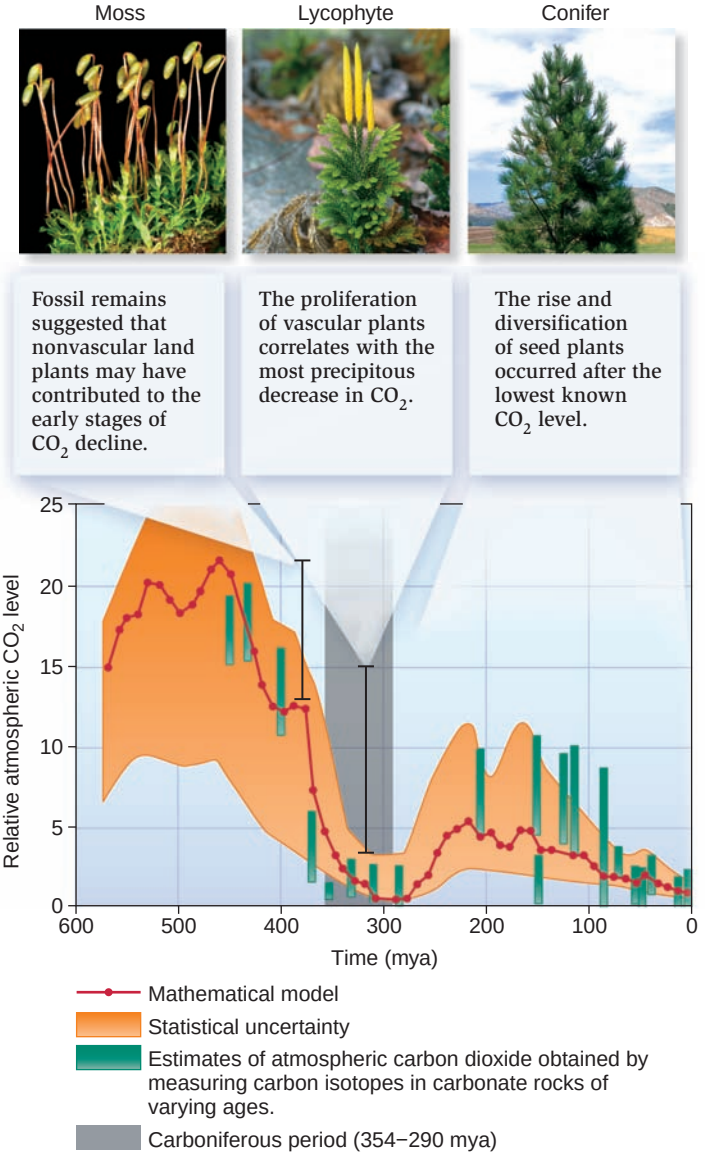

Figure 29.18 Changes in Earth's atmospheric carbon dioxide levels over geological time. Geological evidence indicates that carbon dioxide levels in Earth's atmosphere were once higher than they are now, but that the rise of land plants caused CO_2 to reach the lowest known level about 300 million years ago.

plants. Many groups of plants became extinct, though some survived and persist to the present time. With a severely reduced food supply, most dinosaurs were also doomed, the exceptions being their descendants, the birds. The demise of the dinosaurs left room for birds and mammals to adapt to many kinds of terrestrial habitats.

After the K/T event, ferns dominated long enough to leave huge numbers of fossil spores, and then surviving groups of flowering plants began to diversify into the space left by the extinction of previous plants. The rise of angiosperms fostered the diversification of beetles (see Chapter 33) and other types of insects that associate with plants.

Our brief survey of plant evolutionary history reveals some important diversity principles. While environment certainly influenced the diversification of plants, plant diversification has also changed Earth's environment in ways that affected

Figure 29.19 **Early angiosperms, sources of food for large herbivorous dinosaurs of the Mesozoic era.** The newly discovered fossil angiosperm *Cobbania corrugata* grew in wetlands that were also inhabited by large dinosaurs such as *Ornithomimus*, whose head is illustrated here.

the evolution of other organisms. In addition, plant evolutionary history serves as essential background for a closer focus on the evolution of **critical innovations**, new features that foster the diversification of phyla. Among the critical innovations that appeared during plant evolutionary history, embryos, leaves, and seeds were particularly important.

29.3 The Origin and Evolutionary Importance of the Plant Embryo

The embryo, absent from charophyceans, was probably one of the first critical innovations acquired by land plants. Recall that plant embryos are young sporophytes that develop from zygotes and are enclosed by maternal tissues that provide sustenance. The presence of an embryo is critical to plant reproduction in terrestrial environments. Drought, heat, ultraviolet light, and microbial attack could kill delicate plant egg cells, zygotes, and embryos if these were not protected and nourished by enclosing maternal tissues. The first embryo-producing plants diversified into hundreds of thousands of diverse modern species, as well as many species that have become extinct. A closer look at embryos reveals why their origin and evolution is so important to all land plants.

Plant Embryos Grow Protected Within the Maternal Plant Body

A plant embryo has several characteristic features, some of which were previously described. First, plant embryos are multicellular and diploid (see Section 29.1). Plant embryos develop by repeated mitosis from a single-celled zygote resulting from fertilization (see Figure 29.6b). In addition, we have also learned that plant eggs are fertilized while still enclosed by the maternal plant body and embryos begin their development within the protective confines of maternal tissues (see Figure 29.7). Plant biologists say that plants retain their zygotes and embryos. Third, plant embryo development depends on organic and mineral materials supplied by the mother plant. Nutritive tissues composed of specialized **placental transfer tissues** aid in the transfer of nutrients from mother to embryo. Taking a closer look at placental transfer tissues reveals their valuable role.

Placental transfer tissues function similarly to the placenta present in most mammals, which fosters nutrient movement from the mother's bloodstream to the developing fetus. Plant placental transfer tissues often occur in haploid gametophyte tissues that lie closest to embryos and in the diploid tissues of young embryos themselves. Such transfer tissues contain cells that are specialized in ways that promote the movement of solutes from gametophyte to embryo. For example, the cells of placental transport tissues display complex arrays of finger-like cell-wall ingrowths (Figure 29.20). Because the plant plasma membrane lines this elaborate plant cell wall, the ingrowths vastly increase the surface area of plasma membrane. This increase provides the space needed for abundant membrane transport proteins, which move solutes into and out of cells. With more transport proteins present, materials can move at a faster rate from one cell to another. Experiments have revealed

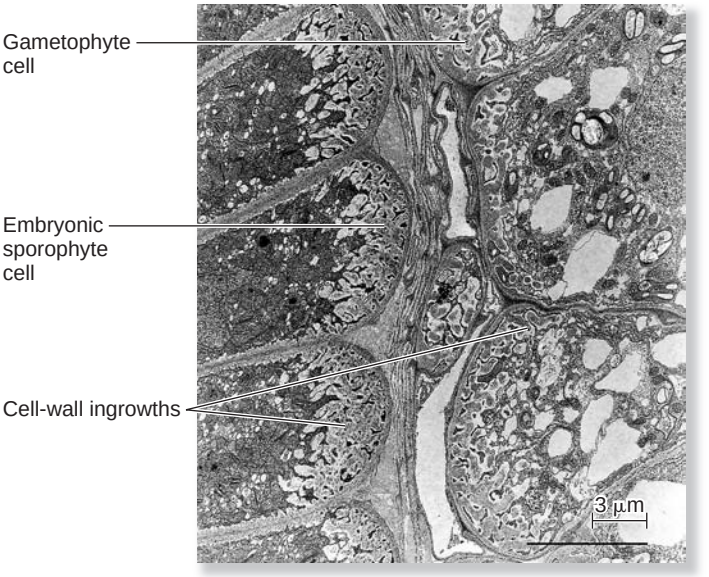

Figure 29.20 **Placental transfer tissue from a plant in the liverwort genus *Monoclea*.** This TEM shows that placental transfer tissues contain specialized cells having extensive finger-shaped cell-wall ingrowths. Such cells help nutrients to move rapidly from parental gametophytes to embryonic sporophytes, a process that fosters plant reproductive success.

Concept check: *How does increasing plasma membrane surface area foster rapid movement of nutrients in placental transfer tissue?*

that dissolved sugars, amino acids, and minerals first move from maternal cells into the intercellular space between maternal tissues and the embryo. Then, transporter proteins in the membranes of nearby embryo cells efficiently import materials into the embryo. Classic experiments have revealed the adaptive value of this process in land plant reproduction.

Feature Investigation

Browning and Gunning Demonstrated That Placental Transfer Tissues Facilitate the Movement of Organic Molecules from Gametophytes to Sporophytes

In the 1970s, plant cell biologists Adrian Browning and Brian Gunning explored placental transfer tissue function. Using a simple moss experimental system, they investigated the rate at which radioactively labeled carbon moves through placental transfer tissues from green gametophytes into young sporophytes. Recall that embryos are very young, few-celled sporophytes and that in mosses and other bryophytes, all stages of sporophyte development are nutritionally dependent on gametophyte tissues. Browning and Gunning investigated nutrient flow into young sporophytes because these slightly older and larger developmental stages were easier to manipulate in the laboratory than were tiny embryos.

In a first step, the investigators grew many gametophytes of the moss *Funaria hygrometrica* in a greenhouse until young sporophytes developed as the result of sexual reproduction (Figure 29.21).

In a second step, they placed black glass sleeves over young sporophytes as a shade to prevent photosynthesis, enclosed moss gametophytes and their attached sporophytes within transparent jars, and supplied the plants with radioactively labeled carbon dioxide for measured time periods known as pulses. Because the moss gametophytes were not shaded, their photosynthetic cells were able to convert the radioactively labeled carbon dioxide into labeled organic compounds, such as sugars and amino acids. Shading prevented the young sporophytes, which possess some photosynthetic tissue, from using labeled CO_2 to produce organic compounds.

In a third step, the researchers added an excess amount of nonradioactive CO_2 to prevent the further uptake of the radio-

4 Pluck young sporophytes of differing sizes from gametophytes. Assay ^{14}C in both sporophytes and gametophytes using a scintillation counter. This was done immediately following the chase, or 2 or 8 hours after the chase.

Determine how much organic carbon flowed into sporophytes during each chase time.

5 THE DATA I

Carbon transfer from gametophyte to sporophyte:

Mean ^{14}C content of 5 gametophytes at 0 chase time	Mean ^{14}C lost from gametophytes after 8-hour chase	Mean ^{14}C gained by sporophytes after 8-hour chase
228 units	145 units	51 units

6 THE DATA II

Sporophyte size effect:

Sporophyte size	Mean ^{14}C content of 8 sporophytes after 2-hour chase
5–7 mm	8.47 ± 4.29 units
11–13 mm	9.93 ± 3.94 units
23–25 mm	24.97 ± 5.30 units

7 CONCLUSION Organic carbon moves from photosynthetic gametophytes into developing sporophytes, facilitated by transfer cell-wall ingrowths. Larger sporophytes absorb more organic carbon than smaller ones.

active CO_2 from their experimental system, a process known as a chase. This process stopped the radiolabeling of photosynthetic products because the vast majority of CO_2 taken up was now unlabeled. (Experiments such as these are known as pulse-chase experiments.) In a final step, Browning and Gunning plucked young sporophytes of different sizes (ages) from gametophytes and measured the amount of radioactive organic carbon present in the separated gametophyte and sporophyte tissues at various times following the chase.

From these data, they were able to calculate the relative amount of organic carbon that had moved from the photosynthetic moss gametophytes to their sporophytes. Browning and Gunning discovered that about 22% of the organic carbon produced by gametophyte photosynthesis was transferred to the young sporophytes during an 8-hour chase period. They also calculated the rate of nutrient transfer from gametophyte to sporophyte and compared this rate to the rate (determined in other studies) at which organic carbon moves within several other plant tissues that lack specialized transfer cells. Browning and Gunning discovered that organic carbon moved from moss gametophytes to young sporophytes nine times faster than organic carbon moves within these other plant tissues. These investigators inferred that the increased rate of nutrient movement could be attributed to placental transfer cell structure, namely, the fact that cell-wall ingrowths enhanced plasma membrane surface area. By comparing the amount of radioactive carbon accumulated by sporophytes of differing sizes, they also learned that larger sporophytes absorbed labeled carbon about three times faster than smaller ones.

These data are consistent with the hypothesis that placental transfer tissues increase plant reproductive success by providing embryos and growing sporophytes with more nutrients than they would otherwise receive. Supplied with these greater amounts of nutrients, sporophytes are able to grow larger than they otherwise would, and eventually they produce more progeny spores.

Experimental Questions

1. What were the goals of the Browning and Gunning investigation?
2. How did Browning and Gunning prevent photosynthesis from occurring in moss sporophytes during the experiment (shown in Figure 29.21), and why did they do this?
3. How did the measurements Browning and Gunning made after adding an excess amount of unlabeled CO_2 lead them to their conclusions?

29.4 The Origin and Evolutionary Importance of Leaves and Seeds

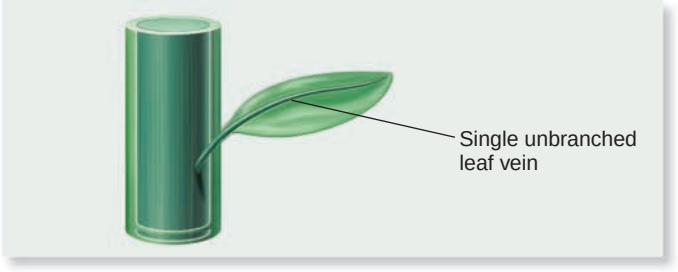
Like plant embryos, leaves and seeds are critical innovations that increased plant fitness and fostered diversification. Unlike the plant embryo, which likely originated just once at the birth of the plant kingdom, leaves and seeds probably evolved several times during plant evolutionary history. Comparative studies of diverse types of leaves and seeds in fossil and living plants suggest how these critical innovations might have originated.

The Large Leaves of Ferns Evolved from Branched Stem Systems

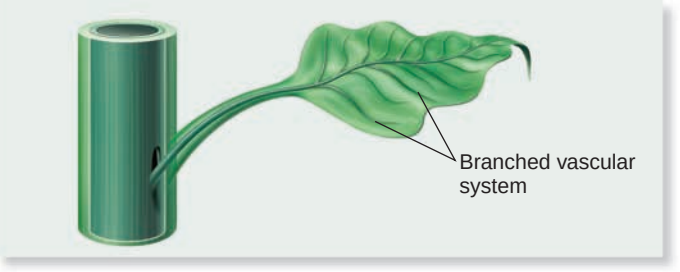
Leaves are the solar panels of the plant world. Their flat structure provides a high surface area that helps leaves to effectively capture sunlight for use in photosynthesis. Among the vascular plants, lycophytes produce the simplest and most ancient type of leaves. Modern lycophytes have tiny leaves, known as **lycophylls** or microphylls, which typically have only a single unbranched vein (Figure 29.22a). Some experts think that these small leaves are modified sporangia.

In contrast, the leaves of ferns and seed plants have extensively branched veins. Such leaves are known as **euphylls** (from the Greek, meaning true leaves) (Figure 29.22b), and the clade that includes pteridophytes and seed plants is known as the **euphyllophytes** (see Figure 29.1). The branched veins of euphylls are able to supply relatively large areas of photosynthetic tissue with water and minerals. Thus, euphylls are typically much larger than lycophylls, explaining why euphylls are also known as megaphylls (from the Greek, meaning large leaves). Euphylls provide considerable photosynthetic advantage to ferns and seed plants, because they provide more surface for solar energy capture than do small leaves. Hence, the evolution of relatively large leaves allowed plants to more effectively accomplish photosynthesis, enabling them to grow larger and produce more progeny.

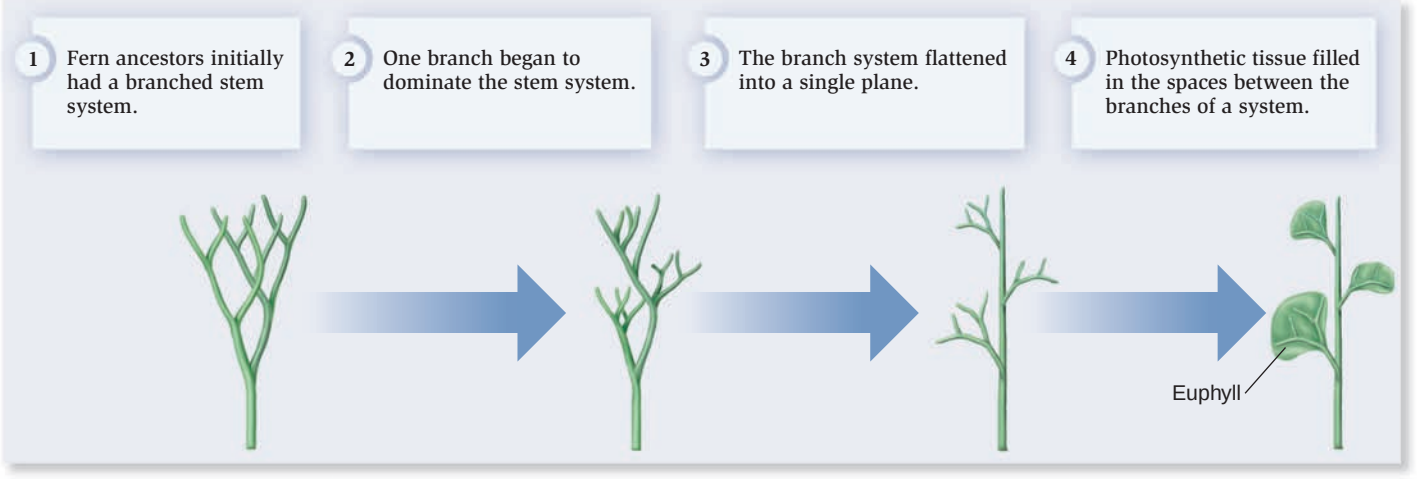
Study of fern fossils indicates that euphylls likely arose from leafless, branched stem systems by a series of steps (Figure 29.22c). First, one branch assumed the role of the main



(a) Lycophyll (small leaf)



(b) Euphyll (large leaf)



(c) Euphyll evolution process in pteridophytes

Figure 29.22 **Lycophylls and euphylls.** **(a)** Most lycophylls possess only a single unbranched leaf vein having limited conduction capacity, explaining why lycophylls are generally quite small. **(b)** Euphylls possess branched vascular systems having greater conduction capacity, explaining why many euphylls are relatively large. **(c)** Fossil evidence suggests how pteridophyte euphylls might have evolved from branched stem systems.

Concept check: *Imagine that the leaves of some other plant group evolved from stem systems that were more highly branched (that is, there were more branches per unit length of stem) than those of ferns. How do you think the leaves of such plants would differ from those of ferns?*

axis, while the other was reduced in size, became flattened in one plane, and finally, the spaces between the branches of this flattened system became filled with photosynthetic tissue. Such a process would explain why euphylls have branched vascular systems; individual veins apparently originated from the separate branches of an ancestral branched stem. Plant evolutionary biologists suspect that euphylls arose several times, and it is unclear whether the leaves of seed plants originated in the same way as those of ferns.

Seeds Develop from the Interaction of Ovules and Pollen

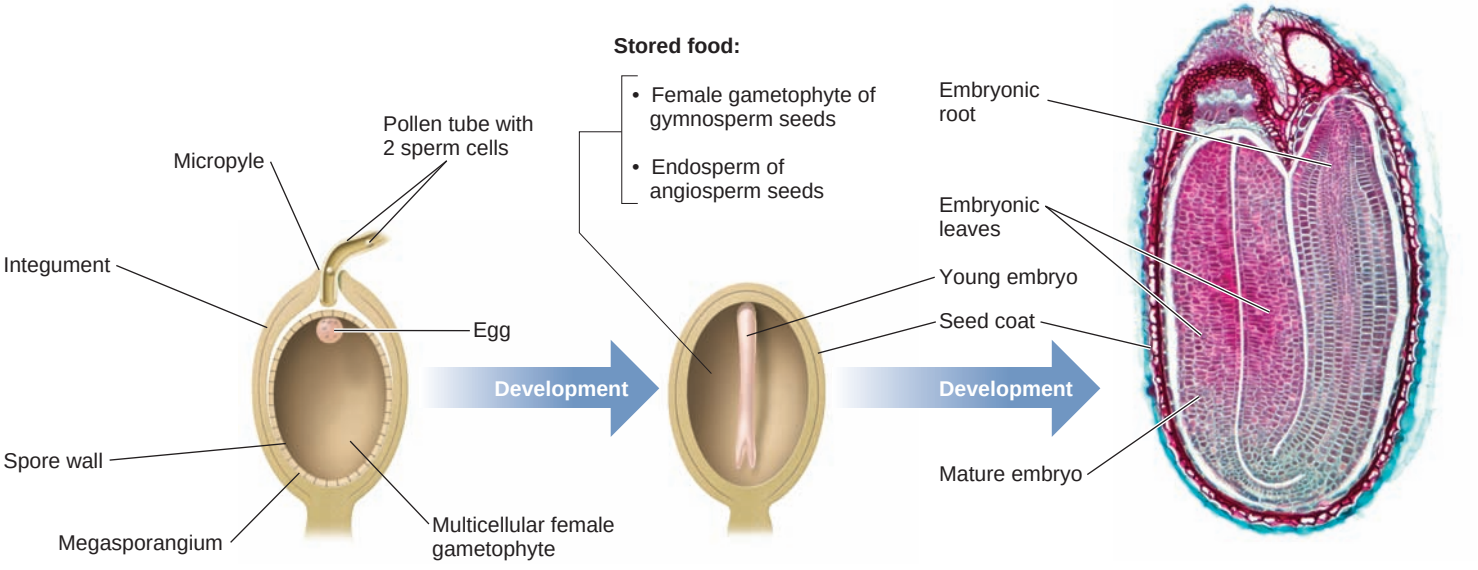
The seed plants dominate modern ecosystems, suggesting that seeds offer reproductive advantages. Seed plants are also the plants with the greatest importance to humans, as described in Chapter 30. For these reasons, plant biologists are interested in understanding why seeds are so advantageous and how they evolved. To consider these questions, we must first take a closer look at seed structure and development.

Plants produce seeds by reproductive structures unique to seed plants, known as ovules and pollen. An **ovule** is a sporangium that typically contains only a single spore that develops into a very small egg-producing gametophyte, the whole megasporangium enclosed by leaflike structures known as **integuments** (Figure 29.23a). You can think of an ovule as being like a nesting doll with four increasingly smaller dolls inside. The smallest doll would correspond to an egg cell; intermediate-sized dolls would represent the gametophyte, spore wall, and megasporangium; and the largest doll would represent the integuments. Fertilization converts such layered ovules into seeds. In seed plants, the sperm needed for fertilization are supplied by **pollen**, tiny male gametophytes enclosed by walls. A closer look at pollen and ovules will help in understanding how seeds develop.

We have earlier noted that all plants produce spores by meiosis within sporangia, and seed plants are no exception. However, seed plants produce two distinct types of spores in two different types of sporangia, a trait known as heterospory. Small **microspores** develop within microsporangia, and larger **megaspores** develop within megasporangia. Male gametophytes develop from the microspores, and the pollen that develops from these microspores is released from microsporangia. Meanwhile, female gametophytes develop and produce eggs while enclosed by protective megaspore walls. The problem with this process is that female gametophytes are not photosynthetic, so they need help in feeding the embryos that develop from fertilized eggs. Female gametophytes get this help from the previous sporophyte generation by remaining attached to it. This is an advantage because the large sporophyte generation is thereby able to provide gametophytes with the nutrients needed for embryo development.

Embryos develop as the result of fertilization, which cannot occur until after **pollination**, the process by which pollen comes close to ovules. Pollination typically occurs by means of wind or animal transport (see Chapter 30). Fertilization occurs in seed plants when a male gametophyte extends a slender pollen tube that carries two sperm toward an egg. The pollen tube enters through an opening in the integument called the micropyle and releases the sperm. The fertilized egg becomes an embryo, and the ovule's integument develops into a protective, often hard and tough **seed coat** (Figure 29.23b,c).

Gymnosperm seeds contain female gametophyte tissue that has accumulated large amounts of protein, lipids, and carbohydrates prior to fertilization. These nutrients are used during both



(a) Mature ovule just prior to fertilization

(b) Developing seed

(c) LM of mature angiosperm seed, sectioned and stained

Figure 29.23 Structure of an ovule developing into a seed.

Concept check: *Can you hypothesize why this angiosperm seed with its mature embryo does not show obvious endosperm tissue?*

embryo development and seed germination to help support growth of the seedling. Angiosperm seeds also contain this useful food supply, but most angiosperm ovules do not store food materials before fertilization. Instead, angiosperm seeds generally store food only after fertilization occurs, ensuring that the food is not wasted if an embryo does not form. How is this accomplished? The answer is a process known as **double fertilization**. This process produces both a zygote and a food storage tissue known as endosperm, a tissue unique to angiosperms. One of the two sperm delivered by each pollen tube fuses with the egg, producing a diploid zygote, as you might expect. The other sperm nucleus fuses with different gametophyte nuclei to form an unusual cell that has more than the diploid number of chromosomes; this cell generates the endosperm food tissue. More information about endosperm can be found in Chapter 39.

Seeds allow embryos access to food supplied by the previous sporophyte generation, an option not available to seedless plants. The layered structure of ovules explains why seeds are also layered, with a protective seed coat enclosing the embryo and stored food. These seed features improve the chances of embryo and seedling survival, thereby increasing seed plant fitness.

Seeds Confer Important Ecological Advantages

Seeds provide plants with numerous ecological advantages. First, many seeds are able to remain dormant in the soil for long periods, until conditions become favorable for germination and seedling growth. Further, seed coats are often adapted in ways that improve dispersal in diverse habitats. For example, many plants produce winged seeds that are effectively dispersed by wind. Other plants produce seeds with fleshy coverings that attract animals, which consume the seeds, digest their fleshy covering, and eliminate them at some distance from the originating plants.

Another advantage of seeds is that they can store considerable amounts of food, which supports embryo growth and helps plant seedlings grow large enough to compete for light, water, and minerals. This is especially important for seeds that must germinate in shady forests. Finally, the sperm of most seed plants can reach eggs without having to swim through water, because pollen tubes deliver sperm directly to ovules. Consequently, seed plant fertilization is not typically limited by lack of water, in contrast to that of seedless plants. Therefore, seed plants are better able to reproduce in arid and seasonally dry habitats. For these reasons, seeds are considered to be a key adaptation to reproduction in a land habitat.

Ovule and Seed Evolution Illustrate Descent with Modification

As we have seen, seed plants reproduce using both spores and seeds, but note that seed plants have not replaced spores with seeds. Rather, seed plants continue to produce spores, and ovules and seeds have evolved from spore-producing structures by descent with modification. Recall that this evolutionary principle involves changes in pre-existing structures and processes. Fossils provide some clues about ovule and seed evolution, and other information can be obtained by comparing reproduction in living lycophytes and pteridophytes.

Most modern lycophytes and pteridophytes release one type of spore that develops into one type of gametophyte. Such plants are considered to be homosporous, and their gametophytes live independently and produce both male and female gametangia (see Figure 29.12). However, some lycophytes and pteridophytes produce and release two distinct kinds of spores: relatively small microspores and larger megaspores, which respectively grow into male and female gametophytes. The larger size of megaspores enables them to store food that later supports developing sporophytes. This reproductive process, known as **heterospory** (meaning different spores), also characterizes all seed plants. The gametophytes produced by heterosporous plants also grow within the confines of microspore and megaspore walls and therefore are known as **endosporic gametophytes**.

An advantage of heterospory is that it mandates cross-fertilization. The eggs and sperm that fuse are derived from different gametophytes and hence from different spores and different meiotic events. This makes it likely that the gametes are of distinct genotypes. Cross-fertilization increases the potential for genetic variation, which aids evolutionary flexibility. Endosporic gametophytes receive protection from environmental damage by surrounding spore walls. From these observations, we can infer that heterospory and endosporic gametophytes were probably also features of seed plant ancestors and constitute early steps toward seed evolution (Figure 29.24). Fossils and modern plants also illustrate subsequent stages in seed evolution, such as retaining megaspores within sporangia, rather than releasing them.

A further step in seed evolution may have been the production of only one megaspore per sporangium rather than multiple spores per sporangium, which is common in seedless plants. Reduction of megaspore numbers (from those present in seedless plants) would have allowed plants to channel more nutrients into each megaspore. A final step might have been the retention of megasporangia on parental sporophytes by the development of integuments (Figure 29.24). As we have noted, this adaptation would allow food materials to flow from mature photosynthetic sporophytes to their dependent gametophytes and young embryos.

Fossils provide information about when and how the process of seed evolution first occurred. Very early fossil seeds such as *Elkinsia polymorpha* and *Archaeosperma arnoldii* were present 365 million years ago, during the Devonian period, which occurred prior to the Coal Age (see Figure 29.1). Paleobotanists Phillippe Gerrienne, Brigette Meyer-Berthaud, and associates reported that fossil reproductive structures of an extinct plant named *Runcaria heinzelinii* may represent a seed precursor (Figure 29.25). These fossil structures had a lacy integument that did not completely enclose the megasporangium.

The evolutionary journey illustrated by the transition from aquatic charophycean algae to bryophytes, to seedless plants, and finally to seed plants reveals how adaptation is related to environmental change, as well as ways in which plants

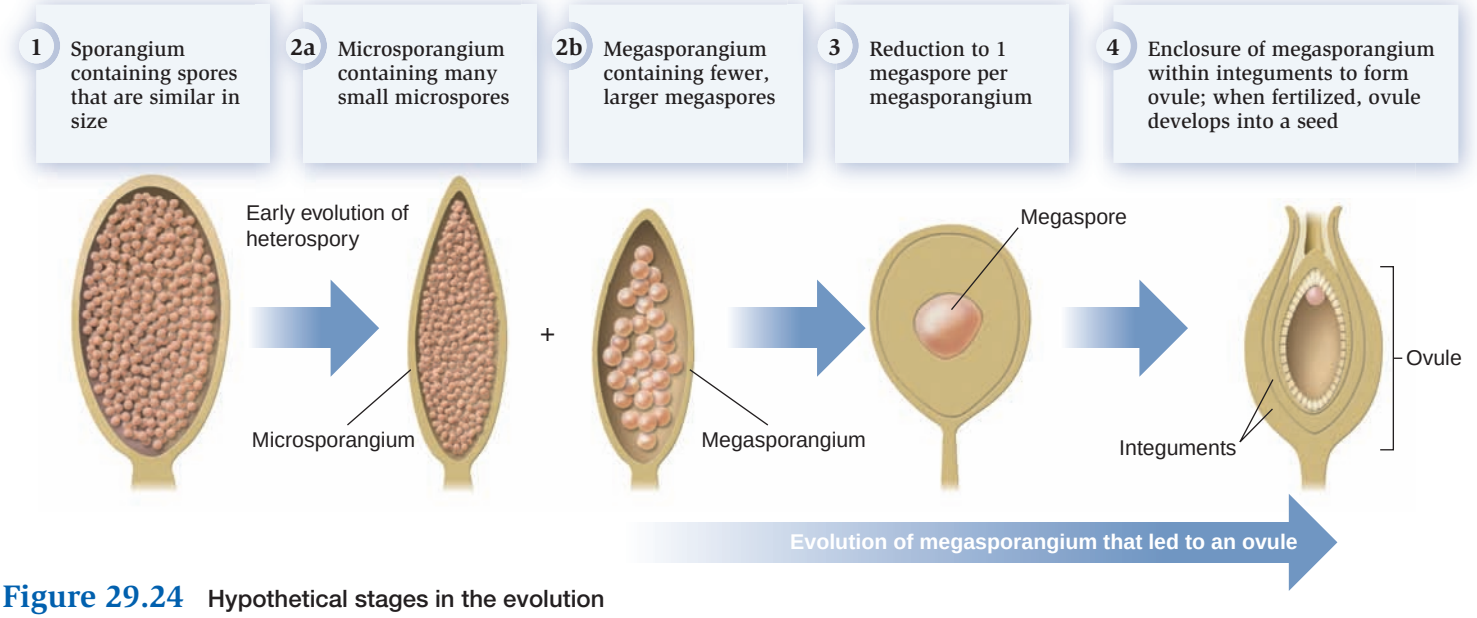


Figure 29.24 **Hypothetical stages in the evolution of seeds.** The parallel evolution of heterospory and endosporic gametophytes in some lycophytes and pteridophytes as well as the seed plants suggests that these features were acquired early in the evolution of seeds. Later-occurring events in the origin of seeds included reduction of the number of megaspores to one per megasporangium and enclosure of the megasporangium by protective, leaflike integuments.

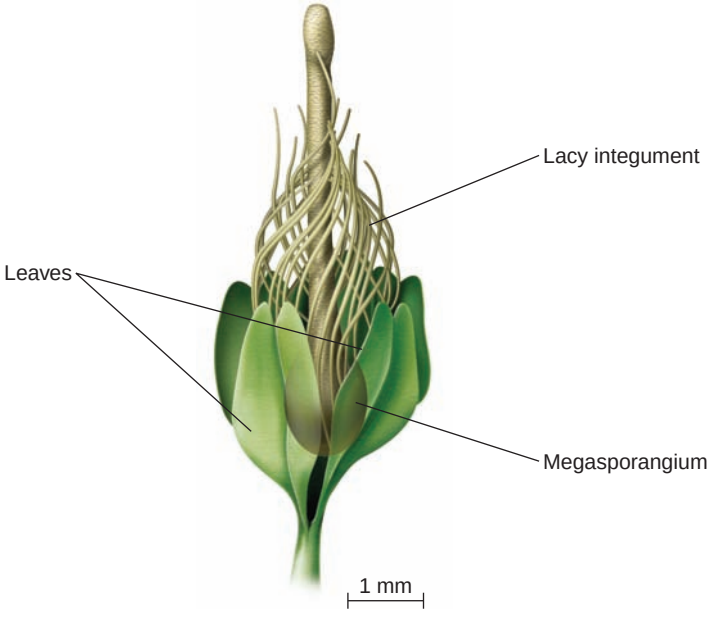

Figure 29.25 **The fossil *Runcaria heinzelinii*, a plant with a probable seed precursor.**

Concept check: *Based on your knowledge of integument function in modern seed plants, can you hypothesize a function for the lacy integument of Runcaria?*

themselves shaped Earth's ecosystems. As a summary of what we have learned in this chapter, Table 29.1 provides a list of the distinguishing features of land plants and their charophycean relatives.

Table 29.1 Distinguishing Features of Modern Charophyceans and Land Plants*

Charophyceans
Primarily aquatic habitat; zygotic life cycle; sporangia absent; sporophytes absent; cell-wall xyloglucans absent
LAND PLANTS (EMBRYOPHYTES)
Primarily terrestrial habitat; sporic life cycle consisting of alternation of two multicellular generations—diploid sporophyte and haploid gametophyte; multicellular embryos are nutritionally dependent for at least some time during development; spore-producing sporangia; gamete-producing gametangia; sporopollenin spore walls; cell-wall xyloglucans
Nonvascular plants (Bryophytes) (**liverworts**, **mosses**, **hornworts**)
Dominant gametophyte generation; supportive, lignin-containing vascular tissue absent; true roots, stems, leaves absent; sporophytes unbranched and unable to grow independently of gametophytes
VASCULAR PLANTS (TRACHEOPHYTES) (lycophytes, pteridophytes, spermatophytes)
Dominant sporophyte generation; lignified water-conducting tissue—xylem; specialized organic food-conducting tissue—phloem; sporophytes branched; sporophytes eventually become independent of gametophytes
SEEDLESS VASCULAR PLANTS (**lycophytes**, **pteridophytes**)
Lycophytes Leaves generally small with a single, unbranched vein (lycophylls or microphylls); sporangia borne on sides of stems
EUPHYLLOPHYTES (**pteridophytes**, SPERMATOPHYTES)
Pteridophytes Leaves relatively large with extensively branched vein system (euphylls or megaphylls); sporangia borne on leaves
SEED PLANTS (SPERMATOPHYTES)
Seeds present; leaves are euphylls
Gymnosperms (**cycads**, **ginkgos**, **conifers**, **gnetophytes**)
Flowers and fruits absent; seed food stored before fertilization in female gametophyte, endosperm absent
Angiosperms (**flowering plants**)
Flowers and fruit present; seed food stored after fertilization in endosperm formed by double fertilization

*Key: **Phyla**; LARGER MONOPHYLETIC CLADES (synonyms). All other classification terms are not clades.

Summary of Key Concepts

29.1 Ancestry and Diversity of Modern Plants

- Plants are multicellular eukaryotic organisms composed of cells having plastids; they display many adaptations to life on land. The modern plant kingdom consists of several hundred thousand species classified into 10 phyla, informally known as the liverworts, mosses, hornworts, lycophytes, pteridophytes, cycads, ginkgos, conifers, gnetophytes, and angiosperms. (Figure 29.1)
- The land plants evolved from ancestors that were probably similar to modern, complex charophycean algae of freshwater habitats. (Figure 29.2)
- The monophyletic liverwort, moss, and hornwort phyla are together known informally as the bryophytes. Bryophytes illustrate early-evolved features of land plants, such as a sporic life cycle involving embryos that develop within protective, nourishing gametophytic tissues. (Figures 29.3, 29.4, 29.5, 29.6)
- Bryophytes differ from other plants in having a dominant gametophyte generation and a dependent, nonbranching, short-lived sporophyte generation. Bryophytes also lack supportive vascular tissues in contrast to other modern plant phyla, which are known as the vascular plants or tracheophytes. (Figures 29.7, 29.8)
- Lycophytes, pteridophytes, and other vascular plants generally possess stems, roots, and leaves having vascular tissues composed of phloem and xylem, cuticle, and stomata, but these groups differ in distinctive ways. (Figures 29.9, 29.10, 29.11)
- The fern life cycle illustrates the dominant sporophyte characteristic of vascular plants. The fern *Ceratopteris richardii* is used as a model genetic system. (Figures 29.12, 29.13)
- Cycads, ginkgos, conifers, and gnetophytes are collectively known as gymnosperms. Gymnosperms produce seeds and inherited an ancestral capacity to produce wood. Angiosperms, the flowering plants, produce seeds, and many also produce wood. Flowers, fruits, and seed endosperm are distinctive features of the angiosperms. (Figures 29.14, 29.15)

29.2 An Evolutionary History of Land Plants

- Paleobiologists and plant evolutionary biologists infer the history of land plants by analyzing the molecular features of modern plants and by comparing the structural features of fossil and modern plants. (Figure 29.16)
- Seedless plants transformed Earth's ecology by fostering soil buildup and altering atmospheric chemistry and climate. (Figures 29.17, 29.18, 29.19)
- The K/T meteorite impact event that occurred 65 million years ago helped cause the extinction of previously dominant dinosaurs and many types of gymnosperms, leaving space into which angiosperms, insects, birds, and mammals diversified.

29.3 The Origin and Evolutionary Importance of the Plant Embryo

- Origin of the plant embryo was a critical innovation that fostered diversification of the land plants. Plant embryos are supported by nutrients supplied by female gametophytes with the aid of specialized placental transfer tissues. (Figure 29.20)
- In a classic experiment, Browning and Gunning inferred that placental transfer tissues were responsible for an enhanced flow rate of nutrients from parental gametophytes to embryos. (Figure 29.21)

29.4 The Origin and Evolutionary Importance of Leaves and Seeds

- Leaves are specialized photosynthetic organs that evolved more than once during plant evolutionary history. The lycophylls of lycophytes are relatively small leaves having a single unbranched vein. Euphyllophyte leaves are larger, with an extensively branched vascular system; they are known as euphylls. Fossils indicate that fern euphylls evolved from branched stem systems. (Figure 29.22)
- Seeds develop from ovules, megasporangia enclosed by leaflike integuments. Pollen produces thin cellular tubes that deliver sperm to eggs produced by female gametophytes. Following pollination and fertilization, ovules develop into seeds. Mature seeds contain stored food and an embryonic sporophyte that develops from the zygote. (Figure 29.23)
- Seeds confer many reproductive advantages, including dormancy through unfavorable conditions, greater protection for embryos from mechanical and pathogen damage, seed coat modifications that enhance seed dispersal, and reduction of plant dependence on water for fertilization. Fossil seeds display stages in seed evolution. (Figures 29.24, 29.25)
- The distinctive traits of charophyceans and the different phyla of land plants reveal the occurrence of descent with modification. (Table 29.1)

Assess and Discuss

Test Yourself

1. The simplest and most ancient phylum of modern land plants is probably
   a. the pteridophytes.
   b. the cycads.
   c. the liverworts.
   d. the angiosperms.
   e. none of the listed choices.
2. An important feature of land plants that originated during the diversification of charophycean algae is
   a. the sporophyte.
   b. spores, which are dispersed in air and coated with sporopollenin.
   c. tracheids.
   d. plasmodesmata.
   e. fruits.
3. A phylum whose members are also known as bryophytes is commonly known as
   a. liverworts.
   b. hornworts.
   c. mosses.
   d. all of the above.
   e. none of the listed choices.
4. Plants possess a life cycle that involves alternation of two multicellular generations: the gametophyte and
   a. the lycophyte.
   b. the bryophyte.
   c. the pteridophyte.
   d. the lignophyte.
   e. the sporophyte.

5. The seed plants are also known as
   a. bryophytes.
   b. spermatophytes.
   c. pteridophytes.
   d. lycophytes.
   e. euphyllophytes.
6. A waxy cuticle is an adaptation that
   a. helps to prevent water loss from tracheophytes.
   b. helps to prevent water loss from charophyceans.
   c. helps to prevent water loss from bryophytes.
   d. aids in water transport within the bodies of vascular plants.
   e. does all of the above.
7. Plant photosynthesis transformed a very large amount of carbon dioxide into decay-resistant organic compounds, thereby causing a low in atmospheric carbon dioxide levels during the geological period known as
   a. the Cambrian.
   b. the Ordovician.
   c. the Carboniferous.
   d. the Permian.
   e. the Pleistocene.
8. Which phylum among the plants listed is likely to have the largest leaves?
   a. liverworts
   b. hornworts
   c. mosses
   d. lycophytes
   e. pteridophytes
9. Euphylls, also known as megaphylls, probably evolved from
   a. the leaves of mosses.
   b. lycophylls.
   c. branched stem systems.
   d. modified roots.
   e. none of the listed choices.
10. A seed develops from
    a. a spore.
    b. a fertilized ovule.
    c. a microsporangium covered by integuments.
    d. endosperm.
    e. none of the above.

Conceptual Questions

1. List several common traits that lead evolutionary biologists to infer that land plants evolved from ancestors related to modern charophycean algae.
2. Why have bryophytes such as mosses been able to diversify into so many species even though they have relatively small, dependent sporophytes?
3. Explain how several structural features help vascular plants to maintain stable internal water content.

Collaborative Questions

1. Discuss at least one difference in environmental conditions experienced by early land plants and ancestral complex charophycean algae.
2. Discuss as many plant adaptations to land as you can.

The Evolution and Diversity of Modern Gymnosperms and Angiosperms

30

The Madagascar periwinkle (*Catharanthus roseus*), one of the many seed plants on which humans depend.

Chapter Outline

The seed plants, gymnosperms and angiosperms, are particularly important in our everyday lives because they are the sources of many products, including wood, paper, beverages, food, cosmetics, and medicines. Leukemia, for example, is effectively treated with vincristine, a drug extracted from the beautiful flowering plant known as the Madagascar periwinkle (*Catharanthus roseus*), pictured in the chapter-opening photo. Vinblastine—another extract from *C. roseus*—is used to treat lymphatic cancers. Taxol, a compound used in the treatment of breast and ovarian cancers, was first discovered in extracts of the Pacific yew tree, a gymnosperm known as *Taxus brevifolia*. Vincristine, vinblastine, taxol, and many other plant-derived medicines are examples of plant secondary metabolites, which are distinct from the products of primary metabolism (carbohydrates, lipids, proteins, and nucleic acids). Secondary metabolites play essential roles in protecting plants from disease organisms and plant-eating animals, and they also aid plant growth and reproduction. Though all plants produce secondary metabolites, these natural products are exceptionally diverse in gymnosperms and angiosperms.

In this chapter, we will learn how the hundreds of thousands of modern seed plants play many additional important roles in the lives of humans and modern ecosystems. This chapter builds on the introduction to seeds and seed plants provided in Chapter 29, focusing on the diversity of modern lineages of gymnosperms and angiosperms. Coevolutionary interactions among angiosperms and animals are presented as major forces influencing the diversification of these groups. This chapter concludes by considering human impacts on seed plant evolution and the importance of seed plants in modern agriculture.

30.1 Overview of the Seed Plants

Figure 30.1 shows our current understanding of the relationships among modern seed plants. As we discussed in Chapter 29, the first seed plants or spermatophytes evolved from earlier seedless vascular plants similar to modern lycophytes and pteridophytes. Following the early diversification of gymnosperms, one ancestral gymnosperm lineage gave rise to the angiosperms, the flowering plants. Today, humans depend upon modern seed plants, particularly the angiosperms, for many services and products. For example, as noted in the introduction, seed plants are major sources of useful medicines. Modern gymnosperms are important sources of wood and other useful materials, whereas the fruit and grain crops that form the basis for much of modern agriculture are angiosperms.

During their evolution, the seed plants inherited many adaptations to life on land from their ancestors and acquired new traits (Figure 30.1). Major critical innovations shared by all seed plants are pollen, ovules, seeds, and wood. As we learned in Chapter 29, pollen allows seed plants to disperse male gametophytes, ovules provide protection and nutrition to female gametophytes and developing embryos, and seeds allow plants to reproduce in diverse habitats. Wood strengthens plants, allowing them to grow tall and produce many branches, leaves, and seeds. We will learn more about these and other critical innovations in this chapter.

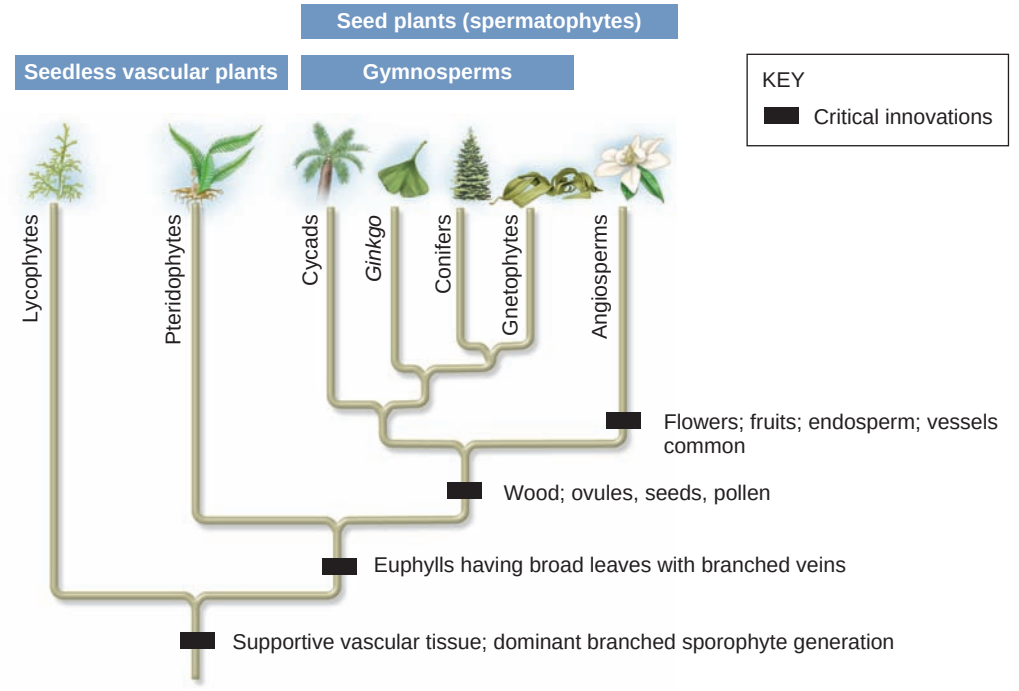

Figure 30.1 Phylogeny of modern seedless and seed plants showing critical innovations.

30.2 The Evolution and Diversity of Modern Gymnosperms

Gymnosperms are plants that produce seeds that are exposed rather than enclosed in fruits, as is the case for angiosperms. The word gymnosperm comes from the Greek *gymnos,* meaning naked (referring to the unclothed state of ancient athletes), and *sperma*, meaning seed. Most modern gymnosperms are woody plants that occur as shrubs or trees. Seeds and wood are adaptations that allow gymnosperms to cope with global climate changes and to live in relatively cold and dry habitats. In this section, we will first consider some fossil plants that help to explain important gymnosperm traits. Then we will survey the structure, reproduction, and ecological roles of modern gymnosperm phyla.

Modern Gymnosperms Arose from Woody Ancestors

Modern gymnosperms include the famous giant sequoias (*Sequoiadendron giganteum*) native to the Sierra Nevada of the western U.S. Giant sequoias are among Earth's largest organisms, weighing as much as 6,000 tons and reaching an amazing 100 m in height. The large size of sequoias and other trees is based on the presence of **wood**, a tissue composed of numerous pipelike arrays of empty, water-conducting cells whose walls are strengthened by an exceptionally tough secondary metabolite known as lignin. These properties enable woody tissues to transport water upward for great distances and also to provide the structural support needed for trees to grow tall and produce many branches and leaves. In modern seed plants, a special tissue known as the **vascular cambium** produces both thick layers of wood and thinner layers of inner bark. The inner bark transports watery solutions of organic compounds. (The structure and function of the vascular cambium, wood, and bark are described in more detail in Chapter 35.) Vascular cambium, wood, and inner bark are critical innovations that helped gymnosperms and other seed plants to compete effectively for light and other resources needed for photosynthesis.

Wood first appeared in a group of plants known as the **progymnosperms** (from the Greek, meaning before gymnosperms). Woody progymnosperms, such as the fossil plant genus *Archaeopteris*, which lived 370 million years ago (mya), were the first trees that had leafy twigs (Figure 30.2). Progymnosperms were able to produce a vascular cambium and wood because their vascular tissue was arranged in a ring around a central pith of nonvascular tissue. (In contrast, the vascular tissue of earlier tracheophytes was arranged differently.) This ring of vascular tissue, known as a **eustele**, contained cells that were able to develop into the vascular cambium as seedlings grew into saplings. The vascular cambium then produced wood, allowing saplings to grow into tall trees. Modern seed plants inherited the eustele, explaining why many gymnosperms and angiosperms are also able to produce vascular cambia and wood. Although progymnosperms were woody plants, fossil evidence indicates that they did not produce seeds. This observation reveals that wood originated before seeds evolved.

Diverse early gymnosperms were the major vegetation present during the Mesozoic era, also known as the Age of Dinosaurs. Some groups of gymnosperms became extinct before or as a result of the K/T event at the end of the Cretaceous period 65 mya (see Chapter 29). Only a few gymnosperm phyla have survived to modern times: cycads (the Cycadophyta); *Ginkgo biloba*, the only surviving member of a once-large phylum termed Ginkgophyta; conifers (the Coniferophyta); and

Figure 30.2 **The progymnosperm *Archaeopteris*, an early tree.** This illustration was reconstructed from fossil data.

gnetophytes (Gnetophyta). These phyla display distinctive reproductive features and play important roles in ecology and human affairs.

Cycads Are Endangered in the Wild but Are Widely Used as Ornamentals

Nearly 300 cycad species occur today, primarily in tropical and subtropical regions. However, many species of cycads are rare, and their tropical forest homes are increasingly threatened by human activities. Many cycads are listed as endangered species, and commercial trade in cycads is regulated by CITES (Convention on International Trade in Endangered Species of Wild Fauna and Flora), a voluntary international agreement.

The structure of cycads is so interesting and attractive that many species are cultivated for use in outdoor plantings or as houseplants. The nonwoody stems of some cycads emerge from the ground much like tree trunks, some reaching 15 m in height, whereas the stems of other cycads are not conspicuous because they are subterranean (Figure 30.3). Cycads display spreading, palmlike leaves (*cycad* comes from a Greek word, meaning palm). Mature leaves of the African cycad *Encephalartos laurentianus* can reach an astounding 8.8 m in length!

In addition to underground roots, which provide anchorage and take up water and minerals, many cycads produce coralloid roots. Such roots extend aboveground and have branching shapes resembling corals (Figure 30.4a). Coralloid roots harbor light-dependent, photosynthetic cyanobacteria within their

Figure 30.4 **Coralloid roots of cycads.** **(a)** Many cycads produce aboveground branching roots that resemble branched corals. **(b)** This magnified cross section of a coralloid root shows a ring of symbiotic blue-green cyanobacteria, which provide the plant with fixed nitrogen.

Concept check: *Why do the coralloid roots grow aboveground?*

tissues. The cyanobacteria, which form a bright blue-green ring beneath root surfaces (Figure 30.4b), are nitrogen fixers that provide their plant hosts with nitrogen minerals crucial to their growth (see Chapter 27).

Recent studies have revealed that the cyanobacteria in the cycad *Cycas micronesica* produce an unusual amino acid that is distributed to the host plant's leaves and seeds. The distinctive amino acid, known as BMAA (β-N-methylamino-L-alanine), is harmful to the health of humans who consume flour made from cycad seeds or the meat of bats that have fed on *C. micronesica* seeds. Botanist Paul Alan Cox and associates linked this toxin to the unusually high occurrence of a dementia resembling Alzheimer disease among the Chamorro people of Guam in the Mariana Islands chain. These researchers also found BMAA in the brain tissues of dementia patients who had not consumed foods originating from cycads. In an effort to understand these cases, Cox and associates examined many types of cyanobacteria from diverse habitats. In 2005, these investigators reported that most cyanobacteria produce BMAA in nature, suggesting that the toxic amino acid could be more widely present in the environment than previously thought. Studies of cycad toxicity have thus revealed a potential human health hazard of widespread concern. Because cycads generally produce a variety of toxins that likely deter herbivorous animals, experts recommend that humans should not consume food products made from these plants.

Cycad reproduction is distinctive in several ways. Individual cycad plants produce conspicuous conelike structures that bear either ovules and seeds or pollen (see Figure 30.3). When mature, both types of reproductive structures emit odors that attract beetles. These insects carry pollen to ovules, where the pollen produces tubes that deliver sperm to eggs.

Ginkgo biloba Is the Last Survivor of a Once-Diverse Group

The beautiful tree *Ginkgo biloba* (Figure 30.5a) is the single remaining species of a phylum that was much more diverse during the Age of Dinosaurs. *G. biloba* takes its species name from the lobed shape of its leaves, which have unusual forked veins (Figure 30.5b). Today, *G. biloba* may be nearly extinct in the wild; widely cultivated modern *Ginkgo* trees are descended from seeds produced by a tree found in a remote Japanese temple garden and brought to Europe by 17th-century explorers.

G. biloba trees are widely planted along city streets because they are ornamental and also tolerate cold, heat, and pollution better than most trees. In addition, these trees are long-lived—individuals can live for more than a thousand years and grow to 30 m in height. Individual trees produce either ovules and seeds or pollen, based on a sex chromosome system much like that of humans. Ovule-producing trees have two X chromosomes; pollen-producing trees have one X and one Y chromosome. Wind disperses pollen to ovules, where pollen grains germinate to produce pollen tubes. These tubes grow through ovule tissues for several months, absorbing nutrients that are used for sperm development. Eventually the pollen tubes burst, delivering flagellate sperm to egg cells. After fertilization, zygotes develop into embryos, and the ovule integument develops into a fleshy, bad-smelling outer seed coat and a hard, inner seed coat (Figure 30.5c). For street-side or garden plantings, people usually select pollen-producing trees to avoid the stinky seeds.

Conifers Are the Most Diverse Modern Gymnosperm Lineage

The conifers (Figure 30.6) are a lineage of trees named for their seed cones, of which pinecones are familiar examples. Conifers have been important components of terrestrial vegetation since the end of the Carboniferous period some 300 mya. Modern conifer families have existed for about 200 million years, including surviving the K/T event about 65 mya, and today include more than 500 species in 50 genera. Conifers are particularly common in mountain and high-latitude forests and are important sources of wood and paper pulp.

Conifers produce simple pollen cones and more complex ovule-bearing cones (Figure 30.7). The pollen cones of conifers

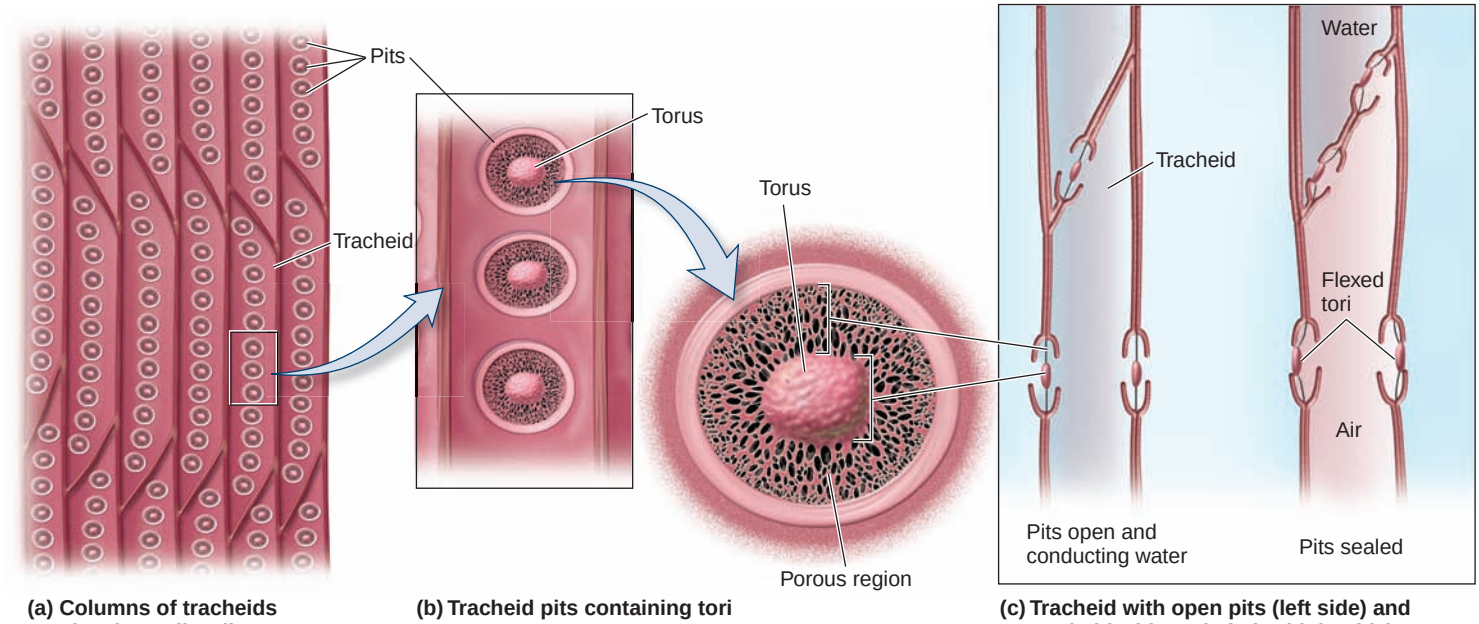
Juniper seeds are used in the production of gin.

bear many leaflike structures, each bearing a microsporangium in which meiosis occurs and pollen grains develop. The ovule cones, also called seed cones, are composed of many short branch systems that bear ovules. Ovules contain female gametophytes within which eggs develop.

When conifer pollen is mature, it is released into the wind, which transports pollen to ovules. When released from pollen tubes, sperm fuse with eggs, generating zygotes that grow into the embryos within seeds. Altogether, it takes nearly 2 years for pine (the genus *Pinus*) to complete the processes of male and female gamete development, fertilization, and seed development (Figure 30.7). The seeds of pine and some other conifers develop wings that aid in wind dispersal (Figure 30.8a). Other conifers, such as yew and juniper, produce seeds or cones with bright-colored, fleshy coatings that are attractive to birds, which help to disperse the seeds (Figure 30.8b,c).

Conifer wood contains many water transport cells known as tracheids that are adapted for efficient conduction even in dry conditions. Like the tracheids of other vascular plants, those of conifers are devoid of cytoplasm and occur in long columns that function like plumbing pipelines (Figure 30.9a). Tracheid side and end walls possess many thin-walled, circular **pits** through which water moves both vertically and laterally from one tracheid to another. Conifer pits are unusual in having a porous



(a) Columns of tracheids showing cell walls (b) Tracheid pits containing tori (c) Tracheid with open pits (left side) and tracheid with sealed pits (right side)

Figure 30.9 **Tracheids in conifer wood.** **(a)** The lignin-rich cell walls of the water-conducting cells called tracheids. **(b)** Detailed view of a portion of a tracheid that shows the thin-walled areas known as pits, each with a torus. **(c)** A water-filled tracheid with open pits and an air-filled tracheid with pits sealed by the flexed tori.

Concept check: *How does the torus foster conifer survival in arid or cold habitats?*

outer region that lets water flow through and a nonporous, flexible central region called the **torus** (plural, tori) that functions like a valve (Figure 30.9b). If conifer tracheids become dry and fill with air, they are no longer able to conduct water. In this case, the torus presses against the pit opening, sealing it (Figure 30.9c). The torus valve thereby prevents air bubbles from spreading to the next tracheid. This conifer adaptation localizes air bubbles, preventing them from stopping water conduction in other tracheids. The presence of tori in their tracheids helps to explain why conifers have been so successful for hundreds of millions of years. Conifer wood (and leaves) may also display conspicuous resin ducts, passageways for the flow of syrup-like resin that helps to prevent attack by pathogens and herbivores. Resin that exudes from tree surfaces may trap insects and other organisms, then harden in the air and fossilize, preserving the inclusions in amber.

Many conifers occur in cold climates and thus display numerous adaptations to such environments. Their conical shapes and flexible branches help conifer trees shed snow, preventing heavy snow accumulations from breaking branches. Conifer leaf shape and structure are adapted to resist damage from drought that occurs in both summer and winter, when liquid water is scarce. Conifer leaves are often scalelike (Figure 30.10a) or needle-shaped (Figure 30.10b); these shapes reduce the area of leaf surface from which water can evaporate. In addition, a thick, waxy cuticle coats conifer leaf surfaces (Figure 30.10c), retarding water loss and attack by disease organisms.

Many conifers are evergreen; that is, their leaves live for more than 1 year before being shed and are not all shed during the same season. Retaining leaves through winter helps conifers start up photosynthesis earlier than deciduous trees, which in spring must replace leaves lost during the previous autumn. Evergreen leaves thus provide an advantage in the short growth season of alpine or high-latitude environments. However, some conifers do lose all their leaves in the autumn. The bald cypress (*Taxodium distichum*) of southern U.S. floodplains, tamarack (*Larix laricina*) of northern bogs, and dawn redwood (*Metasequoia glyptostroboides*) are examples of deciduous conifers. Fossils indicate that dawn redwoods once grew abundantly across wide areas of the Northern Hemisphere until a few million years ago and then disappeared. However, in the 1940s, a forester found a living dawn redwood growing in a remote Chinese village, and subsequent expeditions located forests of the conifers. Since then, dawn redwood trees have been widely planted as ornamentals, prized for their attractive foliage and cones (see Figure 30.6b). As recently as 1994, botanists found a previously unknown conifer species, *Wollemia nobilis*, in an Australian national park. Like the dawn redwood, *Wollemia* is an attractive tree that is likely to become more widely distributed as the result of human cultivation.

Concept check: *In what ways are conifer leaves adapted to resist water loss from their surfaces?*

Gnetophytes Display Unusual Adaptations

Related to conifers, the modern gnetophytes consist of three genera, *Gnetum*, *Ephedra*, and *Welwitschia*, that feature distinctive adaptations. *Gnetum* is unusual among modern gymnosperms in having broad leaves similar to those of many tropical plants (Figure 30.11a). Such leaves foster light capture in the dim forest habitat. More than 30 species of the genus *Gnetum* occur as vines, shrubs, or trees in tropical Africa or Asia. *Ephedra*, a gnetophyte genus native to arid regions of the southwestern U.S., has tiny brown scalelike leaves and green, photosynthetic stems

(a) Genus *Gnetum*

(b) *Ephedra californica*

(c) *Welwitschia mirabilis*

Figure 30.11 **Gnetophytes.** **(a)** A tropical plant of the genus *Gnetum*, displaying broad leaves and reproductive structures. **(b)** *Ephedra californica* growing in deserts of North America, showing miniscule brown leaves on green, photosynthetic stems and reproductive structures. **(c)** *Welwitschia mirabilis* growing in the Namib Desert of southwestern Africa, showing long, wind-shredded leaves and reproductive structures.

(Figure 30.11b). These adaptations help to conserve water by preventing water loss that would otherwise occur from the surfaces of larger leaves. *Ephedra* produces secondary metabolites that aid in plant protection but also affect human physiology. Early settlers of the western U.S. used *Ephedra* to treat colds and other medical conditions. In fact, the modern decongestant drug pseudoephedrine is based on the chemical structure of ephedrine, which was named for and originally obtained from *Ephedra*. Pseudoephedrine sales are now restricted in many places because this compound can be used as a starting point for the synthesis of illegal drugs. Ephedrine has also been used to enhance sports performance, a practice that has elicited medical concern.

Welwitschia, the third gnetophyte genus, has only one living representative species. *Welwitschia mirabilis* is a strange-looking plant that grows in the coastal Namib Desert of southwestern Africa, one of the driest places on Earth (Figure 30.11c). A long taproot anchors a stubby stem that barely emerges from the ground. Two very long leaves grow from the stem but rapidly become wind-shredded into many strips. The plant is thought to obtain most of its water from coastal fog, explaining how *W. mirabilis* can grow and reproduce in such a dry place.

30.3 The Evolution and Diversity of Modern Angiosperms

One ancient gymnosperm group, although it's unclear which one, gave rise to the angiosperms. Angiosperms, the flowering plants, retained many structural and reproductive features from ancestral seed plants. In addition, flowering plants evolved several traits not found or seldom found among other land plants. For example, flowers and fruits are two of the defining features of angiosperms (Figure 30.12), because these features do not occur in other modern plants. The term **angiosperm** is from Greek words, meaning enclosed seed, which reflects the presence of seeds within fruits. The seed nutritive material known as endosperm is another defining feature of the flowering plants (see Chapters 29 and 39). Flowers, fruits, and seed endosperm are critical innovations that foster the production and dispersal of seeds and enclosed embryos. In addition, most angiosperms possess distinctive water-conducting cells, known as **vessels**, which are wider than tracheids and therefore increase the efficiency of water flow through plants. Though similar conducting cells occur in gnetophytes and some seedless plants, such vessels are examples of parallel evolution.

Although humans obtain wood, medicines, and other valuable products from gymnosperms, we depend even more on the angiosperms. Our food, beverages, and spices—flavored by an amazing variety of secondary metabolites—primarily come from flowering plants. People surround themselves with ornamental flowering plants and decorative items displaying flowers or fruit. We also commonly use flowers and fruit in ceremonies. In this section, we focus on how flowers, fruits, and secondary metabolites played key roles in angiosperm diversification. We will also learn that features of flowers, fruits, and secondary metabolites are used to classify and identify angiosperm species.

Flower Organs Evolved from Leaflike Structures

Flowers are complex reproductive structures that are specialized for the efficient production of pollen and seeds. The sexual

Figure 30.12 **Angiosperm flowers and fruits.** Citrus plants display the critical innovations of flowering plants: the flowers and fruits shown here and seed endosperm (not shown).

Concept check: *What other trait occurs widely among angiosperms but rarely among other plants?*

reproduction process of angiosperms depends on flowers. As the flowering plants diversified, flowers of varied types evolved as reproductive adaptations to differing environmental conditions. To understand this process, we can start by considering the basic flower parts and their roles in reproduction.

Flower Parts and Their Reproductive Roles Flowers are produced at stem tips and may contain four types of organs: sepals, petals, pollen-producing stamens, and ovule-producing carpels (Figure 30.13). These flower organs are supported by tissue known as a **receptacle**, located at the tip of a flower stalk—a **pedicel**. The functioning of several genes that control flower organ development explains why carpels are the most central flower organs, why stamens surround carpels, and why petals and sepals are the outermost flower organs (refer back to Figure 19.24).

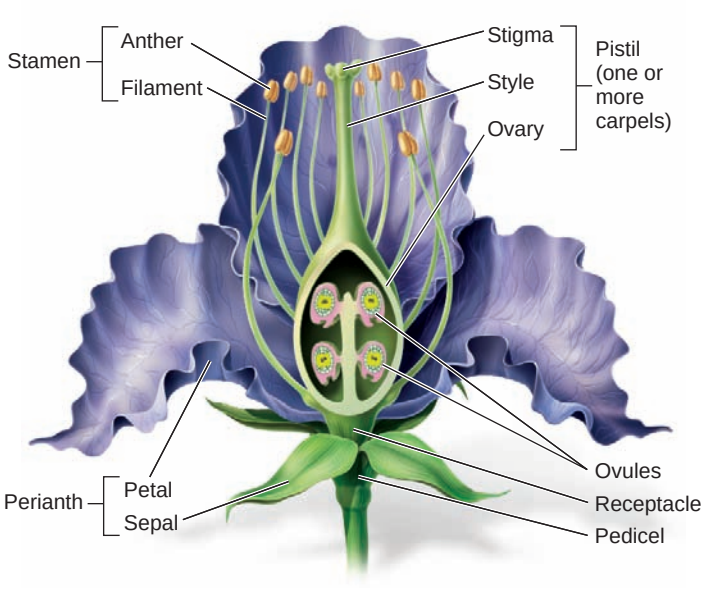

Figure 30.13 **Generalized flower structure.**

Many flowers produce attractive **petals** that play a role in **pollination**, the transfer of pollen among flowers. **Sepals** of many flowers are green and form the outer layer of flower buds. By contrast, the sepals of other flowers look similar to petals, in which case both sepals and petals are known as **tepals**. All of a flower's sepals and petals (or tepals) are collectively known as the **perianth**. Most flowers produce one or more **stamens**, the structures that produce and disperse pollen. Most flowers also contain **carpels**, structures that produce ovules.

Some flowers lack perianths, stamens, or carpels. Flowers that possess all four types of flower organs are known as **complete flowers**, and flowers lacking one or more organ types are known as **incomplete flowers**. Flowers that contain both stamens and carpels are described as **perfect flowers**, and flowers lacking either stamens or carpels are **imperfect flowers**.

Flowers also differ in the numbers of organs they produce. Some flowers produce only a single carpel, others display several separate carpels, and many possess several carpels that are fused together into a compound structure. Both a single carpel and compound carpels are referred to as a **pistil** (from the Latin *pistillum*, meaning pestle) because it resembles the device people use to grind materials to powder in a mortar (Figure 30.13). Only one pistil is present in flowers that have only one carpel and in flowers with fused carpels. By contrast, flowers possessing several separate carpels display multiple pistils.

Pistil structure can be divided into three regions having distinct functions. A topmost portion of the pistil, known as the **stigma**, receives and recognizes pollen of the appropriate species or genotype. The elongate middle portion of the pistil is called the **style**. The lowermost portion of the pistil is the **ovary**, which encloses and protects ovules.

During the flowering plant life cycle (Figure 30.14), the stigma allows pollen of appropriate genetic type to germinate, producing a long pollen tube that grows through the style. The pollen tube thereby delivers sperm cells to ovules and the eggs inside, allowing fertilization. If fertilization occurs, the zygote develops into an embryo, and the ovule develops into a seed. Ovaries (and sometimes additional flower parts) develop into fruits.

Early Flowers Distinctive fossil pollen grains that were deposited about 140 mya are the earliest widely accepted evidence for flowering plants. Fossils of whole plants with flowers and fruits are known from deposits that are about 120 million years old. Flowers were a critical innovation that led to extensive angiosperm diversification. Comparative studies of the structures of modern and fossil flowers suggest how modern stamens and carpels might have arisen. Early fossil flowers and some modern flowers have broad stamens that are leaf-shaped, with elongated, pollen-producing microsporangia on the stamen surface (Figure 30.15a). In contrast, the stamens of most modern plants have become narrowed to form **filaments**, or stalks, that elevate **anthers**, clusters of microsporangia that produce pollen and then open to release it (see Figure 30.13). Filaments and anthers are adaptations that foster pollen dispersal.

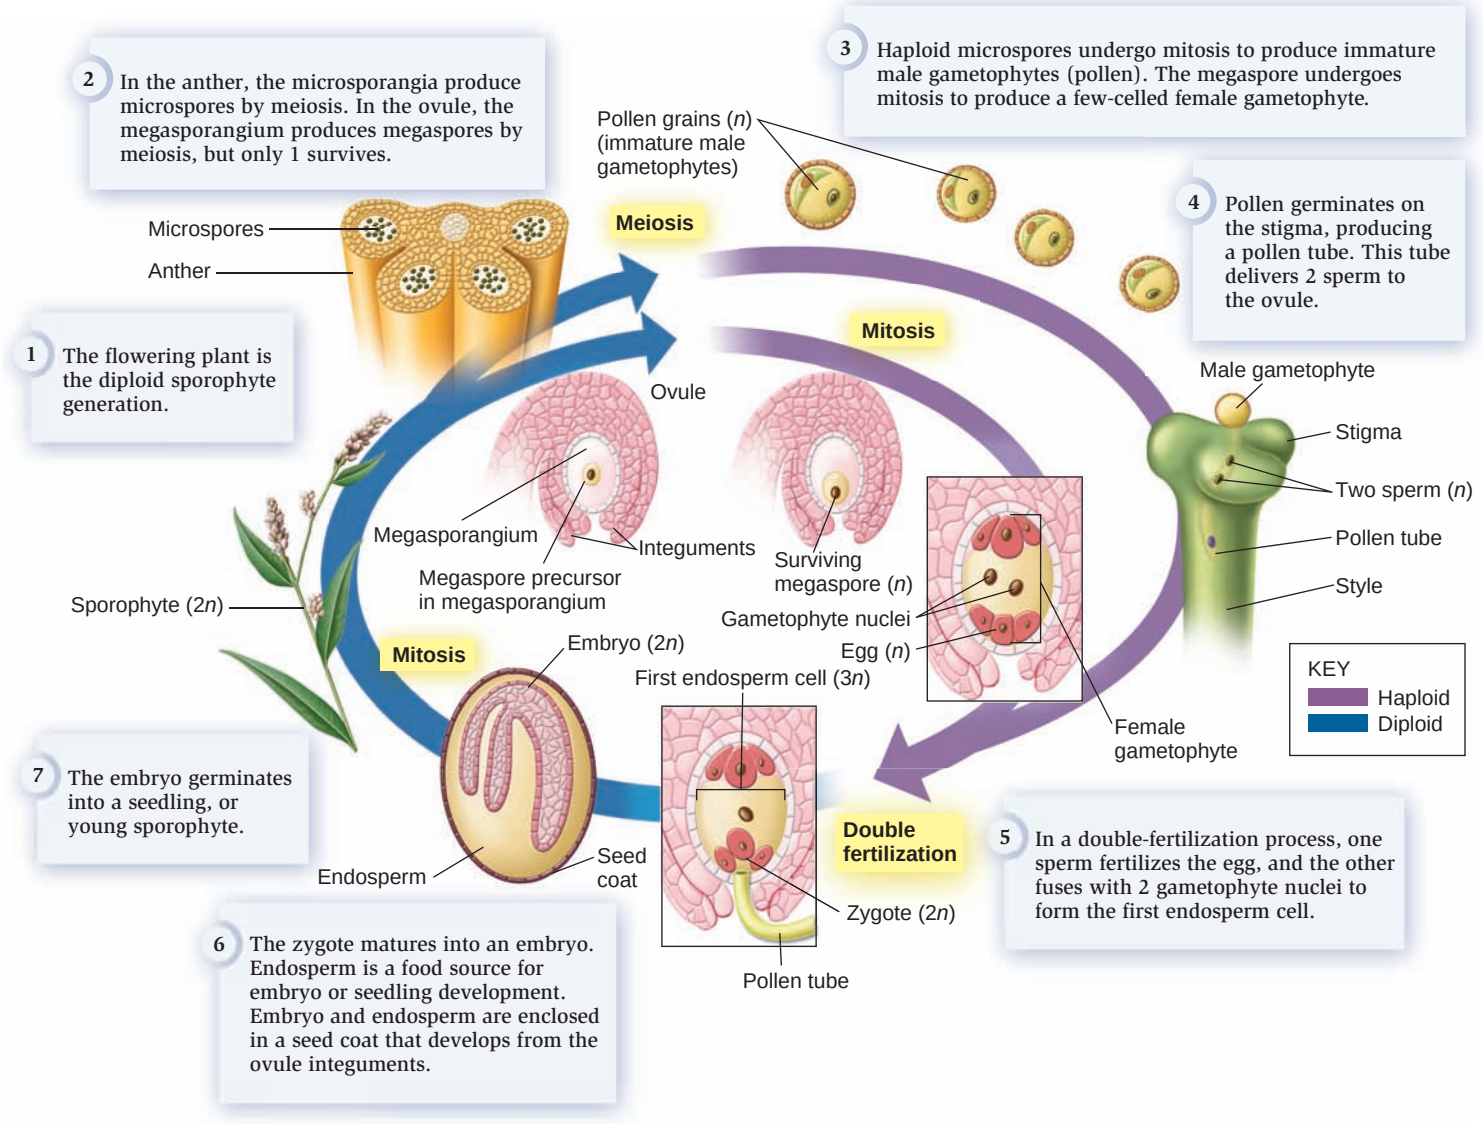

Figure 30.14 The life cycle of a flowering plant, illustrated by the genus *Polygonum*.

Plant biologists hypothesize that carpels evolved from leaflike structures bearing ovules on their surfaces and that such leaves folded over ovules, protecting them. In support of this hypothesis is the observation that the carpels of some early-diverging modern plants are leaflike structures that fold over ovules, with the carpel edges stuck together by secretions (Figure 30.15b). In contrast, most modern flowers produce carpels whose edges have fused together into a tube whose lower portion (ovary) encloses ovules. Plant biologists hypothesize that such evolutionary change increased ovule protection, which would improve plant fitness.

Flowering Plants Diversified into Several Lineages, Including Monocots and Eudicots

Figure 30.16 presents our current understanding of the relationships among angiosperm groups. According to gene-sequencing studies, the earliest-diverging angiosperms are represented by a single modern species called *Amborella trichopoda*, a shrub that lives in cloud forests on the South Pacific island of New Caledonia. The flowers of *A. trichopoda* display hypothesized ancient features. For example, the fairly small flowers have stamens with broad filaments and several separate carpels (Figure 30.17). *A. trichopoda* also lacks vessels in the water-conducting tissues. In contrast, typical angiosperm vessels are present in later-diverging groups of angiosperms, including water lilies, the star anise plant, and other close relatives (see Figure 30.16). Magnoliids, represented by the genus *Magnolia*, are the next-diverging group. Magnoliids are closely related to two very large and diverse angiosperm lineages, the **monocots** and the **eudicots**.

Monocots and eudicots are named for differences in the number of embryonic leaves called cotyledons. Monocot embryos possess one cotyledon, whereas eudicots possess two cotyledons. Monocots differ from eudicots in several additional ways (see Chapter 35). For example, monocots typically have flowers with parts numbering three or some multiple of three (Figure 30.18a). In contrast, eudicot flower parts often occur in fours, fives, or a multiple of four or five (Figure 30.18b).

(b) Carpel evolution

Figure 30.15 Hypothetical evolution of stamens, carpels, and pistils.

Genomes & Proteomes Connection

Whole Genome Duplications Influenced Flowering Plant Diversification

Genome doubling, also known as polyploidy, occurs in a wide variety of eukaryotes (see Figure 15.20), and has happened frequently during the evolutionary history of plants. An estimated 40–70% of all plants are polyploid, meaning that the entire diploid genome has been duplicated at least once. An analysis of the grape (*Vitis vinfera*) genome indicates that different patterns of whole genome duplication occurred in monocots and eudicots after their divergence. Whole genome duplication has the potential to affect species' evolutionary pathways because it offers the opportunity for many genes to diverge, forming gene families. For example, Amelie Veron and colleagues showed how whole genome duplications increased the diversity of an important class of plant transcription factors, the MADS-Box proteins, in seed plants.

Two major types of polyploidy occur in plants. Autopolyploidy occurs when homologous chromosome pairs do not separate during meiosis, a process known as nondisjunction. As a result, plants produce diploid spores, gametophytes, and gametes, when these life stages would otherwise be haploid. The mating of two diploid gametes will produce a tetraploid plant,

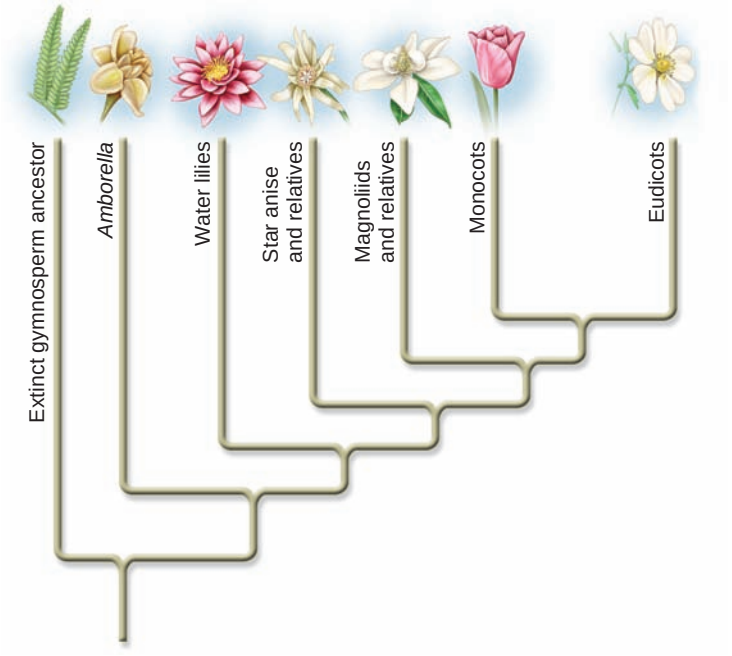

Figure 30.16 A phylogeny showing the major modern angiosperm lineages.

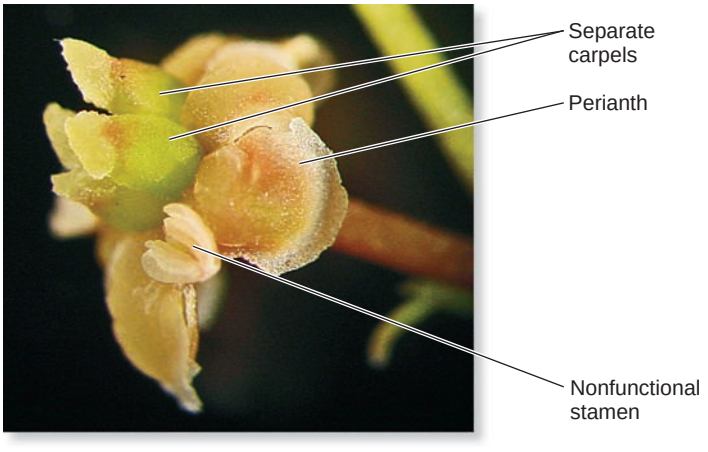

Figure 30.17 ***Amborella trichopoda*** **flower, similar to a hypothesized early flower.** This small flower is only about 3–4 mm in diameter. It displays several central, greenish carpels; nonfunctional stamens; and a pink perianth. This plant species also produces flowers that lack carpels but have many functional stamens.

one having four sets of chromosomes. As the result of a large study of the occurrence of autoploidy in plants, plant evolutionary biologists Douglas and Pamela Soltis and their colleagues concluded that autopolyploidy is an important speciation mechanism in plants. These experts point out that because some autopolyploids have diverged sufficiently from the parental diploid species, they should be given different species names, and that failure to name such polyploids causes natural biodiversity to be underestimated.

(a) A monocot with six tepals

(b) A eudicot with five petals

Figure 30.18 **One characteristic difference between monocots and eudicots: flower part number.** **(a)** Flowers and buds of lily (genus *Lilium*), displaying six tepals. **(b)** A flower and buds of apple (genus *Malus*), showing five flower petals. Sepals are visible around the pink buds.

A second major type of whole genome duplication in plants involves an initial hybridization between two species having different chromosome numbers. Such a hybrid would not be able to produce viable spores because chromosomes could not pair properly at meiosis. However, if such a hybrid plant then undergoes a whole genome duplication process, producing an allopolyploid, homologous chromosomes are available for pairing during meiosis, and viable spores, gametophytes, and gametes can form (see Chapter 15). Many common crops, including wheat and cotton, are allopolyploids, as are wild plants such as the desert sunflowers *Helianthus anomalus*, *H. deserticola*, and *H. paradoxus*. These sunflower hybrids are better adapted to survive drought conditions than are their parent species, *H. annuis* and *H. petiolaris*.

In addition to allopolyploidy, plants are known to obtain mitochondrial genes from other plant species by means of horizontal gene transfer. Genes have moved from one angiosperm species to another and between angiosperms and nonflowering plants, probably by mitochondrial fusion. For example, of the 31 genes present in the mitochondrial genome of the early-diverging flowering plant *Amborella trichopoda*, at least

20 were obtained from other angiosperms or mosses that grow on *A. trichopoda*'s surfaces. Because plant nuclear genomes commonly take up genes from organelles in the same cell, such foreign mitochondrial genes could end up in the nucleus. Hybridization and mitochondrial transfer are mechanisms by which plant lineages undergo reticulate (network-like) as well as treelike evolution.

Flower Diversification Fosters Efficient Seed Production

During the diversification of flowering plants, flower evolution has involved several types of changes that foster the transfer of pollen from one plant to another. Fusion of flower organs, clustering of flowers into groups, and reducing the perianth are some examples of such changes.

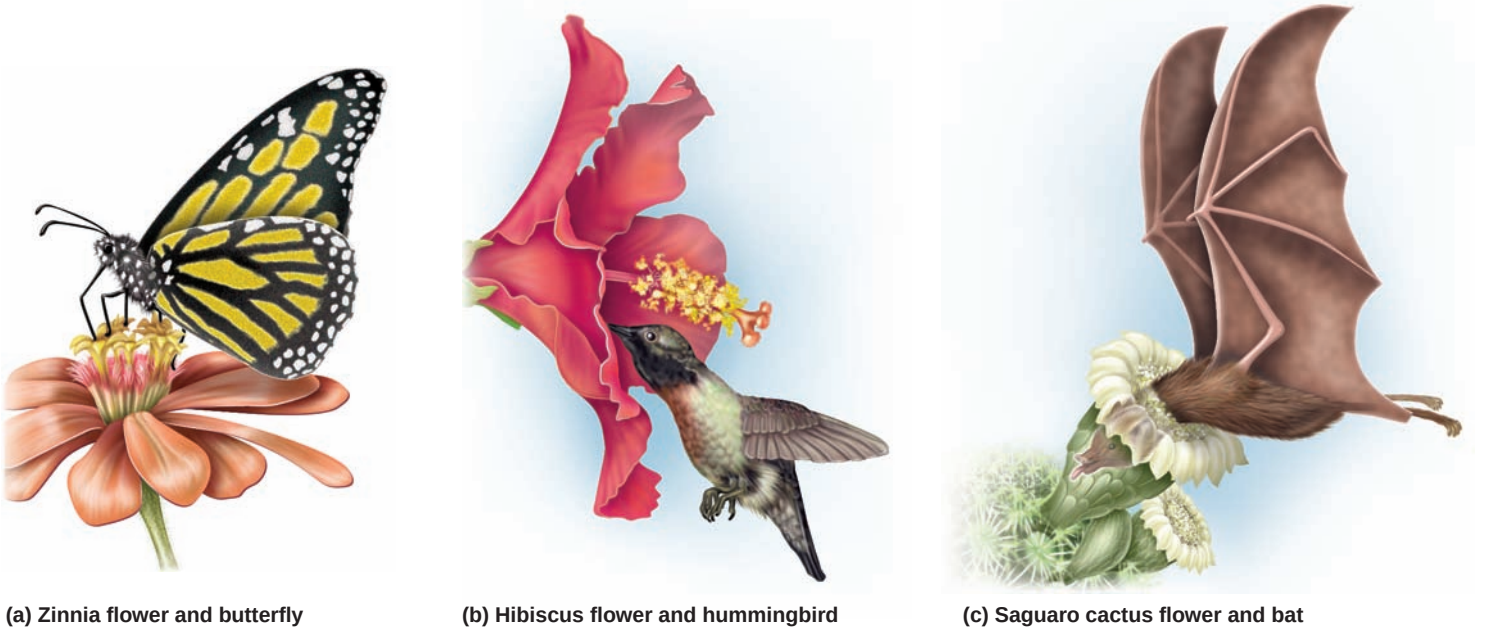
Many flowers have fused petals that form floral tubes. Such tubes tend to accumulate sugar-rich nectar that provides a reward for **pollinators**, animals that transfer pollen among plants. The diameters of floral tubes vary among flowers and are evolutionarily tuned to the feeding structures of diverse animals, which range from the narrow tongues of butterflies to the wider bills of nectar-feeding birds (Figure 30.19). Nectar-feeding bats stick their heads into even larger tubular flowers to lap up nectar with their tongues. Orchids provide another example of ways in which flower parts have become fused; stamens and carpels are fused together into a single reproductive column that is surrounded by attractive tepals (Figure 30.20a). This arrangement of flower organs fosters orchid pollination by particular insects and is a distinctive feature of the orchid family.

Many plants produce flowers in clusters known as **inflorescences**, which occur in several types. The sunflower family features a type of inflorescence in which many small flowers are clustered into a head (Figure 30.20b). The flowers at the center of a sunflower head function in reproduction and lack showy petals, while flowers at the rim have showy petals that attract pollinators. Heads allow pollinators to transfer pollen among a large number of flowers at the same time. The grass family features flowers having few or no perianths, explaining why grass flowers are not showy (Figure 30.20c). This adaptation fosters pollination by wind, because petals would only get in the way of such pollen transfer.

Diverse Types of Fruits Function in Seed Dispersal

Fruits are structures that develop from ovary walls in diverse ways that aid the dispersal of enclosed seeds. Seed dispersal helps to prevent seedlings from competing with their larger parents for scarce resources such as water and light. Dispersal of seeds also allows plants to colonize new habitats. Diverse fruit types illustrate the many ways in which plants have become adapted for effective seed dispersal. Like flower types, fruit types are useful in classifying and identifying angiosperms.

Many mature angiosperm fruits, such as cherries, grapes, and lemons, are attractively colored, soft, juicy, and tasty (Figure 30.21a–c). Such fruits are adapted to attract animals that consume the fruits, digest the outer portion as food, and eliminate the seeds, thereby dispersing them. Hard seed coats prevent such seeds from being destroyed by the animal's digestive system. Strawberries are aggregate fruits, many fruits that all develop from a single flower having multiple pistils



(a) Zinnia flower and butterfly (b) Hibiscus flower and hummingbird (c) Saguaro cactus flower and bat

Figure 30.19 **Floral tubes and coevolved pollinators.** **(a)** This zinnia is composed of an outer rim of showy flowers and a central disc of narrow tubular flowers that produce nectar. Butterflies, but not other pollinators, are able to reach the nectar by means of narrow tongues. **(b)** The hibiscus flower produces nectar in a floral tube whose diameter corresponds to the dimensions of a hummingbird bill. **(c)** The saguaro cactus (*Carnegiea gigantea*) flower forms a floral tube that is wide enough for nectar-feeding bats to get their heads inside. The cactus flower has been drawn here as if it were transparent, to illustrate bat pollination.

(b) A sunflower plant showing inflorescence

(c) Grass flowers lacking showy perianth

Figure 30.20 **Evolutionary changes in flower structure.** **(a)** An orchid of the genus *Cattleya* has fused stamens and pistil, and six tepals, one of which is specialized to form a lower lip. **(b)** An inflorescence (head) of sunflower (genus *Helianthus*). This inflorescence includes a rim of flowers with conspicuous petals that attract pollinators and an inner disc of flowers that lack attractive perianths. **(c)** Grass flowers of the genus *Triticum* lack a showy perianth.

Concept check: *What advantage does the nonshowy perianth of grass flowers provide?*

(a) A fleshy fruit (cherry)

(b) A fleshy berry fruit (grape)

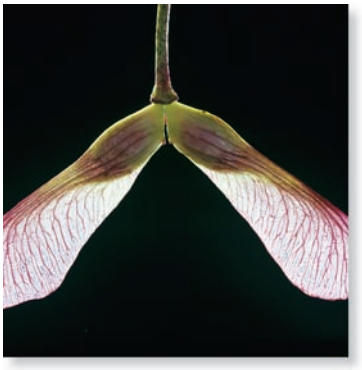
(c) A fleshy fruit (lemon)

(d) An aggregate fruit (strawberry)

(e) A multiple fruit (pineapple)

(f) Legumes with dry pods (peas)

(g) Fruit with husk (coconut)



(h) A dry, winged fruit (maple)

Figure 30.21 **Representative fruit types.** **(a–c)** The cherry drupe, grape berry, and lemon hesperidium are fleshy fruits adapted to attract animals that consume the fruits and excrete the seeds. **(d)** Strawberry is an aggregate fruit, consisting of many tiny, single-seeded fruits produced by a single flower. The fruits are embedded in the surface of a fleshy receptacle that is adapted to attract animal seed-dispersal agents. **(e)** Pineapple is a large multiple fruit formed by the aggregation of smaller fruits, each produced by one of the flowers in an inflorescence. **(f)** Peas produce legumes, fruits that open on two sides to release seeds. **(g)** Coconut fruits possess a fibrous husk that aids dispersal in water. **(h)** Maple trees produce dry fruits with wings adapted for wind dispersal.

(Figure 30.21d). The ovaries of these pistils develop into tiny, single-seeded yellow fruits on a strawberry surface; the fleshy, red, sweet portion of a strawberry develops from a flower receptacle. Aggregate fruits allow a single animal consumer, such as a bird, to disperse many seeds at the same time.

Pineapples (Figure 30.21e) are juicy multiple fruits that develop when many ovaries of an inflorescence fuse together. Such multiple fruits are larger and attract relatively large animals that have the ability to disperse seeds for long distances. Mulberries and figs are additional examples of multiple fruits that provide similar benefits.

The plant family informally known as **legumes** is named for its distinctive fruits, dry pods that open down both sides when seeds are mature, thereby releasing them (Figure 30.21f). Nuts and grains are additional examples of dry fruits. **Grains** are the characteristic single-seeded fruits of cereal grasses such as rice, corn (maize), barley, and wheat. Coconut fruits are adapted for dispersal in ocean currents (Figure 30.21g). Maple trees produce dry and thus lightweight fruits having wings, features that foster effective wind dispersal (Figure 30.21h). Other plants produce dry fruits with surface burrs that attach to animal fur. These are just a few examples of the diverse mechanisms that flowering plants use to disperse their seeds.

Angiosperms Produce Diverse Secondary Metabolites That Play Important Roles in Structure, Reproduction, and Protection

Secondary metabolism involves the synthesis of molecules that are not essential for cell structure and growth (see Chapter 7). These molecules, called **secondary metabolites**, are produced by various prokaryotes, protists, fungi, some animals, and plants, but they are most diverse in the angiosperms. About 100,000 different types of secondary metabolites are known, most of these produced by flowering plants. Because secondary metabolites play essential roles in plant structure, reproduction, and protection, diversification of these compounds has influenced flowering plant evolution. Three major classes of plant secondary metabolites occur: (1) terpenes and terpenoids; (2) phenolics, which include flavonoids and related compounds; and (3) alkaloids (Figure 30.22).

About 25,000 types of plant terpenes and terpenoids are derived from units of the hydrocarbon gas isoprene. Taxol, previously mentioned for its use in the treatment of cancer, is a terpene, as are citronella and a variety of other compounds that repel insects. Rubber, turpentine, rosin, and amber are complex terpenoids that likewise serve important roles in plant biology as well as having useful human applications.

Phenolic compounds are responsible for some flower and fruit colors as well as the distinctive flavors of cinnamon, nutmeg, ginger, cloves, chilies, and vanilla. Phenolics absorb ultraviolet radiation, thereby preventing damage to cellular DNA. They also help to defend plants against insects and disease microbes. Some phenolic compounds found in tea, red wine, grape juice, and blueberries are antioxidants that detoxify free radicals, thereby preventing cellular damage.

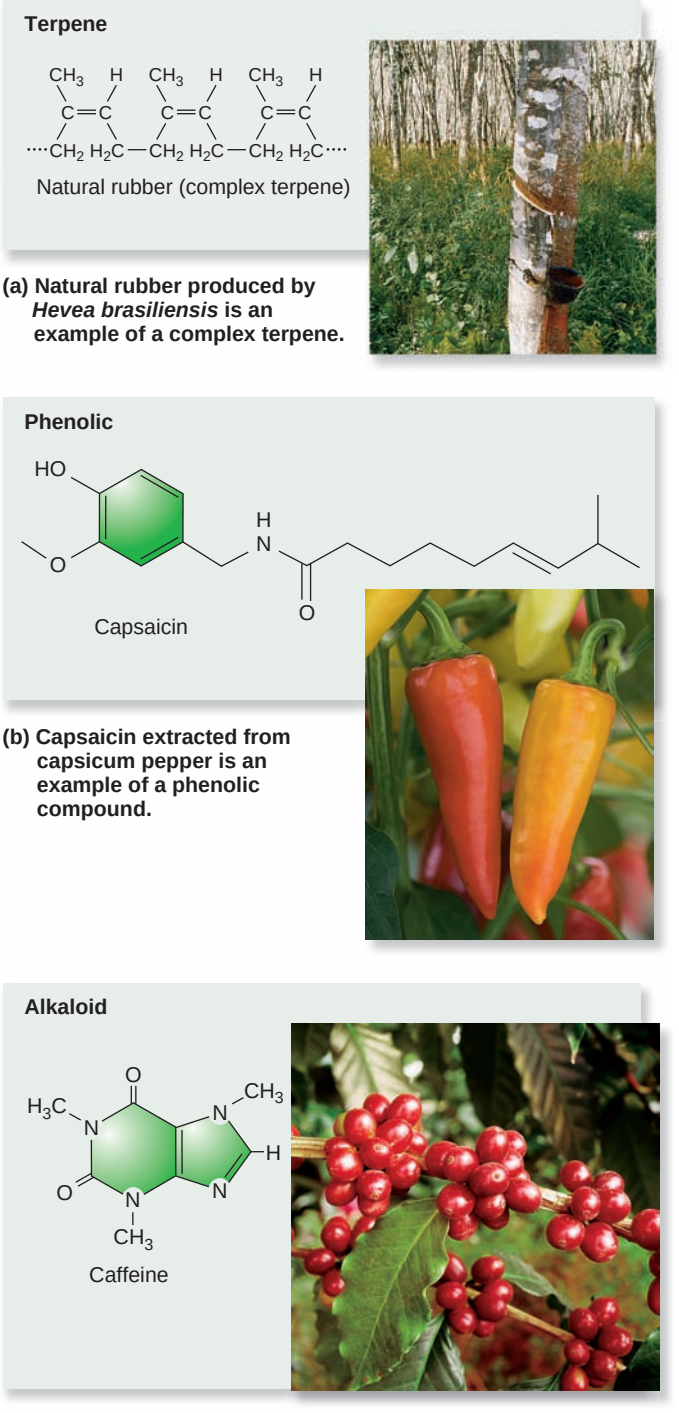


Figure 30.22 Major types of plant secondary metabolites.

Alkaloids are nitrogen-containing secondary metabolites that often have potent effects on the animal nervous system. Plants produce at least 12,000 types of alkaloids, and certain species produce many alkaloids. Caffeine, nicotine, morphine, ephedrine, cocaine, and codeine are examples of alkaloids that influence the physiology and behavior of humans and are thus of societal concern. Like flower and fruit structure, secondary metabolites are useful in distinguishing among Earth's hundreds of thousands of flowering plant species.

Feature Investigation

Hillig and Mahlberg Analyzed Secondary Metabolites to Explore Species Diversification in the Genus *Cannabis*

The genus *Cannabis* has long been a source of hemp fiber used for ropes and fabric. People have also used *Cannabis* in traditional medicine and as a hallucinogenic drug. *Cannabis* produces THC (tetrahydrocannabinol), a type of alkaloid called a cannabinoid. THC and other cannabinoids are produced in glandular hairs that cover most of the *Cannabis* plant's surface but are particularly rich in leaves located near the flowers. THC mimics compounds known as endocannabinoids, which are naturally produced and act in the brain and elsewhere in the body. THC affects humans by binding to receptor proteins in plasma membranes in the same way as natural endocannabinoids. Cancer patients sometimes choose to use cannabis to stimulate their appetite, which can decline as a side effect of cancer treatment.

Because humans have subjected cultivated *Cannabis* plants to artificial selection for so long, plant biologists have been uncertain how cultivated *Cannabis* species are related to those in the wild. In the past, plants cultivated for drug production were often identified as *Cannabis indica*, whereas those grown for hemp were typically known as *Cannabis sativa*. However, these species are difficult to distinguish on the basis of structural features, and the relevance of these names to wild cannabis was unknown. At the same time, species identification has become important for biodiversity studies, agriculture, and law enforcement. For these reasons, plant biologists Karl Hillig and Paul Mahlberg investigated the possibility that ratios of THC to another cannabinoid known as CBD (cannabidiol) might aid in defining *Cannabis* species and identifying plant samples at the species level, as shown in Figure 30.23.

They began by collecting *Cannabis* fruits from nearly a hundred diverse locations around the world and then growing these plants from seed under uniform conditions in a greenhouse.

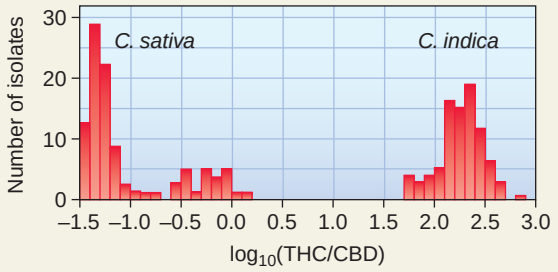
Figure 30.23 Hillig and Mahlberg's analysis of secondary metabolites in the genus *Cannabis*.

GOAL To determine if cannabinoids aid in distinguishing *Cannabis* species.

KEY MATERIALS *Cannabis* fruits obtained from nearly 100 different worldwide sources.

	Experimental level	Conceptual level
1 Grow multiple *Cannabis* plants from seeds under standard conditions in a greenhouse.		Eliminates differential environmental effects on cannabinoid content.
2 Extract cannabinoids from leaves surrounding flowers.		Extracts were made from tissues richest in cannabinoids; this reduces the chance that cannabinoids present in lower levels would be missed.
3 Analyze cannabinoids by gas-liquid chromatography. Determine ratios of THC (tetrahydrocannabinol) to CBD (cannabidiol) in about 200 *Cannabis* plants.		Previous data suggested that ratios of THC to CBD might be different in separate species.  Tetrahydrocannabinol (THC) (R = C_5H_{11} Δ^9)  Cannabidiol (CBD) (R = C_5H_{11})

4 THE DATA



Cannabis plants isolated from diverse sources worldwide formed 2 groups—those having relatively high THC to CBD ratios and those having lower THC to CBD ratios.

Plants having low THC to CBD ratios, often used as hemp fiber sources, corresponded to the species *C. sativa*.

Plants having high THC to CBD ratios, often used as drug sources, corresponded to the species *C. indica*.

5 CONCLUSION Differing cannabinoid ratios support a concept of 2 *Cannabis* species.

6 SOURCE Hillig, K.W., and Mahlberg, P.G. 2004. A chemosystematic analysis of cannabinoid variation in *Cannabis* (Cannabaceae). *American Journal of Botany* 91:966–975.

The investigators next extracted cannabinoids, analyzed them by means of gas-liquid chromatography, and determined the ratios of THC to CBD. The results, published in 2004, suggested that the wild and cultivated *Cannabis* samples evaluated in this study could be classified into two species: *C. sativa*, displaying relatively low THC levels, and *C. indica*, having relatively high THC levels. As a result of this work, ecologists, agricultural scientists, and forensic scientists can reliably use ratios of THC to CBD to classify samples. Similar studies of plant secondary metabolites offer the benefit of uncovering potential new medicinal compounds or other applications of significance to humans.

Experimental Questions

1. Why did the investigators in Figure 30.23 obtain nearly a hundred *Cannabis* fruit samples from around the world?
2. Why did Hillig and Mahlberg grow plants in a greenhouse before conducting the cannabinoid analysis?
3. Why did Hillig and Mahlberg collect samples from the leaves growing nearest the flowers?

30.4 The Role of Coevolution in Angiosperm Diversification

In the previous section, we learned that flowering plants are commonly associated with animals in ways that strongly influence plant evolution. Likewise, plants have influenced animal evolution in a diversity-generating process known as **coevolution**, which is the process by which two or more species of organisms influence each other's evolutionary pathway. During the diversification of flowering plants, coevolution with animals has been a major evolutionary force. Coevolution explains the diverse forms of most flowers and many fruits and how plants accomplish effective pollen and seed dispersal. Human attraction to flowers and fruit also reflects coevolutionary associations. This is because human sensory systems are similar to those of various animals that have coevolved with angiosperms.

Pollination Coevolution Influences the Diversification of Flowers and Animals

Animal pollinators transfer pollen from the anthers of one flower to the stigmas of other flowers of the same species. Pollinators thereby foster genetic variability and plant potential for evolutionary change. Insects, birds, bats, and other pollinators learn the characteristics of particular flowers, visiting them preferentially. This animal behavior, known as constancy or fidelity, increases the odds that a flower stigma will receive pollen of the appropriate species. Animal pollinators offer precision of pollen transfer, which reduces the amount of pollen that plants must produce to achieve pollination. By contrast, wind-pollinated plants must produce much larger amounts of pollen because windblown pollen reaches appropriate flowers by chance.

Flowers attract the most appropriate pollinators by means of attractive colors, odors, shapes, and sizes. Secondary metabolites influence the colors and odors of many flowers. Flavonoids, for example, color many blue, purple, or pink flowers. More than 700 types of chemical compounds contribute to floral odors.

Most flowers reward pollinators with appropriate food: sugar-rich nectar, lipid- and protein-rich pollen, or both. In this way, flowering plants provide an important biological service, providing food for many types of pollinator animals. However, some flowers "trick" pollinators into visiting or trap pollinators temporarily, thereby achieving pollination without actually rewarding the pollinator. Examples include flowers that look and smell like dead meat, thereby attracting flies, which are fooled but accomplish pollination anyway.

Table 30.1 Pollination Syndromes

Animal features	Coevolved flower features
Bees	
Color vision includes UV, not red	Often blue, purple, yellow, white (not red) colors
Good sense of smell	Fragrant
Require nectar and pollen	Provide nectar and abundant pollen
Butterflies	
Good color vision	Blue, purple, deep pink, orange, red colors
Sense odors with feet	Light floral scent
Need landing place	Provide landing place
Feed with long, tubular tongue	Nectar in deep, narrow floral tubes
Moths	
Active at night	Open at night; white or bright colors
Good sense of smell	Heavy, musky odors
Feed with long, thin tongue	Nectar in deep, narrow floral tubes
Birds	
Color vision, includes red	Often colored red
Often require perch	Strong, damage-resistant structure
Poor sense of smell	No fragrance
Feed in daytime	Open in daytime
High nectar requirement	Copious nectar in floral tubes
Hover (hummingbirds)	Pendulous (dangling) flowers
Bats	
Color blind	Light, reflective colors
Good sense of smell	Strong odors
Active at night	Open at night
High food requirements	Copious nectar and pollen provided
Navigate by echolocation	Pendulous or borne on tree trunks

Although many flowers are pollinated by a variety of animals, others have flowers that have become specialized for particular pollinators, and vice versa. These specializations, which have resulted from coevolution, are known as **pollination syndromes** (Table 30.1). For example, odorless red flowers, such as those of hibiscus (see Figure 30.19b), are attractive to birds, which can see the color red but lack a sense of smell. By contrast, bees are not typically attracted to red flowers because bee vision does not extend to the red end of the visible light spectrum. Rather, bees are attracted to blue, purple, yellow, and white flowers having sweet odors. If you are allergic to bee stings or just want to reduce the possibility of being stung, do not dress in bee-attracting flower colors or wear fragrant perfumes when in locales frequented by bees.

Pollination syndromes are also of practical importance in agriculture and in conservation biology. Fruit growers often import colonies of bees to pollinate flowers of fruit crops and so increase crop yields. In recent years, widespread die-offs of bee colonies have become an environmental and agricultural concern. When bee pollinators are not available, growers cannot produce some fruit crops. Some plants have become so specialized to particular pollinators that if the pollinator becomes extinct, the plant becomes endangered. An example is the Hawaiian cliff-dwelling *Brighamia insignis* (Figure 30.24), whose presumed moth pollinator has become extinct. Humans that hand-pollinate *B. insignis* are all that stand between this plant and extinction.

Seed-Dispersal Coevolution Influences the Evolution of Fruits and Particular Animals

As in the case of pollination, coevolution between plants and their animal seed-dispersal agents has influenced both plant fruit characteristics and those of seed-dispersing animals. In addition, flowering plant fruits provide food for animals, an important biological service. For example, many of the plants of temperate forests produce fruits that are attractive to resident birds. Such juicy, sweet fruits have small seeds that readily pass through bird guts. Many plants signal fruit ripeness by undergoing color changes from unripe green fruits to red, orange, yellow, blue, or black (Figure 30.25). Because birds have good color vision, they are able to detect the presence of ripe fruits and consume them before the fruits drop from plants and rot. Apples, strawberries, cherries, blueberries, and blackberries are examples of fruits whose seed dispersal adaptations have made them attractive food for humans as well. By contrast, the lipid-rich fruits of Virginia creeper (*Parthenocissus quinquefolia*) and some other autumn-fruiting plants energize migratory birds but are not tasty to humans. The Virginia creeper's leaves often turn fall colors earlier than surrounding plants, thereby signaling the availability of nutritious, ripe fruit to high-flying birds. Such lipid-rich fruits must be consumed promptly because they rot easily, in which case seed dispersal cannot occur.

Figure 30.24 ***Brighamia insignis*, a plant endangered by the loss of its pollinator.** The pollinator that coevolved with *B. insignis* has become extinct, with the result that the plant is unable to produce seed unless artificially pollinated by humans.

Concept check: What kind of animal likely pollinated B. insignis?

Figure 30.25 **Fruits attractive to animal seed-dispersal agents.** Color and odor signals alert coevolved animal species that fruits are ripe, thus favoring the dispersal of mature seeds.

Table 30.2 Critical Innovations of Seed Plant Groups

Plant group	Innovation	Advantages
All seed plants	Vascular cambium that makes wood and inner bark	Seed plants have the potential to grow tall and produce many branches and reproductive structures.
	Pollen, ovules, seeds	Pollen allows seed plants to disperse male gametophytes. Ovules provide protection and nutrition to female gametophytes and developing embryos. Seeds allow seed plants to reproduce in arid or shady habitats.
Conifers	Tracheid torus	Fosters water flow in arid or cold conditions
	Scales or needle-shaped leaves	Retard water loss from leaf surface
	Conical shape	Sheds snow, preventing damage
	Resin	Protects against pathogens and herbivores
Angiosperms	Flowers	Foster pollen dispersal, ovule protection, pollination, and seed production
	Fruits	Foster seed dispersal
	Endosperm	An efficient way to provide food to embryo of developing seed
	Vessels	Relatively wide diameter fosters water flow
	Many secondary compounds	Provide flower colors and fragrances and protect against herbivores

To help you remember all of what you've learned by reading this chapter so far, Table 30.2 provides a summary of the critical innovations of seed plants. These critical innovations are the result of diversity principles at work. Now we turn to how humans have changed seed plants throughout our shared history.

30.5 Human Influences on Angiosperm Diversification

By means of the process known as **domestication**, which involves artificial selection for traits desirable to humans, ancient humans transformed wild plant species into new crop species. More recently, human populations have increased so much that larger areas of natural habitat are being transformed for human use. Deforestation, for example, often results from the conversion of forests to agricultural land. Such habitat destruction is a leading cause of the extinction of plant and other species. How have humans produced new crop species and influenced the loss of wild species?

Between 10,000 and 5,000 years ago, agriculture originated independently in at least 10 different locations around the world. One of the earliest domesticated crops was an African plant commonly known as the bottle gourd (*Lagenaria sicer-aria*). The bottle gourd was grown for use as containers, musical instruments, and floats for fishing. For planting crops, humans selected seeds from gourds that had thicker rinds because these resisted breakage better than wild gourds. These differences in rind thickness can be detected in fossil remains that are about 10,000 years old. The fossils indicate that bottle gourds were grown as a crop in Asia and from there were transported to the Americas by ancient human colonists.

Cultivated bread wheat (*Triticum aestivum*) was probably among the earliest food crops, having originated more than 8,000 years ago, in what is now southeastern Turkey and northern Syria. Bread wheat originated by a series of steps that included hybridization and whole genome duplication from wild ancestors (*Triticum boeoticum* and *Triticum dicoccoides*). Among the earliest changes that occurred during wheat domestication was the loss of **shattering**, the process by which ears of wild grain crops break apart and disperse their grains. A mutation probably caused the ears of some wheat plants to remain intact, a trait that is disadvantageous in nature but beneficial to humans. Nonshattering ears would have been easier for humans to harvest than normal ears. Early farmers probably selected seed stock from plants having nonshattering ears and other favorable traits such as larger grains. These ancient human selection processes, together with modern breeding efforts, explain why cultivated wheat differs from its wild relatives in shattering and other properties. The accumulation of these trait differences explains why cultivated and wild wheat plants are classified as different species.

About 9,000 years ago, people living in what is now Mexico domesticated a native grass known as teosinte (of the genus *Zea*), producing a new species, *Zea mays*, known as corn or maize. The evidence for this pivotal event includes ancient ears that were larger than wild ones and distinctive fossil pollen. Modern ears of corn are much larger than those of teosinte, corn grains are larger and softer, and modern corn ears do not shatter, as do those of ancestral teosinte (Figure 30.26). These and other trait changes reflect artificial selection accomplished by humans. An analysis of the corn genome, reported in 2005 by Stephen Wright, Brandon Gaut, and coworkers, suggests that human selection has influenced about 1,200 genes.

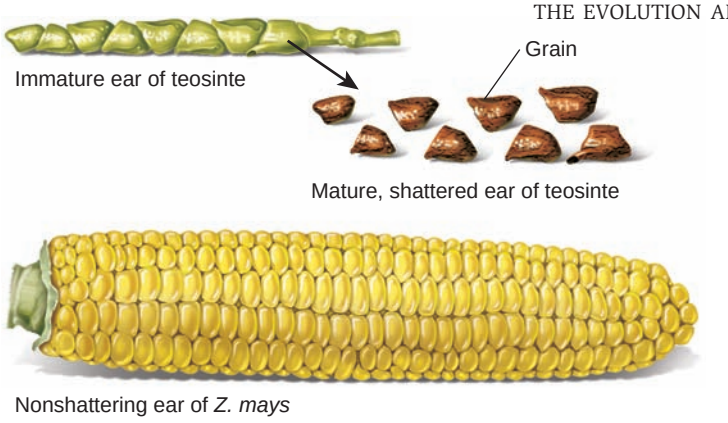


Figure 30.26 Ears and grains of modern corn and its ancestor, teosinte. Domesticated corn ears are larger than those of the ancestral grass teosinte. In addition, corn fruits are softer and more edible than are grains of teosinte.

Concept check: In what other way do corn ears differ from those of teosinte?

Molecular analyses indicate that domesticated rice (*Oryza sativa*) originated from ancestral wild species of grasses (*Oryza nivara* and/or *Oryza rifipogon*). As in the cases of wheat and corn, domestication of rice involved loss of ear shattering. In 2006, Changbao Li, Ailing Zhou, and Tao Sang reported that a key amino acid substitution was primarily responsible for the loss of ear shattering in rice. Ancient humans might have unconsciously selected for this mutation while gathering rice from wild populations, because the mutants would not so easily have shed grains during the harvesting process. Eventually, the nonshattering mutant became a widely planted crop throughout Asia, and today it is the food staple for millions of people.

Although humans generated these and other new plant species, in modern times humans have caused the extinction of plants and other species as the result of habitat destruction. Protecting biodiversity will continue to challenge humans as populations and demands on the Earth's resources increase. Plant biologists are working to identify one or more molecular sequence tools for use in barcoding plants, a process that is also widely used to identify and catalog animals (see Chapter 33). The ability to barcode plants is important to those who monitor international trade in endangered plant species.

Summary of Key Concepts

30.1 Overview of the Seed Plants

- The seed plants inherited features of ancestral seedless plants but display distinctive adaptations. The major phyla of seed plants mainly differ in reproductive features. (Figure 30.1)

30.2 The Evolution and Diversity of Modern Gymnosperms

- Gymnosperms are plants that produce exposed seeds rather than seeds enclosed in fruits. Many gymnosperms produce wood by means of a special tissue called vascular cambium.
- Several phyla of gymnosperms once existed but have become extinct and are known only from fossils. The diversity of modern gymnosperms includes four modern phyla: cycads, *Ginkgo biloba*, the conifers, and the gnetophytes. (Figure 30.2)
- Cycads primarily live in tropical and subtropical regions. Features of cycads include palmlike leaves, nonwoody stems, coralloid roots with cyanobacterial endosymbionts, toxins, and large conelike seed-producing structures. (Figures 30.3, 30.4)
- The tree *Ginkgo biloba* is the last surviving species of a phylum that was diverse during the Age of Dinosaurs. (Figure 30.5)
- Conifers have been widespread and diverse members of plant communities for the past 300 million years, and they are now important sources of wood and paper pulp to humans. Reproduction involves simple pollen cones and complex ovule-producing cones. Conifer wood contains water-conducting tracheids with thin-walled pits with tori that help prevent air bubbles from blocking water flow through the plant. Many conifers display additional adaptations that help them to survive in cold climates. (Figures 30.6, 30.7, 30.8, 30.9, 30.10)
- The gnetophytes display unusual body variations. (Figure 30.11)

30.3 The Evolution and Diversity of Modern Angiosperms

- Angiosperms inherited seeds and other features from ancestors but display distinctive features, such as flowers and fruits. Diversification of flower structure, fruit structure, and secondary metabolites has played important roles in angiosperm evolution. (Figure 30.12)
- Flowers foster seed production and are adapted in various ways that aid pollination in varying circumstances. The major flower organs are sepals, petals, or tepals, stamens, and carpels, but some flowers lack one or more of these organs. Pollination is the transfer of pollen from a stamen to a pistil. Pistils display regions of specialized function: The stigma is a receptive surface for pollen, pollen tubes grow through the style, and ovules develop within the ovary. If pollen tubes successfully deposit sperm near eggs in ovules and fertilization occurs, ovules develop into seeds, and ovaries develop into fruits. Stamens and carpels may have evolved from leaflike structures bearing sporangia. (Figures 30.13, 30.14, 30.15)
- The two largest lineages of flowering plants are the monocots and eudicots. (Figures 30.16, 30.17, 30.18)
- Whole genome duplications arising from autopolyploidy and allopolyploidy and horizontal gene transfer by mitochondrial fusion are mechanisms of reticulate evolution that occur widely in plants.
- Flower diversification involved evolutionary changes such as fusion of parts, changes in symmetry, loss of parts, and aggregation into inflorescences. (Figures 30.19, 30.20)
- Fruits are structures that enclose seeds and aid in their dispersal. Fruits occur in many types that foster seed dispersal in varying circumstances. (Figure 30.21)
- Angiosperms produce three main groups of secondary metabolites: (1) terpenes and terpenoids; (2) phenolics, flavonoids and related compounds; and (3) alkaloids. Secondary metabolites play essential roles in plant structure, reproduction, and defense. (Figure 30.22)
- Hillig and Mahlberg demonstrated the use of particular secondary metabolites in distinguishing species of the genus *Cannabis*. (Figure 30.23)

30.4 The Role of Coevolution in Angiosperm Diversification

- Coevolutionary interactions with animals that serve as pollen- and seed-dispersal agents played a powerful role in the diversification of both flowering plants and animals. (Table 30.1, Figures 30.24, 30.25)
- Human appreciation of flowers and fruits is based on sensory systems similar to those present in the animals with which angiosperms coevolved.
- Seed plants have evolved many critical innovations that have allowed them to be successful for many millions of years. (Table 30.2)

30.5 Human Influences on Angiosperm Diversification

- Humans have produced new crop species by domesticating wild plants. The process of domestication involved artificial selection for traits such as nonshattering ears of wheat, corn, and rice. (Figure 30.26)
- Large human populations are causing habitat destruction, leading to species extinction.

Assess and Discuss

Test Yourself

1. What feature must be present for a plant to produce wood?
   a. a type of conducting system in which vascular bundles occur in a ring around pith
   b. a eustele
   c. a vascular cambium
   d. all of the above
   e. none of the above
2. Which sequence of critical adaptations reflects the order of their appearance in time?
   a. embryos, vascular tissue, wood, seeds, flowers
   b. vascular tissue, embryos, wood, flowers, seeds
   c. vascular tissue, wood, seeds, embryos, flowers
   d. wood, seeds, embryos, flowers, vascular tissue
   e. seeds, vascular tissue, wood, embryos, flowers
3. How long have gymnosperms been important members of plant communities?
   a. 10,000 years, since the dawn of agriculture
   b. 100,000 years
   c. 300,000 years
   d. 65 million years, since the K/T event
   e. 300 million years, since the Coal Age
4. What similar features do gymnosperms and angiosperms possess that differ from other modern vascular plants?
   a. Gymnosperms and angiosperms both produce flagellate sperm.
   b. Gymnosperms and angiosperms both produce flowers.
   c. Gymnosperms and angiosperms both produce tracheids, but not vessels, in their vascular tissues.
   d. Gymnosperms and angiosperms both produce fruits.
   e. none of the above
5. Which part of a flower receives pollen from the wind or a pollinating animal?
   a. perianth c. filament e. ovary
   b. stigma d. pedicel
6. The primary function of a fruit is to
   a. provide food for the developing seed.
   b. provide food for the developing seedling.
   c. foster pollen dispersal.
   d. foster seed dispersal.
   e. None of the above is the primary function.
7. What are some ways in which flowers have diversified?
   a. color
   b. number of flower parts
   c. fusion of organs
   d. aggregation into inflorescences
   e. all of the above
8. Flowers of the genus *Fuchsia* produce deep pink to red flowers that dangle from plants, produce nectar in floral tubes, and have no scent. Based on these features, which animal is most likely to be a coevolved pollinator?
   a. bee c. hummingbird e. moth
   b. bat d. butterfly
9. Which type of plant secondary metabolite is best known for the antioxidant properties of human foods such as blueberries, tea, and grape juice?
   a. alkaloids c. carotenoids e. terpenoids
   b. cannabinoids d. phenolics
10. What features of domesticated grain crops might differ from those of wild ancestors?
    a. the degree to which ears shatter, allowing for seed dispersal
    b. grain size
    c. number of grains per ear
    d. softness and edibility of grains
    e. all of the above

Conceptual Questions

1. Explain why humans should not consume food products made from cycads.
2. Explain why fruits such as apples, strawberries, and cherries are attractive and harmless foods for humans.
3. Is a sunflower really a flower?

Collaborative Questions

1. Where in the world would you have to travel to find wild plants representing all of the gymnosperm phyla, including the three types of gnetophytes?
2. How would you go about trying to solve what Darwin called an “abominable mystery,” that is, the identity of the seed plant group that was ancestral to the flowering plants?

Chapter Outline

Fungi

31

The aboveground reproductive parts of the fungus *Armillaria ostoyae*. Because of the large extent of its underground components, this fungus may be the largest organism in the world.

You might think that the largest organism in the world is a whale or perhaps a giant redwood tree. Amazingly, giant fungi would also be good candidates. For example, an individual of the fungus *Armillaria ostoyae* weighs hundreds of tons, is more than 2,000 years old, and spreads over 2,200 acres of Oregon forest soil! Scientists discovered the extent of this enormous fungus when they found identical DNA sequences in samples taken over this wide area. Other examples of such huge fungi have been found, and mycologists—scientists who study fungi—suspect that they may be fairly common, underfoot yet largely unseen.

Regardless of their size, fungi typically occur within soil or other materials, becoming conspicuous only when reproductive portions such as mushrooms extend above the surface. Even though fungi can be inconspicuous, they play essential roles in the Earth's environment, are associated in diverse ways with other organisms, and have many applications in biotechnology. In this chapter, we will explore the distinctive features of fungal structure, growth, nutrition, reproduction, and diversity. In the process, you will learn how fungi are connected to forest growth, food production and food toxins, sick building syndrome, and other topics of great importance to humans.

31.1 Evolutionary Relationships and Distinctive Features of Fungi

The eukaryotes known as fungi are so distinct from other organisms that they are placed in their own kingdom, the kingdom Fungi (Figure 31.1). Together with certain closely related protists, the kingdom Fungi and the animal kingdom (Metazoa) form a eukaryotic supergroup known as Opisthokonta. Several types of slime molds and other fungus-like protists—though often studied with fungi—are classified with protists rather than true fungi (see Chapter 28). The fungi arose from protists closely related to the modern genus *Nuclearia*, an amoeba that feeds by engulfing cells of algae and bacteria. Early-diverging fungi include microsporidia that parasitize animal cells and several aquatic lineages of microscopic species collectively known as chytrids (formally, Chytridiomycota). Zygomycetes (Zygomycota), represented by black bread molds, are another polyphyletic cluster of relatively early-diverging fungi. The arbuscular mycorrhizal fungi (abbreviated AM fungi) are formally called the Glomeromycota. The ascomycetes (also informally known as the sac fungi and formally as Ascomycota) and the basidiomycetes (club fungi, or Basidiomycota) are later-diverging fungal phyla that display many adaptations to life on land. (Note: The suffixes *mycota* and *mycetes* derive from a Greek word meaning fungus.)

Because fungi are closely related to the animal kingdom, fungi and animals display some common features. For example, both are **heterotrophic**, meaning that they cannot produce their own food but must obtain it from the environment. Fungi use an amazing array of organic compounds as food, which is termed their **substrate**. The substrate could be the soil, a rotting log, a piece of bread, a living tissue, or a wide array of other materials. Fungi are also like animals in having **absorptive nutrition**. Both fungi and the cells of animal digestive systems secrete enzymes that break down complex

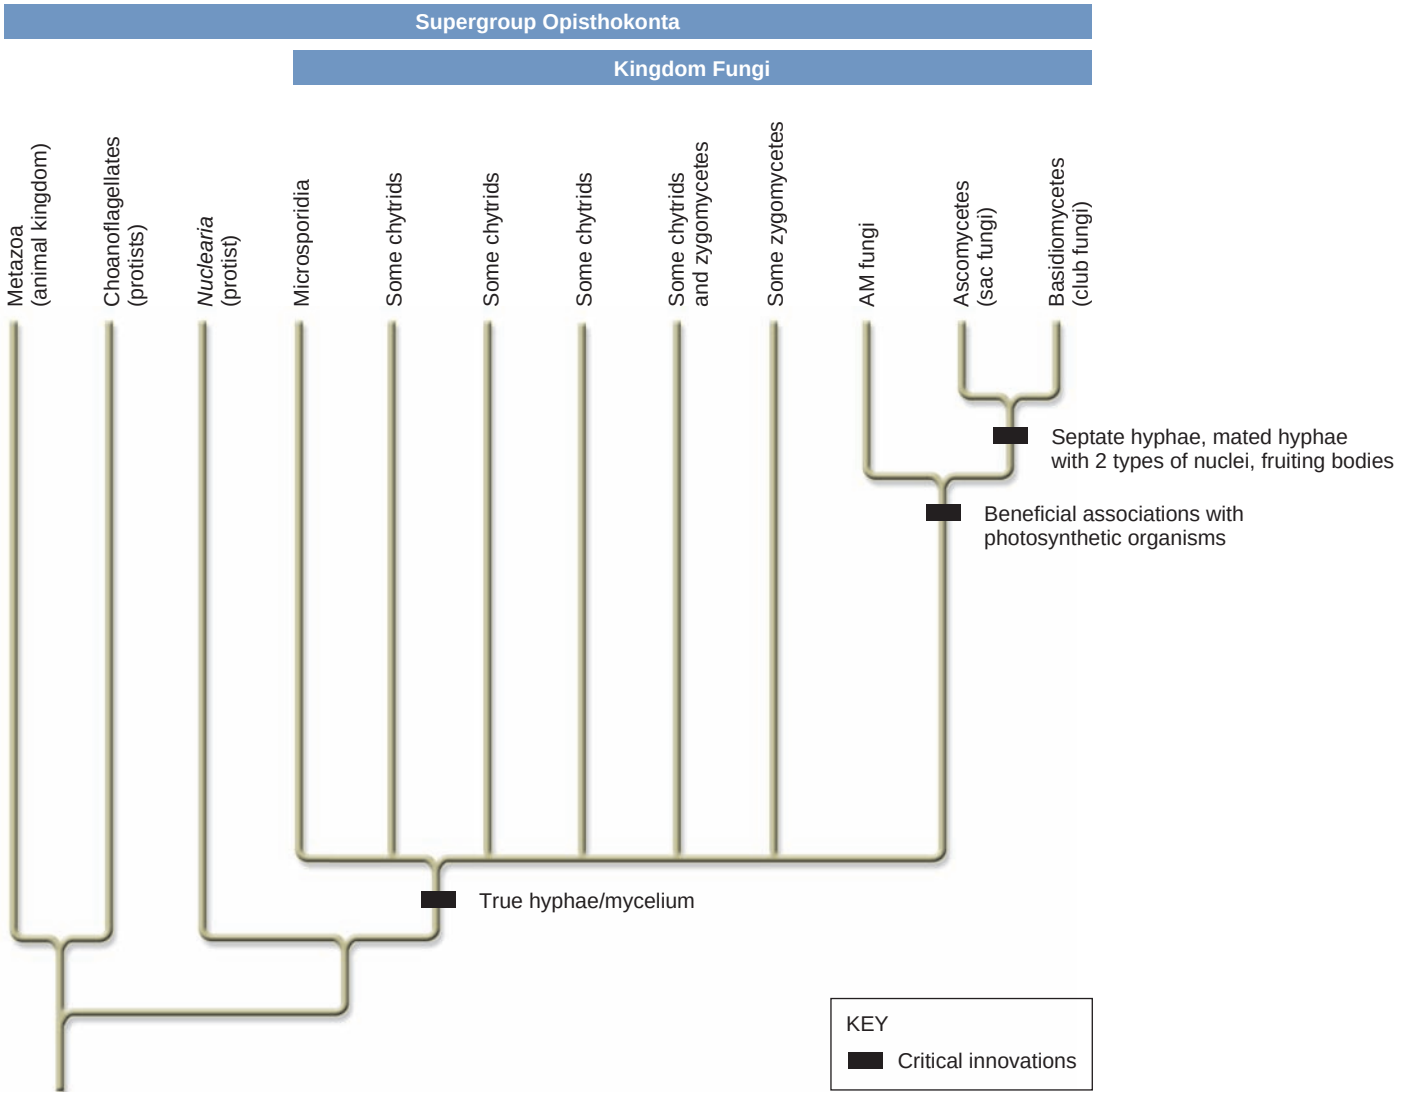

Figure 31.1 **Evolutionary relationships of the fungi.** The kingdom Fungi arose from a protist ancestor similar to the modern genus *Nuclearia*. Five fungal phyla are described in this chapter: the early-diverging chytrids (Chytridiomycota) and zygomycetes (Zygomycota), and the later-diverging AM fungi (Glomeromycota), ascomycetes (Ascomycota), and basidiomycetes (Basidiomycota). Molecular phylogenetic studies indicate that chytrids and zygomycetes are polyphyletic.

organic materials and absorb the resulting small organic food molecules. In addition, both fungi and animals store surplus food as the carbohydrate glycogen in their cells. Despite these nutritional commonalities, fungal structure is quite distinctive.

Fungi Have a Unique Cell-Wall Chemistry and Body Form

Unlike animal cells, which lack rigid cell walls, fungal cells are enclosed by tough cell walls composed of **chitin**, a polysaccharide that contains nitrogen. Chitin, which also forms the exoskeletons of arthropods such as insects, resists bacterial attack, thereby helping to protect fungal cells. Fungal cell walls influence two other features that distinguish fungal cells from animal cells: feeding and motility. Because they have cell walls, fungal cells cannot engulf food particles. In contrast, animal bodies commonly display food ingestion systems, and some animal cells retain an ancient ability to ingest particles. Additionally, the rigid walls of fungal cells, like those of plant cells, restrict the mobility of nonflagellate cells.

Most fungi have a distinctive body known as a **mycelium** (plural, mycelia), which is composed of microscopic, branched filaments known as **hyphae** (singular, hypha) (Figure 31.2). Hyphae and mycelia evolved even before fungi made the transition from aquatic to terrestrial habitats (see Figure 31.1). As mentioned, a fungal mycelium may be very extensive, as in the case of *Armillaria ostoyae* (see chapter-opening photo), but is often inconspicuous because the component hyphae are so tiny and spread out in the substrate. The diffuse form of the fungal mycelium makes sense because most hyphae have the role of gathering food from the substrate. By spreading out, hyphae can absorb food from a large volume of substrate. The gathered

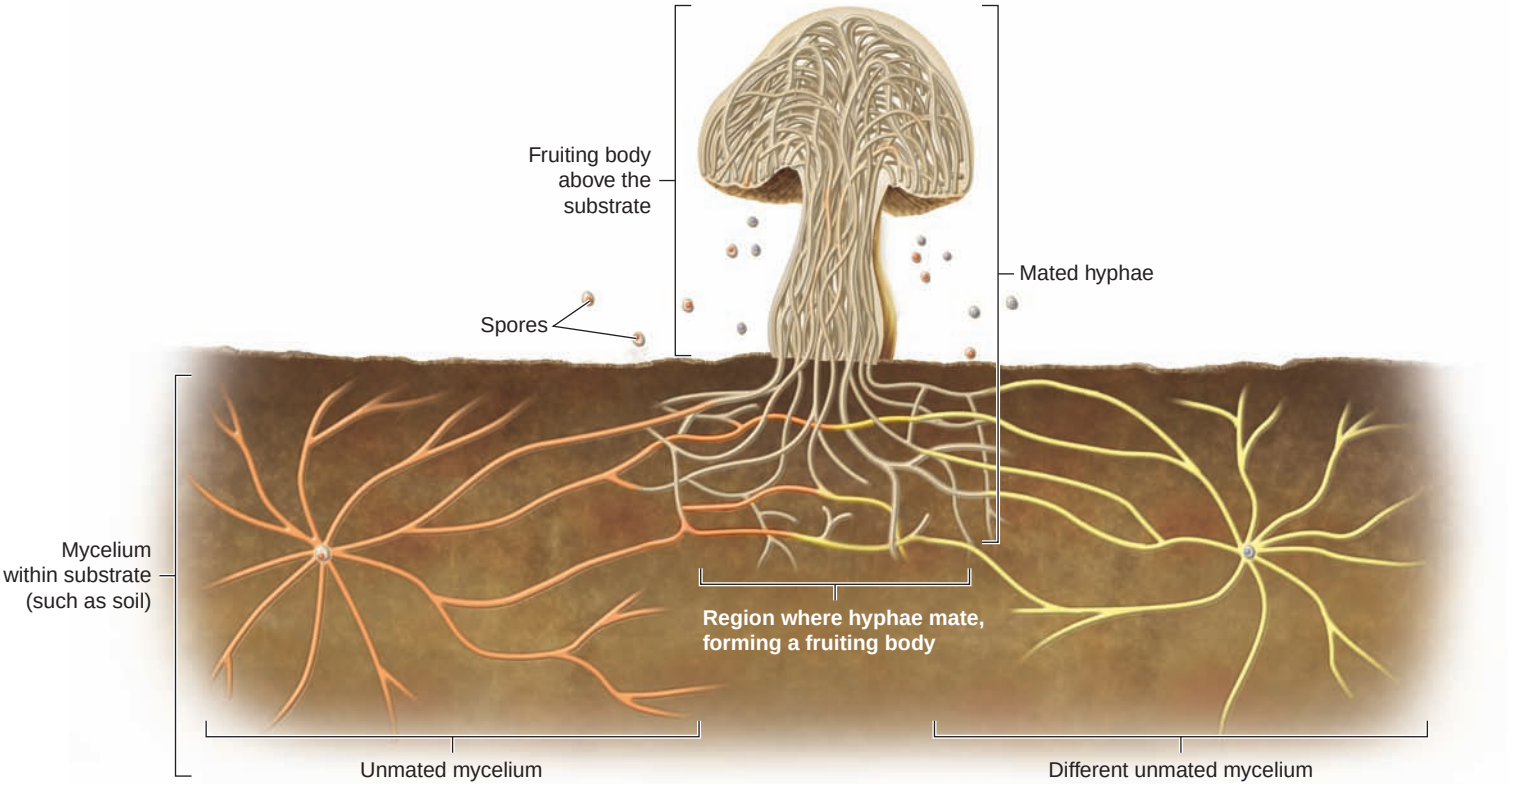

Figure 31.2 **Fungal morphology.** Most of a fungus consists of food-gathering hyphae that grow and branch from a central point to form a diffuse mycelium within a food substrate, such as soil. After a mating process occurs, mated hyphae may aggregate and grow out of the substrate to form fruiting bodies that produce and disperse spores. In suitable sites, spores may germinate, producing new mycelia.

food is used for mycelial growth and for reproduction by means of fruiting bodies, the only parts of fungal bodies that most people see.

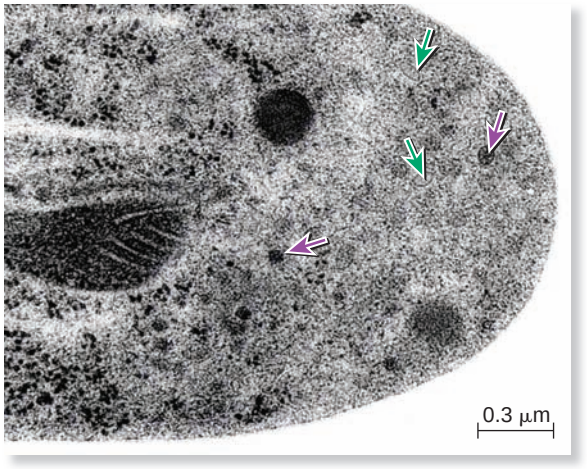
Mushrooms and other types of fungal **fruiting bodies** are often noticeable because they are composed of densely packed hyphae that typically emerge from the substrate (Figure 31.2). Fruiting bodies are composed of hyphae that have undergone a mating process and, as a result, differ genetically and biochemically from unmated hyphae. Experts suspect that mated hyphae secrete signaling substances that cause such hyphae to cluster together and grow into the air, where reproductive cells can be more easily dispersed. Amazingly diverse in form, color, and odor, mature fruiting bodies are specialized to produce and disperse reproductive cells known as **spores**. Produced by the process of meiosis and protected by tough walls, spores reflect a major adaptation to the terrestrial habitat. When fungal spores settle in places where conditions are favorable for growth, they produce new mycelia. When the new mycelia undergo sexual reproduction, they produce new fruiting bodies.

Fungi Have Distinctive Growth Processes

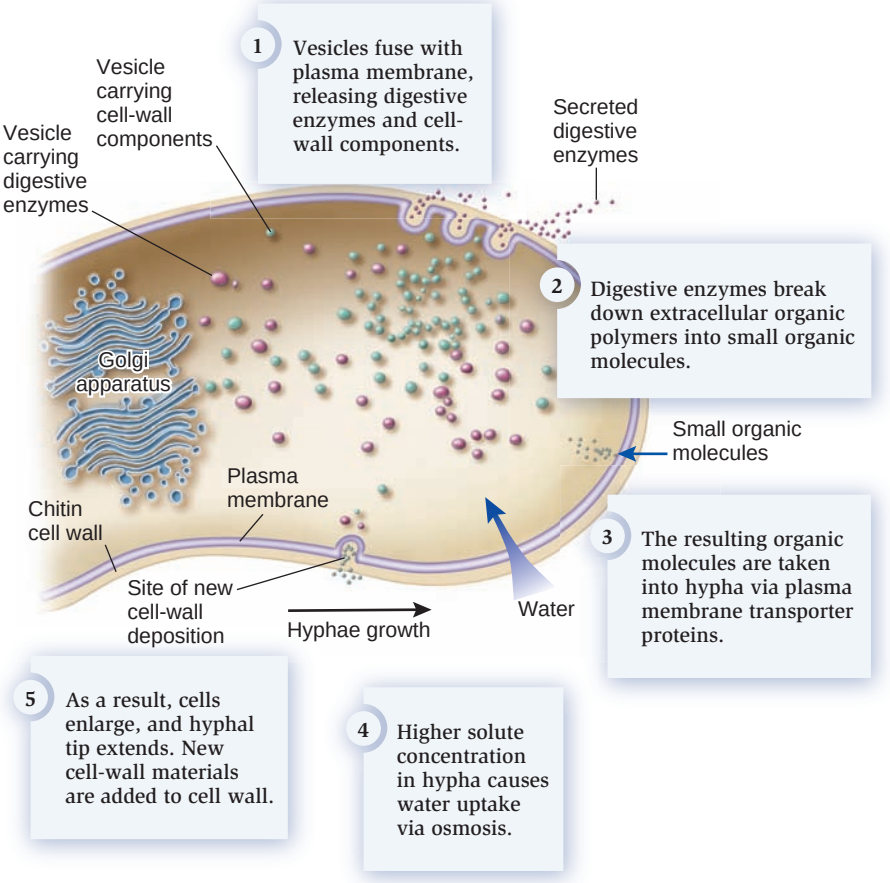
If you have ever watched food become increasingly moldy over the course of several days, you have observed fungal growth. When a food source is plentiful, fungal mycelia can grow rapidly, adding as much as a kilometer of new hyphae per day. The mycelia grow at their edges as the fungal hyphae extend their tips through the undigested substrate. The narrow dimensions and extensive branching of hyphae provide a very high surface area for absorption of organic molecules, water, and minerals.

Hyphal Tip Growth How do hyphae grow? Cytoplasmic streaming and osmosis are important cellular processes in hyphal growth. Osmosis (see Chapter 5) is the diffusion of water through a membrane from an area with a low solute concentration into an area with a high solute concentration. Water enters fungal hyphae by means of osmosis because their cytoplasm is rich in sugars, ions, and other solutes. Water entry swells the hyphal tip, producing the force necessary for tip extension. Masses of tiny vesicles carrying enzymes and cell-wall materials made in the Golgi apparatus collect in the hyphal tip (Figure 31.3). The vesicles then fuse with the plasma membrane. Some vesicles release enzymes that digest materials in the environment, releasing small organic molecules that are absorbed as food. Other vesicles deliver cell-wall materials to the hyphal tip, allowing it to extend.

Hyphal Structure and Nuclear Division The hyphae of most fungi are subdivided into many small cells by cross walls known



(a) Electron micrograph of a hyphal tip with numerous vesicles



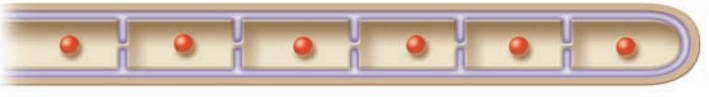
(b) Mechanism of hyphal tip growth

Figure 31.3 **Hyphal tip growth and absorptive nutrition.** **(a)** TEM showing the hyphal tip of *Aspergillus nidulans,* a fungus commonly used as a genetic model system. The tip is filled with membrane-bound vesicles that fuse with the plasma membrane. Purple arrowheads show dark-stained vesicles carrying digestive enzymes, while green arrowheads point out light-stained vesicles carrying cell-wall materials. **(b)** Diagram of a hyphal tip, with vesicles of the same two types, showing the steps of hyphal tip growth.

Concept check: What do you think would happen to fungal hyphae that begin to grow into a substrate having higher solute concentration? How might your answer be related to food preservation techniques such as drying or salting?

as **septa** (singular septum) (Figure 31.4a). In such fungi, known as septate fungi, each round of nuclear division is followed by the formation of a septum that is perforated by a small pore. Septate hyphae appeared after the divergence of the AM fungi, but prior to the divergence of ascomycetes from basidiomycetes (see Figure 31.1). The hyphae of early-diverging fungi are not partitioned into smaller cells. Rather, these hyphae are **aseptate** and multinucleate (Figure 31.4b), a condition that results when nuclei repeatedly divide without intervening cytokinesis. Such aseptate hyphae are described as being coenocytic.

When the nuclei of fungi divide, in most cases, a spindle forms within the nuclear envelope, which does not break down. This **intranuclear spindle** distinguishes nuclear division of fungi from that of animals and plants. (By contrast, in land plants and animals, the nuclear envelope vesiculates during prometaphase and then re-forms at telophase.)

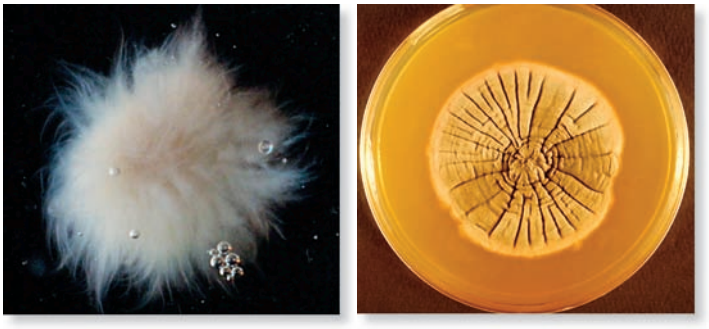


(a) Septate hypha

(b) Aseptate hypha

Figure 31.4 Types of fungal hyphae.

Variations in Mycelium Growth Form Fungal hyphae grow rapidly through a substrate from areas where the food has become depleted to food-rich areas. In nature, mycelia may take an irregular shape, depending on the availability of food. A fungal mycelium may extend into food-rich areas for great distances, as noted at the beginning of the chapter. In liquid laboratory media, fungi will grow as a spherical mycelium that resembles a cotton ball floating in water (Figure 31.5a). Grown in flat laboratory dishes, the mycelium assumes a more two-dimensional growth form (Figure 31.5b).



(a) Mycelium growing in liquid medium

(b) Mycelium growing on flat, solid medium

Figure 31.5 **Fungal shape shifting.** **(a)** When a mycelium, such as that of this *Rhizoctonia solani*, is surrounded by food substrate in a liquid medium, it will grow into a spherical form. **(b)** When the food supply is limited to a two-dimensional supply, as shown by *Neotestudina rosatii* in the laboratory dish here, the mycelium will form a disc. Likewise, distribution of the food substrate determines the mycelium shape in nature.

31.2 Fungal Asexual and Sexual Reproduction

Many fungi are able to reproduce both asexually and sexually by means of microscopic spores, each of which can grow into a new adult. Asexual reproduction is a natural cloning process; it produces genetically identical organisms. Production of asexual spores allows fungi that are well adapted to a particular environment to disperse to similar, favorable places. Sexual reproduction generates new allele combinations that may allow fungi to colonize new types of habitats. Many fungi reproduce both sexually and asexually, although many reproduce only asexually.

Fungi Reproduce Asexually by Dispersing Specialized Cells

Asexual reproduction is particularly important to fungi, allowing them to spread rapidly by means of asexual spores. To reproduce asexually, fungi do not need to find compatible mates or expend resources on fruiting-body formation and meiosis. More than 17,000 fungal species reproduce primarily or exclusively by asexual means. DNA-sequencing studies have revealed that many types of modern fungi that reproduce only asexually have evolved from ancestors that had both sexual and asexual reproduction.

Many fungi produce asexual spores known as **conidia** (from the Greek *konis*, meaning dust) at the tips of hyphae (Figure 31.6). When they land on a favorable substrate, conidia germinate into a new mycelium that produces many more conidia. The green molds that form on citrus fruits are familiar examples of conidial fungi. A single fungus can produce as many as 40 million conidia per hour over a period of 2 days.

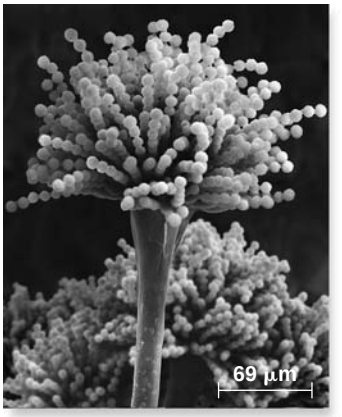


Figure 31.6 **Asexual reproductive cells of fungi.** SEM of the asexual spores (conidia) of *Aspergillus versicolor*, which causes skin infections in burn victims and lung infections in AIDS patients. Each of these small cells is able to detach and grow into an individual that is genetically identical to the parent fungus and so is able to grow in similar conditions.

Concept check: *How might you try to protect a burn patient from infection by a conidial fungus?*

Because they can spread so rapidly, asexual fungi are responsible for costly fungal food spoilage, allergies, and diseases. Medically important fungi that reproduce primarily by asexual means include the athlete's foot fungus (*Epidermophyton floccosum*) and the infectious yeast (*Candida albicans*). **Yeasts** are fungi of various lineages that can occur as unicells; they reproduce by asexual budding (Figure 31.7).

Fungi Have Distinctive Sexual Reproductive Processes

As is typical for eukaryotes, the fungal sexual reproductive cycle involves the union of gametes, the formation of zygotes, and the process of meiosis. However, many aspects of fungal sexual reproduction are unique, including the function of hyphal branches as gametes and the development of fruiting bodies (Figure 31.8).

Fungal Gametes and Mating The gametes of most fungi are cells of hyphal branches. Although most fungi do not have distinguishable male and female gametes, fungal hyphae occur in

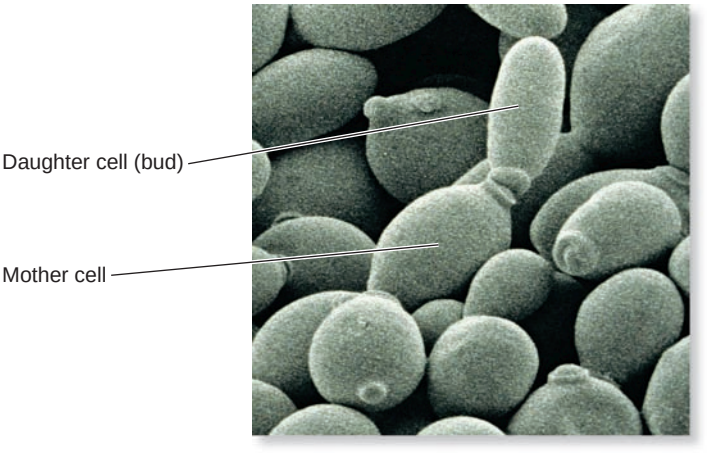

Figure 31.7 **The budding yeast *Saccharomyces cerevisiae*.**

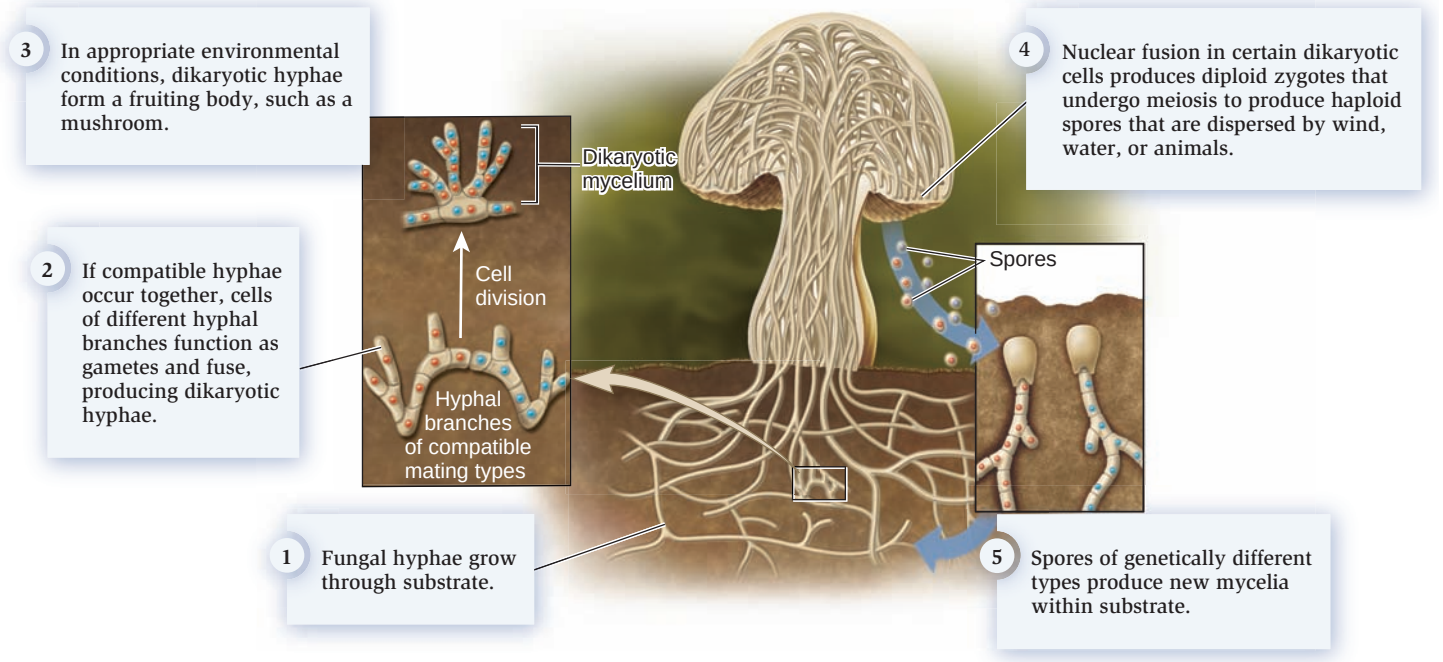

Figure 31.8 The reproductive cycle of many types of fungi.

Concept check: *What kinds of fungi would be unlikely to reproduce in the manner shown?*

multiple mating types that differ biochemically. The compatibility of these mating types is controlled by particular genes. During sexual reproduction, a hyphal branch of one mycelium fuses with a hyphal branch from a different mycelium of the same species and compatible mating type. Exceptions to this process occur in early-diverging fungi that live in the water, which produce flagellate sperm that swim to nonmotile eggs. During fungal evolution, the ability of gametes to produce flagella has been lost several times as different groups of fungi adapted to life in terrestrial habitats.

The actual mating process in fungi is also remarkable. In most sexual organisms, gametes undergo fusion of their cytoplasms, a process known as **plasmogamy**, and then the nuclei fuse in a process known as **karyogamy**. However, in many fungi, the haploid gamete nuclei remain separate for a long time after plasmogamy occurs. During this time period, the gamete nuclei both divide at each cell division, producing a mycelium that is **dikaryotic** (from the Greek, meaning two nuclei) or heterokaryotic (from the Greek, meaning different nuclei). Each cell of a dikaryotic mycelium possesses two unfused gamete nuclei; these are derived from parental nuclei (Figure 31.8). Some fungi persist as dikaryons, producing clones that can live for hundreds of years. Although the nuclei of dikaryotic mycelia remain haploid, alternate copies of many alleles occur in the separate nuclei. Thus, dikaryotic mycelia are functionally diploid. Eventually, dikaryotic mycelia produce fruiting bodies, the next stage of reproduction.

Fruiting Bodies Under appropriate environmental conditions, such as seasonal change, a dikaryotic mycelium may produce a fleshy fruiting body, such as a mushroom, which typically emerges from the substrate (see Figures 31.2, 31.8). All the cells of the fruiting body are dikaryotic. When the fruiting body is mature, the two nuclei in each of many cells at the surface undergo nuclear fusion. This process produces many zygotes, which are the only cells in the fungal life cycle that have a diploid nucleus. In most cases, the fungal zygotes soon undergo meiosis to produce haploid spores. Each spore acquires a tough chitin wall that protects it from drying out and other stresses. Wind, rain, or animals disperse the mature spores, which grow into haploid mycelia. If a haploid mycelium encounters hyphae of an appropriate mating type, hyphal branches will fuse and start the sexual cycle over again.

As we have seen, fruiting bodies usually emerge from the substrate, while most of the fungal mycelium lies inconspicuously within it. Mycelium growth requires organic molecules, minerals, and water provided by the substrate, but in most cases, spores are more easily dispersed if released outside of the substrate. The structures of fruiting bodies vary in ways that reflect different adaptations that foster spore dispersal by wind, rain, or animals. For example, mature puffballs have delicate surfaces upon which just a slight pressure causes the spores to puff out into wind currents (Figure 31.9a). Birds' nest fungi form characteristic egg-shaped spore clusters. Raindrops splash on these clusters and disperse the spores. The fruiting bodies of stinkhorn fungi smell and look like rotting meat (Figure 31.9b), which attracts carrion flies. The flies land on the fungi to investigate the potential meal and then fly away, in the process dispersing spores that stick to their bodies. The fruiting bodies of fungal truffles are also specialized for spore dispersal

(a) Fruiting bodies adapted for dispersal of spores by wind

(b) Fruiting body adapted for dispersal of spores by insects

Figure 31.9 **Fruiting body adaptations that foster spore dispersal.** **(a)** When touched by wind gusts or animal movements, spores puff from fruiting bodies of the puffball fungus (*Lycoperdon perlatum*). **(b)** The fruiting bodies of stinkhorn fungi, such as this *Phallus impudicus*, use foul odors and the colors of dung or rotting meat to attract flies, to which the sticky fungal spores attach and are thereby dispersed.

by animals. However, they are unusual in being produced underground. Mature truffles emit odors that attract wild pigs and dogs, which break up the fruiting structures while digging for them, thereby dispersing the spores. When collectors seek to harvest valuable truffles from forests for the market, they use trained leashed pigs or dogs to locate these fungi.

Many fungi such as truffles are edible, and several species of edible fungi are cultivated for market sale (Figure 31.10). However, the bodies of many fungi produce toxic substances that may deter animals from consuming them (Figure 31.11). For example, several fungi that attack stored grains, fruits, and spices produce **aflatoxins**; these cause liver cancer and are a major health concern worldwide. When people consume the forest mushroom *Amanita virosa*, known as the "destroying angel," they ingest a powerful toxin that may cause liver failure so severe that a transplant may be required. Each year, many people in North America are poisoned when they consume similarly toxic mushrooms gathered in the wild. There is no reliable way for nonexperts to distinguish poisonous from nontoxic fungi; it is essential to receive instruction from an expert before foraging for mushrooms in the woods. Therefore, many experts recommend that it is better to search for mushrooms in the grocery store than in the wild.

Several types of fungal fruiting structures produce hallucinogenic or psychoactive substances. As in the case of fungal toxins, fungal hallucinogens may have evolved as antiherbivore adaptations. Humans have inadvertently experienced their effects. For example, *Claviceps purpurea*, which causes a disease of rye crops and other grasses known as ergot, produces a psychogenic compound related to LSD (lysergic acid diethylamide) (Figure 31.12). Some experts speculate that cases of hysteria, convulsions, infertility, and a burning sensation of the skin that occurred in Europe during the Middle Ages resulted

Figure 31.10 **Several types of edible, delicious fungi available in the market.**

Figure 31.11 **Toxic fruiting body of *Amanita muscaria*.** Common in conifer forests, *A. muscaria* is both toxic and hallucinogenic. Ancient people used this fungus to induce spiritual visions and to reduce fear during raids. This fungus produces a toxin, amanitin, which specifically inhibits RNA polymerase II of eukaryotes (but not prokaryotes).

Concept check: *What effect would the amanitin toxin have on human cells?*

Figure 31.12 **Ergot of rye.** The fungus *Claviceps purpurea* infects rye and other grasses, producing hard masses of mycelia known as ergots in place of some of the grains (fruits). Ergots produce alkaloids related to LSD and thus cause psychotic delusions in humans and animals that consume products made with infected rye. Ergots were used in folk medicine to treat migraine or to hasten childbirth.

from ergot-contaminated rye used in foods. Another example of a hallucinogenic fungus is the "magic mushroom" (*Psilocybe*), which is used in traditional rituals in some cultures. Like ergot, the magic mushroom produces a compound similar to LSD, a controlled substance. Consuming hallucinogenic fungi is risky because the amount used to achieve psychoactive effects is dangerously close to a poisonous dose.

31.3 Fungal Ecology and Biotechnology

The ability of fungi to degrade diverse materials is important in ecology, medicine, and human biotechnology applications. Fungal decomposers, also known as saprobes, are able to decompose nonliving organic materials. Recycling of materials in ecosystems depends on the activities of fungal decomposers. Fungal predators that consume tiny soil animals also play an important role in energy and nutrient cycling. Some fungi may attack living animal or plant tissues, in which case they are considered to function as pathogens, or causes of disease. As hyphae of pathogenic fungi grow through the tissues of plants and animals, they absorb food and minerals from the host, causing disease symptoms. Other fungi form beneficial partnerships with photosynthetic organisms that provide the fungi with organic food without experiencing harm. In return, fungi contribute mineral nutrients, water, and other benefits to their photosynthetic partners. In this section, we focus more closely on the ecological roles of decomposer, predatory, pathogenic, and beneficial fungi.

Decomposer and Predatory Fungi Play Important Ecological Roles

Decomposer fungi are essential components of the Earth's ecosystems. Together with bacteria, they decompose dead organisms and organic wastes, preventing litter buildup. For example, only certain bacteria and fungi can break down cellulose, and a few fungi are the major decomposers of lignin, the decay-resistant component of wood. In the absence of decomposers, ecosystems would become clogged with organic debris. Decomposers are needed to break down organic compounds into carbon dioxide, which is used by algae and plants for photosynthesis. Decomposer fungi and bacteria are also Earth's recycling engineers. They release minerals into the soil and water, where plants and algae take up the minerals for growth. In the absence of fungi and bacteria, such minerals would remain forever bound up in dead organisms, unavailable for the growth of forests, coral reefs, and other communities.

More than 200 species of predatory soil fungi use special adhesive or nooselike hyphae to trap tiny soil animals, such as nematodes, and absorb nutrients from their bodies (Figure 31.13). Such fungi help to control populations of nematodes, some of which attack plant roots. Other fungi obtain nutrients by attacking insects, and certain of these species are used as biological control agents to kill black field crickets, red-legged earth mites, and other pests.

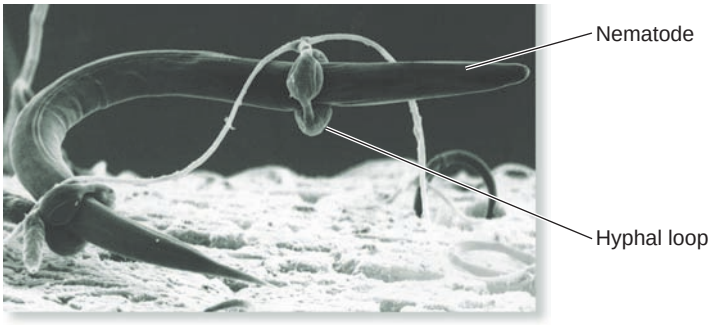

Figure 31.13 **A predatory fungus.** The fungus *Arthrobotrys anchonia* traps nematode worms in hyphal loops that suddenly swell in response to the animal's presence. Fungal hyphae then grow into the worm's body and digest it.

Pathogenic Fungi Cause Plant and Human Diseases

One of the most important ways in which fungi affect humans is by causing diseases of humans and our crop plants. Five thousand fungal species cause serious crop diseases, and recent results show that new diseases can arise by horizontal gene transfer. Wheat rust is an example of a common crop disease caused by fungi (Figure 31.14). Rusts are named for the reddish spores that emerge from the surfaces of infected plants. Many types of plants can be attacked by rust fungi, but rusts are of particular concern when new strains attack crops. For example, in late 2004, agricultural scientists discovered that a devastating rust named *Phakopsora pachyrhizi* had begun to spread in the U.S. soybean crop. This rust kills soybean plants by attacking the leaves, causing complete leaf drop in less than 2 weeks. The disease had apparently spread to U.S. farms by means of spores blown on hurricane winds from South America. To control the spread of fungal diseases, agricultural experts work to

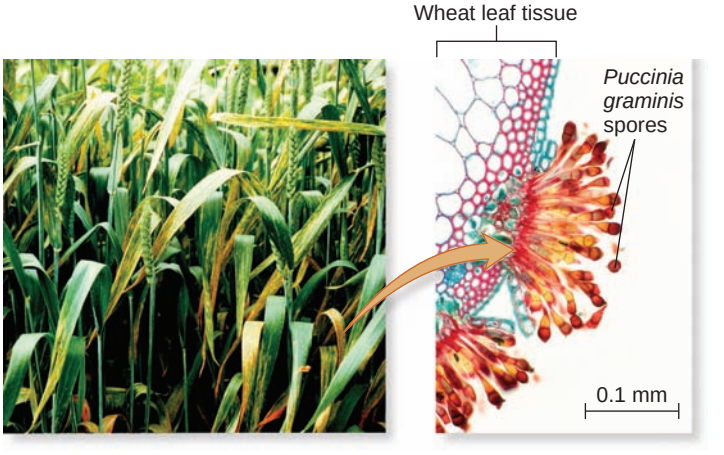

Figure 31.14 **Wheat rust.** The plant pathogenic fungus *Puccinia graminis* grows within the tissues of wheat plants, using plant nutrients to produce rusty streaks of red spores that erupt at the stem and leaf surface where spores can be dispersed. Red spore production is but one stage of a complex life cycle involving several types of spores. Rusts infect many other crops, causing immense economic damage.

identify effective fungicidal chemicals and develop resistant crop varieties.

In addition to being spread by wind, the spores of crop-disease fungi can also be introduced on travelers' clothing and other belongings. To reduce the entry of new crop-disease fungi—as well as crop viruses and insect pests—agricultural customs inspectors closely monitor the entry of plants, soil, foods, and other materials that might harbor these organisms.

Fungi cause several types of disease in humans. For example, athlete's foot and ringworm are common skin diseases caused by fungi that are known as dermatophytes because they colonize the human epidermis. *Pneumocystis carinii* is a fungal pathogen that infects individuals with weakened immune systems, such as AIDS patients, sometimes causing death by pneumonia.

Aspergillus fumigatus is a common conidial mold that can also cause a potentially fatal lung disease. Such harmful conidia-producing molds growing in poorly ventilated, moist places may be the cause of "sick building syndrome," a term used to describe situations in which occupants of a building experience acute health effects that appear to be linked to time spent inside, but where no specific cause can be identified. However, some black molds that also grow on moist building materials are blamed for human illness, even though there is little evidence that they are harmful to adults (Figure 31.15).

Another group of pathogenic fungi is made up of the several types of yeast known as the **dimorphic fungi** (from the Greek, meaning two forms). They live as spore-producing hyphae in the soil but transform into pathogenic yeasts when mammals inhale their wind-dispersed spores (Figure 31.16). Dimorphic fungi include *Blastomyces dermatitidis*, which causes the disease blastomycosis; *Coccidioides immitis,* the cause of coccidiomycosis; and *Histoplasma capsulatum*, the agent of histoplasmosis. These fungal diseases affect the lungs and may spread to other parts of the body, causing severe illness. Host body temperature triggers the change from hyphal to yeast form. Instead of producing spores, in the mammalian body, these pathogenic yeasts reproduce by forming buds that more effectively stick to lung cells, spread within lung tissue, and move to other organs. In 2006, Julie Nemacek, Marcel Wüthrich, and Bruce Klein identified histidine kinase as the sensor protein of dimorphic yeasts that responds to host body heat by switching on the budding yeast form. Because vertebrates lack histidine kinases, this protein is expected to be a useful target for developing antifungal drugs and vaccines.

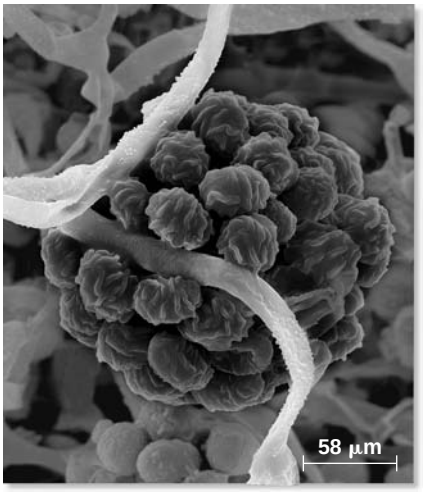

Figure 31.15 An indoor mold fungus. The black mold *Stachybotrys chartarum* is one of several types of conidial fungi that grow on indoor paper and wood that have been wet for an extended period.

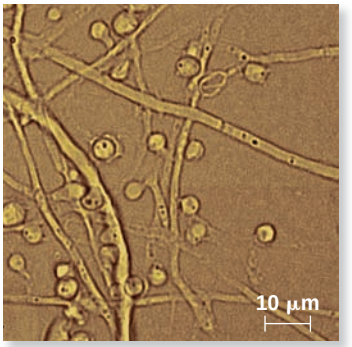
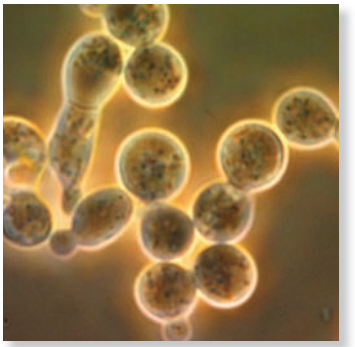


(a) Soil-dwelling hyphal phase



(b) Budding yeast phase in host

Figure 31.16 Dimorphic fungi. **(a)** The soil-dwelling hyphal stage reproduces by airborne spores. **(b)** When a mammal inhales the spores, body heat causes the budding yeast phase to develop and attack host tissues.

Concept check: What kind of medicine could be developed to retard the spread of pathogenic yeasts within body tissues without harming the patient?

Though fungal diseases that attack humans are of medical concern, in nature, fungal pathogens often help to control populations of other organisms, which is an important ecological role. Some fungi play important ecological roles as beneficial partners in associations with other organisms.

Fungi Form Beneficial Associations with Other Species

Fungi form several types of beneficial associations with animals, plants, algae, bacteria, and even viruses. For example, leaf-cutting ants, certain termites and beetles, and the salt marsh snail (*Littoraria irrorata*) cultivate particular fungi for food, much as do human mushroom growers. Other fungi obtain organic food molecules from photosynthetic organisms—plants, green algae, or cyanobacteria—that, in turn, receive benefits from the fungi. Such associations between fungi and photosynthetic organisms are particularly widespread and important in nature and agriculture. We focus next on three types of fungi—mycorrhizal fungi, endophytes, and lichen fungi—that are beneficially associated with photosynthetic organisms.

Mycorrhizae Associations between the hyphae of certain fungi and the roots of most seed plants are known as **mycorrhizae** (from the Greek, meaning fungus roots) (see Chapter 37). Such fungus-root associations are very important in nature and agriculture; more than 80% of terrestrial plants form mycorrhizae. Plants that have mycorrhizal partners receive an increased supply of water and mineral nutrients, primarily

phosphate, copper, and zinc. They do so because an extensive fungal mycelium is able to absorb minerals from a much larger volume of soil than roots alone are able to do (Figure 31.17). Added together, all the branches of a fungal mycelium in 1 m^3 of soil can reach 20,000 km in total length. Experiments have shown that mycorrhizae greatly enhance plant growth in comparison to plants lacking fungal partners. In return, plants provide fungi with organic food molecules, sometimes contributing as much as 20% of their photosynthetic products—a very good investment.

By binding soils, fungal hyphae also reduce water loss and erosion, and they help protect plants against pathogens and toxic wastes. Fungi thereby help plants adapt to and thrive in new sites, thus playing an important role in plant succession (see Chapter 58). For this reason, ecologists increasingly employ mycorrhizal fungi in plant-community restoration projects.

The two most common types of mycorrhizae are endomycorrhizae and ectomycorrhizae. **Endomycorrhizae** (from the Greek *endo*, meaning inside) are partnerships between plants and fungi in which the fungal hyphae penetrate the spaces between root cell walls and plasma membranes and grow along the outer surface of the plasma membrane. In such spaces, endomycorrhizal fungi often form highly branched, bushy arbuscules (from the word "arbor," referring to tree shape). As the arbuscules develop, the root plasma membrane also expands. Consequently, the arbuscules and the root plasma membranes surrounding them have very high surface areas that facilitate rapid and efficient exchange of materials: Minerals flow from fungal hyphae to root cells, and organic food molecules move from root cells to hyphae. These fungus-root associations are known as **arbuscular mycorrhizae**, abbreviated **AM** (Figure 31.18). AM fungi are associated with apple trees, coffee shrubs, and many herbaceous plants, including legumes, grasses, tomatoes, strawberries, and peaches.

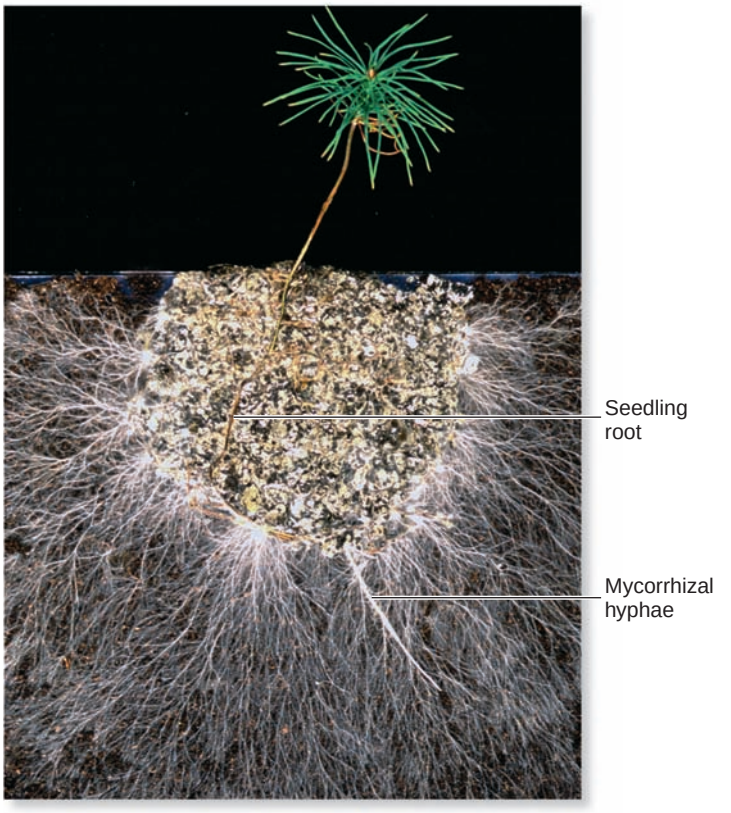


Figure 31.17 **Tree seedling with mycorrhizal fungi.** Hyphae of a mycorrhizal fungus extend farther into the soil than do plant roots, helping plants to obtain mineral nutrients.

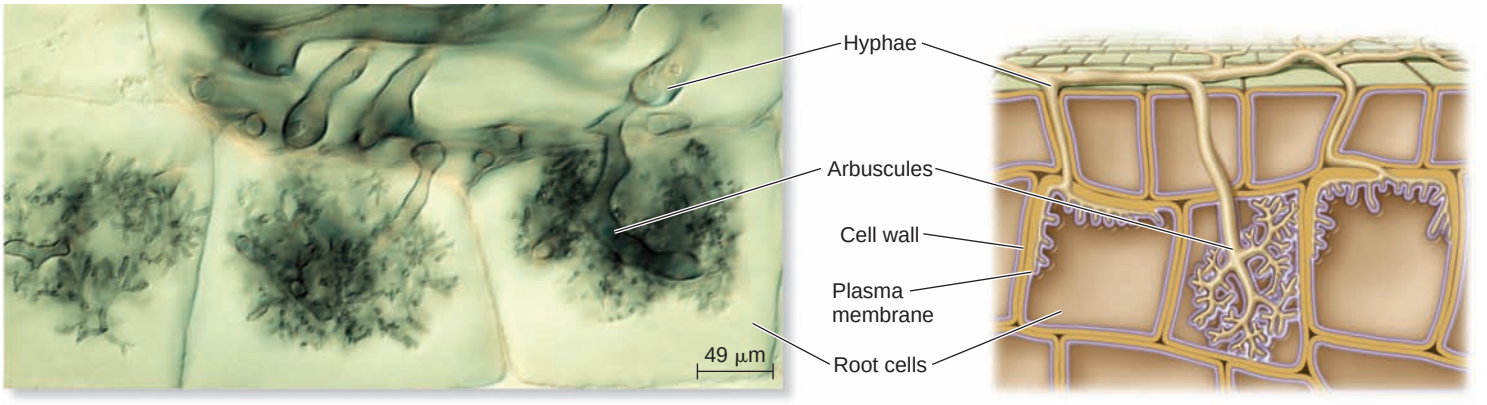
Ectomycorrhizae (from the Greek *ecto*, meaning outside) are beneficial interactions between temperate forest trees and soil fungi. The fungi that engage in such associations are known as ectomycorrhizal fungi. The fruiting body shown in Figure 31.19a was produced by an ectomycorrhizal fungus. The hyphae of ectomycorrhizal fungi coat tree-root surfaces (Figure 31.19b) and grow into the spaces between root cells (Figure 31.19c).



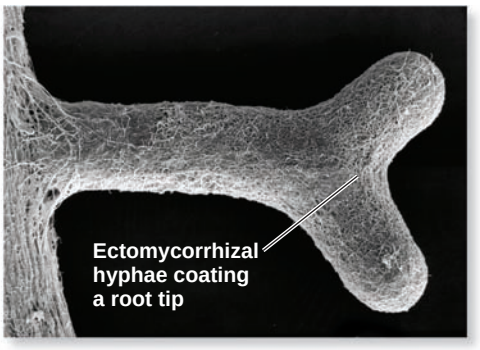
(a) Micrograph of arbuscular mycorrhizae

(b) Hyphae growing between cell walls and plasma membranes

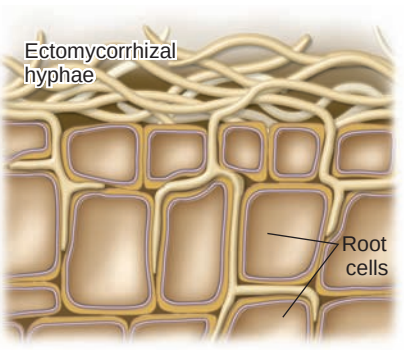
Figure 31.18 **Endomycorrhizae.** **(a)** Light micrograph showing black-stained AM fungi within the roots of the forest herb *Asarum canadensis.* Endomycorrhizal fungal hyphae enter plant roots via root hair cells, and then branches grow in the spaces between root cell walls and plasma membranes. **(b)** Diagram showing the position of highly branched arbuscules. Hyphal branches or arbuscules are found on the surface of the plasma membrane, which becomes highly invaginated. The result is that both hyphae and plant membranes have very high surface areas.

Concept check: *What fungal phylum consists entirely of endomycorrhizal fungi that are completely dependent upon plant hosts?*

(a) Ectomycorrhizal fruiting body



(b) SEM of ectomycorrhizal hyphae



(c) Hyphae invading intercellular spaces

Figure 31.19 **Ectomycorrhizae.** **(a)** The fruiting body of the common forest fungus *Laccaria bicolor*. This is an ectomycorrhizal fungus that is associated with tree roots. **(b)** Ectomycorrhizal fungal hyphae of *L. bicolor* cover the surfaces of young *Pinus resinosa* root tips. **(c)** Diagram showing that the hyphae of ectomycorrhizal fungi do not penetrate root cell walls but grow within intercellular spaces. In this location, fungal hyphae are able to obtain organic food molecules produced by plant photosynthesis.

Concept check: *What benefits do plants obtain from this association?*

Some species of oak, beech, pine, and spruce trees will not grow unless their ectomycorrhizal partners are also present. Mycorrhizae are thus essential to the success of commercial nursery tree production and reforestation projects. New genetic information has illuminated how mycorrhizal fungi form associations with plants.

Genomes & Proteomes Connection

Gene Expression in Ectomycorrhizal Fungi Explains How They Live Both Independently and in Partnership with Plants

The mushroom-forming fungus *Laccaria bicolor* (Figure 31.19a) has become a model system for experimental studies of ectomycorrhizae, because the mycelium grows well by itself and in symbiosis with tree roots, in both nature and the laboratory. Experimental studies of *L. bicolor* have revealed how the fungus colonizes tree roots by forming a dense coating of hyphae on the root surface, producing hyphae that penetrate between root cells, and spreading hyphae from the root outward into the soil. Radiotracer studies have shown that the hyphae located within roots obtain sugar from the host plant, while the external hyphae harvest soil minerals and transfer them to the plant root.

In 2008, an international group of biologists described the genome of *L. bicolor*, thereby explaining many of its characteristics. Investigators found that *L. bicolor* has a larger genome than nonmycorrhizal fungi, with more and larger gene families, suggesting that symbiotic association has accelerated evolution. *Laccaria* also has an especially high number of genes associated with plasma membrane transport, reflecting the complexity of materials exchanged between the fungus and host roots. They found the fungus has many genes that encode small, secreted proteins; these genes are suspected to be involved in establishing and maintaining the symbiotic relationship. For example, one secreted protein has been localized to *L. bicolor* hyphae present within roots, but not hyphae of the same species living in soil. This observation indicates that the plant partner influences gene expression in its fungal partner. Further study of gene expression patterns is expected to reveal more about molecular interactions essential to the mycorrhizal symbiosis.

The genome analysis also revealed that unlike most soil fungi, *L. bicolor* lacks the genetic capacity to break down plant cell-wall materials such as cellulose and lignin, which are abundant in soil and litter. As a result, *L. bicolor* cannot use the organic components of these materials as food. The lack of such genes makes sense because a fungus that readily destroys plant cell walls would not likely be able to establish a mutually beneficial relationship with plant roots. When in symbiotic association with roots, *L. bicolor* relies upon organic material supplied by the plant partner. Given this alternative food source, over evolutionary time, the fungus probably lost functional genes required for cellulose and lignin breakdown. How then are nonsymbiotic mycelia of *L. bicolor* able to survive in the soil? The genome sequence provides a likely answer. *Laccaria bicolor*'s genome includes genes encoding enzymes that may allow this fungus to break down dead insects, bacteria, and other protein-rich organic matter in soil. Such examples illustrate the value of genome sequences in explaining how the proteome controls key ecological functions of pivotal organisms such as mycorrhizal fungi.

Fungal Endophytes Other fungi are known as **endophytes** because they live compatibly within the leaf and stem tissues of various types of plants. The endophytes obtain organic food molecules from plants and, in turn, contribute toxins or antibiotics that deter foraging animals, insect pests, and microbial pathogens. In general, plants that contain nonpathogenic endophytic fungi grow better than plants lacking such fungal partners. Endophytic fungi also help some plants tolerate higher temperatures.

Feature Investigation

Márquez and Associates Discovered That a Three-Partner Association Allows Plants to Cope with Heat Stress

The endophytic fungus *Curvularia protuberata* commonly lives within aboveground tissues of the grass *Dichanthelium lanuginosum*, which is unusual in its ability to grow on very hot soils in thermal areas of Yellowstone National Park. When the soil reaches 38°C, *D. lanuginosum* plants and *C. protuberata* fungi both die unless they live together in a symbiosis. In the symbiotic association, the partners can survive temperatures near 65°C.

In 2007, a team of investigators led by Luis Márquez discovered that a virus is also involved, revealing the occurrence of a three-partner symbiosis (Figure 31.20). These biologists were able to isolate the virus from the fungus and named it *Curvularia* thermal tolerance virus (CthTV) to indicate its host and phenotype. The investigators also noticed that some of their fungal cultures contained very little virus, so they were able to use drying and freeze–thaw cycles to cure such cultures of the virus. This procedure allowed them to experimentally determine the relative abilities of virus-infected and virus-free *C. protuberata* fungus to tolerate high temperatures and confer this property to plant partners. They found that plants having viral-infected fungal endophytes tolerated high temperatures much better than plants that lacked fungal endophytes or possessed virus-free fungal endophytes. Márquez and associates also reintroduced virus to their virus-free fungi and found that such fungi acquired the ability to confer heat tolerance to host plants. Finally, the researchers determined that the virus-infected fungus (but not virus-free fungi) could also protect a distantly related crop plant (tomato) from heat stress. These results add to accumulating evidence that multipartner symbioses are more common than previously realized and demonstrated that endophytic fungi may have useful agricultural applications.

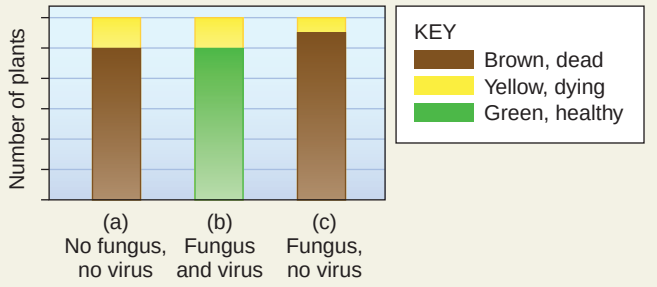
Figure 31.20 **Márquez and associates discovered that a three-partner symbiosis allows plants to cope with heat stress.**

GOAL To determine if a virus is essential to the protective role of endophytic fungi to host plants under heat stress.

KEY MATERIALS *Curvularia* thermal tolerance virus (CthTV), cultures of the endophytic fungus *Curvularia protuberata* infected with CthTV, *C. protuberata* cultures free of CthTV, and *Dichanthelium lanuginosum* plants.

	Experimental level	Conceptual level
1 Plant 25 replicate containers with *D. lanuginosum* lacking fungal symbionts (a) or with *C. protuberata* endophytes that either did (b) or did not (c) have virus.	 (a) No fungus, no virus (b) Fungus and virus (c) Fungus, no virus	Compare the effects of virus on the ability of the fungus to confer heat stress protection.
2 Expose plants to heat stress treatment (up to 65°C) for 2 weeks in a greenhouse.		Keep environmental conditions constant to reduce experimental error.
3 Count the number of plants that were green (alive), yellow (dying), or brown (dead).	 (a) (b) (c)	Assess plant survival in the presence or absence of fungus and/or virus.

4 THE DATA



5 CONCLUSION A virus enhances the protective role of endophytic fungi in this grass species. The next step will be to try to determine just how the virus changes the fungus so that the fungus is able to protect the plant from heat stress.

6 SOURCE Márquez, Luis M. et al. 2007. A virus in a fungus in a plant: Three-way symbiosis required for thermal tolerance. *Science* 315:513–515.

Experimental Questions

1. Would you expect plants that grow on unusually hot soils to have endophytic fungi or not?
2. How did Márquez and associates demonstrate that a virus was important in the heat tolerance of the *Dichanthelium lanuginosum–Curvularia protuberata* symbiosis?
3. How might the results of the work by Márquez and associates be usefully applied in agriculture?

Lichens Multipartner associations are also represented by **lichens**, which are composed of particular fungi, certain photosynthetic green algae and/or cyanobacteria, and non-photosynthetic bacteria such as actinomycetes. There are at least 25,000 lichen species, but these did not all descend from a common ancestor. DNA-sequencing studies suggest that lichens evolved independently in at least five separate fungal lineages. Molecular studies also show that some fungi have lost their ancestral ability to form lichen associations.

Lichen bodies take one of three major forms: (1) crustose—flat bodies that are tightly adherent to an underlying surface (Figure 31.21a); (2) foliose—flat, leaflike bodies (Figure 31.21b); or (3) fruticose—bodies that grow upright (Figure 31.21c) or hang down from tree branches. The photosynthetic green algae or cyanobacteria typically occur in a distinct layer close to the lichen's surface (Figure 31.21d). Lichen structure differs dramatically from that of the fungal component grown separately, demonstrating that the photosynthetic components influence lichen form.

The photosynthetic partner provides lichen fungi with organic food molecules and oxygen, and, in turn, it receives carbon dioxide, water, and minerals from the fungal partner. Lichen fungi also protect their photosynthetic partners from environmental stress. For example, lichens that occupy exposed habitats of high light intensity often produce bright yellow, orange, or red-colored compounds that help prevent damage to the photosynthetic apparatus (see Figure 31.21a). Lichen fungi also produce distinctive organic acids and other compounds that deter animal and microbial attacks.

Many lichens reproduce by both sexual and asexual means, and about one-third of lichen species reproduce only asexually. Asexual reproductive structures include **soredia** (singular, soredium), small clumps of hyphae surrounding a few algal cells

(a) Crustose lichen
(b) Foliose lichen
(c) Fruticose lichen
(d) Microscopic view of a cross section of a lichen

Figure 31.21 **Lichen structure.** **(a)** An orange-colored crustose lichen grows tightly pressed to the substrate. **(b)** The flattened, leaf-shaped genus *Umbilicaria* is a common foliose lichen. **(c)** The highly branched genus *Cladonia* is a common fruticose lichen. **(d)** A handmade thin slice of *Umbilicaria* viewed with a light microscope reveals that the photosynthetic algae occur in a thin upper layer. Fungal hyphae make up the rest of the lichen.

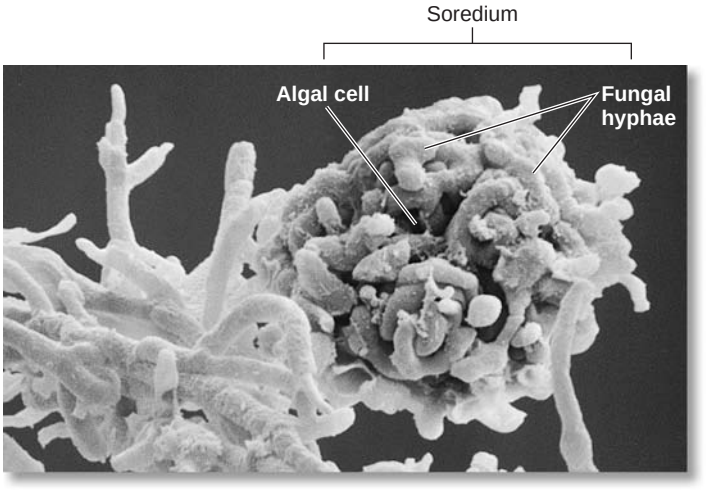


Figure 31.22 **Lichen asexual reproduction.** SEM of a soredium of the lichen *Cladonia coniocraea* that will break off from the parent lichen and disperse in the environment. Soredia are asexual structures that contain algal or cyanobacterial cells wrapped by fungal hyphae.

Concept check: *Do lichens that develop from soredia necessarily contain the same algae that were present in those soredia?*

that can disperse in wind currents (Figure 31.22). Soredia are lichen clones. By forming soredia, lichen fungi can disperse along with their photosynthetic partners.

The fungal partners of many lichens can undergo sexual reproduction, producing fruiting bodies and sexual spores much like those of related fungi that do not form lichens. DNA studies have shown that some lichen fungi can self-fertilize, which is advantageous in harsh environments where potential mates may be lacking. To produce new lichens, hyphae that grow from sexual spores must acquire new photosynthetic partners, but only particular green algae or cyanobacteria are suitable. However, lichens do not always contain the same algal partners as their parents because lichen fungi may switch algal partners, "trading up" for better algae. Partner switching allows lichens to adjust to changes in their environments. In 2008, Matt Nelsen and Andrea Gargas reported that lichens often change algal partners even when the fungal components lack sexual reproduction and depend completely upon algae-bearing soredia for dispersal. The partner-switching concept is based upon observations that within the same lichen family, fungal and algal species may display different phylogenies. Such results indicate that lichen partners do not strongly influence each other's evolutionary diversification. Emerging concepts of lichens as multipartner associations and frequent partner switching show that the lichen symbiosis is more complex than previously thought.

Lichens often grow on rocks, buildings, tombstones, tree bark, soil, or other surfaces that easily become dry. When water is not available, the lichens are dormant until moisture returns. Thus, lichens may spend much of their time in an inactive state, and for this reason, they often grow very slowly. However, because they can persist for long periods, lichens can be very old; some are estimated to be more than 4,500 years old. Lichens occur in diverse types of habitats, and a number grow in some of the most extreme, forbidding terrestrial sites on Earth—deserts, mountaintops, and the Arctic and Antarctic—places where most plants cannot survive. In these locations, lichens serve as a food source for reindeer and other hardy organisms. Though unpalatable, lichens are not toxic to humans and have also served as survival foods for aboriginal peoples in times of shortages.

Lichens are recognized for their soil-building activities, which occur over very long periods of time. Lichen acids help to break up the surfaces of rocks, beginning the process of soil development. Lichens having cyanobacterial partners can also increase soil fertility by adding fixed nitrogen. One study showed that such lichens released 20% of the nitrogen they fixed into the environment, where it is available for uptake by plants.

Lichens are useful as air-quality monitors because they are particularly sensitive to air pollutants such as sulfur dioxide. Air pollutants severely injure the photosynthetic components, causing death of the lichens. The disappearance of lichens serves as an early warning sign of air-pollution levels that are also likely to affect humans. Lichens can also be used to monitor atmospheric radiation levels because they accumulate radioactive substances from the air. After the Chernobyl nuclear power plant accident, lichens in nearby countries became so radioactive that reindeer became unfit for use as human food or in milk production.

Fungi Have Many Applications in Biotechnology

The ability of fungi to grow on many types of substrates and produce many types of organic compounds reflects their diverse ecological adaptations. Humans have harnessed fungal biochemistry in many types of biotechnology applications. Fungal biochemistry is a valuable asset to the chemical, food processing, and waste-treatment industries. A variety of industrial processes use fungi to convert inexpensive organic compounds into valuable materials, such as citric acid used in the soft drink industry, glycerol, antibiotics such as penicillin, and cyclosporine, a drug widely used to prevent rejection of organ transplants. In the food industry, fungi are used to produce the distinctive flavors of blue cheese and other cheeses. Other fungi secrete enzymes that are used in the manufacture of protein-rich tempeh and other food products from soybeans. The brewing and winemaking industries find yeasts essential, and the baking industry depends on the yeast *Saccharomyces cerevisiae* for bread production.

S. cerevisiae is also widely used as a model system for fundamental biological studies. Yeasts are useful in the laboratory because they have short life cycles, are easy and safe for lab workers to maintain, and their genomes are similar to those of animals. Some 31% of yeast proteins have human homologs, and nearly 50% of human genes that have been implicated in heritable diseases have homologs in yeast.

Fungi are increasingly being used in industrial processes to replace chemical procedures that generate harmful waste

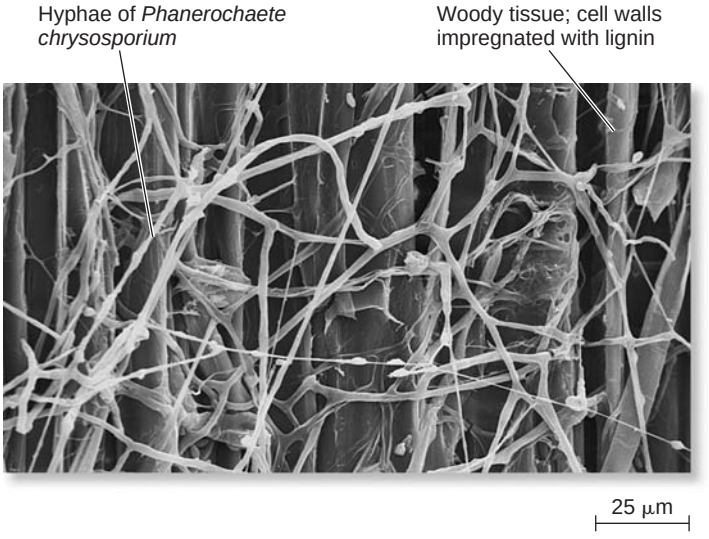

Figure 31.23 **Industrial use of fungi in paper production.** The forest fungus *Phanerochaete chrysosporium* produces a cobweb-like mycelium on the surfaces of rotting wood. This fungus releases enzymes that break down lignin, thereby making plant cell-wall carbohydrates such as cellulose more accessible.

materials. For example, during the production of paper, wood pulp is chemically bleached to remove lignin, but this bleaching process generates harmful compounds, including dioxin, a carcinogenic compound. The forest fungus *Phanerochaete chrysosporium* produces several enzymes that allow it to break down lignin in wood (Figure 31.23). Removal of lignin allows the fungi to gain access to cell-wall polysaccharides, which they break down, thereby releasing sugars that the fungus absorbs as food. Fungal lignin-breaking enzymes such as those produced by *P. chrysosporium* can be used to bleach paper without producing dioxin, thereby reducing a harmful by-product of paper production. In addition, Khadar Valli, Hiroyuki Wariishi, and Michael Gold demonstrated that *P. chrysosporium* is able to decompose dioxin into nontoxic products, suggesting additional potential uses of the fungus in preventing pollution.

31.4 Diversity of Fungi

As noted earlier, the kingdom Fungi is a monophyletic group that arose from a protist ancestor (see Figure 31.1). The modern fungi have been classified into five phyla, listed in Table 31.1 by both their common and formal names: chytrids (Chytridiomycota), zygomycetes (Zygomycota), AM fungi (Glomeromycota), ascomycetes (Ascomycota), and basidiomycetes (Basidiomycota). As mentioned, DNA and other data indicate that the chytrids and the zygomycetes are not monophyletic groups. In this section, we will survey the characteristics of the five phyla of true fungi and examine their distinctive reproductive cycles.

Chytrids Primarily Live in Aquatic Environments

Chytrids are the simplest fungi, and molecular evidence indicates that chytrids were among the earliest fungi to appear. Some chytrids occur as single, spherical cells that may produce hyphae (Figure 31.24), whereas others exist mainly as branched, aseptate hyphae. Chytrids often produce flagellate cells used for spore or gamete dispersal. The presence of a single, posterior flagellum on chytrid spores or gametes links fungi with the ancestry of choanoflagellate protists and animals (see Chapter 28).

Chytrids live in aquatic habitats or in moist soil. Most chytrids are decomposers, but some are parasites of protists (Figure 31.24) and pathogens of plants or animals. For example, the chytrid *Batrachochytrium dendrobatidis* has been associated with declining harlequin frog populations (look ahead to Figure 54.1).

Table 31.1 Distinguishing Features of Fungal Phyla

Common name (Formal name)	Habitat	Ecological role	Reproduction	Examples cited in this chapter
Chytrids (Chytridiomycota)	Water and soil	Mostly decomposers; some parasites	Flagellate spores or gametes	*Batrachochytrium dendrobatidis*
Zygomycetes (Zygomycota)	Mostly terrestrial	Decomposers and pathogens	Nonflagellate asexual spores produced in sporangia; resistant sexual zygospores	*Rhizopus stolonifer*
AM Fungi (Glomeromycota)	Terrestrial	Form mutually beneficial mycorrhizal associations with plants	Distinctively large, nonflagellate, multinucleate asexual spores	The genus *Glomus*
Ascomycetes (Ascomycota)	Mostly terrestrial	Decomposers; pathogens; many form lichens; some are mycorrhizal	Asexual conidia; nonflagellate sexual spores (ascospores) in sacs (asci) on fruiting bodies (ascocarps)	*Aleuria aurantia, Venturia inaequalis, Saccharomyces cerevisiae*
Basidiomycetes (Basidiomycota)	Terrestrial	Decomposers; many are mycorrhizal; less commonly form lichens	Several types of asexual spores; nonflagellate sexual spores (basidiospores) on club-shaped basidia on fruiting bodies (basidiocarps)	*Coprinus disseminatus, Rhizoctonia solani, Armillaria mellea, Puccinia graminis, Ustilago maydis, Phanerochaete chrysosporium, Laccaria bicolor, Amanita muscaria, Phallus impudicus, Lycoperdon perlatum*

Zygomycetes Produce Distinctive Zygospores

The **zygomycetes** feature a mycelium that is mostly composed of aseptate hyphae (those lacking cross walls) and distinctive reproductive structures. For example, like most zygomycetes, the black bread mold *Rhizopus stolonifer* produces asexual spores in enclosures known as **sporangia** (singular, sporangium) (Figure 31.25a). Bread mold sporangia form at hyphal tips in such large numbers that they make moldy bread appear black. Zygomycete sporangia may each release up to 100,000 spores into the air! The great abundance of such spores means that bread molds easily unless the bread contains added retardant chemicals.

Zygomycetes are named for the zygospore, a distinctive feature of their sexual reproduction (Figure 31.25b). Zygospore production begins with the development of **gametangia** (from the Greek, meaning gamete bearers). In the zygomycete fungi,

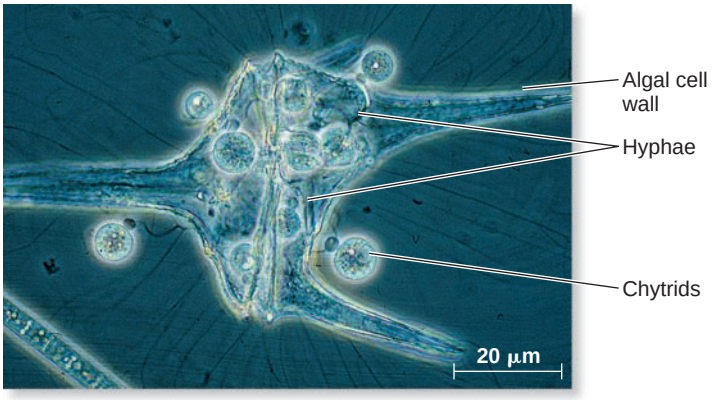

Figure 31.24 **Chytrids growing on a freshwater protist.** The colorless chytrids produce hyphae that penetrate the cellulose cell walls of the dinoflagellate *Ceratium hirundinella,* absorbing organic materials from the alga. Chytrids use these materials to produce spherical flagellate spores that swim away to attack other algal cells.

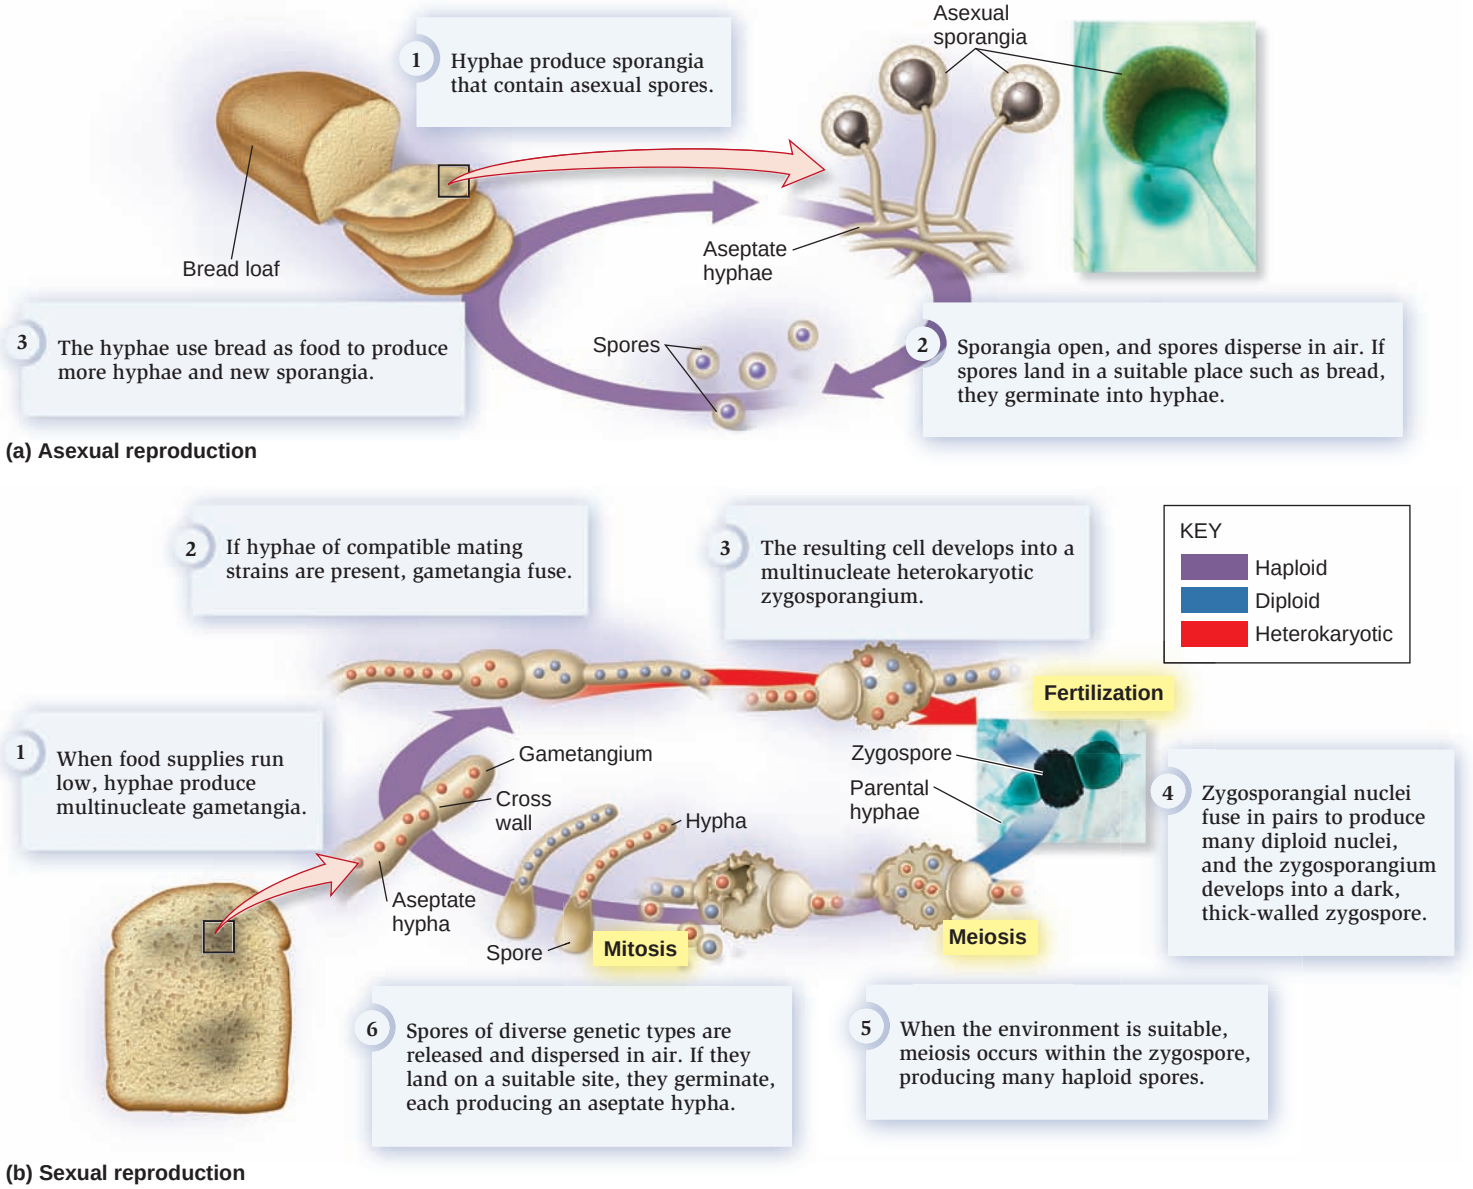

Figure 31.25 The asexual and sexual life cycles of a zygomycete, the black bread mold *Rhizopus stolonifer*.

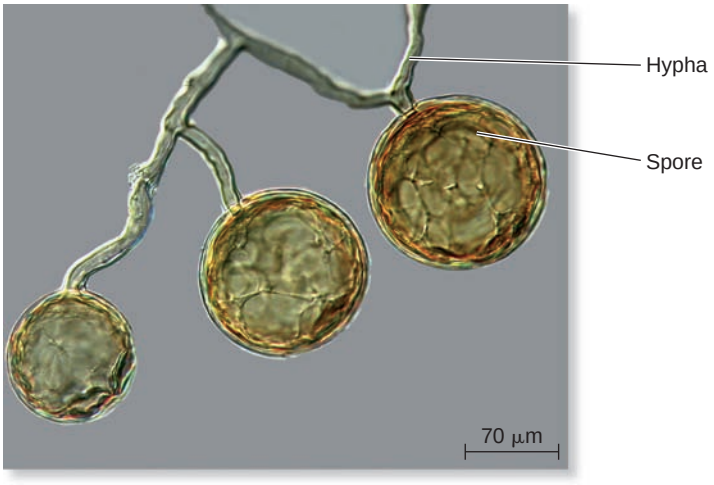

Figure 31.26 **The genus *Glomus*, an example of an AM fungus.** The hyphae of these endomycorrhizal (arbuscular mycorrhizal) fungi are found in roots of many types of plants, aiding them in acquiring water and nutrients. AM fungi produce large, multinucleate spores by asexual processes.

gametangia are hyphal branches whose cytoplasm is isolated from the rest of the mycelium by cross walls. These gametangia enclose gametes that are basically a mass of cytoplasm containing several haploid nuclei. When food supplies run low and if compatible mating strains are present, the gametangia of compatible mating types fuse, as do the gamete cytoplasms. The resulting cell, known as a zygosporangium, contains many haploid nuclei that fuse, producing many diploid nuclei. Eventually, a dark-pigmented, thick-walled **zygospore** matures within the zygosporangium. Each zygospore contains many diploid nuclei and is capable of surviving stressful conditions. When the environment is suitable, the zygospore may undergo meiosis and germinate, dispersing many haploid spores. If the spores land in a suitable place, they germinate to form aseptate hyphae containing many haploid nuclei produced by mitosis. Most zygomycetes live on decaying materials in soil, but some are parasites of plants or animals.

AM Fungi Live with Plant Partners

The phylum Glomeromycota—commonly known as the **AM** (for arbuscular mycorrhizal) **fungi**—have aseptate hyphae and reproduce only asexually by means of unusually large spores with many nuclei (Figure 31.26). Many vascular plants depend on AM fungi, and these fungi are not known to grow separately from plants or cyanobacterial partners.

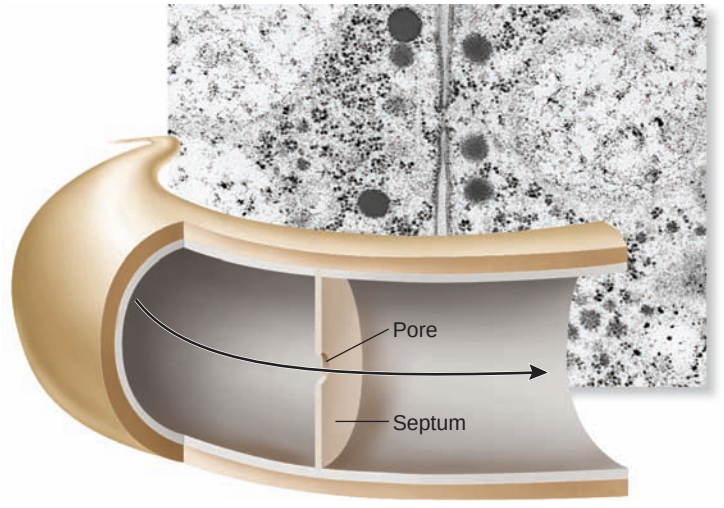
Molecular evidence suggests that Glomeromycota originated around 600 million years ago. Fossils having aseptate hyphae and large spores similar to those of modern Glomeromycota are known from the time when land plants first became common and widespread, about 460 million years ago (see Chapter 30). This and other fossil evidence suggests that the ability of early plants to live successfully on land may have depended on help from fungal associates, as is common today.

Ascomycetes Produce Sexual Spores in Saclike Asci

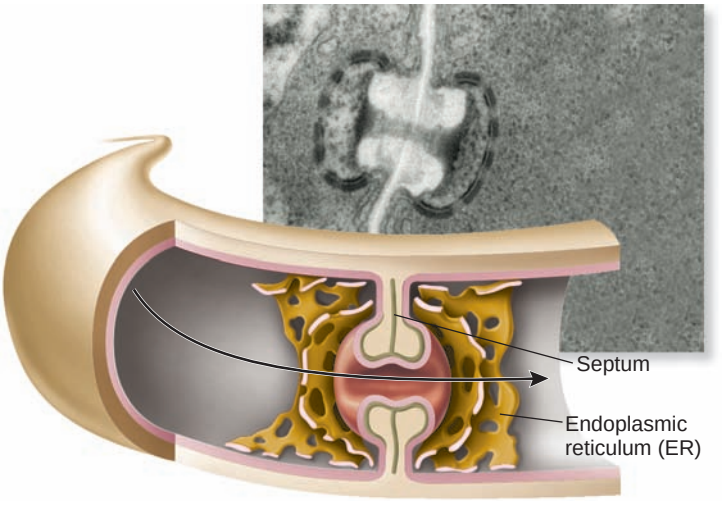
The **ascomycetes** and the basidiomycetes are composed of hyphae subdivided into cells by septa. These septa display distinctive pores, with ascomycete pores being simpler in structure than those of basidiomycetes (Figure 31.27). Such pores allow cytoplasmic structures and materials to pass through the hyphae.

The name ascomycetes derives from unique sporangia known as **asci** (from the Greek *asco*, meaning bags or sacs), which produce sexual spores known as **ascospores** (Figure 31.28). The asci are produced on fruiting bodies known as **ascocarps**. Although many ascomycetes have lost the ability to reproduce sexually, hyphal septa with simple pores (see Figure 31.27a) and DNA data can be used to identify them as members of this phylum.

Ascomycetes occur in terrestrial and aquatic environments, and they include many decomposers as well as pathogens. Important ascomycete plant pathogens include powdery mildews, chestnut blight (*Cryphonectria parasitica*), Dutch elm



(a) Simple pore—ascomycetes



(b) Complex pore—basidiomycetes

Figure 31.27 **Septal pores of ascomycetes and basidiomycetes.** **(a)** The septa of ascomycetes have simple pores at the centers. **(b)** More complex pores distinguish the septa of most types of basidiomycetes.

disease (the genus *Ophiostoma*), and apple scab (*Venturia inaequalis*) (Figure 31.29). Cup fungi (see the ascocarp photo in Figure 31.28) are common examples of ascomycetes. Many yeasts are also ascomycetes. Edible truffles and morels are the fruiting bodies of particular ascomycetes whose mycelia form mycorrhizal partnerships with plants. Ascomycetes are the most common fungal components of lichens.

Basidiomycetes Produce Diverse Fruiting Bodies

DNA-sequencing comparisons indicate that **basidiomycetes**, together with ascomycetes, are the most recently evolved groups of fungi. An estimated 30,000 modern basidiomycete species

Figure 31.29 **Apple infected with the ascomycete fungus *Venturia inaequalis*, which causes apple scab disease.** This fungus grows on leaves, flowers, and fruits, leaving harmless but unsightly scabs on their surfaces. Growers usually try to control apple scab by spraying trees with fungicides.

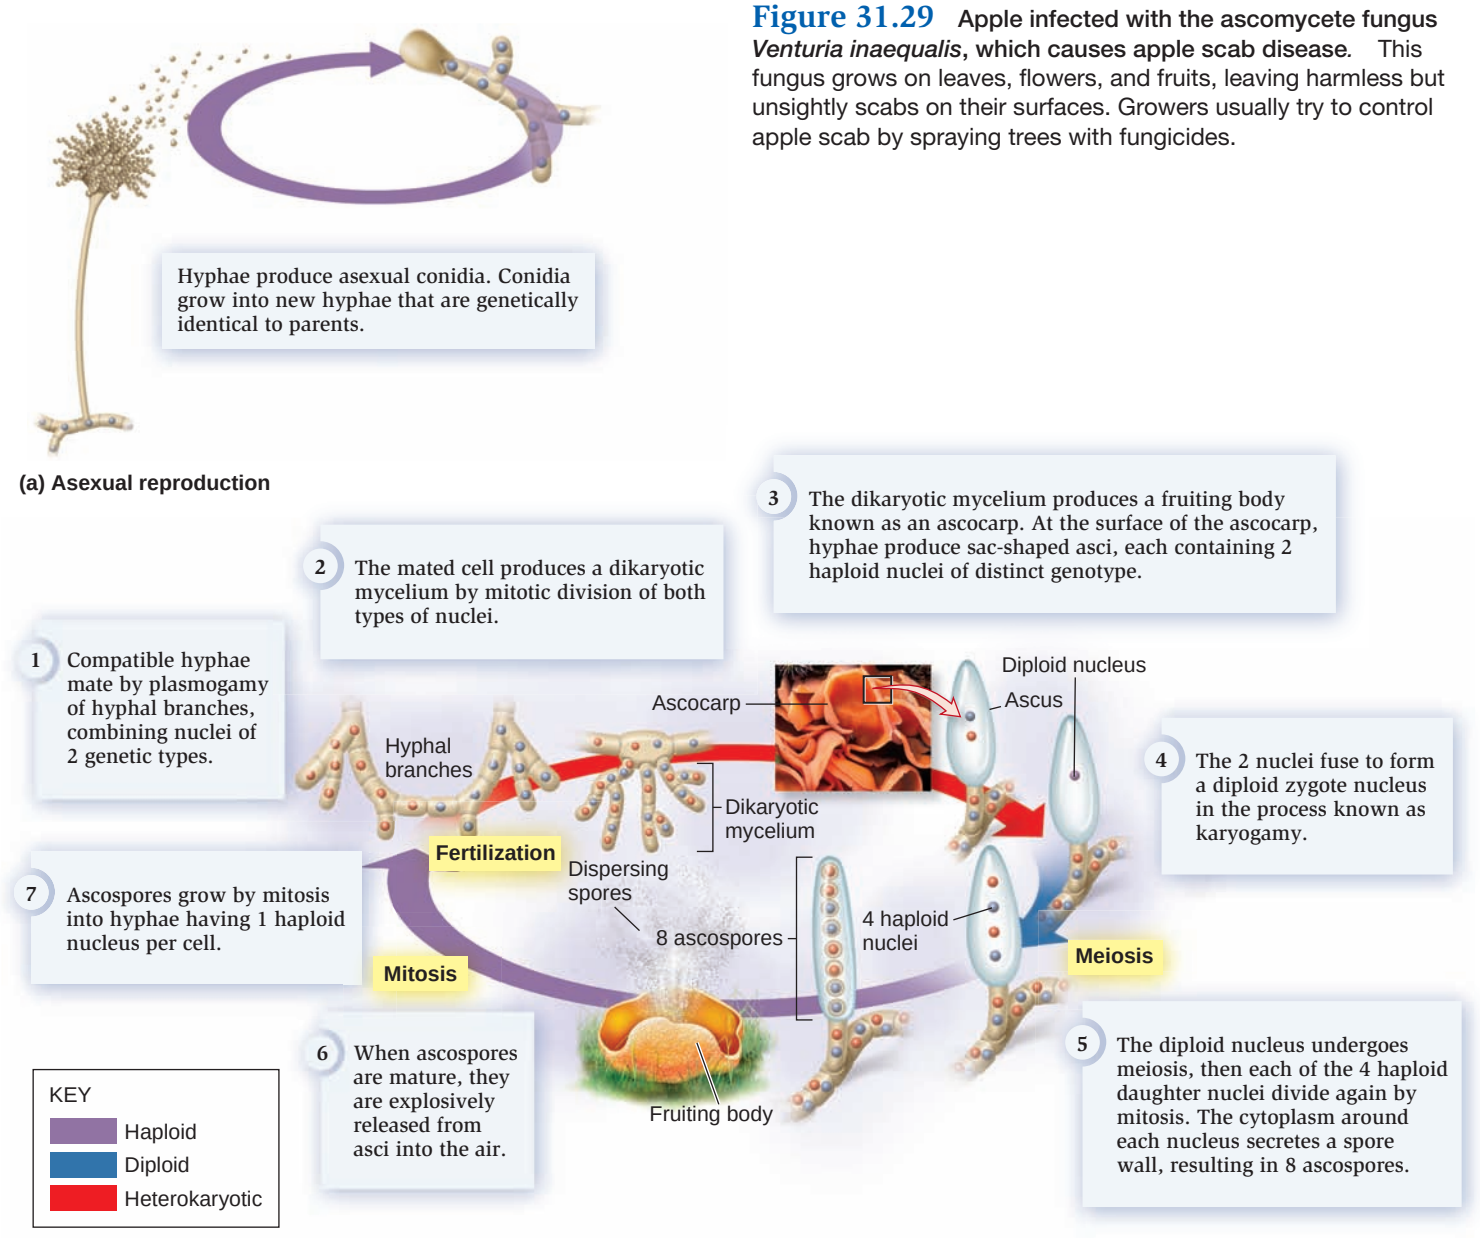


Figure 31.28 **The asexual and sexual life cycles of ascomycete fungi.**

(a) Corn smut

(b) Shelf fungi

Figure 31.30 **Fruiting bodies of basidiomycetes.** **(a)** Corn smut (*Ustilago maydis*) produces dikaryotic mycelial masses within the kernels (fruits) of infected corn plants. These mycelia produce many dark spores in which karyogamy and meiosis occur. Masses of these dark spores cause the smutty appearance. When the spores germinate, they produce basidiospores that can infect other corn plants. **(b)** Shelf fungi, such as this sulfur shelf fungus, are the fruiting bodies of basidiomycete fungi that have infected trees.

are known. Basidiomycetes are very important as decomposers and mycorrhizal partners in forests, producing diverse fruiting bodies commonly known as mushrooms, puffballs, stinkhorns, shelf fungi, rusts, and smuts (Figure 31.30; see also Figures 31.10, 31.11, and 31.12). The fairy rings of mushrooms that people sometimes find in open, grassy areas are ring-shaped arrays of basidiomycete fruiting bodies.

The name given to the basidiomycetes derives from **basidia**, the club-shaped cells that produce sexual spores known as **basidiospores** (Figure 31.31). Basidia are typically located on the undersides of fruiting bodies, which are generally known as **basidiocarps**. Though some basidiomycetes have lost sexual reproduction, they can be identified as members of this phylum by unique hyphal structures known as **clamp connections**, which help distribute nuclei during cell division. Basidiomycetes can also be identified by distinctive septa having complex pores (see Figure 31.27b) and by DNA methods. Basidiomycetes reproduce asexually by various types of spores.

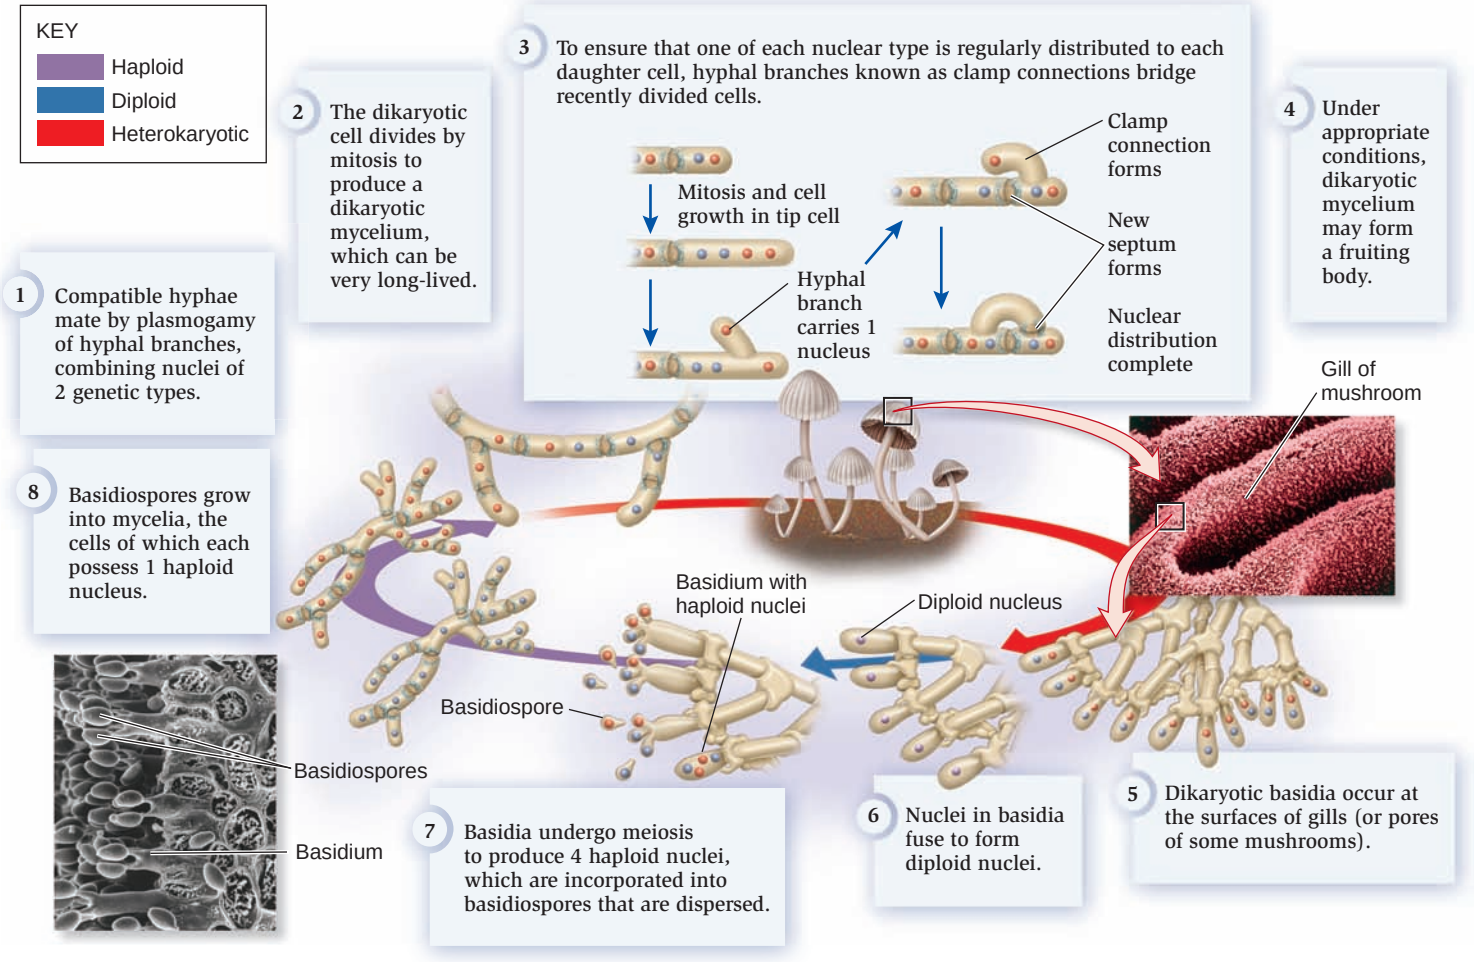

Figure 31.31 The sexual life cycle of the basidiomycete fungus *Coprinus disseminatus*.

Summary of Key Concepts

31.1 Evolutionary Relationships and Distinctive Features of Fungi

- Fungi form a monophyletic kingdom of heterotrophs that are related to the animal kingdom and certain protists. Early-divergent fungi are adapted to aquatic habitats, whereas later-divergent phyla are adapted to life on land. (Figure 31.1)
- Fungal cells possess cell walls composed of chitin, a polysaccharide resistant to microbial attack. Fungal bodies, known as mycelia, are composed of microscopic branched filaments known as hyphae, which appeared early in fungal evolution and grow at their tips. Food-gathering hyphae display absorptive nutrition; they secrete enzymes into food substrates, breaking down complex organic molecules into small organic molecules that are absorbed as food. (Figures 31.2, 31.3)
- The hyphae of later-diverging fungi are subdivided into cells by cross walls known as septa. Early-diverging fungi have aseptate hyphae that are not subdivided into cells. (Figure 31.4)
- Mycelial shape depends on the location of nutrients in the environment, which determines the direction in which cell division and hyphal growth will occur. (Figure 31.5)

31.2 Fungal Asexual and Sexual Reproduction

- Fungi disperse in their environments by means of spores produced by asexual or sexual reproduction. Asexual reproduction allows well-adapted genotypes to spread widely in stable environments. Sexual reproduction fosters the appearance of new traits useful in variable environments.
- Asexual reproduction does not involve mating or meiosis, and it occurs by means of asexual spores such as conidia or by budding. (Figures 31.6, 31.7)
- The gametes of most fungi are hyphal branches. During sexual reproduction, hyphal branches fuse with those of a different mycelium of compatible mating type. In many fungi, dikaryotic hyphae (having two nuclei per cell) that result from mating often persist for long periods before nuclear fusion occurs. Nuclear fusion generates zygotes. Fungal zygotes are the only cells in the life cycle that possess a diploid nucleus. Zygotes undergo meiosis to produce haploid spores, which disperse from fruiting bodies. Spores germinate to produce haploid fungal mycelia. (Figure 31.8)
- Fungi produce diverse types of fruiting bodies that foster spore dispersal by wind, water, or animals. Although many fungal fruiting bodies are edible, many others produce defensive toxins or hallucinogens. (Figures 31.9, 31.10, 31.11, 31.12)

31.3 Fungal Ecology and Biotechnology

- Fungi play important roles in nature as decomposers or predators and by forming beneficial associations with other organisms. Species of pathogenic fungi cause disease. (Figures 31.13, 31.14, 31.15, 31.16)
- Mycorrhizae are common associations between fungi and plant roots. Endomycorrhizae commonly form highly branched arbuscules in the spaces between root cell walls and plasma membranes. Ectomycorrhizae coat root surfaces, extending into root intercellular spaces. (Figures 31.17, 31.18, 31.19)
- A genome sequence newly available for *Laccaria bicolor* helps to explain the molecular basis of key traits of ectomycorrhizal fungi.
- Endophytic fungi often live compatibly within stems and leaves of plants, helping them to resist heat stress and attack by herbivores and disease microbes. (Figure 31.20)
- Lichens are multispecies partnerships between fungi, photosynthetic green algae and/or cyanobacteria, and other bacteria. Lichens can reproduce asexually by means of structures such as soredia, which consist of fungal hyphae wrapped around a few algal cells. When lichen fungi reproduce sexually, the hyphae arising from spore germination must find new algal partners, and lichen fungi often switch algal partners. (Figures 31.21, 31.22)
- Lichens occur in diverse habitats, including harsh environments, and often grow slowly and to great age. Lichens help to build soils and are useful air-quality monitors.
- Fungal biochemistry is useful in the chemical, food processing, and waste-treatment industries, and fungi are increasingly used to replace chemical procedures that generate harmful waste materials. The yeast *Saccharomyces cerevisiae* is important to the brewing and baking industries and is widely used as a laboratory model system. (Figure 31.23)

31.4 Diversity of Fungi

- Currently, fungi are classified into five phyla, commonly known as chytrids, zygomycetes, AM fungi, ascomycetes, and basidiomycetes. (Table 31.1)
- Chytrids are among the simplest and earliest-divergent fungi. They commonly occur in aquatic habitats and moist soil, where they produce flagellate reproductive cells. (Figure 31.24)
- Zygomycetes are named for their distinctive, large zygospores, the result of sexual reproduction. Common black bread mold and other zygomycetes reproduce asexually by means of many small spores. (Figure 31.25)
- The AM fungi produce distinctive large, multinucleate spores, and they form beneficial arbuscular mycorrhizal relationships with many types of plants. (Figure 31.26)
- Ascomycetes produce sexual ascospores in saclike asci located at the surfaces of fruiting bodies known as ascocarps. Many are lichen symbionts. The septa of hyphae have simple pores. (Figures 31.27, 31.28, 31.29)
- Basidiomycetes produce sexual basidiospores on club-shaped basidia located on the surfaces of fruiting bodies known as basidiocarps. Such fruiting bodies take a wide variety of forms, including mushrooms, puffballs, stinkhorns, shelf fungi, rusts, and smuts. The hyphae of basidiomycete fungi are characterized by complex pores in septa and clamp connections, structures that aid in distributing nuclei of two types after cell division occurs in dikaryotic hyphae. (Figures 31.30, 31.31)

Assess and Discuss

Test Yourself

1. Fungal cells differ from animal cells in that fungal cells
   a. lack ribosomes, though these are present in animal cells.
   b. lack mitochondria, though these occur in animal cells.
   c. have cell walls, whereas animal cells lack rigid walls.
   d. lack cell walls, whereas animal cells possess walls.
   e. none of the above
2. Conidia are
   a. cells produced by some fungi as the result of sexual reproduction.
   b. fungal asexual reproductive cells produced by the process of mitosis.
   c. structures that occur in septal pores.
   d. the unspecialized gametes of fungi.
   e. none of the above.
3. What are mycorrhizae?
   a. the bodies of fungi, composed of hyphae
   b. fungi that attack plant roots, causing disease
   c. fungal hyphae that are massed together into stringlike structures
   d. fungi that have symbiotic partnerships with algae or cyanobacteria
   e. mutually beneficial associations of particular fungi and plant roots
4. Where could you find diploid nuclei in an ascomycete or basidiomycete fungus?
   a. in spores
   b. in cells at the surfaces of fruiting bodies
   c. in conidia
   d. in soredia
   e. all of the above
5. Which fungi are examples of hallucinogen producers?
   a. *Claviceps* and *Psilocybe*
   b. *Epidermophyton* and *Candida*
   c. *Pneumocystis carinii* and *Histoplasma capsulatum*
   d. *Saccharomyces cerevisiae* and *Phanerochaete chrysosporium*
   e. *Cryphoenectria parasitica* and *Ventura inaequalis*
6. What role do fungal endophytes play in nature?
   a. They are decomposers.
   b. They are human pathogens that cause skin diseases.
   c. They are plant pathogens that cause serious crop diseases.
   d. They live within the tissues of grasses and other plants, helping to protect plants from herbivores, pathogens, and heat stress.
   e. All of the above are correct.
7. What forms do lichens take?
   a. crusts, flat bodies
   b. foliose, leaf-shaped bodies
   c. fruticose, erect or dangling bodies
   d. single cells
   e. a, b, and c
8. Lichens consist of a partnership between fungi and what other organisms?
   a. red algae and brown algae
   b. green algae, cyanobacteria, and heterotrophic bacteria
   c. the roots of vascular plants
   d. choanoflagellates and *Nuclearia*
   e. none of the above
9. How can ascomycetes be distinguished from basidiomycetes?
   a. Ascomycete hyphae have simple pores in their septa and lack clamp connections, whereas basidiomycete hyphae display complex septal pores and clamp connections.
   b. Ascomycetes produce sexual spores in sacs, whereas basidiomycetes produce sexual spores on the surfaces of club-shaped structures.
   c. Ascomycetes are commonly found in lichens, whereas basidiomycetes are less commonly partners in lichen associations.
   d. Ascomycetes are not commonly mycorrhizal partners, but basidiomycetes are commonly present in mycorrhizal associations.
   e. All of the above are correct.
10. Which group of organisms listed is most closely related to the kingdom Fungi?
    a. the animal kingdom
    b. the green algae
    c. the land plants
    d. the bacteria
    e. the archaea

Conceptual Questions

1. Explain three ways that fungi are like animals and two ways in which fungi resemble plants.
2. Explain why some fungi produce toxic or hallucinogenic compounds.
3. Explain three ways in which fungi function as beneficial partners with autotrophs and what benefit the fungi receive from the partnerships.

Collaborative Questions

1. Thinking about the natural habitats closest to you, where could you find fungi, and what roles do these fungi play?
2. Imagine that you are helping to restore the natural vegetation on a piece of land that had long been used to grow crops. You are placed in charge of planting pine seedlings (*Pinus resinosa*) and fostering their growth. In what way could you consider using fungi?

An Introduction to Animal Diversity

32

Chapter Outline

Two of the staggering variety of animal species on Earth. These species include thousands of vertebrates and millions of invertebrates.

Animals constitute a very species-rich kingdom. Well over a million species have been found and described by biologists, with many more species likely awaiting discovery and classification. Beyond being members of this kingdom ourselves, humans are dependent on animals. We eat many different kinds of animals, use a diverse array of animal products, and employ animals such as horses and oxen as a source of labor. We enjoy many animal species as companions and are dependent on other species to test lifesaving drugs. However, we are in competition with animals such as insects that threaten our food supply and are parasitized by others. With such a huge number and diversity of existing animals and with animals featuring so prominently in our lives, understanding animal diversity is of paramount importance. Researchers have spent great effort in determining the unique characteristics of different taxonomic groups and identifying their evolutionary relationships.

Since the time of Carl Linnaeus in the 1700s, scientists have classified animals based on their morphology, that is, on their physical structure. Then, as now, a lively debate has surrounded the question of what constitutes the "correct" animal phylogeny. In the 1990s, animal classifications based on similarities in DNA and rRNA became more common. Quite often, classifications based on morphology and those based on molecular data were similar, but some important differences arose. In this chapter, we will begin by defining the key characteristics of animals and then take a look at the major features of the animal body plans that form the basis of the traditional view of animal classification. We will explore how new molecular evidence has made significant alterations to this categorization of the animal kingdom and examine some of the similarities and differences between the morphological and molecular-based phylogenies. As more molecular-based evidence becomes available, systematists will likely continue to redraw the tree of animal life. Thus, as you read this chapter, keep in mind that animal classification is now, and will continue to be, a work in progress.

32.1 Characteristics of Animals

The Earth contains over a million known animal species, living in environments from the deep sea to the desert and exhibiting an amazing array of characteristics. Most animals move and eat multicellular prey, and therefore, they are loosely differentiated from species in other kingdoms. However, coming up with a firm definition of an animal is tricky, because animals are so diverse that biologists can find exceptions to nearly any given characteristic. Even so, a number of key features exist that can help us broadly characterize the group we call animals (Table 32.1).

In brief, **animals** are multicellular heterotrophs whose cells lack cell walls. Most animals have nerves, muscles, the capacity to move at some point in their life cycle, and the ability to reproduce sexually, with sperm fusing directly with eggs. Unlike plants, animals cannot synthesize their essential organic molecules from inorganic sources and so must feed on other organisms. Many, if not most, animals are capable of some type of movement or locomotion in order to acquire food or escape predators. This ability has led to the development of specialized systems of sensory structures and a nervous system to coordinate movement and prey capture. Sessile species, such as barnacles, use bristled appendages to obtain food. In many such

Table 32.1 Common Characteristics of Animals

Characteristic	Example
Multicellularity	Even relatively simple types of animals such as sponges are multicellular, in contrast to the single-celled eukaryotic microorganisms called protists (see Chapter 28).
Heterotrophs	Animals obtain their food by eating other organisms or their products. This contrasts with plants and algae, which are autotrophs and essentially make their own food.
No cell walls	While plant, fungal, and bacterial cells are rigid because they possess a cell wall, animal cells lack a cell wall and are quite flexible.
Nervous tissue	The presence of a nervous system in most animals enables them to respond rapidly to environmental stimuli.
Movement	Most animals have a muscle system, which, combined with a nervous system, allows them to move in their environment.
Sexual reproduction	Most animals reproduce sexually, with small, mobile sperm uniting with a much larger egg to form a fertilized egg, or zygote.
Extracellular matrix	Proteins such as collagen bind animal cells together to give them added support and strength.
Characteristic cell junctions	Animals have characteristic cell junctions, called anchoring, tight, and gap junctions.
Special clusters of *Hox* genes	All animals possess *Hox* genes, which function in patterning the body axis (see Chapter 19).
Similar rRNA	Animals have very similar genes that encode for RNA of the small ribosomal subunit (SSU) rRNA.

sessile species, although adults are immobile, the larvae can swim. The lack of a rigid cell wall and the existence of nerves and muscles facilitate movement but reduce structural support. Instead, animal cells exist in an extensive extracellular matrix that forms strong fibers outside of the cell (see Chapter 10). Additionally, a group of unique cell junctions, called anchoring, tight, and gap junctions, plays an important role in holding animal cells in place and allowing cell communication.

The history of animal life spans over 590 million years, starting at the end of the Proterozoic era, when marine invertebrates appeared (refer back to Figure 22.9). A profusion of animal phyla appeared during the Cambrian explosion, 533–525 million years ago, including sponges, jellyfish, corals, flatworms, mollusks, annelid worms, the first arthropods, and echinoderms, plus many phyla that no longer exist today. The causes of this sudden increase in animal life at this time are not fully understood, but three reasons have been proposed. First, species proliferation may have been related to a favorable environment, which was warm and wet with no evidence of ice at the poles. At the same time, atmospheric oxygen levels were high, permitting increased metabolic rates, and the ozone layer had developed, blocking out harmful ultraviolet radiation and allowing complex life to thrive in shallow water and, eventually, land. Second, the evolution of the *Hox* gene complex may have permitted much variation in morphology. Third, as new types of predator evolved, prey developed new methods of predator avoidance. This evolutionary arms race may have caused a proliferation of predator and prey types. These hypotheses are not mutually exclusive and may well have operated at the same time.

Five hundred and twenty million years ago, the first vertebrates, fishes, appeared at roughly the same time as the first land plants. The appearance of land plants represented a viable food source for any animals that could utilize them. However, terrestrial organisms faced the problem of drying out, or desiccation. This problem necessitated the development of features that enabled animals to venture onto land, in much the same way as seeds and other adaptations permitted plants to colonize terrestrial habitats (see Chapter 29). Such features include internal fertilization and the development of a tough, protective shell around the eggs of many species. The amniotic egg appeared during the Carboniferous period, about 300 million years ago, and was responsible for the success of the reptiles, which appeared during this period. Reptiles were to dominate the Earth for many millions of years during the rise and fall of the dinosaurs. Mammals also appeared at the same time as dinosaurs and were to inherit the Earth as the dinosaurs disappeared in a changing climate about 65 million years ago.

32.2 Traditional Classification of Animals

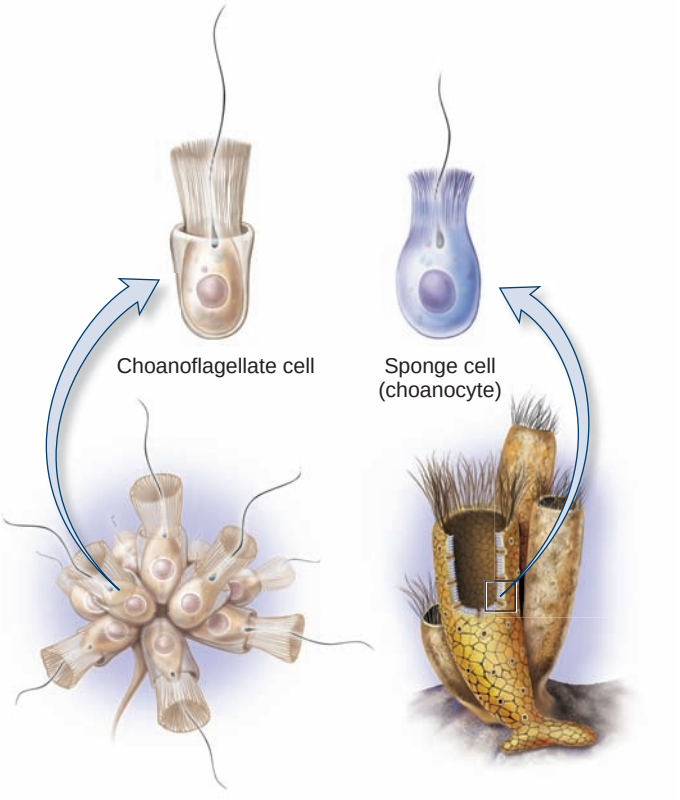
Although animals constitute an extremely diverse kingdom, most biologists agree that the kingdom is monophyletic, meaning that all taxa have evolved from a single common ancestor. Today, scientists recognize about 35 animal phyla. At first glance, many of these phyla seem so distantly related to one another (for example, chordates and jellyfish) that making sense of this diversity with a classification scheme seems very challenging. However, over the course of centuries, scientists have come to some basic conclusions about the evolutionary relationships among animals. In this section, we explore the major features of animal body plans and development that are the basis of the traditional view of animal phylogeny. But first, let's look at where this diversity started.

Animals Evolved from a Choanoflagellate Ancestor

With the monophyletic nature of the animal kingdom in mind, scientists have attempted to characterize the organism from which animals most likely evolved. According to research, the most likely ancestor is a colonial flagellated protist that is probably related to the present-day protists known as choanoflagellates. Choanoflagellates are tiny, single-celled organisms, each with a single flagellum surrounded by a collar composed of

cytoplasmic tentacles (Figure 32.1a). A number of species are colonial, usually taking the form of a cluster of undifferentiated cells on a single stalk. Scientists think that some of these cells may have gradually taken on specialized functions—for example, movement or nutrition—while still maintaining coordination with other cells and cell types.

As shown in Figure 32.1b, colonial choanoflagellate cells bear a striking similarity to cell types found in sponges, which are the simplest animals. As discussed later, evolutionary changes to this simple body plan resulted in critical innovations that led to more complex body plans found in other animals. Molecular data also point to choanoflagellates as the common animal ancestor.



(a) Colonial choanoflagellate (b) Sponge

Figure 32.1 Early animal characteristics: A comparison of a colonial choanoflagellate and a sponge. Both types of organisms have very similar types of cells, which are used for feeding. The structure of sponges is described in Chapter 33 (look ahead to Figure 33.2).

Concept check: Why are sponges considered animals but simple choanoflagellates are not?

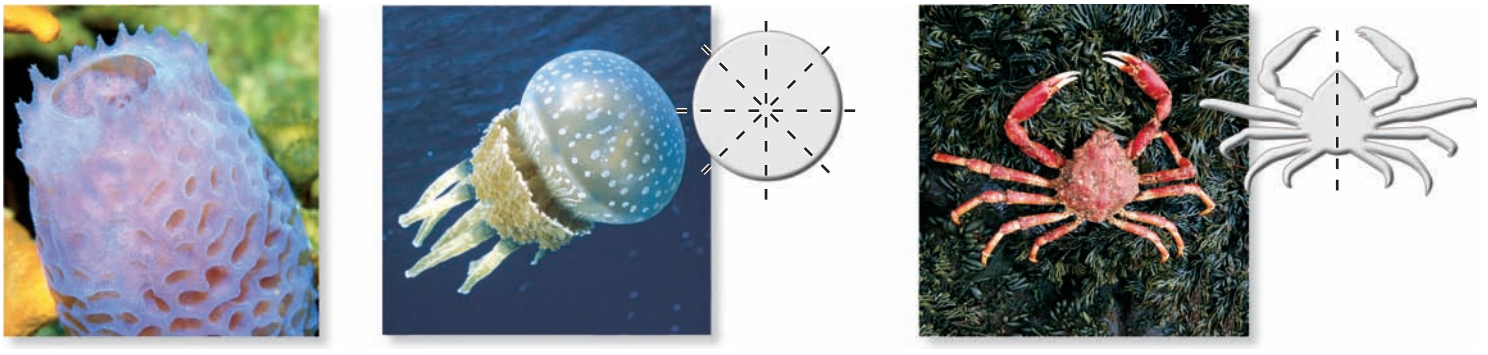
The Traditional Classification of Animals Is Based on Body Plans

Without the availability of modern molecular techniques, biologists traditionally classified animal diversity in terms of these four main morphological and developmental features of animal body plans:

1. presence or absence of different tissue types;
2. type of body symmetry;
3. presence or absence of a true body cavity;
4. specific features of embryonic development.

We will discuss each of these major features of animal body plans next.

Tissues Collectively, animals are known as **Metazoa**. Animals can be divided into two subgroups based on whether or not they have specialized types of tissues, that is, stable associations of cells that have a similar structure and function. The **Parazoa** (from the Greek, meaning alongside animals) are not generally thought to possess specialized tissue types or organs, although they may have several distinct types of cells. Those cells can change their shape and location, making any associations temporary. The Parazoa consist of a single phylum, Porifera (sponges) (Figure 32.2a). In contrast, the **Eumetazoa** (from the Greek, meaning true animals) have more than one type of tissue and, for the most part, have different types of organs.



(a) Parazoa: no tissue types (b) Eumetazoa: two tissue types
Radiata: radial symmetry
(c) Eumetazoa: three tissue types
Bilateria: bilateral symmetry

Figure 32.2 Early divisions in the animal phylogeny. Animals can be categorized based on **(a)** the absence of different tissue types (Parazoa; the sponges) or **(b,c)** the presence of tissues (Eumetazoa; all other animals). Further categorization is based on the presence of (b) radial symmetry (Radiata; the cnidarians and ctenophores) or (c) bilateral symmetry (Bilateria; all other animals).

Symmetry The Eumetazoa are divided according to their type of symmetry. Symmetry refers to the existence of balanced proportions of the body on either side of a median plane. Radially symmetric animals, the **Radiata**, can be divided equally by any longitudinal plane passing through the central axis (Figure 32.2b). Such animals are often circular or tubular in shape, with a mouth at one end, and include the animals called cnidarians and ctenophores (jellyfish and related species).

Bilaterally symmetric animals, the **Bilateria**, can be divided along a vertical plane at the midline to create two halves (Figure 32.2c). Thus, a bilateral animal has a left side and a right side, which are mirror images, as well as a **dorsal** (upper) and a **ventral** (lower) side, which are not identical, and an **anterior** (head) and a **posterior** (tail) end. Bilateral symmetry is strongly correlated with both the ability to move through the environment and **cephalization**, the localization of sensory structures at the anterior end of the body. Such abilities allow animals to encounter their environment initially with their head, which is best equipped to detect and consume prey and, in turn, detect and respond to predators and other dangers.

Another key difference between the Radiata and Bilateria is that radial animals have two embryonic cell layers, called **germ layers**, whereas bilateral animals have three germ layers. In all animals except the sponges, the growing embryo develops different layers of cells through a process known as **gastrulation** (Figure 32.3).

Fertilization of an egg by a sperm creates a diploid zygote. The zygote then undergoes **cleavage**, a succession of rapid cell divisions with no significant growth that produces a hollow sphere of cells called a **blastula**. In gastrulation, an area in the blastula folds inward, or invaginates, creating in the process a structure called a gastrula with the primary germ layers. The inner layer of cells becomes the **endoderm**, which lines the **archenteron**, or primitive digestive tract. The outer layer, or **ectoderm**, covers the surface of the embryo and differentiates into the epidermis and nervous system.

The Bilateria develop a third layer of cells, termed the **mesoderm**, between the ectoderm and endoderm. Mesoderm forms the muscles and most other organs between the digestive tract and the ectoderm. Because the Bilateria have these three distinct germ layers, they are often referred to as **triploblastic**, whereas the Radiata, which have only ectoderm and endoderm, are termed **diploblastic**.

Body Cavity The next three major divisions in the classification of animals concern the development in bilaterally symmetrical animals of a fluid-filled body cavity called a **coelom**. In many animals, the body cavity is completely lined with mesoderm and is called a true coelom. Animals with a true coelom are termed **coelomates** (Figure 32.4a). If the fluid-filled cavity is not completely lined by tissue derived from mesoderm, it is known as a pseudocoelom (Figure 32.4b). Animals with a pseudocoelom, including rotifers and roundworms, are termed **pseudocoelomates**. Some animals, such as flatworms, lack a fluid-filled body cavity and are termed **acoelomates** (Figure 32.4c). Instead of fluid, this region contains mesenchyme tissue.

A body cavity has many important functions, perhaps the most important being that its fluid is relatively incompressible and therefore cushions internal organs such as the heart and intestinal tract, helping to prevent injury from external forces. A body cavity also enables internal organs to move and grow independently of the outer body wall. Furthermore, in some soft-bodied invertebrates, such as earthworms, the coelom functions as a **hydrostatic skeleton**, a fluid-filled body cavity surrounded by muscles that gives support and shape to the

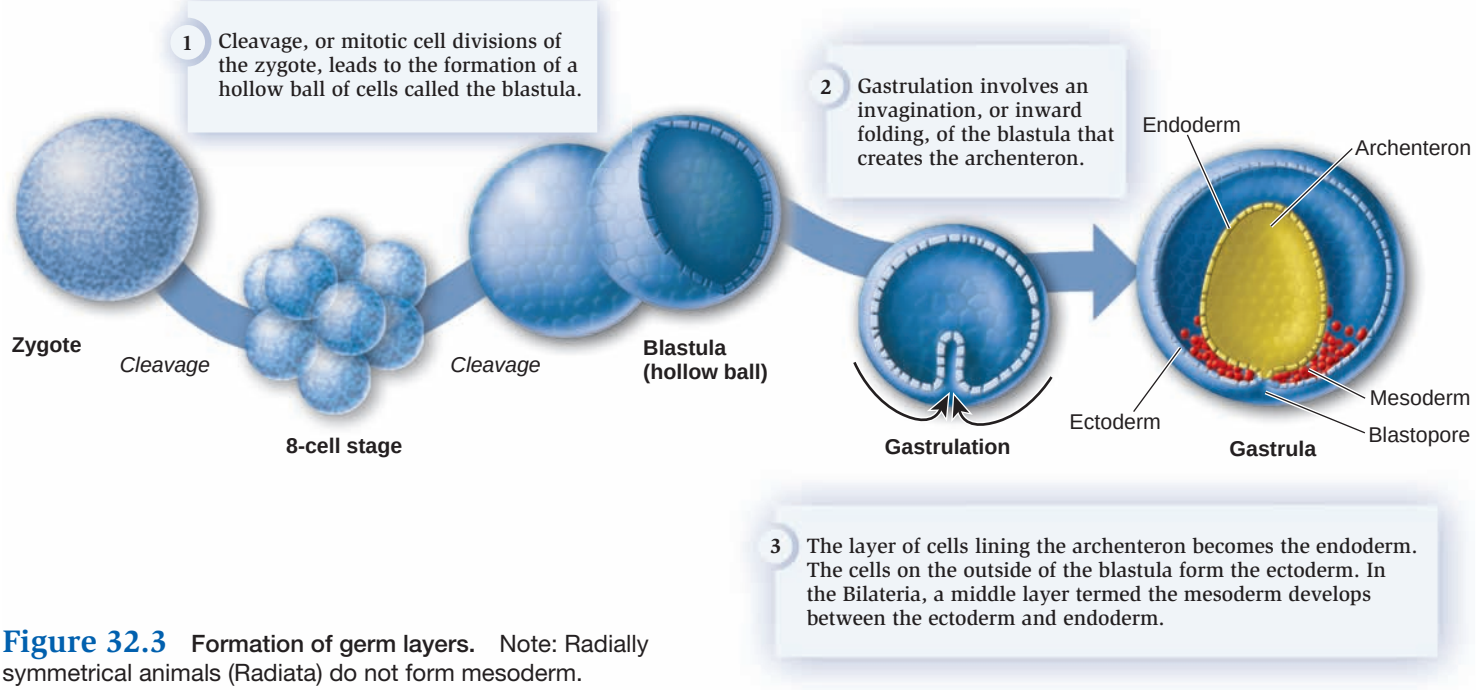


Figure 32.3 Formation of germ layers. Note: Radially symmetrical animals (Radiata) do not form mesoderm.

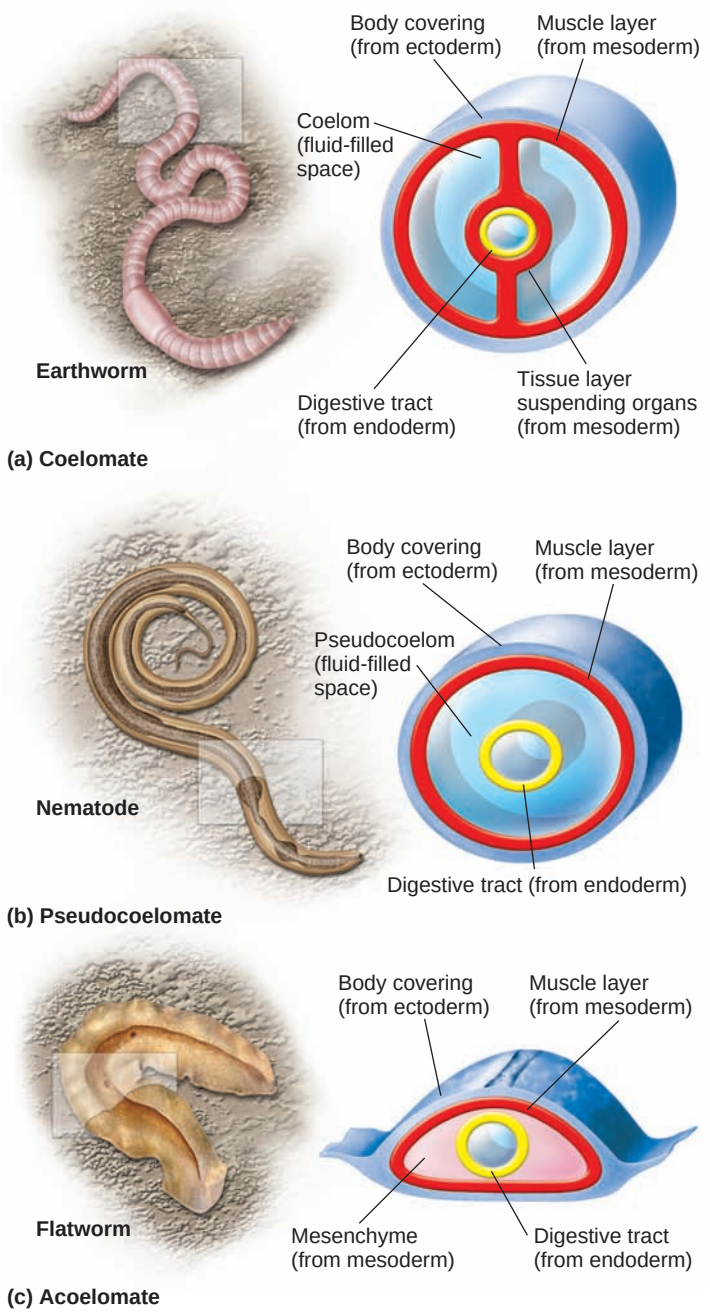

Figure 32.4 **The three basic body plans of bilaterally symmetrical animals.** Cross sections of each animal are shown on the right.

Concept check: What advantages does a coelom confer for movement?

body of organisms. Muscle contractions at one part of the body push this fluid toward another part of the body. This type of movement can best be observed in an earthworm (look ahead to Figure 44.1a). Finally, in some organisms, the fluid in the body cavity also acts as a simple circulatory system.

Specific Features of Embryonic Development In the developing zygote, cleavage may occur by two mechanisms (Figure 32.5a). In **spiral cleavage**, the planes of cell cleavage are oblique to the vertical axis of the embryo, resulting in an arrangement in which newly formed upper cells lie centered between the underlying cells. Animals that exhibit spiral cleavage are called **protostomes** and include mollusks, annelid worms, and arthropods. In **radial cleavage**, the cleavage planes are either parallel or perpendicular to the vertical axis of the egg. This results in tiers of cells, one directly above the other. Animals exhibiting radial cleavage are called **deuterostomes** and include echinoderms and chordates.

Protostome development is also characterized by so-called **determinate cleavage**, in which the fate of each embryonic cell is determined very early (Figure 32.5b). If one of the cells is removed from a four-cell mollusk embryo, neither the single cell nor the remaining three-cell mass can form viable embryos, and development is halted. In contrast, deuterostome development is characterized by **indeterminate cleavage**, in which each cell produced by early cleavage retains the ability to develop into a complete embryo. For example, when one cell is excised from a four-cell sea urchin embryo, both the single cell and the remaining three can go on to form viable embryos. Other embryonic cells compensate for the missing cells. In human embryos, if individual embryonic cells separate from one another early in development, identical twins can result.

In addition to differences in cleavage patterns, protostomes and deuterostomes differ in other embryonic features. The most fundamental of these concerns the development of a mouth and anus (Figure 32.5c). In gastrulation, the endoderm forms an indentation, the **blastopore**, which is the opening of the archenteron to the outside. In protostomes (from the Greek *protos*, meaning first, and *stoma*, meaning mouth), the blastopore becomes the mouth. If an anus is formed in a protostome, it develops from a secondary opening. In contrast, in the deuterostomes (from the Greek *deuteros*, meaning second), the blastopore becomes the anus, and the mouth is formed from the secondary opening.

Further Methods of Classification In the traditional phylogenetic tree of animal life, more recent branches are based on features such as the possession of an exoskeleton (arthropods) or the development of a notochord (chordates). One other key feature of the animal body plan is the presence or absence of segmentation. In **segmentation**, the body is divided into regions called segments. It is most obvious in the annelids, or segmented worms, but it is also evident in arthropods and chordates (Figure 32.6). In annelids, each segment contains the same set of blood vessels, nerves, and muscles. Some segments may differ, such as those containing the brain or the sex organs, but many segments are very similar. In chordates, we can see segmentation in the backbone and muscles.

The advantage of segmentation is that it allows specialization of body regions. For example, as we will see in Chapter 33, arthropods exhibit a vast degree of specialization of their segments. Many insects have wings and only three pairs of legs, whereas centipedes have no wings and many legs. Crabs, lobsters, and shrimp have highly specialized thoracic appendages that aid in feeding. Let's now take a look at how we are

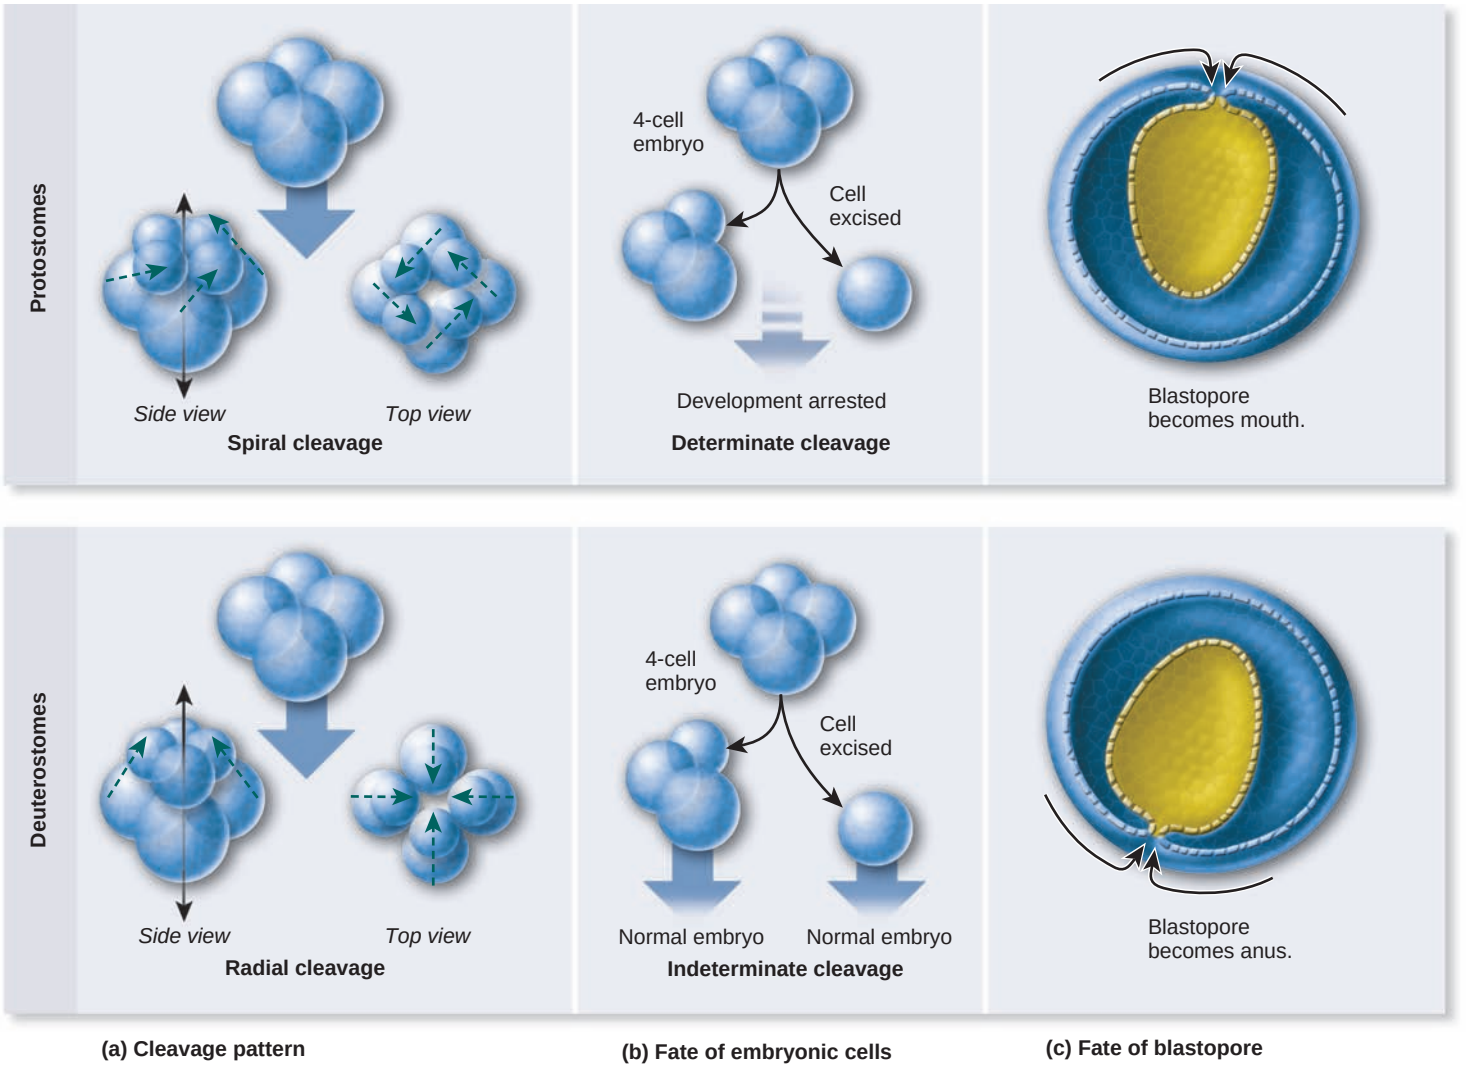

Figure 32.5 **Differences in embryonic development between protostomes and deuterostomes.** **(a)** Many protostomes have spiral cleavage, and most deuterostomes have radial cleavage. The dashed arrows indicate the direction of cleavage. **(b)** Protostomes have determinate cleavage, whereas deuterostomes have indeterminate cleavage. **(c)** In protostomes, the blastopore becomes the mouth. In deuterostomes, the blastopore becomes the anus.

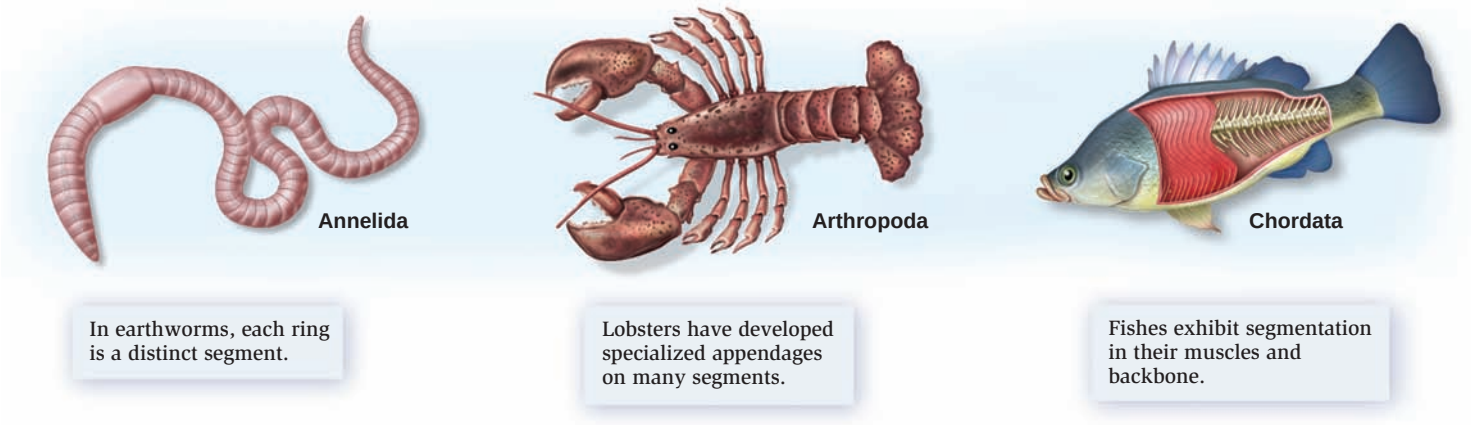

Figure 32.6 **Segmentation.** Annelids, arthropods, and chordates all exhibit segmentation.

beginning to understand the genetic basis for some of these morphological traits. Recent studies have shown that changes in specialization among arthropod body segments can be traced to relatively simple changes in homeotic, or *Hox*, genes.

Genomes & Proteomes Connection

Changes in *Hox* Gene Expression Control Body Segment Specialization

***Hox* genes**, which are present in all animals, are genes that are involved in pattern formation in early embryos. In the 1990s, Michalis Averof and coworkers showed how relatively simple changes in the expression patterns of these genes can account for the large variation in arthropod appendage types. As described in Chapter 19, animals have several *Hox* genes that are expressed in particular regions of the body. Some are expressed in anterior segments; others are expressed in posterior segments (refer back to Figure 19.17). The *Hox* genes are designated with numbers 1 through 13.

Shifts in patterns of expression of *Hox* genes in the embryo along the anteroposterior axis are prominent in evolution. In vertebrates, the transition from one type of vertebra to another, for example, from cervical (neck) to thoracic (chest) vertebrae, is also controlled by particular *Hox* genes (Figure 32.7). The site of the cervical/thoracic boundary appears to be influenced by the *HoxC-6* gene. Differences in its relative position of expression, which occurs prior to vertebrae development, control neck length in vertebrates. In mice, which have a relatively short neck, the expression of *HoxC-6* begins between vertebrae numbers 7 and 8. In chickens and geese, which have longer necks, the expression begins farther back, between vertebrae 14 and 15, or 17 and 18, respectively. The forelimbs also arise at this boundary in all vertebrates. Interestingly, snakes, which essentially have no neck or forelimbs, do not exhibit this boundary, and *HoxC-6* expression occurs immediately behind their heads. This in effect means that snakes got longer by losing their neck and lengthening their chest.

Evolutionary and development biologist Sean Carroll has remarked that it is very satisfying to find that the evolution of body forms and novel structures in two of the most successful and diverse animal groups, arthropods and vertebrates, is shaped by the shifting of *Hox* genes. It also reminds us of one of the basic tenets of diversity—that modern organisms illustrate Darwin's concept of descent with modification. Much of the diversity in animal phyla can be seen as variations on a common theme.

A traditional view of animal phylogeny based on body plans is illustrated in Figure 32.8. This phylogeny was accepted by most biologists for over a century. However, in addition to providing us with new information about the genetic basis of morphological traits, molecular methods are giving us new insights into the relationships between animals.

32.3 Molecular Views of Animal Diversity

Biologists are using molecular techniques to classify animals by comparing similarities in their DNA and ribosomal RNA. An advantage of the molecular approach is that genetic sequences among different species are easier to quantify and compare than are morphological data. The DNA sequence contains four easily identified and mutually exclusive characters: the bases A, T, G, and C (RNA has A, U, G, and C). Contrast this with

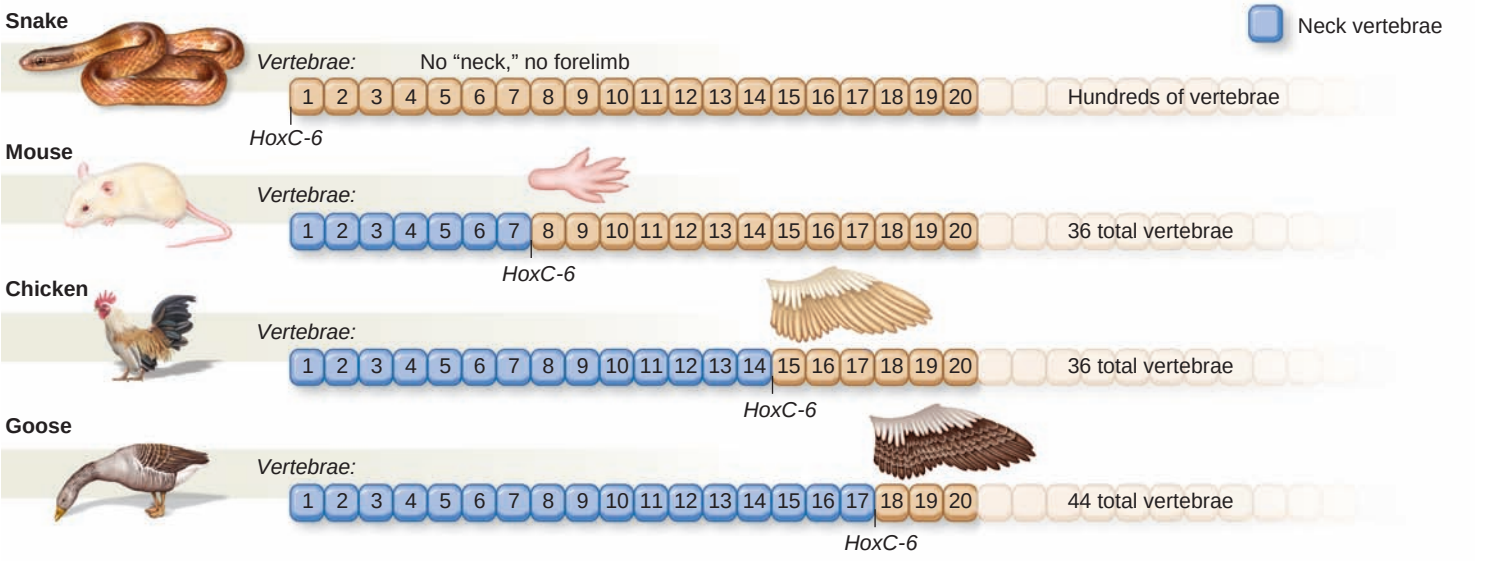

Figure 32.7 Relationship between *HoxC-6* gene expression and neck length. In vertebrates, the transition between neck and trunk vertebrae is controlled by the position of the *HoxC-6* gene. In snakes, the expression of this gene is shifted so far forward that a neck does not develop.

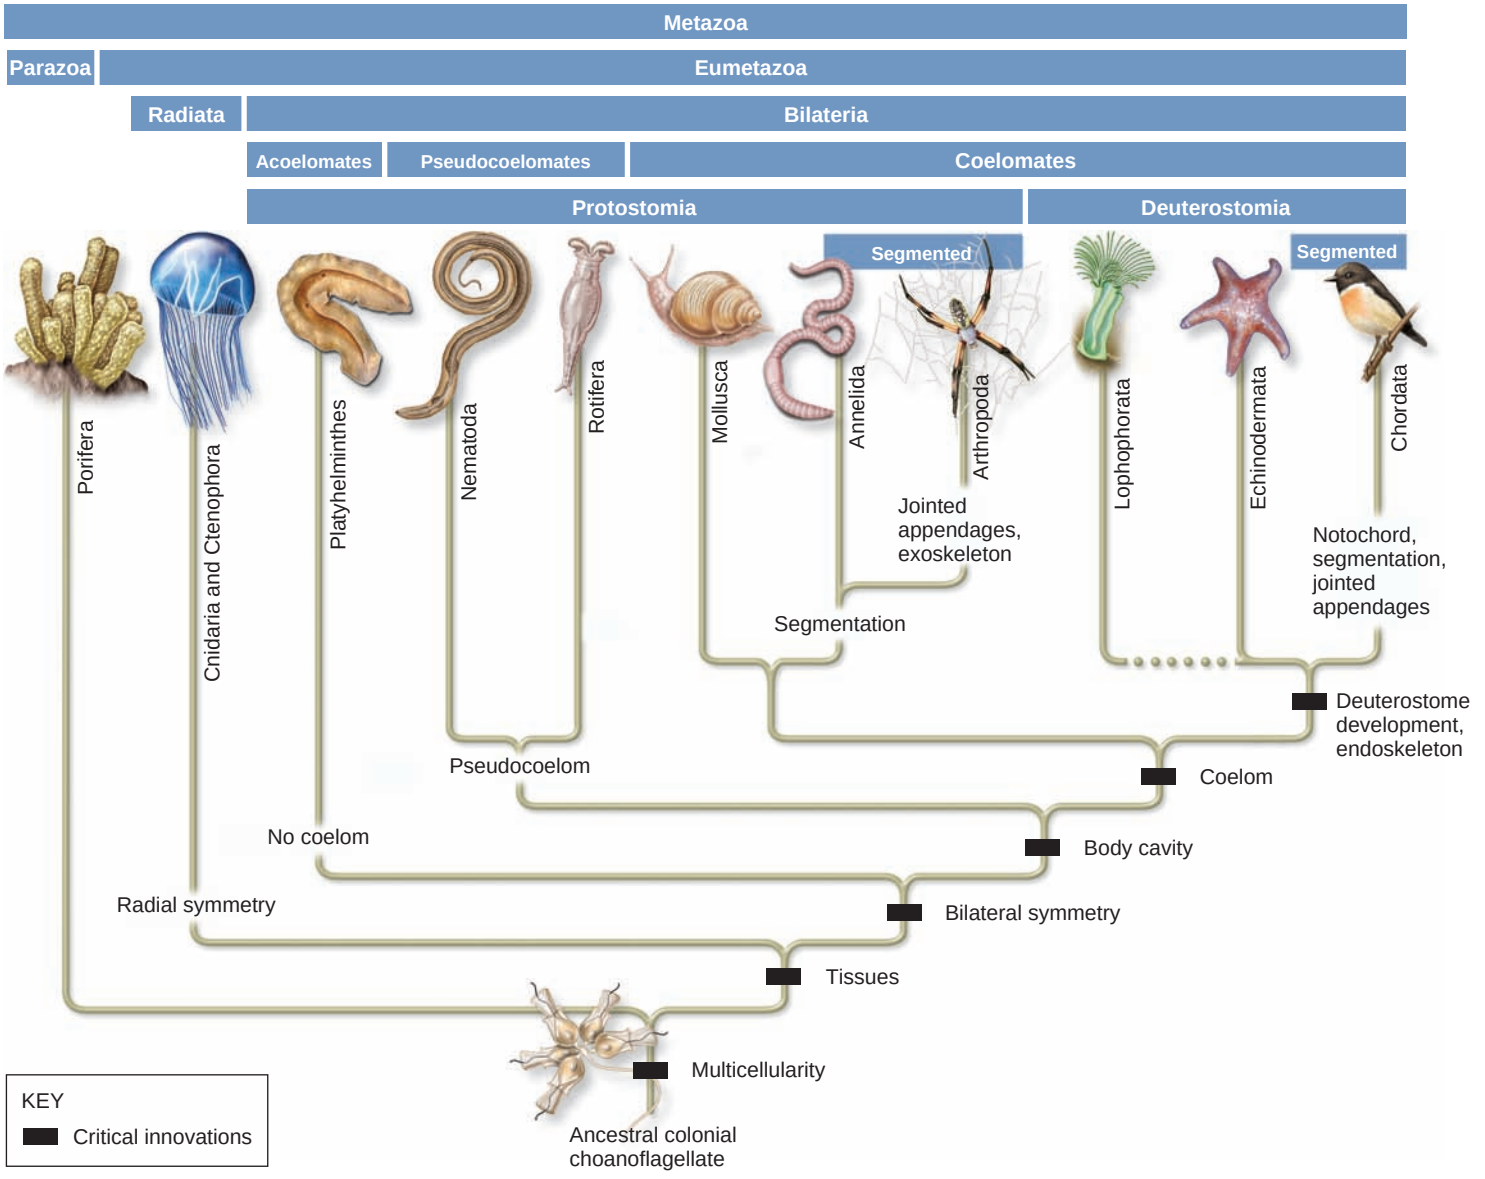

Figure 32.8 **An animal phylogeny based on body plans.** Though there are about 35 different animal phyla, we will focus our discussions here and in the next two chapters on the 11 groups with the greatest numbers of species. The dotted line represents the uncertainty of including the lophophorates with the deuterostomes.

morphological and embryological data, where characters are scored more subjectively, often based on the qualitative assessment of many traits. Traditional analysis left us with many unanswered questions about relationships between animals; we can now use molecular data to try and make sense of these earlier data. Scientists are combining the two types of information to try to arrive at the interpretation that agrees most closely with the available evidence.

To perform molecular analyses, scientists have often focused on comparing sequences of nucleotides in the gene that encodes RNA of the small ribosomal subunit (SSU rRNA) (see Chapter 26). SSU rRNA is a large molecule that contains a lot of genetic information. Furthermore, the molecule is universal in all organisms, and its base pair sequence has changed very slowly over large periods of time. In addition to the SSU rRNA gene, researchers have also studied *Hox* genes. These genes are important because many branches in the traditional phylogeny are based on early developmental differences, so examination of the genes that regulate these differences should provide insight into the evolution of animal development and to understanding how, when, and why animal body plans diversified.

Phylogenies based on SSU rRNA and *Hox* genes are similar and, in many cases, agree with the structure of the traditional phylogenetic tree. For example, recent analyses of genes have strengthened the view that animals form a single clade. In particular, studies of both small subunit (SSU) rRNA and *Hox* genes provide supportive evidence. We can appreciate this by comparing a portion of the sequence of the SSU rRNA genes

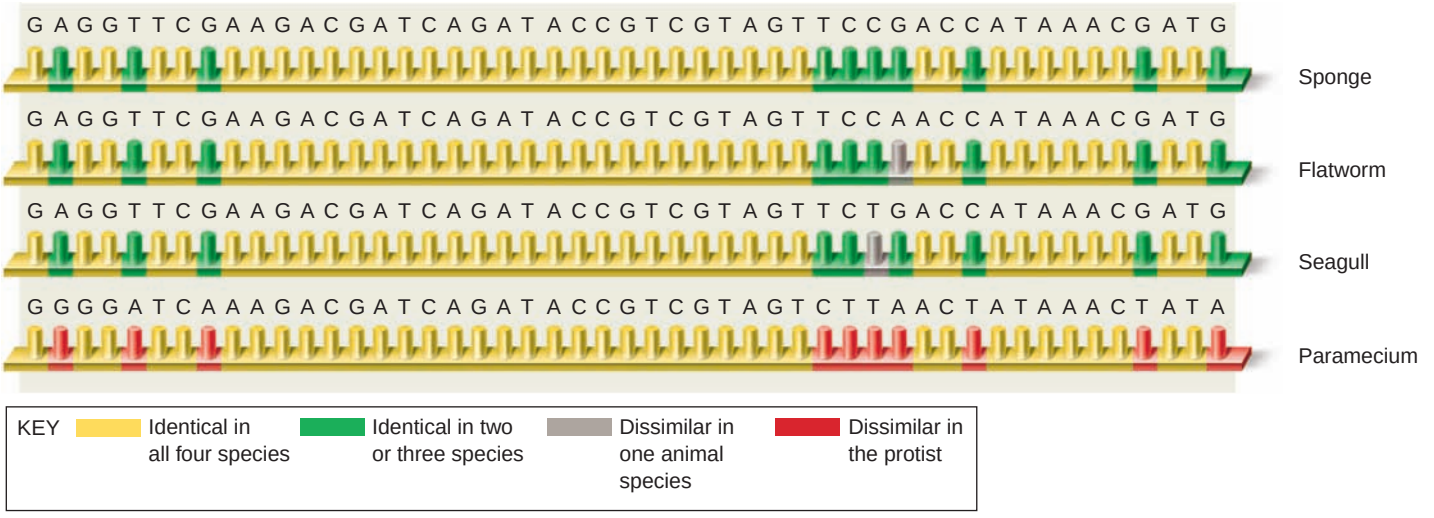

Figure 32.9 Comparison of small subunit (SSU) rRNA gene sequences from three animals and a protist. Note the similarities between the animals, even though they are very different species, and the differences with the protist. This and other comparative studies of gene sequences underscore the likelihood that animals share a common ancestor.

of a sponge, flatworm, and seagull (Figure 32.9), in much the same way as we did in Chapter 12 (refer back to Figure 12.17). The three animal sequences are very similar compared to that of the paramecium (a protist) shown in the figure.

In addition to the clade Metazoa being monophyletic, molecular phylogeny is in agreement with traditional phylogeny on the following features of the animal kingdom.

1. At the earliest stages of evolution, a split occurred between Parazoa and Eumetazoa.
2. There was also an early split between Radiata and Bilateria, with most animal phyla belonging to the Bilateria.
3. Both the echinoderms and the chordates belong to a clade called the Deuterostomia.

However, phylogenies based on molecular data contain some important differences from those based on assessment of body plans. In this section, we examine the similarities and differences between the new molecular phylogeny and the traditional phylogeny. We begin with one of the most influential of the molecular studies, a paper by Anna Marie Aguinaldo and colleagues, which established evidence for a new clade of molting animals, the Ecdysozoa. This study represented a scientific breakthrough because it underscored the value of molecular phylogenies.

Feature Investigation

Aguinaldo and Colleagues Used SSU rRNA to Analyze the Taxonomic Relationships of Arthropods to Other Taxa

In 1997, Anna Marie Aguinaldo, James Lake, and colleagues analyzed the relationships of arthropods to other taxa by sequencing the complete gene that encodes SSU rRNA from a variety of representative taxa (Figure 32.10). Total genomic DNA was isolated using standard techniques and amplified by the polymerase chain reaction (PCR). PCR fragments were then subjected to DNA sequencing, a technique described in Chapter 20. Using approaches that we have described in Chapter 26, the evolutionary relationships among 50 species were determined. The resulting data indicated the existence of a monophyletic clade—the **Ecdysozoa**—containing the nematodes and arthropods.

The hypothesis that nematodes are more closely related to arthropods than previously thought has important ramifications. First, it implies that two well-researched model organisms, *Caenorhabditis elegans* (a nematode) and the fruit fly *Drosophila melanogaster* (an arthropod), are more closely related than had been believed (compare their positions in Figures 32.8 and 32.11). Second, traditional classification assumed that arthropods and annelids were closely related to each other. The new molecular phylogeny suggests otherwise.

Figure 32.10 A molecular animal phylogeny based on sequencing of SSU rRNA.

Concept check: *What are the major differences between molecular and traditional phylogenies?*

GOAL To determine the evolutionary relationships among many animal species.

KEY MATERIALS Cellular samples from about 50 animals in different taxa.

	Experimental level	Conceptual level
1 Isolate DNA from animals and subject the DNA to polymerase chain reaction (PCR) to obtain enough material for DNA sequencing. PCR is described in Chapter 20.	For more detail, refer back to Figure 20.6. 	The goal of PCR is to amplify a region in the SSU rRNA gene.
2 Sequence the amplified DNA by dideoxy sequencing, also described in Chapter 20.	For more detail, refer back to Figure 20.8. 	Dideoxy sequencing, in which DNA strands are separated according to their lengths by subjecting them to gel electrophoresis, is used to determine the base sequence of DNA.
3 Compare the DNA sequences and infer phylogenetic relationships using the cladistic approach described in Chapter 26.		The cladistic approach compares traits that are either shared or not shared by different species.

4 THE DATA

This process resulted in a large group of DNA sequences that were then analyzed with the use of computer programs. This analysis, along with other studies, suggested a revised phylogeny, shown in Figure 32.11.

5 CONCLUSION The molecular phylogeny agrees with the body plan phylogeny in most areas. It resolves the position of the lophophorates and establishes the Lophotrochozoa and Ecdysozoa as sister groups within the Protostomia.

6 SOURCE Aguinaldo, A.M. et al. 1997. Evidence for a clade of nematodes, arthropods, and other moulting animals. *Nature* 387 (6632):489–493.

Experimental Questions

1. What was the purpose of the study conducted by Aguinaldo and colleagues?
2. What was the major finding of this particular study?
3. What impact does the new view of nematode and arthropod phylogeny have on other areas of research?

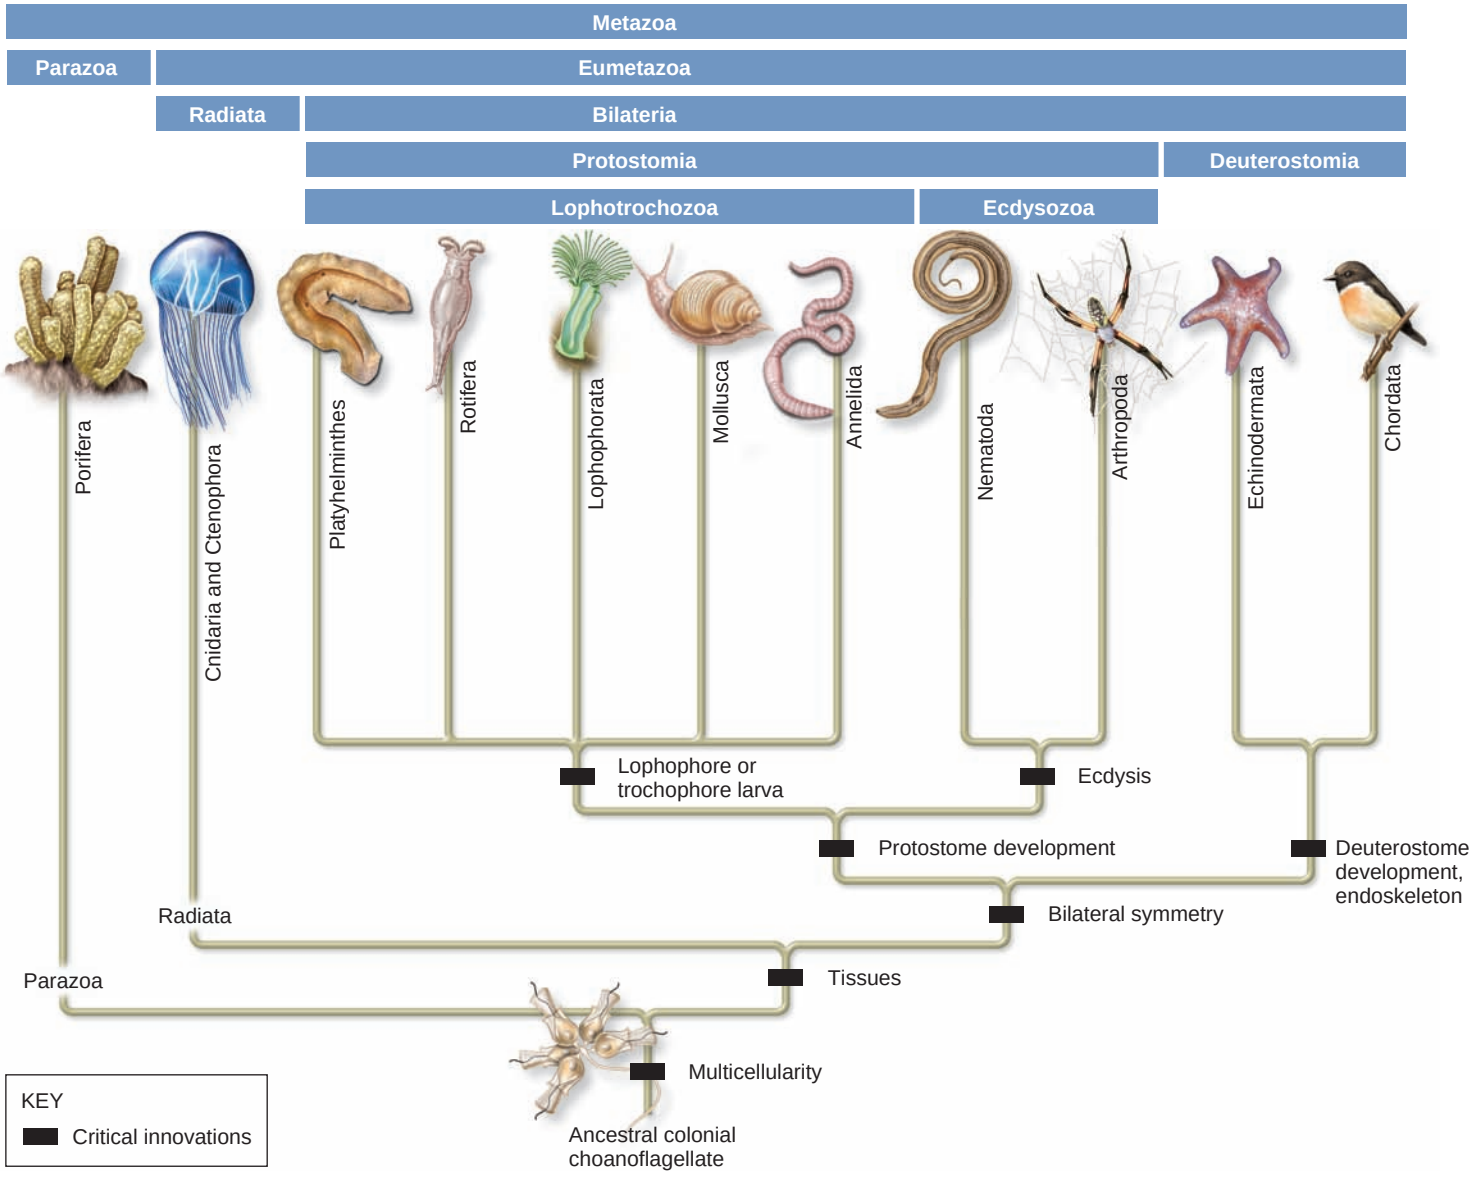

Figure 32.11 **A revised animal phylogeny based on molecular data.** Compared to Figure 32.8, the main differences are the formation of the Lophotrochozoa and Ecdysozoa clades.

Concept check: *What is the sister group to the deuterostomes in this figure? How is this different from the phylogeny based on the body plan?*

Molecular Phylogeny Has Some Important Differences from Traditional Phylogeny

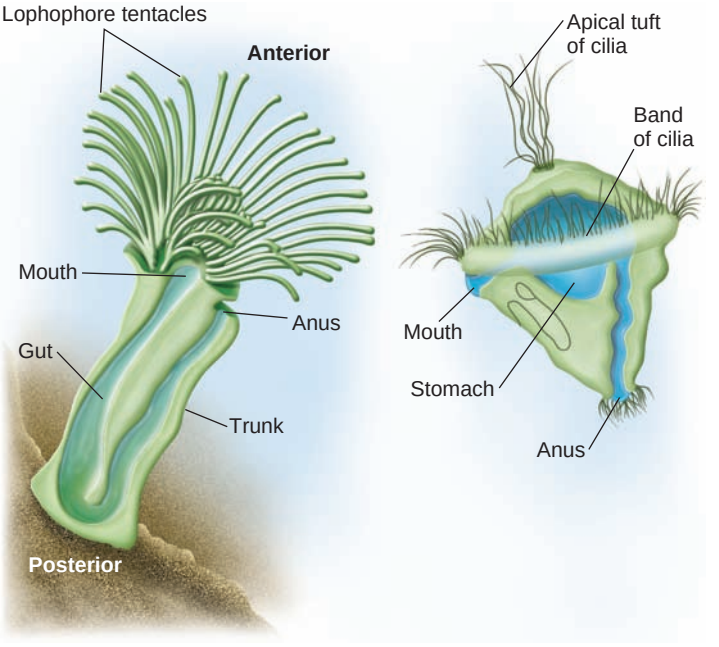
Recent molecular analyses of evolutionary relationships among animals, including the analysis done by Aguinaldo and colleagues, have revealed two additional key differences between traditional models and newer models (Figure 32.11). The two differences concern the division of the protostomes into two separate clades and the division of animals into groups by the presence or absence of a body cavity.

Protostomes: Ecdysozoa and Lophotrochozoa The most important difference between molecular and traditional phylogenies involves relationships among the Bilateria. In the traditional view of animal phylogeny, the bilaterally symmetrical animals are split into two clades, the Protostomia and Deuterostomia, reflecting two basic modes of embryonic development. If you look back at Figure 32.8, you will see that the various protostome taxa were partitioned into different groups. You will also find that the classification of a group called the Lophophorata under the deuterostomes has been uncertain.

However, recent molecular studies, from James Lake and others, suggest a different grouping. The deuterostomes are still separate, but the protostomes are divided into two major clades: the Ecdysozoa, primarily the nematodes and arthropods, and the **Lophotrochozoa**, which encompasses the mollusks, annelids, and several other phyla (Figure 32.11). When some morphologists looked at their data given this new information,

Figure 32.12 **Ecdysis.** The Ecdysozoa are a clade of animals exhibiting ecdysis, the periodic shedding (molting) and re-formation of the exoskeleton.

Concept check: *What are the main members of the Ecdysozoa?*



(a) Lophophore of a phoronid worm **(b) Trochophore larva**

Figure 32.13 **Characteristics of the Lophotrochozoa.** **(a)** A lophophore, a crown of ciliated tentacles, generates a current to bring food particles into the mouth. **(b)** The trochophore (Greek, for wheel-bearer) larval form is found in several animal lineages.

they found there was also morphological support for these new groupings. Let's look at what morphological features make each of these groups unique.

The Ecdysozoa is so named because all of its members secrete a nonliving cuticle, typically an external skeleton (exoskeleton); think of the hard shell of a dragonfly or that of a crab. As these animals grow, the exoskeleton becomes too small, and the animal molts, or breaks out of its old exoskeleton, and secretes a newer, larger one (Figure 32.12). This molting process is called ecdysis; hence the name Ecdysozoa. While this group was named for this morphological characteristic, it is strongly supported as a separate clade by molecular evidence such as similarities in DNA.

Although the Lophotrochozoa clade was organized primarily through analysis of molecular data, its name stems from two morphological features seen in organisms of this clade. The "lopho" part is derived from the **lophophore**, a horseshoe-shaped crown of tentacles used for feeding that is present on some members of the group (Figure 32.13a). The "trocho" part refers to the **trochophore larva**, a distinct larval stage characterized by having a band of cilia around its middle (Figure 32.13b). Trochophore larvae are found in many of the Lophotrochozoa phyla, such as polychaete worms (which are annelids) and mollusks, indicating their similar ancestry.

In traditional phylogeny, much debate surrounded the classification of the Lophophorata, comprised of three minor phyla that possess lophophores—the Bryozoa, Phoronida, and Brachiopoda. Although these taxa exhibited some characteristics of protostomes and some of deuterostomes, as mentioned, they were often classified under Deuterostomia (see Figure 32.8). However, molecular data support their inclusion within the Lophotrochozoa, along with mollusks and annelids (see Figure 32.11).

Body Cavity The second important difference between molecular and traditional phylogenies involves the presence or absence of a body cavity. In the traditional view of animal phylogeny, the bilaterally symmetrical animals are divided into those lacking a coelom (acoelomates), those with a pseudocoelom (pseudocoelomates), and those possessing a coelom (coelomates) (see Figure 32.8). The Platyhelminthes, or flatworms, are classified as acoelomate and are thus seen as separate from coelomate phyla. Molecular evidence, however, now suggests that the flatworms should be included with the Lophotrochozoa. In this view, flatworms are not early-diverging acoelomate animals. Rather, they evolved from an ancestor that possessed a coelom but lost it during evolutionary modification. Similarly, molecular-based phylogeny places the rotifers and nematodes, the pseudocoelomate phyla, within the Lophotrochozoa and Ecdysozoa, respectively. Thus, molecular data suggest that the presence or absence of a coelom or pseudocoelom, a distinction traditionally used in the construction of animal phylogenies, may not be a useful way to classify animals.

While molecular analyses have provided key insights regarding animal evolution, a comparison of the molecular and traditional phylogenies reveals more similarities than differences. Most of the major branch points in the phylogenies are in agreement. As a reference, Table 32.2 summarizes the basic characteristics of the major animal phyla.

In the following two chapters, the discussion of animal phylogeny is based primarily on findings of molecular data.

Table 32.2 Summary of the Basic Characteristics of the Major Animal Phyla

Feature	Porifera (sponges)	Cnidaria and Ctenophora (hydra, anemones, jellyfish)	Platyhelminthes (flatworms)	Rotifera (rotifers)	Lophophorata (bryozoans and others)	Mollusca (snails, clams, squids)	Annelida (segmented worms)	Nematoda (roundworms)	Arthropoda (insects, arachnids, crustaceans)	Echinodermata (sea stars, sea urchins)	Chordata (vertebrates and others)
											
Estimated number of species	8,000	11,000	20,000	2,000	4,000+	110,000	15,000	20,000	1,000,000+	7,000+	52,000+
Level of organization	Cellular; lack tissues and organs	Tissue; lack organs	Organs	Organs	Organs	Organs	Organs	Organs	Organs	Organs	Organs
Symmetry	Absent	Radial	Bilateral	Bilateral	Bilateral	Bilateral	Bilateral	Bilateral	Bilateral	Bilateral larvae, radial adults	Bilateral
Cephalization	Absent	Absent	Present	Present	Reduced	Present	Present	Present	Present	Absent	Present
Germ layers	Absent	Two	Three	Three	Three	Three	Three	Three	Three	Three	Three
Body cavity	Absent	Absent	Absent	Pseudocoelom	Coelom	Reduced coelom	Coelom	Pseudocoelom	Reduced coelom	Coelom	Coelom
Segmentation	Absent	Absent	Absent	Absent	Absent	Absent	Present	Absent	Present	Absent	Present (but reduced)

In Chapter 33, we will discuss the diversity of all the phyla in the Parazoa, Radiata, Lophotrochozoa, Ecdysozoa and Deuterostomia, the latter including the phylum Echinodermata and invertebrate members of the phylum Chordata; these are all the animals without a backbone. In Chapter 34, we will turn our attention to the backboned members of the phylum Chordata, including fishes, amphibians, reptiles, birds, and mammals.

Summary of Key Concepts

32.1 Characteristics of Animals

- Animals constitute a very species-rich kingdom. They share a number of key characteristics, including multicellularity, heterotrophic feeding, the possession of nervous and muscle tissues, and sexual reproduction. (Table 32.1)

32.2 Traditional Classification of Animals

- The animal kingdom is monophyletic, meaning that all taxa have evolved from a single common ancestor.
- The traditional classification of animals is based on five morphological and developmental features of animal body plans.
- Biologists hypothesize that animals evolved from a colonial choanoflagellate. (Figure 32.1)
- Animals can be categorized according to the absence of different types of tissues (the Parazoa or sponges) and the presence of tissues (Eumetazoa or all other animals). The Eumetazoa can also be divided according to their type of symmetry, whether radial (Radiata, the cnidarians and ctenophores) or bilateral (Bilateria, all other animals). (Figure 32.2)
- The Radiata have two embryonic cell layers (germ layers) called the endoderm and the ectoderm. The Bilateria develop a third germ layer termed the mesoderm, which develops between the endoderm and the ectoderm. (Figure 32.3)
- Animals can be classified according to the presence or absence of a coelom, or true body cavity. Animals with a coelom are termed coelomates. Animals that possess a pseudocoelom, or coelom that is not completely lined by tissue derived from mesoderm, are called pseudocoelomates. Those animals lacking a fluid-filled body cavity are termed acoelomates. (Figure 32.4)
- Animals are also classified according to patterns of embryonic development. Animals with spiral cleavage are called protostomes, and those exhibiting radial cleavage are considered deuterostomes. In protostomes, the blastopore, or opening of the gut to the outside, becomes the mouth; in deuterostomes, the blastopore becomes the anus. (Figure 32.5)
- Segmentation, the division of the body into identical subunits called segments, is another key feature of the animal body plan. (Figure 32.6)
- Shifts in the pattern of expression of *Hox* genes are prominent in evolution. In vertebrates, the transition from one type of vertebra to another is controlled by certain *Hox* genes. (Figure 32.7)
- Traditional methods of classification based on body plan produce a particular animal phylogeny. (Figure 32.8)

32.3 Molecular Views of Animal Diversity

- New molecular techniques that compare similarities in DNA and ribosomal RNA of animals support the view that all animals share a common ancestor. (Figure 32.9)

- In many cases, phylogenies based on molecular techniques are similar to those of traditional approaches; however, some important differences exist. Recent molecular studies propose a division of the protostomes into two major clades: the Ecdysozoa and the Lophotrochozoa. (Figures 32.10, 32.11)
- The Ecdysozoa is so named because its members secrete a nonliving cuticle, typically an exoskeleton, or external skeleton. Ecdysis is the periodic shedding and re-formation of the exoskeleton. (Figure 32.12)
- The Lophotrochozoa are grouped primarily through analysis of molecular data, but they are distinguished by two morphological features—the lophophore, a crown of tentacles used for feeding, and the trochophore larva, a distinct larval stage. The lophophorates were often classified as deuterostomes, but molecular data support their inclusion within the Lophotrochozoa. (Figure 32.13)
- Molecular evidence suggests that the acoelomate flatworms evolved from a coelomate ancestor and should therefore be classified under the Lophotrochozoa.
- Each animal phylum shows a distinctive set of general characteristics. (Table 32.2)

Assess and Discuss

Test Yourself

1. Which of the following is not a distinguishing characteristic of animals?
   a. the capacity to move at some point in their life cycle
   b. possession of cell walls
   c. multicellularity
   d. heterotrophy
   e. All of the above are characteristics of animals.
2. Which is the correct hierarchy of divisions in the animal kingdom, from most inclusive to least inclusive?
   a. Eumetazoa, Metazoa, Protostomia, Ecdysozoa
   b. Parazoa, Radiata, Lophotrochozoa, Deuterostomia
   c. Metazoa, Eumetazoa, Bilateria, Protostomia
   d. Radiata, Eumetazoa, Deuterostomia, Ecdysozoa
   e. none of the above
3. Bilateral symmetry is strongly correlated with
   a. the ability to move through the environment.
   b. cephalization.
   c. the ability to detect prey.
   d. a and b.
   e. a, b, and c.
4. In triploblastic animals, the inner lining of the digestive tract is derived from
   a. the ectoderm.
   b. the mesoderm.
   c. the endoderm.
   d. the pseudocoelom.
   e. the coelom.
5. Pseudocoelomates
   a. lack a fluid-filled cavity.
   b. have a fluid-filled cavity that is completely lined with mesoderm.
   c. have a fluid-filled cavity that is partially lined with mesoderm.
   d. have a fluid-filled cavity that is not lined with mesoderm.
   e. have an air-filled cavity that is partially lined with mesoderm.
6. Protostomes and deuterostomes can be classified based on
   a. cleavage pattern.
   b. destiny of the blastopore.
   c. whether the fate of the embryonic cells is fixed early during development.
   d. how the coelom is formed.
   e. all of the above.
7. Indeterminate cleavage is found in
   a. annelids.
   b. mollusks.
   c. nematodes.
   d. vertebrates.
   e. all of the above.
8. Naturally occurring identical twins are possible only in animals that
   a. have spiral cleavage.
   b. have determinate cleavage.
   c. are protostomes.
   d. have indeterminate cleavage.
   e. a, b, and c
9. Genes involved in the patterning of the body axis, that is, in determining characteristics such as neck length and appendage formation, are called
   a. small subunit (SSU) rRNA genes.
   b. *Hox* genes.
   c. metameric genes.
   d. determinate genes.
   e. none of the above.
10. A major difference between the molecular phylogeny of animals and traditional phylogeny of animals is that
    a. the presence or absence of the mesoderm is not important in molecular phylogeny.
    b. molecular phylogeny suggests that all animals do not share a single common ancestor.
    c. body symmetry, whether radial or bilateral, is not an important determinant in molecular phylogeny.
    d. molecular phylogeny does not include the echinoderms in the deuterostome clade.
    e. molecular phylogeny suggests that the presence or absence of a coelom is not important for classification.

Conceptual Questions

1. The traditional classification is based on what four features of animal body plans?
2. Distinguish between radial and bilateral symmetry.
3. Why might sea urchins be valuable in developmental studies?

Collaborative Questions

1. Discuss the many ways that animals can impact humans, both positively and negatively.
2. Discuss the similarities and differences between the molecular and morphological phylogenies.

The Invertebrates

33

What is this organism, and how does it feed?

If you thought the organism shown in the opening photograph was an underwater plant, complete with long leaflike structures and roots, you'd be wrong. This organism is a type of echinoderm, called a feather star, and is related to sea stars. Its long arms catch food particles floating in the ocean current, and tiny tube feet pass these particles into special food gutters that run along the center of each arm and empty into the mouth. The number of arms varies between species and may reach 200. Feather stars can creep along the ocean floor by means of rootlike projections called cirri. While there are about 550 species of feather stars in existence today, some fossil formations are packed with feather star fragments, showing how successful the group was in the past.

The history of animal life on Earth has evolved over hundreds of millions of years. Some scientists suggest that changing environmental conditions, such as a buildup of dissolved oxygen and minerals in the ocean or an increase in atmospheric oxygen, eventually permitted higher metabolic rates and increased the activity of a wide range of animals. Others suggest that with the development of sophisticated locomotor skills, a wide range of predators and prey evolved, leading to an evolutionary arms race in which predators evolved powerful weapons and prey evolved more powerful defenses against them. Such adaptations and counteradaptations would have led to a proliferation of different lifestyles and taxa.

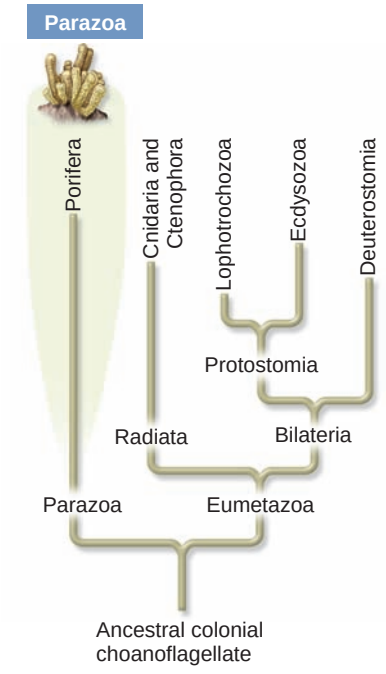
Chapter Outline

Over the next two chapters, we will survey the wondrous array of animal life on Earth (see chapter-opening photo). In this chapter, we examine the **invertebrates**, or animals without a backbone, a category that makes up more than 95% of all animal species. We begin by exploring some of the earliest animal lineages, the Parazoa and Radiata. We then turn to the Lophotrochozoa and Ecdysozoa, the two sister groups of protostomes introduced in Chapter 32. Finally, we will examine the deuterostomes, focusing here on the echinoderms and the invertebrate members of the phylum Chordata.

Figure 33.1 gives a summary of our current understanding of the relationships between these groups. Although the more modern molecular classification outlined in Chapter 32 serves as the basis for this phylogeny and for our discussion of animal lineages, we will not ignore the concept of body plans, because it still can provide clues about how different phyla have evolved. The newer molecular phylogeny is still in its infancy, and many refinements will undoubtedly be made as increasing numbers of genes from more species are sequenced and compared. For this reason, many biologists are not yet ready to totally set aside the older body-plan-based phylogeny.

Figure 33.1 An animal phylogeny. This phylogenetic tree summarizes our current understanding about the relationships between animal groups.

33.1 Parazoa: Sponges, the First Multicellular Animals



The Parazoa consist of one phylum, Porifera (from the Latin, meaning pore bearers), whose members are commonly referred to as sponges. Sponges are loosely organized and lack true tissues, groups of cells that have a similar structure and function. However, sponges are multicellular and possess several types of cells that perform different functions. Biologists have identified approximately 8,000 species of sponges, the vast majority of which are marine. Sponges range in size from only a few millimeters across to more than 2 m in diameter. The smaller sponges may be radially symmetrical, but most have no apparent symmetry. Some sponges have a low encrusting growth form, whereas others grow tall and erect (Figure 33.2a). Although adult sponges are sessile, that is, anchored in place, the larvae are free-swimming.

The body of a sponge looks similar to a vase pierced with small holes or pores (Figure 33.2b). Water is drawn through these pores, or ostia (singular, ostium), into a central cavity, the **spongocoel**, and flows out through the large opening at the top called the osculum. The water enters the pores by the beating action of the flagella of the **choanocytes**, or collar cells, that line the spongocoel (Figure 33.2c). In the process, the choanocytes trap and eat small particulate matter and tiny plankton. As we noted in Chapter 32, because of striking morphological and molecular similarities between choanocytes and choanoflagellates, a group of modern protists having a single flagellum, scientists think that sponges originated from a common choanoflagellate ancestor.

A layer of flattened epithelial cells similar to those making up the outer layer of other phyla protects the sponge body. In between the choanocytes and the epithelial cells lies a gelatinous, protein-rich matrix called the **mesohyl**. Within this matrix are mobile cells called **amoebocytes** that absorb food from choanocytes, digest it, and carry the nutrients to other cells. Thus, considerable cell-to-cell contact and communication exists in sponges. Sponges are unique among the major animal phyla in using the phagocytic mode of feeding, in common with some protists.

Some amoebocytes can also form tough skeletal fibers that support the body. In many sponges, this skeleton consists of sharp **spicules** formed of calcium carbonate or silica. For example, some deep-ocean species, called glass sponges, are distinguished by needle-like silica spicules that form elaborate lattice-like skeletons. The presence of such tough spicules may help explain why there is not much predation of sponges. Sponge spicules come in a diverse array of shapes and sizes, and they are valuable taxonomic tools by which to distinguish different types of sponges. In a small family of carnivorous sponges, the spicules are sticky and capture small crustaceans. In these sponges, other cells migrate around the immobilized crustaceans and digest them extracellularly. Not all sponges

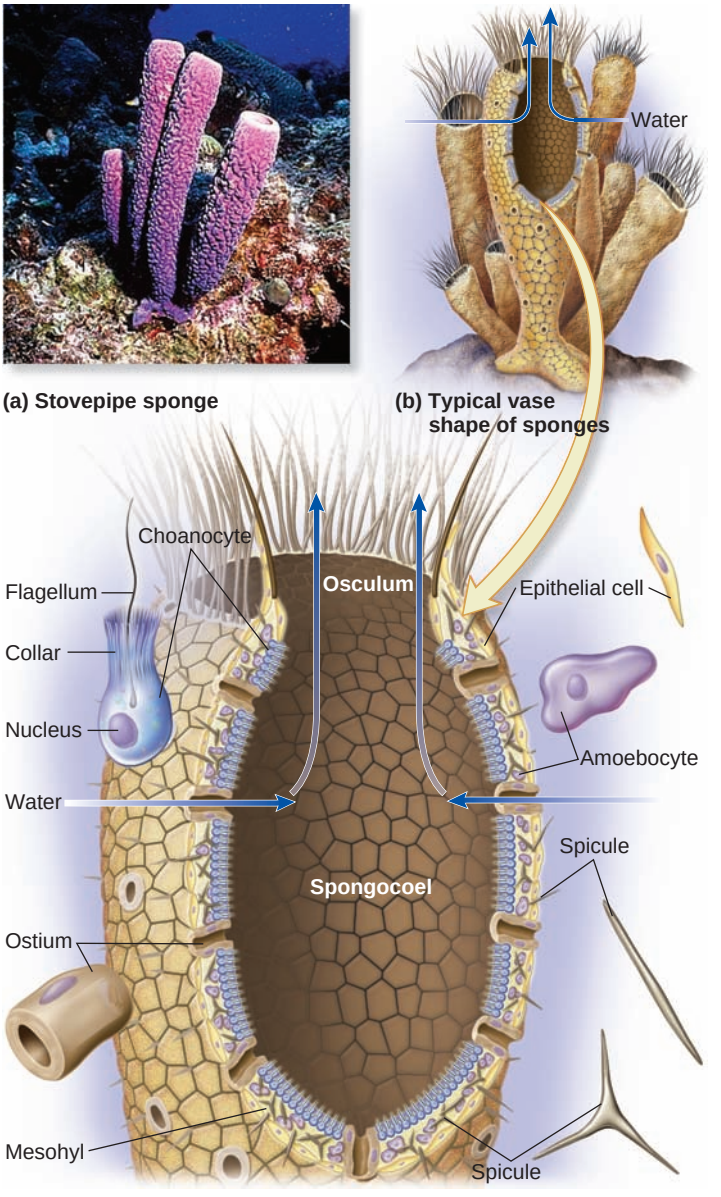


Figure 33.2 **Sponge morphology.** **(a)** The stovepipe sponge (*Aplysina archeri*) is a common sponge found on Caribbean reefs. **(b)** Many sponges have a vaselike shape. **(c)** A cross section reveals that sponges are truly multicellular animals, having various cell types but no distinct tissues.

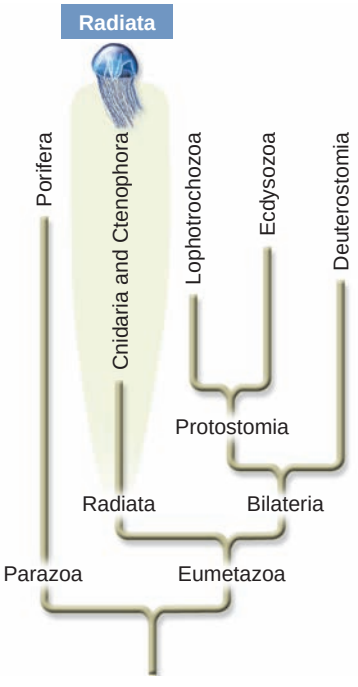
Concept check: *If sponges are soft and sessile, why aren't they eaten by other organisms?*

have spicules, however. Others have fibers of a tough protein called **spongin** that lend skeletal support. Spongin skeletons are still commercially harvested and sold as bath sponges. Many species produce toxic defensive chemicals, some of which are thought to have possible antibiotic and anti-inflammatory effects in humans.

Around the turn of the 20th century, biologist Henry V. Wilson made the incredible discovery that if a sponge is dissociated into its individual cells after being passed through a sieve, its cells can reaggregate into a functional sponge within a short time. Wilson concluded that in order to do this, individual cells recognized and reaggregated with other cells of their own kind. Researchers have since discovered that the cells of other multicellular organisms also recognize cells of their own kind and tend to adhere to each other when mixed with other types of cells. For example, in mammals, liver cells recognize and stick better to other liver cells, and brain cells recognize and adhere to brain cells.

Sponges reproduce through both sexual and asexual means. Most sponges are **hermaphrodites** (from the Greek, for the Greek god Hermes and the goddess Aphrodite), individuals that can produce both sperm and eggs. Gametes are derived from amoebocytes or choanocytes. The eggs remain in the mesohyl, and the sperm are released into the water and carried by water currents to fertilize the eggs of neighboring sponges. Zygotes develop into flagellated swimming larvae that eventually settle on a suitable substrate to become sessile adults. In asexual reproduction, a small fragment or bud may detach and form a new sponge.

33.2 Radiata: Jellyfish and Other Radially Symmetrical Animals



The Radiata consists of two closely related phyla: the Cnidaria (from the Greek *knide*, meaning nettle, and *aria*, meaning related to; pronounced nid-air'-e-ah) and the Ctenophora (from the Greek *ktenos*, meaning comb, and *phora*, meaning bearing; pronounced teen-o-for'-ah). Members of the Radiata phyla, or radiates, are mostly found in marine environments, although a few are freshwater species, such as Hydra. The Cnidaria includes hydra, jellyfish, box jellies, sea anemones, and corals, and the Ctenophora consists of the comb jellies. The diploblastic Radiata have only two embryonic germ layers: the ectoderm and the endoderm, which give rise to the epidermis and the gastrodermis, respectively. A gelatinous substance called the **mesoglea** connects the two layers. In jellyfish, the mesoglea is enlarged and forms the buoyant, transparent jelly, whereas in coral, the mesoglea is very thin. The Radiata is the first clade with true tissues.

Both cnidarians and ctenophores possess a **gastrovascular cavity**, where extracellular digestion takes place. This feature allows the ingestion of larger food particles and represents a major advance over the sponges, which use only intracellular digestion. Most radiates have tentacles around the mouth that aid in food detection and capture. Radiates also have true nerve cells arranged as a **nerve net** consisting of interconnected neurons with no central control organ. In nerve nets, nerve impulses pass in either direction along a given neuron. In this section, we will provide an overview of the biology and diversity of the cnidarians and ctenophores.

The Cnidarians Have Specialized Stinging Cells

Most cnidarians exist as two different body forms and associated lifestyles: the sessile **polyp** or the motile **medusa** (Figure 33.3). For example, jellyfish exist predominantly in the medusa form, and corals exhibit only the polyp form. Many cnidarians, such as *Obelia*, have a life cycle that prominently features both polyp and medusa stages (Figure 33.4).

The polyp form has a tubular body with an opening at the oral (top) end that is surrounded by tentacles and functions as both mouth and anus (see Figure 33.3a). The aboral (bottom) end is attached to the substrate. In the 18th century, the Swiss naturalist Abraham Trembley discovered that when a freshwater hydra was cut in two, each part not only survived but could also regenerate the missing half. Polyps exist colonially, as they do in corals, or alone, as in sea anemones.

Corals take dissolved calcium and carbonate ions from seawater and precipitate them as limestone underneath their bodies. In some species, this leads to a buildup of limestone deposits. As each successive generation of polyps dies, the limestone remains in place, and new polyps grow on top. Thus, huge underwater limestone deposits called coral reefs are formed (look ahead to Figure 54.27b). The largest of these is Australia's Great Barrier Reef, which stretches over 2,300 km. Many other extensive coral reefs are known, including the reef system along the Florida Keys, all of which occur in warm water, generally between 20°C and 30°C.

The free-swimming medusa form has an umbrella-shaped body with an opening that serves as both mouth and anus on the concave underside that is surrounded by tentacles (see Figure 33.3b). More mobile medusae possess simple sense organs near the bell margin, including organs of equilibrium called **statocysts** and photosensitive organs known as **ocelli**. When one side of the bell tips upward, the statocysts on that side are stimulated, and muscle contraction is initiated to right the medusa. The ocelli allow medusae to position themselves in particular light levels.

One of the unique and characteristic features of the cnidarians is the existence of stinging cells called **cnidocytes**, which

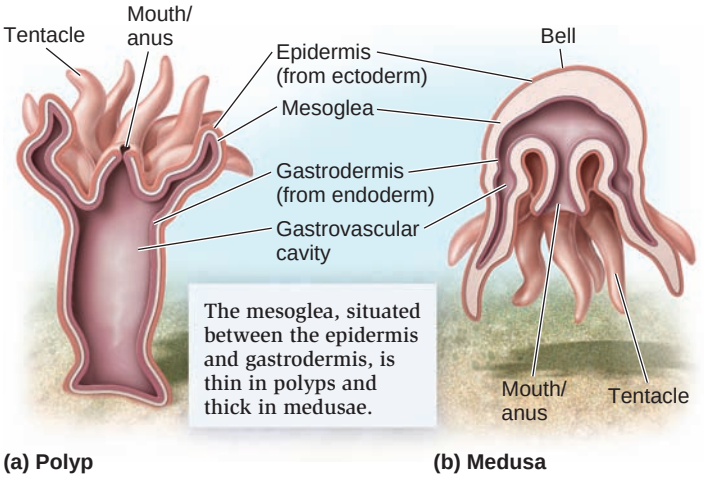


Figure 33.3 **Polyp and medusa forms of cnidarians.** Both **(a)** polyp and **(b)** medusa forms have two layers of cells, an outer epidermis (from ectoderm) and an inner layer of gastrodermis (from endoderm). In between is a layer of mesoglea, which is thin in polyps, such as corals, and thick in medusae, such as most jellyfish.

function in defense or the capture of prey (Figure 33.5a). Cnidocytes contain **nematocysts**, powerful capsules with an inverted coiled and barbed thread. Each cnidocyte has a hairlike trigger called a **cnidocil** on its surface. When the cnidocil is touched or a chemical stimulus is detected, the nematocyst is discharged, and its filament penetrates the prey and injects a small amount of toxin. Small prey are immobilized and passed into the mouth by the tentacles. Alternatively, some nematocyst filaments can be sticky rather than stinging. After discharge, the cnidocyte is absorbed, and a new one grows to replace it. The nematocysts of most cnidarians are not harmful to humans, but those on the tentacles of the larger jellyfish and the Portuguese man-of-war (Figure 33.5b) can be extremely painful and even fatal. Tentacles of the largest jellyfish, *Cyanea arctica*, may be over 40 m long.

Muscles and nerves exist in their simplest forms in cnidarians. Contractile muscle fibers are found in both the epidermis and gastrodermis. Although not true muscles, which only arise from the mesoderm and therefore do not appear in diploblastic animals, these muscle fibers can contract to change the shape of the animal. For example, in the presence of a predator, an anemone can expel water very quickly through its open mouth and shrink down to a very small body form. The muscle fibers work against the fluid contained in the body, which thus acts as a hydrostatic skeleton. The nerve net that conducts signals from sensory nerves to muscle cells allows coordination of simple movements and shape changes.

The phylum Cnidaria consists of four classes—Hydrozoa (small jellyfish, *Obelia* and the Portuguese man-of-war), Scyphozoa (large jellyfish), Anthozoa (sea anemones and corals), and Cubozoa (box jellies). The distinguishing characteristics of these classes are shown in Table 33.1.

The Ctenophores Have a Complete Gut

Ctenophores, also known as comb jellies, are a small phylum of fewer than 100 species, all of which are marine and look very much like jellyfish (Figure 33.6). They have eight rows of cilia on their surface that resemble combs. The coordinated beating of the cilia, rather than muscular contractions, propels the ctenophores. Averaging about 1–10 cm in length, comb jellies are probably the largest animals to use cilia for locomotion. There are even a few ribbon-like species up to 1 m long.

Comb jellies possess two long tentacles but lack stinging cells. Instead, they have colloblasts, cells on the tentacles that

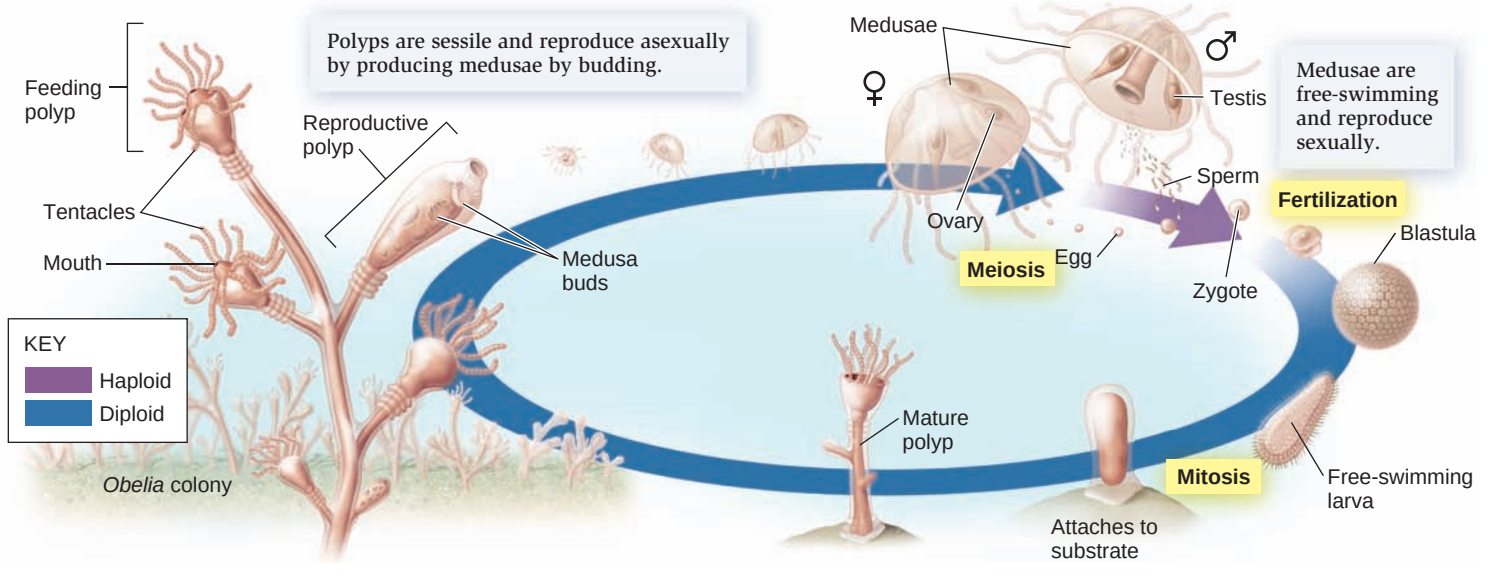

Figure 33.4 **Life cycle of *Obelia*, a colonial cnidarian.** This species exhibits both polyp and medusa stages.

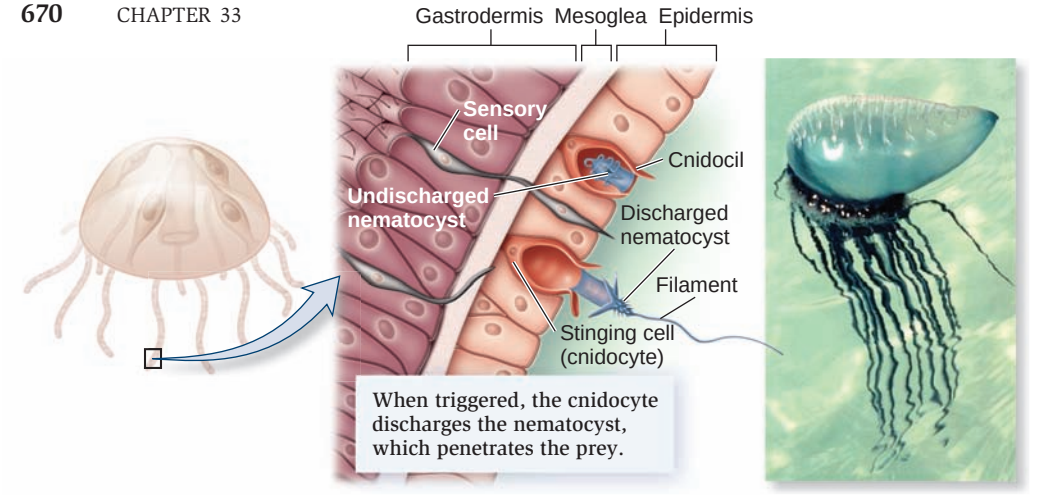
Concept check: *What are the dominant life stages of the following types of cnidarians: jellyfish, sea anemone, and Portuguese man-of-war?*



(a) Cnidocytes

(b) Portugese man-of-war

Figure 33.5 **Specialized stinging cells of cnidarians, called cnidocytes.** **(a)** Cnidocytes, which contain stinging capsules called nematocysts, are situated in the tentacles. **(b)** The Portuguese man-of-war (*Physalia physalis*) employs cnidocytes that can be lethal to humans.

Table 33.1 Main Classes and Characteristics of the Cnidaria

	Class and examples (est. # of species)	Class characteristics
	Hydrozoa: *Obelia*, Portuguese man-of-war, *Hydra*, some corals (2,700)	Mostly marine; most have both polyp and medusa stages, with polyp stage often colonial
	Scyphozoa: jellyfish (200)	All marine; medusa stage dominant and large (up to 2 m); reduced polyp stage
	Anthozoa: sea anemones, sea fans, most corals (6,000)	All marine; polyp stage dominant; medusa stage absent; many are colonial
	Cubozoa: box jellies, sea wasps (20)	All marine; medusa stage dominant; box-shaped

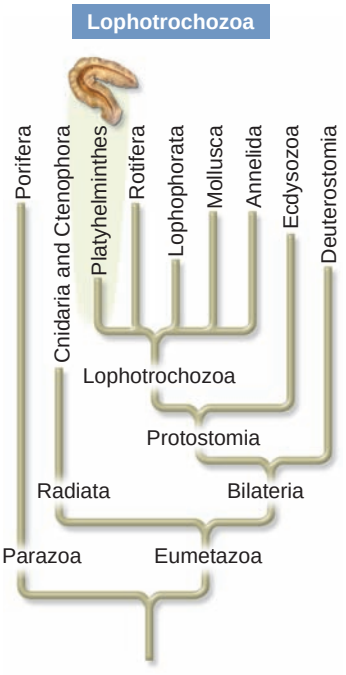
Figure 33.6 **A ctenophore.** Ctenophores are called comb jellies because of the eight rows of cilia on their surfaces that resemble combs.

secrete a sticky substance onto which small prey adhere. The tentacles are then drawn over the mouth. As with cnidarians, digestion occurs in the gastrovascular cavity, but waste and water are eliminated through two anal pores. Thus, the comb jellies possess the first complete gut. Prey are generally small and may include tiny crustaceans called copepods and small fishes. Comb jellies are often transported around the world in ships' ballast water. *Mnemiopsis leidyi*, a ctenophore species native to the Atlantic coast of North and South America, was accidentally introduced into the Black and Caspian seas in the 1980s. With a plentiful food supply and a lack of predators, *Mnemiopsis* underwent a population explosion and ultimately devastated the local fishing industries.

All ctenophores are hermaphroditic, possessing both ovaries and testes, and gametes are shed into the water to eventually form a free-swimming larva that grows into an adult. There is no polyp stage. Nearly all ctenophores exhibit **bioluminescence**, a phenomenon that results from chemical reactions that give off light rather than heat. Individuals can be particularly evident at night, and ctenophores that wash up onshore can make the sand or mud appear luminescent.

33.3 Lophotrochozoa: The Flatworms, Rotifers, Lophophorates, Mollusks, and Annelids

In the traditional view of animal phylogeny (refer back to Figure 32.8), the bilaterally symmetrical animals are split into those with no coelom (the platyhelminthes), those with a pseudocoelom (the nematodes and rotifers), and those with a coelom (the remaining phyla). However, as we explored in Chapter 32, molecular data suggest a different grouping in which



the deuterostomes are separate, and the protostomes are divided into two major lineages: the Lophotrochozoa and the Ecdysozoa (refer back to Figure 32.11). The Lophotrochozoa are a diverse group that includes taxa that possess either a lophophore (a crown of ciliated tentacles) or a distinct larval stage called a trochophore. In this grouping are seven major Lophotrochozoan phyla: the Platyhelminthes (flatworms), Rotifera (rotifers), Lophophorata (the lophophorates, a group of three phyla), Mollusca (mollusks), and Annelida (segmented worms). In this section, we explore the distinguishing characteristics of these phyla, beginning with some of the simplest lophotrochozoans, the Platyhelminthes.

The Phylum Platyhelminthes Consists of Flatworms with No Coelom

Platyhelminthes (from the Greek *platy*, meaning flat, and *helminth*, meaning worm), or flatworms, lack a specialized respiratory or circulatory system to transport gases. They must obtain oxygen by diffusion, which makes a flattened shape necessary in that no cell can be too far from the surface. Flatworms were among the first animals to develop an active predatory lifestyle. Platyhelminthes, and indeed most animals, are bilaterally symmetrical, with a head bearing sensory appendages (Figure 33.7).

The flatworms are also believed to be the first animals to develop three embryonic germ layers—ectoderm, endoderm, and mesoderm—with mesoderm replacing the simpler gelatinous mesoglea of cnidarians. As such, they are said to be triploblastic. The muscles in flatworms, which are derived from mesoderm, are well developed. The development of mesoderm was therefore a critical evolutionary innovation in animals, because it also led to the development of more sophisticated organs. Flatworms are sometimes regarded as the first animals to reach the organ-system level of organization. Because mesoderm fills the body spaces around the gastrovascular cavity, the flatworms are acoelomate—they lack a fluid-filled body cavity in which the gut is suspended.

The digestive system of flatworms is incomplete, with only one opening, which serves as both mouth and anus, as in cnidarians. Most flatworms possess a muscular pharynx that may be extended through the mouth. The pharynx opens to a gastrovascular cavity, where food is digested. In large flatworms, the gastrovascular cavity is branched enough to distribute nutrients to all parts of the body. Any undigested material is egested back out through the pharynx. The incomplete digestive system

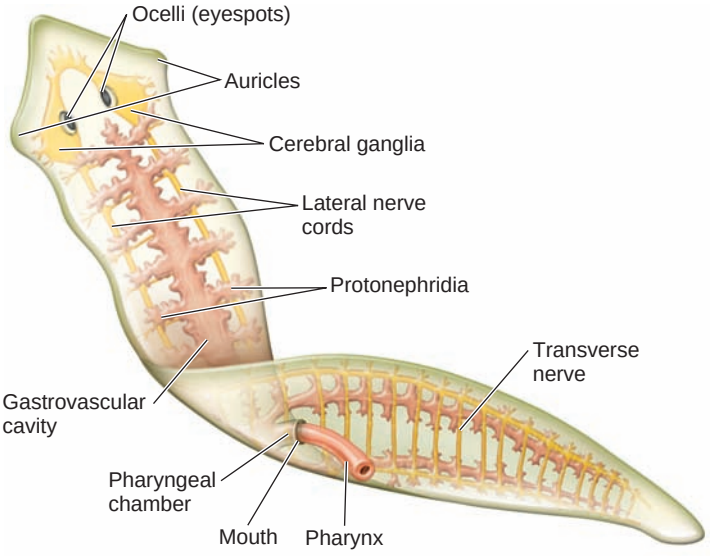


Figure 33.7 **Body plan of a flatworm.** Flatworm morphology as represented by a planarian, a member of the class Turbellaria.

Concept check: *How do flatworms breathe?*

of flatworms prevents continuous feeding. Some flatworms are predators, but many species invade other animals as parasites.

Flatworms have a distinct excretory system, consisting of **protonephridia**, two lateral canals with branches capped by **flame cells**. Protonephridia are dead-end tubules lacking internal openings. The flame cells, which are ciliated and waft water through the lateral canals to the outside (look ahead to Figure 49.7), primarily function in maintaining osmotic balance between the flatworm's body and the surrounding fluids. Simple though this system is, its development was key to permitting the movement of animals into freshwater habitats and even moist terrestrial areas.

At the anterior end of some free-living flatworms are light-sensitive eyespots, or ocelli, as well as chemoreceptive and sensory cells that are concentrated in organs called auricles. A pair of **cerebral ganglia** receives input from photoreceptors in eyespots and sensory cells. From the ganglia, a pair of lateral nerve cords running the length of the body allows rapid movement of information from anterior to posterior. In addition, transverse nerves form a nerve net on the ventral surface similar to that of cnidarians. Thus, flatworms retain the cnidarian-style nervous system, while possessing the beginnings of the more centralized type of nervous system (with one-way fast conduction nerves) seen throughout much of the rest of the animal kingdom.

In all the Platyhelminthes, reproduction is either sexual or asexual. Most species are hermaphroditic but do not fertilize their own eggs. Flatworms can also reproduce asexually by splitting into two parts, with each half regenerating the missing fragment.

The four classes of flatworms are the Turbellaria, Monogenea, Trematoda (flukes), and Cestoda (tapeworms) (Table 33.2). Turbellarians are the only free-living class of flatworms and are widespread in lakes, ponds, and marine environments. Monogeneans are relatively simple external parasites of fish

Table 33.2 Main Classes and Characteristics of Platyhelminthes

	Class and examples (est. # of species)	Class characteristics
	Turbellaria: planarian (3,000)	Mostly marine; free-living flatworms; predatory or scavengers
	Monogenea: fish flukes (1,000)	Marine and freshwater; usually external parasites of fish; simple life cycle (no intermediate host)
	Trematoda: flukes (11,000)	Internal parasites of vertebrates; complex life cycle with several intermediate hosts
	Cestoda: tapeworms (5,000)	Internal parasites of vertebrates; complex life cycle, usually with one intermediate host; no digestive system; nutrients absorbed across epidermis

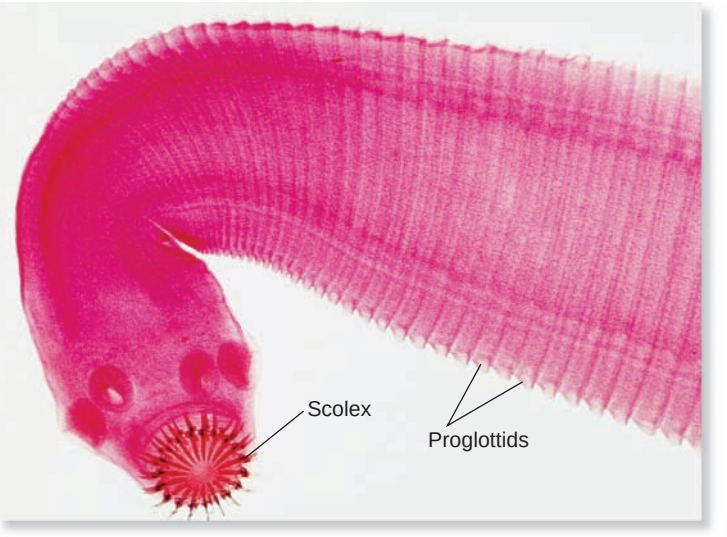

Figure 33.8 **A tapeworm, *Taenia pisiformis*, a member of the class Cestoda.** Note the tiny hooks and suckers that make up the scolex. Each segment is a proglottid, replete with eggs.

with just one species of host. Both trematodes and cestodes are internally parasitic and therefore are of great medical and veterinary importance. They possess a variety of organs of attachment, such as hooks and suckers, that enable them to remain embedded within their hosts. For example, cestodes attach to their host by means of an organ at the head end called a scolex (Figure 33.8). They have no mouth or gastrovascular cavity and absorb nutrients across the body surface. Behind the scolex is a long ribbon of similar segments called proglottids. These are essentially segments of sex organs that develop thousands of eggs. The proglottids are continually shed in the host's feces. Cestodes often require two separate vertebrate host species, such as pigs or cattle, to begin their life cycle and humans to complete their development. Many tapeworms can live inside humans who consume undercooked, infected meat—hence the value of thoroughly cooking meat.

The life history of trematodes is even more complex than that of cestodes, involving multiple hosts. The first host, called the intermediate host, is usually a mollusk, and the final host, or definitive host, is usually a vertebrate, but often a second or even a third intermediate host is involved. In the case of the Chinese liver fluke (*Clonorchis sinensis*) (Figure 33.9), (1) the adult parasite lives and reproduces in the definitive host, a human. (2) The resultant embryos are called miracidia. They are encapsulated to form eggs and pass from the host via the feces. (3) An intermediate host, such as a snail, eats the eggs. The miracidia are released and transform into sporocysts. (4) The sporocysts asexually produce more sporocysts, which are called rediae. (5) The rediae reproduce asexually to produce cercariae. Cercariae bore their way out of the snail and (6) infect their second intermediate host, fishes, by entering via the gills. (At this stage, some trematodes infect their definitive hosts directly by boring into their feet when in water.) Here, the cercariae develop into metacercarial cysts (juvenile flukes) and lodge in fish muscle, which the definitive host will eat, allowing the cycle to continue. In the definitive host, the cyst protects the metacercaria from the host's gastric juices. From the small intestine, the metacercariae travel to the liver and grow into adult flukes, and the life cycle begins anew. The life cycle of a trematode can involve at least seven stages: adult, egg (encapsulated miracidium), miracidium, sporocyst, rediae, cercaria, and metacercaria. Because of the low probability of each larva reaching a suitable host, trematodes must produce large numbers of offspring to ensure that some survive.

Blood flukes, genus *Schistosoma*, are the most common parasitic trematodes infecting humans; they cause the disease known as schistosomiasis. Over 200 million people worldwide, primarily in tropical Asia, Africa, and South America, are infected with schistosomiasis, also called Bilharzia. The inch-long adult flukes can live for years in human hosts, and the release of eggs may cause chronic inflammation and blockage in many organs. Untreated schistosomiasis can lead to severe damage to the liver, intestines, and lungs and can eventually lead to death. Sewage treatment and access to clean water can greatly reduce infection rates.

Members of the Phylum Rotifera Have a Pseudocoelom and a Ciliated Crown

Members of the phylum Rotifera (from the Latin *rota*, meaning wheel, and *fera*, meaning to bear) get their name from their ciliated crown, or **corona**, which, when beating, looks similar to a rotating wheel (Figure 33.10). Most rotifers are microscopic animals, usually less than 1 mm long, and some have beautiful colors. There are about 2,000 species of rotifers, most of which inhabit fresh water, with a few marine and terrestrial species. Most often they are bottom-dwelling organisms, living on the pond floor or along lakeside vegetation.

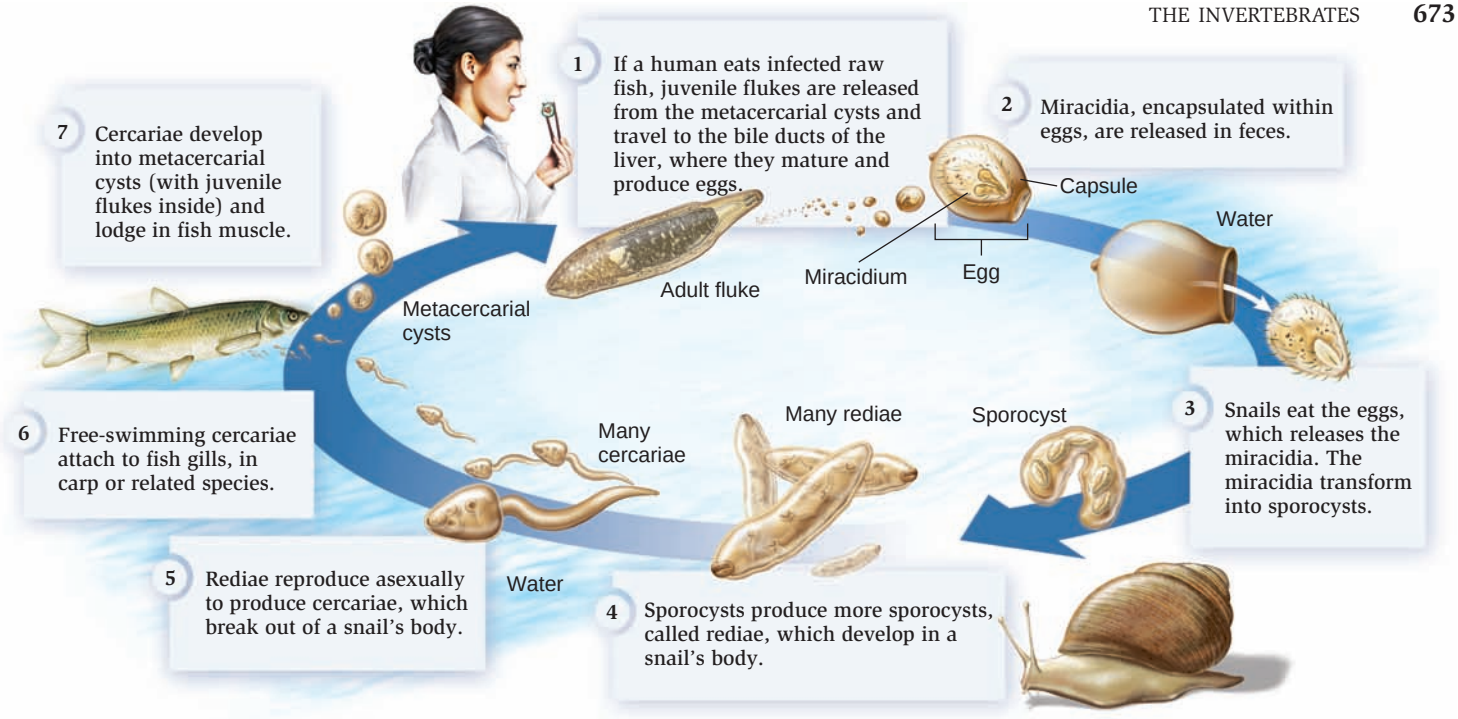

Figure 33.9 **The complete life cycle of a trematode.** As an example, this figure shows the life cycle of the Chinese liver fluke (*Clonorchis sinensis*).

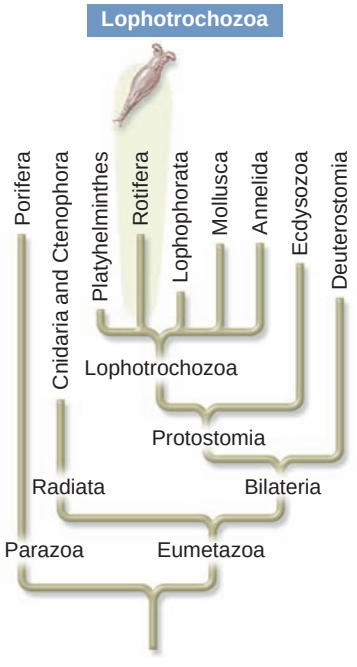

Rotifers have an alimentary canal, a digestive tract with a separate mouth and anus, which means they can feed continuously. The corona creates water currents that propel the animal through the water and that waft small planktonic organisms or decomposing organic material toward the mouth. The mouth opens into a circular, muscular pharynx called a **mastax**, which has jaws for grasping and chewing. The mastax, which in some species can protrude through the mouth to seize small prey, is a structure unique to rotifers. The body of the rotifer bears a jointed foot with one to four toes. **Pedal glands** in the foot secrete a sticky substance that aids in attachment to the substrate. The internal organs lie within a pseudocoelom, a fluid-filled body cavity that is not completely lined with mesoderm. The pseudocoelom serves as a hydrostatic skeleton and as a medium for the internal transport of nutrients and wastes. Rotifers also have a pair of protonephridia with flame bulbs that collect excretory and digestive waste and drain into a cloacal bladder, which passes waste to the anus. The nervous system consists of nerves that extend from the sensory organs, especially the eyespots and some bristles on the corona, to the brain.

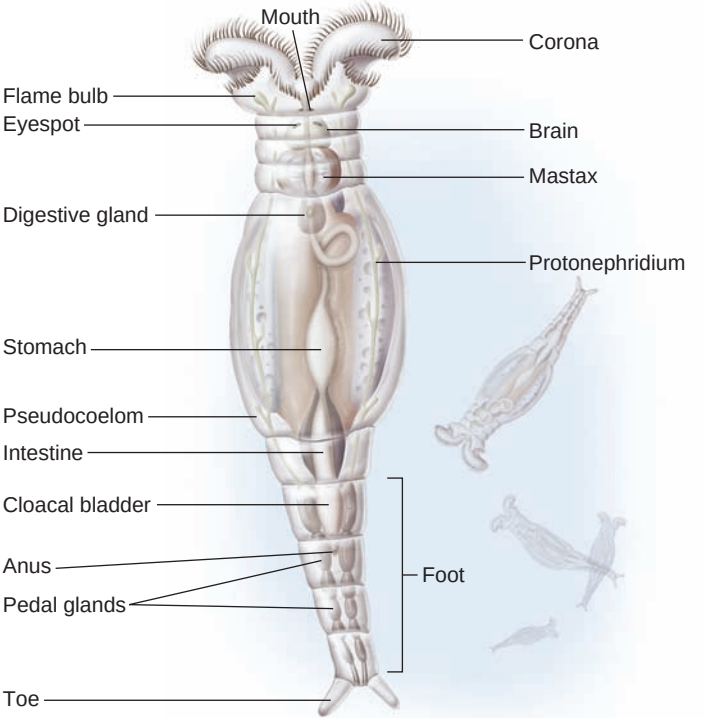

Figure 33.10 **Body plan of a common rotifer, *Philodina* genus.**

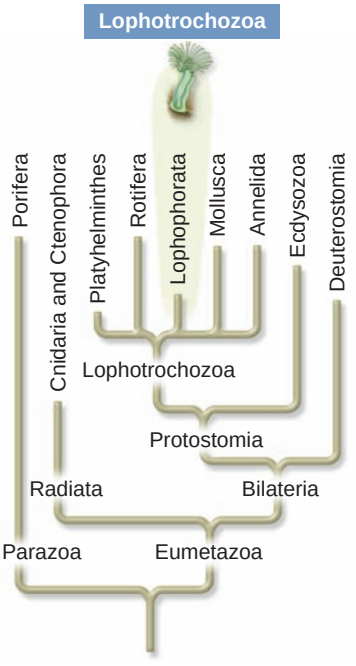
Reproduction in rotifers is unique. In some species, unfertilized diploid eggs that have not undergone meiotic division develop into females through a process known as **parthenogenesis**. In other species, some unfertilized eggs develop into females, whereas others develop into degenerate males that cannot feed and live only long enough to produce and release sperm that fertilize the females. The resultant fertilized eggs

form zygotes, which have a thick shell and can survive for long periods of harsh conditions, such as if a water supply dries up, before developing into new females. Because the tiny zygotes are easily transported, rotifers show up in the smallest of aquatic environments, such as roof gutters or birdbaths.

The Lophophorata Includes Three Closely Related Phyla: Phoronida, Bryozoa, and Brachiopoda



The lophophorates consist of three distinct phyla: the Phoronida, the Bryozoa, and the Brachiopoda. They all possess a lophophore, a ciliary feeding device (refer back to Figure 32.13a), and a true coelom (refer back to Figure 32.4a). The lophophore is a circular fold of the body wall bearing tentacles that draw water toward the mouth. Because a thin extension of the coelom penetrates each tentacle, the tentacles also serve as a respiratory device. Gases diffuse across the tentacles and into or out of the coelomic fluid and are carried throughout the body. All three phyla have a U-shaped alimentary canal, with the anus located near the mouth but outside of the lophophore.

Phylum Phoronida Members of the Phoronida (from the Greek *phoros*, meaning bearer, and the Latin *nidus*, meaning nest) are elongated, tube-dwelling marine worms ranging in size from 1 mm to 50 cm in length. They live in a tough, leather-like chitinous tube that they secrete; this tube is often buried in the ground so only the lophophore sticks out (Figure 33.11a). The lophophore can be retracted quickly in the presence of danger. Only about 15 species of phoronids are found worldwide.

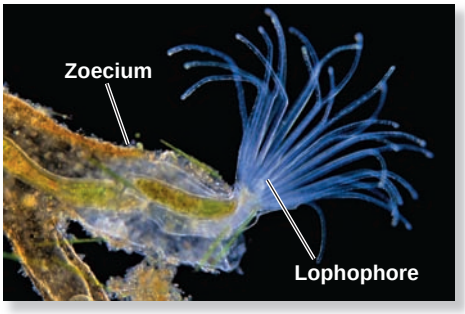
Phylum Bryozoa The bryozoans (from the Greek *bryon*, meaning moss, and *zoon*, meaning animal) are small colonial animals, most of which are less than 0.5 mm long, that can be found encrusted on rocks in shallow aquatic environments. They look very much like plants. There are about 4,000 species, many of which encrust boat hulls and have to be scraped off periodically. Within the colony, each animal secretes and lives inside a nonliving case called a zoecium (Figure 33.11b). The walls of the zoecium may be composed of chitin or calcium carbonate. For this reason, bryozoans have been important reef-builders. They date back to the Ordovician era, and many fossil forms have been discovered and identified.

Phylum Brachiopoda Brachiopods (from the Greek *brachio*, meaning arm, and *podos*, meaning foot) are marine organisms with two shell halves, much like clams (Figure 33.11c). Unlike bivalve mollusks, however, which have a left and right valve (side) of the shell, brachiopods have a dorsal and ventral valve. Brachiopods are bottom-dwelling species that attach to the substrate via a muscular pedicle. Although they are now a relatively small group, with about 300 living species, brachiopods flourished in the Paleozoic and Mesozoic eras—about 30,000 fossil species have been identified. Some of these fossil forms tell of organisms that reached 30 cm in length, although their modern relatives are only 0.5–8.0 cm long.

The Mollusca Is a Large Phylum Containing Snails, Slugs, Clams, Oysters, Octopuses, and Squids

Mollusks (from the Latin *mollis*, meaning soft) constitute a very large phylum, with over 100,000 living species, including organisms as diverse as snails, clams and oysters, octopuses and squid, and chitons. They are an ancient group, as evidenced by the classification of about 35,000 fossil species. Mollusks have a considerable economic, aesthetic, and ecological importance to humans. Many serve as sources of food, including scallops, oysters, clams, and squids. A significant industry involves the farming of oysters to produce cultured pearls, and rare and beautiful mollusk shells are extremely valuable to collectors. Snails and slugs can damage vegetables and ornamental plants, and boring mollusks can penetrate wooden ships and wharfs. Mollusks are

(a) A phoronid worm

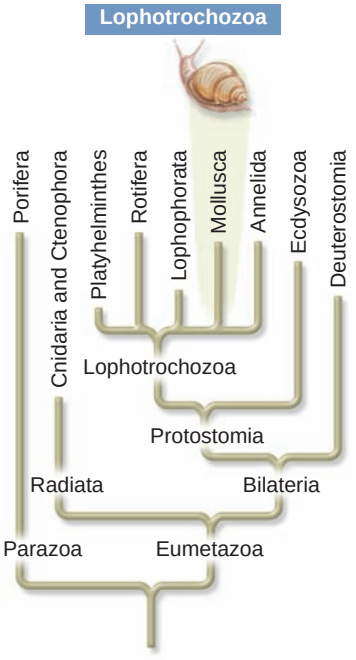


(b) A bryozoan

(c) A brachiopod, the northern lamp shell

Figure 33.11 **Lophophorates.** **(a)** A phoronid worm (*Phoronis californica*) buried in the sand with the lophophore extended. **(b)** Bryozoans are colonial lophophorates that reside on a nonliving case called a zoecium. **(c)** Brachiopods, including this northern lamp shell (*Terebratulina septentrionalis*), have dorsal and ventral shells.

Concept check: *What are the two main functions of the lophophore?*



intermediate hosts to many parasites, and several exotic species have become serious pests. For example, populations of the zebra mussel (*Dreissena polymorpha*) were introduced into North America from Asia via ballast water from transoceanic ships. Since their introduction, they have spread rapidly throughout the Great Lakes and an increasing number of inland waterways, adversely impacting native organisms and clogging water intake valves to municipal water-treatment plants around the lakes.

One common feature of the mollusks is their soft body, which exists, in many species, under a protective external shell. Most mollusks are marine, although some have colonized fresh water. Many snails and slugs have even moved onto land, but they survive only in humid areas and where the calcium necessary for shell formation is abundant in the soil. The ability to colonize freshwater and terrestrial habitats has led to a diversification of mollusk body plans. Thus, we again see how organismal diversity is related to environmental diversity.

While great variation in morphology occurs between classes, mollusks have a basic body plan consisting of three parts (Figure 33.12). A muscular **foot** is usually used for movement, and a **visceral mass** containing the internal organs rests atop the foot. The **mantle**, a fold of skin draped over the visceral mass, secretes a shell in those species that form shells. The mantle often extends beyond the visceral mass, creating a chamber called the **mantle cavity**, which houses delicate **gills**, filamentous organs that are specialized for gas exchange. A continuous current of water, often induced by cilia present on the gills or by muscular pumping, flushes out the wastes from the mantle cavity and brings in new oxygen-rich water.

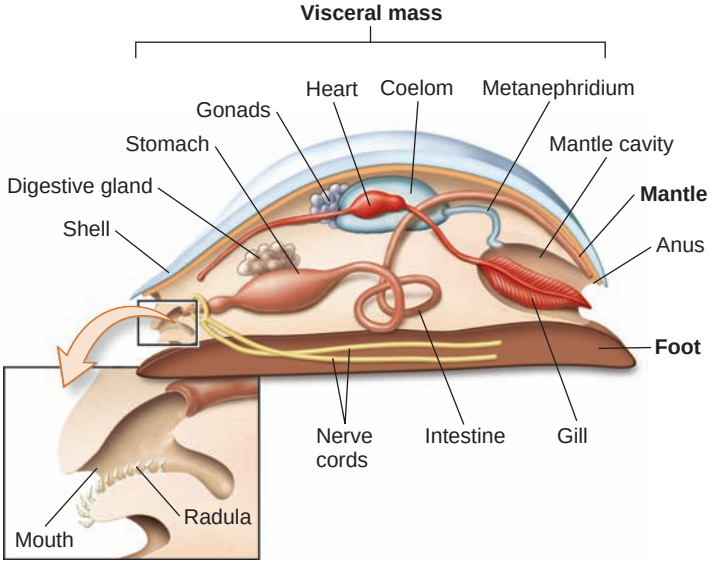


Figure 33.12 **The mollusk body plan.** The generalized body plan of a mollusk includes the characteristic foot, mantle, and visceral mass.

Concept check: *Do molluscan hearts pump blood?*

Mollusks are coelomate organisms, but the coelom is confined to a small area around the heart. The mollusks' organs are supplied with oxygen and nutrients via a circulatory system. Mollusks have an **open circulatory system** with a heart that pumps body fluid called hemolymph through vessels and into sinuses. Sinuses are the open, fluid-filled cavities between their internal organs. The organs and tissues are therefore continually bathed in hemolymph. From these sinuses, the hemolymph drains into vessels that take it to the gills and then back to the heart. Organs called **metanephridia** extract nitrogenous and other wastes. Metanephridia have ciliated funnel-like openings inside the coelom connected to ducts that lead to the exterior mantle cavity. The pores from the metanephridia discharge wastes into this cavity. The anus also opens into the mantle cavity. The metanephridial ducts may also serve to discharge sperm or eggs from the gonads. The nervous system varies from simple ganglia and nerve chords in most species to much larger brains and sophisticated organs of touch, smell, taste, and vision in octopuses.

The mollusk's mouth may contain a **radula**, a unique, protrusible, tonguelike organ that has many teeth and is used to eat plants, scrape food particles off rocks, or, if the mollusk is predatory, bore into shells of other species and tear flesh. In the cone shells (genus *Conus*), the radula is reduced to a few poison-injecting teeth on the end of a long proboscis that is cast about in search of prey, such as a worm or even a fish. Some Indo-Pacific cone shell species produce a neuromuscular toxin that can kill humans. Other mollusks, particularly bivalves, have lost their radula and are suspension feeders that filter water brought in by ciliary currents.

Most shells are complex three-layered structures secreted by the mantle that continue to grow as the mollusk grows. Shell growth is often seasonal, resulting in distinct growth lines on the shell, much the same as tree rings (Figure 33.13a). Using shell growth patterns, biologists have discovered some bivalves that are over 100 years old. The innermost layer of the shells of oysters, mussels, abalone, and other mollusks is a smooth, iridescent lining called nacre, which is commonly known as mother-of-pearl and is often collected from abalone shells for jewelry. Actual pearl production in mollusks, primarily oysters, occurs when a foreign object, such as a grain of sand, becomes lodged between the shell and the mantle, and layers of nacre are laid down around it to reduce the irritation.

Most mollusks have separate sexes, although some are hermaphroditic. Gametes are usually released into the water, where they mix and fertilization occurs. In some snails, however, fertilization is internal, with the male inserting sperm directly into the female. Internal fertilization was a key evolutionary development, enabling some snails to colonize land, and can be considered a critical innovation that fostered extensive

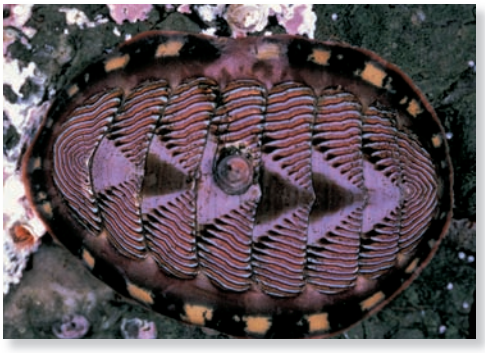
adaptive radiation. In many species, reproduction involves the production of a trochophore larva that develops into a **veliger**, a free-swimming larva that has a rudimentary foot, shell, and mantle.

Of the eight molluscan classes, the four most common are the Polyplacophora (chitons), Gastropoda (snails and slugs), Bivalvia (clams and mussels), and Cephalopoda (octopuses, squids, and nautiluses) (Table 33.3). Chitons are marine mollusks with a shell composed of eight separate plates (Figure 33.13b). Chitons are common in the intertidal, and they creep along when covered by the tide. Feeding occurs by scraping algae off rock surfaces. When the tide recedes, the muscular foot holds the chiton tight to the rock surface, preventing desiccation. The class Gastropoda (from the Greek *gaster*, meaning stomach, and *podos*, meaning foot) is the largest group of mollusks and encompasses about 75,000 living species, including snails, periwinkles, limpets, and other shelled members. The class also includes species such as slugs and nudibranchs, whose shells have been greatly reduced or completely lost during their evolution (Figure 33.13c). Most gastropods are marine

Table 33.3 Main Classes and Characteristics of Mollusks

	Class and examples (est. # of species)	Class characteristics
	Polyplacophora: chitons (860)	Marine; eight-plated shell
	Gastropoda: snails, slugs, nudibranchs (75,000)	Marine, freshwater, or terrestrial; most with coiled shell, but shell absent in slugs and nudibranchs; radula present
	Bivalvia: clams, mussels, oysters (30,000)	Marine or freshwater; shell with two halves or valves; primarily filter feeders with siphons
	Cephalopoda: octopuses, squids, nautiluses (780)	Marine; predatory, with tentacles around mouth, often with suckers; shell often absent or reduced; closed circulatory system; jet propulsion via siphon

(a) A Quahog clam, class Bivalvia



(b) A chiton, class Polyplacophora

(c) A sea slug, class Gastropoda

(d) An octopus, class Cephalopoda

Figure 33.13 Mollusks. **(a)** A bivalve shell, class Bivalvia, with growth rings. Quahog clams (*Mercenaria mercenaria*) can live over 20 years. **(b)** A chiton (*Tonicella lineata*), a polyplacophoran with a shell made up of eight separate plates. **(c)** A nudibranch (*Phyllidia ocellata*). The nudibranchs are a gastropod subclass whose members have lost their shell altogether. **(d)** The highly poisonous blue-ringed octopus (*Hapalochlaena lunulata*), a cephalopod.

or freshwater species, but some species, including snails and slugs, have also colonized land. Most gastropods are slow-moving animals that are weighed down by their shell. Unlike bivalves, gastropods have a one-piece shell, into which the animal can withdraw to escape predators.

The 780 species of Cephalopoda (from the Greek *kephale*, meaning head, and *podos*, meaning foot) are the most morphologically complex of the mollusks and indeed among the most complex of all invertebrates. Most are fast-swimming marine predators that range from organisms just a few centimeters in size to the colossal squid (*Mesonychoteuthis hamiltoni*), which is known to reach over 13 m in length and 495 kg (1,091 lbs) in weight. A cephalopod's mouth is surrounded by many long arms commonly armed with suckers. Octopuses have 8 arms with suckers, and squids and cuttlefish have 10 arms—8 with suckers and 2 long tentacles with suckers limited to their ends. Nautiluses have from 60 to 90 tentacles around the mouth. All cephalopods have a beaklike jaw that allows them to bite their prey, and some, such as the blue-ringed octopus (*Hapalochlaena lunulata*), deliver a deadly poison through their saliva (Figure 33.13d). Only one group, the nautiluses, has retained its external shell. In octopuses, the shell is not present, and in squid and cuttlefish, it is greatly reduced and internal. However, the fossil record is full of shelled cephalopods, called ammonites, some of which were as big as truck tires (Figure 33.14). They became extinct at the end of the Cretaceous period, although the reasons for this are not well understood.

The foot of some cephalopods has become modified into a muscular siphon. Water drawn into the mantle cavity is quickly expelled through the siphon, propelling the organisms forward or backward in a kind of jet propulsion. Such vigorous movement requires powerful muscles and a very efficient circulatory system to deliver oxygen and nutrients to the muscles. Cephalopods are the only mollusks with a **closed circulatory system**, in which blood flows throughout an animal entirely within a series of vessels. One of the advantages of this type of system is that the heart can pump blood through the tissues rapidly. The blood of cephalopods contains the copper-rich protein hemocyanin for transporting oxygen. Less efficient than the iron-rich hemoglobin of vertebrates, hemocyanin gives the blood a blue color.

The nautiluses are impeded by a coiled, chambered shell and so do not move as fast as the jet-propelled squids and octopuses (Figure 33.15). As it grows, the nautilus secretes a new chamber and seals off the old one with a **septum** (plural, septa). The older chambers are gas filled and act as buoyancy chambers. A thin strip of living tissue called the siphuncle removes liquid from the old chamber and replaces it with gas. The gas pressure within the chambers is only 1 atmosphere, despite the fact that nautiluses may be swimming at 400 m depths at a pressure of about 40 atmospheres. The shell's structure is strong enough to withstand this amount of pressure differential.

Cephalopods have a well-developed nervous system and brain that support their active lifestyle. Their sense organs, especially their eyes, are also very well developed. Many cephalopods (with the exception of nautiluses) have an ink sac

Figure 33.14 **A fossil ammonite.** These shelled cephalopods were abundant in the Cretaceous period.

that contains the pigment melanin; the sac can be emptied to provide a "smokescreen" to confuse predators. In many species, melanin is also distributed in special pigment cells in the skin, which allows for color changes. Octopuses often change color when alarmed or during courtship, and they can rapidly change color to blend in with their background and escape detection. The central nervous system of the octopus is among the most complex in the invertebrate world. Behavioral biologists have demonstrated that octopuses can behave in sophisticated ways, and scientists are currently debating to what degree they are capable of learning by observation.

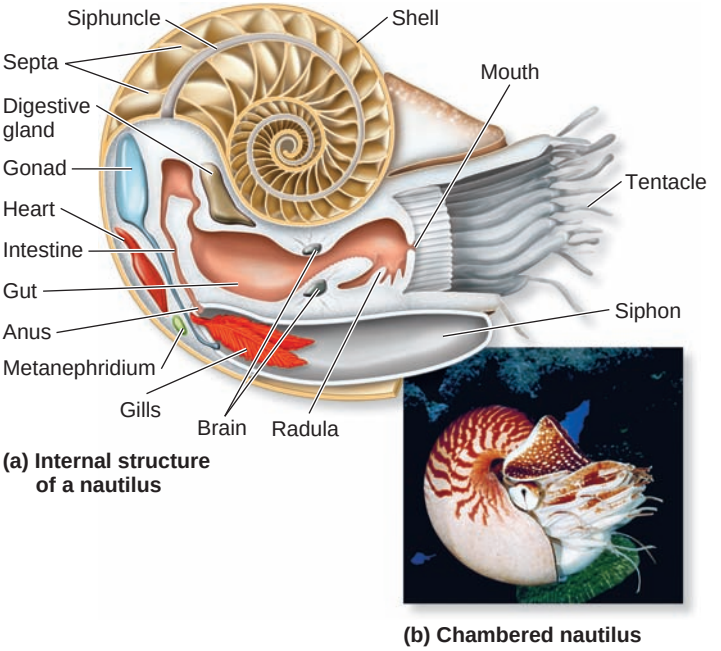


Figure 33.15 **The nautilus.** **(a)** A longitudinal section of a nautilus, showing the coiled shell with many chambers. The animal secretes a new chamber each year and lives only in the new one. **(b)** The chambered nautilus (*Nautilus pompilius*).

Feature Investigation

Fiorito and Scotto's Experiments Showed Invertebrates Can Exhibit Sophisticated Observational Learning Behavior

We tend to think of the ability to learn from others as a vertebrate phenomenon, especially among species that live in social groups. However, in 1992, Italian researchers Graziano Fiorito and Pietro Scotto demonstrated that octopuses can learn by observing the behavior of other octopuses (Figure 33.16). This was a surprising finding, in part because *Octopus vulgaris*, the species they studied, lives a solitary existence for most of its life.

In their experiments, octopuses were trained to attack either a red ball or a white ball by use of a reward (a small piece of fish placed behind the ball that it could not see) and a punishment (a small electric shock for choosing the wrong ball). This type of learning is called classical conditioning (see Chapter 55). Because octopuses are color blind, they must distinguish between the relative brightness of the balls. Octopuses were considered to be trained when they made no mistakes in five trials. Observer octopuses in adjacent tanks were then allowed to watch the trained octopuses attacking the balls. In the third part of the experiment, the observer octopuses were themselves tested. In these cases, observers nearly always attacked the same color ball as they had observed the demonstrators attacking. In addition, learning by observation was achieved more quickly than the original training. This remarkable behavior is considered by some to be the precursor to more complex forms of learning, including problem solving.

Figure 33.16 Observational learning in octopuses.

HYPOTHESIS Octopuses can learn by observing another's behavior.

STUDY LOCATION Laboratory setting with *Octopus vulgaris* collected from the Bay of Naples, Italy.

	Experimental level	Conceptual level
1 Train 2 groups of octopuses, one to attack white balls, one to attack red. These are called the demonstrator octopuses.	Reward choice of correct ball (with fish) and punish choice of incorrect ball (with electric shock). Training is complete when octopus makes no "mistakes" in 5 trials.	Conditions a demonstrator octopus to attack a particular color of ball.
2 In an adjacent tank, allow observer octopus to watch trained demonstrator octopus.	Observer; Demonstrator	Observer octopus may be learning the correct ball to attack by watching the demonstrator octopus.
3 Drop balls into the tank of the observer octopus. Test the observer octopus to see if it makes the same decisions as the demonstrator octopus.	Observer	If the observer octopus is learning from the demonstrator octopus, the observer octopus should attack the ball of the same color as the demonstrator octopus was trained to attack.

4 THE DATA

Participant	Color of ball chosen in 5 trials*	
	Red	White
Observers (watched demonstrator attack red)	4.31	0.31
Observers (watched demonstrator attack white)	0.40	4.10
Untrained (did not watch demonstrations)	2.11	1.94

*Average of 5 trials; data do not always sum to 5, because some trials resulted in no balls being chosen.

5 CONCLUSION Invertebrate animals are capable of learning from watching other individuals behave, in much the same way as vertebrate species learn from watching others.

Experimental Questions

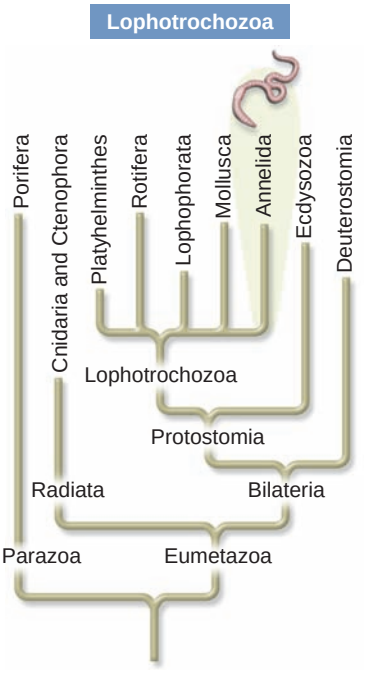
1. What was the hypothesis tested by Fiorito and Scotto?
2. What were the results of the experiment? Did these results support the hypothesis?
3. What is the significance of performing the experiment on both trained and untrained octopuses?

The Phylum Annelida Consists of the Segmented Worms

If you look at an earthworm, you will see little rings all down its body. Indeed, the phylum name Annelida is derived from the Latin *annulus*, meaning little ring. Each ring is a distinct segment of the annelid's body, with each segment separated from the one in front and the one behind by septa (Figure 33.17). Segmentation, the division of the body into compartments that are often very similar to each other, is a critical evolutionary innovation in the annelids and confers at least three major advantages.

First, many components of the body are repeated in each segment, including blood vessels, nerves, and excretory and reproductive organs. Excretion is accomplished by metanephridia, paired excretory organs in every segment that extract waste from the blood and coelomic fluid, emptying it to the exterior via pores in the skin (look ahead to Figure 49.8). If the excretory organs in one segment fail, the organs of another segment will still function.

Second, annelids possess a fluid-filled coelom that acts as a hydrostatic skeleton. In unsegmented coelomate animals, muscle contractions can distort the entire body during movement. However, such distortion is minimized in segmented animals, which allows for more effective locomotion over solid surfaces. In an earthworm, when the circular muscles around a segment contract against the hydrostatic skeleton, that segment becomes elongated. When the longitudinal muscles contract, the segment becomes compact. Waves of muscular contraction ripple down the segments, which elongate or contract independently.



Third, segmentation also permits specialization of some segments, especially at the annelid's anterior end. Therefore, although segments are often similar, they are not identical. This contrasts with tapeworms where most segments are identical. As a rule, as we move from more simple to more complex animals, segments become more specialized. Annelids have a relatively sophisticated nervous system involving a pair of cerebral ganglia that connect to a subpharyngeal ganglion (Figure 33.17). From there, a large ventral nerve cord runs down the entire length of the body. The ventral nerve chord is unusual because it contains a few very large nerve cells called **giant axons** that facilitate high-speed nerve conduction and rapid responses to stimuli. Such axons are found in other invertebrates, the best known of which is the squid.

Annelids have a double transport system. Both the circulatory system and the coelomic fluid carry nutrients, wastes, and respiratory gases, to some degree. The circulatory system

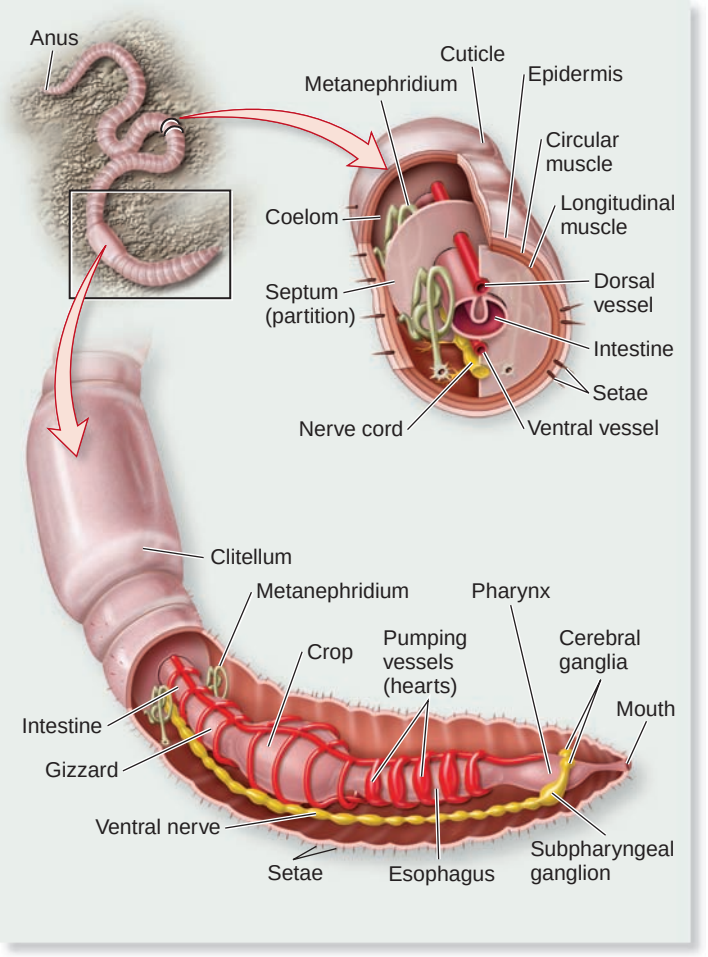


Figure 33.17 **The segmented body plan of an annelid, as illustrated by an earthworm.** The segmented nature of the worm is apparent internally as well as externally. Individual segments are separated by septa.

Concept check: *What are some of the advantages of segmentation?*

is usually closed, with dorsal and ventral vessels connected by five pairs of pumping vessels that serve as muscular hearts. The blood of most annelid species contains the respiratory pigment hemoglobin. Respiration occurs directly through the permeable skin surface, which restricts annelids to moist environments. The digestive system is complete and unsegmented, with many specialized regions: mouth, pharynx, esophagus, crop, gizzard, intestine, and anus. Sexual reproduction involves two individuals, often of separate sexes, but sometimes hermaphrodites, which exchange sperm via internal fertilization. In some species, asexual reproduction by fission occurs, in which the posterior part of the body breaks off and forms a new individual.

Annelids are a large phylum with about 15,000 described species. Its members include marine polychaete worms, the familiar earthworm, and leeches. They range in size from less than 1 mm to enormous Australian earthworms that can reach a size of 3 m. All annelids except the leeches have chitinous bristles, called **setae**, on each segment. In one class, the polychaetes, these are situated on fleshy, footlike **parapodia** (from the Greek, meaning almost feet) that are pushed into the substrate to provide traction during movement. Many annelid species burrow into soil or into muddy marine sediments and extract nutrients from ingested soil or mud. Some annelids also feed on dead or living vegetation, whereas others are predatory or parasitic.

The phylum Annelida consists of two main classes: the Polychaeta and Clitellata (Table 33.4). Members of the Polychaeta have a pair of parapodia on every segment. Members of the Clitellata do not have parapodia but possess a clitellum, a glandular region of the body that has a role in reproduction. There are two main subclasses within Clitellata: the Oligochaeta, the earthworms, and the Hirudinea, the leeches.

Class Polychaeta With over 10,000 species, the Polychaeta is the most species-rich class of the annelids. Many polychaetes are brightly colored, and all have many long setae bristling out of their body (polychaete is from the Greek, meaning many bristles). Most of them are marine organisms, living in burrows in the mud or sand, or in rock crevices, and they are often abundant in the intertidal mudflats. They are important prey for predators such as fishes and crustaceans. The polychaete head is well developed and, in predatory species, may exhibit powerful jaws. Some species are filter feeders and have a crown of tentacles that sticks up out of the mud while the bulk of the worm remains hidden.

Class Clitellata, Subclass Oligochaeta The Oligochaeta (from the Greek, meaning few bristles) includes the common earthworms and many species of freshwater worms. Earthworms play a unique and beneficial role in conditioning the soil, primarily due to the effects of their burrows and castings. Earthworms ingest soil and leaf tissue to extract nutrients and in the process create burrows in the Earth. As plant material and soil pass through the earthworm's digestive system, it is finely ground in

Table 33.4 Main Classes and Characteristics of Annelids

	Class and examples (est. # of species)	Class characteristics
	Polychaeta: marine worms (10,000)	Well-developed head; usually free-living; parapodia present; many setae
	Clitellata, subclass Oligochaeta: terrestrial and freshwater worms such as earthworms (3,500)	Less-developed head; fewer setae; no parapodia
	Clitellata, subclass Hirudinea: leeches (630)	Mostly ectoparasites; suckers present at both ends; flattened body; reduced coelom; no setae

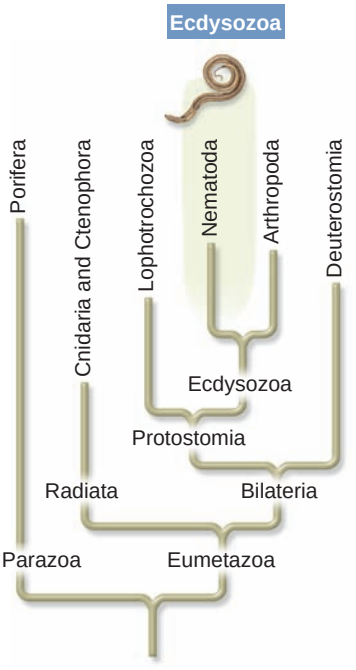
the gizzard into smaller fragments. Once excreted, this material—called castings—enriches the soil. Because a worm can eat its own weight in soil every day, worm castings on the soil surface can be extensive. The biologist Charles Darwin was interested in earthworm activity, and his last work, *The Formation of Vegetable Mould, through the Actions of Worms, with Observations on Their Habits*, was the first detailed study of earthworm ecology. In it, he wrote, "All the fertile areas of this planet have at least once passed through the bodies of earthworms."

Class Clitellata, Subclass Hirudinea Leeches are primarily found in freshwater environments, but there are also some marine species as well as terrestrial species that inhabit warm, moist areas such as tropical forests. Leeches have a fixed number of segments, usually 34, though the septa have disappeared in most species. Most leeches feed as blood-sucking parasites of vertebrates. They have powerful suckers at both ends of the body, and the anterior sucker is equipped with razor-sharp jaws that can bore or slice into the host's tissues. The salivary secretion of leeches (hirudin) acts as an anticoagulant to stop blood clotting. Leeches can suck up to several times their own weight in blood. They were once used in the medical field in the practice of bloodletting, the withdrawal of often considerable quantities of blood from a patient in the erroneous belief that this would prevent or cure illness and disease. Even today, leeches may be used after surgeries, particularly those involving the reattachment of digits (Figure 33.18). In these cases, the blood vessels are not fully reconnected and much excess blood accumulates, causing a swelling called a hematoma. This excess blood switches off the delivery of new blood and stops the formation of new vessels. If leeches remove the accumulated blood, new capillaries will be more likely to form, and the tissues will become healthy.

Unlike cestode and trematode flatworms, which are internally parasitic and quite host specific, leeches are generally external parasites that feed on a broad range of hosts, including fishes, amphibians, and mammals. However, there are always exceptions. *Placobdelloides jaegerskioeldi* is a parasitic leech that lives only in the rectum of hippopotamuses.

Figure 33.18 A leech, a member of the class Hirudinea. This species, *Hirudo medicinalis*, is sucking blood from a hematoma, a swelling of blood that can occur after surgery.

33.4 Ecdysozoa: The Nematodes and Arthropods



The Ecdysozoa is the sister group to the Lophotrochozoa. While the separation is supported by molecular evidence, the Ecdysozoa is named for a morphological characteristic, the physical phenomenon of ecdysis, or molting (refer back to Figure 32.12). All ecdysozoans possess a **cuticle**, a nonliving cover that serves to both support and protect the animal. Once formed, however, the cuticle typically cannot increase in size, which restricts the growth of the animal inside. The solution for growth is the formation of a new, softer cuticle under the old one. The old one then splits open and is sloughed off, allowing the new, soft cuticle to expand to a bigger size before it hardens. Where the cuticle is thick, as in arthropods, it impedes the diffusion of oxygen across the skin. Such species acquire oxygen by lungs, gills, or a set of branching, air-filled tubes called tracheae. A variety of appendages specialized for locomotion evolved in many species, including legs for walking or swimming and wings for flying.

The ability to shed the cuticle opened up developmental options for the ecdysozoans. For example, many species undergo a complete metamorphosis, changing from a wormlike larva into a winged adult. Animals with internal skeletons cannot do this because growth occurs only by adding more minerals to the existing skeleton. Another significant adaptation is the development of internal fertilization. This trait evolved independently in the vertebrates.

Because of these innovations, ecdysozoans are an incredibly successful group. Of the eight ecdysozoan phyla, we will consider the two most common: the nematodes and arthropods. The grouping of nematodes and arthropods is a relatively new idea and implies that the process of molting arose only once in animal evolution. In support of this, certain hormones that stimulate molting have been discovered to exist in both nematodes and arthropods. Furthermore, in 2007, Julie Dunning Hotopp and colleagues demonstrated the existence of lateral gene transfer (the movement of genes between distantly related organisms) between these groups. Elements of the bacterial genome *Wolbachia pipientis* were found in four insect and four nematode species. This both provides a mechanism for the acquisition of new genes by these eukaryotes and further underscores the idea that nematodes and arthropods are related.

The Phylum Nematoda Consists of Small Pseudocoelomate Worms Covered by a Tough Cuticle

The nematodes (from the Greek *nematos*, meaning thread), also called roundworms, are small, thin worms that range from less than 1 mm to about 5 cm (Figure 33.19), although some parasitic species measuring 1 m or more have been found in the placenta of sperm whales. Nematodes are ubiquitous organisms that exist in nearly all habitats, from the poles to the tropics. They are found in the soil, in both freshwater and marine environments, and inside plants and animals as parasites. A shovelful of soil may contain a million nematodes. Over 20,000 species are known, but there are probably at least five times as many undiscovered species.

Nematodes have several distinguishing characteristics. A tough cuticle covers the body. The cuticle is secreted by the epidermis and is made primarily of **collagen**, a structural protein also present in vertebrates. The cuticle is shed periodically as the nematode grows. Beneath the epidermis are longitudinal muscles but no circular muscles, which means that muscle contraction results in more thrashing of the body than smoother wormlike movement. The pseudocoelom functions as both a hydrostatic skeleton and a circulatory system. Diffusion of gases occurs through the cuticle. Roundworms have a complete digestive tract composed of a mouth, pharynx, intestine, and anus. The mouth often contains sharp, piercing organs called **stylets**, and the muscular pharynx functions to suck in food. Excretion of metabolic waste occurs via two simple tubules that have no cilia or flame cells.

Nematode reproduction is usually sexual, with separate males and females, and fertilization takes place internally. Females are generally larger than males and can produce prodigious numbers of eggs, in some cases, over 100,000 per day. Development in some nematodes is easily observed because the organism is transparent and the generation time is short. For these reasons, the small, free-living nematode *Caenorhabditis elegans* has become a model organism for researchers to study (refer back to Figure 19.1b). In 2002, the Nobel Prize in Medicine or Physiology was shared by Sydney Brenner, Robert Horvitz, and John Sulston for their studies of the genetic regulation of development and programmed cell death in *C. elegans*. This nematode has 1,090 somatic cells, but 131 die, leaving exactly 959 cells. The cells die via a genetically controlled cell death. Many diseases in humans, including acquired immunodeficiency syndrome (AIDS), cause extensive cell death, whereas others, such as cancer and autoimmune diseases, reduce cell death so that cells that should die do not. Researchers are studying the process of programmed cell death in *C. elegans* in the hope of finding treatments for these and other human diseases.

Figure 33.19 Scanning electron micrograph of a nematode within a plant leaf.

A large number of nematodes are parasitic in humans and other vertebrates. The large roundworm *Ascaris lumbricoides* is a parasite of the small intestine that can reach up to 30 cm in length. Over a billion people worldwide carry this parasite. Although infections are most prevalent in tropical or developing countries, the prevalence of *A. lumbricoides* is relatively high in rural areas of the southeastern U.S. Eggs pass out in feces and can remain viable in the soil for years. Eggs require ingestion before hatching into an infective stage. Hookworms (*Necator americanus*), so named because their anterior end curves dorsally like a hook, are also parasites of the human intestine. The eggs pass out in feces, and recently hatched hookworms can penetrate the skin of a host's foot to establish a new infection. In areas with modern plumbing, these diseases are uncommon.

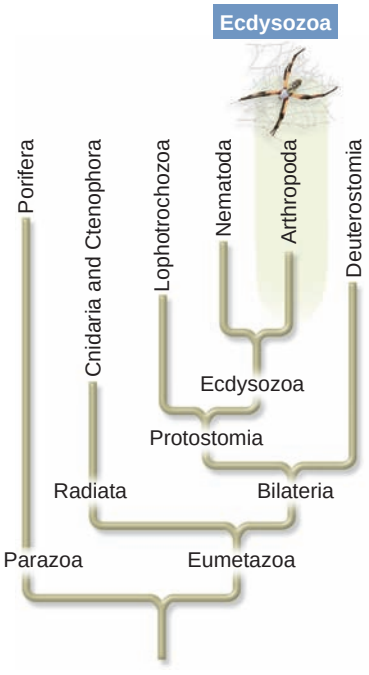
Pinworms (*Enterobius vermicularis*), while a nuisance, have relatively benign effects on their hosts. The rate of infection in the U.S., however, is staggering: 30% of children and 16% of adults are believed to be hosts. Adult pinworms live in the large intestine and migrate to the anal region at night to lay their eggs, which causes intense itching. The resultant scratching spreads the eggs. In the tropics, some 250 million people are infected with *Wuchereria bancrofti*, a fairly large (100 mm) worm that lives in the lymphatic system, blocking the flow of lymph, and, in extreme cases, causing elephantiasis, or extreme swelling of the legs and other body parts (Figure 33.20). Females release tiny, live young called microfilariae, which are transmitted to new hosts via mosquitoes.

The Phylum Arthropoda Contains the Spiders, Millipedes and Centipedes, Insects, and Crustaceans, Species with Jointed Appendages

The arthropods (from the Greek *arthron*, meaning joint, and *podos*, meaning foot) constitute perhaps the most successful phylum on Earth. About three-quarters of all described living species are arthropods, and scientists have estimated they are also numerically common, with an estimated 10^{18}, or a billion billion, individual organisms present on Earth. The huge success of the arthropods, in terms of their sheer numbers and diversity, is related to a body plan that permits these animals to live in all the major biomes on Earth, from the poles to the tropics, and from marine and freshwater habitats to dry land.

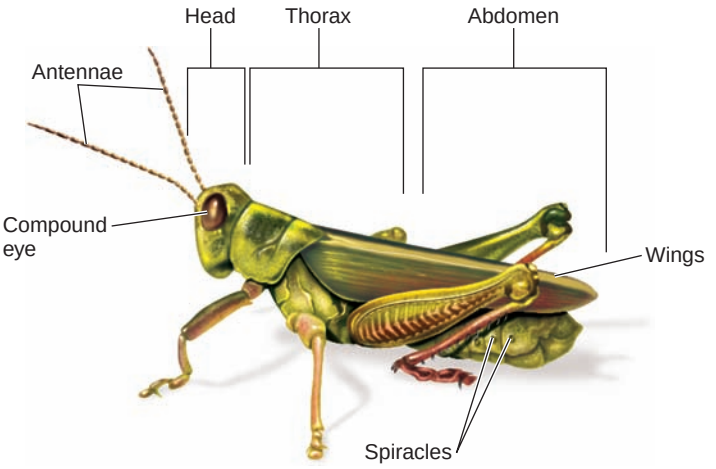
Figure 33.20 **Elephantiasis in a human leg.** The disease is caused by the nematode parasite *Wuchereria bancrofti*, which lives in the lymphatic system and blocks the flow of lymph.

Concept check: *What other nematodes are parasitic in humans?*

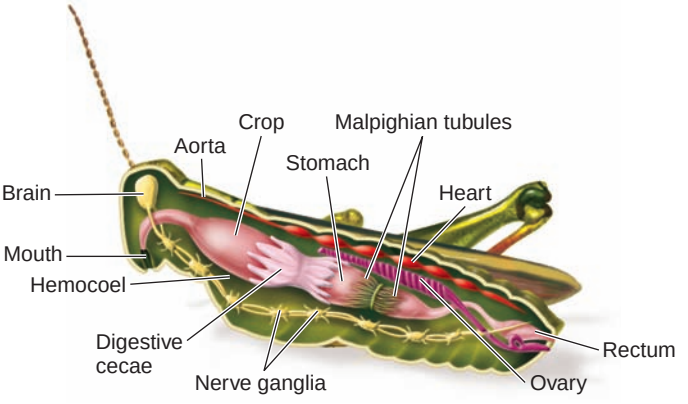


The body of a typical arthropod is covered by a hard cuticle, an **exoskeleton** (external skeleton), made of layers of chitin and protein. The cuticle can be extremely tough in some parts, as in the shells of crabs, lobsters, and even beetles, yet be soft and flexible in other parts, between body segments and segments of appendages, to allow for movement. In the class of arthropods called crustaceans, the exoskeleton is reinforced with calcium carbonate to make it extra hard. The exoskeleton provides protection and also a point of attachment for muscles, all of which are internal. It is also relatively impermeable to water, a feature that may have enabled many arthropods to conserve water and colonize land, in much the same way as a tough seed coat allowed plants to colonize land (see Chapter 29). From this point of view, the development of a hard cuticle was a critical innovation. It also reminds us that the ability to adapt to diverse environmental conditions can itself lead to increased organismal diversity.

Arthropods are segmented, and many of the segments bear appendages for locomotion, food handling, or reproduction. In many orders, the body segments have become fused into functional units, or **tagmata**, such as the head, thorax, and abdomen of an insect (Figure 33.21). Cephalization is extensive,



(a) External anatomy



(b) Internal anatomy

Figure 33.21 **Body plan of an arthropod, as represented by a grasshopper.**

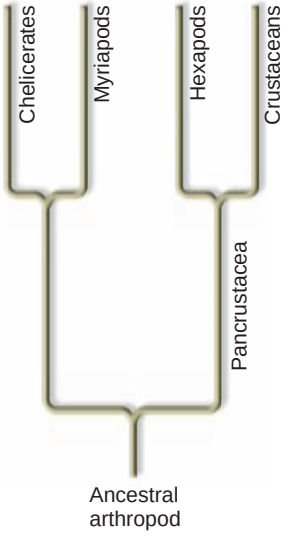
and arthropods have well-developed sensory organs, including organs of sight, touch, smell, hearing, and balance. Arthropods have compound eyes composed of many independent visual units called **ommatidia** (singular, ommatidium) (look ahead to Figure 43.14). Together, these lenses render a mosaic-like image of the environment. Some species, particularly some insects, possess additional simple eyes, or ocelli, that are probably only capable of distinguishing light from dark.

The arthropod brain is quite sophisticated, consisting of two or three ganglia connected to several smaller ventral nerve ganglia. Like most mollusks, arthropods have an open circulatory system (look ahead to Figure 47.2), in which hemolymph is pumped from the heart into the aorta or short arteries and then into the open sinuses that coalesce to form the hemocoel. From the hemocoel, gases and nutrients diffuse into tissues. The hemolymph flows back into the heart via pores, called ostia, that are equipped with valves.

Because the cuticle impedes the diffusion of gases through the body surface, arthropods possess special organs that permit gas exchange. In aquatic arthropods, these consist of feathery gills that have an extensive surface area in contact with the surrounding water. Terrestrial species have a highly developed

tracheal system (look ahead to Figure 48.7). On the body surface, pores called **spiracles** provide openings to a series of finely branched air tubes within the body called trachea. The tracheal system delivers oxygen directly to tissues and cells. Some spiders have book lungs, consisting of a series of sheetlike structures, like the pages of a book, extending into a hemolymph-filled chamber on the underside of the abdomen. Gases also diffuse across thin areas of the cuticle.

The digestive system is complex and often includes a mouth, crop, stomach, intestine, and rectum. The stomach has glands called digestive cecae that secrete digestive enzymes. Excretion is accomplished by specialized metanephridia or, in insects and some other taxa, by **Malpighian tubules**, delicate projections from the digestive tract that protrude into the hemolymph (look ahead to Figure 49.9). Nitrogenous wastes are absorbed by the tubules and emptied into the gut. The intestine and rectum reabsorb water and salts. This excretory system, allowing the retention of water, was another critical innovation that permitted the colonization of land by arthropods.



The history of arthropod classification is extensive. One scheme proposed two groups: the mandibulates, such as insects, which possessed jaws, and the chelicerates, such as spiders, which instead possessed pincers. Another scheme classified taxa according to whether they had one pair of unbranched antennae (called uniramous) versus one pair of branched antennae (called biramous) or none, the chelicerates. Such differences in classification led many to question whether the group was even monophyletic, or derived from a common ancestor. Three separate ancestral phyla, corresponding to the uniramia (insects and relatives), biramia (crustaceans), and chelicerates (spiders and scorpions) were proposed. However, a 2002 molecular study by Jeffrey Boore and colleagues, together with morphological data, suggest a different scheme with five main subphyla: one now-extinct subphyla, Trilobita (trilobites), and four living subphyla, Chelicerata (spiders and scorpions), Myriapoda (millipedes and centipedes), Hexapoda (insects), and Crustacea (crabs and relatives) (Table 33.5). In Boore's scheme, the Trilobita were among the earliest-diverging arthropods. The lineage then split into two groups. One, often referred to as the Pancrustacea, contained the insects and crustaceans. The other, with no overarching name, contained the Myriapods and Chelicerates. Molecular evidence suggests insects are more closely related to crustaceans than they are to spiders or millipedes and centipedes.

Subphylum Trilobita: Extinct Early Arthropods The trilobites were among the earliest arthropods, flourishing in shallow seas of the Paleozoic era, some 500 million years ago, and dying out about 250 million years ago. Most trilobites were bottom feeders and were generally 3–10 cm in size, although some reached almost 1 m in length (Figure 33.22). Like many arthropods, they had three main tagmata: the head, thorax, and abdomen. Trilobites also had two dorsal grooves that divided the body longitudinally into three lobes—an axial lobe and two pleural lobes—a structural characteristic giving the class its name. Most of the body segments showed little specialization. In contrast, later-diverging arthropods developed specialized appendages on many segments, including appendages for grasping, walking, and swimming.

Table 33.5 Main Subphyla and Characteristics of Arthropods

	Subphyla and examples (est. # of species)	Class characteristics
	Chelicerata: spiders, scorpions, mites, ticks, horseshoe crabs, and sea spiders (74,000)	Body usually with cephalothorax and abdomen only; six pairs of appendages, including four pairs of legs, one pair of fangs, and one pair of pedipalps; terrestrial; predatory or parasitic
	Myriapoda: millipedes and centipedes (13,000)	Body with head and highly segmented trunk. In millipedes, each segment with two pairs of walking legs; terrestrial; herbivorous. In centipedes, each segment with one pair of walking legs; terrestrial; predatory, poison jaws
	Hexapoda: insects such as beetles, butterflies, flies, fleas, grasshoppers, ants, bees, wasps, termites and springtails (>1 million)	Body with head, thorax, and abdomen; mouthparts modified for biting, chewing, sucking, or lapping; usually with two pairs of wings and three pairs of legs; mostly terrestrial, some freshwater; herbivorous, parasitic, or predatory
	Crustacea: crabs, lobsters, shrimp (45,000)	Body of two to three parts; three or more pairs of legs; chewing mouthparts; usually marine

Subphylum Chelicerata: The Spiders, Scorpions, Mites, and Ticks The Chelicerata consists mainly of the class Arachnida, which contains predatory spiders and scorpions as well as the ticks and mites, some of which are blood-sucking parasites that feed on vertebrates. The two other living classes are the Merostomata, the horseshoe crabs (four species), and the Pycnogonida, the sea spiders (1,000 species), both of which are marine, reflecting the groups' marine ancestry. All species have a body consisting of two tagmata: a fused head and thorax, called a **cephalothorax**, and an abdomen (Figure 33.23a). All

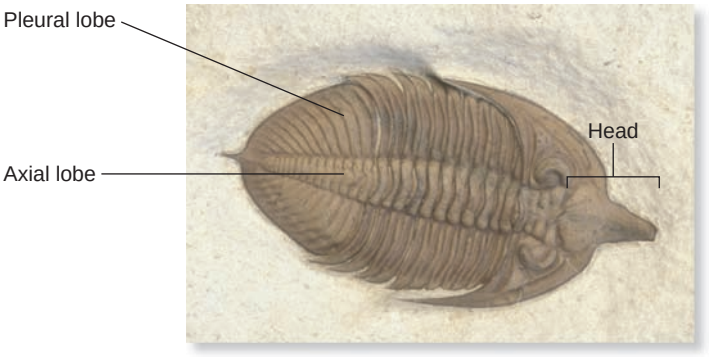


Figure 33.22 **A fossil trilobite.** About 4,000 fossil species of these early arthropods, including *Huntonia huntonesis* shown here, at about 20 cm long, have been described.

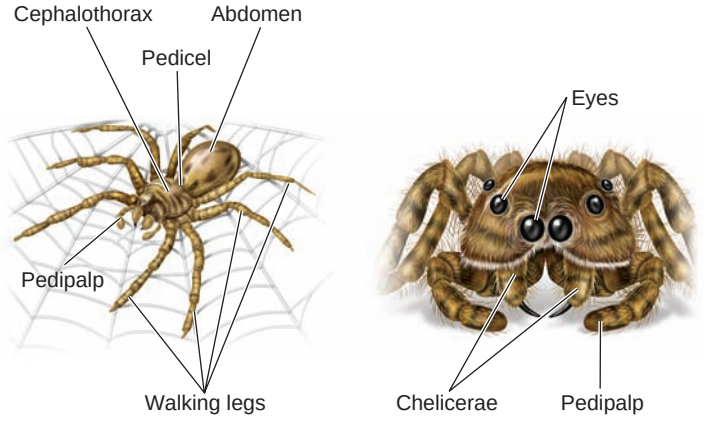
species also possess six pairs of appendages: the chelicerae, or fangs; a pair of **pedipalps**, which have various sensory, predatory, or reproductive functions; and four pairs of walking legs (Figure 33.23b).

In spiders (order Araneae), the cephalothorax and abdomen are joined by a **pedicel**, a narrow, waistlike point of attachment. The fangs, or chelicerae, are supplied with venom from poison glands. Most spider bites are harmless to humans, although they are very effective in immobilizing and/or killing their insect prey. Venom from some species, including the black widow (*Latrodectus mactans*) and the brown recluse (*Loxosceles reclusa*), are potentially, although rarely, fatal to humans. The toxin of the black widow is a neurotoxin, which interferes with the functioning of the nervous system, whereas that of the brown recluse is hemolytic, meaning it destroys tissue around the bite. After the spider has subdued its prey, it pumps digestive fluid into the tissues via the fangs and sucks out the partially digested meal.

Spiders have abdominal silk glands, called spinnerets, and many spin webs to catch prey (Figure 33.24a). The silk is a protein that stiffens after extrusion from the body because the mechanical shearing causes a change in the organization of the amino acids. Silk is stronger than steel of the same diameter but is more elastic than Kevlar, the material used in bulletproof vests. Each family constructs a characteristic size and style of



(a) External anatomy (b) Close-up of head

Figure 33.23 Spider morphology.

web and can do it perfectly on its first attempt, indicating that web spinning is an innate (inherited) behavior (see Chapter 55). Spiders also use silk to wrap up prey and to construct egg sacs. Interestingly, spiders that are fed drugged food (flies) spin their webs differently than undrugged spiders (Figure 33.24b,c). Some scientists have suggested that web-spinning spiders be used to test substances for the presence of drugs or even to indicate environmental contamination. Not all spiders use silk extensively. Some spiders, including the wolf spider, actively pursue their prey (Figure 33.25a).

Scorpions (order Scorpionida) are generally tropical or subtropical animals that feed primarily on insects, though they may eat spiders and other arthropods as well as smaller reptiles and mice. Their pedipalps are modified into large claws, and their abdomen tapers into a stinger, which is used to inject venom. While the venom of most North American species is generally not fatal to humans, that of the *Centruroides* genus from deserts in the U.S. Southwest and Mexico can be deadly. Fatal species are also found in India, Africa, and other countries. Unlike spiders, which lay eggs, scorpions bear live young that the mother then carries around on her back until they have their first molt (Figure 33.25b).

Figure 33.25 **Common arachnids.** **(a)** This wolf spider (*Lycosa tarantula*) does not spin a web but instead runs after its prey. Note the pedipalps, which look like short legs. **(b)** The Cape thick-tailed scorpion (*Parabuthus capensis*) is highly venomous and carries its white young on its back. **(c)** SEM of a chigger mite (*Trombicula alfreddugesi*) that can cause irritation to human skin and spread disease. **(d)** These South African bont ticks (*Amblyomma hebraeum*) are feeding on a white rhinoceros.

Concept check: *What is one of the main characteristics distinguishing arachnids from insects?*

In mites and ticks (order Acari), the two main body segments (cephalothorax and abdomen) are fused and appear as one large segment. Many mite species are free-living scavengers that feed on dead plant or animal material. Other mites are serious pests on crops, and some, like chiggers (*Trombicula alfreddugesi*), are parasites of humans that can spread diseases such as typhus (Figure 33.25c). Chiggers are parasites only in their larval stage. Chiggers do not bore into the skin; it is their bite and salivary secretions that cause skin irritation. *Demodex brevis* is a hair-follicle mite that is common in animals and humans. The mite is estimated to be present in over 90% of adult humans. Although the mite causes no irritation in most humans, *Demodex canis* causes the skin disease known as mange in domestic animals, particularly dogs.

Ticks are larger organisms than mites, and all are ectoparasitic, feeding on the body surface, on vertebrates. Their life cycle includes attachment to a host, sucking blood until they are replete, and dropping off the host to molt (Figure 33.25d). Ticks can carry a huge variety of viral and bacterial diseases, including Lyme disease, a bacterial disease so named because it was first found in the town of Lyme, Connecticut, in the 1970s.

Subphylum Myriapoda: The Millipedes and Centipedes Myriapods have one pair of antennae on the head and three pairs of appendages that are modified as mouth parts, including mandibles that act like jaws. The millipedes and centipedes, both wormlike arthropods with legs, are among the earliest terrestrial animal phyla known. Millipedes (class Diplopoda) have two pairs of legs per segment, as their name denotes (from the Latin *diplo*, meaning two, and *podos*, meaning feet), not 1,000 legs, as their common name suggests (Figure 33.26a). They are slow-moving herbivorous creatures that eat decaying leaves and other plant material. When threatened, the millipede's response is to roll up into a protective coil. Many millipede species also have glands on their underside that can eject a variety of toxic, repellent secretions. Some millipedes are brightly colored, warning potential predators that they can protect themselves.

Class Chilopoda (from the Latin *chilo*, meaning lip, and *podos*, meaning feet), or centipedes, are fast-moving carnivores that have one pair of walking legs per segment (Figure 33.26b). The head has many sensory appendages, including a pair of antennae and three pairs of appendages modified as mouthparts, including powerful claws connected to poison glands. The toxin from venom of some of the larger species, such as *Scolopendra heros*, is powerful enough to cause pain in humans. Most species do not have a waxy waterproofing layer on their cuticle and so are restricted to moist environments under leaf litter or in decaying logs, usually coming out at night to actively hunt their prey.

Subphylum Hexapoda: A Diverse Array of Insects and Close Relatives Hexapods are six-legged arthropods. Most are insects, but there are a few earlier-diverging noninsect hexapods, including soil-dwelling groups such as collembolans, that molecular studies have shown represent a separate but related lineage. Insects are in a class by themselves (Insecta), literally and figuratively. There are more species of insects than all other species of animal life combined. One million species of insects have been described, and, according to best estimates, 9 million more species await description. At least 90,000 species of insects have been identified in the U.S. and Canada alone. Genetic barcoding can help resolve many taxonomic dilemmas between closely related species.

(a) Two millipedes

(b) A centipede

Figure 33.26 **Millipedes and centipedes.** **(a)** Millipedes have two pairs of legs per segment. **(b)** The venom of the giant centipede (*Scolopendra heros*) is known to produce significant swelling and pain in humans.

Insects are the subject of an entire field of scientific study, **entomology**. They are studied in large part because of their significance as pests of the world's agricultural crops and carriers of some of the world's most deadly diseases. Insects live in all terrestrial habitats, and virtually all species of plants are fed upon by at least one, usually tens, and sometimes, in the case of large trees, hundreds of insect species. Because insects eat approximately one-quarter of the world's crops, we are constantly trying to find ways to reduce insect pest densities. Pest reduction often involves chemical control (the use of pesticides) or biological control (the use of living organisms) to reduce pest populations. Many species of insects are also important pests or parasites of humans and livestock, both by their own actions and as vectors of diseases such as malaria and sleeping sickness.

In contrast, insects also provide us with many types of essential biological services. We depend on insects such as honeybees to pollinate our crops. Bees also produce honey, and silkworms are the source of silk fiber. Despite the revulsion they provoke in us, fly larvae (maggots) are important in the decomposition process of both dead plants and animals. In addition, we use insect parasites and predators in biological control.

Of paramount importance to the success of insects was the development of wings, a feature possessed by no other arthropod and indeed no other living animal except birds and bats. Unlike vertebrate wings, however, insect wings are actually outgrowths of the body wall cuticle and are not true segmental appendages. This means that insects still have all their walking legs. Insects are thus like the mythological horse Pegasus, which sprouted wings out of its back while retaining all four legs. In contrast, birds and bats have one pair of appendages (arms) modified for flight, which leaves them considerably less agile on the ground.

The great diversity of insects is illustrated by the fact that there are 35 different orders, some of which have over 100,000 species. The most common of the orders are discussed in Table 33.6. Different orders of insects have slightly different wing structures, and many of the orders are based on wing type (their names often include the root *pter-*, from the Greek *pteron*, meaning wing). In beetles (Coleoptera), only the back pair of wings is functional, as the front wings have been hardened into protective shell-like coverings under which the back pair folds when not in use. Wasps and bees (Hymenoptera) have two pairs of wings hooked together that move as one wing. Flies (Diptera) possess only one pair of wings (the front pair); the back pair has been modified into a small pair of balancing organs, called halteres, that act like miniature gyroscopes. Butterflies (Lepidoptera) have wings that are covered in scales (from the Greek *lepido*, meaning scale); other insects generally have clear, membranous wings. In ant and termite colonies, the queen and the drones (males) retain their wings, whereas female individuals called workers have lost theirs. Other species, such as fleas and lice, are completely wingless.

Insects in different orders have also evolved a variety of mouthparts in which the constituent parts, the mandibles and maxillae, are modified for different functions (Figure 33.27). Grasshoppers, beetles, dragonflies, and many others have mouthparts adapted for chewing. Mosquitoes and many plant pests have mouthparts adapted for piercing and sucking. Butterflies and moths have a coiled tongue (**proboscis**) that can be uncoiled, enabling them to drink nectar from flowers. Finally, some flies have lapping, spongelike mouthparts that sop up liquid food. Their varied mouthparts allow insects to specialize their feeding on virtually anything: plant matter, decaying organic matter, and other living animals. The biological diversity of insects is therefore related to environmental diversity, in this case, the variety of foods that insects eat. Parasitic insects attach themselves to other species, and there are even some insect parasites (called hyperparasites) that feed on other parasites, proving, as the 18th-century English poet Jonathan Swift noted

> Big fleas have little fleas
> upon their backs to bite 'em;
> little fleas have smaller fleas
> and so *ad infinitum*.

All insects have separate sexes, and fertilization is internal. During development, the majority (approximately 85%) of insects undergo a change in body form known as **complete metamorphosis** (from the Greek *meta*, meaning change, and *morph*, meaning form) (Figure 33.28a). Complete metamorphosis has four types of stages: egg, larva, pupa, and adult. In these species, the larval stage is often spent in an entirely different habitat from that of the adult, and larval and adult forms use different food sources. Consequently, they do not compete directly for the same resources. The dramatic body transformation from larva to adult occurs in the pupa stage. The remaining insects undergo **incomplete metamorphosis**, in which change is more gradual (Figure 33.28b). Incomplete metamorphosis has only three types of stages: egg, nymph, and adult. Young insects, called nymphs, look like miniature adults when they hatch from their eggs. As they grow and feed, they shed their skin several times, each time entering a new instar, or stage of growth.

Finally, some insects, such as bees, wasps, ants, and termites, have developed complex social behavior and live cooperatively in underground or aboveground nests. Such colonies exhibit a division of labor, in that some individuals forage for food and care for the brood (workers), others protect the nest (soldiers), and some only reproduce (the queen and drones) (Figure 33.29).

Genomes & Proteomes Connection

Barcoding: A New Tool for Classification

As mentioned, insects are a very species-rich taxa. For example, there are at least 3,500 species of mosquitoes, many of them hard to tell apart. Some mosquitoes transmit deadly diseases such as malaria and yellow fever and are subject to stringent control measures in many countries. Other mosquito species are relatively benign. Distinguishing mosquito species in the field is not easy. The mosquito barcoding initiative aims to catalog each species by using DNA and building up a mosquito

Table 33.6 Main Orders and Characteristics of Insects

Order and examples (est. # of species)		Order characteristics
Coleoptera: beetles, weevils (500,000)		Two pairs of wings (front pair thick and leathery, acting as wing cases, back pair membranous); armored exoskeleton; biting and chewing mouthparts; complete metamorphosis; largest order of insects
Hymenoptera: ants, bees, wasps (190,000)		Two pairs of membranous wings; chewing or sucking mouthparts; many have posterior stinging organ on females; complete metamorphosis; many species social; important pollinators
Diptera: flies, mosquitoes (190,000)		One pair of wings with hind wings modified into halteres (balancing organs); sucking, piercing, or lapping mouthparts; complete metamorphosis; larvae are grublike maggots in various food sources; some adults are disease vectors
Lepidoptera: butterflies, moths (180,000)		Two pairs of colorful wings covered with tiny scales; long tubelike tongue for sucking; complete metamorphosis; larvae are plant-feeding caterpillars; adults are important pollinators
Hemiptera: true bugs; assassin bug, bedbug, chinch bug, cicada (100,000)		Two pairs of membranous wings; piercing or sucking mouthparts; incomplete metamorphosis; many plant feeders; some predatory or blood feeders; vectors of plant diseases
Orthoptera: crickets, grasshoppers (30,000)		Two pairs of wings (front pair leathery, back pair membranous); chewing mouthparts; mostly herbivorous; incomplete metamorphosis; powerful hind legs for jumping
Odonata: damselflies, dragonflies (6,500)		Two pairs of long, membranous wings; chewing mouthparts; large eyes; predatory on other insects; incomplete metamorphosis; larvae aquatic; considered early-diverging insects
Phthiraptera: sucking lice (2,400)		Wingless ectoparasites; sucking mouthparts; flattened body; reduced eyes; legs with clawlike tarsi for clinging to skin; incomplete metamorphosis; very host specific; vectors of typhus
Siphonaptera: fleas (2,600)		Wingless, laterally flattened; piercing and sucking mouthparts; adults are bloodsuckers on birds and mammals; jumping legs; complete metamorphosis; vectors of plague
Isoptera: termites (2,000)		Two pairs of membranous wings when present; some stages wingless; chewing mouthparts; social species; incomplete metamorphosis

DNA catalog. Field researchers will be able to quickly analyze the DNA of a particular species and identify it based on existing bar codes. Appropriate control measures can then be instigated if it is a disease carrier.

The barcoding project was developed in 2003 by Dr. Paul Herbert of the University of Guelph, Ontario. He made the analogy that the large diversity of products in a grocery store can each be distinguished with a relatively small barcode. Though the diversity of the world's animal species is considerably larger, Dr. Herbert reasoned that all species could be distinguished using their DNA. The complete genome would be too large to analyze rapidly, so Dr. Herbert suggested analyzing a small piece of DNA of all species. The DNA sequence he proposed is the first 684 base pairs of a gene called *CO1*, for cyto-

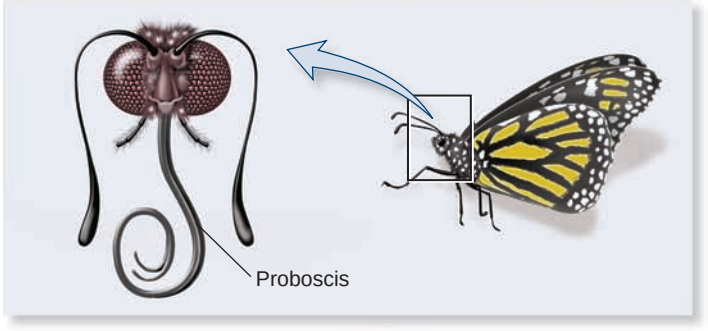
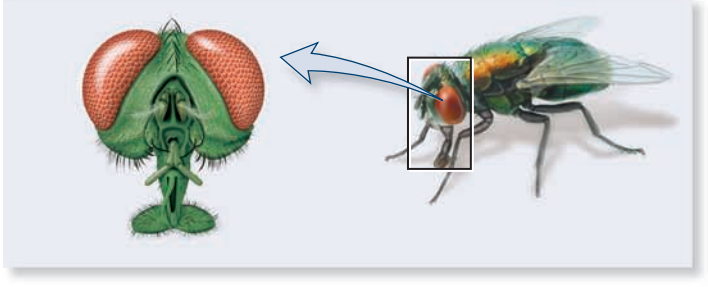
(b) Piercing and blood sucking (mosquito)



(c) Nectar sucking (butterfly)



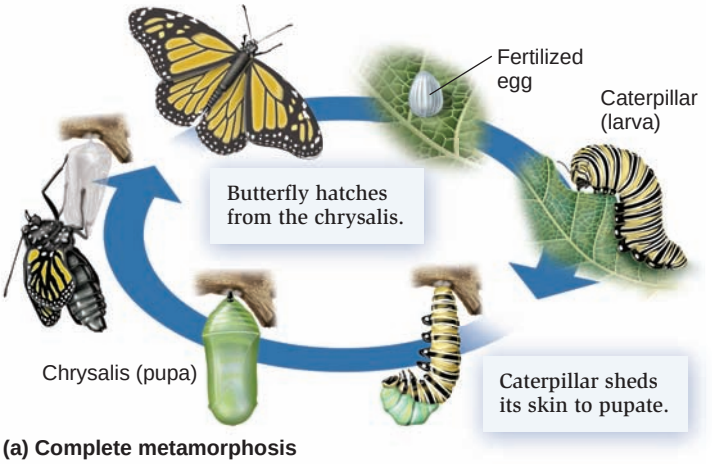
(d) Sponging liquid (housefly)

Figure 33.27 **A variety of insect mouthparts.** Insect mouthparts have become modified in ways that allow insects to feed by a variety of methods, including **(a)** chewing (Orthoptera, Coleoptera, and others), **(b)** piercing and blood sucking (Diptera), **(c)** nectar sucking (Lepidoptera), and **(d)** sponging up liquid (Diptera).

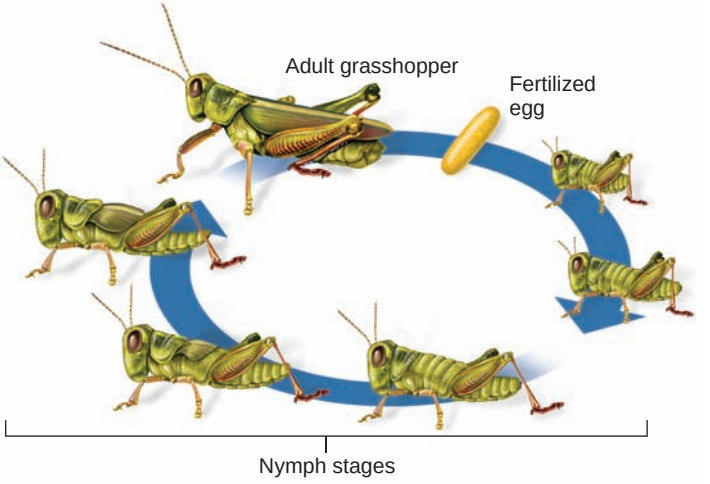
Concept check: *Insects have a variety of mouthparts. Name two other key insect adaptations.*

chrome oxidase. All animals have this gene, and it occurs in the mitochondria, so it avoids the reshuffling of genetic material that occurs in nuclear genes. A key element is that although this part of the *CO1* gene varies widely between species, it hardly varies at all between individuals of the same species—only 2%.

Dr. Herbert foresees the day when all species can be identified by their DNA barcode. A huge advantage is that only a small piece of tissue is necessary. The specimen can come from adult or immature individuals, a great help considering much insect taxonomy is based solely on adults. The technique also has immense potential for vertebrates and plants. When dead birds carrying avian flu washed up on the shores of Scotland, the birds were so decomposed they were hard to identify. Without identification it was hard to know where the birds came from and whether there were any more in the area. They later turned out to be swans. Barcoding could have determined this



(a) Complete metamorphosis



(b) Incomplete metamorphosis

Figure 33.28 **Metamorphosis.** **(a)** Complete metamorphosis, as illustrated by the life cycle of a monarch butterfly. The adult butterfly has a completely different appearance than the larval caterpillar. **(b)** Incomplete metamorphosis, as illustrated by the life cycle of a grasshopper. The eggs hatch into nymphs, essentially miniature versions of the adult.

quickly. Aviation groups are also interested in bird barcoding. Following airplane–bird collisions, they would like to remove bird tissue from planes, identify the species, and then possibly be able to avoid its known migration routes. Barcodes for plants, based on a DNA sequence of the *matK* gene, were proposed in 2008. This simple barcode might be insufficient for plant identification in only a few instances, where hybrids are involved. Many scientists anticipate the day when handheld field barcoding identification devices appear. At the moment, barcoding involves a laboratory analysis taking about an hour and costing $2.00 per sample. Nevertheless, Dr. Herbert hopes to have half-a-million barcodes online by 2012.

Subphylum Crustacea: Crabs, Lobsters, Barnacles, and Shrimp The crustaceans are common inhabitants of marine environments, although some species live in fresh water and a few are terrestrial. Many are economically important food items for humans, including crabs, lobsters, crayfish, and shrimp, and smaller species are important food sources for other predators.

The crustaceans are unique among the arthropods in that they possess two pairs of antennae at the anterior end of the body—the antennule (first pair) and antenna (second pair) (Figure 33.30). In addition, they have three or more sensory and feeding appendages that are modified mouthparts: the mandibles, maxillae, and maxillipeds. These are followed by walking legs and, often, additional abdominal appendages, called swimmerets, and a powerful tail consisting of a telson and uropod. In some orders, the first pair of walking legs, or chelipeds, is modified to form powerful claws. A lost crustacean appendage can regrow. The head and thorax are often fused together, forming the cephalothorax. In many species, the cuticle covering the head extends over most of the cephalothorax, forming a hard protective fold called the **carapace**. For growth to occur, a crustacean must shed the entire exoskeleton.

Many crustaceans are predators, but others are scavengers, and some, such as barnacles, are suspension feeders. Gas exchange typically occurs via gills, and crustaceans, like other arthropods, have an open circulatory system. Crustaceans possess two excretory organs: antennal glands and maxillary glands, both modified metanephridia, which open at the bases of the antennae and maxillae, respectively. Reproduction usually involves separate sexes, and fertilization is internal. Most species carry their eggs in brood pouches under the female's body. Eggs of most species produce larvae that must go through many different molts prior to assuming adult form. The first of these larval stages, called a **nauplius**, is very different in appearance from the adult crustacean (Figure 33.31).

(a) Worker and soldier ants (b) Queen ant

Figure 33.29 The division of labor in insect societies. Individuals from the same insect colony may appear very different. Among these army ants (*Eciton burchelli*) from Paraguay, there are **(a)** workers that forage for the colony, soldiers that protect the colony from predators, and **(b)** the queen, which reproduces and lays eggs.

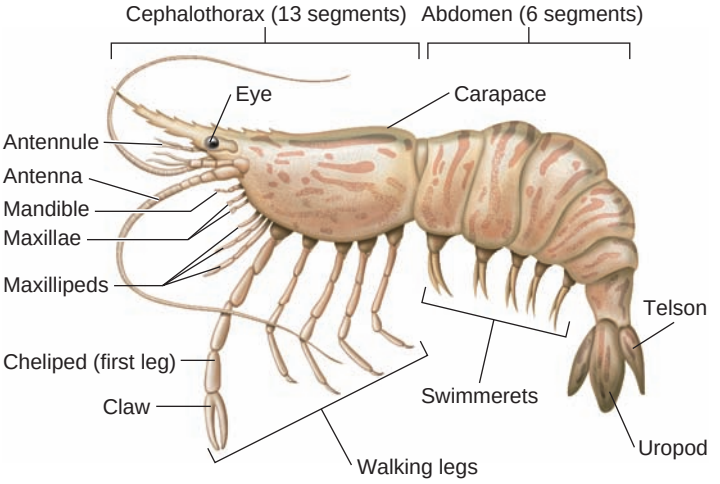


Figure 33.30 Body plan of a crustacean, as represented by a shrimp.

While there are many crustacean clades, most are small and obscure, although many feature prominently in marine food chains, a series of organisms in which each member of the chain feeds on and derives energy from the member below it. These include the Ostracoda, Copepoda, Cirripedia, and Malacostraca. Ostracods are tiny creatures that superficially resemble clams, and copepods are tiny and abundant planktonic crustaceans, both of which are a food source for filter-feeding organisms and small fish. The clade Cirripedia is composed of the barnacles, crustaceans whose carapace forms calcified plates that cover most of the body (Figure 33.32a). Their legs are modified into feathery filter-feeding structures.

Malacostracans are divided into many orders. Euphausiacea are shrimplike krill that grow to about 3 cm and provide a large part of the diet of many whales. The order Isopoda contains many small species that are parasitic on marine fishes. There are also terrestrial isopods, better known as pill bugs, or wood lice, that retain a strong connection to water and need to live in moist environments such as leaf litter or decaying logs (Figure 33.32b). When threatened, they curl up into a tight ball, making it difficult for predators to get a grip on them.

The most famous Malacostracan order, however, is the Decapoda, which includes the crabs and lobsters, the largest crustacean species (Figure 33.32c). As their name suggests, these decapods have 10 walking legs (five pairs), although the first pair is invariably modified to support large claws. Most decapods are marine, but there are many freshwater species, such as crayfish, and in hot, moist tropical areas, even some terrestrial species called land crabs. The larvae of many larger crustaceans

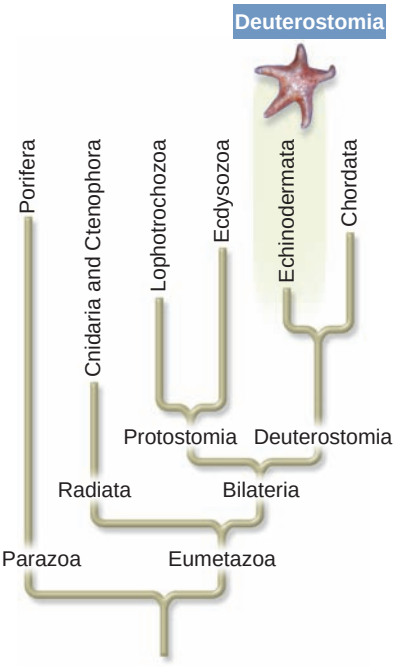
Figure 33.31 **Crustacean larva.** The nauplius is a distinct larval type possessed by most crustaceans, which molts several times before reaching maturity.

are planktonic and grow to about 3 cm. These are abundant in some oceans and are a staple food source for many species.

33.5 Deuterostomia: The Echinoderms and Chordates

As we explored in Chapter 32, the deuterostomes are grouped together because they share similarities in patterns of development (refer back to Figure 32.5). Molecular evidence also supports a deuterostome clade. All animals in the phylum Chordata, which includes the vertebrates, are deuterostomes. Interestingly, so is one invertebrate group, the phylum Echinodermata, which includes the sea stars, sea urchins, and sea cucumbers. While there are far fewer phyla and species of deuterostomes than protostomes, the species are generally much more familiar to us. After all, we humans are deuterostomes. While the majority of the deuterostome clade will be discussed in Chapter 34, we will conclude our discussion of invertebrate biology by turning our attention to the invertebrate deuterostomes. In this section, we will explore the phylum Echinodermata and then introduce the phylum Chordata, looking in particular at its distinguishing characteristics and at its two invertebrate subphyla: the cephalochordates, commonly referred to as the lancelets, and the urochordates, also known as the tunicates.

The Phylum Echinodermata Includes Sea Stars and Sea Urchins, Species with a Water Vascular System



The phylum Echinodermata (from the Greek *echinos*, meaning spiny, and *derma*, meaning skin) consists of a unique grouping of deuterostomes. A striking feature of all echinoderms is their modified radial symmetry. The body of most species can be divided into five parts pointing out from the center. As a consequence, cephalization is absent in most classes. There is no brain and only a simple nervous system consisting of a central nerve ring from which radial branches to each limb arise. The radial symmetry of echinoderms is secondary, however, because the free-swimming larvae have bilateral symmetry and metamorphose into the radially symmetrical adult form.

Most echinoderms have an **endoskeleton** (internal skeleton) composed of calcareous plates overlaid by a thin skin (Figure 33.33). The skeleton is covered with spines and jawlike pincers called pedicellariae, the primary purpose of which is to deter settling of animals such as barnacles. These structures can also possess poison glands.

A portion of the coelom has been adapted to serve as a unique **water vascular system**, a network of canals that branch into tiny **tube feet** that function in movement, gas exchange, feeding, and excretion (see inset to Figure 33.33). The water vascular system is powered by hydraulic power, that is, by water pressure generated by the contraction of muscles that enables the extension and contraction of the tube feet, allowing echinoderms to move only very slowly.

(a) Goose barnacles—order Cirripedia

(b) Pill bug—order Isopoda

(c) Coral crab—order Decapoda

Figure 33.32 **Common crustaceans.** **(a)** Goose barnacles (*Lepas anatifera*). **(b)** Pill bug, or wood louse (*Armadillium vulgare*). **(c)** Coral crab (*Carpilius maculates*).

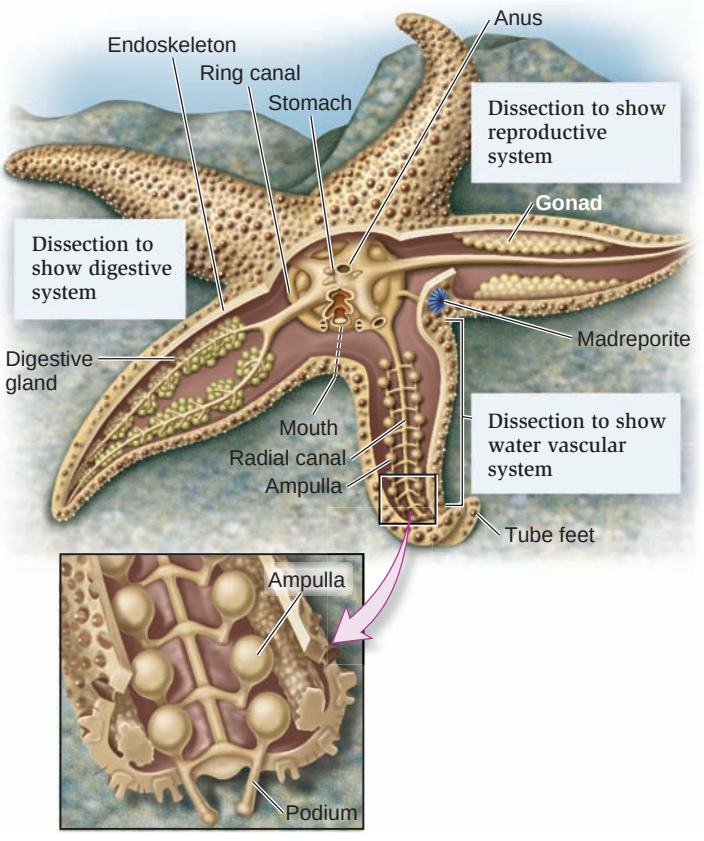


Figure 33.33 **Body plan of an echinoderm, as represented by a sea star.** The arms of this sea star have been dissected to different degrees to show the echinoderm's various organs. The inset shows a close-up view of the tube feet, part of the water vascular system characteristic of echinoderms.

Concept check: *Echinoderms and chordates are both deuterostomes. What are three defining features of deuterostomes?*

Water enters the water vascular system through the **madreporite**, a sievelike plate on the animal's surface. From there it flows into a **ring canal** in the central disc, into five radial canals, and into the tube feet. At the base of each tube foot is a muscular sac called an **ampulla**, which stores water. Contractions of the ampullae force water into the tube feet, causing them to straighten and extend. When the foot contacts a solid surface, muscles in the foot contract, forcing water back into the ampulla. Sea stars also use their tube feet in feeding, where they can exert a constant and strong pressure on bivalves, whose adductor muscles eventually tire, allowing the shell to open slightly. At this stage, the sea star everts its stomach and inserts it into the opening. It then digests its prey, using juices secreted from extensive digestive glands. Sea stars also feed on sea urchins, brittle stars, and sand dollars, prey that cannot easily escape them.

Echinoderms cannot osmoregulate, so no species have entered freshwater environments. No excretory organs are present. For some species, both respiration and excretion of nitrogenous waste take place by diffusion across their tube feet. Coelomic fluid circulates around the body.

Most echinoderms exhibit **autotomy**, the ability to intentionally detach a body part, such as a limb, that will later regenerate. In some species, a broken limb can even regenerate into a whole animal. Some sea stars regularly reproduce by breaking in two. Most echinoderms reproduce sexually and have separate sexes. Fertilization is usually external, with gametes shed into the water. Fertilized eggs develop into free-swimming larvae, which become sedentary adults.

While over 20 classes of echinoderms have been described from the fossil record, only 5 main classes of echinoderms exist today: the Asteroidea (sea stars), Ophiuroidea (brittle stars), Echinoidea (sea urchins and sand dollars), Crinoidea (sea lilies and feather stars), and Holothuroidea (sea cucumbers). The key features of the echinoderms and their classes are listed in Table 33.7.

The most unusual of the echinoderms are members of the class Holothuroidea, the sea cucumbers. These animals really do look like a cucumber rather than a sea star or sea urchin (Figure 33.34). The hard plates of the endoskeleton are less extensive, so the animal appears and feels fleshy. Sea cucumbers possess specialized respiratory structures called respiratory trees that pump water in and out of the anus. They are typically deposit feeders, ingesting sediment and extracting nutrients.

When threatened by a predator, a few tropical species of sea cucumber can eject sticky, toxic substances from their anus. If these do not deter the predator, a member of these species can undergo the process of evisceration—ejecting its digestive

Table 33.7 Main Classes and Characteristics of Echinoderms

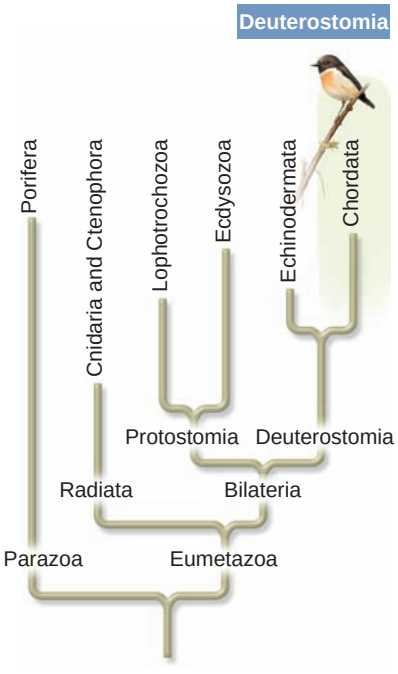
	Class and examples (est. # of species)	Class characteristics
	Asteroidea: sea stars (1,600)	Five arms; tube feet; predatory on bivalves and other echinoderms; eversible stomach
	Ophiuroidea: brittle stars (2,000)	Five long, slender arms; tube feet not used for locomotion; no pedicellariae; browse on sea bottom or filter feed
	Echinoidea: sea urchins, sand dollars (1,900)	Spherical (sea urchins) or disc-shaped (sand dollars); no arms; tube feet and moveable spines; pedicellariae present; many feed on seaweeds
	Crinoidea: sea lilies and feather stars (700)	Cup-shaped; often attached to substrate via stalk; arms feathery and used in filter feeding; very abundant in fossil record
	Holothuroidea: sea cucumbers (1,200)	Cucumber-shaped; no arms; spines absent; endoskeleton reduced; tube feet; browse on sea bottom

Figure 33.34 The edible sea cucumber, *Holothuria edulis*, on the Great Barrier Reef, Australia.

Concept check: *What are two unique features of an echinoderm?*

tract, respiratory structures, and gonads from the anus. If the sea cucumber survives, it can regenerate its organs later. The pearl fish has a particularly intriguing relationship with sea cucumbers. It takes advantage of the sea cucumber's defenses by darting inside its anus for protection. At first, the sea cucumber resists the pearl fish, but because it breathes through its anus, it is only a matter of time before another opportunity is afforded to the fish.

The Phylum Chordata Includes All the Vertebrates and Some Invertebrates



The deuterostomes consist of two major phyla: the echinoderms and the chordates (from the Greek *chorde*, meaning string). As deuterostomes, both phyla share similar developmental traits. In addition, both have an endoskeleton, consisting in the echinoderms of calcareous plates and in chordates, for the most part, of bone. However, the echinoderm endoskeleton functions in much the same way as the arthropod exoskeleton, in that its primary function is providing protection. The chordate endoskeleton serves a very different purpose. In early-divergent chordates, the endoskeleton is composed of a single flexible rod situated dorsally, deep inside the body. Muscles move this rod, and their contractions cause the back and tail end to move from side to side, permitting a swimming motion in water. The endoskeleton becomes more complex in different lineages that develop limbs, as we will see in Chapter 34, but it is always internal, with muscles attached. This arrangement permits the possibility of complex movements, including the ability to move on land.

Let's take a look at the four critical innovations in the body design of chordates that distinguish them from all other animal life (Figure 33.35):

1. **Notochord.** Chordates are named for the **notochord**, a single flexible rod that lies between the digestive tract and the nerve cord. Composed of fibrous tissue encasing fluid-filled cells, the notochord is stiff yet flexible and provides skeletal support for all early-diverging chordates. In most chordates, such as vertebrates, a more complex jointed backbone usually replaces the notochord; its remnants exist only as the soft material within the discs of vertebrae.
2. **Dorsal hollow nerve cord.** Many animals have a long nerve cord, but in nonchordate invertebrates, it is a solid tube that lies ventral to the alimentary canal. In contrast, the nerve cord in chordates is a hollow tube that develops dorsal to the alimentary canal. In 1822, the French naturalist Geoffroy Saint-Hilaire argued that this difference suggested that the ventral side of nonchordate invertebrates (as exemplified by the lobster) was homologous to the dorsal side of vertebrates. Some recent molecular work suggests that, as Hilaire first proposed, an inversion of the dorsoventral axis occurred during animal evolution. In vertebrates, the dorsal hollow nerve cord develops into the brain and spinal cord.
3. **Pharyngeal slits.** Chordates, like many animals, have a complete gut, from mouth to anus. However, in chordates, slits develop in the pharyngeal region, close to the mouth, that open to the outside. This permits water to enter through the mouth and exit via the slits, without having to go through the digestive tract. In early-divergent chordates, **pharyngeal slits** function as a filter-feeding

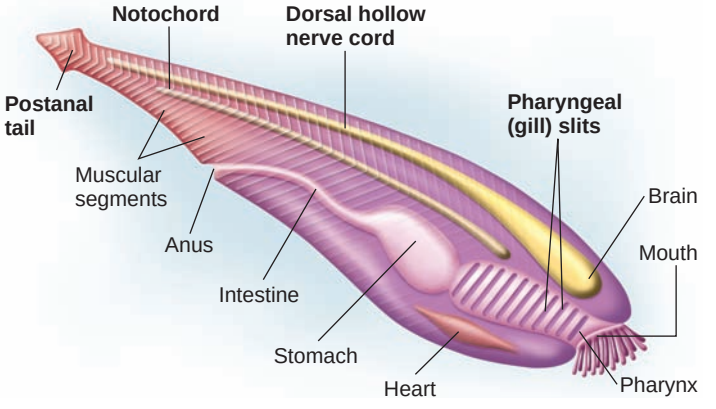


Figure 33.35 **Chordate characteristics.** The generalized chordate body plan has four main features: notochord, dorsal hollow nerve cord, pharyngeal slits, and postanal tail.

device, whereas in later-divergent chordates, they develop into gills for gas exchange. In terrestrial chordates, the slits do not fully form, and they become modified for other purposes, such as the auditory (Eustachian) tubes in ears.

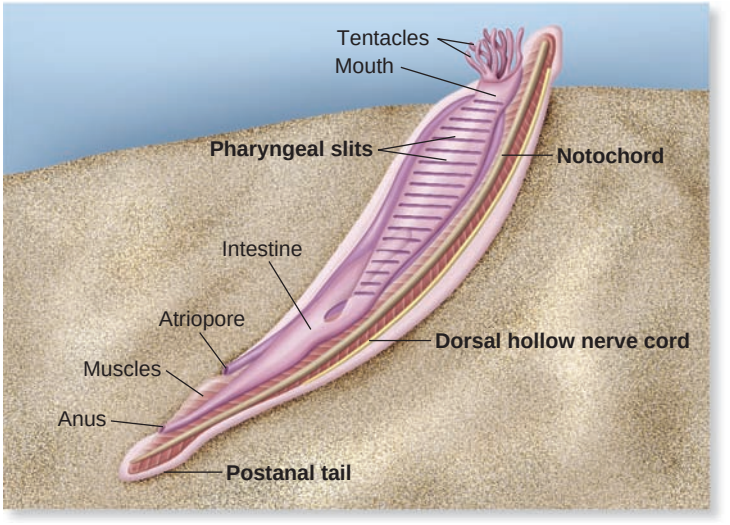
4. **Postanal tail.** Chordates possess a postanal tail of variable length that extends posterior to the anal opening. In aquatic chordates such as fishes, the tail is used in locomotion. In terrestrial chordates, the tail may be used in a variety of functions or may be absent, as in humans. In virtually all other nonchordate phyla, the anus is at the end of the body.

Although few chordates apart from fishes possess all of these characteristics in their adult life, they all exhibit them at some time during development. For example, in adult humans, the notochord becomes the spinal column, and the dorsal hollow nerve cord becomes the central nervous system. However, humans exhibit pharyngeal slits and a postanal tail only during early embryonic development. All the pharyngeal slits, except one, which forms the auditory tubes in the ear, are eventually lost, and the postanal tail regresses to form the tailbone (the coccyx).

The phylum Chordata consists of the invertebrate chordates—the subphylum Cephalochordata (lancelets) and the subphylum Urochordata (tunicates)—along with the subphylum Craniata, which includes Vertebrata. Although the Craniata is by far the largest of these subphyla, biologists have focused on the Cephalochordata and Urochordata for clues as to how the chordate phylum may have evolved. Comparisons of gene sequences coding for 18S rRNA show that these two subphyla are our closest invertebrate relatives (Figure 33.36).

Subphylum Cephalochordata: The Lancelets The cephalochordates (from the Greek *cephalo*, meaning head) look a lot more chordate-like than do tunicates. They are commonly referred to as lancelets, in reference to their bladelike shape and size, about 5–7 cm in length (Figure 33.37a). Lancelets are a small subphylum of 26 species, all marine filter feeders, with 4 species occurring in North American waters. Most of them belong to the genus *Branchiostoma*.

(a) Lancelet in the sand



(b) Body plan of the lancelet

Figure 33.37 **Lancelets.** (a) A bladelike lancelet. (b) The body plan of the lancelet clearly displays the four characteristic chordate features.

The lancelets live mostly buried in sand, with only the anterior end protruding into the water so that they can filter feed through the mouth. Lancelets have the four distinguishing chordate characteristics: a clearly discernible notochord (extending well into the head), dorsal hollow nerve cord, pharyngeal slits, and postanal tail (Figure 33.37b). Water enters the mouth and

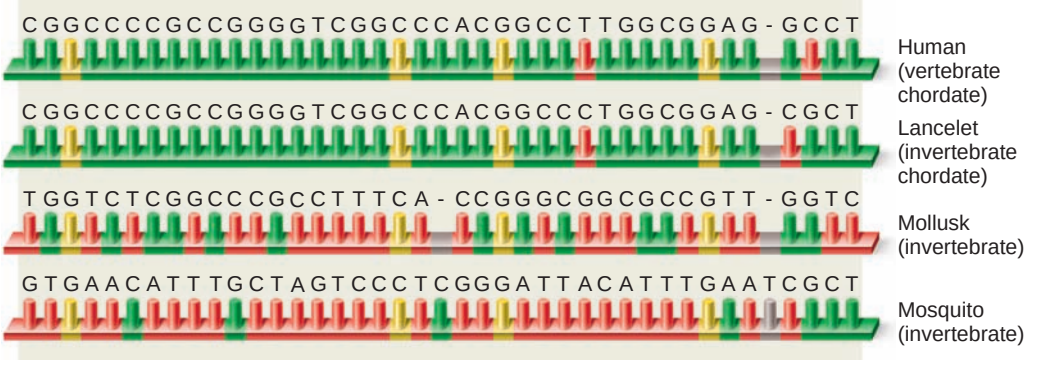


Figure 33.36 **Comparison of small subunit rRNA gene sequences of chordate and nonchordate species.** The similarities between the invertebrate chordates (represented by the lancelet) and the vertebrates (represented by a human) suggest they are indeed our closest invertebrate relatives.

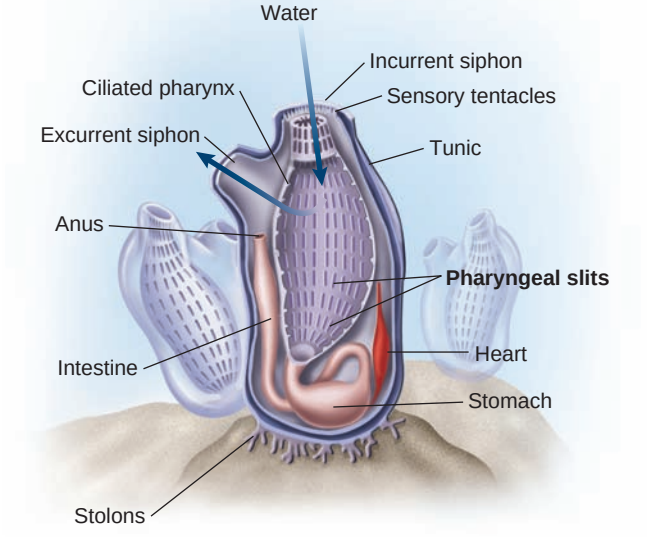
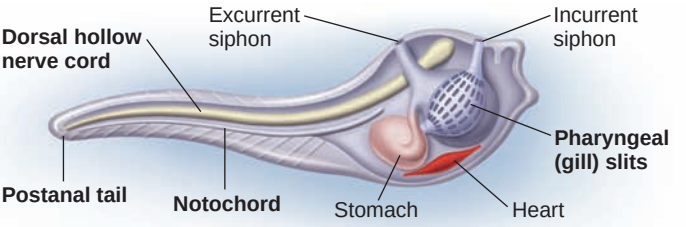


(a) Adult tunicate



(b) The larval form of the tunicate

(c) Typical tunicate

Figure 33.38 **Tunicates.** **(a)** Body plan of the sessile, filter-feeding adult tunicate. **(b)** The larval form, which shows the four characteristic chordate features, has been proposed as a possible ancestor of modern vertebrates. **(c)** The blue tunicate, *Rhopalaea crassa.*

moves into the pharynx, where it is filtered through the pharyngeal slits. A mucous net across the pharyngeal slits traps food particles, and ciliary action takes the food into the digestive tract, while water exits via the atriopore. Gas exchange generally takes place across the body surface. Although the lancelet is usually sessile, it can leave its sandy burrow and swim to a new spot, using a sequence of serially arranged muscles that appear like chevrons (<<<<) along its sides. These muscles reflect the segmented nature of the lancelet body.

Subphylum Urochordata: The Tunicates The urochordates (from the Greek *oura*, meaning tail) are a group of 3,000 marine species also known as tunicates. Looking at an adult tunicate, you might never guess it is a relative of modern vertebrates. The only one of the four distinguishing chordate characteristics that it possesses is pharyngeal slits (Figure 33.38a). The larval tunicate, in contrast, looks like a tadpole and exhibits all four chordate hallmarks (Figure 33.38b). The larval tadpole swims for only a few days, usually without feeding. Larvae settle on and attach to a rock surface via rootlike extensions called stolons. Here the larvae metamorphose into adult tunicates and in the process lose most of their chordate characteristics. In 1928, the marine biologist Walter Garstang suggested modern vertebrates arose from a larval tunicate form that had somehow acquired the ability to reproduce. Recent analyses of molecular data have led Frédéric Delsuc and colleagues to propose that tunicates are the closest living relatives of vertebrates. These authors also group the cephalochordates most closely with the echinoderms. This means the common ancestor of living deuterostomes was a free-living, bilaterally symmetrical animal with gill slits, a segmented body, and a sophisticated brain. This ancestral line split into two groups, the echinoderm–cephalochordate group and the tunicate–vertebrate group. Echinoderms lost most of their ancestral features, but cephalochordates did not. In this view, tunicates lost their segmentation and most became sedentary, whereas vertebrates did not.

Adult tunicates are marine animals, some of which are colonial and others solitary, that superficially resemble sponges or cnidarians. Tunicates are filter feeders that draw water through the mouth through an **incurrent siphon**, using a ciliated pharynx, and filter it through extensive pharyngeal slits. The food is trapped on a mucous sheet; passes via ciliary action to the stomach, intestine, and anus; and exits through the excurrent siphon. The whole animal is enclosed in a nonliving **tunic** that it secretes, made of a protein and a cellulose-like material called tunicin. Tunicates are also known as sea squirts for their ability to squirt out water from the excurrent siphon when disturbed. There is a rudimentary circulatory system with a heart and a simple nervous system of relatively few nerves connected to sensory tentacles around the incurrent siphon. The animals are mostly hermaphroditic.

As a reference, Table 33.8 describes the common body characteristics of the various animal phyla that we have considered in this chapter.

Table 33.8 Summary of the Physical Characteristics of the Major Animal Phyla

Feature	Porifera (sponges)	Cnidaria and Ctenophora (hydra, anemones, jellyfish)	Platyhelminthes (flatworms)	Rotifera (rotifers)	Lophophorata (bryozoans and others)	Mollusca (snails, clams, squid)	Annelida (segmented worms)	Nematoda (roundworms)	Arthropoda (insects, arachnids, crustaceans)	Echinodermata (sea stars, sea urchins)	Chordata (vertebrates and others)
											
Digestive system	Absent	Gastrovascular cavity; ctenophores have complete gut	Gastrovascular cavity	Complete gut (usually)	Complete gut	Complete gut	Complete gut	Complete gut	Complete gut	Usually complete gut	Complete gut
Circulatory system	Absent	Absent	Absent	Absent	Absent; open; or closed	Open; closed in cephalopods	Closed	Absent	Open	Absent	Closed
Respiratory system	Absent	Absent	Absent	Absent	Absent	Gills	Absent	Absent	Trachae; gills; or book lungs	Tube feet; respiratory tree	Gills; lungs
Excretory system	Absent	Absent	Protonephridia with flame cells	Protonephridia	Metanephridia	Metanephridia	Metanephridia	Excretory tubules	Excretory glands resembling metanephridia	Absent	Kidneys
Nervous system	Absent	Nerve net	Brain; cerebral ganglia; lateral nerve chords; nerve net	Brain; nerve cords	No brain; nerve ring	Ganglia; nerve cords	Brain; ventral nerve cord	Brain; nerve cords	Brain; ventral nerve cord	No brain; nerve ring and radial nerves	Well-developed brain; dorsal hollow nerve cord
Reproduction	Sexual; asexual (budding)	Sexual; asexual (budding)	Sexual (most hermaphroditic); asexual (body splits)	Mostly parthenogenetic; males appear only rarely	Sexual (some hermaphroditic); asexual (budding)	Sexual (some hermaphroditic)	Sexual (some hermaphroditic)	Sexual (some hermaphroditic)	Usually sexual (some hermaphroditic)	Sexual (some hermaphroditic); parthenogenetic; asexual by regeneration (rare)	Sexual; rarely parthenogenetic
Support	Endoskeleton of spicules and collagen	Hydrostatic skeleton	Hydrostatic skeleton	Hydrostatic skeleton	Exoskeleton	Hydrostatic skeleton and shell	Hydrostatic skeleton	Hydrostatic skeleton	Exoskeleton	Endoskeleton of plates beneath outer skin	Endoskeleton of cartilage or bone

Summary of Key Concepts

33.1 Parazoa: Sponges, the First Multicellular Animals

- Invertebrates, or animals without a backbone, make up more than 95% of all animal species. An early lineage—the Parazoa—consists of one phylum, the Porifera, or sponges. Although sponges lack true tissues, they are multicellular animals possessing several types of cells. (Figures 33.1, 33.2)

33.2 Radiata: Jellyfish and Other Radially Symmetrical Animals

- The Radiata consists of two phyla: the Cnidaria (hydra, jellyfish, box jellies, sea anemones, and corals) and the Ctenophora (comb jellies). Radiata have only two embryonic germ layers: the ectoderm and endoderm, with a gelatinous substance (mesoglea) connecting the two layers.
- Cnidarians exist as two forms: polyp and medusa. A characteristic feature of cnidarians is their stinging cells, or cnidocytes, which function in defense and prey capture. Ctenophores possess the first complete gut, and nearly all exhibit bioluminescence. (Figures 33.3, 33.4, 33.5, 33.6, Table 33.1)

33.3 Lophotrochozoa: The Flatworms, Rotifers, Lophophorates, Mollusks, and Annelids

- The Lophotrochozoa include taxa that possess either a lophophore or trochophore larva. Platyhelminthes, or flatworms, are regarded as the first animals to have the organ-system level of organization. (Figure 33.7, Table 33.2)
- The four classes of flatworms are the Turbellaria, Monogenea, Trematoda (flukes), and Cestoda (tapeworms). Flukes and tapeworms are internally parasitic, with complex life cycles. (Figures 33.8, 33.9)
- Rotifers are microscopic animals that have a complete digestive tract with separate mouth and anus; the mastax, a muscular pharynx, is a structure unique to the rotifers. (Figure 33.10)
- The lophophorates consist of the phoronids, bryozoa, and brachiopods, all of which possess a lophophore, a ciliary feeding structure. (Figure 33.11)
- The mollusks, which constitute a large phylum with over 100,000 diverse living species, have a basic body plan with

three parts—a foot, a visceral mass, and a mantle—and an open circulatory system. (Figures 33.12, 33.13)

- The four most common mollusk classes are the polyplacophora (chitons), gastropoda (snails and slugs), bivalvia (clams and mussels), and cephalopoda (octopuses, squids, and nautiluses). (Table 33.3)
- Cephalopods are among the most complex of all invertebrates. They are the only mollusks with a closed circulatory system; they have a well-developed nervous system and brain and are believed to exhibit learning by observation. (Figures 33.14, 33.15, 33.16)
- Segmentation, in which the body is divided into compartments, is a critical evolutionary innovation in the annelids, although specialization of segments is only minimally present at the anterior end. (Figure 33.17)
- Annelids are a large phylum with two main classes: Polychaeta (the most species-rich class) and Clitellata (which includes the earthworms and leeches). (Table 33.4, Figure 33.18)

33.4 Ecdysozoa: The Nematodes and Arthropods

- The ecdysozoans are so named for their ability to shed their cuticle, a nonliving cover providing support and protection. The two most common ecdysozoan phyla are the nematodes and the arthropods.
- Nematodes, which exist in nearly all habitats, have a cuticle made of collagen, a structural protein. The small, free-living nematode *Caenorhabditis elegans* is a model organism. Many nematodes are parasitic in humans, including *Wuchereria bancrofti*, which causes elephantiasis. (Figures 33.19, 33.20)
- Arthropods are perhaps the most successful phylum on Earth. The arthropod body is covered by a cuticle made of layers of chitin and protein, and it is segmented, with segments fused into functional units called tagmata. (Figure 33.21)
- The five main subphyla of arthropods are Trilobita (trilobites; now extinct), Chelicerata (spiders, scorpions, and relatives), Myriapoda (millipedes and centipedes), Hexapoda (insects), and Crustacea (crabs and relatives). (Table 33.5, Figures 33.22, 33.23, 33.24, 33.25, 33.26)
- More insect species are known than all other animal species combined. The barcoding project developed in 2003 by Paul Herbert aims to distinguish all species by a small piece of their DNA; this may be useful in identifying some of the millions of insect species. (Table 33.6)
- The development of a variety of wing structures and mouthparts was a key to the success of insects. (Figure 33.27)
- Insects undergo a change in body form during development, either complete metamorphosis or incomplete metamorphosis, and have developed complex social behaviors. (Figures 33.28, 33.29)
- Most crustacean orders are small and feature prominently in marine food chains. The most well-known order of crustaceans is the Decapoda, which includes the crabs, lobsters, and shrimp. (Figures 33.30, 33.31, 33.32)

33.5 Deuterostomia: The Echinoderms and Chordates

- The Deuterostomia includes the phyla Echinodermata and Chordata. A striking feature of the echinoderms is their radial symmetry, which is secondary; the free-swimming larvae are bilaterally symmetrical. Echinoderms possess a unique water vascular system. (Figure 33.33)
- Five main classes of echinoderms exist today: the Asteroidea (sea stars), Ophiuroidea (brittle stars), Echinoidea (sea urchins and sand dollars), Crinoidea (sea lilies and feather stars), and Holothuroidea (sea cucumbers). (Table 33.7, Figure 33.34)
- The phylum Chordata is distinguished by four critical innovations: the notochord, dorsal hollow nerve chord, pharyngeal slits, and postanal tail. (Figure 33.35)
- The subphylum Cephalochordata (lancelets) and subphylum Urochordata (tunicates) are invertebrate chordates. Genetic studies have shown that tunicates are the closest invertebrate relatives of the vertebrate chordates (subphylum Craniata). (Figures 33.36, 33.37, 33.38, Table 33.8)

Assess and Discuss

Test Yourself

1. Choanocytes are
   a. a group of protists that are believed to have given rise to animals.
   b. specialized cells of sponges that function to trap and eat small particles.
   c. cells that make up the gelatinous layer in sponges.
   d. cells of sponges that function to transfer nutrients to other cells.
   e. cells that form spicules in sponges.
2. Why aren't sponges eaten more by predators?
   a. They are protected by silica spicules.
   b. They are protected by toxic defensive chemicals.
   c. They are eaten; it's just that the leftover cells reaggregate into new, smaller sponges.
   d. Both a and b are correct.
   e. a, b, and c are correct.
3. Which of the following organisms can produce female offspring through parthenogenesis?
   a. cnidarians c. choanocytes e. annelids
   b. flukes d. rotifers
4. What organisms can survive without a mouth, digestive system, or anus?
   a. cnidarians c. echinoderms e. nematodes
   b. rotifers d. cestodes
5. Which phylum does not have at least some members with a closed circulatory system?
   a. Lophophorata
   b. Arthopoda
   c. Annelida
   d. Mollusca
   e. All of the above phyla have some members with a closed circulatory system.

6. A defining feature of the Ecdysozoa is
   a. a segmented body.
   b. a closed circulatory system.
   c. a cuticle.
   d. a complete gut.
   e. a lophophore.
7. In arthropods, the tracheal system is
   a. a unique set of structures that function in ingestion and digestion of food.
   b. a series of branching tubes extending into the body that allow for gas exchange.
   c. a series of tubules that allow waste products in the blood to be released into the digestive tract.
   d. the series of ommatidia that form the compound eye.
   e. none of the above.
8. Characteristics of the class Arachnida include
   a. two tagmata.
   b. six walking legs.
   c. an aquatic lifestyle.
   d. a lobed body.
   e. both b and d.
9. Incomplete metamorphosis
   a. is characterized by distinct larval and adult stages that do not compete for resources.
   b. is typically seen in arachnids.
   c. involves gradual changes in life stages where young resemble the adult stage.
   d. is characteristic of the majority of insects.
   e. always includes a pupal stage.
10. Echinodermata are <u>not</u> a member of which clade?
    a. protostomia
    b. bilateria
    c. eumetazoa
    d. metazoa
    e. They are a member of all the above clades.

Conceptual Questions

1. Compare and contrast the five main feeding types discussed in the chapter.
2. Define nematocyst, and explain its function.
3. Explain the difference between complete metamorphosis and incomplete metamorphosis.

Collaborative Questions

1. What animals exhibit complete metamorphosis?
2. Discuss the four defining characteristics of chordates.

Chapter Outline

The Vertebrates

34

Giant pandas (*Ailuropoda melanoleuca*). The species, shown here in Sichuan, China, is one of many charismatic vertebrate species. Because the giant panda is an endangered species, conservation efforts are underway to try to protect the remaining populations.

Vertebrates range in size from tiny fishes weighing 0.1 g to huge whales of over 100,000 kg. They occupy nearly all of Earth's habitats, from the deepest depths of the oceans to mountaintops and the sky beyond. Throughout history, humans have depended on many vertebrate species for their welfare. They have domesticated species such as horses, cattle, pigs, sheep, and chickens and have kept countless species, including cats and dogs, as pets. Many other vertebrate species are the subjects of conservation efforts, as we will see in Chapter 60 (also see chapter-opening photo). Some vertebrate species that require large areas for their survival are considered to be umbrella species. Their preservation will help ensure the conservation of others.

In Chapter 33, we discussed two chordate subphyla, the Cephalochordates (lancelets) and Urochordates (tunicates). The third subphylum of chordates, the Craniata, with about 53,000 species, is by far the largest and most dominant group of chordates. In this chapter, we begin by outlining the characteristics of **craniates**, chordates that have a brain encased in a skull. We will take a brief look at the hagfish, a craniate that has some, but not all, vertebrate characteristics. In the remainder of the chapter, we will explore the characteristics of vertebrates, discussing the evolutionary development of the major vertebrate classes, including fishes, amphibians, reptiles, and mammals.

Our current understanding of the relationships between the vertebrate groups is shown in Figure 34.1. Nested within the vertebrates are various clades based on morphological characteristics. For example, most vertebrates have jaws and are collectively known as gnathostomes. Many gnathostomes have four limbs for movement and are known as tetrapods. Next, we explain these sequential divisions in the vertebrate lineage.

34.1 The Craniates: Chordates with a Head

Although all vertebrates are craniates, not all craniates are vertebrates. There is one type of animal, the eel-like hagfish, whose characteristics place it within the craniates but not within the vertebrates. Hagfish do not have a vertebral column—one of the vertebrate characteristics—but they do have a skull, in this case, one made of cartilage and not bone. (Therefore, despite its name, the hagfish cannot be considered a true fish.) Paleontologists in China have recently discovered similar fishlike fossils that date to around 530 million years ago, the time of the Cambrian explosion. These are believed to be the earliest known craniates. What makes an animal a craniate?

Craniates Are Distinguished by a Cranium and Neural Crest

Craniates have two defining characteristics that distinguish them from invertebrate chordates:

1. **Cranium.** In craniates, the anterior end of the nerve cord elaborates to form a more developed brain that is encased in a protective bony or cartilaginous housing called the **cranium**. This continues the trend of cephalization—the development of the head end in animals.

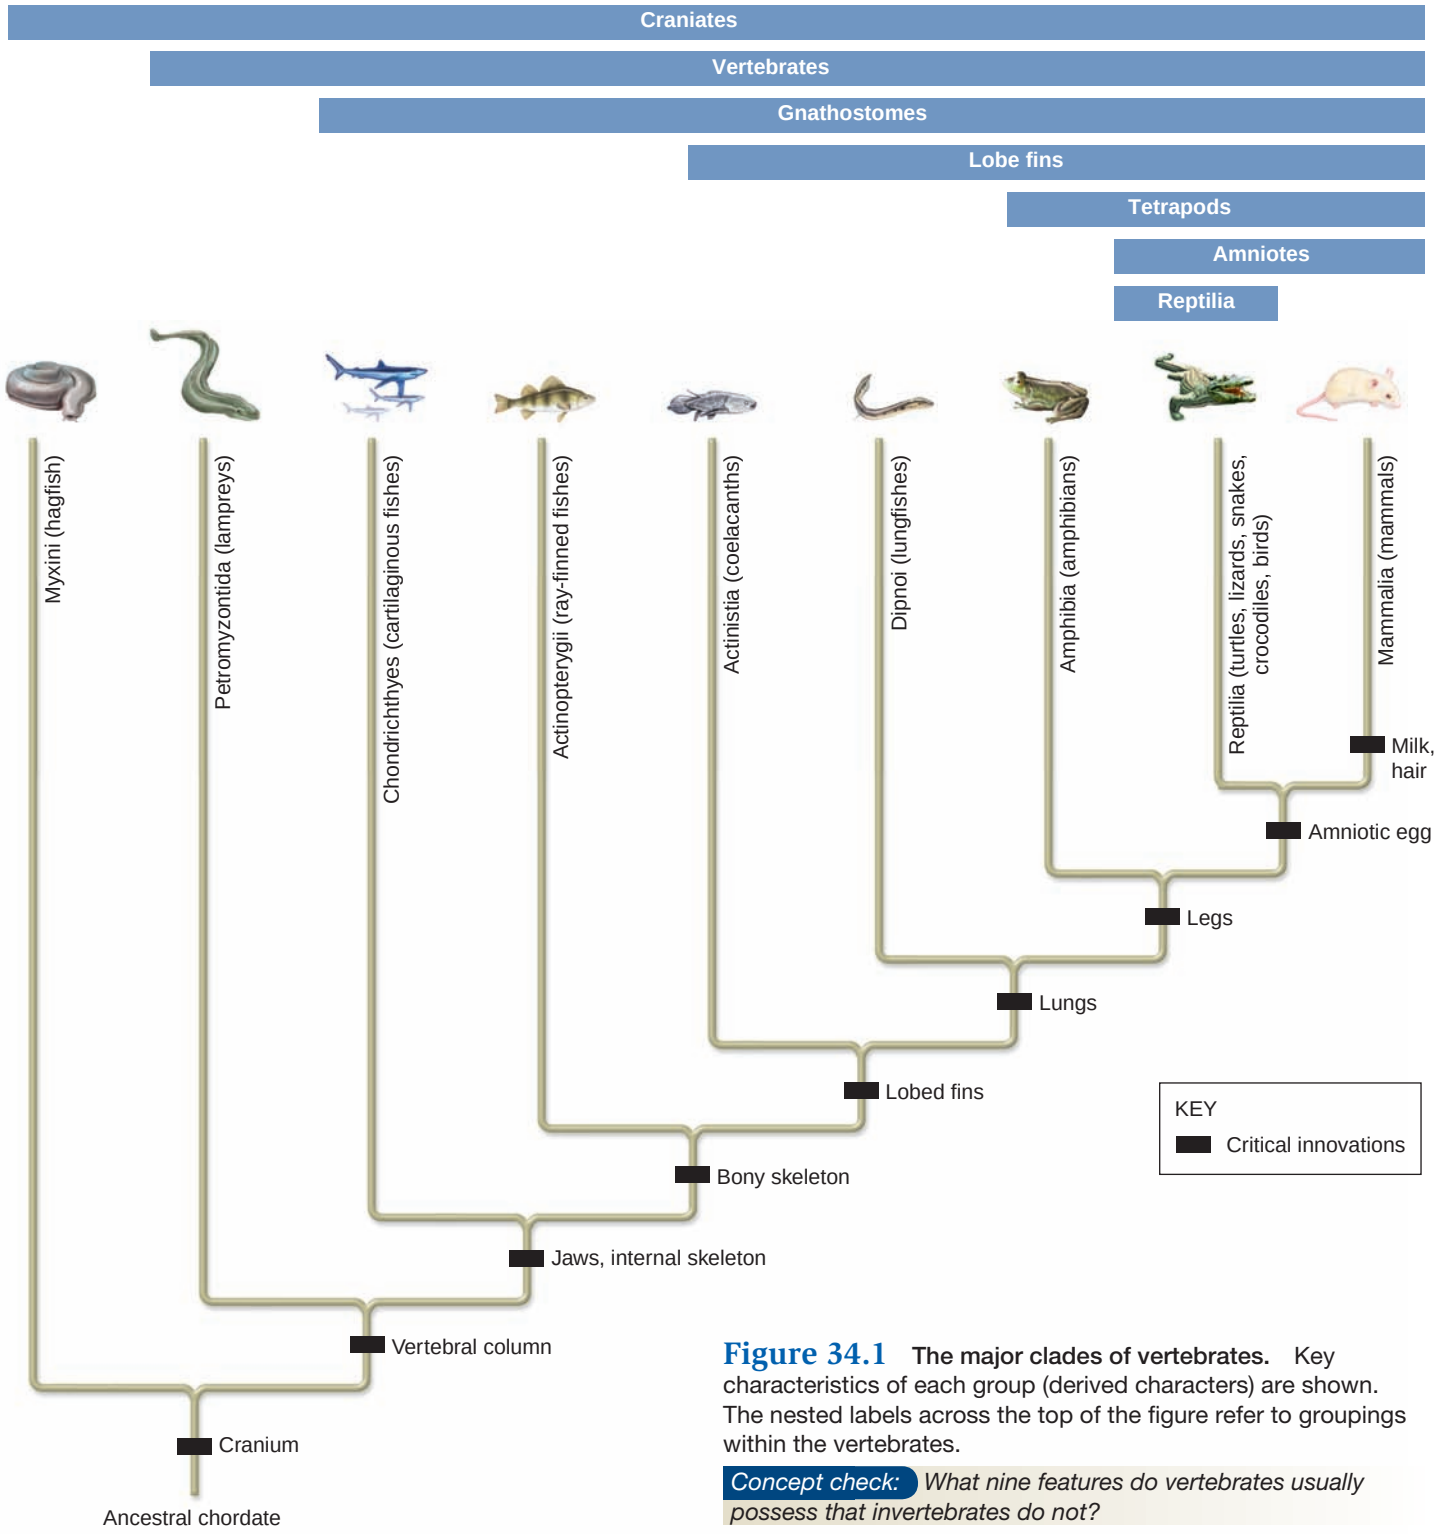

Figure 34.1 **The major clades of vertebrates.** Key characteristics of each group (derived characters) are shown. The nested labels across the top of the figure refer to groupings within the vertebrates.

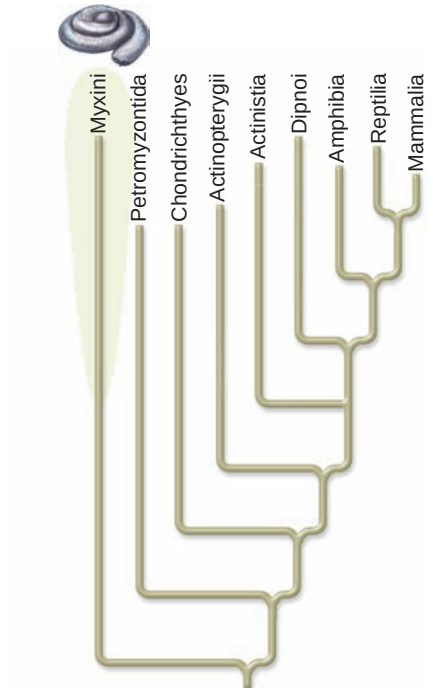
Concept check: *What nine features do vertebrates usually possess that invertebrates do not?*

2. **Neural crest.** The **neural crest** is a group of embryonic cells found on either side of the neural tube as it develops. The cells disperse throughout the embryo, where they contribute to the development of the skeleton, especially the cranium and other structures, including jaws and teeth.

Although these are the main distinguishing characteristics of craniates, there are others. For example, craniates have at least two clusters of *Hox* genes, compared to the single cluster of *Hox* genes in tunicates and lancelets. This additional gene cluster is believed to have permitted increasingly complex morphologies than those possessed by invertebrate chordates.

The Hagfish, Class Myxini, Are the Simplest Living Craniates



The hagfish are entirely marine craniates that lack eyes, jaws, and fins as well as vertebrae (Figure 34.2). The hagfish skeleton consists largely of a notochord and a cartilaginous skull that encloses the brain. The lack of a vertebral column leads to extensive flexibility. Hagfish live in the cold waters of northern oceans, close to the muddy bottom. Essentially blind, hagfish have a very keen sense of smell and are attracted to dead and dying fish, which they attach themselves to via toothed plates on the mouth. The powerful tongue then rasps off pieces of tissue. However, most of their diet consists of dead or disabled marine worms and other invertebrates. Though the hagfish cannot see approaching predators, they have special glands that produce copious amounts of slime, which may deter predatory attacks. When provoked, the hagfish's slime production increases dramatically, enough to potentially distract predators or coat their gills and interfere with breathing. Hagfish can sneeze to free their nostrils of their own slime.

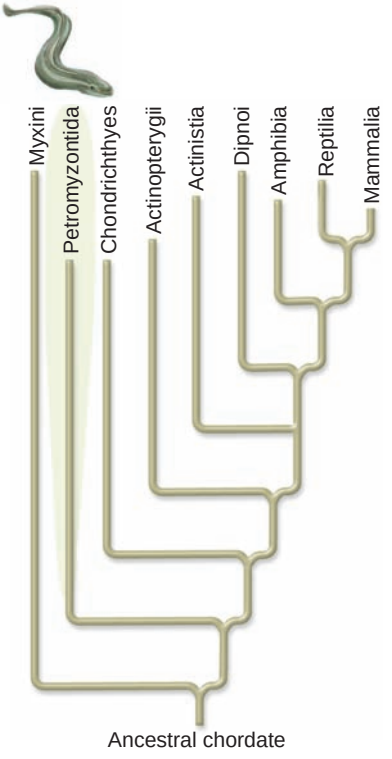
Figure 34.2 **The hagfish: a craniate that is not a vertebrate.** The hagfish possesses craniate characteristics (a skull and neural crest) but is not a true fish or vertebrate.

Concept check: *Why isn't the hagfish a true fish?*

34.2 Vertebrates: Craniates with a Backbone

The **vertebrates** (from the Latin *vertebratus*, meaning back boned) retain all chordate characteristics we outlined in Chapter 33 and all craniate characteristics noted previously, as well as possessing several additional traits, including the following:

1. **Vertebral column.** During development in vertebrates, the notochord is replaced by a bony or cartilaginous column of interlocking **vertebrae** that provides support and also protects the nerve cord, which lies within its tubelike structure.
2. **Endoskeleton of cartilage or bone.** The cranium and vertebral column are parts of the endoskeleton, the living skeleton of vertebrates that forms within the animal's body. Most vertebrates also have two pairs of appendages, whether fins, legs, or arms. The endoskeleton is composed of either bone or cartilage, both of which are very strong materials, yet they are more flexible than the chitin found in insects and other arthropods. The endoskeleton also contains living cells that secrete the skeleton, which grows with the animal, unlike the nonliving exoskeleton of arthropods.
3. **Diversity of internal organs.** Vertebrates possess a great diversity of internal organs, including a liver, kidneys, endocrine glands, and a heart with at least two chambers. The liver is unique to vertebrates, and the vertebrate kidneys, endocrine system, and heart are more complex than are analogous structures in other taxa.



Although these features are exhibited in all vertebrate classes, some classes developed critical innovations that helped them succeed in specific environments such as on land or in the air. For example, birds developed feathers and wings, structures that enable most species to fly. In fact, each of the vertebrate classes is distinctly different from one another, as outlined in Table 34.1. One of the earliest innovations was the development of jaws. All vertebrates except some early-diverging

Table 34.1 The Main Classes and Characteristics of Living Vertebrates

Class		Examples (approx. # of species)	Main characteristics
Petromyzontida		Lampreys (41)	Early-diverging fishes with jawless sucking mouth; no appendages, that is, fins; parasitic on fishes
Chondrichthyes		Sharks, skates, rays (850)	Fishes with cartilaginous skeleton; teeth not fused to jaw; no swim bladder; well-developed fins; internal fertilization; single blood circulation
Actinopterygii		Ray-finned fishes, most bony fish (24,600)	Fishes with ossified skeleton; single gill opening covered by operculum; fins supported by rays, fin muscles within body; swim bladder often present; mucous glands in skin
Actinistia		Lobe-finned fishes, of which coelacanths are the only living members (2)	Fishes with ossified skeleton; bony extensions, together with muscles, project into pectoral and pelvic fins; swim bladder filled with oil
Dipnoi		Lungfishes (6)	Fishes with ossified skeleton; rudimentary lungs allow fishes to come to the surface to gulp air; limblike appendages
Amphibia		Frogs, toads, salamanders (4,000)	Tetrapods; adults able to live on land; fresh water needed for reproduction; development usually involving metamorphosis from tadpoles; adults with lungs and double blood circulation; moist skin; shell-less eggs
Testudines		Turtles (330)	Body encased in hard shell; no teeth; head and neck retractable into shell; eggs laid on land
Lepidosauria		Lizards, snakes (7,800)	Lower jaw not attached to skull; skin covered in scales
Crocodilia		Crocodiles, alligators (23)	Four-chambered heart; large aquatic predators; parental care of young
Aves		Birds (9,600)	Feathers; hollow bones; air sacs; reduced internal organs; endothermic; four-chambered heart
Mammalia		Mammals (5,500)	Mammary glands; hair; specialized teeth; enlarged skull; external ears; endothermic; highly developed brains; diversity of body forms

fishes possessed jaws. Today, the only jawless vertebrates are lampreys.

The lampreys, class Petromyzontida, are eel-like fishes that lack jaws. Lampreys are unlike members of other vertebrate clades because they lack both a hinged jaw and true appendages. However, lampreys do possess a notochord surrounded by a cartilaginous rod that represents a rudimentary vertebral column; therefore, they represent one of the earliest-diverging groups of vertebrates.

Lampreys can be found in both marine and freshwater environments. Marine lampreys are parasitic as adults. They grasp other fish with their circular mouth (Figure 34.3a) and rasp a hole in the fish's side, sucking blood, tissue, and fluids until they are full (Figure 34.3b). Reproduction of all species is similar, whether they live in marine or freshwater environments. Males and females spawn in freshwater streams, and the resultant larval lampreys bury into the sand or mud, much like lancelets (refer back to Figure 33.37a), emerging to feed on small invertebrates or detritus at night. This stage can last for 3 to 7 years, at which time the larvae metamorphose into adults. In most freshwater species, the adults do not feed at all but quickly mate and die. Marine species migrate from fresh water back to the ocean, until they return to fresh water to spawn and then die. Although many other species of jawless fishes would evolve and thrive for over 300 million years, they all became extinct by the end of the Devonian period. Jawed fishes, which had appeared in the mid-Ordovician period, about 470 million years ago, radiated in both fresh and salt water.

(b) A sea lamprey feeding

Figure 34.3 The lamprey, a modern jawless fish. **(a)** The sea lamprey (*Petromyzon marinus*) has a circular, jawless mouth. **(b)** A sea lamprey feeding on a fish.

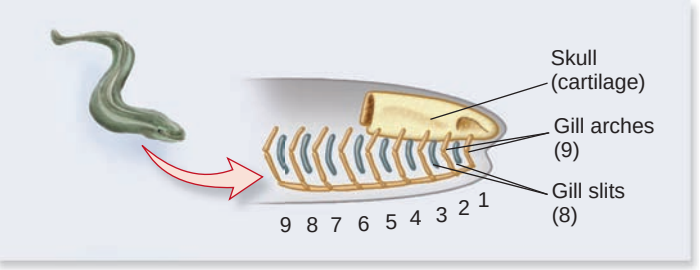
34.3 Gnathostomes: Jawed Vertebrates

All vertebrate species that possess jaws are called **gnathostomes** (from the Greek, meaning jaw mouth) (see Figure 34.1). In contrast, the jawless species are termed agnathans (meaning without jaws). Gnathostomes are a diverse clade of vertebrates that include fishes, amphibians, reptiles, and mammals. The earliest-diverging gnathostomes were fishes. Biologists have identified about 25,000 species of living fishes, more than all other species of vertebrates combined. Most are aquatic, gill-breathing species that usually possess fins and a scaly skin. There are four separate classes of jawed fishes, each of which has distinguishing characteristics (see Table 34.1): the Chondrichthyes (cartilaginous fishes), Actinopterygii (ray-finned fishes), Actinistia (coelacanths), and Dipnoi (lungfishes).

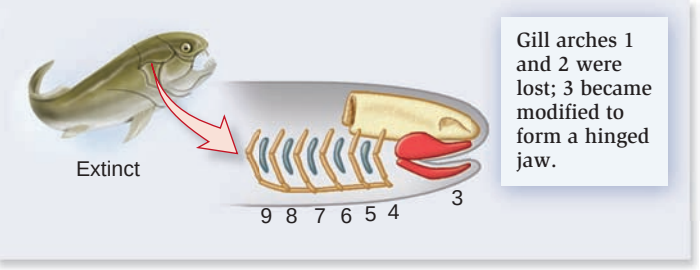
The jawed mouth was a significant evolutionary development. It enabled an animal to grip its prey more firmly, which may have increased its rate of capture, and to attack larger prey species, thus increasing its potential food supply. Accompanying the jawed mouth was the development of more sophisticated head and body structures, including two pairs of appendages called fins. Gnathostomes also possess two additional *Hox* gene clusters (bringing their total to four), which permitted increased morphological complexity.

The hinged jaw developed from the pharyngeal arches, cartilaginous or bony rods that help to support the respiratory tissue. Primitive jawless fishes had nine gill arches surrounding the eight gill slits (Figure 34.4a). During the late Silurian period, about 417 million years ago, some of these gill arches became modified in jawless fishes. The first and second gill arches were lost, while the third and fourth pairs became modified to form the jaws (Figure 34.4b,c). This is how evolution usually works; body features do not appear *de novo*, but instead, existing features become modified to serve other functions.

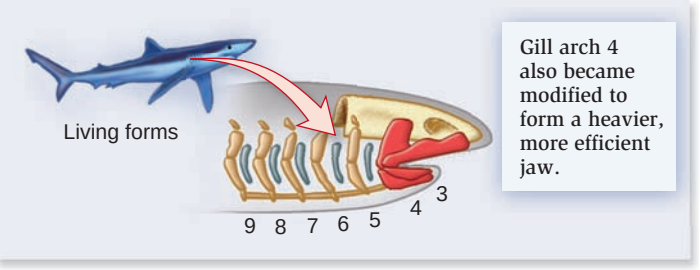
By the mid-Devonian period, two classes of jawed fishes, the Acanthodii (spiny fishes) and Placodermi (armored fishes) were common. Some of the placoderms were huge individuals,



(a) Primitive jawless fishes



(b) Early jawed fishes (placoderms)



(c) Modern jawed fishes (cartilaginous and bony fishes)

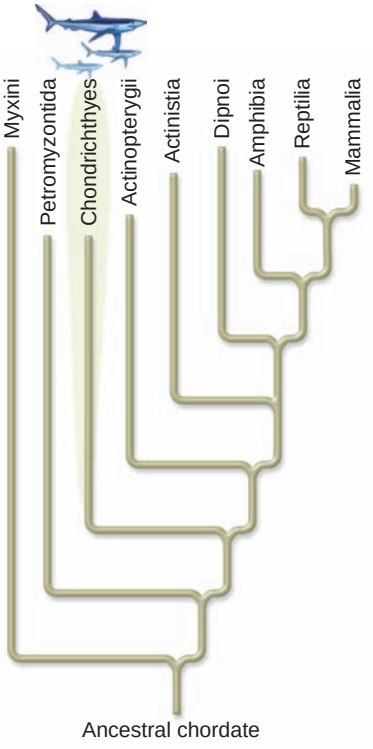
Figure 34.4 The evolution of the vertebrate jaw. **(a)** Primitive fishes and extant jawless fishes such as lampreys have nine cartilaginous gill arches that support eight gill slits. **(b)** In early jawed fishes such as the placoderms, the first two pairs of gill arches were lost, and the third pair became modified to form a hinged jaw. This left six gill arches (4–9) to support the remaining five gill slits, which were still used in breathing. **(c)** In modern jawed fishes, the fourth gill arch also contributes to jaw support, allowing stronger, more powerful bites to be delivered.

over 9 m long. Both classes died out by the end of the Devonian as part of one of several mass extinctions that occurred in the Earth's geological and biological history. The reasons for this extinction are not well understood, but other types of jawed fishes present at the same time—the cartilaginous and bony fishes—did not go extinct. We will discuss the fishes in these classes next.

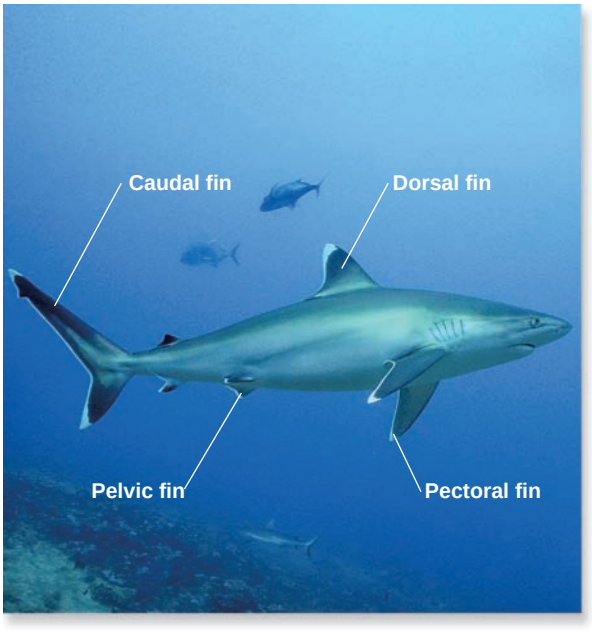
Chondrichthyans: The Cartilaginous Fishes

Members of the class Chondrichthyes (the **chondrichthyans**)—sharks, skates, and rays—are also called cartilaginous fishes because their skeleton is composed of flexible cartilage rather than bone. The cartilaginous skeleton is not considered an ancestral character but rather a derived character. This means that the ancestors of the chondrichthyans had bony skeletons but that members of this class subsequently lost this feature. This hypothesis is reinforced by the observation that during development, the skeleton of most vertebrates is cartilaginous, and then it becomes bony (ossified) as a hard calcium-phosphate matrix replaces the softer cartilage. A change in the developmental sequence of the cartilaginous fishes is believed to prevent the ossification process.

In the Carboniferous period, 354–290 million years ago, sharks were the great predators of the ocean. Aided by fins, sharks became fast, extremely efficient swimmers (Figure 34.5a). Perhaps the most important fin for propulsion is the large and powerful caudal fin, or tail fin, which, when swept from side to side, thrusts the fish forward at great speed. For example, great white sharks (*Carcharodon carcharias*) can swim at over 40 km per hour, and Mako sharks (*Isurus oxyrinchus*) have been clocked at nearly 50 km per hour. The paired pelvic fins (at the back) and pectoral fins (at the front) act like flaps on airplane wings, allowing the shark to dive deeper or rise to the surface. They also aid in steering. In addition, the dorsal fin (on the back) acts as a stabilizer to prevent the shark from rolling in the water as the tail fin pushes it forward.

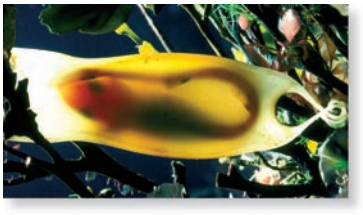


Sharks were among the earliest fishes to develop teeth. Their teeth evolved from rough scales on the skin that also contain dentin and enamel. Although shark's teeth are very sharp and hard, they are not set into the jaw, as are human teeth, so they break off easily. To offset this, the teeth are continually replaced, row by row (Figure 34.5b). Sharks may have 20 rows of teeth, with the front pair in active use and the ones behind



(a) Silvertip shark

(b) Rows of shark teeth



(c) Shark egg pouch

(d) Stingray

Figure 34.5 **Cartilaginous fishes.** **(a)** The silvertip shark (*Carcharhinus albimarginatus*) is one of the ocean's most powerful predators. **(b)** Close-up of the mouth of a sand tiger shark (*Carcharias taurus*), showing rows of teeth. **(c)** This mermaid's purse (egg pouch) of a dogfish shark (*Scyliorhinus canicula*) is entwined in vegetation to keep it stationary. **(d)** Stingrays are essentially flattened sharks with very large pectoral fins.

ready to grow in as replacements when needed. Tooth replacement time varies from 9 days in the cookie-cutter shark (named for its characteristic of biting round plugs of flesh from its prey) to 242 days in great whites. Some experts estimate that certain sharks can use up to 20,000 teeth in a lifetime.

All chondrichthyans are denser than water, which theoretically means that they would sink if they stopped swimming. Many sharks never stop swimming and maintain buoyancy via the use of their fins and a large oil-filled liver. Another advantage of swimming is that water continually enters the mouth and is forced over the gills, allowing sharks to extract oxygen and breathe. How then do skates and rays breathe when they rest on the ocean floor? These species, and a few sharks such as the nurse shark, use a muscular pharynx and jaw muscles to pump water over the gills. In these and indeed all species of fishes, the heart consists of two chambers, an atrium and a ventricle, that contract in sequence. They employ what is known as a single circulation, in which blood is pumped from the heart to capillaries in the gills to collect oxygen, and then it flows through arteries to the tissues of the body, before returning to the heart (look ahead to Figure 47.4a).

Many active predators possess a variety of acute senses, and sharks are no exception. They have a powerful sense of smell, facilitated by sense organs in the nostrils (sharks and other fishes do not use nostrils for breathing). They can see well but cannot distinguish colors. Although sharks have no eardrum, they can detect pressure waves generated by moving objects. All jawed fishes have a row of microscopic organs in the skin, arranged in a line that runs laterally down each side of the body, that can detect movements in the surrounding water. This system of sense organs, known as the **lateral line**, senses pressure waves and sends nervous signals to the inner ear and then on to the brain.

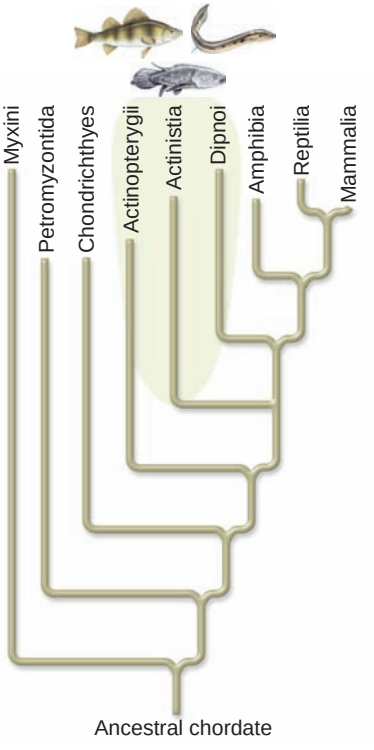
Fertilization is internal in chondrichthyans, with the male transferring sperm to the female via a pair of **claspers**, modifications of the pelvic fins. Some shark species are **oviparous**, that is, they lay eggs, often inside a protective pouch called a mermaid's purse (Figure 34.5c). The eggs, which are not guarded by either parent, then hatch into tiny sharks. In **ovoviparous** species, the eggs are retained within the female's body, but there is no placenta to nourish the young. A few species are **viviparous**; the eggs develop within the uterus, receiving nourishment from the mother via a placenta. Both ovoviparous and viviparous sharks give birth to live young.

The sharks have been a very successful vertebrate group, with many species identified in the fossil record. Although many species died out in the mass extinction at the end of the Permian period (290–248 million years ago), the survivors underwent a period of further speciation in the Mesozoic era, when most of the 375 modern species appeared.

Skates and rays are essentially flattened sharks that cruise along the ocean floor by using hugely expanded pectoral fins. In addition, their thin and whiplike tails are often equipped with a venomous barb used in defense (Figure 34.5d). Most of the 475 or so species of skates and rays feed on bottom-dwelling crustaceans and mollusks.

The Bony Fishes

Bony fishes are the most numerous of all types of fishes, with more individuals and more species (about 24,600) than any other. Most authorities now recognize three living classes: the Actinopterygii (ray-finned fishes), the Actinistia (coelacanths), and the Dipnoi (lungfishes). Fishes in all three classes possess a bony skeleton and scale-covered skin. The skin of bony fishes, unlike the rough skin of sharks, is slippery and slimy because the scales are covered by a thin epidermal layer containing glands that produce mucus, an adaptation that reduces drag during swimming. Just as in the cartilaginous fishes, water is drawn over the gills for breathing, but in bony fishes, a protective flap called an **operculum** covers the gills (Figure 34.6). Muscle contractions around the gills and operculum draw water across the gills so that bony fishes do not need to swim continuously to breathe. Some early bony fishes lived in shallow, oxygen-poor waters and developed lungs as an embryological offshoot of the pharynx. These fish could rise to the water surface and gulp air. As we will see, modern lungfishes operate in much the same fashion. In most bony fishes, these lungs evolved into a **swim bladder**, a gas-filled, balloon-like structure that helps the fish remain buoyant in the water even when it is completely stationary. In less-derived fishes, the gut and swim bladder are connected via a duct, and the fishes can fill their swim bladder by gulping air. In more-derived species, the swim bladder is connected to the circulatory system, and gases are transported in and out of the blood, allowing the fishes to change the volume of the swim bladder and so to rise and sink. Therefore, unlike the sharks, many bony fishes can remain motionless and use a "sit-and-wait" ambush style. These three features—bony skeleton, operculum, and swim bladder—distinguish bony fishes from cartilaginous fishes.



Reproductive strategies of bony fishes vary tremendously, but most species reproduce via external fertilization, with the female shedding her eggs and the male depositing sperm on top of them. While adult bony fishes can maintain their buoyancy, their eggs tend to sink. This is why many species spawn in shallow, more oxygen- and food-rich waters and why coastal areas are such important fish nurseries.

Bony fishes have colonized nearly all aquatic habitats. Following the cooling of the newly formed planet Earth, rain

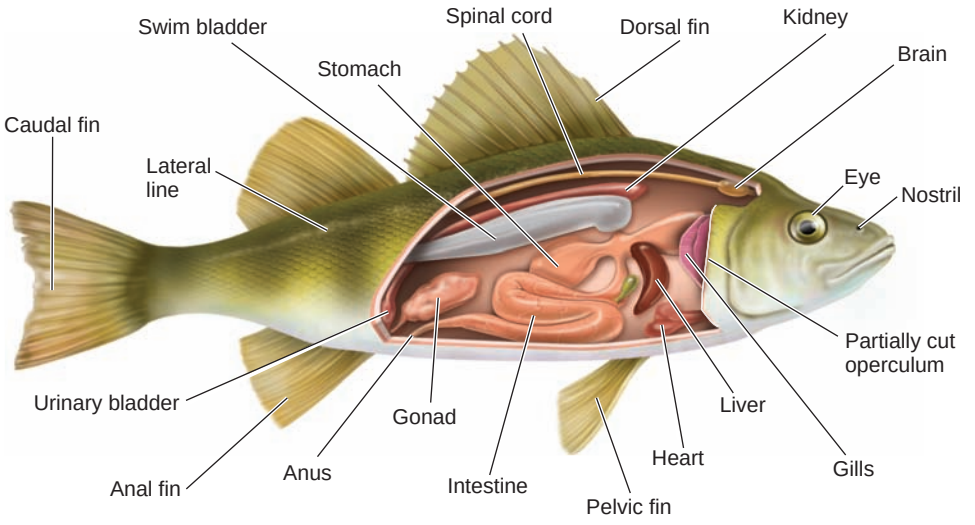


Figure 34.6 Generalized body plan of a bony fish.

fell continuously, and the oceans were filled with fresh water. Later, as water evaporated from the oceans and sodium, potassium, and calcium were added via runoff from the land, the oceans became salty. Therefore, most fishes probably evolved in freshwater habitats and secondarily became adapted to marine environments. This, of course, required the development of physiological adaptations to the different osmotic problems seawater presents compared to fresh water (see Chapter 49).

The most species-rich class of bony fishes is the Actinopterygii, or **ray-finned fishes**, which includes all bony fishes except the coelacanths and lungfishes. In Actinopterygii, the fins are supported by thin, bony, flexible rays and are moved by muscles on the interior of the body. The class has a diversity of forms, from lionfish and large predatory moray eels to delicate sea dragons (Figure 34.7). Whole fisheries are built around the harvest of species such as cod, anchovies, and salmon.

The Actinistia (coelacanths) and Dipnoi (lungfishes) are both considered Sarcopterygii, or **lobe fins**. The name Sarcopterygii used to refer solely to the lobe-finned fishes, but since it has become clear that terrestrial vertebrates (tetrapods) evolved from such fishes, the definition of the group has been expanded to include both lobe-finned fishes and tetrapods (see Figure 34.1). In the **lobe-finned fishes**, the fins are supported by skeletal extensions of the pectoral and pelvic areas that are moved by muscles within the fins.

The fossil record revealed that the Actinistia, or coelacanths, were a very successful group in the Devonian period, but all fishes of the class were believed to have died off at the end of the Mesozoic era, some 65 million years ago. You can therefore imagine the scientific excitement when in 1938, a modern coelacanth was discovered as part of the catch of a boat fishing near the Chalumna River in South Africa (Figure 34.8). Intensive searches in the area revealed that coelacanths were living in deep waters off the southern African coast and especially off a group of islands near the coast of Madagascar called the Comoros Islands. Another species was found more recently in Indonesian waters.

Early-diverging lobe-finned fishes probably evolved in fresh water and had lungs, but the coelacanth lost them and returned to the sea. One distinctive feature of this group is a special joint in the skull that allows the jaws to open extremely wide and gives the coelacanth a powerful bite. As further evidence of the coelacanth's unusual body plan, its swim bladder is filled with oil rather than gas, although it serves a similar purpose—to increase buoyancy.

The Dipnoi, or **lungfishes**, like the coelacanths, are also not currently a very species-rich class, having just three genera

(a) Lionfish (*Pterois volitans*)

(b) Whitemouth moray eel (*Gymnothorax meleagris*)

(c) Leafy sea dragon (*Phycodurus eques*)

Figure 34.7 The diversity of ray-finned fishes.

Concept check: *What features distinguish ray-finned fishes from sharks?*

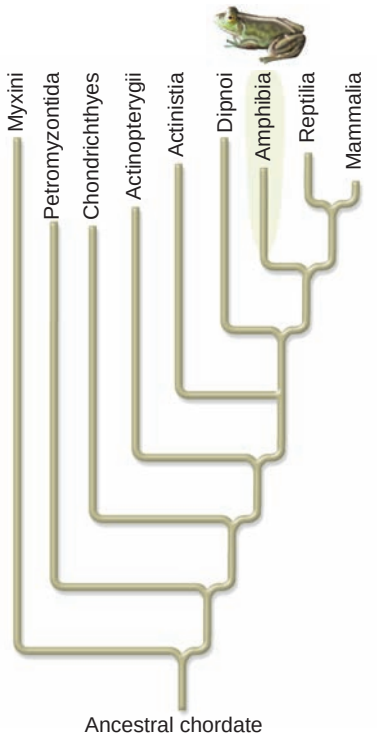
Concept check: *How are lungfishes similar to coelacanths?*

and six species (Figure 34.9). Lungfishes live in oxygen-poor freshwater swamps and ponds. They have both gills and lungs, the latter of which enable them to come to the surface and gulp air. In fact, lungfish will drown if they are unable to breathe air. When ponds dry out, some species of lungfish can dig a burrow and survive in it until the next rain. Because they also have muscular lobe fins, they are often able to successfully traverse quite long distances over shallow-bottomed lakes that may be drying out.

The morphological features of coelacanths, lungfishes, and primitive terrestrial vertebrates, together with the similarity of their nuclear genes, suggest to many scientists that lobe-fin ancestors gave rise to three lineages: the coelacanths, the lungfishes, and the tetrapods. In the next section we will examine the biology of tetrapods in more detail.

34.4 Tetrapods: Gnathostomes with Four Limbs

During the Devonian period, from about 417 to 354 million years ago, a diversity of plants colonized the land. The presence of plants served as both a source of oxygen and an extensive food source for animals that ventured out of the aquatic environment. Terrestrial arthropods, especially insects, evolved to feed on these plants and provided an additional food source for any vertebrate that could colonize the land.



The transition to life on land involved a large number of adaptations. Paramount among these were adaptations preventing desiccation and making locomotion and reproduction on land possible. We have seen that the lungfishes evolved the ability to breathe air. In this section, we begin by outlining the development of the **tetrapods**, vertebrate animals having four legs or leglike appendages. We will discuss the first terrestrial vertebrates and their immediate descendants, the amphibians. We will then explore the characteristic features and diversity of modern amphibians.

The Origin of Tetrapods Involved the Development of Four Limbs

Over the Devonian period, fossils record the evolution of sturdy lobe-finned fishes that became fishes with four limbs. The abundance of light and nutrients in shallow waters encouraged a profusion of plant life and the invertebrates that fed on them. The development of lungs enabled lungfishes to colonize these productive yet often oxygen-poor waters. Here, the ability to move in shallow water chock full of plants and debris was more vital than the ability to swim swiftly through open water and may have favored the progressive development of sturdy limbs. As an animal's weight began to be borne more by the limbs, the vertebral column strengthened, and hip bones and shoulder bones were braced against the backbone for added strength. Such modifications, while seemingly dramatic, are believed to be caused by relatively simple changes in the expression of genes, especially *Hox* genes (see Feature Investigation). In particular, *Hox* genes 9–13 work together to specify limb formation from the proximal to the distal direction, meaning from close to the point of attachment to the body to the terminal end of the limb (Figure 34.10).

One of the transitional forms between fish and tetrapods was *Tiktaalik rosae*, nicknamed a fishapod, which we discussed back in Figure 23.5. Fishapods had broad skulls with eyes mounted on the top, and lungs. They also possessed pectoral fins with five finger-like bones. This is an important species, for it may represent a so-called stem species, a common tetrapod

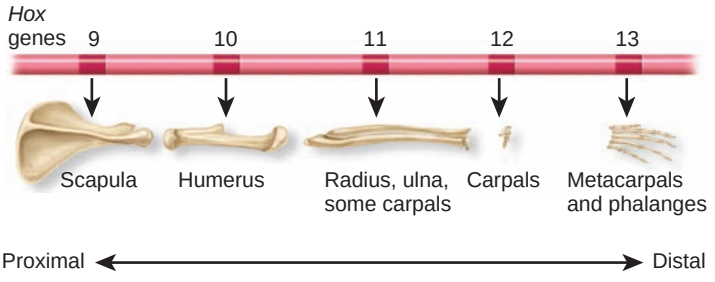


Figure 34.10 **The roles of *Hox* genes 9–13 in specifying limb formation from the proximal to distal direction.** The axis of limb development in mice is shown, together with the associated genes.

ancestor located at the beginning of the tetrapod branch on the tree of life. Eventually, species more like modern amphibians evolved, species that were still tied to water for reproduction but increasingly fed on land. In these species, the vertebral column, hip bones, and shoulder bones grew even sturdier. Such changes were needed as the animal's weight was no longer supported by water but was borne entirely on the limbs. The evolution of a rib cage provided protection for the internal organs, especially the lungs and heart.

By the middle of the Carboniferous period, about 320 million years ago, species similar to modern amphibians had become common in the terrestrial environment. For example, *Cacops* was a large amphibian, as big as a pony (Figure 34.11). Its skin was heavy and tough, an adaptation that helped prevent water loss; its breathing was accomplished more by lungs than by skin; and it possessed **pentadactyl limbs** (limbs ending in five digits). With a bonanza of terrestrial arthropods to feast on, the amphibians became very numerous and species rich, and the mid-Permian period, some 260 million years ago, is sometimes known as the Age of Amphibians. However, most of the large amphibians became extinct at the end of the Permian period, coincident with the radiation of the reptiles, though whether the rise of reptiles was responsible for the extinction of amphibians is not known. This was the largest extinction event in history, and many other organisms went extinct as well. Most surviving amphibians were smaller organisms resembling modern species.

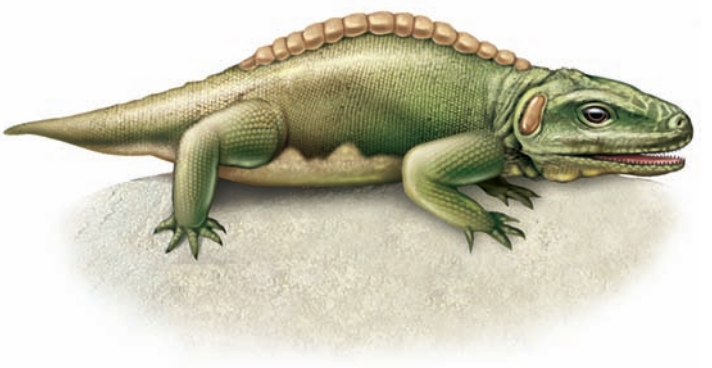

Figure 34.11 **A primitive tetrapod.** *Cacops* was a large, early amphibian of the Permian period.

Concept check: *What were the advantages to animals of moving on to land?*

Feature Investigation

Davis, Capecchi, and Colleagues Provide a Genetic-Developmental Explanation for Limb Length in Tetrapods

The development of limbs in tetrapods was a vital step that allowed animals to colonize land. The diversity of vertebrate limb types is amazing, from fins in fish and marine mammals to legs and arms in primates to different wing types in bats and birds. Early in vertebrate evolution, an ancestral gene complex was duplicated twice to give rise to four groups of genes, called *Hox A*, *B*, *C*, and *D*, which controlled limb development. In 1995, Allen Davis, Mario Capecchi, and colleagues analyzed the effects of mutations in specific *Hox* genes that are responsible for determining limb formation in mice. The vertebrate forelimb is divided into three zones, humerus (upper arm), radius and ulna (forearm), and carpals, metacarpals, and phalanges (digits). The authors had no specific hypothesis in mind; their goal was to understand the role of *Hox* genes in limb formation. As described in Figure 34.12, they began with strains of mice carrying loss-of-function mutations in *HoxA-11* or *HoxD-11* that, on their own, did not cause dramatic changes in limb formation. They bred the mice to obtain offspring carrying one, two, three, or four loss-of-function mutations. Double mutants exhibited dramatically different phenotypes not seen in mice homozygous for the individual mutations. The radius and ulna were almost entirely eliminated.

As seen in the data, the mutations affected the formation of limbs. For example, the wrist contains seven bones: three proximal carpals—called navicular lunate (NL), triangular (T), and pisiform (P)—and four distal carpals (d1–d4). In mice with the genotypes *aaDD* and *AAdd*, the proximal carpal bones are usually fused together. Individual heterozygotes (*AADd* and *AaDD*) do not show this defect, but compound heterozygotes (*AaDd*) often do. Therefore, any two mutant alleles (either from both *HoxA-11* and *HoxD-11* or one from each locus) will cause carpal fusions. Deformities became even more severe with three mutant alleles (*Aadd* or *aaDd*) or four mutant alleles (*aadd*) (data not shown in the figure). Thus, scientists have shown that relatively simple mutations can control relatively large changes in limb development.

Figure 34.12 Relatively simple changes in *Hox* genes control limb formation in tetrapods.

GOAL To determine what role *Hox* genes have in limb development in mice.

KEY MATERIALS Mice with individual mutations in *HoxA-11* and *HoxD-11* genes.

	Experimental level	Conceptual level
1 Breed mice with individual mutations in *HoxA-11* and *HoxD-11* genes. (The *A* and *D* refer to wild-type alleles; *a* and *d* are mutant alleles.)	 *AaDd* mice The mice bred were heterozygous for both genes (*AaDd*).	Based on previous studies, researchers expect mutant mice to produce viable offspring, perhaps with altered limb morphologies.
2 Using molecular techniques described in Chapter 20, obtain DNA from the tail and determine the genotypes of offspring.		The resulting genotypes would occur in Mendelian ratios, generating mice with different combinations of wild-type and mutant alleles.
3 Stain the skeletons and compare the limb characteristics of the wild-type mice (*AADD*) to those of strains carrying mutant alleles in one or both genes.		Mutant mice may have altered bone morphologies. 
	AD	Ad	aD	ad
AD	AADD	AADd	AaDD	AaDd
Ad	AADd	AAdd	AaDd	Aadd
aD	AaDD	AaDd	aaDD	aaDd
ad	AaDd	Aadd	aaDd	aadd ← Double mutant

9:3:3:1 phenotypic ratio

4 THE DATA

Genotype	Carpal bone fusions (% of mice showing the fusion)			
	Normal (none fused)	NL fused to T	T fused to P	NL fused to T and P
AADD	100	0	0	0
AaDD	100	0	0	0
aaDD	33	17	50	0
AADd	100	0	0	0
AAdd	0	17	17	67
AaDd	17	17	33	33

5 **CONCLUSION** Relatively simple mutations involving two genes can cause large changes in limb development.

Experimental Questions

1. What was the purpose of the study conducted by A. P. Davis and colleagues?
2. How were the researchers able to study the effects of individual genes?
3. Explain the results of the experiment shown in Figure 34.12 and how this relates to limb development in vertebrates.

Amphibian Lungs and Limbs Are Adaptations to a Semiterrestrial Lifestyle

Amphibians (from the Greek, meaning two lives) live in two worlds: They have successfully invaded the land but most must return to the water to reproduce. One of the first challenges terrestrial animals had to overcome was breathing air when on land. Amphibians can use the same technique as lungfishes: They open their mouths to let in air. Alternatively, they may take in air through their nostrils. They then close and raise the floor of the mouth, creating a positive pressure that pumps air into the lungs. This method of breathing is called **buccal pumping**. In addition, the skin of amphibians is much thinner than that of fishes, and amphibians absorb oxygen from the air directly through their outer moist skin or through the skin lining of the inside of the mouth or pharynx.

Amphibians have a three-chambered heart, with two atria and one ventricle. One atrium receives blood from the body, and the other receives blood from the lungs. Both atria pump blood into the single ventricle, which pumps some blood to the lungs and some to the rest of the body (look ahead to Figure 47.4b). This form of circulation allows the tissues to receive well-oxygenated blood at a higher pressure than is possible via single circulation, because some of the blood that returns to the heart is directly pumped to the tissues without being slowed down by passage through the lung capillaries. This development enhances the delivery of nutrients and oxygen to the tissues, but it is still not maximally efficient because some oxygenated and deoxygenated blood are mixed in the ventricle.

Because the skin of amphibians is so thin, the animals face the problem of desiccation, or drying out. As a consequence, even amphibian adults are more abundant in damp habitats, such as swamps or rain forests, than in dry areas. Also, most amphibians cannot venture too far from water because their larval stages are still aquatic. In frogs and toads, fertilization is generally external, with males shedding sperm over the gelatinous egg masses laid by the females in water (Figure 34.13a). The fertilized eggs lack a shell and would quickly dry out if exposed to the air. They soon hatch into tadpoles (Figure 34.13b), small fishlike animals that lack limbs and breathe through gills. As the tadpole nears the adult stage, the tail and gills are resorbed, and limbs and lungs appear (Figure 34.13c). Such a dramatic change in body form is known as metamorphosis, a process regulated by hormones from the thyroid gland. There are a few species of amphibians that do not require water to reproduce. These species are ovoviparous or viviparous, retaining the eggs in the reproductive tract and giving birth to live young.

Modern Amphibians Include a Variety of Frogs, Toads, Salamanders, and Caecilians

Approximately 4,800 living amphibian species are known, and the vast majority of these, nearly 90%, are frogs and toads of

(a) Gelatinous mass of amphibian eggs

(b) Tadpole

(c) Tadpole undergoing metamorphosis

Figure 34.13 **Amphibian development in the wood frog (*Rana sylvatica*).** **(a)** Amphibian eggs are laid in gelatinous masses in water. **(b)** The eggs develop into tadpoles, aquatic herbivores with a fishlike tail that breathe through gills. **(c)** During metamorphosis, the tadpole loses its gills and tail and develops limbs and lungs.

(a) Tree frog

(b) A caecilian

(c) Mud salamander

Figure 34.14 **Amphibians.** **(a)** Most amphibians are frogs and toads of the order Anura, including this red-eyed tree frog (*Agalychnis callidryas*). **(b)** The order Gymnophiona includes wormlike caecilians such as this species from Colombia, *Caecilia nigricans*. **(c)** The order Caudata includes species such as this mud salamander (*Pseudotriton montanus*).

Concept check: *Do all amphibians produce tadpoles?*

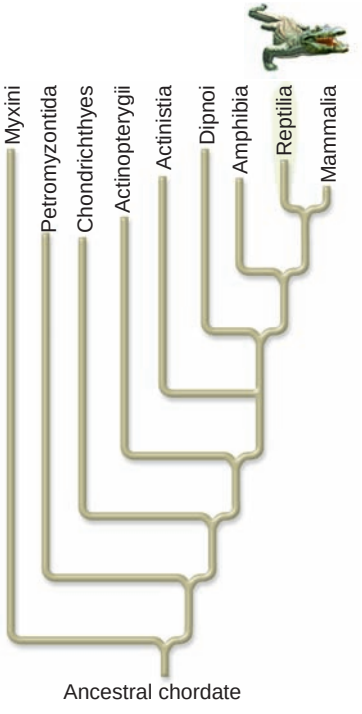
the order Anura (from the Greek, meaning without tail) (Figure 34.14a). The other two orders are the Gymnophiona (from the Greek, meaning naked snake), the wormlike caecilians, and the Caudata (from the Latin, meaning tail visible), the salamanders. Global warming is currently threatening many anurans with extinction (see Chapter 54).

Adult anurans are carnivores, eating a variety of invertebrates by catching them on a long, sticky tongue. In contrast, the aquatic larvae (tadpoles) are primarily herbivores. Frogs generally have smooth, moist skin and long hind legs, making them excellent jumpers and swimmers. In addition to secreting mucus, which keeps their skin moist, some frogs can also secrete poisonous chemicals that deter would-be predators. Some amphibians advertise the poisonous nature of their skin with warning coloration (look ahead to Figure 57.10b). Others use camouflage as a way of avoiding detection by predators. Toads have a drier, bumpier skin and shorter legs than frogs. They are less impressive leapers than frogs, but toads can better tolerate drier conditions.

Caecilians (order Gymnophiona) are a small order of about 160 species of legless, nearly blind amphibians (Figure 34.14b). Most are tropical and burrow in forest soils, but a few live in ponds and streams. They are secondarily legless, which means they evolved from legged ancestors. Caecilians eat worms and other soil invertebrates and have tiny jaws equipped with teeth. In this order, fertilization is internal, and females usually bear live young. The young are nourished inside the mother's body by a thick, creamy secretion known as uterine milk. In most caecilian species, the young grow into adults about 30 cm long, though species up to 1.3 m in length are known.

The salamanders (order Caudata) possess a tail and have a more elongate body than anurans (Figure 34.14c). During locomotion, they seem to sway from side to side, perhaps reminiscent of how the earliest tetrapods may have walked. Like frogs, salamanders often have colorful skin patterns that advertise their distastefulness to predators. Salamanders retain their moist skin by living in damp areas under leaves or logs or beneath lush vegetation. They generally range in size from 10 to 30 cm. Fertilization is usually internal, with females using their cloaca to pick up sperm packets deposited by males. A very few salamander species do not undergo metamorphosis, and the newly hatched young resemble tiny adults. However, some species, such as the axolotl, retain the gills and tail fins characteristic of the larval stage into adulthood, a phenomenon known as paedomorphosis (refer back to Figure 25.16b).

34.5 Amniotes: Tetrapods with a Desiccation-Resistant Egg



As mentioned, although amphibians live successfully in a terrestrial environment, they must lay their eggs in water or in a very moist place, so their shell-less eggs do not dry out on exposure to air. Thus, a critical innovation in animal evolution was the development of a shelled egg that sheltered the embryo from desiccating conditions on land. A shelled egg containing fluids was like a personal enclosed pond for each developing individual. Such an egg evolved in the common ancestor of turtles, lizards, snakes, crocodiles, birds, and mammals—a group of tetrapods collectively known as the **amniotes**. The amniotic egg permitted animals to lay their eggs in a dry place so that reproduction was no longer tied to water. It was truly a critical innovation. The amniotic egg untethered animals from water in much the same way as the development of seeds liberated plants from water (see Chapter 29).

In time, the amniotes came to dominate the Earth. Mammals are considered amniotes, too, because even though most of them do not lay eggs, they retain other features of amniotic reproduction. In this section, we begin by discussing in detail the morphology of the amniotic egg and other adaptations that

permitted animal species to become fully terrestrial. We then discuss the biology of the reptiles, the first group of vertebrates to fully exploit land.

The Amniotic Egg and Other Innovations Permitted Life on Land

The **amniotic egg** (Figure 34.15) contains the developing embryo and the four separate extraembryonic membranes that it produces:

1. The innermost membrane is the **amnion**, which protects the developing embryo in a fluid-filled sac called the amniotic cavity.
2. The **yolk sac** encloses a stockpile of nutrients, in the form of yolk, for the developing embryo.
3. The **allantois** functions as a disposal sac for metabolic wastes.
4. The **chorion**, along with the allantois, provides gas exchange between the embryo and the surrounding air.

Surrounding the chorion is the albumin, or egg white, which also stores nutrients. The **shell** provides a tough, protective covering that is not very permeable to water and prevents the embryo from drying out. However, the shell remains permeable to oxygen and carbon dioxide, so the embryo can breathe. In birds, this shell is hard and calcareous, whereas in reptiles and early-diverging mammals such as the platypus and echidna, it is soft and leathery. In most mammals, however, the embryos embed into the wall of the uterus and receive their nutrients directly from the mother.

Along with the amniotic egg, other critical innovations that enabled the conquest of land include the following:

- **Desiccation-resistant skin.** Whereas the skin of amphibians is moist and aids in respiration, the skin of amniotes is thicker and water resistant and contains keratin, a tough protein. This requires that most gas exchange takes place through the lungs.
- **Thoracic breathing.** Amphibians use buccal pumping to breathe, contracting the mouth to force air into the lungs. In contrast, amniotes use **thoracic breathing**, in which coordinated contractions of muscles expand the rib cage, creating a negative pressure to suck air in and then forcing it out later. This results in a greater volume of air being displaced with each breath than with buccal pumping.
- **Water-conserving kidneys.** The ability to concentrate wastes prior to elimination and thus conserve water is an important role of the amniotic kidneys.
- **Internal fertilization.** Because sperm cannot penetrate a shelled egg, fertilization occurs internally, within the female's body before the shell is secreted. In this process, the male of the species often uses a copulatory organ (penis) to transfer sperm into the female reproductive tract. However, birds usually transfer sperm from cloaca to cloaca.

Reptiles Include Turtles, Lizards, Snakes, Crocodilians, Dinosaurs, and Birds

Early amniote ancestors gave rise to all modern amniotes we know today, from lizards and snakes to birds and mammals.

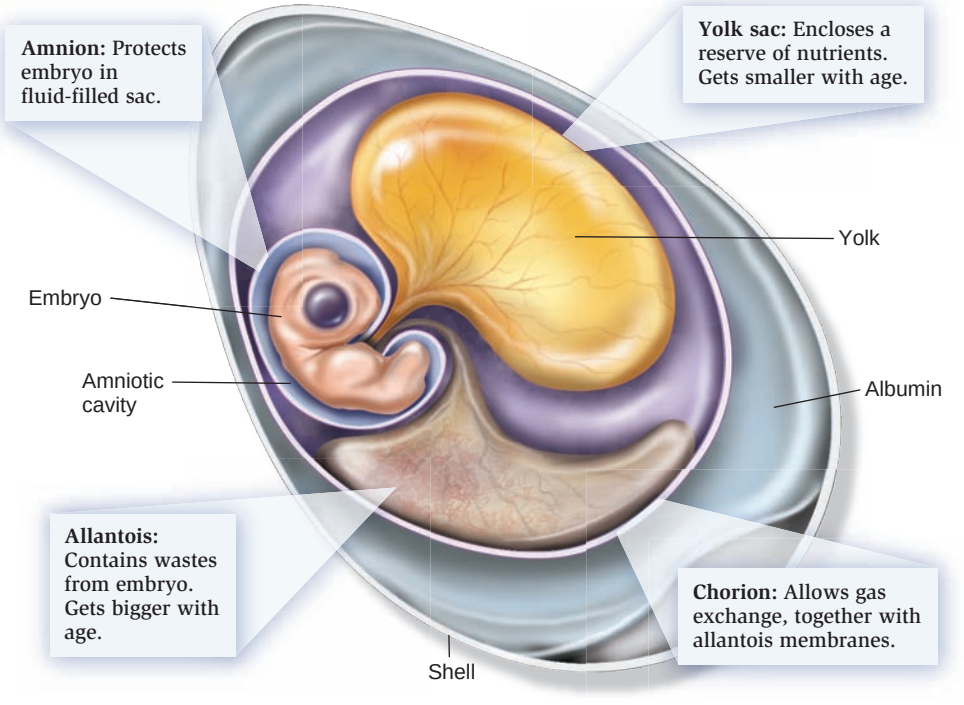


Figure 34.15 The amniotic egg.

Concept check: *What are some of the other critical innovations of amniotes?*

(a) Green turtle

(b) Florida worm lizard

(c) Gila monster

Figure 34.16 **A variety of reptiles.** **(a)** A green turtle (*Chelonia mydas*) laying eggs in the sand in Malaysia. **(b)** The Florida worm lizard (*Rhineura floridana*) is an amphisbaenian, a type of legless soil-burrowing lizard. **(c)** The Gila monster (*Heloderma suspectum*), one of only two venomous lizards, is an inhabitant of the desert Southwest of the U.S. and of Mexico.

The traditional view of amniotes involved three living classes: the reptiles (turtles, lizards, snakes, and crocodilians), birds, and mammals. As we will see later in the chapter, modern systematists have argued that enough similarities exist between birds and the classic reptiles that birds should be considered part of the reptilian lineage. This is the classification scheme that we will follow in this chapter. The fossil record includes other reptilian classes, all of which are extinct, including two classes of dinosaurs (ornithischian and saurischian dinosaurs), flying reptiles (pterosaurs), and two classes of ancient aquatic reptiles (icthyosaurs and plesiosaurs).

Class Testudines: The Turtles Turtles is an umbrella term for terrestrial species, also called tortoises, and aquatic species, sometimes known as terrapins. The turtle lineage is ancient and has remained virtually unchanged for 200 million years. The major distinguishing characteristic of the turtle is a hard protective shell into which the animal can withdraw its head and limbs. In most species, the vertebrae and ribs are fused to form this shell. All turtles lack teeth but have sharp beaks for biting.

Most turtles are aquatic and have webbed feet. The forelimbs of marine species have evolved to become large flippers. All turtles, even the aquatic species, lay their eggs on land, usually in soft sand. The gender of hatchlings is temperature dependent, with high temperatures producing more females (see also Chapter 16). Marine species often make long migrations to sandy beaches to lay their eggs (Figure 34.16). Most land tortoises are quite slow movers, possibly due to a low metabolic rate and a heavy shell. However, they are very long-lived species, often surviving for 120 years or more. Furthermore, turtles do not appear to show reproductive senescence or aging, reproducing continually throughout their lifetime. Most organs such as the liver, lungs, and kidneys of a centenarian turtle function as effectively as do organs in young individuals, prompting genetic researchers to examine the turtle genome for longevity genes. Many turtle species are in danger of extinction, due to egg hunting, destruction of habitat and nesting sites, and death from entanglement in fishing nets.

Class Lepidosauria: Lizards and Snakes The class Lepidosauria is the largest class within the traditional reptiles, with about 4,800 species of lizards (order Sauria) and 3,000 species of snakes (order Serpentes). Many species have an elongated body form. One of the defining characteristics of the orders is a **kinetic skull**, in which the joints between various parts of the skull are extremely mobile. The lower jaw does not join directly to the skull but rather is connected by a multijointed hinge, and the upper jaw is hinged and movable from the rest of the head. This allows the jaws to open relatively wider than other vertebrate jaws, with the result that lizards, and especially snakes, can swallow large prey (Figure 34.17). Nearly all species are carnivores.

Figure 34.17 **The kinetic skull.** In snakes and lizards, both the top and bottom of the jaw is hinged on the skull, thereby permitting large prey to be swallowed. This Halloween snake (*Pliocercus euryzonus*) is swallowing a Costa Rican rain frog.

A main difference between lizards and snakes is that lizards generally have limbs, whereas snakes do not. Leglessness is a derived condition, meaning snake ancestors possessed legs but later lost them. Also, snakes may be venomous, whereas lizards usually are not. However, there are exceptions to these general rules. Many legless lizard species exist (see Figure 34.16b), and two lizards are venomous: the Gila monster (*Heloderma suspectum*) of the U.S. Southwest (see Figure 34.16c) and the Mexican beaded lizard (*Heloderma horridum*). A more reliable distinguishing characteristic is that lizards have movable eyelids and external ears (at least ear canals), whereas snakes do not.

Class Crocodilia: The Crocodiles and Alligators The Crocodilia is a small class of large, carnivorous, aquatic animals that have remained essentially unchanged for nearly 200 million years (Figure 34.18). Indeed, these animals existed at the same time as the dinosaurs. Most of the 23 recognized species live in tropical or subtropical regions. There are only two extant species of alligators: one living in the southeastern U.S. and one found in China.

While the class is small, it is evolutionarily very important. Crocodiles have a four-chambered heart, a feature they share with birds and mammals (look ahead to Figure 47.4c). In this regard, crocodiles are more closely related to birds than to any other living reptile class. Their teeth are set in sockets, a feature typical of the dinosaurs and the earliest birds. Similarly, crocodiles care for their young, another trait they have in common with birds. These and other features suggest that crocodiles and birds are more closely related than crocodiles and lizards. As with turtles, nest temperature influences the sex ratio of offspring. With crocodiles, however, when temperatures are warm, more males are produced. Biologists are concerned that global warming may reduce the number of breeding females, leading to extinction of some species.

Classes Ornithischia and Saurischia: The Dinosaurs In 1841, the English paleontologist Richard Owen coined the term **dinosaur** (from the Greek, meaning terrible lizard) to describe some of the wondrous fossil animals discovered in the 19th century. About 215 million years ago, dinosaurs were the dominant tetrapods on Earth and remained so for 150 million years, far longer than any other vertebrate. The two main classes were the ornithischian, or bird-hipped dinosaurs, which were herbivores such as *Stegosaurus*; and the saurischian, or lizard-hipped dinosaurs, which were fast, bipedal carnivores such as *Tyrannosaurus* (Figure 34.19). In contrast to the limbs of lizards, amphibians, and crocodiles, which splay out to the side, the legs of dinosaurs were positioned directly under the body, like pillars, a position that could help support their heavy body. Because less energy was devoted to lifting the body from the ground, some dinosaurs are believed to have been fast runners. Members of different but closely related classes—the pterosaurs (the first vertebrates to fly) and ichthyosaurs and plesiosaurs (marine reptiles)—were also common at this time.

Dinosaurs were the biggest animals ever to walk on the planet, with some animals weighing up to 50 tonnes (metric tons) or over 100,000 pounds. The variety of the thousands of dinosaur species found in fossil form around the world is staggering. However, perhaps not surprisingly for such long-extinct species, scientists are still hotly debating the details of their lives. For example, an issue still unresolved is whether some dinosaur species were **endothermic**, that is, capable of generating and retaining body heat through their metabolism, just as birds and mammals are. Another issue is whether dinosaurs exhibited parental care of their young.

(a) American alligator

(b) American crocodile

Figure 34.18 Crocodilians. The Crocodilia is an ancient class that has existed unchanged for millions of years. **(a)** Alligators, such as this American alligator (*Alligator mississippiensis*), have a broad snout, and the lower jaw teeth close on the inside of the upper jaw (and thus are almost completely hidden when the mouth is closed). **(b)** Crocodiles, including this American crocodile (*Crocodylus acutus*), have a longer, thinner snout, and the lower jaw teeth close on the outside of the upper jaw (and thus are visible when the mouth is closed).

Concept check: In what ways are crocodilians similar to birds?

(a) Ornithischian (*Stegosaurus*) (b) Saurischian (*Tyrannosaurus*)

Figure 34.19 Classes of dinosaurs. (a) Herbivorous ornithischians included *Stegosaurus*, and (b) carnivorous saurischians included bipedal species such as *Tyrannosaurus rex.*

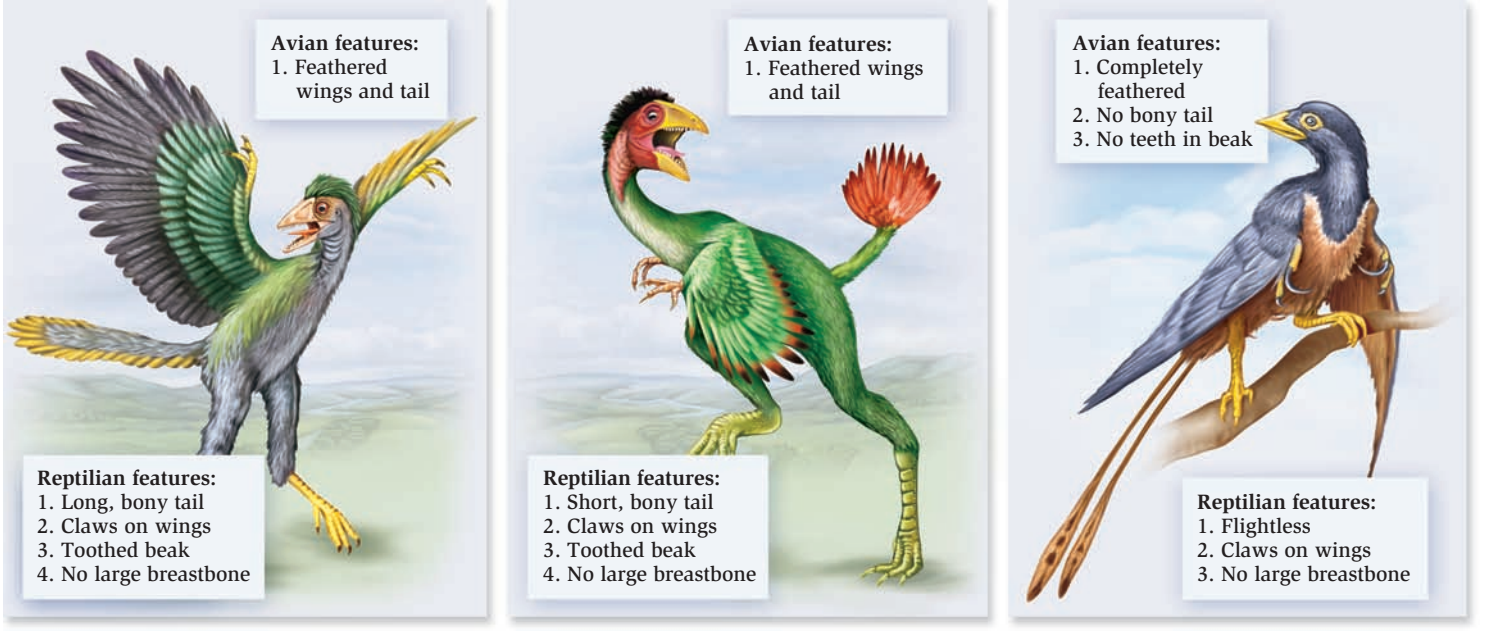
All dinosaurs, and many other animals, went extinct quite abruptly at the end of the Cretaceous period, about 65 million years ago. Although widely attributed to climatic change brought about by the impact of a meteorite or comet, scientists continue to debate the cause of this mass extinction. We do not yet know why all the dinosaurs died out, while many other animals, including small mammals, survived.

Class Aves: The Birds The defining characteristics of birds (class Aves, plural of the Latin *avis*, meaning bird) are that they have feathers and nearly all species can fly. As we will see, the ability to fly has shaped nearly every feature of the bird body. The other vertebrates that have evolved the ability to fly, the bats and the now-extinct pterosaurs, used skin stretched tight over elongated limbs to fly. Such a surface can be irreparably damaged, though some holes may heal remarkably quickly. In contrast, birds use feathers, epidermal outgrowths that can be replaced if damaged. Recent studies in cell signaling show that the developmental changes necessary for animals to grow feathers instead of scales may not be that complex at the molecular level.

In the rest of this section, we will discuss the likely evolution of birds from dinosaur ancestors, outline the key characteristics of birds, and provide a brief overview of the various bird orders.

Modern Birds Probably Evolved from Small, Feather-Covered Dinosaurs

To trace the evolution of birds, we must look for transitional forms, the earliest type of animals that had feathers. One of the first known fossils exhibiting the faint impression of feathers was *Archaeopteryx lithographica* (from the Greek, meaning ancient wings and stone picture), found in a limestone quarry in Germany in 1861. The fossil was dated at 150 million years old. Except for the presence of feathers, *Archaeopteryx* appears to have had features similar to those of dinosaurs (Figure 34.20a). First, the fossil had an impression of a long tail with many vertebrae, a dinosaur feature. Some modern birds have long tails, but they are made of feathers, with the actual tailbone being much reduced. Second, the wings had claws halfway down the leading edge, another dinosaur-like character. Among modern birds, only the hoatzin, a South American swamp-inhabiting bird, has claws on its wings, which enable the chicks to climb back into the nest if they fall out. A third dinosaur-like feature



(a) *Archaeopteryx lithographica* (b) *Caudipteryx zoui* (c) *Confuciusornis sanctus*

Figure 34.20 Transitional forms between dinosaurs and birds. (a) *Archaeopteryx lithographica* was a Jurassic animal with dinosaur-like features as well as wings and feathers. (b) *Caudipteryx zoui* was a dinosaur with feathers on its tail and wings. (c) *Confuciusornis sanctus* was a birdlike animal with a horny, toothless beak.

is *Archaeopteryx*'s toothed beak. Fourth, the fossils show that *Archaeopteryx* lacked an enlarged breastbone, a feature that modern birds possess to anchor their large flight muscles, so it likely could not fly.

Similarities between the structure of the skull, feet, and hind leg bones have led scientists to conclude that *Archaeopteryx* is closely related to **theropods**, a group of bipedal saurischian dinosaurs. (Note that despite their name, the ornithiscian, or bird-hipped dinosaurs, were not ancestral to modern birds.) The wings and feathers of *Archaeopteryx* may have enabled it to glide from tree to tree, helped to it keep warm, or cut out the glare when folded over its head when hunting, in much the same way as some herons fold their wings over their heads when they are fishing. Later, the wings and feathers may have taken on functions of flight. We often find that evolution proceeds when previously evolved structures are co-opted into different uses, a diversity principle known as descent with modification.

In 1997, paleontologists unearthed fossils of about the same age as *Archaeopteryx* in China that similarly suggest a close kinship between dinosaurs and modern birds. *Caudipteryx zoui* was a dinosaur-like animal with feathers on its wings and tail and a toothed beak (Figure 34.20b). *Confuciusornis sanctus* was a small, flightless but completely feathered dinosaur lacking the long, bony tail and toothed jaw found in other theropod dinosaurs. Its large tail feathers may have functioned in courtship displays (Figure 34.20c).

These three species—*Archaeopteryx*, *Caudipteryx*, and *Confuciusornis*—help trace a lineage from dinosaurs to birds. By the early Cretaceous period, and only a relatively short period after *Archaeopteryx* evolved, the fossil record shows the existence of a huge array of bird types resembling modern species. These were to share the skies with pterosaurs for 70 million years, before eventually having the airways to themselves.

Birds Have Feathers, a Lightweight Skeleton, Air Sacs, and Reduced Organs

Modern birds possess many characteristics that reveal their reptilian ancestry. For example, they have scales on their feet and legs, and they lay shelled eggs. In addition, however, among living animals they have four features unique to birds, all of which are associated with flight.

1. **Feathers.** Feathers are modified scales that keep birds warm and enable flight (Figure 34.21a). Soft, downy feathers maintain heat, while stiffer contour feathers, supported on a modified forelimb, give the wing the airfoil shape it needs to generate lift. Each contour feather develops from a follicle, a tiny pit in the skin. If a feather is lost, a new one can be regrown. The contour feathers consist of many paired barbs, each of which supports barbules that contain hooks that interlock with barbules from neighboring barbs to give the feather its shape (Figure 34.21b).
2. **Air sacs.** Flight requires a great deal of energy generated from an active metabolism that requires abundant oxygen. Birds have nine air sacs—large, hollow sacs that may extend into the bones (look ahead to Figure 48.13). On inhalation, air passes into the posterior air sacs. On exhalation, this air is forced into the lungs, where oxygen is extracted. On the next inhalation, the air moves from the lungs into the anterior air sacs. On the next exhalation,

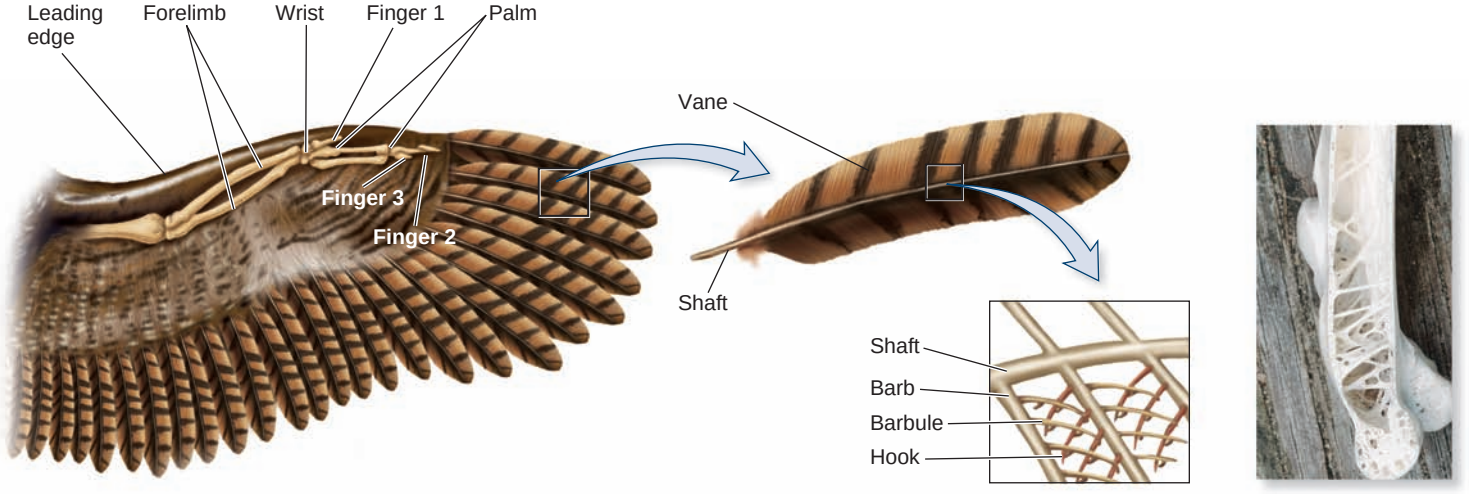


Figure 34.21 **Features of the bird wing and feather.** **(a)** The wing is supported by an elongated and modified forelimb with extended fingers. **(b)** Each feather has a hollow shaft that supports many barbs, which, in turn, support barbules that interlock with hooks to give the feather its form. **(c)** The bones of a pelican (*Pelicanus occidentalis*) are hollow but crisscrossed with a honeycomb structure that provides added strength.

Concept check: *What adaptations in birds help reduce their body weight to enable flight?*

the air leaves the anterior air sacs. Air is therefore being constantly moved across the lungs during inhalation and exhalation. While making bird breathing very efficient, this process also makes birds especially susceptible to airborne toxins (hence, the utility of the canary in the coal mine; the bird's death signaled the presence of harmful carbon dioxide or methane gas that was otherwise unnoticed by miners).

3. **Reduction of organs.** To decrease the total mass the bird must carry, some organs are reduced in size or are lacking altogether. For example, birds have only one ovary and can carry relatively few eggs. As a result, they lay fewer eggs than most other reptile species. In fact, the gonads of both males and females are reduced, except during the breeding season, when they increase in size. Most birds also lack a urinary bladder. In addition, teeth loss has reduced weight at the head end.
4. **Lightweight bones.** Most bird bones are thin and hollow and are crisscrossed internally by tiny pieces of bone to give them a honeycomb structure (Figure 34.21c). However, because the limb bones are large, bird skeletons weigh about the same as the skeleton of a comparably sized mammal. An enlarged breastbone, or **sternum**, provides an anchor on which a bird's powerful flight muscles attach. These muscles may contribute up to 30% of the bird's body weight. Birds' skulls are lighter than skulls from mammals of approximately the same weight. The bird skull lacks teeth, but the keratin of bird beaks is tough and malleable, and it takes very different shapes in different species, depending on the function of the beak (Figure 34.22).

Birds also have other distinct features, though mammals also possess some of these. For example, birds have a warm body temperature, which ensures rapid metabolism and the quick production of ATP that these active organisms need to fuel flight and other activities. In fact, birds' body temperatures are generally 40–42°C, considerably warmer than the human body's average of 37°C. Birds have a double circulation and a four-chambered heart to ensure rapid blood circulation. Rapid flight also requires acute vision, and bird vision is among the best in the vertebrate world. Generally, plant material is not energy-rich enough to supply the dietary needs of birds, so most birds are carnivores, eating insects and other invertebrates. However, some birds, such as parrots, eat just the more-nutrient-rich fruits and seeds. Bird eggs also have to be kept warm for successful development, which entails brooding by an adult bird. Often, the males and females take turns brooding so that one parent can feed and maintain its strength. Picking successful partners is therefore an important task, and birds often engage in complex courtship rituals.

There Are Many Orders of Birds, All with the Same Body Plan

Birds are the most species-rich class of terrestrial vertebrates, with 28 orders, 166 families, and about 9,600 species (Table 34.2). Despite this diversity, birds lack the variety of body shapes that exist in the other endothermic class of vertebrates, the mammals, where some species swim, others fly, others walk on four legs, and yet others walk only on two legs. Most birds fly, and therefore, most have the same general body shape. The biggest departures from this body shape are the flightless birds, including the cassowaries, emus, and ostriches. These birds have smaller wing bones, and the keel on the breastbone is greatly reduced or absent. Penguins are also flightless birds whose upper limbs are modified as flippers used in swimming.

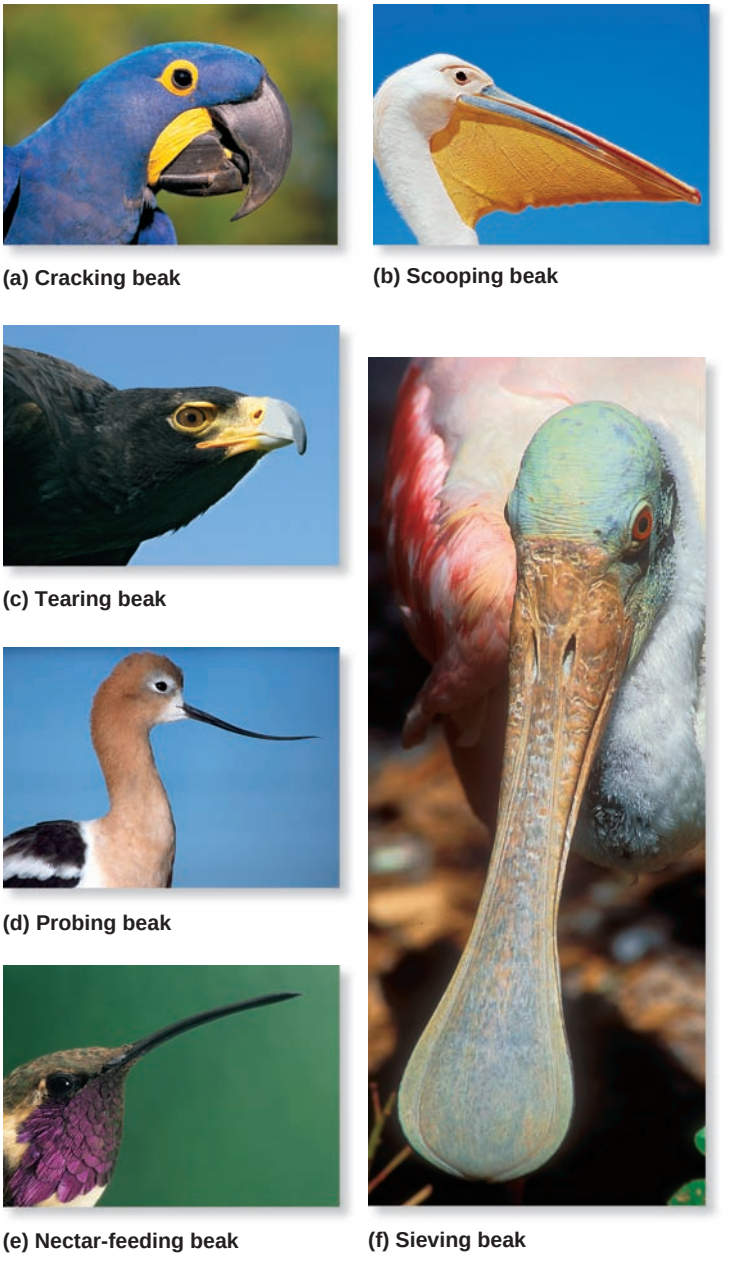

Figure 34.22 **A variety of bird beaks.** Birds have evolved a variety of beak shapes used in different types of food gathering. **(a)** Hyacinthe macaw (*Anodorhynchus hyacinthinus*)—cracking. **(b)** White pelican (*Pelecanus onocrotalus*)—scooping. **(c)** Verreaux's eagle (*Aquila verreauxii*)—tearing. **(d)** American avocet (*Recurvirostra americana*)—probing. **(e)** Lucifer hummingbird (*Calothorax lucifer*)—nectar feeding. **(f)** Roseate spoonbill (*Ajaia ajaia*)—sieving.

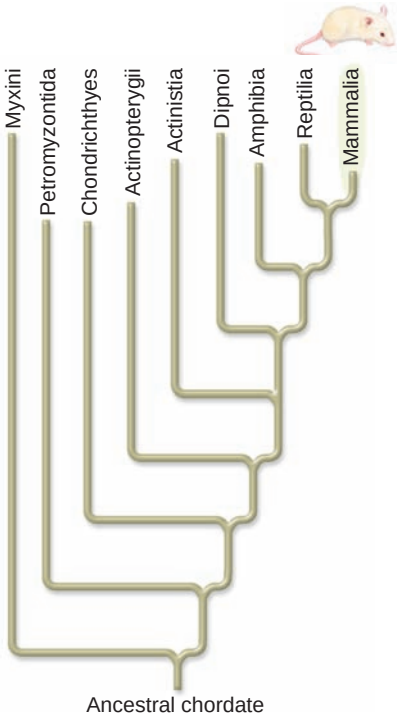
Table 34.2 The Main Orders of Birds, in Order of Species Richness

Order	Examples (approx. # of species)	Main characteristics
Passeriformes 	Robins, starlings, sparrows, warblers (5,300)	Perching birds with perching feet; songbirds
Apodiformes 	Hummingbirds, swifts (430)	Fast fliers with rapidly beating wings; small bodies
Piciformes 	Woodpeckers, toucans (380)	Large with specialized beaks; two toes pointing forward and two backward
Psittaciformes 	Parrots, cockatoos (340)	Large, powerful beaks
Chadradriiformes 	Seagulls, wading birds (330)	Shorebirds
Columbiformes 	Doves, pigeons (300)	Round bodies; short legs
Falconiformes 	Eagles, hawks, kestrels, vultures (290)	Diurnal carnivores; birds of prey; powerful talons; strong beaks
Galliformes 	Chickens, pheasants, quail (270)	Often large birds; weak flyers; ground nesters
Coraciiformes 	Hornbills, kingfishers (200)	Large beaks; cavity nesters
Anseriformes 	Ducks, swans, geese (150)	Able to swim; webbed feet; broad bills
Strigiformes 	Owls (150)	Nocturnal carnivores; powerful talons; strong beaks
Pelecaniformes 	Pelicans, frigate birds, cormorants (55)	Large, colonial fish eaters; often tropical
Sphenisciformes 	Penguins (18)	Flightless; wings modified into flippers for swimming; marine; Southern Hemisphere
Casuariformes 	Cassowaries, emus (3)	Large, flightless; Australia and New Guinea
Struthioniformes 	Ostrich (1)	Large, flightless; only two toes; Africa only

34.6 Mammals: Milk-Producing Amniotes

Mammals evolved from amniote ancestors earlier than birds. About 225 million years ago, the first mammals appeared in the mid-Triassic period. They evolved from small mammal-like reptiles that went extinct about 170 million years ago. Mammals survived, although most are believed to have been small, insect-eating species that lived in the shadows of dinosaurs. However, in January 2005, two fossils of a 130-million-year-old mammalian genus called *Repenomamus* were discovered that challenge the notion of mammals as small insect eaters. One fossil was of an animal estimated to weigh about 13 kg (30 lb), and the other had the remains of a baby dinosaur in its stomach.

After the extinction of the dinosaurs in the Cretaceous period, some 65 million years ago, mammals flourished. Today, biologists have identified about 5,500 species of mammals with a diverse array of lifestyles, from fishlike dolphins to bird-like bats, and from small insectivores such as shrews to large



herbivores such as giraffes and elephants. The range of sizes and body forms of mammals is unmatched by any other group, and mammals are prime illustrations of the concept that organismal diversity is related to environmental diversity. In this section, we will outline the features that distinguish mammals from other taxa. We will also examine the diversity of mammals that exists on Earth and will end by turning our attention to primates and, in particular, to the evolution of humans.

Mammals Have Mammary Glands, Hair, Specialized Teeth, and an Enlarged Skull

The distinguishing characteristics of mammals are the possession of mammary glands, hair, specialized teeth, and an enlarged skull.

- **Mammary glands.** Mammals, or the class Mammalia (from the Latin *mamma*, meaning breast), are named after the female's distinctive **mammary glands**, which secrete milk. Milk is a fluid rich in fat, sugar, protein, and vital minerals, especially calcium. Newborn mammals suckle this fluid, which helps promote rapid growth.
- **Hair.** All mammals have hair, although some have more than others. Whales have hair in utero, but adults are hairless or retain only a few hairs on their snout. Humans are relatively hairless. In some animals, the hair is dense and is referred to as fur. In some aquatic species such as beavers, the fur is so dense it cannot be thoroughly wetted, so the hair underneath remains dry. Mammals are endothermic, and their fur is an efficient insulator. Hair can also take on functions other than insulation. Many mammals, including cats, dogs, walruses, and whales, have sensory hairs called vibrissae (Figure 34.23a). Hair can be of many colors, to allow the mammals to blend into their background (Figure 34.23b). In some cases, as in porcupines and hedgehogs, the hairs become long, stiffened, and sharp (quills) and serve as a defense mechanism (Figure 34.23c).
- **Specialized teeth.** Mammals are the only vertebrates with highly differentiated teeth—incisors, canines, premolars, and molars—that are adapted for different types of diets (Figure 34.24). Although teeth are generally present in all species, different teeth are larger, smaller, lost, or reduced, depending on diet. Of particular importance to carnivores such as wolves are the piercing canine teeth, whereas herbivorous species such as deer depend on their chisel-like incisors to snip off vegetation and on their many molars to grind plant material. Only mammals chew their food in this fashion. Rodent incisors grow continuously throughout life, and species such as beavers wear them down by gnawing tough plant material such as wood. Mammals that have different types of teeth are called heterodont; others, such as dolphins, where the teeth are of uniform size and shape, are called homodont.
- **Enlarged skull.** The mammalian skull differs from other amniote skulls in several ways. First, the brain is enlarged and is contained within a relatively large skull. Second, mammals have a single lower jawbone, unlike reptiles, whose lower jaw is composed of multiple bones. Third, mammals have three bones in the middle ear, as opposed to reptiles, which have one bone in the middle ear. Fourth, most mammals, except some seals, have external ears.

(a) Sensory hairs

(b) Camouflaged coat

(c) Defensive quills

Figure 34.23 **Mammalian hair.** **(a)** The sensory hairs (vibrissae) of the walrus (*Odobenus rosmarus*). **(b)** The camouflaged coat of a bobcat (*Lynx rufus*). **(c)** The defensive quills of the crested porcupine (*Hystrix africaeaustralis*).

(a) Biting teeth

(b) Grinding teeth

(c) Gnawing teeth

(d) Tusks

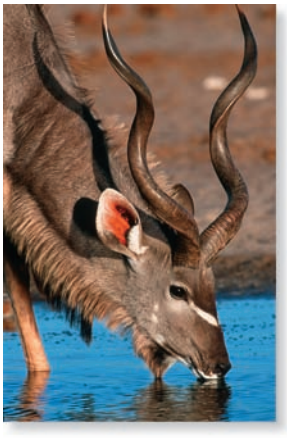
(e) Grasping teeth

Figure 34.24 Mammalian teeth. Mammals have different types of teeth, according to their diet. **(a)** The wolf has long canine teeth for biting its prey. **(b)** The deer has a long row of molars for grinding plant material. **(c)** The beaver, a rodent, has long, continually growing incisors used to gnaw wood. **(d)** The elephant's incisors are modified into tusks. **(e)** Dolphins and other fishes or plankton feeders have numerous small teeth for grasping prey.

In addition to those uniquely mammalian characteristics, some, but not all, mammals possess these additional features:

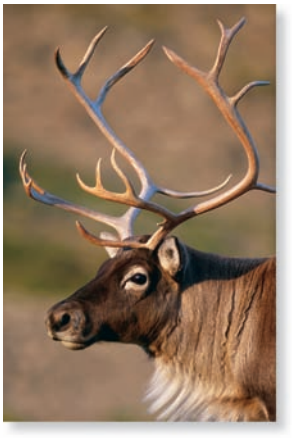
- **The ability to digest plants.** Apart from tortoises and marine iguanas, certain species of mammals are the only large vertebrates alive today that can exist on a steady diet of grasses or tree leaves; indeed, most large mammals are herbivores. Though mammals cannot digest cellulose, the principal constituent of the cell wall of many plants, some species have a large four-chambered stomach containing cellulose-digesting bacteria. These bacteria can break down the cellulose and make the plant cell contents available to the animal. Others have an extensive cecum or large intestine where digestion occurs.
- **Horns and antlers.** Mammals are the only living class of vertebrates to possess horns or antlers. Many mammals, especially antelopes, cattle, and sheep, have horns, typically consisting of a bony core that is a permanent outgrowth of the skull surrounded by a hairlike keratin sheath, as shown in the large antelope called a kudu (Figure 34.25a). Rhinoceros horns are outgrowths of the epidermis, consisting of very tightly matted hair (Figure 34.25b). In contrast, deer antlers are made entirely of bone (Figure 34.25c). Deer grow a new set of antlers each year and shed them after the mating season. Hooves are also made of keratin and protect an animal's toes from the impact of its feet striking the ground.

Figure 34.25 Horns and antlers in mammals. Mammals have a variety of outgrowths that are used for defense or by males as weapons in contests over females. **(a)** The horns of this male kudu (*Tragelaphus strepsiceros*) are bony outgrowths of the skull covered in a keratin sheath. **(b)** The horns of the black rhinoceros (*Diceros bicornis*) are outgrowths of the epidermis, made of tightly matted hair. **(c)** The antlers of the caribou (*Rangifer tarandus*), also known as reindeer, are made entirely of bone and are grown and shed each year.



(a) Skull outgrowths

(b) Epidermal outgrowths



(c) Bony antlers

Mammals Are the Most Diverse Group of Vertebrates Living on Earth

Modern mammals are incredibly diverse (Table 34.3). They vary in size from tiny insect-eating bats, weighing in at only 2 g, to leviathans such as the blue whale, the largest animal ever known, which tips the scales at 100 tonnes (over 200,000 lbs). The 26 different mammalian orders are divided into two distinct subclasses. The subclass Prototheria contains only the order Monotremata, or **monotremes**, which are found in Australia and New Guinea. There are only five species: the duck-billed platypus (Figure 34.26a) and four species of echidna, a spiny animal resembling a hedgehog. Monotremes are early-diverging mammals that lay eggs rather than bear live young, lack a placenta, and have mammary glands with poorly developed nipples. The mothers incubate the eggs, and upon hatching, the young simply lap up the milk as it oozes onto the fur.

The subclass Theria contains all remaining live-bearing mammals. The Theria are divided into two clades, the Metatheria and the Eutheria. The clade Metatheria, or the **marsupials**, is a group of seven orders, with about 280 species, including the rock wallaby pictured in Figure 34.26b. Once widespread, members of this order are now largely confined to Australia, although some marsupials exist in South America, and one species—the opossum—is found in North America. Fertilization is internal, and reproduction is viviparous in marsupials. Marsupials have a placenta that nourishes the embryo. Unlike other mammals, however, marsupials are extremely small when they

Table 34.3 The Main Orders of Mammals, in Order of Species Richness

Order	Examples (approx. # of species)	Main characteristics
Rodentia	Mice, rats, squirrels, beavers, porcupines (2,277)	Plant eating; gnawing habit, with two pairs of continually growing incisor teeth
Chiroptera	Bats (1,116)	Insect or fruit eating; small; have ability to fly; navigate by sonar; nocturnal
Soricomorpha	Shrews, moles (428)	Insect eaters; primitive placental mammals
Primates	Monkeys, apes, humans (404)	Opposable thumb; binocular vision; large brains
Carnivora	Cats, dogs, weasels, bears, seals, sea lions (286)	Flesh-eating mammals; canine teeth
Artiodactyla	Deer, antelopes, cattle, sheep, goats, camels, pigs (240)	Herbivorous hoofed mammals, usually with two toes, hippopotamus and others with four toes; many with horns or antlers
Diprotodontia	Kangaroos, koalas, opossums, wombats (143)	Pouched mammals mainly found in Australia
Lagomorpha	Rabbits, hares (92)	Powerful hind legs; rodent-like teeth
Cetacea	Whales, dolphins (84)	Marine fishes or plankton feeders; front limbs modified into flippers; no hind limbs; little hair except on snout
Erinaceomorpha	Hedgehogs, moonrats (24)	Insect eaters; nocturnal; hedgehogs with stiff spines
Perissodactyla	Horses, zebras, tapirs, rhinoceroses (18)	Hoofed herbivorous mammals with odd number of toes, one (horses) or three (rhinoceroses)
Monotremata	Duck-billed platypuses, echidna (5)	Egg-laying mammals found only in Australia and New Guinea
Proboscidea	Elephants (3)	Long trunk; large, upper incisors modified as tusks

(a) Prototherian (duck-billed platypus)

(c) Eutherian (orangutan)

(b) Metatherian (rock wallaby)

Figure 34.26 Diversity among mammals. **(a)** Prototherians, such as this duck-billed platypus (*Ornithorhynchus anatinus*), lay eggs, lack a placenta, and possess mammary glands with poorly developed nipples. **(b)** Metatherians, or marsupials, such as this rock wallaby (*Petrogale assimilis*), feed and carry their developing young, or "joeys," in a ventral pouch. **(c)** Gestation lasts longer in eutherians, and their young are more developed at birth, as illustrated by this young orangutan (*Pongo pygmaeus*).

are born (often only 1 or 2 cm) and make their way to a ventral pouch called a marsupium for further development.

All the other mammalian orders are members of the clade Eutheria and are considered **eutherians**, or placental mammals, such as the orangutans shown in Figure 34.26c. Eutherians have a long-lived and complex placenta, compared to that of marsupials. In eutherians, fertilization is internal, and reproduction is viviparous, but the developmental period, or gestation, of the young is prolonged.

Of all the world's animals, the diversity of vertebrates, and especially mammals, is the most threatened by human activities. Many species are hunted for food. Others, such as wild cats and whales, are hunted for their products (fur and oil, respectively), and still others, such as the oryx, have simply been shot for sport.

Primates Are Mammals with Opposable Thumbs and a Large Brain

Of the mammalian orders, the primates, and specifically humans, have had the greatest impact on the world. Primates are primarily tree-dwelling species that are believed to have evolved from a group of small, arboreal insect-eating mammals about 85 million years ago, before dinosaurs went extinct. Primates have several defining characteristics, mostly relating to their tree-dwelling nature:

- **Grasping hands.** All primates have grasping hands, a characteristic that enables them to hold onto branches (see Figure 34.28a,b). Most primate species also possess an **opposable thumb**, a thumb that can be placed opposite the fingers of the same hand, which gives them a precision grip and enables the manipulation of small objects. All primates except humans also have an opposable big toe.
- **Large brain.** Acute vision and other senses enhancing the ability to move quickly through the trees require the efficient processing of large amounts of information. As a result, the primate brain is large and well developed. In turn, this has facilitated complex social behaviors.
- **At least some digits with flat nails instead of claws.** This feature is believed to aid in the manipulation of objects.
- **Binocular vision.** Primates have forward-facing eyes that are positioned close together on a flattened face, though some other mammals share this characteristic. Jumping from branch to branch requires accurate judgment of distances. This is facilitated by binocular vision, in which the field of vision for both eyes overlaps, producing a single image.
- **Complex social behavior and well-developed parental care.**

Some of these characteristics are possessed by other animals. For example, binocular vision occurs in owls, grasping hands are found in raccoons, and relatively large brains occur in marine mammals. Primates are defined by possessing the whole suite of these characteristics together. Primates may be classified in several ways. Taxonomists often divide them into two groups: the strepsirrhini and the haplorrhini (Figure 34.27). The **strepsirrhini** contain the smaller species such as bush babies, lemurs, and pottos. These are generally nocturnal and smaller-brained primates with eyes positioned a little more

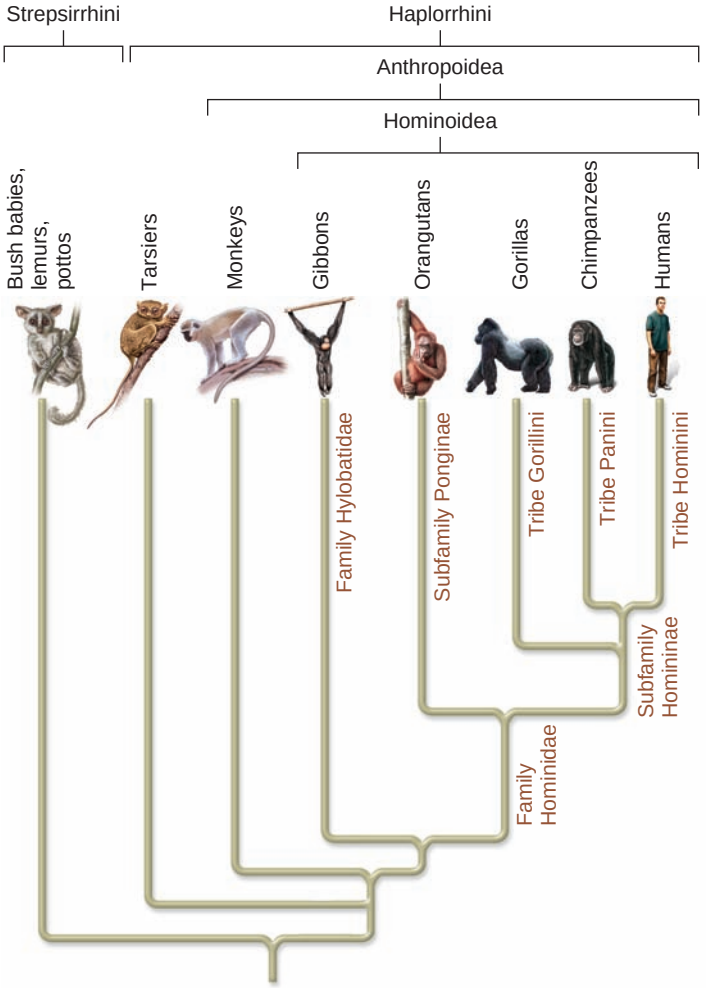


Figure 34.27 Evolutionary tree of the primates.

toward the side of their heads (Figure 34.28a). The strepsirrhini are named for their wet noses with no fur at the tip. The **haplorrhini** have dry noses with a fully furred nose tip and fully forward-facing eyes. This group consists of the larger-brained and diurnal **anthropoidea**: the monkeys (Figure 34.28b) and the **hominoidea** (gibbons, orangutans, gorillas, chimpanzees, and humans) (Figure 34.28c). The tarsiers also belong in the haplorrhini, despite their small size, based on their forward-facing eyes and DNA similarities to the monkeys and apes.

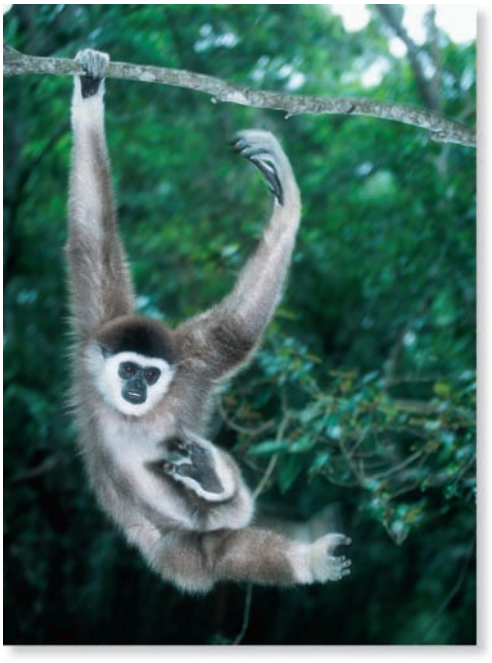
What differentiates monkeys from hominoids? Most monkeys have tails, whereas hominoids do not. In addition, apes have more mobile shoulder joints, broader rib cages, and a shorter spine. These features aid in brachiation, a swinging movement in trees. Apes also possess relatively long limbs and short legs and, with the exception of gibbons, are much larger than monkeys. The 20 species of hominoids are split into two groups: the lesser apes (family Hylobatidae), or the gibbons; and the greater apes (family Hominidae), or the orangutans, gorillas, chimpanzees, and humans (Figure 34.29). The lesser apes are strictly arboreal, whereas the greater apes often descend to the ground to feed.

Figure 34.28 **Primate classification.** Many authorities divide the primates into two groups: **(a)** the strepsirrhini (smaller, nocturnal species such as this bush baby), and the haplorrhini (larger diurnal species). Haplorrhini comprise **(b)** the monkeys and tarsiers, such as this Capuchin monkey, *Cebus capucinus*, and **(c)** the hominoids, species such as this white-handed gibbon (*Hylobates lar*).

Concept check: *What are the defining features of primates?*

(a) Strepsirrhini (lesser bush baby)

(b) Anthropoidea (capuchin monkey)



(c) Hominoidea (white-handed gibbon)

(a) Gorilla (*Gorilla gorilla*)

(b) Chimpanzee (*Pan troglodytes*)

(c) Human (*Homo sapiens*)

Figure 34.29 **Members of the family Hominidae.** The orangutan is also a member of this group. **(a)** Gorillas, the largest of the living primates, are ground-dwelling herbivores that inhabit the forests of Africa. **(b)** Chimpanzees are smaller, omnivorous primates that also live in Africa. The chimpanzees are the closest living relatives of modern humans. **(c)** Humans are also members of the family Hominidae.

Although humans are closely related to chimpanzees and gorillas, they did not evolve directly from them. Rather, all hominoid species shared a common ancestor. Recent molecular studies show that gorillas, chimpanzees, and humans are more closely related to one another than they are to gibbons and orangutans, so scientists have split the family Hominidae into groups, including the subfamily Ponginae (orangutans) and the subfamily Homininae (gorillas, chimpanzees, and humans and their ancestors). In turn, the Homininae are split into three tribes: the Gorillini (gorillas), the Panini (chimpanzees), and the Hominini (humans and their ancestors). The sequencing of the chimpanzee genome by the Chimpanzee Sequencing and Analysis Consortium in 2005 allowed detailed comparisons to be made with the human genome.

Genomes & Proteomes Connection

Comparing the Human and Chimpanzee Genetic Codes

A male chimp called Clint who lived at a primate research center in Atlanta provided the DNA used to sequence the chimp genome. The 2005 publication of the chimpanzee genome followed the 2003 publication of the human genome (see Chapter 21) and allowed scientists to make detailed comparisons between the two species. These comparisons revealed that the sequence of base pairs making up both species' genomes differ by only 1.23%, 10 times less than the difference between the mouse and rat genomes. Compared to mice and rats, chimps and humans both carry what appear to be high levels of potentially harmful repetitive sequences. Such sequences may have permitted adaptation to environmental change but also have made primates more prone to genetic diseases. The chimpanzee genome in particular shows that it has been attacked frequently by retroviral elements similar to those present in the HIV virus. Comparisons of human and chimpanzee proteomes revealed that 29% of all proteins are identical, but most others differ by only one or two amino acid substitutions.

Many of the genetic differences between chimps and humans result from chromosome inversions and duplications. Geneticists have found over 1,500 inversions between the chimp and human genomes. Although many inversions occur in the noncoding regions of the genome, the DNA in these regions may regulate the expression of the genes in the coding regions. Duplications and deletions are also common. For example, one gene that codes for a subunit of a protein found in areas of the brain occurs in multiple copies in a wide range of primates, but humans have the most copies. However, humans appear to have lost a gene called *caspase-12*, which in other primates may protect against Alzheimer disease.

Some interesting genetic differences were apparent between chimps and humans even before their entire genomes were sequenced. In 1998, Ajit Varki and colleagues investigated a molecule called sialic acid that occurs on cell surfaces and acts as a locking site for pathogens such as malaria and influenza. They found an altered form of the molecule in humans, coded for by a single damaged gene, which may explain why humans are more susceptible to these diseases than are chimpanzees. A little later, molecular geneticist Svante Pääbo discovered differences between humans and chimps in a gene called *FOXP2* that plays a role in speech development. Proteins coded for by this gene differ in just two locations of a 715-amino-acid sequence. Humans with a defective *FOXP2* gene have difficulty articulating words, underscoring its importance.

Finally, another team led by David Reich discovered that the human X chromosome diverged from the chimpanzee X chromosome about 1.2 million years later than the other chromosomes. This may indicate that the human and chimp lineages split apart, then later interbred before diverging again. This would explain why many fossils appear to exhibit traits of both humans and chimps, because they may actually have been hybrids.

Humans Evolved from Ancestral Primates

About 6 million years ago in Africa, a lineage that led to humans began to separate from other primate lineages. The evolution of humans should not be viewed as a neat, stepwise progression from one species to another. Rather, human evolution, like the evolution of most species, can be visualized more like a tree, with one or two **hominin** species—members of the Homininae tribe—likely coexisting at the same point in time, with some eventually going extinct and some giving rise to other species (Figure 34.30).

The key characteristic differentiating hominins from other apes is that hominins walk on two feet, that is, they are **bipedal**. At about the time when hominins diverged from other ape lineages, the Earth's climate had cooled, and the forests of Africa had given way to grassy savannas. A bipedal method of locomotion and upright stance may have been advantageous in allowing hominins to peer over the tall grass of the savanna to see predators or even prey.

Bipedalism is correlated with many anatomical changes in hominins. First, the opening of the skull where the spinal cord enters shifted forward, allowing the spine to be more directly underneath the head. Second, the hominin pelvis became broader to support the additional weight. And third, the lower limbs, used for walking, became relatively larger than those in other apes. These are the types of anatomical changes paleontologists look for in the fossil record to help determine whether fossil remains are hominin. The earliest group of hominins included several species of a smaller-brained genus, *Australopithecus*. *A. afarensis* is generally regarded as the common ancestor of most of these species. From there, the evolution of different species becomes somewhat hazy. It is generally agreed that two genera evolved from *Australopithecus*, the robust *Paranthropus* and the more gracile *Homo*. The early stages of the evolution of *Homo* species, and their differentiation from at least two possible *Australopithecus*, have not yet been determined with any certainty. However, the later divergence of various *Homo* species is a little better understood.

Australopithecines Since 1924, when the first fossil australopithecine (from the Latin *austral*, meaning southern, and the Greek *pithecus*, meaning ape) was found in South Africa, hundreds of fossils of this group have been unearthed all over southern and eastern Africa, the areas where fossil deposits are best exposed to paleontologists. This was a widespread group, with at least six species. In 1974, paleontologist Donald Johanson unearthed the skeleton of a female *Australopithecus afarensis* in the Afar region of Ethiopia and dubbed her Lucy. The Beatles' song "Lucy in the Sky with Diamonds" was playing in the camp the night when Johanson was sorting the unearthed bones. Over 40% of the skeleton had been preserved, enough to provide a good idea of the physical appearance of australopithecines. Compared to modern humans, all were relatively small, about 1–1.5 m in height and around 18 kg in weight (Figure 34.31). Females were much smaller than males, a condition known as sexual dimorphism. Examination of the bones revealed that *A. afarensis* walked on two legs. They possessed a facial structure and brain size (about 500 cubic centimeters [cc]) similar to those of a chimp.

In the 1930s, the remains of bigger-boned hominids were found. Two of the larger species now considered to be a separate genus, *Paranthropus*, weighed about 40 kg and lived contemporaneously with australopithecines and members of *Homo* species. *Paranthropus* were vegetarians with enormous jaws used for grinding up tough roots and tubers. Both *Paranthropus* species died out rather suddenly about 1.5–2.0 million years ago. Although *Australopithecus africanus* was thought to have evolved slightly later than *A. afarensis*, its bones had been found much earlier than those of *A. afarensis*. In the 1920s, Raymond Dart described *A. africanus* from infant bones

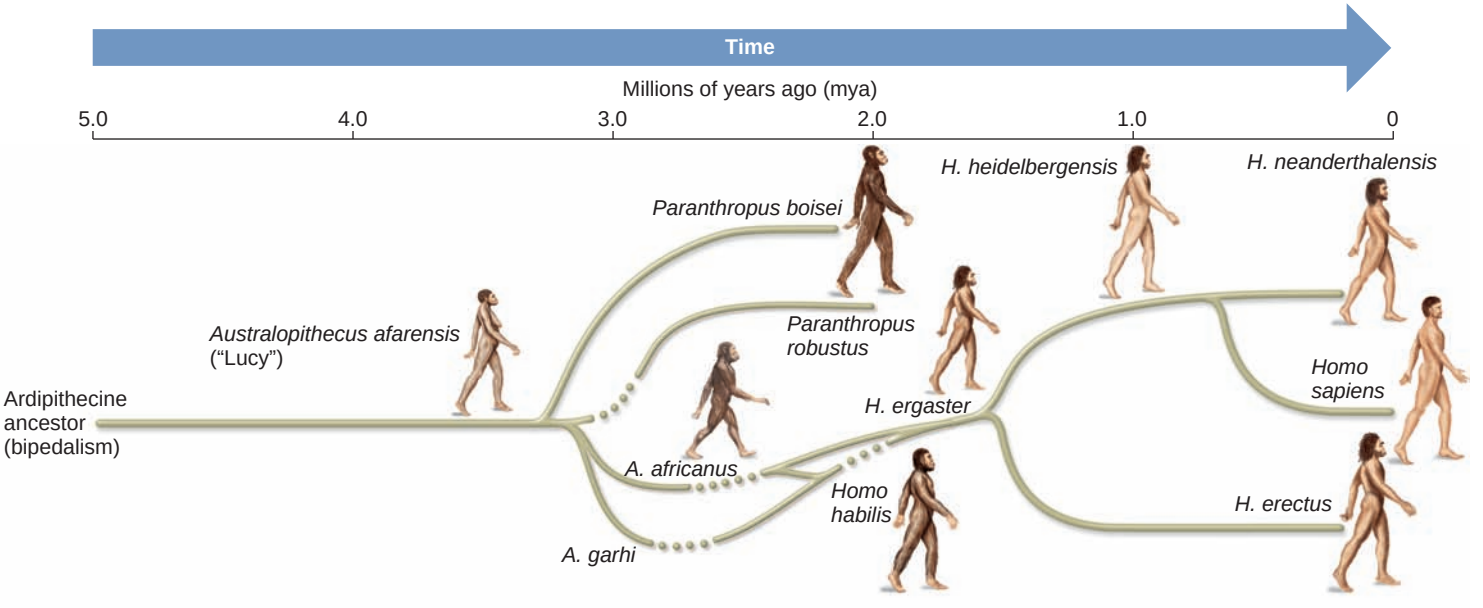


Figure 34.30 **A possible scenario for human evolution.** In this human family tree (based on the ongoing work of Donald Johanson), several hominin species lived contemporaneously with one another, but only one lineage gave rise to modern humans (*Homo sapiens*).

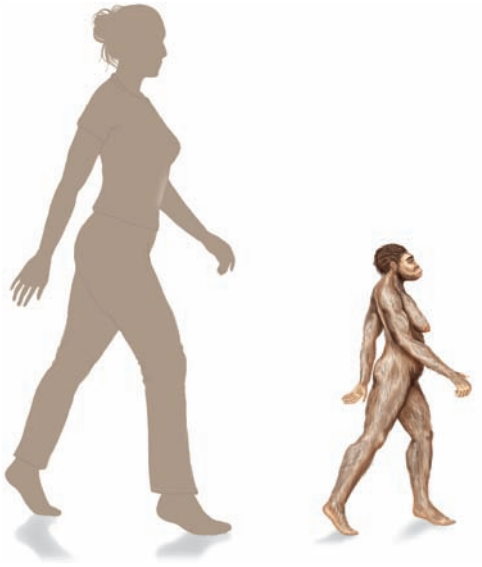

Figure 34.31 A modern woman compared to an australopithecine. Compared to modern humans, Australopithecines, as illustrated by this reconstruction of the famous fossil "Lucy," were much smaller and lighter.

discovered in a cave in Taing, South Africa. The type specimen was called Taing child. The well-preserved skull was small but was well rounded, quite unlike those of chimpanzees and gorillas. Also, the positioning of the head on the vertebral column suggested bipedalism. These facts suggested to Dart that he had found a transitional form between apes and humans. However, it would take another 20 years and the discovery of more fossils to convince the scientific world to support Dart's view. In 1996, remains of another species, *A. garhi*, were also found in the Afar region. They were somewhat of a surprise in that the dentition suggested similarities with *Paranthropus boisei*. "Garhi" means surprise in the local Afar language. The position of both *A. garhi* and *A. africanus* as ancestors of modern humans has been the subject of much debate. Both have been viewed as dead-end cousins or the ancestors of the first members of the genus *Homo*.

The Genus Homo and Modern Humans In the 1960s, paleontologist Louis Leakey found hominin fossils estimated to be about 2 million years old in Olduvai Gorge, Tanzania. Two particularly interesting observations stand out about these fossils. First, reconstruction of the skull showed a brain size of about 680 cc, larger than that of *Australopithecus*. Second, the fossils were found with a wealth of stone tools. As a result, Leakey assigned the fossils to a new species, *Homo habilis*, from the Latin, meaning handy man. The discovery of several more *Homo* fossils followed, but there have been no extensive finds, as there were with Lucy. This makes it difficult to determine which *Australopithecus* lineage gave rise to the *Homo* lineage (see Figure 34.30), and scientists remain divided on this point.

Homo habilis lived alongside *Paranthropus* but had much smaller jaws and teeth, indicating that it probably ate large quantities of meat. The smaller jaw provided more space in the skull for brain development. *Homo habilis* probably scavenged most of its meat from the kills of large predators. A meatier diet is easier to digest and is rich in nutrients and energy. The human brain uses a lot of energy, 20% of the body's total energy production. The meat-eating habit helped propel the increasing brain size in humans. Stone tools also allowed *H. habilis* to smash open bones and extract protein-rich bone marrow. Cut marks on animal bones of the period are testament to this behavior.

Although we are not clear exactly how, we think *H. habilis* probably gave rise to one of the most important species of *Homo*, *Homo ergaster*. *Homo ergaster* was a hominin that evolved in Africa; it had a human-looking face and skull, with downward-facing nostrils. *Homo ergaster* was also a tool user, and now the tools, such as hand axes, were larger and more sophisticated. *Homo ergaster* evolved in a period of global cooling and drying that reduced tropical forests even more and promoted savanna conditions. Hairlessness and sweating may also have evolved at this time as an adaptation to the sunny environment. A leaner body shape was evident. We know this from so-called Turkana boy, a fossil teenage boy found in Kenya in 1984. Though only 13 years old, scientists predict he would have been about 185 cm (6 ft 1 in) when adult, much the same height as the Masai tribesman that inhabit the area today. A dark skin probably protected *H. ergaster* from the sun's rays. The hips had narrowed, and the size of the head increased, which may have produced more difficulty in childbirth and eventually led to human babies being born earlier. Earlier birth leads to prolonged childhood care compared to that in other apes. Prolonged childcare required well-nourished mothers, who would have benefited from the support of their male partner. Some anthropologists have suggested this was the beginning of family groups.

H. ergaster is thought to have given rise to many species, including *Homo erectus*, *Homo heidelbergensis*, *Homo neanderthalensis*, and *Homo sapiens*. A possible time line and geographic location for these species are given in Figure 34.32. *Homo ergaster* probably was the first type of human to leave Africa, as similar bones have been found in the Eurasian country of Georgia. *H. ergaster* is believed to be a direct ancestor of modern humans, with *Homo heidelbergensis* viewed as an intermediary step. Living contemporaneously with *H. heidelbergensis* was another descendent of *H. ergaster, Homo erectus*.

H. erectus was a large hominin, as large as a modern human but with heavier bones and a smaller brain capacity of between 750 and 1,225 cc (modern brain size is about 1,350 cc). Fossil evidence shows that *H. erectus* was a social species that used tools, hunted animals, and cooked over fires. The meat-eating habit may have sparked a migration in *H. erectus*, because carnivores had larger ranges than similar-sized herbivores, their prey being scarcer per unit area. *H. erectus* spread out of Africa soon after the species appeared, over a million years ago, and fossils have been found as far away as China and Indonesia. The first fossil was found by Dutch physician Eugene Dubois in 1891 on the Indonesian island of Java. Stone tools are rarely found in these Asian sites, suggesting *H. erectus* based their technology on other materials, for example, bamboo, which

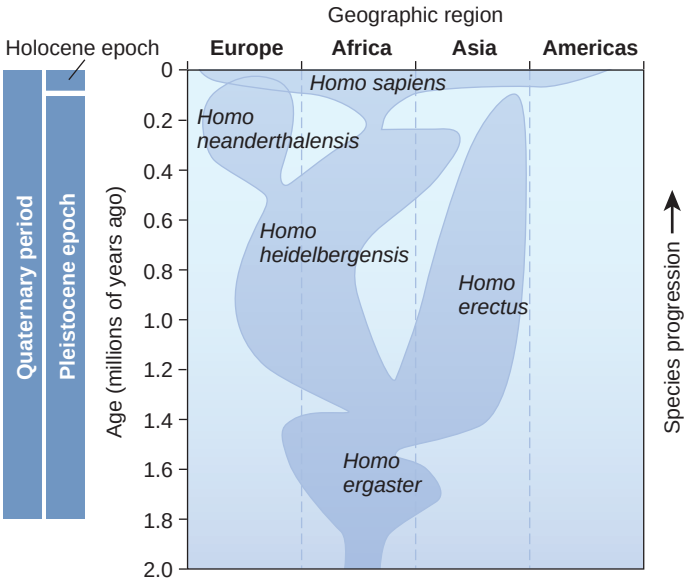

Figure 34.32 One view of the temporal and geographic evolution of hominid populations.

was abundant at that time. Bamboo is strong yet lightweight and could have been used to make spears. These people may even have used rafts to take to the seas. *H. erectus* went extinct about 100,000 years ago, for reasons that are unclear but may be related to the spread of *Homo sapiens* into its range.

Homo heidelbergensis was similar in body form to modern humans. Large caches of their bones were found in Spain, at the bottom of a 14 m (45 ft) shaft known as La Sima de Los Huesos (the pit of bones). Similar remains were also found at Boxgrove in England. Shinbones recovered from Boxgrove suggest males stood around 180 cm (6 ft) and weighed 88 kg (196 pounds). Skulls were large, with brain volumes from 1,100 to 1,400 cc, similar to modern humans. Animal bones from these sites showed cut marks from stone blades beneath tooth marks from carnivores. This showed humans were killing large prey before scavengers arrived. Horses, giant deer, and rhinoceroses were common prey and would have required much skill and cooperation to hunt.

Homo heidelbergensis gave rise to two species, *H. neanderthalensis* and *H. sapiens*. *H. neanderthalensis* was named for the Neander Valley of Germany, where the first fossils of its type were found. In the Pleistocene epoch (Figure 34.32), the ice ages were locked in a cycle of advance and retreat, and the European landscape often turned into a snowy tundra. The more gracile body form of *H. heidelbergensis* evolved into a shorter, stockier body form that was better equipped to conserve heat; we now call this type of human Neanderthal. Neanderthals also possessed a more massive skull and larger brain size than modern humans, about 1,450 cc, perhaps associated with their bulk. Males were about 168 cm (5 ft 6 in) in height and would have been very strong by modern standards. They had a large face with a prominent bridge over the eyebrows, a large nose, and no chin. They lived predominantly in Europe, with a range extending to the Middle East. Their muscular physique was well suited to the rigors of hunting prey. Paleontologists have found a high rate of head and neck injuries in Neanderthal bones, similar to that seen in present-day rodeo riders. This suggests that close encounters with large prey often resulted in blows that knocked the hunters off their feet. The hyoid bone, which holds the voice box in place, was well developed, suggesting speech was used. However, about 30,000 years ago, this species was replaced by another hominin species, *H. sapiens* (from the Latin, meaning wise man), our own species. *H. sapiens* was a taller, lighter-weight species with a slightly smaller brain capacity than that of the Neanderthals.

Paleontologists remain divided as to whether *H. sapiens* evolved in Africa and spread from there to other areas of the world, or whether premodern humans such as *H. ergaster* that migrated from Africa evolved to become modern humans in different parts of the world. The first model, the Out of Africa hypothesis, suggests that after the evolution of hominins in Africa, they migrated to other continents three times, once for *H. ergaster*, once for *H. erectus*, and once for *H. sapiens*. Then *H. sapiens* would have gradually replaced species such as *H. erectus* and *H. neanderthalensis* in other parts of the world. Some scientists find this difficult to accept, however, and suggest that human groups have evolved from *H. ergaster* populations in a number of different parts of the world, a model known as the multiregional hypothesis. According to this hypothesis, gene flow between neighboring populations prevented the formation of several different species.

Studies of human mitochondrial DNA (mtDNA), which occurs only in the cellular organelles called mitochondria, show that all modern people share a common ancestor, dubbed "mitochondrial Eve," dating to about 170,000 years ago. This evidence is consistent with the Out of Africa model, because the common ancestor would have to be much older than that to support the multiregional hypothesis. Furthermore, 2006 analyses of DNA from Neanderthal bones show it to be distinct from the DNA of *H. sapiens*, even though Neanderthals and humans share 99.5% of their genome. This also suggests that there was no interbreeding between Neanderthals and the *H. sapiens* who migrated into Europe.

Evidence overall appears to support the Out of Africa hypothesis. In this scenario, *H. ergaster* evolved in Africa and spread to Asia and Europe. Later, *H. erectus* evolved in Africa and spread into Asia, and *H. neanderthalensis* evolved in Europe. Both these species shared the same fate, extinction at the hands of the later-evolving *H. sapiens*. *Homo sapiens* evolved in Africa about 170,000 years ago from *H. heidelbergensis*. The mtDNA data suggest a migration of *Homo sapiens* from eastern Africa to other parts of the globe beginning 170,000–150,000 years ago (Figure 34.33). Modern humans spread first into the Middle East and Asia, then later into Europe and Australia, finally crossing the Bering Strait to the Americas.

Much remains to be resolved in human evolution, and new data constantly forces us to rethink our hypotheses. Unexpected finds surface and have to be explained. For example, in 2004, the remains of a small human on the Indonesian island of Flores were discovered and were given the name *Homo florensiensis*, nicknamed "hobbits" by the media. Many species—for example, deer and elephants—develop into small forms in insular situations, so hobbit humans seemed plausible. Since then, many

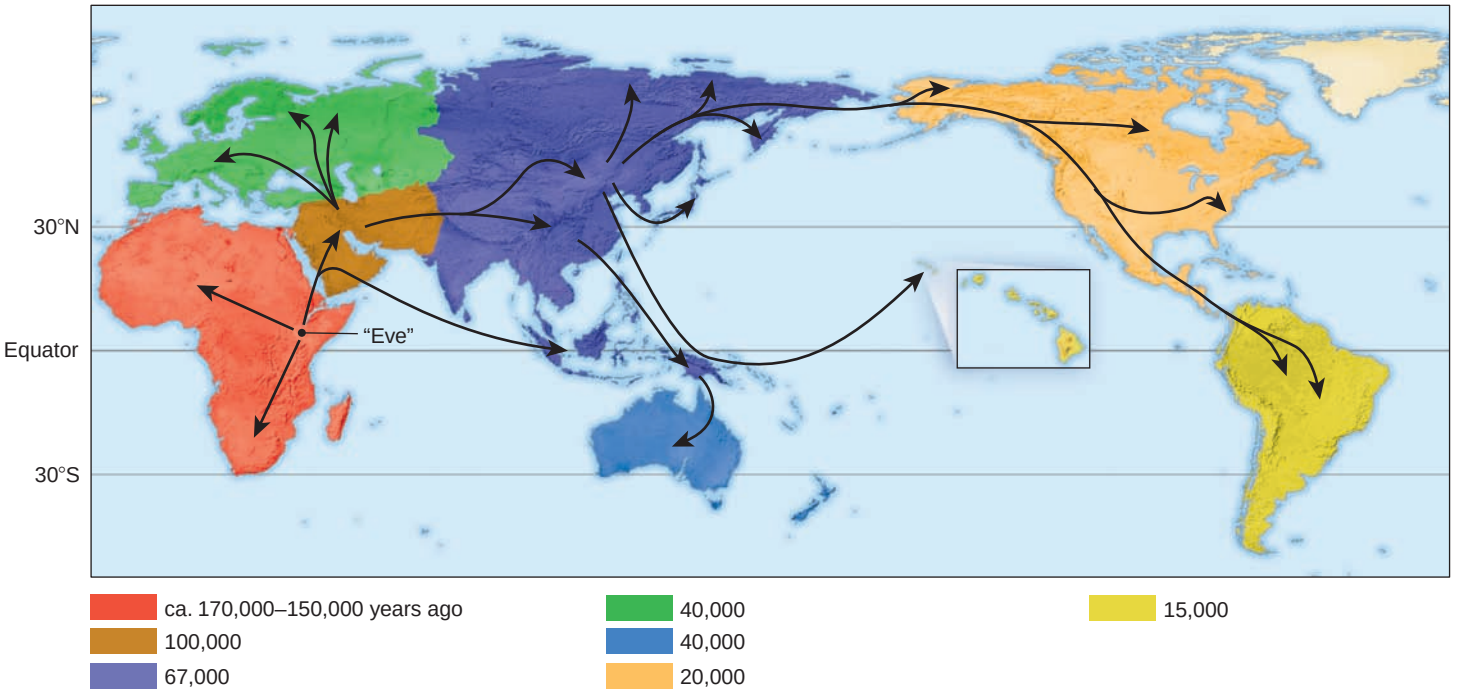

Figure 34.33 **The probable origin and spread of *Homo sapiens* throughout the world.** This map, based on differences of mtDNA throughout current members of the world's population, suggests *Homo sapiens* originated from "mitochondrial Eve" in east Africa. About 100,000 years ago, the species spread into the Middle East and from there to Asia, Europe, Australia, and the Americas.

researchers have suggested these people were modern humans who were suffering from a genetic disorder. Even modern humans on Flores are pygmies. Pathological dwarfism would have made these people even smaller. Only *H. sapiens* tools have been found at the area where the bones occur, suggesting these individuals were indeed dwarf forms of modern humans.

Summary of Key Concepts

34.1 The Craniates: Chordates with a Head

- The subphylum Vertebrata is the largest and most dominant group of chordates, occupying nearly all of Earth's major habitats. All vertebrates are craniates. (Figure 34.1)
- Craniates have two defining characteristics that distinguish them from invertebrate chordates: a cranium and a neural crest. The hagfish (class Myxini) is considered an early-diverging modern craniate; it is the only living craniate that is not a vertebrate. (Figure 34.2)

34.2 Vertebrates: Craniates with a Backbone

- Vertebrates have several characteristic features, including a vertebral column, endoskeleton of cartilage or bone, and internal organs. Of the 11 different vertebrate classes, 5 are classes of fishes, reflecting the dominance of fishes. (Table 34.1)
- Early diverging vertebrates lacked jaws. Today the only jawless vertebrates are lampreys. (Figure 34.3)

34.3 Gnathostomes: Jawed Vertebrates

- A critical innovation in vertebrate evolution is the hinged jaw, which first developed in fishes. Lampreys, eel-like fish, lack a hinged jaw. The hinged jaw evolved from cartilaginous gill arches. (Figure 34.4)
- The chondrichthyans (sharks, skates, and rays) have a skeleton composed of flexible cartilage and powerful appendages called fins. They are active predators with acute senses and were among the earliest fishes to develop teeth. (Figure 34.5)
- Bony fishes consist of the Actinopterygii (ray-finned fishes, the most species-rich class), Actinistia (coelacanths), and the Dipnoi (lungfishes). In Actinopterygii, the fins are supported by thin, flexible rays and moved by muscles inside the body. (Figures 34.6, 34.7)
- The lobe fins comprise the lobe-finned fishes (Actinistia and Dipnoi) and the tetrapods. In the lobe-finned fishes, the fins contain their own muscles. (Figures 34.8, 34.9)

34.4 Tetrapods: Gnathostomes with Four Limbs

- Fossils record the evolution of lobe-finned fishes to fishes with four limbs. Recent research has shown that relatively simple mutations control large changes in limb development. (Figures 34.10, 34.11, 34.12)
- Amphibians live on land but return to the water to reproduce. The larval stage undergoes metamorphosis, losing gills and tail for lungs and limbs. (Figure 34.13)
- The majority of amphibians belong to the order Anura (frogs and toads). Other orders are the Gymnophiona (caecilians) and Caudata (salamanders). (Figure 34.14)

34.5 Amniotes: Tetrapods with a Desiccation-Resistant Egg

- The amniotic egg permitted animals to become fully terrestrial. Other critical innovations included desiccation-resistant skin, thoracic breathing, water-conserving kidneys, and internal fertilization. (Figure 34.15)

- Living reptilian classes include the Testudines (turtles), Lepidosauria (lizards and snakes), Crocodilia (crocodiles), and Aves (birds). Other reptilian classes, all of which are extinct, include two classes of dinosaurs (Ornithischia and Saurischia). (Figures 34.16, 34.17, 34.18, 34.19)
- Three species—*Archaeopteryx*, *Caudipteryx*, and *Confuciusornis*—help trace a lineage from dinosaurs to birds. (Figure 34.20)
- The four key characteristics of birds are feathers, a lightweight skeleton, air sacs, and reduced organs. Birds are the most species-rich class of terrestrial vertebrates. The diversity of bird beaks reflects the varied methods they use for feeding. (Figures 34.21, 34.22, Table 34.2)

34.6 Mammals: Milk-Producing Amniotes

- The distinguishing characteristics of mammals are the possession of mammary glands, hair, specialized teeth, and an enlarged skull. Other unique characteristics of some mammals are the ability to digest plants and possession of horns or antlers. Mammal tooth shape varies according to diet. (Figures 34.23, 34.24, 34.25)
- Two subclasses of mammals exist: the Prototheria (monotremes) and the Theria (the live-bearing mammals). The live-bearing mammals are, in turn, divided into the Metatheria (marsupials) and Eutheria (placental mammals). (Table 34.3, Figure 34.26)
- Many defining characteristics of primates relate to their tree-dwelling nature and include grasping hands, large brain, nails instead of claws, and binocular vision. (Figures 34.27, 34.28, 34.29)
- About 6 million years ago in Africa, a lineage that led to humans began to separate from other primate lineages. A key characteristic of hominins (extinct and modern humans) is bipedalism.
- Human evolution can be visualized like a tree, with a few hominin species coexisting at the same point in time, some eventually going extinct, and some giving rise to other species. (Figures 34.30, 34.31)
- The Out of Africa hypothesis suggests that the migration of hominins from Africa happened at least three times, with *Homo sapiens* gradually replacing other hominin species in other parts of the world (Figure 34.32). The multiregional hypothesis proposes that human groups evolved in a number of different parts of the world. Most scientists believe the Out of Africa hypothesis is better supported by the data.
- Data from human mitochondrial DNA suggest all humans derive from a "mitochondrial Eve" that originated in east Africa. From there, *Homo sapiens* spread to Asia and then to all other parts of the globe. (Figure 34.33)

Assess and Discuss

Test Yourself

1. Which of the following is <u>not</u> a defining characteristic of craniates?
   a. cranium
   b. neural crest
   c. two clusters of *Hox* genes
   d. protective housing around the brain
   e. cephalization
2. The presence of a bony skeleton, an operculum, and a swim bladder are all defining characteristics of
   a. Myxini.
   b. lampreys.
   c. Chondrichthyes.
   d. bony fishes.
   e. amphibians.
3. Organisms that lay eggs are said to be
   a. oviparous.
   b. ovoviparous.
   c. viviparous.
   d. placental.
   e. none of the above.
4. Which clade does not include frogs?
   a. craniates
   b. gnathostomes
   c. tetrapods
   d. amniotes
   e. lobe fins
5. In some amphibians, the adult retains certain larval characteristics, which is known as
   a. metamorphosis.
   b. parthenogenesis.
   c. cephalization.
   d. paedomorphosis.
   e. hermaphrodism.
6. The membrane of the amniotic egg that serves as a site for waste storage is
   a. the amnion.
   b. the yolk sac.
   c. the allantois.
   d. the chorion.
   e. the albumin.
7. Which characteristic qualifies lizards as gnathostomes?
   a. a cranium
   b. a skeleton of bone or cartilage
   c. a hinged jaw
   d. the possession of limbs
   e. amniotic eggs
8. Which of the following is <u>not</u> a distinguishing characteristic of birds?
   a. amniotic egg
   b. feathers
   c. air sacs
   d. lack of certain organs
   e. lightweight skeletons
9. What is <u>not</u> a derived trait of primates?
   a. opposable thumb
   b. grasping hands
   c. prehensile tail
   d. flat nails
   e. large brain
10. Despite their small size and nocturnal habits, tarsiers are classed with much larger monkeys and apes as *Haplorrhini*. This is based on which of the following characteristics?
    a. dry fully furred noses
    b. forward-facing eyes
    c. DNA similarities
    d. a and b
    e. a, b, and c

Conceptual Questions

1. How is vertebrate movement accomplished in a similar way to arthropod movement, and how is it different?
2. Explain the function of the lateral line and the operculum.
3. List the four extraembryonic membranes in the amniotic egg, and explain the function of each.

Collaborative Questions

1. By what means can vertebrates move?
2. Discuss the three different ways mammals bring their offspring into the world.

An Introduction to Flowering Plant Form and Function

35

Representatives of two major groups of flowering plants. These corn and soybean plants display similar architecture common to flowering plants, yet differ in other structural and reproductive features.

Chapter Outline

Corn, more formally known as *Zea mays*, soybean (*Glycine max*), and the common bean (*Phaseolus vulgaris*) are among the world's most important agricultural crop plants. Farmers grow corn for food and production of ethanol, a gasoline additive. The seeds of beans and related plants are extraordinarily rich sources of protein in the human diet and therefore of particular importance to vegetarians. Because both are flowering plants, corn and beans have many features in common, including stems, roots, leaves, flowers, fruits, and seeds. However, corn and soybean plants also display differences in these features, as you can see in the chapter-opening photo. In fact, the hundreds of thousands of modern flowering plants display an amazing variety of forms that represent adaptations to diverse habitats.

This chapter provides an introduction to the flowering plants, focusing on fundamental principles of structure and function. These principles will help to explain why flowering plants resemble each other in many ways, yet differ in features that influence plant roles in nature and agriculture. We will begin by describing the general life of a flowering plant—from seed germination to reproductive maturity. A survey of major plant structural features and growth processes will follow. Finally, we will consider diverse stem, leaf, and root adaptations. These topics provide essential background for subsequent chapters in this unit, which focus on flowering plant behavior, nutrition, transport, and reproduction and development.

35.1 From Seed to Seed—The Life of a Flowering Plant

Several major events punctuate the lives of flowering plants, also known as the **angiosperms**. When seeds germinate, dormant embryos wake to metabolic activity and begin the process of seedling development. Seedlings grow and develop into mature plants capable of reproduction. Finally, flowers produce and fruits disperse the next generation of seeds. In this section, we will briefly survey the life of flowering plants, focusing on the basic structural features of each life stage.

Seedlings Develop from Embryos in Seeds

Seeds are reproductive structures produced by flowering plants and other seed plants, usually as the result of sexual reproduction. Seeds contain embryos that develop into young plants—seedlings—when seeds germinate. The embryo is an essential stage in the sexual cycle of a flowering plant. The plant sexual cycle explains how embryos typically arise (Figure 35.1).

Sexual reproduction in plants requires two multicellular stages: a gamete-producing **gametophyte** and a spore-producing **sporophyte**. In the life cycle of plants, these two life stages alternate with one another, a process called **alternation of generations**. Flowering plants produce relatively large sporophytes and microscopic gametophytes that grow and develop within flowers. Diploid sporophytes produce haploid spores by the process of meiosis. These spores grow into gametophytes that produce plant gametes—eggs and sperm. Fusion of egg and sperm in the process of fertilization generates a diploid zygote, which undergoes repeated mitotic divisions to form the plant **embryo**.

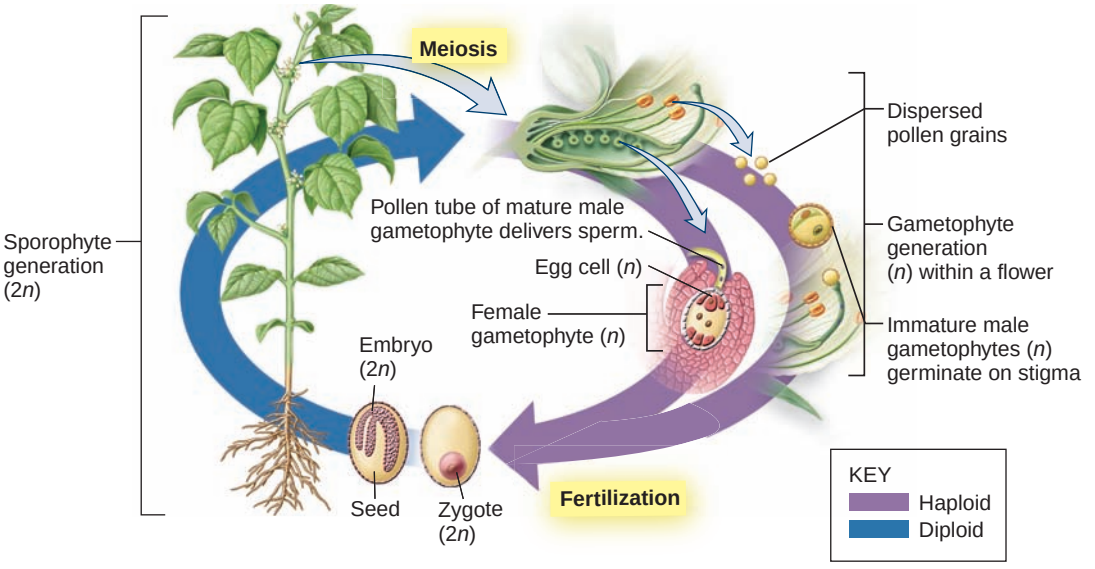

Figure 35.1 The plant sexual cycle. The sexual cycle of flowering plants involves alternation of sporophyte and gametophyte generations. In flowering plants, the sporophyte is the dominant, conspicuous generation, whereas the tiny gametophytes are mostly hidden within flowers. The bean plant shown here produces both male and female gametophytes. Embryos form when eggs produced by female gametophytes are fertilized by sperm produced by male gametophytes. Embryos, which are the young sporophytes of the next generation, are dispersed from plants within seeds.

The plant embryo is a very young sporophyte that lies dormant within seeds, accompanied by a supply of stored food and enclosed by a tough, protective seed coat (Figure 35.2a). The seed coat protects the delicate embryo during the dispersal of seeds from parent plants into the environment. Dispersed seeds may remain dormant in the soil—sometimes for long periods—but germinate when temperature, moisture, and light conditions are favorable. Such conditions activate embryo metabolism, causing embryos to enlarge and break the seed coat. Once free of the seed coat, embryos grow into seedlings (Figure 35.2b), and if sufficient resources such as water and minerals are available, seedlings develop into mature plants (Figure 35.2c). **Growth** is an increase in weight or size. **Development** is a series of changes in the state of a cell, tissue, organ, or organism.

The plant body is composed of three types of organs: stems, leaves, and roots. **Stems** produce leaves and branches and bear the reproductive structures of mature plants. **Leaves** are flattened structures that emerge from stems and are often specialized in ways that enable photosynthesis. Stems and leaves together make up the plant **shoot** (Figure 35.2b). Mature plants often possess multiple stems bearing many leaves, which together form the **shoot system**. **Roots** provide anchorage in the soil and also foster efficient uptake of water and minerals. The aggregate of a plant's roots make up the **root system** (Figure 35.2c).

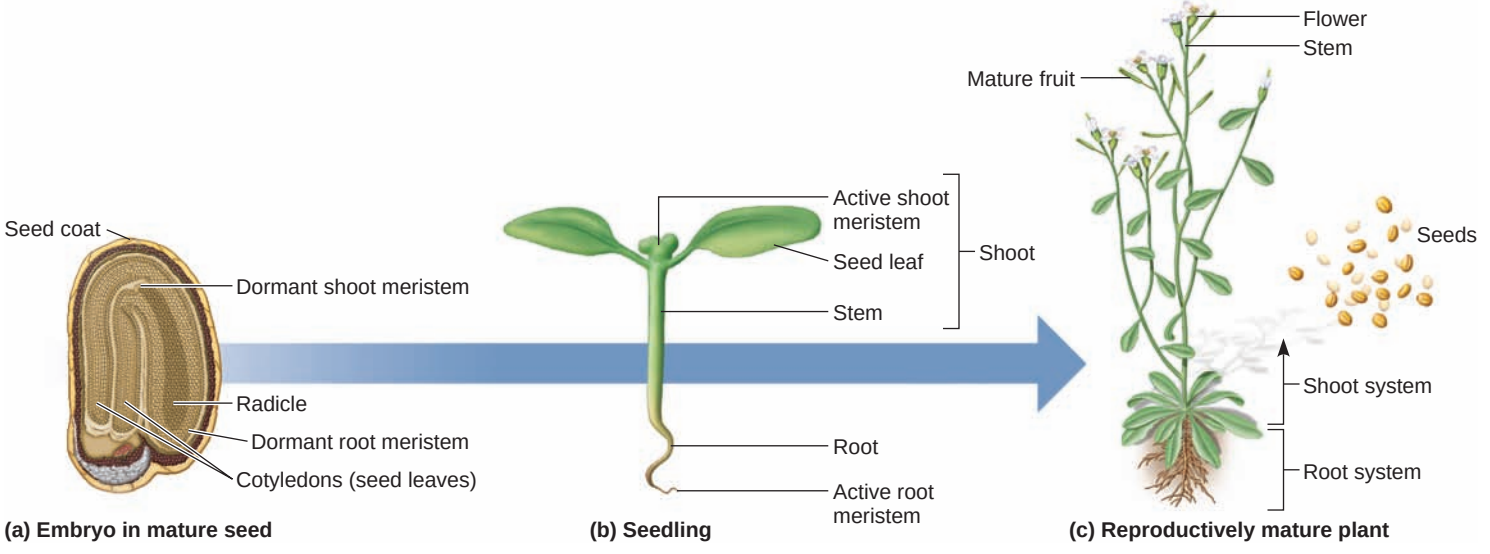

Figure 35.2 The seed-to-seed life of flowering plants. This example depicts the life of the eudicot *Arabidopsis thaliana*, widely used as a model organism for understanding the genetics of plant structure and development. **(a)** Seed embryos possess embryonic leaves, known as cotyledons; a dormant shoot meristem; an embryonic root, known as a radicle; and a dormant root meristem. **(b)** When seeds germinate, the shoot and root meristems become active. Meristem activity allows the radicle to produce the seedling root and the young shoot of the seedling to grow and produce leaves. **(c)** Reproductively mature plants have branched shoot and root systems and bear flowers and fruits that disperse seeds.

Stems, leaves and roots are organs so important to plants that they are present even in seed embryos and seedlings. A short, stemlike region of the embryo, known as a **hypocotyl**, produces embryonic leaves known as **cotyledons**, or seed leaves. These structures often store food that supplies energy for seedling development. Peas and peanuts are examples of cotyledons that are rich in nutrients, explaining their food value to humans. The embryonic root, known as the **radicle**, is the first organ to emerge from a germinating seed and allows the uptake of the water and minerals needed for seedling growth (Figure 35.2b).

The process of body and organ development involves the differentiation of specialized cells having distinctive structure and function. Seedlings and mature plants produce new tissues in areas called meristems. A **meristem** (from the Greek *merizein*, meaning to divide) is a region of undifferentiated cells that produces new tissues by cell division. A dormant meristem occurs at the shoot and root tips of seed embryos, and these meristems become active in seedlings (Figure 35.2a,b). In mature plants, active meristems occur at each stem and root tip. Such meristems are known as shoot and root **apical meristems** because they occur at shoot and root tips, also known as apices.

Mature Sporophytes Develop from Seedlings

As seedlings develop into mature sporophytes, the aboveground shoot typically becomes green and photosynthetic and thus able to produce organic food. Photosynthesis powers the transformation of seedlings into mature plants. The development of mature plants encompasses both **vegetative growth**, a process that increases the size of the shoot and root systems, and reproductive development. Vegetative growth and reproductive development involve **organ systems**, structures that are composed of more than one organ. Branches, buds, flowers, seeds, and fruits are organ systems. The hierarchy of structure in a mature plant, ranging from specialized cells, tissues, organs, and organ systems to root and shoot systems, is shown in Figure 35.3.

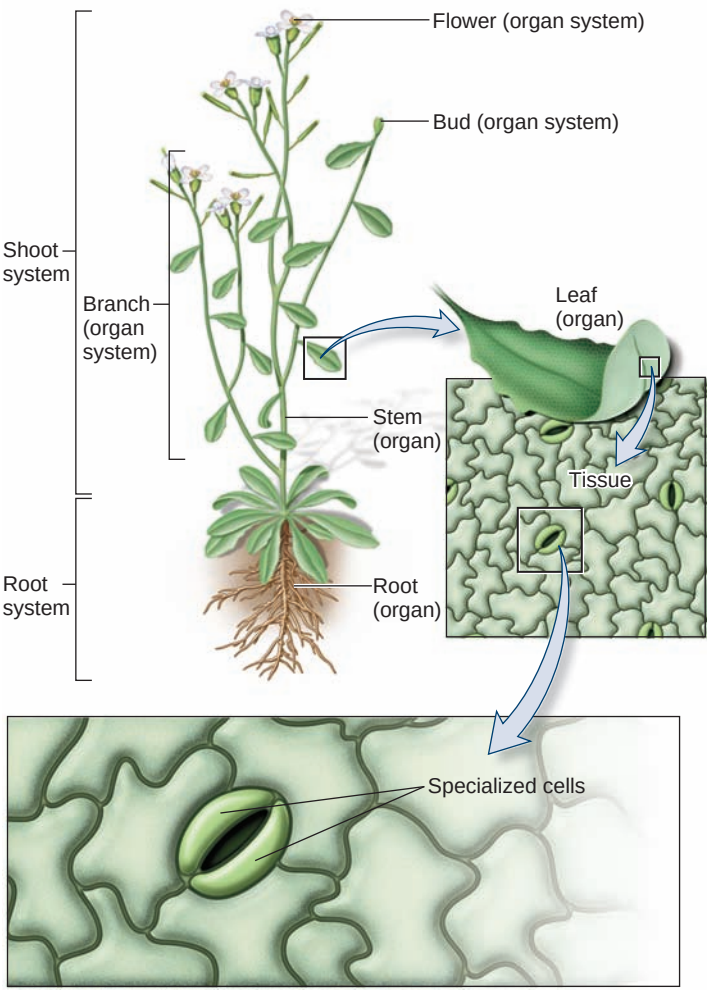

Figure 35.3 **Levels of biological organization in a plant.** Flowering plant sporophyte bodies consist of a root system and a shoot system. Shoot systems produce organ systems such as buds, flowers, fruits, and seeds, which are composed of organs, tissues, and specialized cells. Root systems are composed of organs, tissues, and specialized cells.

Concept check: *Do roots have organ systems?*

Vegetative Growth During their growth, plant shoots produce **buds**, miniature shoots each having a dormant shoot apical meristem. Scaly modified leaves protect bud contents. Under favorable conditions, the bud scales fall off, and the vegetative buds open. Newly opened buds display young leaves on a short shoot. The shoot apical meristem then becomes active, producing new stem tissue and leaves. In this way, buds generate leafy branches. A bud is an example of an organ system because it contains more than one organ.

Shoots often display **indeterminate growth**, meaning that apical meristems continuously produce new stem tissues and leaves as long as conditions remain favorable. This process explains how very large plants can develop from seedlings. However, plant size is also under genetic control, so some plants remain small even when they are mature. The tiny floating plants of *Lemna* species, commonly known as duckweeds, which sometimes cover the surfaces of ponds in summer, are examples of plants whose small size is genetically determined.

Reproductive Development Under favorable conditions, mature plants produce reproductive structures: flowers, seeds, and fruits. **Flowers** and floral buds are reproductive shoots that develop when shoot apical meristems produce flower parts instead of new stem tissues and leaves. Flower development occurs under the control of several genes whose roles are well understood (refer back to Figure 19.24). In contrast to shoots (which often show indeterminate growth), flowers are produced by **determinate growth**, which is growth of limited duration. A floral shoot no longer produces new stem growth or leaves. Therefore, vegetative growth and reproductive development are alternative processes. In order to flower, a plant must give up some of its potential to continue vegetative growth.

Flower tissues enclose and protect tiny male and female gametophytes during their growth and development (see

Figure 35.1). Female gametophytes produce eggs within structures known as ovules, produced in the ovary of a flower pistil. Male gametophytes begin their development within pollen grains produced in the anthers of a flower stamen. Pollen is dispersed to the flower pistil, whereupon pollen grains may germinate, producing a tube that delivers sperm to eggs. Fertilization generates zygotes, which develop into embryos, and also triggers the process by which ovules develop into seeds and flower parts develop into fruits. **Fruits** thus enclose seeds and function in seed dispersal. Flower buds, flowers, fruits, and seeds are organ systems because they consist of more than one organ. For example, flowers typically contain several leafy organs, including sepals and petals, as well as stamens and pistils, which evolved from leaves (refer back to Chapter 30).

Flowering Plants Vary in the Structure of Organs and Organ Systems

With some exceptions, flowering plants occur in two groups, informally known as the **eudicots** and the **monocots**. These groups take their names from the number of seed leaves (cotyledons) that are present on seed embryos. For example, bean plants and relatives, which possess two (*di*) seed leaves, are examples of eudicots. Corn, which has only one (*mono*) seed leaf, is an example of a monocot. Eudicots and monocots also vary in the structure of other organs and organ systems. For example, eudicot flowers typically have petals and other parts numbering four, five, or a multiple of those numbers, whereas monocot flower parts usually occur in threes or a multiple of three. Stems, roots, leaves, and pollen of eudicots and monocots also vary in distinctive ways, as shown in Table 35.1.

Flowering Plants Vary in Seed-to-Seed Lifetime

The seed-to-seed lifetime of a flowering plant can vary from a few weeks to many years. Plants that die after producing seed during their first year of life are known as **annuals**. Corn and the common bean are examples of annual crops whose nutrient-rich seeds are harvested within a few months after planting, and must be replanted at the beginning of each new growing season. Plants that do not reproduce during the first year of life but may reproduce within the following year are known as **biennials**. Such plants often store food in fleshy roots during the first year of growth, and this food fuels reproduction during the second or later year of life. Humans use some of these fleshy roots for food, including carrots, parsnips, and sugar beets. Trees are examples of **perennials**, plants that live for more than 2 years, often producing seed each year after they reach reproductive maturity. Many flowering plants use environmental signals to time flowering in ways that enhance seed production. Temperature and day length are examples of environmental factors that determine flowering time. Plant seed-to-seed lifetimes are also influenced by the longevity of their seeds. Seeds of some plants are able to germinate after more than a thousand years of dormancy, whereas other plant seeds are unable to remain alive for long periods.

Table 35.1 Distinguishing Features of Eudicots and Monocots, Two Major Groups of Flowering Plants

Feature	Eudicots	Monocots
Number of seed leaves (cotyledons)	Two 	One 
Number of flower parts	Usually four, five, or multiples of these 	Usually three or multiple of three 
Stem vascular bundles	Arranged in a ring 	Scattered Root system	Branched taproot 	Fibrous; adventitious Leaf venation	Netted or branched 	Often parallel Pollen	Three pores or slits 	One pore or slit 

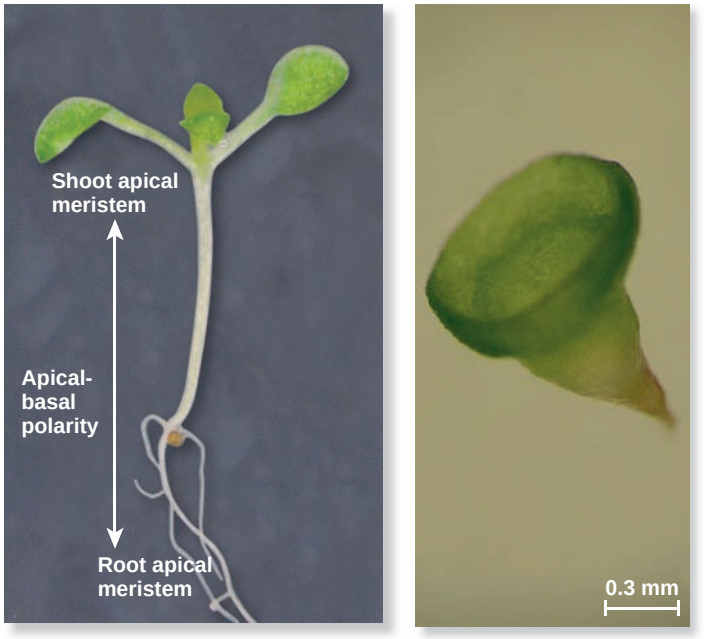
In this section, we have seen that the life of a flowering plant includes seed germination, seedling development into mature plants, and reproduction. We have also learned that sexual reproduction requires two stages that alternate with each other, a process known as alternation of generations. During the plant sexual cycle, a parental sporophyte produces many gametophytes in flowers, from which develop the next generation of young sporophytes—embryos in seeds. In this way, a single plant can produce many progeny. We have also surveyed the basic components of embryo, seedling, and adult plant structure. These topics provide a valuable background as we focus more closely on principles of plant structure, growth, and development.

35.2 How Plants Grow and Develop

Plant growth and development depends on four processes that are also essential to animal growth and development: cell division, growth, cell specialization, and programmed cell death. Other general principles of plant growth and development include (1) development and maintenance of a characteristic architecture throughout life, (2) increase in length by the activity of apical meristems, (3) maintenance of a population of youthful stem cells in meristems, and (4) expansion of cells in controlled directions, by water uptake. Woody plants have the additional feature of increasing in width by the activity of lateral meristems. All of these features are under genetic control and can be studied by the use of mutants showing abnormal structure and development. Several examples of informative mutants are discussed in this chapter.

Plants Display a Distinctive Architecture

In plant biology, the term apical has two distinct meanings. As we have seen, apical refers to the tips or apices of shoots and roots, as in shoot apical meristems or root apical meristems. A second meaning for apical is the part of a plant that projects upward, which is the top of the shoot. By contrast, the bottom of a root is termed the basal region. So the shoot apical meristem occurs at the apical pole, and the root apical meristem occurs at the basal pole. This property, known as **apical-basal polarity**, explains why plants produce shoots at their tops and roots at their lower regions. Apical-basal polarity originates during embryo development. As seedlings and maturing plants grow in length by the activity of shoot and root meristems, apical-basal polarity is maintained (Figure 35.4a). Apical-basal polarity is under the control of genes such as *GNOM*; mutations in such genes result in plant embryos that are cone shaped or spherical and thus lack features of apical-basal polarity (Figure 35.4b).



(a) Normal seedling (b) Abnormal *GNOM* mutants

Figure 35.4 **Plant apical-basal polarity.** **(a)** Normal plants exhibit apical-basal polarity, as shown by this seedling. Such growth occurs at two meristems, one at the shoot (SAM) and one at the root (RAM). **(b)** *GNOM* mutants of *Arabidopsis thaliana* lack apical-basal polarity and thus produce abnormal embryos and seedlings.

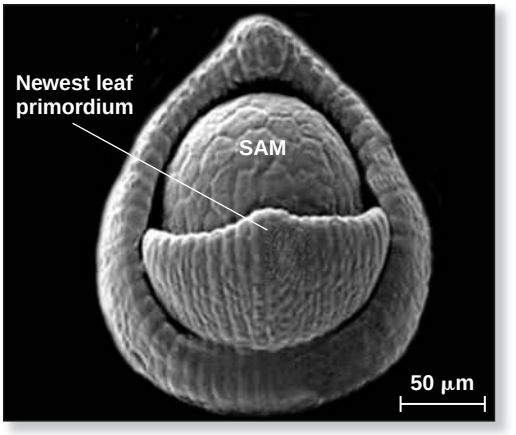


Figure 35.5 **Plant radial symmetry.** This top-down view of a shoot apical meristem reveals the radial symmetry of the shoot. Any line drawn from one edge of the surface to another that also passes through the center will divide the shoot into equal pieces. Leaf primordia are produced in circles or spirals around the shoot axis.

Concept check: *How could you determine that roots have radial symmetry?*

A second architectural feature common to plants is **radial symmetry**. Plant embryos normally display a cylindrical shape, also known as an axis, which is retained in the stems and roots of seedlings and mature plants. A thin slice or cross section of an embryo, stem, or root is typically circular in shape. Another component of radial symmetry is that most plants produce new leaves or flower parts in circular whorls, or spirals, around shoot tips (Figure 35.5). Buds and branches likewise emerge from stems in radial patterns, as do lateral roots from a central root axis. Together, apical-basal polarity and radial symmetry explain why diverse plant species have a fundamentally similar architecture.

Primary Meristems Increase Plant Length and Produce Plant Organs

We have previously noted that plant embryos grow into seedlings by adding new cells from only two growth points, the **shoot apical meristem** (commonly abbreviated as **SAM**) and the **root apical meristem** (**RAM**). During plant development, the SAM and RAM of the embryo give rise to many apical meristems located in the buds of shoots and at the tips of roots.

As a SAM grows, it leaves behind meristematic tissues that increase plant length and produce new organs. Such meristems are known as the **primary meristems**, and in a process known as **primary growth**, they ultimately produce primary tissues and organs of diverse types (Table 35.2). Tissues differ in their cellular complexity. Simple primary tissues are those composed of only one or two cell types; complex primary tissues are made of more cell types. As described in Section 35.3, the primary meristems of woody plants also give rise to secondary or lateral meristems. In a process known as **secondary growth**, the secondary meristems increase the girth of plant stems and roots by producing secondary tissues (Table 35.2).

Shoot apical meristems produce three primary meristems called protoderm, procambium, and ground meristem, which are present in young stems and leaves (Figure 35.6). The **protoderm** generates the outermost **dermal tissue**. The **procambium** produces **vascular tissues**, which make up a vascular system that conducts materials within the plant body and also provide support. The **ground meristem** gives rise to **ground tissues** defined by their locations—either between dermal and vascular tissues or at the center of mature stems, where it is called pith. Even so, plant biologists have discovered that plant cell specialization and tissue development do not depend much on the lineage (the parentage) of a cell or tissue. Chemical influences are much more important in determining the type of specialized tissue that will be produced by unspecialized plant cells.

Table 35.2 Examples of Tissues and Specialized Cells Found in Flowering Plants*

Simple primary tissues (composed of one or two cell types)	**Plant cell types found in those tissues**
Parenchyma	Parenchyma cells
Collenchyma	Collenchyma cells
Sclerenchyma	Fibers and sclereids
Root endodermis	Endodermal cells
Root pericycle	Pericycle cells
Complex primary tissues (composed of at least two cell types)	**Plant cell types found in those tissues**
Leaf or stem epidermis	Flattened epidermal cells, trichomes, stomatal guard cells
Root epidermis	Flattened epidermal cells, root hairs
Leaf mesophyll	Spongy parenchyma cells, palisade parenchyma cells
Leaf, stem, or root xylem	Tracheids, vessel elements, fibers, parenchyma cells
Leaf, stem, or root phloem	Sieve-tube elements, companion cells, fibers, parenchyma cells
Simple and complex secondary tissues	**Plant cell types found in those tissues**
Secondary xylem (wood)	Tracheids, vessel elements, fibers, parenchyma
Secondary phloem (inner bark)	Sieve-tube elements, companion cells, fibers, parenchyma
Outer bark	Cork cells

*This list does not include all of the tissues and cell types found in flowering plants. Some of these examples will be described later in this chapter.

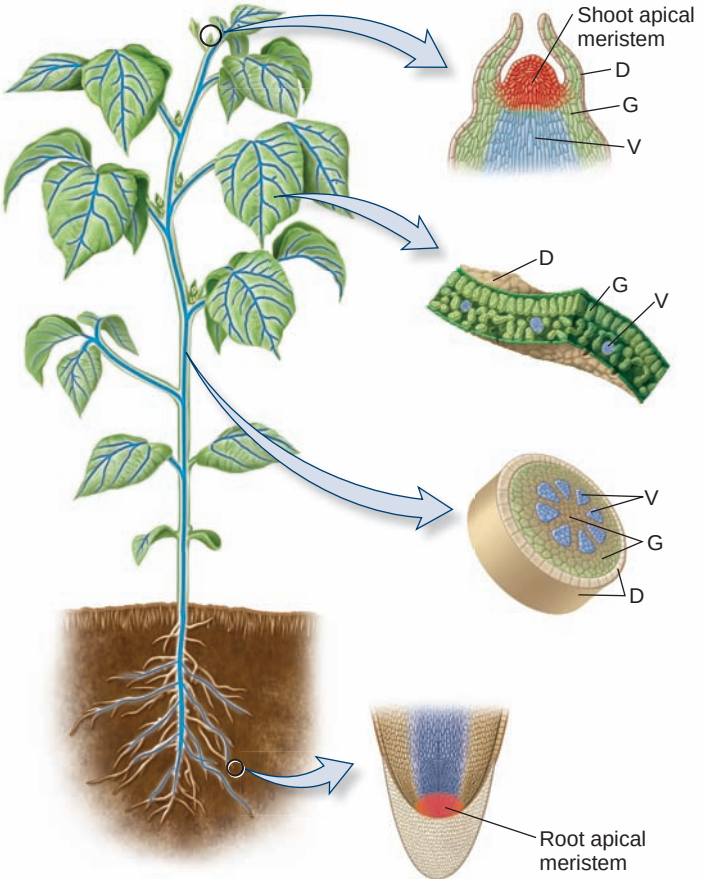

Figure 35.6 **Shoot apical meristems and the primary tissues they produce.** Shoot apical meristems generate three primary meristems: Protoderm produces the dermal tissues (D) (light brown), ground meristem produces ground tissues (G) (green or brown), and procambium yields vascular tissues (V) (blue). The vascular systems of leaves, stem, and root are connected.

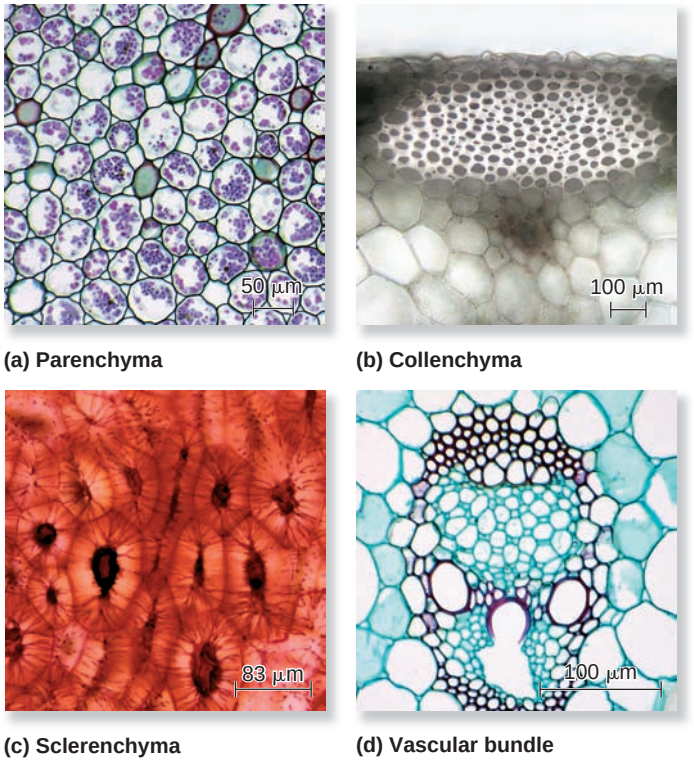
Primary Stem Structure and Development New primary stem tissues arise by the cell division activities of primary meristems located near the bases of SAMs. A layer of dermal tissue known as the **epidermis** develops at the stem surface. The epidermis produces a waxy surface coating known as the **cuticle**, which helps to reduce water loss from the plant surface. The epidermis and cuticle also help to protect plants from damage by insects and disease microorganisms.

Beneath the epidermis lies the stem **cortex**, which is largely composed of a ground tissue known as **parenchyma tissue** (Figure 35.7a). This tissue is composed of only one cell type, thin-walled cells known as **parenchyma cells**. These cells often store starch in plastids and therefore serve as an organic food reserve. Stem parenchyma also has the ability to undergo cell division (meristematic capacity), which aids wound healing

when stems are damaged. The cell division capability of stem parenchyma also explains how people are able to grow new plants from stem cuttings. Stems also contain **collenchyma tissue** (Figure 35.7b), composed of flexible **collenchyma cells**; and rigid **sclerenchyma tissue** (Figure 35.7c), composed of two types of tough-walled sclerenchyma cells termed **fibers** and **sclereids**.

New water- and food-conducting tissues develop at the core of a young shoot. These conducting tissues are known as **primary vascular tissues** because they develop from new cells produced by the SAM. Vascular tissues occur in two forms, **xylem** and **phloem**, which are each composed of several types of specialized tissues and cells (see Section 35.3 and Table 35.2). Newly formed stem xylem and phloem connect with older conducting tissues that extend throughout the stem system and are linked with vascular tissues of the root system. Xylem and phloem conduct water, minerals, and organic food resources needed for continued cell division in shoot meristems, and for stem growth and development. Primary vascular tissues are typically arranged in elongate clusters known as **vascular bundles** that appear round or oval when cross-cut (Figure 35.7d). In the primary stems of beans and other eudicots, the vascular bundles are arranged in a ring, which is easily seen in thin slices made across a stem (see Table 35.1). In contrast, in the stems of corn and other monocots, the vascular bundles are scattered.



(a) Parenchyma (b) Collenchyma

(c) Sclerenchyma (d) Vascular bundle

Figure 35.7 Examples of tissues produced by primary shoot meristems. (a) Parenchyma, (b) collenchyma, (c) sclerenchyma, and (d) a vascular bundle composed of complex xylem and phloem tissues.

Leaf Structure and Development Young leaves are produced at the sides of a SAM as small bumps known as **leaf primordia** (see Figure 35.5). As young leaves develop, they acquire vascular tissue that is connected to the stem xylem and phloem (Figure 35.8a) and become flattened, a process that expands the area of leaf surface available for light collection during photosynthesis. In the cases of some leaves, thinness is an adaptation that helps them to shed excess heat. Leaves also become bilaterally symmetrical, meaning that they can be divided into two equal halves in only one direction, from the leaf tip to its base (Figure 35.8b).

In addition, upper (adaxial—upper surface) and lower (abaxial—lower surface) leaf tissues develop differently in several ways that foster photosynthesis (Figure 35.8c). For example, the more shaded abaxial leaf epidermis usually displays larger numbers of pores, known as **stomata** (from the Greek word *stoma*, meaning mouth), than the sunnier adaxial leaf surface. When open, stomata allow CO_2 to enter and water vapor and O_2 to escape leaf tissues. Closure of stomata helps to prevent excess water loss from plant surfaces. Many leaves also show another example of differentiation between the adaxial and abaxial regions in the positions of different types of photosynthetic ground tissue. The adaxial **palisade parenchyma** consists of closely packed, elongated cells adapted to absorb sunlight efficiently, whereas abaxial **spongy parenchyma** contains rounder cells separated by abundant air spaces. These air spaces, located near stomata, foster CO_2 absorption and O_2 release by leaves. Together, the palisade and spongy parenchyma are known as the leaf **mesophyll**.

Leaf veins composed of vascular tissue commonly occur at the junction of palisade and spongy parenchyma, or within the spongy parenchyma (Figure 35.8c). Leaf parenchyma tissues are green and active in photosynthesis, a process that requires water, carbon dioxide, and dissolved minerals. Parenchyma cells can only take up carbon dioxide that has first dissolved into water, a feature inherited from ancient aquatic algal ancestors. For this reason, in order to perform photosynthesis, leaf parenchyma cells must be bathed in water. The xylem tissues of veins conduct water and minerals throughout leaf tissues, fostering photosynthesis. Phloem tissues of leaf veins carry the sugar products of photosynthesis from leaf cells to stem vascular tissues. In this way, sugar produced in leaves can be exported to other parts of the plant.

Root System Structure and Development In beans and most other eudicots, a main root develops from the embryonic root and then produces branch roots, also known as lateral roots. Such a root system of eudicots is known as a **taproot system**; this kind of root system has one main root with many branch roots (see Figure 35.6). In contrast, the embryonic root of most monocots dies soon after seed germination, and it is replaced by a **fibrous root system** consisting of multiple roots that grow from the stem base (see Table 35.1). Fibrous roots are examples of **adventitious roots**, structures that are produced on the surfaces of stems (and sometimes leaves) of both monocots and eudicots. Roots that develop at the bases of stem cuttings are also adventitious roots.

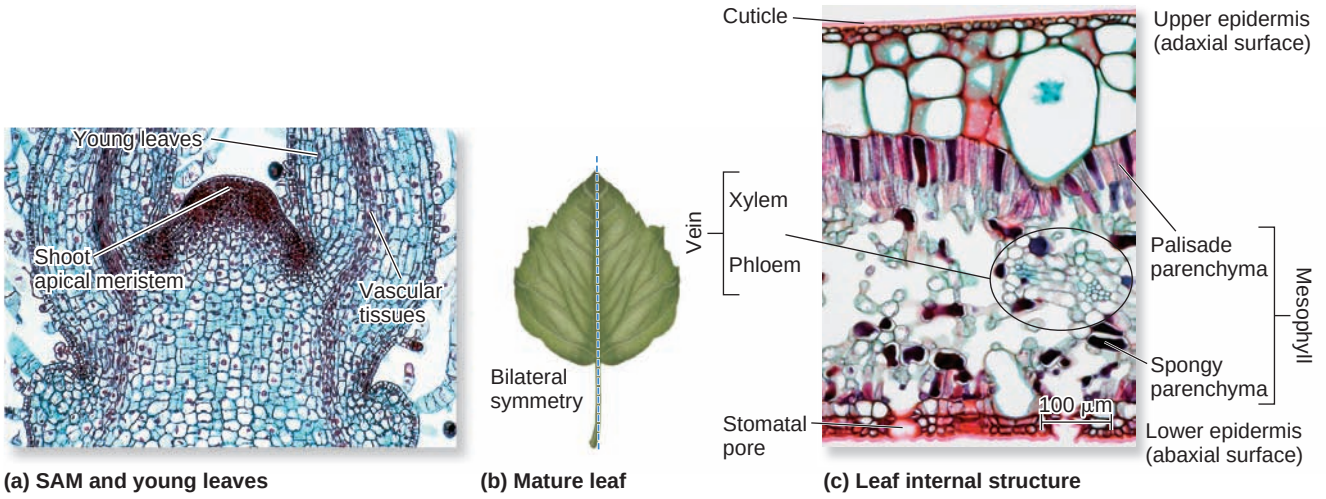


Figure 35.8 **Leaf development and structure.** **(a)** Young leaves develop at the sides of SAMs, as shown in this thinly sliced, stained shoot tip. Note that the darkly stained vascular tissues of young leaves are connected to those of the stem. **(b)** Mature leaves are typically thin and flat and show bilateral symmetry. **(c)** An internal view of a thinly sliced and stained leaf reveals top to bottom (adaxial to abaxial) tissue differentiation. A layer of palisade parenchyma lies just beneath the upper epidermis capped with a waxy cuticle. Veins of conducting tissue (xylem and phloem) are embedded in the photosynthetic mesophyll. Spongy parenchyma lies above the lower epidermis, which displays stomatal pores. These structural features of mature foliage leaves facilitate photosynthesis.

Concept check: *What advantage do plant leaves obtain by having stomatal pores on the lower epidermal surface?*

As we have earlier noted, the tips of roots and their branches each possess an apical meristem that adds new cells. Expansion of these new cells allows roots to grow into the soil. As they lengthen, roots produce branches but not from buds, as is the case for stems. Instead, branch roots develop from meristematic tissues located within the root (see Section 35.4). The root system both anchors plants in the soil and plays an essential role in harvesting water and mineral nutrients. Root tissues are usually not green and photosynthetic. They must rely on organic compounds transported from the shoot. The plant root system and shoot system therefore depend on each other.

Plant Meristems Contain Youthful Stem Cells

Plant meristems include undifferentiated, youthful cells earlier known as initials and more recently referred to as **stem cells**. In the late 19th century, the biologist Alexander Maximow coined the term *Stammzelle*, which is derived from the German words *stamm*, meaning stem, such as a plant stem, and *zelle*, meaning cell. Maximow used the term "stem cell" to describe animal cells that remain undifferentiated but are also able to generate specialized tissues. Animal stem cells are currently much in the news because of their potential for use in the treatment of damaged human tissues. The term stem cell is now also widely used for cells located within the plant meristem that likewise remain undifferentiated but also can produce new tissues. In the context of plant development, the term does not mean any cell located in a plant stem, only the undifferentiated cells located within the meristems of the shoot and root.

When plant stem cells divide, they produce two cells, one that remains young and unspecialized plus another cell. This second cell may differentiate into various types of specialized cells, but it often retains the ability to divide. As a result of these properties, stem cell numbers influence the size of a meristem, which, in turn, affects plant growth.

Plant Cells Expand in a Controlled Way by Absorbing Water

As we have observed, meristem production of new cells is an important component of plant growth. In addition, plant growth involves cell expansion. The diameters of newly formed stem and root cells are usually equal in all dimensions, but many soon begin to extend lengthwise, thereby helping shoots and roots to grow longer. Cell extension occurs when water enters the central vacuole by osmosis (Figure 35.9). As the central vacuole expands, the cell wall also expands and increases the cell's volume. By taking up water, plant cells can enlarge quickly, allowing rapid plant growth. Bamboo, for instance, can grow taller by 2 m within a week and can grow up to 30 m in less than three months! The importance of water uptake in cell expansion helps to explain why plant growth is so dependent on water supply.

Plant cell walls contain cellulose microfibrils that are held together by cross-linking polysaccharides. When plant cells and their vacuoles absorb water, pressure builds on cell walls. In response to this pressure and under acidic conditions, proteins unique to plants—known as expansins—are produced. **Expansins** unzip cross-linking cell-wall polysaccharides from cellulose microfibrils so that the cell wall can stretch (Figure 35.10). As a result, cells enlarge, often by elongating in a particular direction, which is important to plant form. Some plant cells are able to elongate up to 20 times their original length.

The direction in which a plant cell expands depends on the arrangement of cellulose microfibrils in its cell wall, which is determined by the orientation of cytoplasmic microtubules.

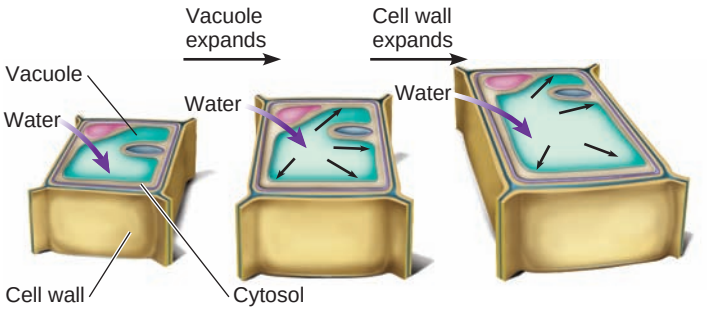

Figure 35.9 Plant cells expand by taking up water into their vacuoles.

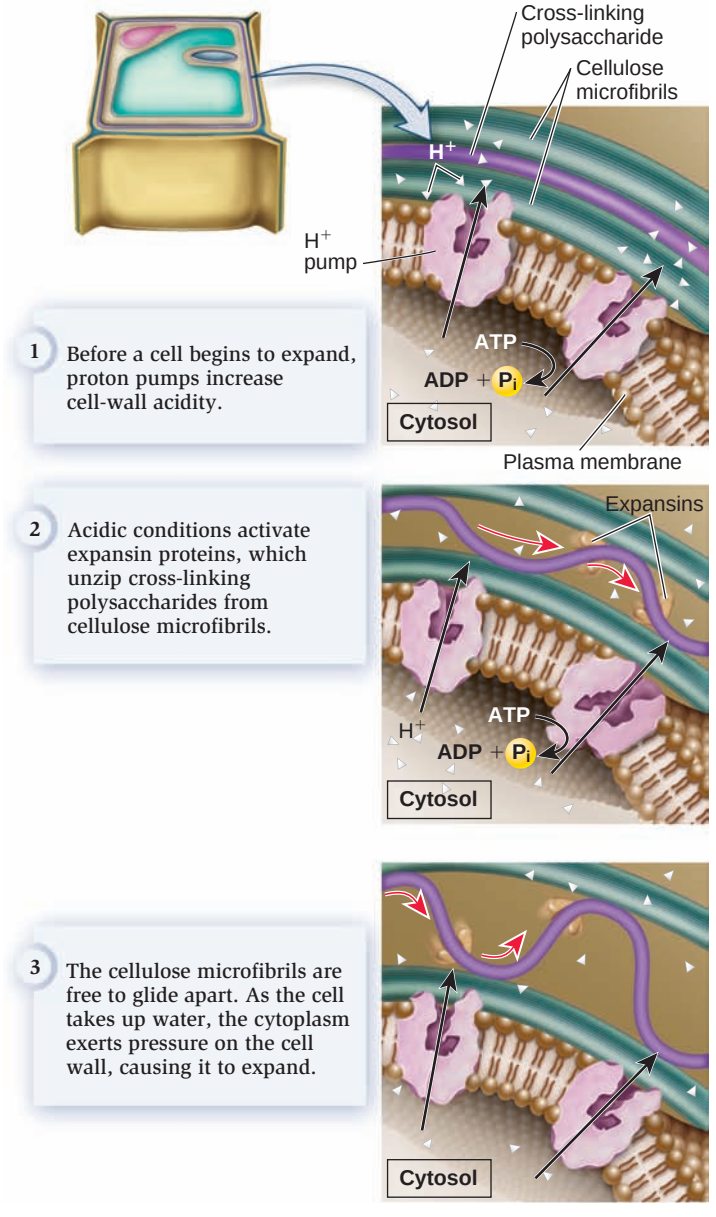

Figure 35.10 A hypothetical model of the process of cell-wall expansion.

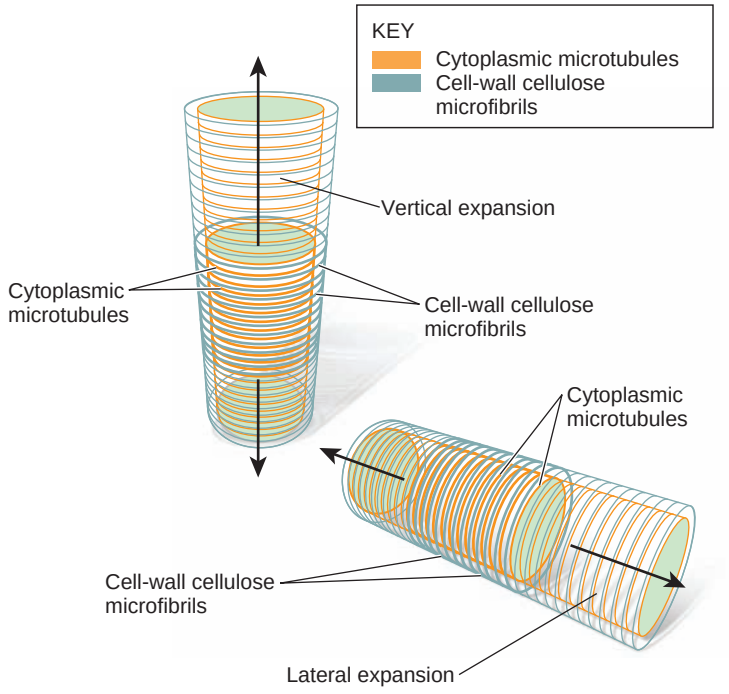

Figure 35.11 **Control of the direction of plant cell expansion by microfibrils and microtubules.** Plant cells enlarge in the direction perpendicular to encircling cell-wall cellulose microfibrils, which run parallel to the orientation of underlying cytoplasmic microtubules.

These microtubules are thought to influence the positions of cellulose-synthesizing protein complexes located in the plant plasma membrane. The protein complexes connect sugars to form cellulose polymers, spinning cellulose microfibrils onto the cell surface to form the cell wall. As a result, cell-wall cellulose microfibrils encircle cells in the same orientation as underlying cytoplasmic microtubules (Figure 35.11). Because cellulose microfibrils do not extend lengthwise, plant cell walls expand more easily in a direction perpendicular to them. To visualize this process, imagine encircling a spherical balloon with several parallel bands of tape before it has been completely inflated. The tape bands, which do not extend lengthwise, represent encircling cellulose microfibrils. As you add more air, the balloon will tend to extend in the direction perpendicular to the bands of tape.

Microtubules control not only the direction of cell expansion but also the plane of cell division, which is also critical to plant form. The *FASS* gene mutation in the model plant *Arabidopsis* illustrates the importance of microtubule orientation to plant structure. In cells of these mutants, microtubules are randomly arranged, resulting in cell division planes that are abnormal, cells that do not elongate, and mature plants with abnormal, stubby organs.

35.3 The Shoot System: Stem and Leaf Adaptations

As we have seen, the shoot system includes all of a plant's stems, branches, leaves, and buds. It also produces flowers and fruits when the plant has reached reproductive maturity. Thus,

the shoot system is essential to plant growth, photosynthesis, and reproduction. In this section, we examine stem and leaf structure and development in more detail. We will observe that features of shoot stems and leaves vary among plants in ways that explain plant ecological function in nature and that these features are very useful to us in distinguishing plant species.

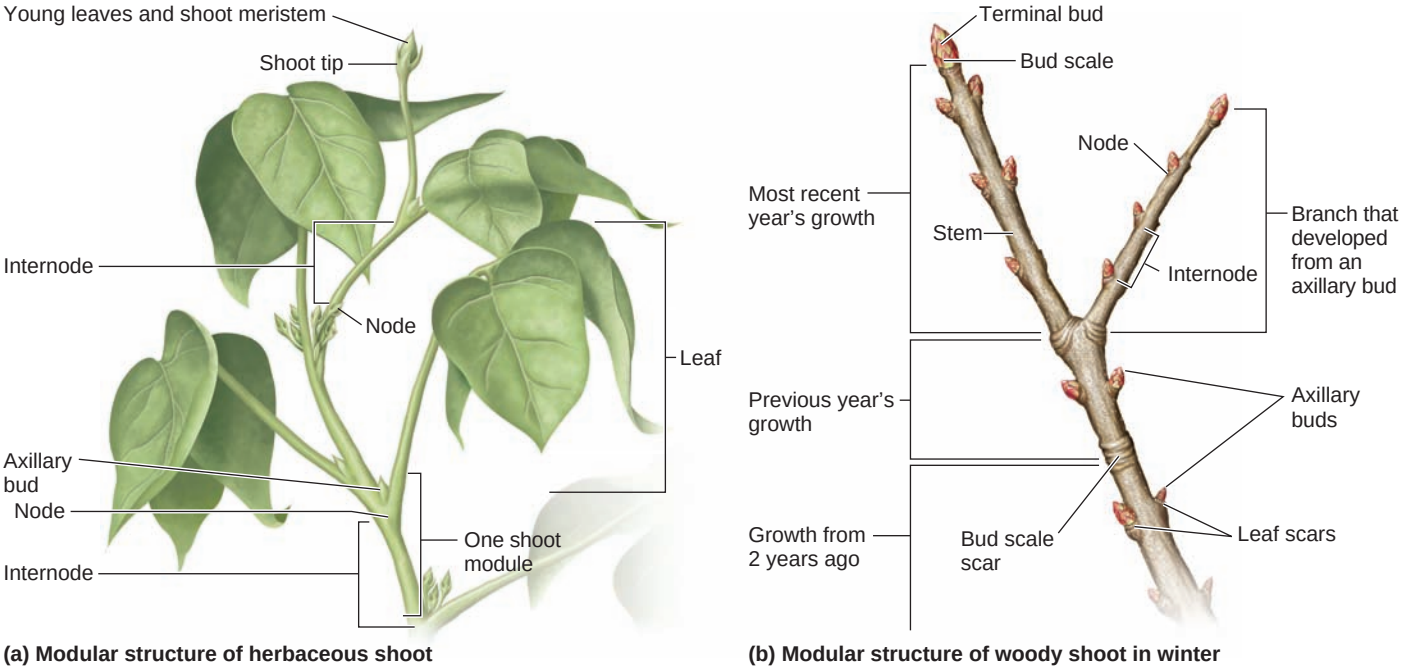
Shoot Systems Have a Modular Structure

More than 200 years ago, the German author, politician, and scientist Johann Wolfgang von Goethe realized that plants are modular organisms, composed of repeated units. Shoots are notably modular (Figure 35.12). Each shoot module, often known as a phytomere, consists of four parts: a stem node, an internode, a leaf, and an axillary meristem or bud. A **node** is the stem region from which one or more leaves emerge. An **internode** is the region of stem between adjacent nodes. Differences in numbers and lengths of internodes help to explain why plants differ in height. Each time a young leaf is produced at the SAM, a new meristem develops in the upper angle formed where the leaf emerges from the stem. This angle is known as an axil (from the Greek *axilla*, meaning armpit), and the meristem formed there is called an **axillary meristem**. Such axillary meristems generate **axillary buds**, which can produce flowers or branches known as lateral shoots. Such new branches bear a SAM at their tips. SAMs located at the apices of both main and lateral shoots produce new leaves. What causes new leaves to arise? The answer involves chemical messengers known as hormones.

Hormones and Differential Gene Expression Influence Leaf Development

As we have noted, leaf primordia are surface bumps of tissue that develop at the sides of a SAM (see Figure 35.5). Production of such leaf primordia is under the control of a hormone known as **auxin**. In general, **hormones** are signaling molecules that exert their effects at a site distant from the place where such compounds are produced. Plant hormones are important in coordinating both plant development and plant responses to environmental conditions and are discussed in more detail in Chapter 36.

The outermost epidermal layer of cells at shoot tips produces auxin, which moves from cell to cell by means of specific membrane transport proteins. Auxin accumulates in particular locations because cells of the shoot apex differ in their ability to import and export auxin. When auxin accumulates in a particular apical region, the hormone causes expansin gene expression to increase. When expansin loosens their cell walls (see Figure 35.10), cells expand by taking up water, thereby forming a tissue bulge—a leaf primordium. The development of leaf primordia depletes auxin from nearby tissue, with the result that the next leaf primordium will develop in a different place on the shoot apex, where the auxin level is higher. Such changes in auxin concentration on the surface of the shoot explain why



(a) Modular structure of herbaceous shoot

(b) Modular structure of woody shoot in winter

Figure 35.12 **The modular organization of plant shoots.** **(a)** The top end of an herbaceous stem showing the shoot modules. Each module consists of a node with its associated leaf and axillary meristem or bud and an internode. **(b)** The modular organization shown by a woody stem as it appears during winter. Axillary buds lie above the scars left by leaf fall. Regions between successive sets of bud scale scars mark each year's growth.

Concept check: *If a twig has five sets of bud scale scars, how old is the twig likely to be?*

leaf (and flower) primordia develop in spiral or whorled patterns around the shoot tip. The youngest leaf primordia occur closest to the shoot tip, and successively older leaf primordia occur on the sides of the shoot tip (see Figure 35.5).

Hormones also influence the transformation of primordia into leaves. The cells of leaf primordia do not produce a protein known as KNOX, which is produced by other shoot meristematic cells. KNOX is a transcription factor, a protein that regulates gene transcription. The absence of KNOX proteins induces leaf primordia to produce a plant hormone known as **gibberellic acid**. This hormone stimulates both cell division and cell enlargement, causing young leaves to grow.

Other molecules produced by a SAM direct leaf flattening and differentiation of adaxial and abaxial leaf tissues (see Figure 35.8c). These signaling effects were first demonstrated in 1955 by plant developmental biologist Ian Sussex, who made surgical cuts around leaf primordia, thereby isolating them from chemical substances produced by the meristem. The isolated primordia retained their initial cylindrical, radially symmetrical structure rather than becoming flat and bilaterally symmetrical, as they should. Later, investigators discovered that a particular set of genes expressed in young primordia causes leaf adaxial tissues to develop and that a different set of genes specifies abaxial tissue development. What causes this differential gene expression? In 2004, plant biologists Catherine Kidner and Robert Martienssen reported that a specific type of microRNA (miRNA; described in Chapter 13) accumulates in the abaxial regions of a developing leaf. In this location, the miRNA interrupts expression of the set of genes that specify adaxial tissue development and allows expression of the genes specifying abaxial fate, helping to explain why leaf adaxial and abaxial tissues differ. Other types of miRNA molecules can influence leaf shape, which helps explain the diversity of leaf shapes produced by different plant species.

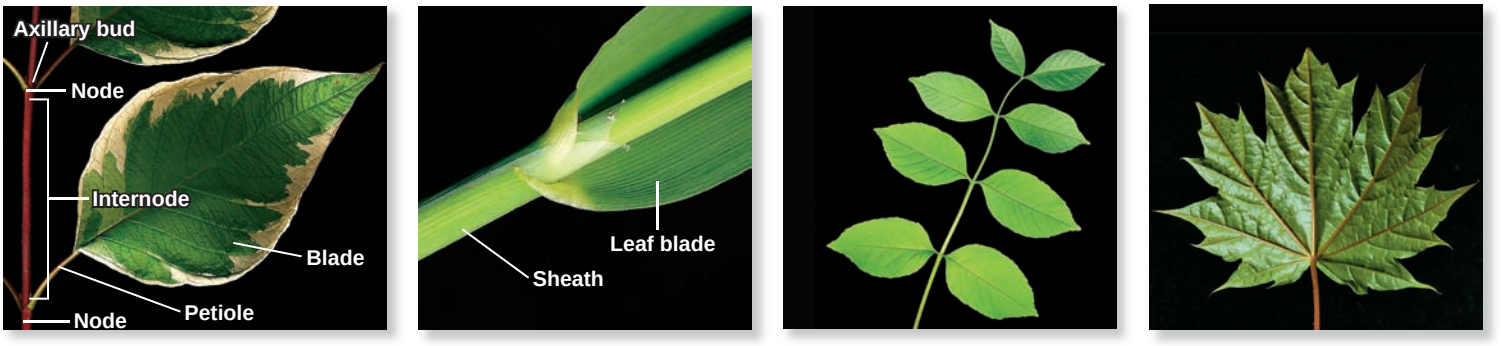
Leaf Shape and Surface Features Reflect Adaptation to Environmental Stress

As we have noted, leaf flatness facilitates solar energy collection, and thinness helps leaves to avoid overheating. Leaf shape and surface features also reflect adaptation to stressful environmental conditions.

Leaf Form The flattened portion of a leaf is known as the leaf **blade**. In beans and most other eudicots, blades are attached to the stem by means of a stalk known as a **petiole**, and an axillary bud occurs at the junction of stem and petiole (Figure 35.13a). In contrast, corn and other monocots have leaf blades that grow directly from the stem, encircling it to form a leaf sheath (Figure 35.13b).

Leaf shape can be simple or compound, each having particular advantages. Simple leaves have only one blade, though the edges may be smooth, toothed, or lobed. Simple leaves are advantageous in shady environments because they provide maximal light absorption surface, but they can overheat in sunny environments. As an evolutionary response to the heating stress, the blades of some leaves have become highly dissected into leaflets. Such leaves are known as compound leaves (Figure 35.13c). You can distinguish leaflets from leaves because leaflets lack axillary buds at their bases. Compound leaves are common in hot environments because leaflets foster heat dissipation. During the development of at least some compound leaves, the transcription factor KNOX becomes active shortly after the leaf primordia form, causing these primordia to produce multiple growth points that generate the leaflets. In contrast, during simple leaf development, KNOX is not active, because the expression of other proteins suppresses such *KNOX* gene expression.

Leaf Vein Patterns Leaf vein patterns are known as venation. Eudicot leaves occur in two major venation forms. They may have a single main vein from which smaller lateral veins diverge in a feather-like pattern known as **pinnate** venation (Figure 35.13a). Alternatively, several main veins may spread from a common point on the petiole like the fingers of your hand, a pattern known as **palmate** venation (Figure 35.13d). In both cases, small veins connect in a netted pattern (see Table 35.1). Most monocot leaves have a distinctive parallel venation (Figure 35.13b).



(a) Eudicot stem with simple leaf and pinnate venation

(b) Monocot stem and leaf

(c) A compound leaf

(d) A simple leaf and palmate venation

Figure 35.13 **Examples of variation in leaf form.** **(a)** A simple eudicot leaf, showing blade, petiole, and axillary bud. This leaf has a pinnate venation pattern. **(b)** The leaf of a monocot, showing parallel veins. The base of the leaf encircles the stem. **(c)** A compound leaf divided into leaflets. **(d)** A simple leaf having palmate venation.

Feature Investigation

Lawren Sack and Colleagues Showed That Palmate Venation Confers Tolerance of Leaf Vein Breakage

In 2008, Lawren Sack and associates studied the adaptive value of leaf venation patterns by comparing water conduction after injury in pinnately and palmately veined leaves (Figure 35.14). They hypothesized that vascular redundancy would confer tolerance of vein breakage of the type that would occur during mechanical injury or insect damage. To test the hypothesis, the investigators experimentally cut a main vein in the leaves of several plants belonging to seven different plant species: four having pinnately veined leaves and three having palmately veined leaves. They conducted the experiments in vivo, that is, in the plant's natural forest environment. After the wounds had healed, the investigators measured the extent of water flow within the leaves at two or three places on each leaf. They found that across all species examined, palmately veined leaves tolerated the disruption in water flow better than pinnately veined leaves. Leaves with palmate venation have several main veins rather than just one, as in the case of leaves with pinnate venation, which could reduce the impact of disruption by providing transport around injured veins. Although palmate venation provides redundancy in case a main vein becomes damaged, it is more costly in terms of materials needed to construct the additional main veins.

Figure 35.14 Sack and colleagues investigated the function of palmate venation.

HYPOTHESIS Palmate venation provides vascular redundancy, which allows leaves to tolerate vein breakage.

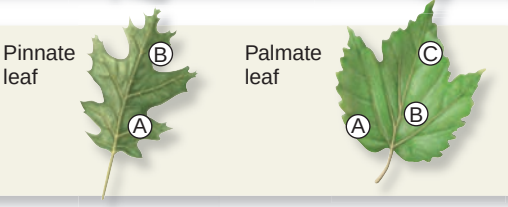
KEY MATERIALS Seven species of trees or shrubs at Harvard Forest, Petersham, MA.

	Experimental level	Conceptual level
1 Identify 7 species, 4 with pinnately veined leaves and 3 with palmately veined leaves. For each species, the researchers analyzed 10 leaves on 3 different plants.		Locate pinnate and palmate leaves for comparison.
2 With the leaf still attached to the plant, use a scalpel to cut across 1 primary vein in 5 experimental leaves but not 5 control leaves.		This procedure initially cuts off water supply via 1 primary vein.
3 Cover the cuts with medical tape on both top and bottom of leaves. Tape same area of uncut control leaves.		The tape prevents infection. Controls: Tape is applied to controls for experimental consistency.

4 Fold cardboard over base of cut leaves, forming a splint. Splint the same area of uncut control leaves.

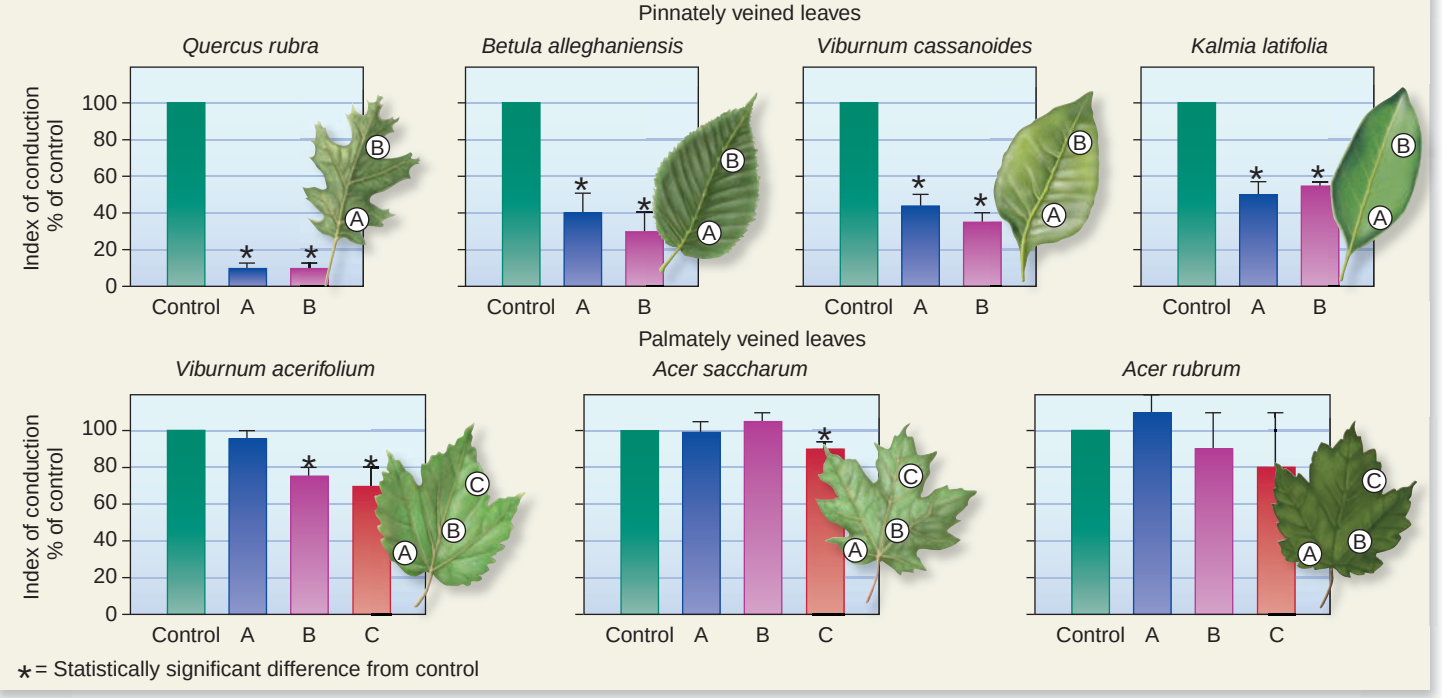
The cardboard prevents leaf collapse.
Control: Cardboard is applied to controls for experimental consistency.

5 Measure water conduction 2–9 weeks after treatment, in 2 regions (A, B) of each pinnate leaf and in 3 regions (A, B, C) of each palmate leaf.



After 2–9 weeks, the cuts had healed.
Measurement of water conduction will determine the effect of the vein cut.

6 THE DATA



7 CONCLUSION Palmately veined leaves did not suffer as much conduction loss from a primary vein cut as did pinnately veined leaves.

8 SOURCE Sack, L. et al. 2008. Leaf palmate venation and vascular redundancy confer tolerance of hydraulic disruption. *Proceedings of the National Academy of Sciences of the U.S.* 105:1567–1572.

Experimental Questions

1. Why did Sack and associates conduct their studies of palmate venation on plants growing in a forest rather than in a greenhouse?
2. Why did Sack and colleagues splint pinnately veined leaves?
3. Why did Sack and associates measure leaf water conduction at two or more places on each leaf?

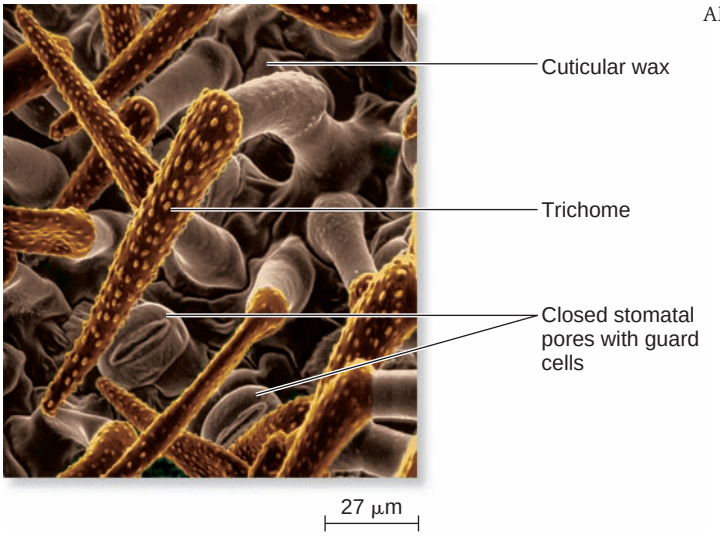


Figure 35.15 **Leaf surface features.** These features, viewed by SEM, include cuticular wax, trichomes, and stomatal pores with guard cells.

Leaf Surface Features Leaf surfaces also show adaptive features. As we have previously noted, a layer of epidermal tissue occurs at upper and lower leaf surfaces (see Figure 35.8c). These epidermal cells secrete a cuticle composed of protective wax and polyester compounds. The cuticle helps plants to avoid drying in the same way that enclosure in waxed paper keeps food moist. Plants that grow in very arid climates often have thick cuticles, whereas plants native to moist habitats typically have thinner cuticles. Cuticles also filter damaging ultraviolet (UV) radiation, reduce attack by microbes and animals, and foster a self-cleaning process by which water droplets and debris wash from the leaf surface.

Some leaf epidermal cells may differentiate into spiky or hairlike projections known as **trichomes** (Figure 35.15). Blankets of trichomes offer protection from excessive light, UV radiation, extreme air temperature, excess water loss, or attack by herbivores—animals that consume plant tissues. Broken trichomes of the stinging nettle, for example, release a caustic substance that irritates animals' skin, causing them to avoid these plants. Leaf epidermal cells include pairs of specialized guard cells located on either side of stomatal pores (Figure 35.15). These **guard cells** allow stomatal pores to be open during moist conditions and to close when conditions are dry, thereby preventing plants from losing too much water. The genetic basis of stomatal guard cell development is becoming increasingly well understood.

Genomes & Proteomes Connection

Genetic Control of Stomatal Development

The flowering plant *Arabidopsis thaliana* is a model plant that is widely used to explore the genetic basis for plant structure and development. Several features increase *A. thaliana*'s utility for such studies: It is small in size, it has a fast seed-to-seed life cycle, it produces a relatively large number of seeds, and the genome has been sequenced. Mutants of this plant have been used to identify the genes controlling many aspects of plant structure and development, including the development of specialized stomatal guard cells.

Guard-cell development begins with an unspecialized protodermal cell that divides unequally (Figure 35.16). The larger of the two progeny cells eventually becomes a flat, puzzle piece–shaped epidermal cell, while the smaller is called a meristemoid because it functions like a stem cell. Meristemoids undergo one or more unequal cell divisions, producing more puzzle piece–shaped epidermal cells before finally dividing equally to produce a pair of guard cells. Genetic studies of *A. thaliana* have revealed that the meristemoid secretes a protein that inhibits division by adjacent cells but does not affect cells farther away. This process distributes stomata evenly and prevents too many of them from forming, which could increase the loss of water from plant surfaces.

In 2007, two teams, led by Lynn Pillitteri and Cora MacAlister, respectively, independently reported experiments with *A. thaliana* showing how three closely related genes control guard-cell development. A gene called *SPEECHLESS* starts the process by establishing the first unequal cell divisions of meristemoids. A protein encoded by the *MUTE* gene then causes meristemoids to stop dividing unequally so that equal divisions can produce the two guard cells (Figure 35.16). Disabling mutations of these two genes cause the plant epidermis to completely

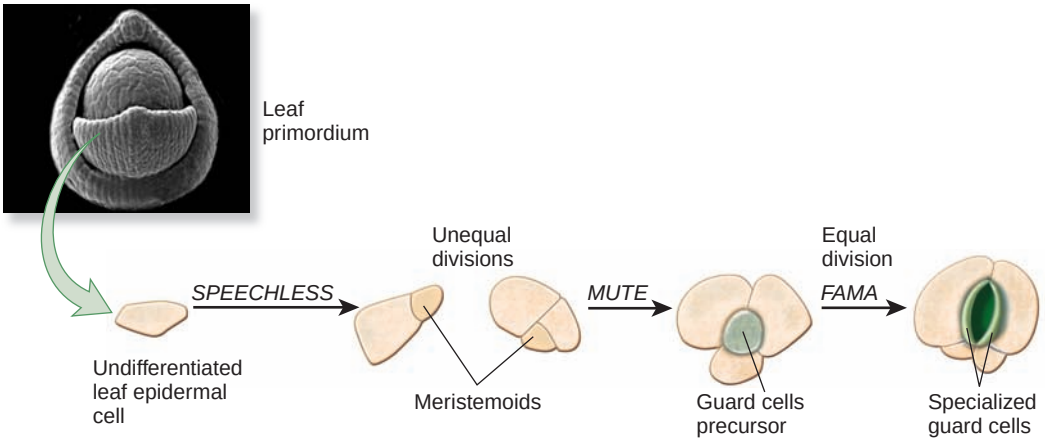

Figure 35.16 **The development of stomatal guard cells, controlled by three genes.**

(a) Tendrils (b) Bud scales (c) Bracts (d) Spines

Figure 35.17 **Examples of modified leaves.** **(a)** The tendrils of an American vetch plant are modified leaves that help the plant attach to a trellis. **(b)** Bud scales, such as those on this sycamore bud, are modified leaves that protect buds from winter damage. **(c)** The attractive red bracts of poinsettia are modified leaves that function like flower petals to attract pollinator insects to the small flowers. **(d)** Cactus spines, such as these on this giant saguaro, are modified leaves that function in defense.

Concept check: *Because cactus leaves are so highly modified for defense that they cannot effectively accomplish photosynthesis, how do cacti obtain organic compounds?*

lack stomatal pores (and so lack epidermal "mouths" and be speechless or mute). Finally, the gene *FAMA* directs guard-cell specialization. The proteins encoded by these plant genes are members of a type known as basic helix-loop-helix (bHLH) proteins (see Chapter 13) (similar proteins control the development of muscle and nerve cells in animals).

Modified Leaves Perform Diverse Functions

Though most leaves function primarily as photosynthetic organs, some plants produce leaves that are modified in ways that allow them to play other roles. For example, threadlike tendrils that help some plants attach to a supporting structure are modified leaves or leaflets (Figure 35.17a). The tough scales that protect buds on plants such as the sycamore from winter damage are modified leaves (Figure 35.17b). Poinsettia "petals" are actually modified leaves known as bracts, which are larger and more brightly colored than the flowers they surround and help attract pollinators (Figure 35.17c). Cactus spines are actually modified leaves that have taken on a defensive role, leaving photosynthesis to the cactus stem (Figure 35.17d).

Stems May Contain Primary and Secondary Vascular Systems

Stems, leaves, roots, buds, flowers, and fruits all contain vascular systems composed of xylem and phloem tissues that conduct water, minerals, and organic compounds. **Herbaceous plants** such as corn and bean produce mostly primary vascular tissues. In contrast, **woody plants** produce both primary and secondary vascular tissues. A comparison of primary and secondary vascular tissues will aid in understanding their roles.

Primary Vascular Tissues **Primary vascular tissues** are composed of primary xylem and phloem. Primary xylem is a complex tissue containing several cell types (see Table 35.2). These include unspecialized parenchyma cells; stiff fibers that provide structural support; and two types of cells that have differentiated in ways that facilitate water transport: tracheids and vessel elements. Arranged in pipeline-like arrays, **tracheids** and **vessel elements** conduct water, along with dissolved minerals and certain organic compounds (Figure 35.18). Mature tracheids and vessel elements are no longer living cells, and the absence

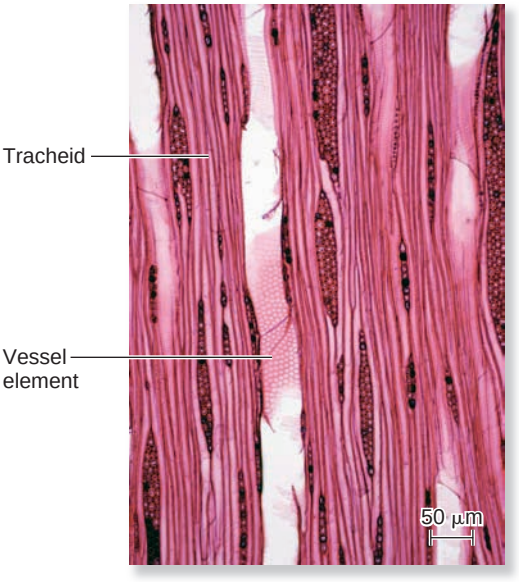

Figure 35.18 **Water-conducting cells of the xylem.** In this thinly sliced portion of a stem, the stained, lignin-impregnated walls of narrow tracheids and wider vessel elements can be distinguished.

of cytoplasm facilitates water flow. During development, these cells lose their cytoplasm by the process of programmed cell death. Why then don't the cell walls of tracheids and vessel elements break down or collapse? They are impregnated with a tough polymer known as lignin. The rigid cell walls of tracheids and vessel elements not only foster water conduction but also help support the plant body.

In contrast to xylem, living phloem tissue transports organic compounds such as sugars and certain minerals in a watery solution. Phloem tissue includes **sieve-tube elements**, thin-walled living cells that are arranged end to end to form pipelines (Figure 35.19). Pores in the end walls of sieve-tube elements allow solutions to move from one cell to another. Phloem tissue also includes companion cells that aid sieve-tube element metabolism, supportive fibers, and parenchyma cells (see Table 35.2). Phloem fibers are tough-walled sclerenchyma cells that are surprisingly long, 20–50 mm, and valued for their high strength. The phloem fibers of hemp (*Cannabis sativa*), flax (*Linum usitatissimum*), jute (*Corchorus capsularis*), kenaf (*Hibiscus cannabinus*), and ramie (*Boehmeria nivea*) are commercially important in the production of rope, textiles, and paper.

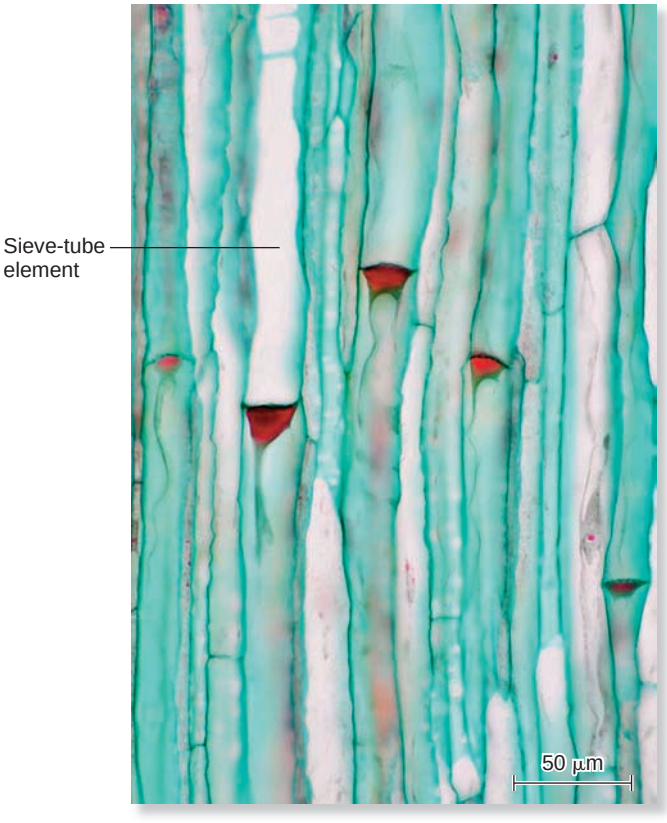

Figure 35.19 **Food-conducting cells of the phloem.** This thinly sliced portion of a stem shows stained, thin-walled sieve-tube elements that conduct watery solutions of organic compounds such as sugar and certain minerals.

Secondary Vascular Tissues Woody plants begin life as herbaceous seedlings that possess only primary vascular systems. But as these plants mature, they produce secondary vascular tissues and bark. Secondary vascular tissues are composed of secondary xylem and secondary phloem. **Secondary xylem** is also known as **wood**, and **secondary phloem** is the **inner bark**. **Outer bark** is protective layers of mostly dead cork cells that cover the outside of woody stems and roots. Therefore, bark includes both inner bark (secondary phloem) and outer bark (cork). Woody plants produce secondary vascular tissues by means of **secondary meristems**, also known as **lateral meristems**, which form rings of actively dividing cells that encircle the stem. The two types of secondary meristems are vascular cambium and cork cambium, which are derived from primary meristems (Figure 35.20). In particular, the vascular cambium is derived from procambium, and cork cambium is derived from ground tissue (Figure 35.21).

The secondary meristem known as **vascular cambium** is a ring of dividing cells that produces secondary xylem to its interior and secondary phloem to its exterior (Figure 35.22). Secondary xylem conducts most of a woody plant's water and minerals. Cell divisions that occur in secondary meristems increase the girth of woody stems. During each new growing season, the vascular cambium produces new cylinders of secondary xylem and secondary phloem. In temperate trees, each year's addition of new secondary xylem forms growth rings that can be observed on the cut stem surfaces. If environmental conditions favor plant growth, the growth rings formed at that time will be wider than those formed during stressful conditions. Climatologists use growth ring widths in samples of old

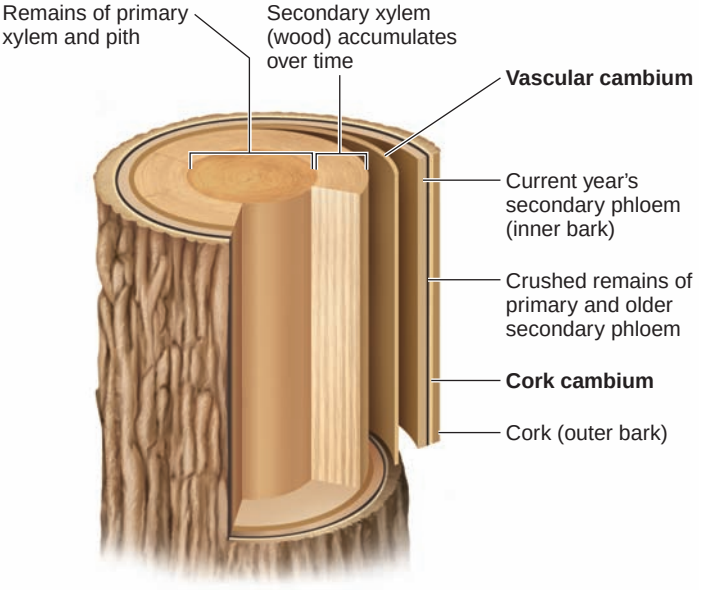

Figure 35.20 **Formation of wood and bark by secondary (lateral) meristems.** The vascular cambium is a thin cylinder of tissue that produces a thick cylinder of wood (secondary xylem) toward the inside of the stem and a thinner cylinder of inner bark (secondary phloem) toward the outside of the stem. The cork cambium forms an outer coating of protective cork (outer bark).

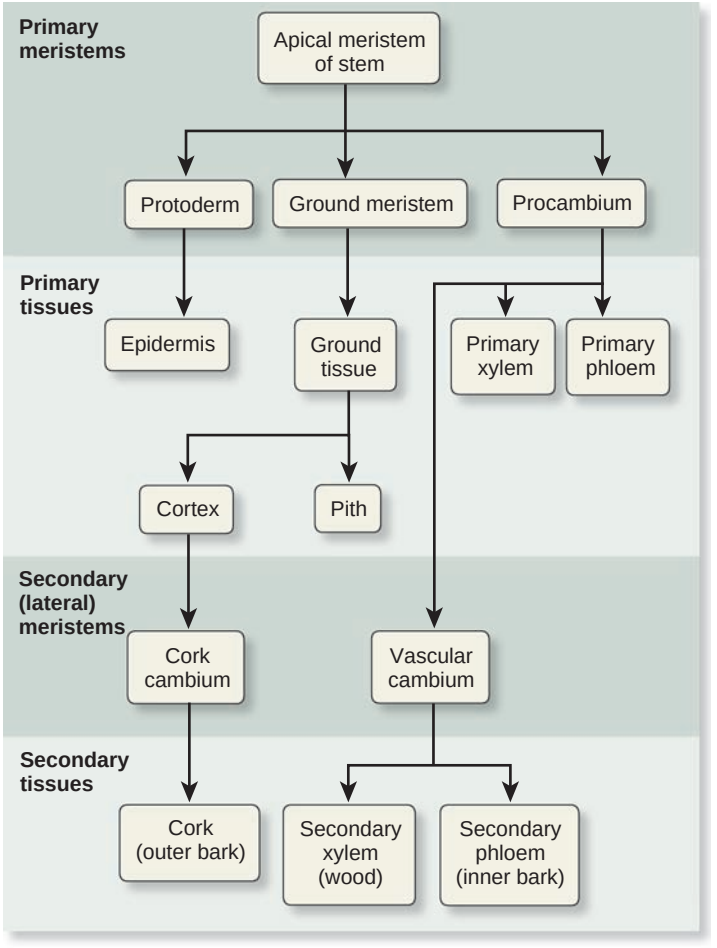

Figure 35.21 An overview of the process of primary and secondary growth in a woody stem.

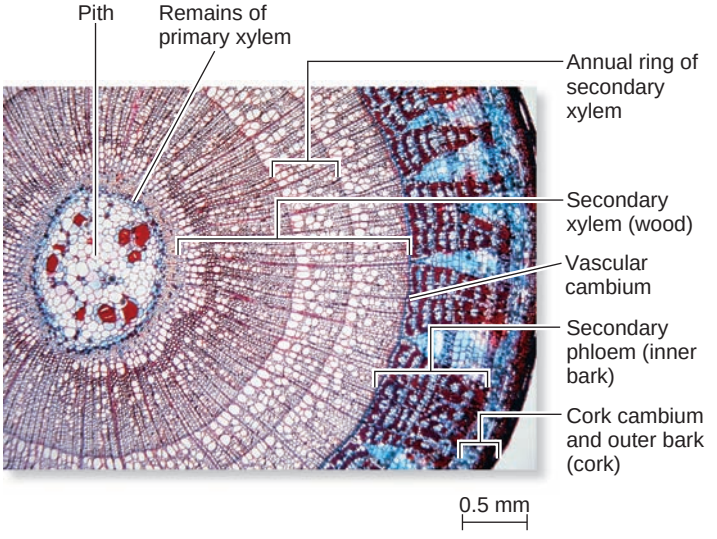

Figure 35.22 **The anatomy of a tree trunk.** Each year, a new cylinder of wood is produced; this yearly wood production appears as annual rings on the cut surface of a woody stem.

Concept check: *Why do tree trunks have a thicker layer of wood (secondary xylem) than of inner bark (secondary phloem)?*

wood to deduce past climatic conditions, and archeologists use growth ring data to determine the age of wood constructions and artifacts left by ancient cultures.

Secondary xylem may transport water for several years, but usually only the current year's production of secondary phloem is active in food transport. This is because thin-walled sieve elements typically live for only a year. Thus, only a thin layer of phloem, the **inner bark**, is responsible for most of the sugar transport in a large tree. Deep abrasion of tree bark may damage this thin phloem layer, disrupting a tree's food transport. If a groove is cut all the way around a tree trunk—a process known as girdling—the tree will die because all of its functional phloem transport routes will have been interrupted.

As a young woody stem begins to increase in diameter, its thin epidermis eventually ruptures and is replaced by outer bark, which is composed of protective cork tissues. Cork is produced by a secondary meristem called the **cork cambium**, another ring of actively dividing cells. The cork cambium surrounds the secondary phloem (see Figures 35.20 and 35.22). Cork cells are dead when mature, and their walls are layered with suberin, a material that helps to prevent both attack by microbial pathogens and water loss from the stem surface. Cork tissues also produce tannins, compounds that protect against pathogens by inactivating their proteins. The cracked surfaces of tree trunks are dead cork tissues of the outer bark. Commercial cork is sustainably harvested from the cork oak tree (*Quercus suber*) for production of flooring material, bottle stoppers, and other items. Additional information about the structure and function of primary and secondary xylem and phloem can be found in Chapter 38.

Modified Stems Display Diverse Forms and Functions

Stems mostly grow upright because light is required for photosynthesis. But some stems, known as rhizomes, occur underground and grow horizontally. For example, potato tubers are the swollen, food-storing tips of rhizomes. Grass stems also grow horizontally, as either rhizomes just beneath the soil surface or stolons, which grow along the soil surface. The leaves and reproductive shoots of grasses grow upward from the point where they are attached to these horizontal stems. Grass blades continue to elongate from their bases even if you cut their tips off, explaining why lawns must be mowed repeatedly during the growing season. The horizontal stems of grasses are adaptations that help to protect vulnerable shoot apical meristems against natural hazards such as fire and grazing animals.

35.4 Root System Adaptations

Roots play the essential roles of absorbing water and minerals, anchoring plants in soil, and storing nutrients. The external form of roots varies among flowering plants, reflecting adaptation to particular life spans or habitats. In contrast, root internal structure is more uniform. In this section, we first consider

variation in root external structure and then focus on root internal structure and development.

Modified Roots Display Diverse External Forms and Functions

As we have observed, the common bean and other eudicots display an underground taproot system, whereas corn and other monocots have a fibrous root system (see Table 35.1). Plants produce several other types of roots that provide adaptive advantages. For example, corn and many other plants produce supportive prop roots from the lower portions of their stems. Many tropical trees grow in such thin soils that the trees are vulnerable to being blown down in windstorms. Such trees often produce dramatic aboveground buttress roots that help keep trees upright (Figure 35.23a). Many mangrove trees that grow along tropical coasts produce pneumatophores (Greek meaning breath bearers), roots that grow upward into the air (Figure 35.23b). Functioning like snorkels, pneumatophores absorb oxygen-rich air, which diffuses to submerged roots growing in oxygen-poor sediments. This is necessary because all roots require a supply of oxygen in order to produce ATP, which is needed to power the uptake of mineral nutrients (see Chapter 37).

(a) Buttress roots

(b) Pneumatophores

Figure 35.23 Modified aboveground roots. **(a)** Buttress roots help to keep tropical trees such as this *Pterocarpus hayesii* from toppling in windstorms. **(b)** Pneumatophores produced by mangroves are roots that extend upward into the air. These roots take up air and then transmit it to underwater roots that grow in oxygen-poor sediments.

Root Internal Growth and Tissue Specialization Occur in Distinct Zones

We now turn to root internal structure and development. In their study of gene expression in *Arabidopsis* roots, plant molecular biologists Kenneth Birnbaum and associates identified 15 distinct cell types. Such studies reveal that roots are amazingly complex in structure. However, for our purposes, a simpler microscopic examination of root internal structure reveals three major zones: (1) a root apical meristem (RAM), (2) a zone of root elongation, and (3) a zone of maturation in which specialized cells can be observed (Figure 35.24).

Root Apical Meristem and Root Cap As we have discussed earlier, an apical meristem occurs at the tips of roots and their branches. Like the SAM, the RAM contains stem cells, but these are organized differently in root apices. Root stem cells surround a tiny region of cells that rarely divide, known as the quiescent center. Signals emanating from the quiescent center keep nearby stem cells in an undifferentiated state. Root stem cells farther away from the quiescent center produce new cells in multiple directions. Toward the root tip, stem cells produce columella cells that sense gravity and touch, which helps roots extend downward into the soil and around obstacles such as rocks. At the sides of the quiescent center, stem cells produce a protective root cap and epidermal cells. Root tip epidermal cells secrete a sticky substance called mucigel that lubricates root growth through the soil and has other beneficial functions. Toward the shoot, root stem cells generate cells that become ground and vascular tissues.

Zones of Elongation and Maturation Above the RAM lies the **zone of elongation**, in which cells extend by water uptake, thereby dramatically increasing root length (Figure 35.24). Above and overlapping with the zone of elongation is the **zone of maturation**, where most root cell differentiation and tissue specialization occur. Specialized root tissues include mature vascular tissues at the root core, an enclosing cylinder of cells known as the pericycle, another cell cylinder called the endodermis (meaning inside skin), and epidermal cells at the root surface. Relatively unspecialized parenchyma cells form a cortex that lies between the endodermis and the epidermis. Starting with the epidermis and moving inward, we will take a closer look at these root tissues and factors that control their development.

The zone of maturation can be identified by the presence of numerous microscopic hairs that emerge from the root epidermis. **Root hairs** are specialized epidermal cells that can be as long as 1.3 cm, about the width of your little finger, but are only 10 μm in diameter. Their small diameter allows root hairs to obtain water and minerals from soil pores that are too narrow for even the smallest roots to enter. Root hair plasma membranes are rich in transport proteins that use ATP to selectively absorb materials from the soil (see Chapter 37).

The production of hairs from root epidermal cells is controlled by the activity of the gene *GLABRA-2* (from the Latin

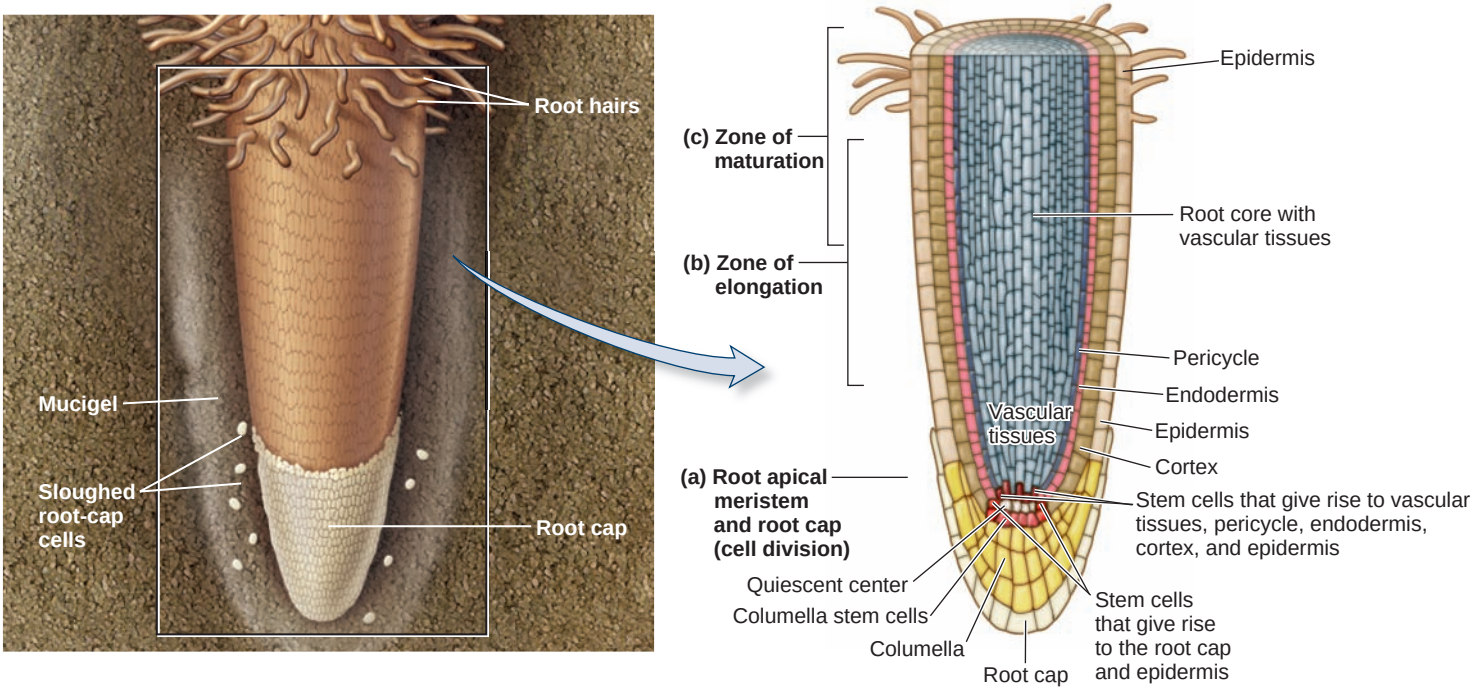

Figure 35.24 **Three zones of root growth.** A longitudinal view of a typical root reveals three major zones: **(a)** a root apical meristem region that includes stem cells, a quiescent zone, columella, and a root cap; **(b)** a zone of elongation; and **(c)** a zone of maturation, characterized by specialized cells and tissues including epidermal root hairs, cylinders of endodermis and pericycle tissue, and a core of vascular tissue.

glaber, meaning bald) (Figure 35.25). Whether this gene is expressed or not depends on the position of an epidermal cell. If an epidermal cell contacts two cortical cells, *GLABRA-2* is repressed and other genes are expressed, causing a root hair to develop. In contrast, no hair will develop if an epidermal cell lies in contact with only one cortical cell. A mutation that disables *GLABRA-2* in every epidermal cell causes all of them to produce root hairs.

Root hairs are so delicate that they are easily damaged by abrasion as roots grow through the soil, and they live for only 4 or 5 days. As a result, root hairs are absent from older regions above the zone of maturation. To compensate, roots must continually produce new root hairs. The average rate of root hair production has been estimated at more than 100 million per day for some plants. One reason that gardeners use care when transplanting seedlings is to prevent extensive damage to the root hair zone.

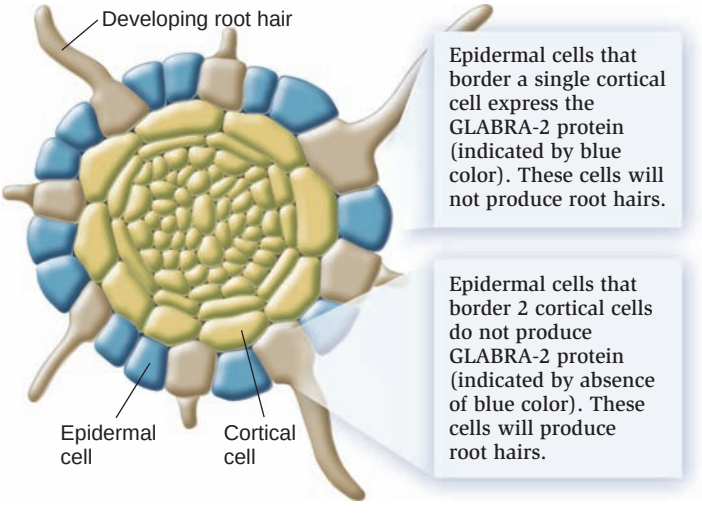

Figure 35.25 **A cross section of a root showing the genetic control of root-hair development.** The *Arabidopsis* gene *GLABRA-2* affects root-hair development.

The epidermis of mature roots encloses a region of ground parenchyma known as the root cortex (Figure 35.26). Much like the stem cortex, root cortex cells are often rich in starch and therefore serve as a food storage site for plants. The root cortex of some plants contains intercellular air spaces that arise from programmed cell death and provide routes for oxygen diffusion within the root. Water and dissolved minerals also diffuse from the environment into roots through spaces between cortex cells, stopping only when they reach a specialized tissue known as **endodermis**, an important component of the mechanism by which roots absorb selected minerals (see Chapter 37).

A cylinder of tissue having cell division (meristematic) capacity, known as the **pericycle**, encloses the root vascular tissue (Figure 35.26). The pericycle produces lateral (branch) roots that force their way through the cortex to the surface. This process differs from the way that stems produce branches by means of buds. In the model plant *Arabidopsis thaliana*, the expression of a gene known as *ARABIDILLO* is known to promote lateral root development. In some roots, the pericycle generates a vascular cambium that produces wood—secondary xylem. Such woody roots also possess a cork cambium that makes a protective covering of suberin-coated cork tissue. Like woody stems, woody roots produce primary vascular tissues

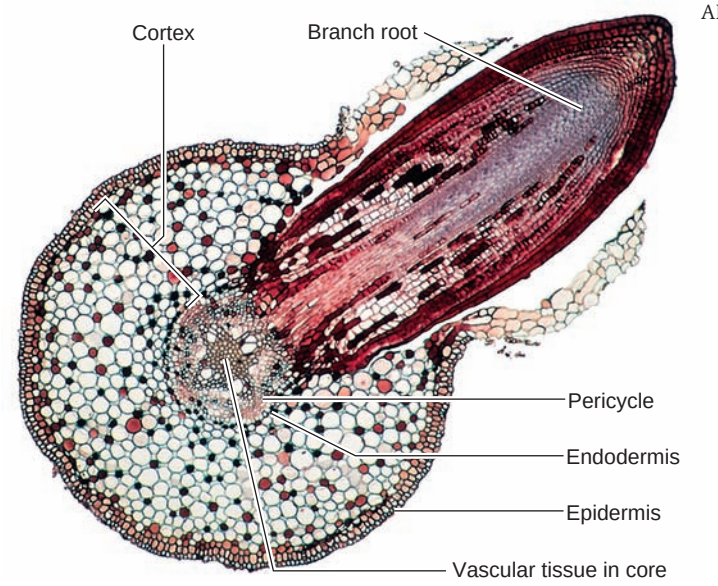

Figure 35.26 **Cross section of a mature root.** This stained light micrograph shows the epidermis and cortex of a root surrounding a central core of vascular tissue. An inner cortex layer is the endodermis, which surrounds a cylinder of meristematic pericycle tissue. The pericycle has produced a young branch (lateral) root that has grown through the cortex and the epidermis.

Concept check: *Why must lateral roots be produced in this way?*

in their youth and secondary vascular tissues at maturity. The woody roots of trees are sometimes visible aboveground.

Finally, the primary vascular system in a mature root includes xylem and phloem; in dicot roots, strands of phloem enclose a core of xylem. The xylem exports water and minerals upward to shoots, and the phloem imports a watery solution of organic compounds from the shoots.

Summary of Key Concepts

35.1 From Seed to Seed—The Life of a Flowering Plant

- Seed embryos, seedlings, and mature plants are components of the sporophyte generation in the plant sexual cycle; tiny gametophytes develop and grow within flowers. (Figure 35.1)
- Plant organs are composed of tissues that contain specialized cells. The basic plant organs are roots, stems, and leaves. Shoot systems include stems and stem branches, and stems produce leaves, buds, flowers, and fruits. Root systems include one or more main roots with branches. Buds, flowers, fruits, and seeds are organ systems, composed of more than one organ. (Figures 35.2, 35.3)
- The two major groups of flowering plants, eudicots and monocots, differ in the structure of their seed embryos, flowers, stems, roots, leaves, and pollen. (Table 35.1)

35.2 How Plants Grow and Develop

- The principles of plant growth and development include the presence of a fundamental architecture featuring apical-basal polarity and radial symmetry throughout the life of a plant. (Figures 35.4, 35.5)
- Plants grow by producing new cells at meristems and controlled cell enlargement involving water uptake.
- Shoot apical meristems produce primary meristems that increase plant length and produce organs. Lateral meristems give rise to secondary tissues in many species. (Table 35.2, Figure 35.6)
- The simple plant tissues, containing one or two cell types, include parenchyma, collenchyma, and sclerenchyma. Complex plant tissues include the vascular tissues known as xylem and phloem, and the primary vascular tissues occur in vascular bundles. (Figure 35.7)
- Leaves develop from primordia at shoot apices. Foliage leaves have internal and external structure that is adapted for photosynthetic functions. (Figure 35.8)
- Meristems include youthful stem cells, whose numbers influence plant growth and structure and are thus genetically controlled.
- Plant cells are able to expand under conditions that result in loosening of cell-wall components, and by water uptake into vacuoles. The direction in which plant cells expand is determined by the arrangement of wall cellulose microfibrils, which is influenced by the orientation of microtubules in the nearby cytoplasm. (Figures 35.9, 35.10, 35.11)

35.3 The Shoot System: Stem and Leaf Adaptations

- Shoots are modular systems; each module includes a node, internode, leaf, and axillary meristem or bud. An axillary bud develops in leaf axils; such buds may grow into new branches. (Figure 35.12)
- Variations in leaf structure reflect adaptations that aid photosynthesis or protect against stress. For example, Sack and colleagues demonstrated that palmate leaves provide conducting system redundancy useful in coping with vein damage. (Figures 35.13, 35.14, 35.15)
- Stomatal guard cell differentiation is controlled by several genes. (Figure 35.16)
- Leaves function not only in photosynthesis but they also play other roles, including attachment, attraction, and protection. (Figure 35.17)
- Herbaceous plants are those whose stems produce little or no wood and are mostly composed of primary vascular tissues. The primary vascular tissues are primary xylem and primary phloem. (Figures 35.18, 35.19)
- In addition to primary tissues, woody plants—trees, shrubs, and lianas—possess secondary meristems that produce wood and bark. The vascular cambium produces secondary xylem (wood) and secondary phloem (inner bark). The cork cambium produces cork tissues that form outer bark. (Figures 35.20, 35.21, 35.22)
- Stems occur in diverse forms that reflect adaptation to environmental conditions. Examples include grass rhizomes, which grow horizontally underground and are therefore better protected from fire and grazing animals (as well as lawnmowers).

35.4 Root System Adaptations

- Roots occur in multiple forms that reflect adaptation to environmental conditions. Examples of aboveground roots include prop roots, buttress roots, and pneumatophores. (Figure 35.23)
- The internal organization of roots is comparatively uniform, and three major zones can be recognized with the use of a microscope: the root apical meristem and root cap, a zone of cell and root elongation, and a zone of tissue maturation. Features of the mature root include epidermal root hairs that aid nutrient uptake, a food-storing cortex, an endodermis that functions in mineral selection, a pericycle that produces lateral (branch) roots (and vascular cambium in the case of woody roots), and an inner core of vascular tissue. (Figures 35.24, 35.25, 35.26)

Assess and Discuss

Test Yourself

1. Where would you look to find the gametophyte generation of a flowering plant?
   a. at the shoot apical meristem
   b. at the root apical meristem
   c. in seeds
   d. in flower parts
   e. Flowering plants lack a gametophyte generation.
2. What is a radicle?
   a. an embryonic leaf
   b. an embryonic stem
   c. an embryonic root
   d. a mature root system of a monocot
   e. an organism that has extreme political views
3. Which type of plant is most likely to have food-rich roots that are useful as human food?
   a. an annual
   b. a biennial
   c. a perennial
   d. a centennial
   e. plants that grow along coastal shorelines
4. Which of the following terms best describes the distinctive architecture of plants?
   a. radial symmetry and apical-basal polarity
   b. bilateral symmetry and apical-basal polarity
   c. radial symmetry and absence of apical-basal polarity
   d. bilateral symmetry and absence of apical-basal polarity
   e. absence of symmetry and absence of apical-basal polarity
5. Which is the most accurate description of how plants grow?
   a. by the addition of new cells at meristems that include stem cells
   b. by cell enlargement as the result of water uptake
   c. by both the addition of new cells and cell expansion
   d. by addition of fat cells
   e. all of the above
6. Where would you look for leaf primordia?
   a. at a vegetative shoot tip
   b. at the root apical meristem
   c. at the vascular cambium
   d. at the cork cambium
   e. in a floral bud
7. Which leaf tissues display the greatest amount of air space?
   a. the adaxial epidermis
   b. the abaxial epidermis
   c. the palisade parenchyma
   d. the spongy parenchyma
   e. the vascular tissues
8. What are adventitious roots?
   a. roots that develop on plant cuttings that have been placed in water
   b. buttress roots that grow from tree trunks
   c. the only kinds of roots produced by monocots, because their embryonic root dies soon after seed germination
   d. any root that is produced by stem (or sometimes leaf) tissue, rather than developing directly from the embryonic root
   e. all of the above
9. During its development, a tracheid will elongate in a direction parallel to the shoot or root axis. Based on this information, what can you say about the orientation of cellulose cell-wall microfibrils and cytoplasmic microtubules in this developing tracheid?
   a. The microfibrils will be oriented perpendicularly (at right angles) to the long axis of the developing tracheid, encircling it, but the cytoplasmic microtubules will be oriented parallel to the direction in which the tracheid is elongating.
   b. Microfibrils and microtubules will both be oriented perpendicularly (at right angles) to the elongating axis of the tracheid.
   c. Microfibrils and microtubules will both be oriented parallel to the direction of tracheid elongation.
   d. Microfibrils will be oriented parallel to the direction of tracheid elongation, but microtubules will be perpendicular (at right angles) to both the microfibrils and the elongating tracheid.
   e. None of the above is correct.
10. What are examples of woody plants?
    a. trees
    b. shrubs
    c. woody vines, known as lianas
    d. all of the above
    e. none of the above

Conceptual Questions

1. What would be the consequences if overall plant architecture were bilaterally symmetrical?
2. What would be the consequences if leaves were radially symmetrical (shaped like spheres or cylinders)?
3. Why are most tall plants also woody, rather than herbaceous?

Collaborative Questions

1. Find a tree stump or a large limb that has recently been cut from a tree (or imagine doing so). Which of the following features could you locate with the unaided eye: the outer bark, the inner bark, the secondary xylem, the vascular cambium, annual rings?
2. Which physical factors would you expect influence shoot growth most strongly? Which physical factors would you expect most strongly influence underground root growth?

Chapter Outline

Flowering Plants: Behavior

36

Behavior of the snow buttercup. The snow buttercup (*Ranunculus adoneus*) holds its flowers above the surface of the snow. The flowers move so they always face the sun during the day, a behavior known as sun tracking.

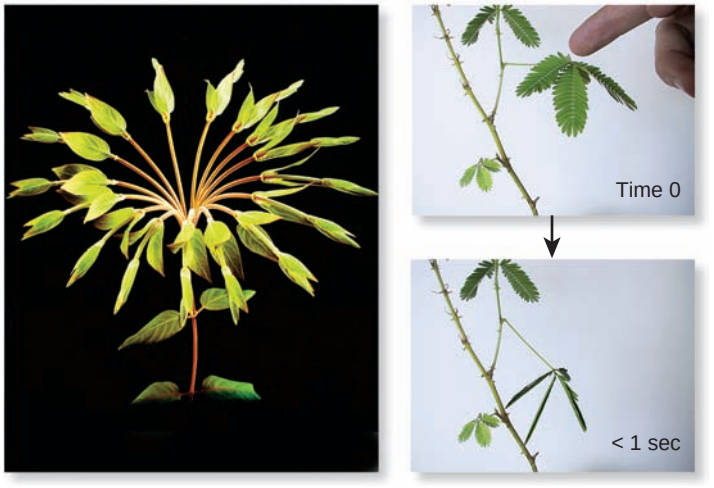
The snow buttercup (*Ranunculus adoneus*) grows in deep snowbanks in the high Rocky Mountains, with flower stems protruding above the snow surface toward the sun, as shown in the chapter-opening photo. Amazingly, snow buttercup flowers change their position so they face the sun throughout the day, a process known as sun tracking. Experiments have demonstrated that sun tracking warms snow buttercup flowers, thereby favoring pollen development and germination. Thus, sun tracking is an adaptation that increases snow buttercup reproductive fitness. Leaves of alfalfa, lupine, soybean, common bean, cotton, and other plants may also track the sun, a process that aids in photosynthesis. Sun tracking is but one example of the many ways in which plants display behavior—that is, responses to stimuli. Although sun tracking and some other plant responses are relatively rapid, plants often display behavior such as changes in growth and development that occur more slowly.

We begin this chapter with an overview of the diverse types of stimuli that induce plant behavior and consider how plant cells perceive and respond to stimuli by means of signal transduction pathways. Next, we will learn about plant hormones, internal mobile molecules that influence plant behavior. Finally, we consider how plant responses to environmental stimuli such as light foster survival and reproduction.

36.1 Overview of Plant Behavioral Responses

As mentioned, **behavior** is defined as a response to a stimulus. Therefore, plants display behavior because they exhibit many types of responses to stimuli. Examples include plant movements, some types of which were described in 1880 by Charles Darwin and his son Francis in their book *The Power of Movement in Plants*. Modern time-lapse photography reveals that most plants are constantly in motion, bending, twisting, or rotating in dancelike movements known as nutation (Figure 36.1a). Some plants display quite rapid movements, illustrated by the sensitive plant (*Mimosa pudica*), whose leaves quickly fold when touched, then open more slowly (Figure 36.1b). Plants also display behavior when they grow and develop in response to stimuli, though such responses are slower. For example, plant shoots typically grow toward light and against the pull of gravity, and most roots grow toward water and in the same direction as the gravitational force. Seeds germinate when they detect the presence of sufficient light and moisture for successful seedling growth. Producing flowers, fruit, and seeds only at the season most favorable for reproductive success is a behavioral response to environmental change. Plants also sense attack by disease microbes or hungry animals and take protective actions.

One reason why humans are often unaware of plant behavior is that it typically occurs on a longer timescale than our sensory systems are adapted to notice. Consequently, time-lapse photography, as shown in Figure 36.1a, is often needed to reveal slow plant movements. Although we typically are more aware of animal behavior than that of plants, plant behavior is important to humans because it influences agricultural productivity and plant roles in nature. To gain a more complete understanding of plant behavior, we will begin by surveying the types of stimuli that cause plant responses.



(a) Nutation movements (b) Leaf folding

Figure 36.1 **Examples of plant movements.** **(a)** Sixteen superimposed photographs of a shoot of the honeysuckle vine *Lonicera japonica*, taken over a period of 2 hours, reveal the circular movement known as nutation. **(b)** Photographs of the sensitive plant (*Mimosa pudica*) made before and shortly after a touch reveal the rapid process of leaf folding. Even if only one leaflet is touched, electrical signals travel throughout the complex leaf, causing the entire organ to fold. The leaves will eventually unfold.

Plant Behavior Involves Responses to Internal and External Stimuli

Most people are aware that both internal chemical hormones and environmental factors influence animal behavior. Bird nesting behavior in spring, for example, involves hormonal changes triggered by seasonal conditions. Plants likewise respond to both internal and environmental influences (Figure 36.2).

Internal Stimuli Plants respond to mobile internal chemical signals that are produced within the body and move from one location to another, and act at very low concentrations. These chemical signals are small compounds generally known as **hormones**, phytohormones, or plant growth substances. Hormones often interact with each other and with external stimuli to maintain a stable internal environment (homeostasis) and enable progress through life stages.

Environmental Stimuli Plants sense and respond to many types of external physical and biological stimuli (Figure 36.2). Physical stimuli in natural plant environments include light, atmospheric gases such as CO_2 and water vapor, temperature, touch, wind, gravity, soil water, rocks and other barriers to root growth, and soil minerals. Biological stimuli include herbivores (animals that consume plant parts), airborne pathogens (disease-causing microbes), organic chemicals emitted from neighboring plants, and beneficial or harmful soil organisms. Crop plants also respond to applications of agricultural chemicals, which may include hormones. That plants have evolved

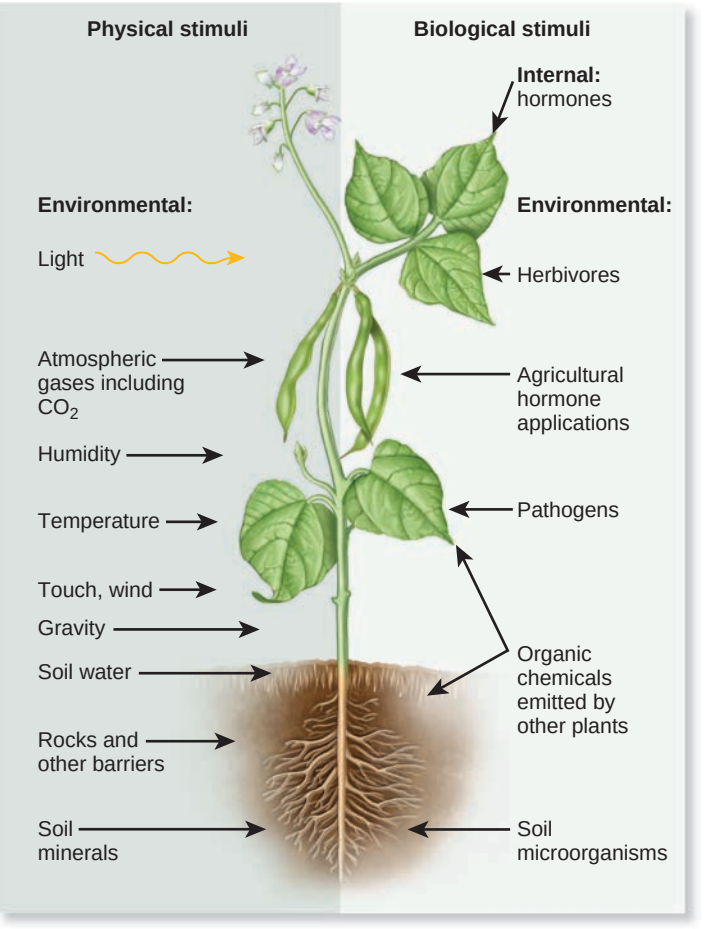


Figure 36.2 **Types of plant stimuli.** Plants respond to both physical and biological stimuli. Stimuli may be internal to the plant or come from the environment.

such a broad array of sensory capacity is not surprising, because all of the listed environmental influences affect plant survival and reproduction.

Plant Responses to Environmental Stimuli Though plants lack the specialized sense organs typical of animals, receptor molecules located in plant cells sense stimuli and cause responses. When many cells of a tissue receive and respond to the same chemical or physical signal, entire organs or plant bodies display behavior. For example, houseplants tend to grow toward a light source such as a window. This process, known as positive **phototropism**, involves both a cellular perception of light and a growth response of stem tissue to an internal chemical signal. In general, a **tropism** is a growth response that is dependent on a stimulus that occurs in a particular direction.

How can an environmental signal such as directional light cause stem movements? In the case of phototropism, the plant senses the direction of light and responds by changing the location of a plant hormone known as auxin. The auxin moves into cells where it influences gene expression. We will next consider how plant cells more generally receive signals and transmit them intracellularly, a process known as signal transduction.

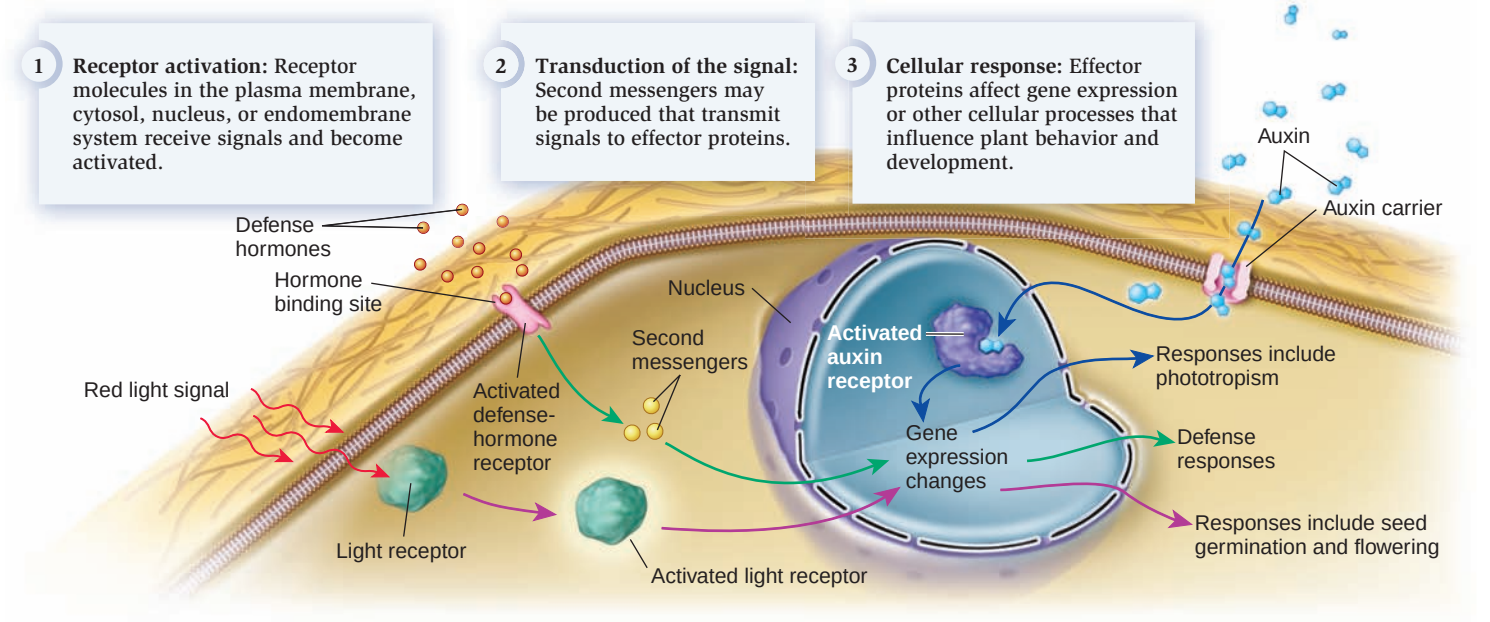

Figure 36.3 **An overview of plant signal transduction.** Plant cells respond to hormonal signals produced within the plant body, as well as to environmental stimuli. Three different signal transduction processes are shown here: those started by light, a defense hormone having a plasma membrane receptor, and auxin having a receptor located in the nucleus.

Plant Signal Transduction Involves Receptors, Messengers, and Effectors

Signal transduction is the process in which a cell perceives a physical or chemical signal, thereby switching on an intracellular pathway that leads to a cellular response (Figure 36.3). The process of signal transduction occurs in three stages: receptor activation, transduction of the signal via second messengers, and a cellular response (refer back to Figure 9.4).

Receptors (also known as sensors) are proteins that become activated when they receive a specific type of signal (Figure 36.3). Receptors occur in diverse cellular locations. Whereas some plant defense-hormone receptors are located within the plasma membrane, light receptors may occur in the cytosol, and auxin receptors are located in the nucleus. Some activated receptors directly generate a response, such as an increased flow of ions across a membrane. In contrast, many activated receptors first bind to signaling molecules that initiate an intracellular signaling pathway. For example, the binding of brassinosteroid defense hormones to plasma membrane receptors results in the intracellular production of signaling molecules called second messengers.

Second messengers transmit messages from many types of activated receptors. Cyclic AMP, inositol trisphosphate (IP_3), and calcium ions are major types of second messengers in animal and plant cells. Calcium ions are particularly common messengers in plant cells. Touch and various other stimuli cause calcium ions to flow from storage sites in the ER lumen into the cytosol. Calmodulin or other calcium-binding proteins then bind the calcium ions. Calcium binding alters the structure of such proteins, causing them to interact with other cell proteins or to alter enzymatic function.

Effectors are molecules that directly influence cellular responses. In plants, calcium-dependent protein kinases (CDPKs) are particularly important effector molecules. Signal transduction ends when an effector causes a cellular response, such as opening or closing an ion channel or switching the transcription of particular genes on or off. A single activated receptor can dispatch many second messenger molecules, which, in turn, can activate scores of effectors, leading to many molecular responses within a single cell.

Now that we have considered how plant cells perceive and respond to stimuli, we are prepared to focus more closely on the roles of plant hormones.

36.2 Plant Hormones

As we have seen, plant hormones are chemical signals transported within the plant body that bind to cellular receptors, thereby causing responses. Plant hormones include about a dozen types of small molecules that are synthesized in metabolic pathways that also make amino acids, nucleotides, sterols, or secondary metabolites. Auxins, cytokinins, gibberellins, ethylene, abscisic acid, and brassinosteroids are considered to be the major plant hormones (Table 36.1). Individual plant hormones often have multiple effects, and different concentrations or combinations of hormones can produce distinct growth or developmental responses. Several plant hormones are known to act by causing the removal of gene repressors, thereby allowing gene expression to occur. This general mechanism allows hormones to cause relatively rapid responses. A closer look at the major types of plant hormones reveals their multifaceted roles.

Table 36.1 The Major Types of Plant Hormones

Type of plant hormone	Chemical structure of an example	Functions (Note: this is a partial, not complete list)
Auxins	Indoleacetic acid (IAA) 	Establish apical-basal polarity, induce vascular tissue development, mediate phototropism, promote formation of adventitious roots, inhibit leaf and fruit drop, and stimulate fruit development
Cytokinins	Zeatin 	Promote cell division, influence cell specialization and plant aging, activate secondary meristem development, promote adventitious root growth, and promote shoot development on callus
Gibberellins	Gibberellic acid 	Stimulate cell division and cell elongation, stimulate stem elongation and flowering, and promote seed germination
Ethylene	Ethylene 	Promotes seedling growth, induces fruit ripening, plays a role in leaf and petal aging and drop, coordinates defenses against osmotic stress and pathogen attack
Abscisic acid	Abscisic acid 	Slows or stops metabolism during environmental stress, induces bud and seed dormancy, prevents seed germination in unfavorable conditions, and promotes stomatal closing
Brassinosteroids	Brassinolide 	Promote cell expansion, stimulate shoot elongation, retard leaf drop, stimulate xylem development, and promote stress responses

Auxins Are the Master Plant Hormones

Plants produce several types of **auxins**, which are considered to be the master plant hormones because they influence plant structure, development, and behavior in many ways, often working with other hormones. Indoleacetic acid (IAA) is one plant auxin (Table 36.1), but other natural and artificial compounds have similar structures and effects. In this section, we will refer to this family of related compounds simply as auxin.

Auxin exerts so many effects because it promotes the expression of diverse genes, together known as **auxin-response genes**. Under low auxin conditions, proteins called Aux/IAA repressors prevent plant cells from expressing these genes. The repressor proteins prevent gene expression by binding to activator proteins at gene promoters. When the auxin concentration is high enough, auxin molecules glue repressors onto a protein complex called TIR1, which causes the breakdown of the repressors. Free of the repressors, the activator proteins enhance the expression of auxin-response genes.

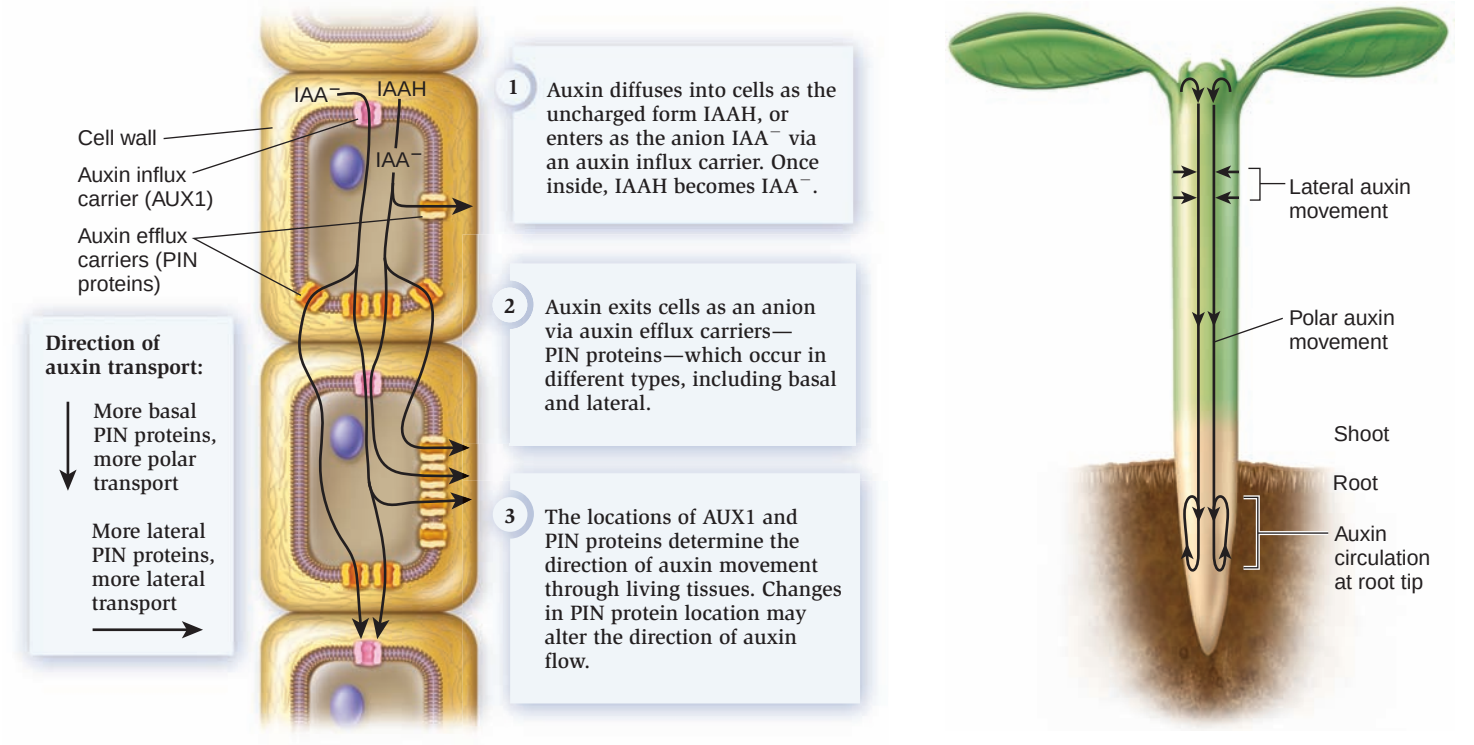
Auxin Transport The way in which auxin is transported into and out of cells is integral to its effects in plants. Auxin is produced in apical shoot tips and young leaves, and it is directionally transported from one living parenchyma cell to another. Auxin in an uncharged form (IAAH) may enter cells from intercellular spaces by means of diffusion; however, the negatively charged form (IAA^-) requires the aid of AUX1, a plasma membrane protein known as the **auxin influx carrier**. Several types of proteins, called PIN proteins, transport auxin out of cells. They are named for the pin-shaped shoot apices of

plants having mutations in *PIN* genes. Because they transport auxin out of cells, PIN proteins are called **auxin efflux carriers**. They are necessary because in the cytoplasm, auxin occurs as a charged ion that does not readily diffuse out of cells.

In shoots, AUX1 is located at the apical ends of cells, whereas PIN proteins often occur at the basal ends (Figure 36.4a). This polar distribution of auxin carriers explains why auxin primarily flows downward in shoots and into roots, a process called **polar transport** (Figure 36.4b). However, the locations of auxin carriers can also change within cell plasma membranes, allowing lateral or upward transport of auxin. Differences in the presence and positions of auxin carrier proteins explain variations in auxin concentration within plants. By measuring the local auxin concentration, plant cells determine their position within the plant body and respond by dividing, expanding, or specializing.

Auxin Effects In nature, auxin influences plants throughout their lifetimes. Auxin establishes the apical-basal polarity of seed embryos, induces vascular tissue to differentiate, mediates phototropism, promotes formation of adventitious roots, and stimulates fruit development. Many of auxin's effects are also of practical importance to humans. Auxin is used to produce some types of seedless fruit, retard premature fruit drop in orchards, and stimulate root development on stem cuttings. Auxin produced by intact shoot tips inhibits lateral bud growth, a process known as apical dominance. Gardeners know that if they remove the topmost portion of a plant shoot, nearby lateral buds will begin to grow and produce new branches, allowing plants to become bushier. Such decapitation disrupts the flow of auxin from the shoot apex. Recent research suggests that a class of newly discovered hormones known as strigolactones also influence shoot branching. These carotenoid-derived terpenes, synthesized in roots and shoots, are transported to buds where they are thought to work with auxin. Although there is still much to learn about auxin function, auxin's role in phototropism has been elucidated by a series of experiments, as described next.

The Role of Auxin in Phototropism In the 1880s, Charles Darwin and his son Francis were the first to publish results of experiments on plant phototropism. The Darwins performed their experiments on cereal seedlings, whose tips are protected by a sheath of tissue called a coleoptile. In a simple but elegant experiment, the Darwins covered either the tips or lower portions of coleoptiles with shading materials such as blackened glass tubes, left other seedlings uncovered, and removed the tips of some seedlings. They then compared how those seedlings responded to illumination from the side. The seedlings



(a) Cellular mechanism of auxin transport

(b) Auxin transport throughout a plant

Figure 36.4 **Auxin transport.** **(a)** Polar and lateral auxin transport is controlled by the distribution of auxin efflux carriers located in the plasma membrane. When efflux carriers primarily occur at the basal ends of cells, auxin will flow downward. Auxin may flow laterally when auxin efflux carriers occur at the sides of cells. **(b)** In a whole plant, auxin primarily flows downward from shoot tips to root tips, where it then flows upward for a short distance.

Concept check: *How could auxin carriers be organized to allow auxin to move upward in roots?*

whose tips were left uncovered grew toward the light, whereas seedlings whose tips were covered or removed did not. The Darwins concluded that seedling tips transmit some "influence" to lower portions, causing them to bend toward the light. You can probably guess what this influence was, but technology available at the time did not allow the Darwins to determine this.

Three decades later, in the 1910s, Danish botanist Peter Boysen-Jensen confirmed the Darwins' results and demonstrated that the influence was a chemical substance that diffused from the tips of the seedlings to other parts. To do this, Boysen-Jensen cut off the tips of oat seedlings and placed either a porous layer of gelatin or a nonporous material such as a sheet of the mineral mica on the cut surface. Then he replaced the tips. Oat seedlings layered with porous gelatin displayed a normal phototropic response, bending toward the light, but those layered with nonporous mica did not. Boysen-Jensen's experiment demonstrated that the phototropic substance was a diffusible chemical, but exactly which one, and how it worked, remained unknown. A series of additional experiments provided some answers.

Feature Investigation

Experiments Performed by Went and Briggs Revealed the Role of Auxin in Phototropism

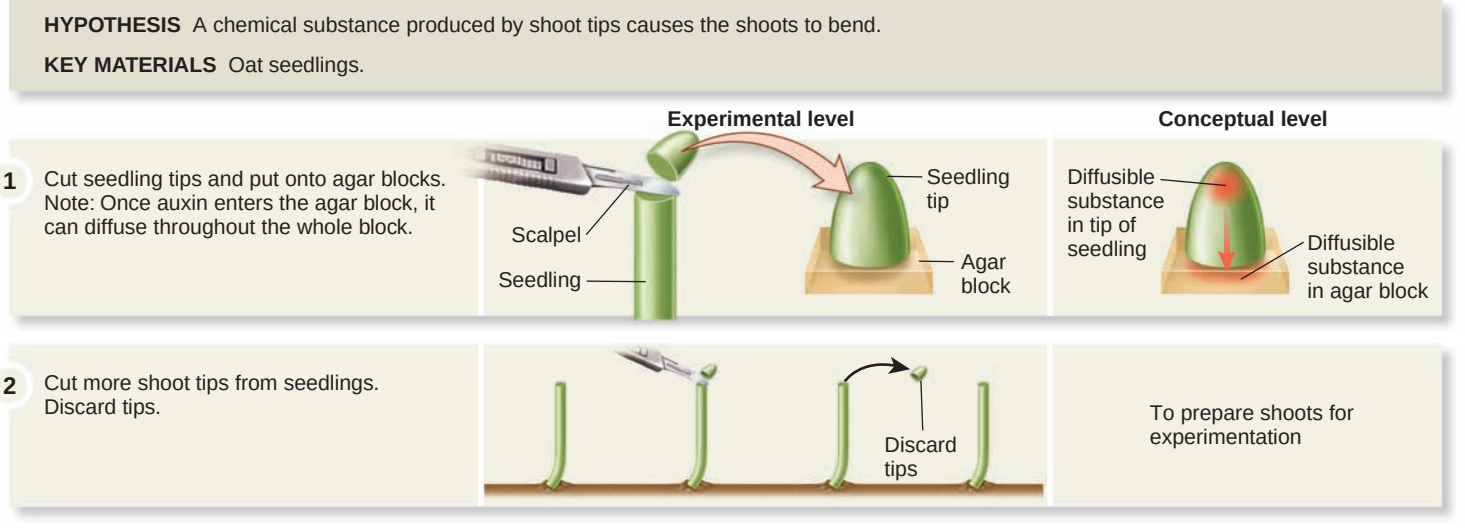
In the 1920s, the Dutch plant physiologist Frits Went named the substance discovered by Boysen-Jensen auxin (from the Greek word *auxein*, meaning to increase). Although the chemical structure of auxin was not determined until 1934, Went performed experiments that helped explain how auxin works, as shown in Figure 36.5a. In a first step, Went cut the tips off of oat seedlings and placed these tips onto agar blocks. Agar, a complex polysaccharide derived from red algae, forms a mesh capable of holding considerable water and dissolved compounds. Agar's permeability to auxin is similar to that of the protein gelatin used by Boysen-Jensen, but agar is much more stable at room temperature and more resistant to microbial breakdown and therefore is easier to use in laboratory experiments. In Went's experiment, the auxin diffused from cut seedling tips into these agar blocks. In the next steps, he treated decapitated seedlings in one of four ways: (A) placed auxin-laden agar blocks off-center on some, (B) placed auxin-laden blocks evenly on others, (C) placed plain agar blocks off-center on some, and (D) left some uncapped. All seedlings were then kept in darkness throughout the experiment. Only seedlings that were capped off-center with an auxin-laden block grew in the direction away from the agar block. This experiment demonstrated that auxin application could substitute for the directional light stimulus, and it suggested that asymmetric auxin distribution is the mechanism by which light causes plants to bend.

Subsequently, Went and N. O. Cholodny independently proposed that light causes auxin to move to the unlit side of seedling tips, causing cells on that side to elongate more, which results in bending. But other scientists argued that bending could result if light destroys auxin on the illuminated side of a seedling. In the 1950s, American plant biologist Winslow Briggs designed two experiments to test these alternate hypotheses.

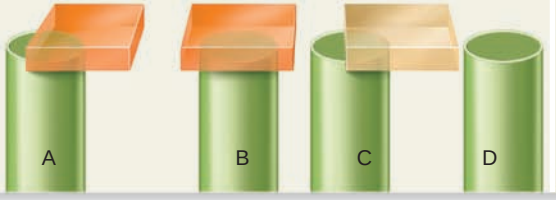
To test the hypothesis that auxin might be destroyed by light, Briggs first grew corn seedlings in the dark. Then he cut off their tips, put the tips on agar blocks, and exposed some to darkness and others to directional light. During this process, auxin from tips diffused evenly into the agar blocks. If auxin were destroyed by light, agar blocks under lighted tips should receive less auxin than blocks under tips kept in the dark.

Figure 36.5 **Went and Briggs demonstrated the relationship between light perception and auxin function.** **(a)** The Went experiment. **(b)** The Briggs experiment.

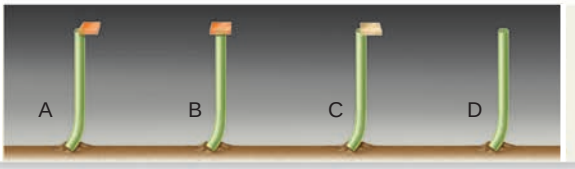
(a) Went experiment



3 A Cap some shoots off-center with agar blocks from step 1.
B Cap some shoots evenly with agar blocks from step 1.
C Cap some shoots off-center with plain agar blocks (control).
D Leave some shoots uncapped (control).



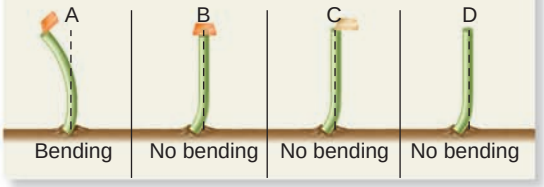
4 Place all shoots in darkness.



Seedling growth will be affected by caps, not by light.

5 THE DATA

Degree of bending among treated shoots:



6 CONCLUSION Uneven distribution of a diffusible tip substance, named auxin, causes bending.

Went's new hypothesis:
Light causes auxin to move to unlit side of shoots, causing cells on that side to elongate more.

(b) Briggs experiment 2

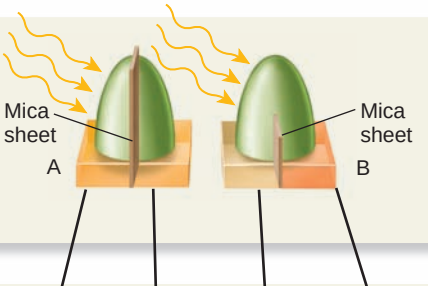
HYPOTHESIS Directional light causes auxin to move to the shaded side of shoot tips.

KEY MATERIALS Corn seedlings.

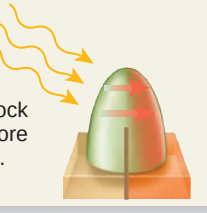
Experimental level | **Conceptual level**

1 Place shoot tips on agar blocks.

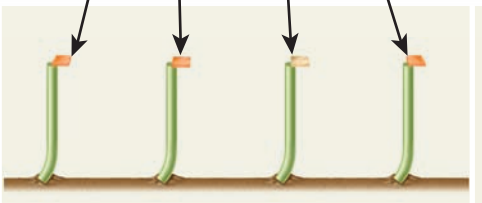
2 Divide some tip/block combinations completely with a mica sheet, which prevents diffusion between the 2 halves of the tip and agar block. Divide some tip/block combinations only partially with a mica sheet. This allows auxin diffusion across the tip, but not across the agar block. Expose both to directional light.



If directional light causes auxins to move to shaded side of shoot tips, agar block in B will contain more auxin on right side.

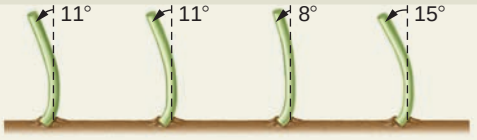


3 Remove agar block halves from tips. Place agar halves onto right sides of shoots, which have their tips removed.



If directional light causes auxins to move laterally, the block half beneath the left side of the partially divided tip shown in B should cause the least shoot bending, whereas the block half beneath the right side of B should cause the greatest amount of bending.

4 THE DATA



5 CONCLUSION In A, the mica sheets prevented auxin from moving to the shaded side of tips. In B, auxin was able to move in response to directional light. Agar block pieces from the shaded side of tips contained more auxin and therefore caused greater shoot bending. Hypothesis is correct.

6 SOURCE Briggs, W.R. 1963. Mediation of phototropic responses of corn coleoptiles by lateral transport of auxin. *Plant Physiology* 38(3):237–247.

The auxin destruction hypothesis also predicts that when agar blocks from lighted tips are placed on one side of decapitated seedlings, they should cause less bending than would blocks from tips kept in the dark. However, Briggs discovered that both types of agar blocks caused the same amount of shoot bending. This result is not consistent with the hypothesis that light destroys auxin.

In a second experiment, Briggs tested the Cholodny–Went hypothesis that light causes auxin to move to the shaded side of seedlings (Figure 36.5b). Briggs set shoot tips onto agar blocks (step 1) and then used a mica sheet (which is impervious to auxin) to completely divide some tips and blocks into halves (step 2A). In other cases, he divided blocks completely but left tips incompletely divided, allowing auxin to diffuse across tips but not the block halves (step 2B). Then Briggs exposed all sets of tips and blocks to directional light. He predicted that auxin would not be able to move across tips having complete mica barricades but that auxin would be able to move across tips that had been only partially divided. Auxin diffused from tips into blocks, but it could not diffuse evenly across blocks divided by mica sheets. When Briggs later placed the agar block halves on decapitated shoots (step 3), those receiving auxin from completely divided tips were bent by the same amount. By contrast, agar block halves from the lit side of partially divided tips induced less bending, while halves from the unlit side of partially divided tips caused the most bending (see the data in Figure 36.5b). These experimental results support the hypothesis that unidirectional light causes auxin to accumulate on the shaded side. Modern plant scientists would explain such auxin movement as the result of lateral transport involving PIN proteins.

How might auxin accumulation cause phototropic bending? One widely held hypothesis is that auxin accumulation on the shaded side of a plant shoot causes plasma membrane proton pumps located there to work at a faster rate. In response, the cell wall becomes more acidic, which activates expansins, proteins that break cross-links between cellulose microfibrils and allow cells to elongate (refer back to Figure 35.10). This process might explain how auxin accumulation in cells located on the shaded side of shoot tips causes them to elongate more than do cells on the sunny side, causing the tip to bend toward the light.

Experimental Questions

1. Use the text discussion to draw a diagram illustrating the experiment that Briggs did in order to determine whether or not light destroys auxin.
2. What is the current hypothesized mechanism by which auxin accumulation causes shoot bending in response to directional light?
3. Figure 36.5 illustrates experiments performed with four seedling tips. Would this number really be enough to allow conclusions to be made about how such seedling tips would generally respond?

Cytokinins Stimulate Cell Division

Like auxins, the plant hormones known as **cytokinins** play varied and important roles throughout the lives of plants. The name of these hormones reflects their major effect—an increase in the rate of plant cytokinesis, or cell division. Root tips are major sites of cytokinin production, but shoots and seeds also make this plant hormone. Transported in the xylem to meristems and other plants parts, cytokinins bind to receptors in the plasma membrane. At shoot and root tips, cytokinins influence meristem size, stem cell activity, and vascular tissue development. Cytokinins are also involved in root and shoot growth and branching, the production of flowers and seeds, and leaf senescence (aging).

Plant Tissue Culture In the laboratory, cytokinin and auxin are essential to cloning plants. This involves a process, known as **plant tissue culture**, which is used commercially to produce thousands of identical plants having the same desirable characteristics. Plant tissue culture begins with pieces of stem, leaf, or root that have been removed from a plant, and their surfaces are sterilized to prevent growth of microbes (Figure 36.6, step 1). The cleaned plant pieces are then placed into dishes containing nutrients (minerals, vitamins, and sugar) and various proportions of auxin and cytokinin. If the proportions of auxin and cytokinin are about the same (1:1), plant cells undergo division, forming a mass of white tissue known as a callus (step 2). If the callus is then transferred to a new dish containing the same nutrients, with auxin-to-cytokinin proportions greater than 10:1, the callus will form roots (step 3). Auxin-to-cytokinin proportions of less than 10:1 will cause the callus to develop green shoots (step 4). Thus, by altering the ratios of auxin and cytokinin, entire plants can be regenerated from a callus. A single callus can be divided into many pieces and each piece treated with these hormones, thereby producing many hundreds of identical new plants.

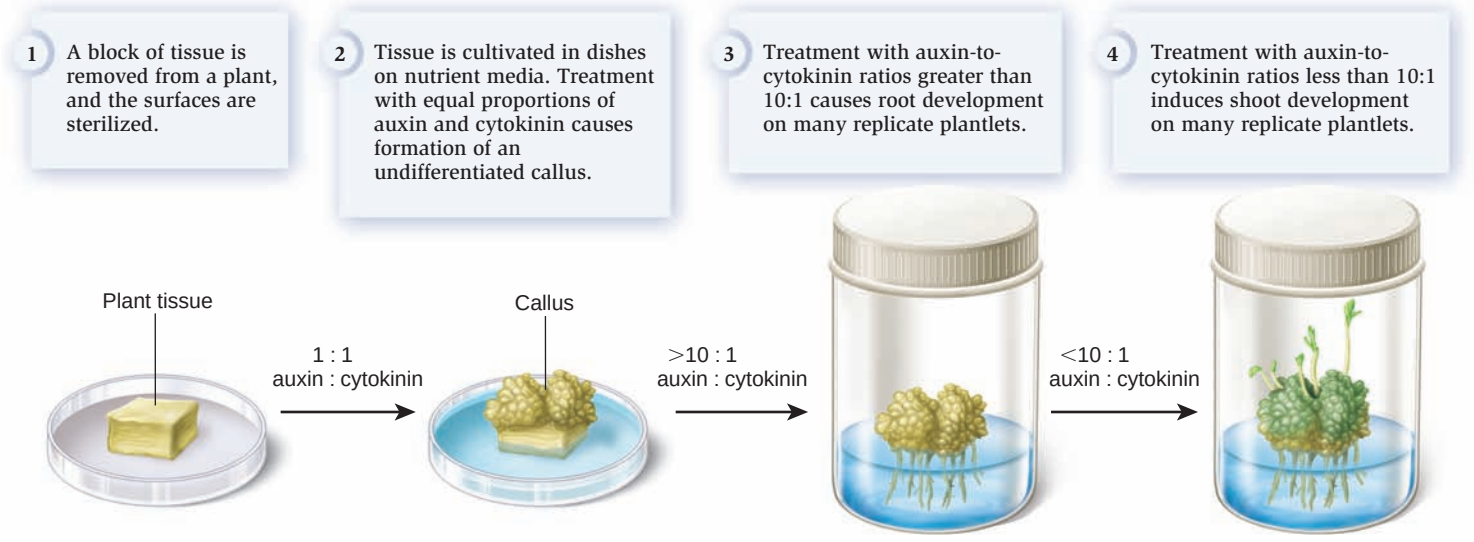


Figure 36.6 **The process of plant tissue culture.** Plant tissue culture illustrates the impact of different proportions of auxin and cytokinin on plant organ development.

Concept check: *How do commercial growers use this process to produce many identical plants?*

Gibberellins Stimulate Cell Division and Elongation

The **gibberellins** (also known as gibberellic acids, or GA; see Table 36.1) are another family of plant hormones. Gibberellins are produced in apical buds, roots, young leaves, and seed embryos. In addition to promoting shoot development on laboratory calluses, gibberellins interact with light and other hormones to foster seed germination and enhance stem elongation and flowering in nature. Gibberellins also retard leaf and fruit aging. These multiple effects largely arise from gibberellin's stimulatory effects on cell division and elongation.

More than a hundred different forms of gibberellin have been found. Many kinds of dwarf plants are short because they produce less gibberellin than taller varieties of the same species. The dwarf strain of pea plants Mendel used in some of his breeding experiments is an example. When dwarf varieties of plants are experimentally sprayed with gibberellin, their stems grow to normal heights. However, dwarf wheat and rice crops are valued in agriculture because they can be more productive and less vulnerable to storm damage than taller varieties. Since the discovery of gibberellin, plant scientists have discovered how this plant hormone works at the molecular level and how gibberellin regulation of plant growth evolved, our next topics.

Genomes & Proteomes Connection

Gibberellin Function Arose in a Series of Stages During Plant Evolution

In flowering plants, gibberellin works by helping to liberate repressed transcription factors. In the absence of gibberellin, DELLA proteins bind particular transcription factors needed for the expression of gibberellin-responsive genes (Figure 36.7a). In this way, DELLAs function as brakes that restrain cell division and expansion. But when sufficient gibberellin is present, it binds receptor proteins called GID1 (Figure 36.7b). Gibberellin-binding increases the ability of GID1 proteins to interact with DELLA proteins, starting a process that leads to the destruction of DELLAs. In the absence of DELLA proteins, transcription factors are able to bind the promoter regions of gibberellin-responsive genes, allowing their expression. As a result, cell division and expansion occur, leading to growth. This efficient system integrates the effects of many signals that affect plant growth: the hormones auxin, ethylene, and abscisic acid, as well as light and environmental stress.

In 2007, Yuki Yasumura, Nicholas Harberd, and their colleagues reported that the gibberellin-DELLA mechanism for regulating the growth of flowering plants arose in a stepwise fashion. They discovered this by comparing the DELLA and GID1 proteins of flowering plants with homologous proteins of a bryophyte and a lycophyte. The seedless lycophytes, the oldest living phylum of vascular plants, first appeared millions of years before the first flowering plants, and the seedless, nonvascular bryophytes arose millions of years before the first vascular plants (see Figure 30.1). The investigators studied the interactions of DELLA proteins with GID1 and evaluated the extent to which gibberellin enhanced DELLA-GID1 binding and growth in these different groups of plants.

The results indicated that the bryophyte possesses DELLA and GID1 proteins, but these proteins don't interact, and bryophyte DELLA does not repress growth. In contrast, differences in the protein structure of lycophyte DELLAs enable them to interact with GID1 and gibberellin, but without detectably influencing growth. Neither the bryophyte nor the lycophyte showed detectable growth responses to gibberellin, though their DELLAs were able to repress growth when expressed in a flowering plant. This pattern led the biologists to propose that

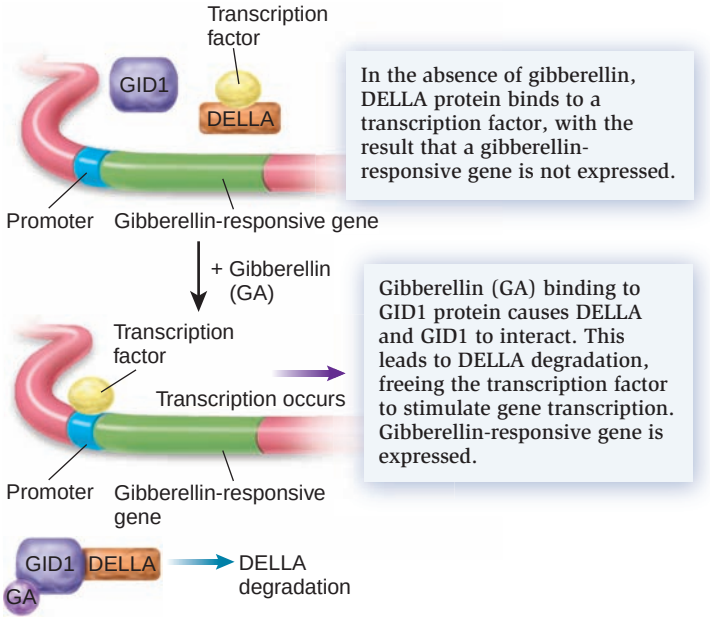

Figure 36.7 **Gibberellin works by releasing trapped transcription factors.** **(a)** In the absence of gibberellin, DELLA binds transcription factors, and gibberellin-response genes are not expressed. **(b)** When gibberellin binds to the protein GID1, GID1 can bind DELLA proteins. Such binding causes DELLA proteins to be degraded. As a result, transcription factors that had been bound to DELLA proteins are released and can bind to gene promoters, thereby inducing gene expression.

DELLA-mediated repression of plant growth evolved after the divergence of lycophytes but prior to the appearance of the first flowering plants (Figure 36.8). Though the necessary components (DELLAs and GID1 proteins) were earlier present, they did not assemble into a growth regulation system until later in plant evolutionary history.

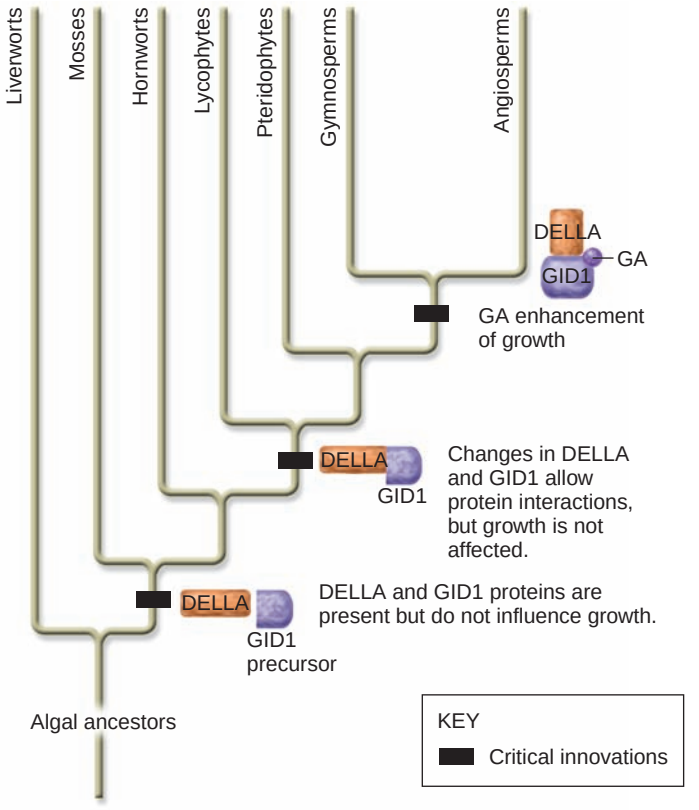

Figure 36.8 **Evolution of the gibberellin-DELLA system.** The gibberellin-DELLA system that controls growth of flowering plants evolved in a step-by-step fashion. Although DELLA and GID1 proteins are present in a bryophyte, they do not interact, nor does gibberellin bind to GID1. In lycophytes, GID1 interacts with DELLA, but the system does not influence growth. The growth responses of gibberellin apparently evolved after the divergence of lycophytes.

Ethylene Influences Cell Expansion

The plant hormone **ethylene** is particularly important in coordinating plant developmental and stress responses. Ethylene is a simple hydrocarbon gas produced during seedling growth, flower development, and fruit ripening (see Table 36.1). In the root tip, ethylene determines how many stem cells remain inactive in the quiescent center and how many cells undergo divisions. This hormone also plays important roles in defense against osmotic stress and pathogen attack, and leaf and petal aging and drop. As a gas, ethylene is able to diffuse through the plasma membrane and cytosol to bind to ethylene receptors localized in the endoplasmic reticulum. When activated by ethylene binding, these receptors inactivate a protein kinase known as CTR1. This action ultimately enables transcription factors to induce the transcription of various genes.

People first noticed the effects of ethylene gas on plants in the 1800s when they observed that street-side trees exposed to leaking street lanterns unexpectedly lost their leaves. A 17-year-old student in St. Petersburg, Russia, Dimitry Neljubov, performed the first experiments to explore the effects of illumination gas on plants. He exposed pea seedlings grown in the laboratory to illumination gas and noticed that the pea seedlings grew sideways rather than upward. Then he tested the individual chemical components of illumination gas for the same effect. After conducting many experiments, in 1901, Neljubov reported that ethylene was the only component of illumination gas that caused the seedlings to grow horizontally and that ethylene was effective in very low concentrations (as low as 0.06 parts per million in air). Later, scientists established that ethylene influences cell expansion, often in association with auxin. Ethylene does this by increasing the disorder of microtubules within cells, thereby causing random orientation of cellwall microfibrils. As a result, cells exposed to ethylene tend to expand in all directions rather than elongating.

Ethylene's effects on cell expansion explain this hormone's important role in dicot seedling growth. The tender apical meristems of seedlings could be easily damaged during their growth through crusty soil. Ethylene helps seedlings avoid such damage by inducing what is known as the triple response (Figure 36.9). First, ethylene prevents the seedling stem and root from elongating. Second, the hormone induces the stem and root to swell radially, thereby increasing in thickness. Together, these responses strengthen the seedling stem and root. Third,

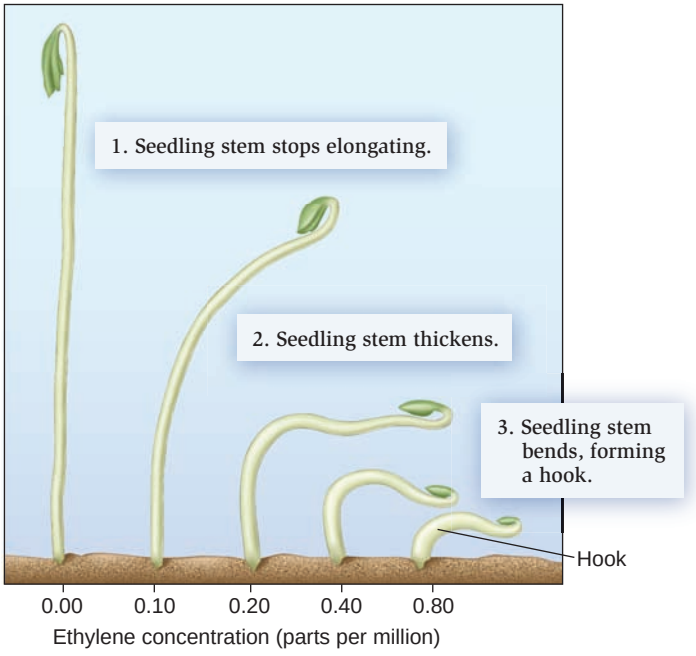

Figure 36.9 Seedling growth showing the triple response to ethylene. When applied at levels above a particular concentration (0.80 ppm), ethylene causes seedlings to cease elongation, swell radially, and bend to form a hook that can push upward through the soil. Ethylene produced naturally within seedlings causes the same response.

Concept check: What adaptive advantage does this seedling behavior provide?

the seedling stem bends so that embryonic leaves and the delicate meristem grow horizontally rather than vertically; this is the sideways growth response that Neljubov first observed. The bent portion of the stem, known as a hook, then pushes up through the soil. The hook forms as the result of an imbalance of auxin across the stem axis, which causes cells on one side of the stem to elongate faster than cells on the other side. Ethylene drives this auxin imbalance.

Knowledge of the effects of ethylene on fruit has been very useful commercially. Ripe fruit can be easily damaged during transit, but tomatoes and apples can be picked before they ripen for transport with minimal damage. At their destination, such fruit can be ripened by treatment with ethylene. However, fruit that becomes overripe may exude ethylene, which hastens ripening in nearby, unripe fruit. For this reason, fruit that must be stored for extended periods is kept in ethylene-free environments.

Several Hormones Help Plants Cope with Environmental Stresses

Several plant hormones share the property of helping plants respond to environmental stresses such as flooding, drought, high salinity, cold, heat, and attack by disease microorganisms and animal herbivores. These protective hormones include the major plant hormones known as **abscisic acid** and **brassinosteroids** (see Table 36.1). Additional protective hormones are salicylic acid (SA), whose chemical structure is similar to that of aspirin, and a peptide known as systemin. The fragrant compound jasmonic acid, whose structure is similar to that of mammalian prostaglandins, and the gas nitric oxide (NO) are also protective plant hormones.

Abscisic Acid Abscisic acid, abbreviated as ABA, was named at a time when plant biologists thought that it played a role in leaf or fruit drop, also known as abscission. Later, they discovered that ethylene actually causes leaf and fruit abscission, whereas abscisic acid slows or stops plant metabolism when growing conditions are poor. For example, ABA may induce bud and seed dormancy. Dormant buds and seeds resume growth only when specific environmental signals reveal the onset of conditions suitable for survival. In preparation for winter, ABA stimulates the formation of tough, protective scales around the buds of perennial plants. Seed coats of apple, cherry, and other plants also accumulate ABA, which prevents seeds from germinating unless temperature and moisture conditions are favorable for seedling growth. Water-stressed roots also produce ABA, which is then transported to shoots, where (together with ABA produced by water-stressed leaf mesophyll) it helps to prevent water loss from leaf surfaces by inducing leaf pores (stomata) to close. ABA receptors are G-protein-coupled receptors (GPCRs) located in the plasma membrane (see Chapter 9). ABA-binding causes the release of G protein, which begins the process of signal transduction.

Brassinosteroids Brassinosteroids are named after the cruciferous plant genus *Brassica* (which includes cabbage and broccoli), from which they were first identified. However, seeds, fruit, shoots, leaves, and flower buds of all types of plants contain brassinosteroids. These plant hormones induce vacuole water uptake and influence enzymes that alter cell-wall carbohydrates, thereby fostering cell expansion. Mutations that affect brassinosteroid synthesis cause plants to exhibit dwarfism. Such plants have small, dark green cells because their tissues are unable to expand. Brassinosteroids also impede leaf drop, help grass leaves to unroll, and stimulate xylem development. They can be applied to crops to help protect plants from heat, cold, high salinity, and herbicide injury.

Brassinosteroids are chemically related to animal steroid hormones, such as human sex hormones. However, unlike animal steroid hormones, which bind to receptors in the nucleus or cytosol, brassinosteroids bind to receptors in the plasma membrane. When they bind brassinosteroids, the membrane receptors inhibit a protein that would otherwise target certain transcription factors for destruction. These transcription factors accumulate and influence gene expression, particularly genes that affect time of flowering. Brassinosteroid action thereby illustrates the general principle that plant hormones often work by removing the brakes from gene expression.

In this section, we have surveyed the roles of major plant hormones produced within plants. While plant hormones coordinate many genetically determined developmental processes, they also help plants to respond to environmental stimuli, our next topic.

36.3 Plant Responses to Environmental Stimuli

Plants encounter many types of environmental challenges and behave accordingly. Take seed germination, for example. If buried seeds were to germinate beneath soil layers too deep for light to penetrate, or beneath a cover of established plants, seedlings would not be able to obtain sufficient light for photosynthesis and would die. A related reproductive challenge for plants is to flower at times of the year that are most beneficial for achieving pollination or seed dispersal. How do plants determine if there is enough light for seeds to germinate and for seedlings to grow? How do plants determine when to flower?

The answer is that plants possess cellular systems for measuring light and determining the seasonal time of year. Using these systems, plant seeds germinate only when there is sufficient light for seedling growth, and flowering occurs during the most advantageous season. Therefore, plants can sense and respond to their light environments. Plants are also able to respond to other physical and biological stimuli. In this section, we survey plant responses to these external stimuli, beginning with light.

Plants Detect Light and Measure Day Length

A plant's ability to measure and respond to light amounts and day length, a process called **photoperiodism**, is based on the presence of light receptors within cells. Such light sensors, known as **photoreceptors**, are distinct from the light-absorbing pigments that function in photosynthesis. Each type of photoreceptor has a light-absorbing component as well as other regions that respond to light absorption by switching on signal transduction pathways. Responses by many cells in a tissue or organ cumulatively result in behaviors such as sun tracking, phototropism, flowering, and seed germination.

Blue-Light Receptors Cryptochromes and phototropins are two types of blue-light receptors—molecules that absorb and respond to blue light. Experiments suggest that receptors called **cryptochromes** help young seedlings determine if their light environment is bright enough to allow photosynthesis. If not, seedlings continue to elongate through the soil, toward the light.

Phototropin is the main blue-light sensor involved in phototropism. The light-activated form of this sensor has two components: a protein that has a kinase domain and a flavin pigment that can absorb blue light. In the dark, the flavin is not covalently bound to the protein. However, when the flavin absorbs blue light, it changes conformation and becomes able to covalently bind to the protein. Flavin binding, in turn, changes the conformation of the phototropin protein, allowing it to phosphorylate itself by means of the protein kinase domain. When a plant organ is exposed to directional blue light, phototropin becomes phosphorylated. In this way, a light signal is converted into a chemical signal. However, the events that connect phosphorylation to changes in auxin movement in phototropism, discussed previously, are so far unknown.

Phytochrome, the Red- and Far-Red-Light Receptor Many plant growth and developmental processes are influenced by **phytochrome**, a red- and far-red-light receptor. Phytochrome operates much like a light switch, flipping back and forth between two conformations (Figure 36.10). When red light is

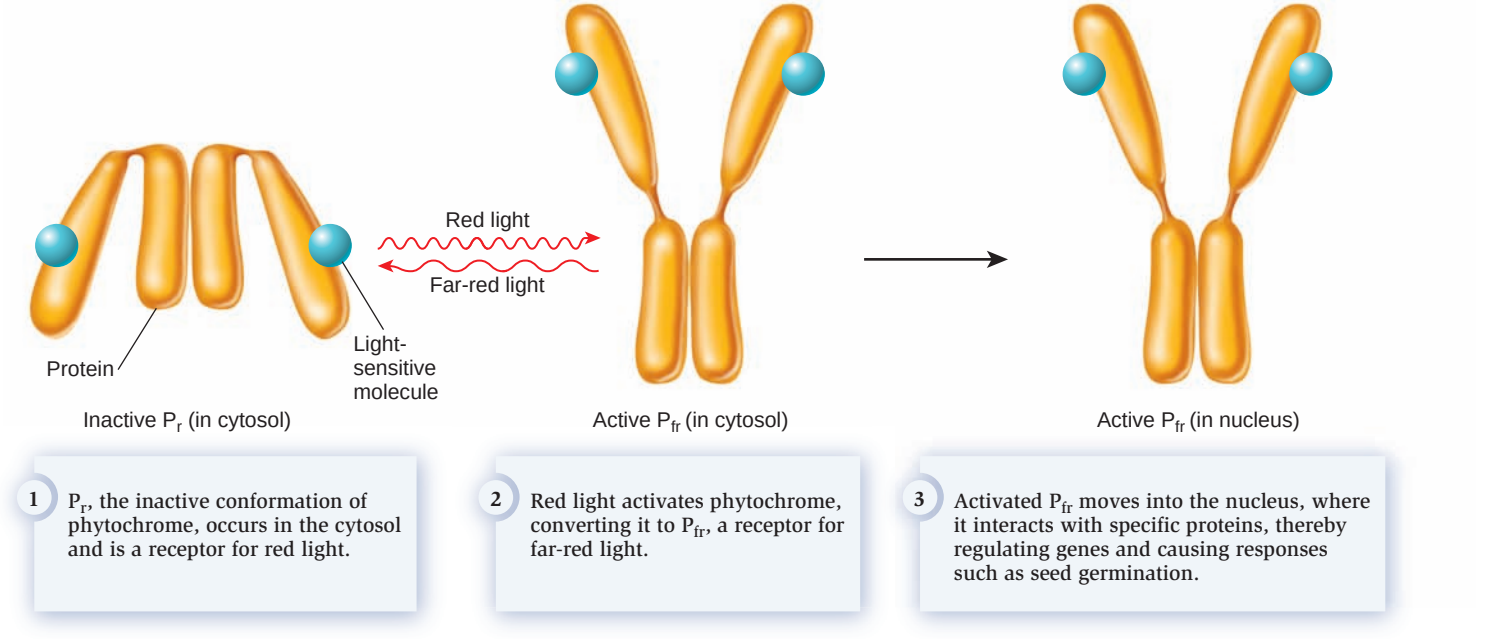

Figure 36.10 How phytochrome acts as a molecular light switch.

Concept check: What kind of light does the active conformation of phytochrome absorb, and what kind of change does such absorption cause?

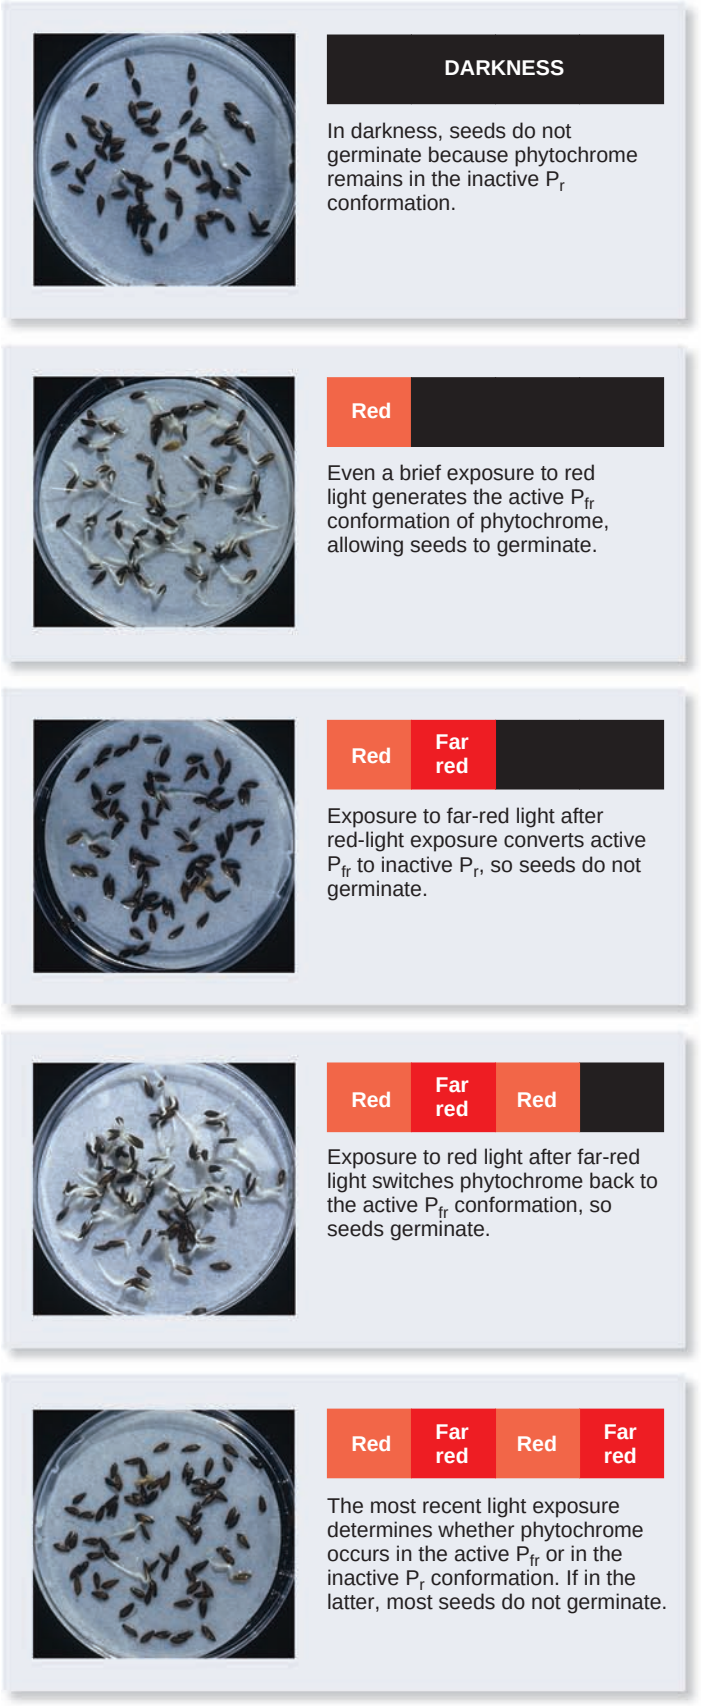

Figure 36.11 How phytochrome influences seed germination.

Concept check: Describe the change in phytochrome that would occur if a deeply buried seed were uncovered enough to receive sunlight.

abundant, as in full sunlight, phytochrome absorbs red light and changes to a conformation that absorbs only far-red light (light having a wavelength longer than that of red light). This form of phytochrome, known as P_{fr}, activates cellular responses—such as seed germination—which are described later. When left in the dark for a long period, P_{fr} slowly transforms into the inactive red light–absorbing conformation, known as P_r. Far-red light is more abundant than red light in situations such as deep within a canopy of leaves, because chlorophyll absorbs most of the available red light. In this environment, P_{fr} rapidly switches to P_r, which can only absorb red light and does not activate cellular responses.

The role of phytochrome as a plant "light switch" has been shown experimentally in studies of lettuce-seed germination. Researchers have found that water-soaked lettuce seeds will not germinate in darkness, but they will germinate if exposed to as little as 1 minute of red light (Figure 36.11). This amount of light exposure is sufficient to transform a critical amount of P_r to the active P_{fr} conformation, which stimulates germination. However, if this brief red-light treatment is followed by a few minutes of treatment with far-red light, the lettuce seeds will not germinate. This short period of far-red illumination is enough to convert seed P_{fr} back to the inactive P_r conformation.

The most recent light exposure determines whether the phytochrome occurs in the active or inactive conformation. In nature, if seeds are close enough to the surface that their phytochrome is switched on by red light, the seeds will germinate. But if seeds are buried too deeply for red light to penetrate, they will not germinate. In this way, seeds can sense if they are close enough to the surface to begin the germination process.

Most of our understanding of phytochrome's effect on gene expression comes from the study of the model plant *Arabidopsis*. This plant has five phytochrome genes (*PHYA* to *PHYE*). Each of the five types of phytochrome is composed of two proteins, each having a light-sensitive chromophore (see Figure 36.10). In the dark, phytochrome molecules in the P_r state reside in the cytosol. After exposure to red light, activated phytochrome (P_{fr}) molecules typically move from the cytosol to the nucleus. Within the nucleus, P_{fr} interacts with a transcription factor protein known as PIF3 (phytochrome interacting factor 3). PIF3 binds to the regulatory elements of several phytochrome-responsive genes, functioning as a positive regulator of some genes and as a negative regulator of others.

Photoperiodism Phytochromes also play a critical role in photoperiodism, the response to relative lengths of darkness that influence the timing of dormancy and flowering. Flowering plants can be classified as long-day, short-day, or day-neutral plants. When scientists named these groups, they thought that plants measured the amount of daylight. Researchers later discovered that plants actually measure night length.

Lettuce, spinach, radish, beet, clover, gladiolus, and iris are examples of **long-day plants** because they flower in spring or early summer, when the night period is shorter (and thus the day length is longer) than a defined period (Figure 36.12). In contrast, asters, strawberries, dahlias, poinsettias, potatoes, soybeans, and goldenrods are examples of **short-day plants**

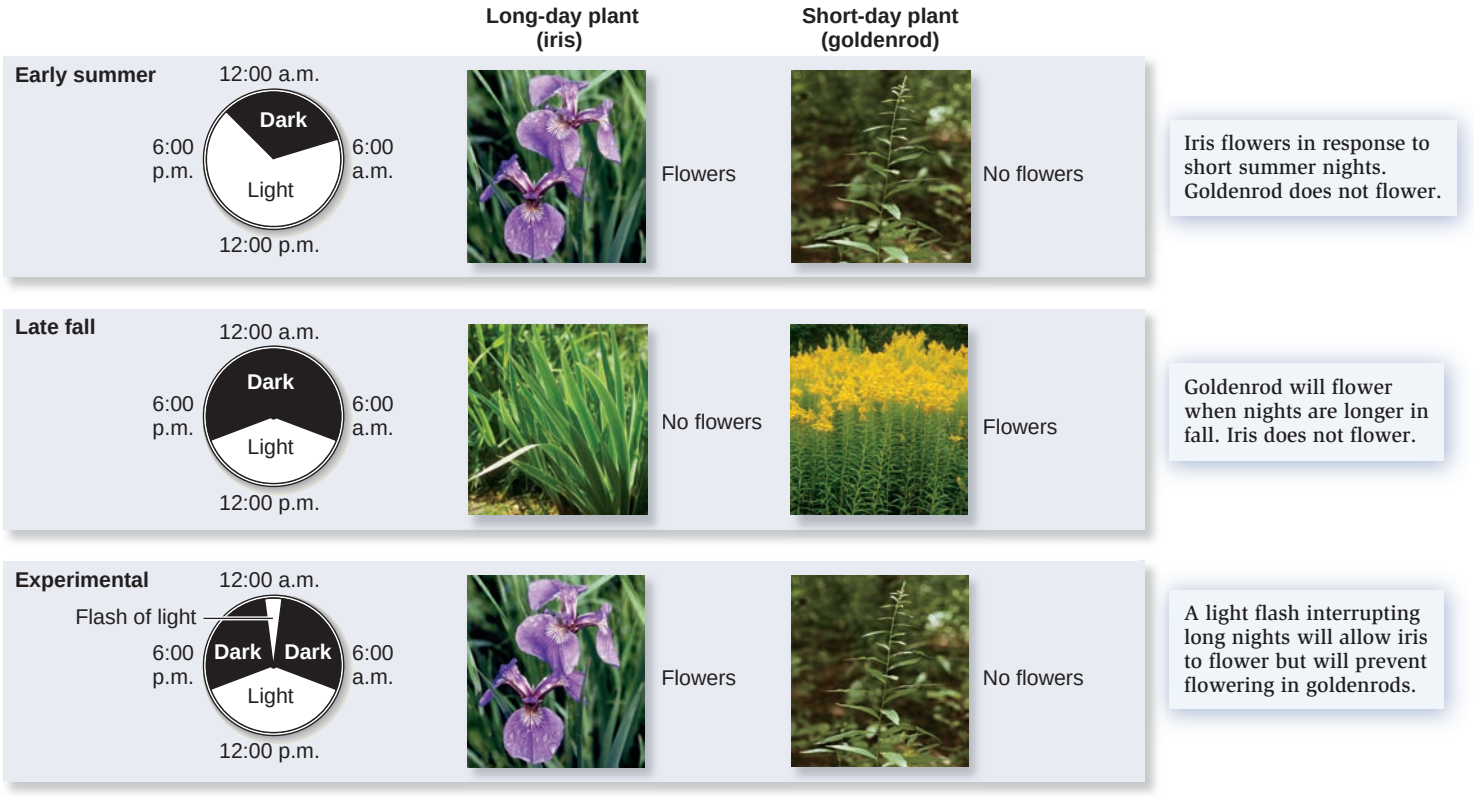

Figure 36.12 **Flowering and photoperiodism.** Iris is a long-day plant that flowers in response to the short nights of late spring and early summer, whereas goldenrod is a short-day plant that flowers in response to the longer nights of autumn. The length of night is the critical factor, as shown by the effects of light flashes.

Concept check: *What would happen if you gave these plants a brief exposure to darkness in the middle of the daytime?*

because they flower only when the night length is longer than a defined period. Such night lengths occur in late summer, fall, or winter, when days are short. As shown in Figure 36.12, when plants are given an experimental light flash in the middle of a long dark period, the long-day plants flower while the short-day plants do not. These results indicate that both types of plants measure night length. Roses, snapdragons, cotton, carnations, dandelions, sunflowers, tomatoes, and cucumbers flower regardless of the night length, as long as day length meets the minimal requirements for plant growth, and are thus known as **day-neutral plants**.

Ornamental plant growers manipulate night length to produce flowers for market during seasons when they are not naturally available. For example, chrysanthemums are short-day plants that usually flower in the fall, but growers use light-blocking shades to increase night length in order to produce flowering plants at any season.

Shading Responses Phytochrome also mediates plant responses to shading. These responses include the extension of leaves from shady portions of a dense tree canopy into the light, and growth that allows plants to avoid being shaded by neighboring plants. These growth responses occur by the elongation of branch internodes. Leaves detect shade as an increased proportion of far-red light to red light. This means that more of the phytochrome in shaded leaves is in the inactive (P_r) state than is the case for leaves in the sun. Activated phytochrome (P_{fr}) inhibits the growth of shoot internodes, but phytochrome in the inactivated state does not, so branches bearing shaded leaves extend toward sunlight.

Plants Respond to Gravity and Touch

Have you ever wondered what causes plant stems to generally grow upward and roots downward? The upward growth of shoots and the downward growth of roots are behaviors known as **gravitropism**, growth in response to the force of gravity. Shoots are said to be negatively gravitropic because they often grow in the direction opposite to gravitational force. If a potted plant is turned over on its side, the shoot will eventually bend and begin to grow vertically again (Figure 36.13). Most roots are said to be positively gravitropic because they grow in the same direction as the gravitational force.

Both roots and shoots detect gravity by means of starch-heavy plastids known as **statoliths**, which are located in specialized gravity-sensing cells called statocytes. In shoots, statocytes are located in a tissue known as the endodermis, which forms a sheath around vascular tissues. In roots, gravity-sensing cells primarily occur in the center of the root cap, in a region called the columella.

Figure 36.13 **Negative gravitropism in a shoot.** This tomato shoot system has resumed upward growth after being placed on its side. Upward growth started about 4 hours after the plant was turned sideways; this photo was taken 20 hours later. Shoots sense gravity by means of starchy statoliths present in stem tissue near the central vascular tissue.

Gravity causes the relatively heavy statoliths to sink, which causes changes in calcium ion messengers that affect the direction of auxin transport. This process induces changes in the direction of shoot or root growth. For example, in a root that becomes oriented horizontally, the statoliths are pulled by gravity to the lower sides of statocytes (Figure 36.14). The change in statolith position causes auxin to move to cells on the lower sides of roots. In roots, auxin inhibits cell elongation (in contrast to its action in shoots). Therefore, root growth slows on the lower side, while cell elongation continues normally on the upper side. This process causes the root to bend, so that it eventually grows downward again.

Recent studies suggest that gravity responses are related to touch responses, known as **thigmotropism** (from the Greek *thigma*, meaning touch). For example, when roots encounter rocks or other barriers to their downward growth in the soil, they display a touch response that temporarily supersedes their response to gravity. Such roots grow horizontally until they get around the barrier, whereupon downward growth in response to gravity resumes. Plant shoots also respond to touch; examples include vines with tendrils that wind around or clasp supporting structures. Wind also induces touch responses. In very windy places, trees tend to be shorter than normal, giving them the advantage of being less likely to blow over than are taller trees. In the laboratory, plant scientists have simulated natural touch responses by rubbing plant stems and found that this treatment can result in shorter plants. Touch causes the release of calcium ion messengers that influence gene expression.

More rapid responses to touch, such as leaf folding by the sensitive plant (see Figure 36.1b), are based on changes in the water content of cells within a structure known as a pulvinus (plural, pulvini), a swelling located at the base of attachment of each pair of leaflets in complex leaves. A pulvinus consists of a thick layer of parenchyma cells that surrounds a core of vascular tissue (Figure 36.15). When the leaflet of a sensitive plant is touched, an action potential opens ion channels in parenchyma cells near the lower surfaces of the pulvini. These cells lose potassium and chloride ions, causing water to flow out and the cells to become flattened. This bends the leaflets together, starting the leaflet-folding process. The action potential generated at the touch site also flows through the leaflet, causing many or all of the leaflets to also bend, with the result that the entire leaf folds. Reversal of this process allows the leaf to unfold. This type of movement is known as a nastic response rather than a tropism, because the direction of the stimulus does not control the response.

The action of pulvini also explains some plant movements that are unrelated to touch, including sleep movements and sun tracking. Sleep movements are changes in leaf position that occur in response to day–night cycles. Sun tracking, as mentioned at the beginning of this chapter, is the movement of leaves or flowers in response to the sun's position.

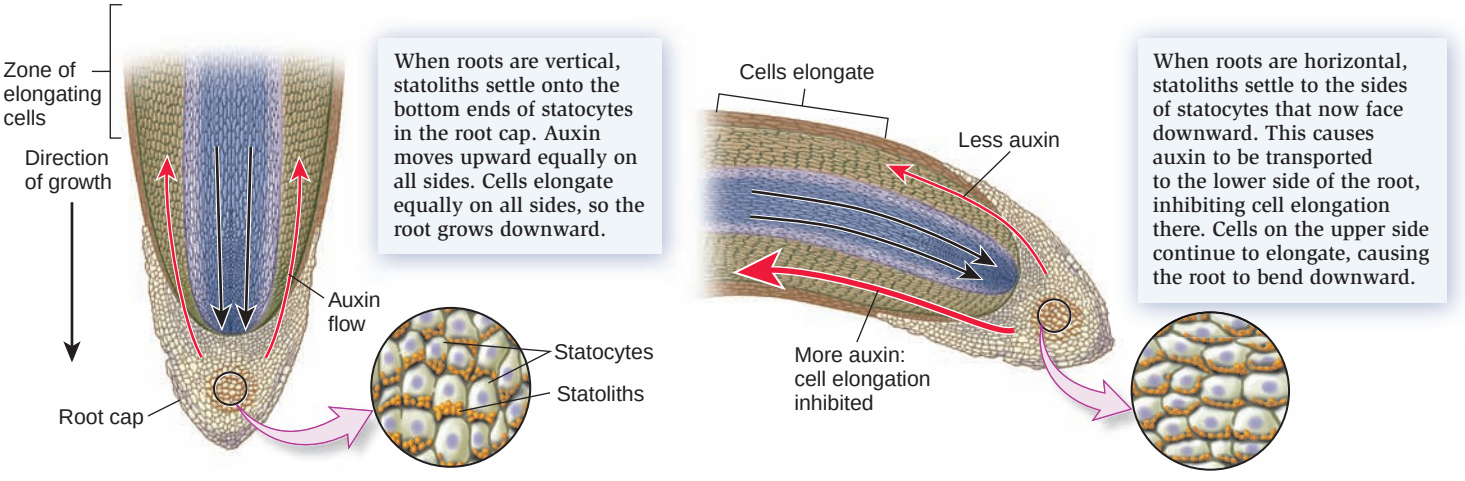

Figure 36.14 **Positive gravitropism in a root.** Root-tip cells sense gravity by means of starchy statoliths present in cells at the center of the root cap.

Concept check: *Is there any other environmental signal that roots could use to achieve downward growth?*

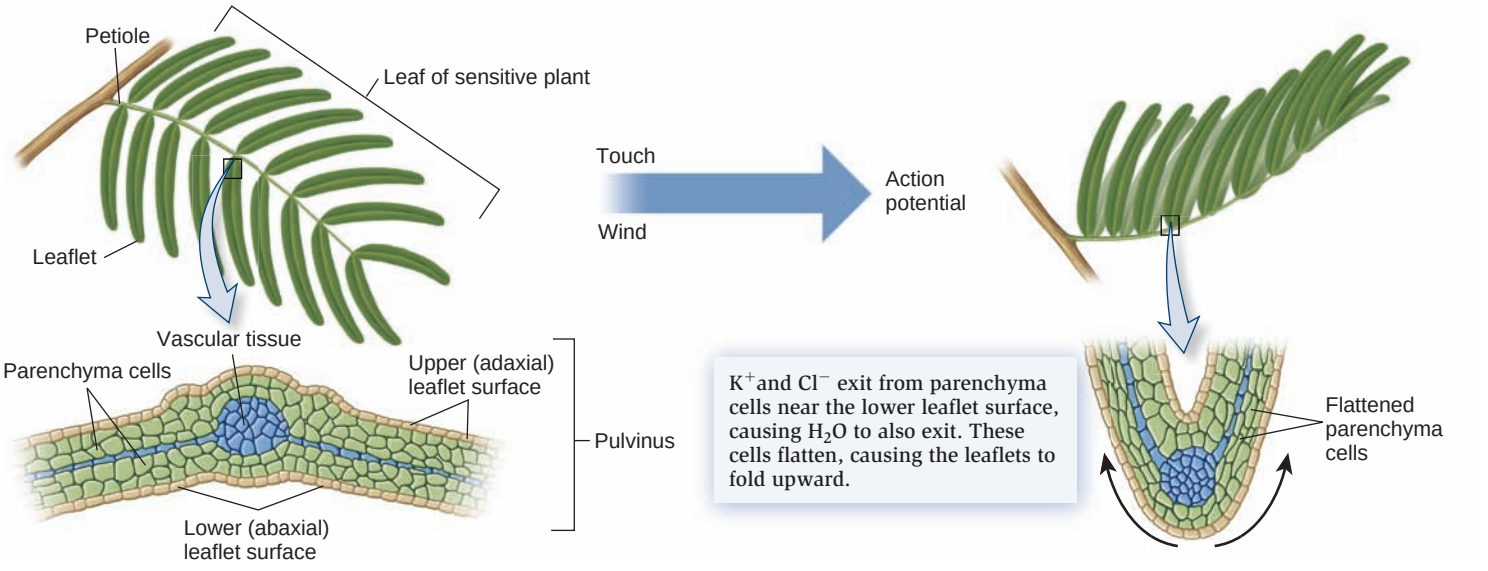

Figure 36.15 **Leaf folding in the sensitive plant: how pulvini change the positions of leaflets.** The electrical signals known as action potentials result from the rapid flow of ions through membrane ion channels. Electrical signals spread from one cell to another through plasmodesmata. Cells near the lower surface of the pulvinus respond to ion flow by losing water, causing them to flatten.

Plants Respond to Physical Stresses Such as Flooding and Drought

Plants display many types of adaptations that help them cope with unfavorable growth conditions, such as flooding and drought. These responses are often mediated by hormones.

The major harmful effect of flooding is that too much water makes roots unable to obtain sufficient oxygen to fuel respiratory processes. Without oxygen from the air, roots cannot produce the ATP needed to absorb minerals from soil. Many plants reduce the effects of flooding by producing **aerenchyma**, a tissue containing large, snorkel-like airways that allow more oxygen to flow from shoots to the submerged roots (Figure 36.16). In some plants, aerenchyma formation is developmentally programmed, and in others, it is a response to change in environmental conditions. For example, aerenchyma develops in the roots of many plants native to wetland habitats even when the soil is not wet. Aerenchyma can also form in the roots of plants such as corn as a response to flooding. This mechanism of formation involves the action of ethylene, which leads to controlled cell death, followed by cell collapse.

Drought is related to several other environmental stresses—high salinity, heat, and cold—all of which reduce the amount of liquid water present in plant cells. Most plants that lose half or more of their water are unable to recover. Thus, plants possess diverse adaptations that reduce water loss, and the hormone abscisic acid often coordinates these responses.

One way in which plants cope with drought stress is by regulating aquaporins, proteins that form water channels in plasma membranes. Aquaporins allow plant cells to take up or lose water much faster than could be accomplished by diffusion alone. Because water uptake is such an important component of plant growth responses and movements, plants regulate

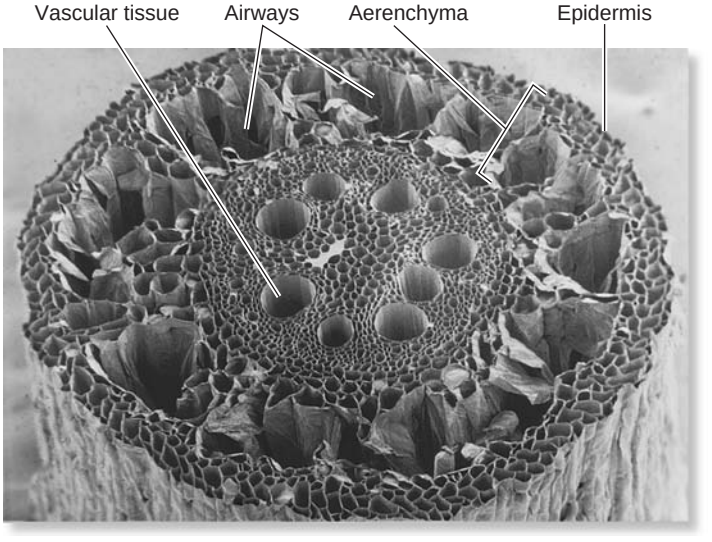

Figure 36.16 **A plant response to flooding.** A slice of a root is shown in this micrograph. Air channels in aerenchyma tissue allow air to readily flow to roots from shoots even when the plant is partially submerged.

Concept check: *What are two ways in which aerenchyma tissue is formed?*

water channel opening and closing. In 2006, Susanna Törnroth-Horsefield, Per Kjellbom, and coworkers described the X-ray crystallographic structure of spinach plasma membrane aquaporin from cells experiencing different levels of water stress. These investigators found that under drought conditions, particular aquaporin amino acids lose phosphate groups, causing a loop of the protein to block the membrane channel. This helps to prevent plant cells from losing water via these pores. When

water becomes available again, phosphorylation of aquaporin causes displacement of the loop, thereby opening the pore for water passage. Drought-stressed plants also close their stomata. Stomatal closure and other plant responses to water stress are described in Chapter 38.

Plants Respond to Biological Stresses Such as Herbivore and Pathogen Attack

Plants are vulnerable to attack by animal herbivores and pathogens—disease-causing viruses, bacteria, and fungi. Structural barriers such as cuticles, epidermal trichomes, and outer bark help to reduce infection and herbivore attack (see Chapter 35). Like other organisms, plants use microRNAs and nucleic acid–degrading enzymes as defenses against attacking viruses. Plants also use many types of chemical defenses to deter herbivores and respond to pathogens. Such defenses explain why remarkably little natural vegetation is lost to herbivore or pathogen attack. However, agricultural crops can be more vulnerable to attack than their wild counterparts. This is because some protective adaptations have been lost during crop domestication as the result of genetic changes that increase edibility. For this reason, crop scientists are particularly interested in understanding plant defense behavior, with the goal of being able to breed or genetically engineer crop plants that are better protected from pests.

Plant Responses to Herbivores Plants use a wide variety of chemical defenses against herbivores. Defense compounds include the secondary metabolites: alkaloids, terpenes and terpenoids, phenolics, and phytoalexins. Some of these substances act directly on herbivores, making plants taste bad so that herbivores learn to avoid them. Other chemical compounds function indirectly. For example, when attacked by insect caterpillars, cruciferous plants release terpenoids that attract the bodyguard wasp (*Cotesia rubecula*), which attacks the caterpillars.

Mouth secretions and damage caused by attacking insects mobilize a variety of plant defenses. Self-defenses against herbivores may involve the action of plant hormones (Figure 36.17). For example, when insects wound tomato plants, damaged cells release the peptide hormone systemin. This protective hormone induces undamaged cells to produce the hormone jasmonic acid (JA), which functions as an alarm system. JA travels in the phloem or through the air to undamaged parts of the plant, inducing widespread production of defensive compounds (see Figure 36.17, step 2a). Airborne compounds released from herbivore-damaged plants may also attract the enemies of insect attackers.

In addition, nearby plants may also detect these airborne signals and respond by similarly arming themselves against attack (see Figure 36.17, step 2b). JA functions in plant cells by binding to the protein inhibitors of transcription factors. Such JA-binding leads to inhibitor destruction, freeing the

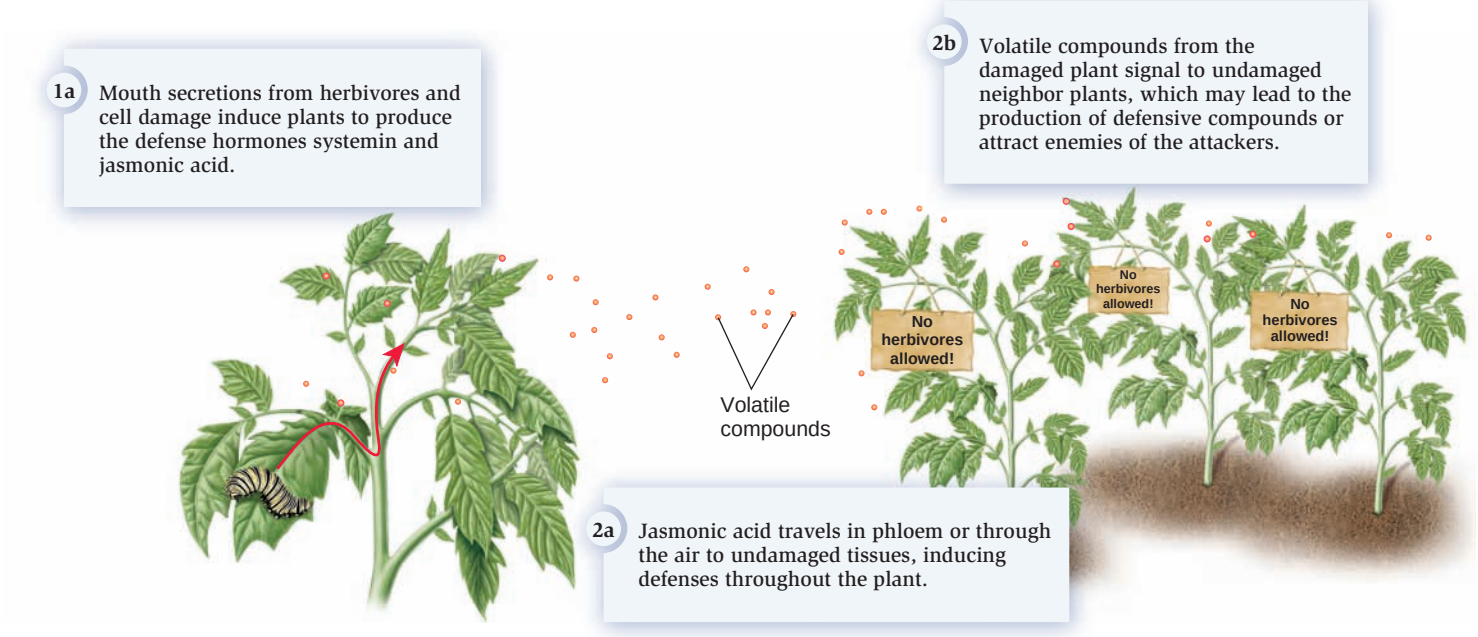

Figure 36.17 **Plant responses to herbivore attack.** **(1a)** Leaf damage induces local defensive responses, including production of compounds that travel through the plant and cause defense responses elsewhere. In addition, insect mouth secretions and tissue damage may cause the attacked plant to release volatile compounds. **(2a)** These volatile compounds foster the development of defenses in undamaged parts of the same plant. **(2b)** Such volatile compounds may also induce defenses in neighboring plants, which then become less vulnerable to herbivores. Volatile compounds may also attract predators that feed on the herbivore attacker.

Concept check: *What advantage would a predator obtain by responding to the volatile signals emitted from herbivore-damaged plants? What adaptive advantage could a plant obtain by attracting the enemies of its attackers?*

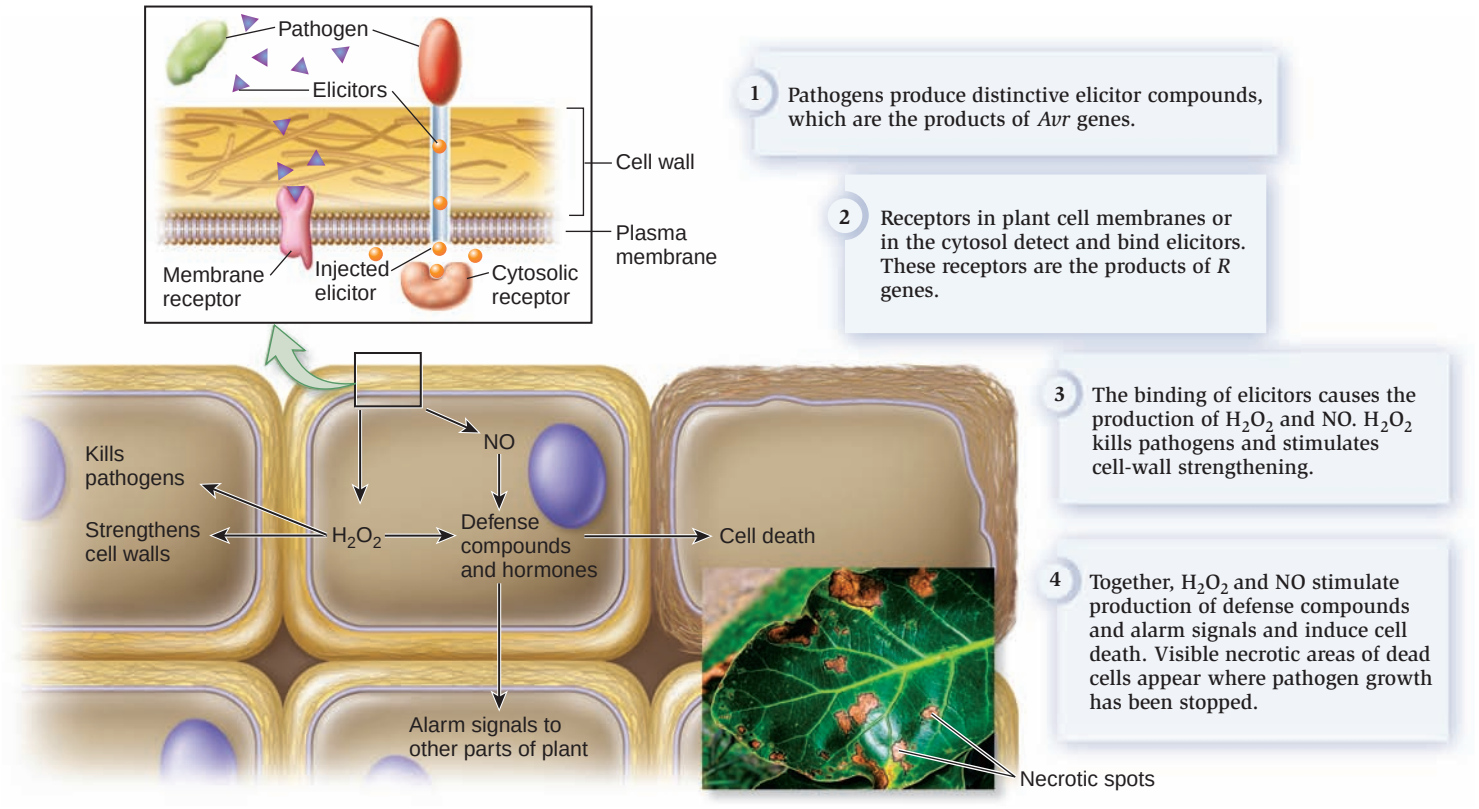

Figure 36.18 Pathogen/plant interactions and the hypersensitive response to pathogen attack.

transcription factors to start gene expression. In this way, the alarm system is activated only when necessary.

Plant Responses to Pathogen Attack Bacterial and fungal pathogens produce many types of compounds known as **elicitors**. Such elicitors promote **virulence**, the infection of cells and tissues. A peptide produced by the plant pathogenic bacterium *Pseudomonas syringae* and the fungal cell-wall compound chitin are examples of elicitors. Despite their name, **avirulence genes** (***Avr* genes**) encode virulence-enhancing elicitors (Figure 36.18, step 1). Some bacteria inject elicitors into plant cells by means of syringe-like systems that are also used to attack animal cells. Fungal pathogens often deliver elicitors by means of structures known as haustoria. These haustoria (from a Latin word, meaning to drink) are also the means by which fungi penetrate the host cell walls and absorb nutrients.

In response to pathogen attack, plants have evolved defense systems based on about 20 types of **resistance genes** (***R* genes**) (Figure 36.18, step 2). Many alleles of *R* genes occur in plant populations, providing plants with a large capacity to cope with different types of pathogens. Most resistance genes encode proteins that function as receptors for elicitors. Some elicitor receptors occur in plasma membranes, allowing early detection of pathogens. Receptors in the cytosol recognize elicitors that have been injected into cells.

In 1955, based on studies of rust fungi and flax plants (*Linum usitatissimum*), plant pathologist H. H. Flor proposed the gene-for-gene hypothesis to explain how the interaction of *Avr* and *R* gene products influences disease. If a plant is genetically unable to produce a receptor that can recognize a pathogen's elicitor, disease will result. By contrast, plants successfully resist disease when the product of a dominant *R* gene (a receptor) recognizes a pathogen's dominant *Avr* gene product (elicitor). Receptor-elicitor binding stimulates signal transduction pathways that induce plant defensive responses. As described next, the hypersensitive response is a local defensive response, whereas systemic acquired resistance occurs throughout the plant body. These responses are of great importance to agricultural scientists as they endeavor to find new ways to protect crop plants from attack by herbivores and pathogens.

The Hypersensitive Response to Pathogen Attack The plant **hypersensitive response** (**HR**) occurs when a plant recognizes the elicitors released by a pathogen and responds in such a way that the disease symptoms are limited (Figure 36.18, steps 3 and 4). This plant defensive response has several components. One of these is increased production of hydrogen peroxide (H_2O_2), which can kill infectious agents and helps strengthen the cell wall by cross-binding polymers. The hormone NO is also produced as part of the hypersensitive response. Together with H_2O_2, it stimulates the synthesis of hydrolytic enzymes, defensive secondary metabolites, the hormone salicylic acid (SA), and tough lignin in cell walls of nearby tissues. NO also induces cell death, which deprives pathogens of food and helps

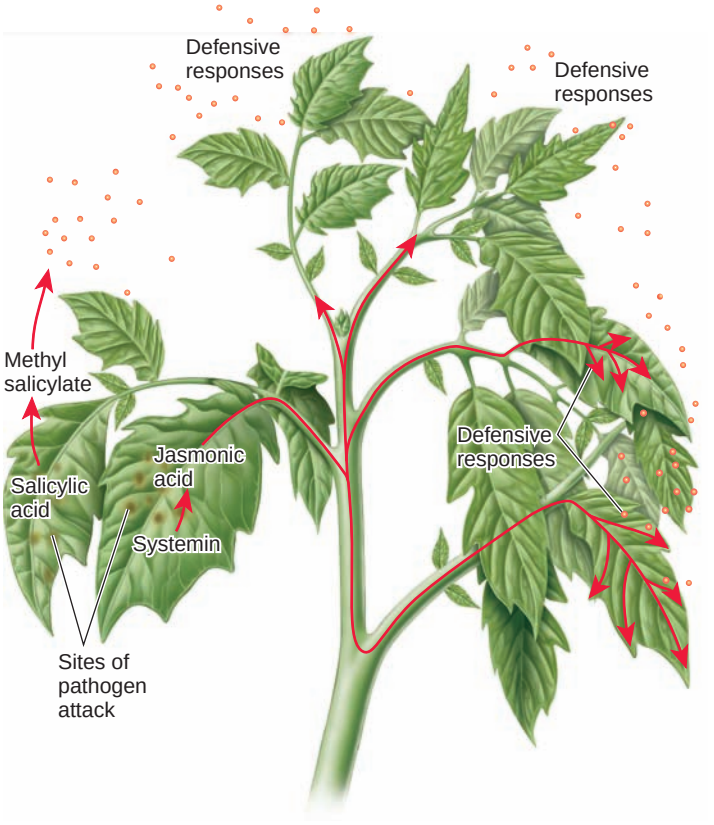

Figure 36.19 Systemic acquired resistance to pathogen attack.

Concept check: *In what way is systemic acquired resistance to pathogens similar to plant responses to herbivore attack?*

to prevent their spread. Necrotic spots are brown patches on plant organs that reveal where disease pathogens have attacked plants and where plant tissues have battled back. SA or the related compound methyl salicylate signals other parts of the plant, which respond by preparing defenses.

Systemic Acquired Resistance A localized hypersensitive response can result in the production of alarm signals that travel to noninfected regions of a plant and induce widespread resistance to diverse pathogens. This response of the whole plant, known as **systemic acquired resistance** (**SAR**), is a type of plant immune system (Figure 36.19). The SAR system uses the same type of long-distance signaling process that is associated with herbivore attack (see Figure 36.17). At or near a wound, systemin induces the production of jasmonic acid in nearby vascular tissues. Jasmonic acid is then transported throughout the plant. In addition, the hormone salicylic acid can be converted to volatile methyl salicylate, which diffuses into the air surrounding a plant, inducing resistance in noninfected tissues. In response, plant tissues may produce defensive enzymes, which can break down pathogen cell walls, or they may generate tannins, which are toxic to microorganisms. Experimental infection of *Arabidopsis* leaves with the bacterial pathogen *Pseudomonas syringae* led to induction of SAR within 6 hours.

Summary of Key Concepts

36.1 Overview of Plant Behavioral Responses

- Plants sense and respond to diverse internal stimuli and external signals and thus display behavior. (Figures 36.1, 36.2)
- During the process of signal transduction, cellular receptors respond to environmental stimuli as well as to internal hormonal signals. The process involves receptor activation, transduction of the signal by messengers, and cellular response due to effectors. (Figure 36.3)
- Cellular responses include changes in gene expression and ion channels that influence plant growth, development, reproduction, chemistry, and movements such as sun tracking and leaf folding.

36.2 Plant Hormones

- Plant hormones interact with environmental stimuli to control plant development, growth, and behavior. (Table 36.1)
- Auxin plays an important role in many aspects of plant behavior, including phototropism—as demonstrated by the classic experiments of the Darwins, Went, Briggs, and others. Auxin can be transported downward or upward (polar transport) and sideways (lateral transport) in the plant. The position of auxin influx and efflux carriers determines the direction of auxin transport. (Figures 36.4, 36.5)
- Other major plant hormones are the cytokinins, gibberellins, ethylene, abscisic acid, and brassinosteroids. Auxin and cytokinin are used in plant tissue culture. (Figure 36.6)
- Gibberellin function illustrates the general principle that plant hormones often act to release cellular brakes on gene expression. The components of a system by which gibberellin and cell proteins interact to influence plant growth evolved in a step-by-step fashion. (Figures 36.7, 36.8)
- The gaseous hormone ethylene plays an important role in seed germination. (Figure 36.9)

36.3 Plant Responses to Environmental Stimuli

- Light-sensitive pigments such as cryptochrome, phototropin, and phytochrome allow plants to respond to light stimuli and influence sun tracking, seed germination, and photoperiodic control of flowering. (Figures 36.10, 36.11, 36.12)
- Plant shoots and roots respond to gravity (in the process of gravitropism) by means of starch-heavy statoliths located within statocytes. Sun tracking and rapid touch responses (thigmotropism), such as leaf folding in sensitive plants, depend on changes in the water content of cells in structures known as pulvini. (Figures 36.13, 36.14, 36.15)
- Plants cope with physical stresses such as flooding and drought, often through the production of special tissue (aerenchyma), the involvement of hormones, and the regulation of plasma membrane proteins called aquaporins. (Figure 36.16)
- Plants cope with biological stresses such as herbivore and pathogen attack by means of structural and chemical

adaptations. Injured plant parts produce volatile hormones that signal other parts of the same plant and nearby plants to produce defensive responses. Plant pathogens begin their attack by producing elicitor compounds encoded by avirulence (*Avr*) genes. If an attacked plant can produce a compound that interferes with that elicitor, encoded by an *R* (resistance) gene, then the plant can resist infection by that pathogen. The hypersensitive response (HR) is a local defensive response to pathogen attack, whereas systemic acquired resistance (SAR) is a whole-plant defensive response. (Figures 36.17, 36.18, 36.19)

Assess and Discuss

Test Yourself

1. The major types of plant hormones include
   a. cyclic AMP, IP_3, and calcium ions.
   b. calcium, CDPKs, and DELLA proteins.
   c. auxin, cytokinin, and gibberellin.
   d. cryptochrome, phototropin, and phytochrome.
   e. statoliths, pulvini, and aerenchyma.
2. Phototropism is
   a. the production of flowers in response to a particular day length.
   b. the production of flowers in response to a particular night length.
   c. the growth response of a plant, organ system, or organ to directional light.
   d. the growth response of a plant, organ system, or organ to gravity.
   e. the growth response of a plant, organ system, or organ to touch.
3. What is the most accurate order of events during signal transduction?
   a. first, receptor activation; then, messenger signaling; and last, an effector response
   b. first, an effector response; then, messenger signaling; and last, receptor activation
   c. first, messenger signaling; then, receptor activation; and last, an effector response
   d. first, an effector response; then, receptor activation; and last, messenger signaling
   e. none of the above
4. Which of the plant hormones is known as the "master hormone," and why?
   a. cytokinin, because many plant functions require cell division
   b. gibberellins, because growth is essential to many plant responses
   c. abscisic acid, because it is necessary for leaf and fruit drop
   d. brassinosteroids, because water uptake is so fundamental to plant growth
   e. auxin, because there are many different auxin-response genes
5. Gaseous hormones are able to enter cells without requiring special membrane transporter systems. Which of the major plant hormones is a diffusible gas?
   a. auxin
   b. gibberellin
   c. cytokinin
   d. ethylene
   e. abscisic acid
6. Photoreceptor molecules allow plant cells to detect light of particular wavelengths. Which of these molecules is considered to be a plant photoreceptor?
   a. cryptochrome
   b. phototropin
   c. phytochrome
   d. a, b, and c are all correct
   e. no earlier answer listed is correct
7. Thigmotropism is a plant response to
   a. light.
   b. cold.
   c. touch.
   d. gravity.
   e. drought.
8. Which response is an adaptation to flooding?
   a. geotropism
   b. stomatal closure
   c. photoperiodism
   d. production of aerenchyma
   e. opening aquaporins
9. What are avirulence genes?
   a. plant genes that encode proteins that prevent infection (virulence)
   b. plant genes that cause infection when the proteins they encode bind to pathogen elicitors
   c. pathogen genes that prevent the pathogens from causing plant disease
   d. pathogen genes that encode elicitors that foster disease in plants
   e. none of the above
10. How do plants defend themselves against pathogens?
    a. Plants produce resistance molecules (usually proteins) that bind pathogen elicitors, thereby preventing disease.
    b. Plants display a hypersensitive response that limits the ability of pathogens to survive and spread.
    c. Plants display systemic acquired resistance, whereby an infection induces immunity to diverse pathogens in other parts of a plant.
    d. All of the above are correct.
    e. None of the above.

Conceptual Questions

1. Why can plants be said to display behavior?
2. Why do plants produce so many types of resistance (*R*) genes?
3. Because diverse plants exude volatile compounds in response to herbivore or pathogen attack, some experts have written about "talking trees." Is there any such thing?

Collaborative Questions

1. Why are most wild plants distasteful, and some even poisonous, to people?
2. How could you increase the resistance of a particular crop plant species to particular types of herbivores?

Chapter Outline

Flowering Plants: Nutrition

37

The leaves of the sundews (*Drosera rotundifolia* and *D. intermedia*), shown with a trapped fly, are a plant adaptation for the acquisition of nutrients.

Many types of fascinating carnivorous (meat-eating) plants grow abundantly in wetlands around the world, even though the soils in these places are infertile. How is this possible? Like most plants, carnivorous plants are photosynthetic and thus produce their own organic food from carbon dioxide and water, using sunlight as an energy source. These resources are abundant in wetlands, but wetland soils are low in other nutrients such as nitrogen that are needed for plant growth. Carnivorous plants, such as the sundews pictured in the chapter-opening photo, have adapted by obtaining nutrients from the bodies of trapped insects and other small animals. Carnivorous plants lure animals with enticing fragrances, brightly colored leaves, or glistening sugar-rich drops of nectar. The unsuspecting prey fall into deep, water-filled pitchers; become ensnared by gluelike mucilage; or are trapped within the walls of leafy jails whose doors suddenly snap shut. Decomposition of the animal bodies releases nutrients that plant leaves quickly absorb. Other wild and cultivated plants face similar nutritional challenges and likewise display adaptations that help them acquire sufficient resources for growth and reproduction.

This chapter focuses on plant nutrition, the processes by which plants obtain essential resources. We will begin by describing the resources needed by plants for completion of their seed-to-seed life cycle in good health. Next, we will explore the role of soil as an essential resource for plants. Last, we will examine the biological sources of plant nutrients, focusing on nutritional associations between plants and microorganisms, sources of nutrients for carnivorous plants, and how some plants obtain nutrients from other plants. An understanding of these topics is crucial for those who seek ways to grow more plant-derived food for humans without causing harmful mineral pollution of Earth's waters. Plant nutritional information is also useful to people who tend gardens or houseplants.

37.1 Plant Nutritional Requirements

Let's begin our consideration of plant nutritional requirements by defining nutrients more specifically. A **nutrient** is a substance that is metabolized by or incorporated into an organism. Deficiency symptoms develop in plants that receive too little of these substances, and the scarcity of nutrients selects for adaptations that help plants to acquire them.

Like other organisms, plants have a specific set of nutritional requirements. **Essential nutrients** are defined as those substances needed by plants in order to complete their reproductive cycle, while avoiding the symptoms of nutrient deficiency. For healthy growth and reproduction, green plants require light and certain minerals, defined here as inorganic substances with specific chemical compositions that are formed by geological processes (Figure 37.1). Carbon dioxide (CO_2) is primarily absorbed from air, while water and more than a dozen elements—such as potassium, nitrogen, and calcium—are primarily taken up from soil in the form of dissolved ions.

Elements required by plants play many roles in plant metabolism, often functioning as enzyme cofactors (Table 37.1). Elements that are generally required in amounts of at least 1 g/kg of plant dry matter are known as **macronutrients**. In contrast, elements that are needed in amounts at or less than 0.1 g/kg of plant dry mass are known as **micronutrients**, or trace elements. Because insufficient amounts of light, carbon dioxide, water, and other mineral nutrients can limit the extent of green

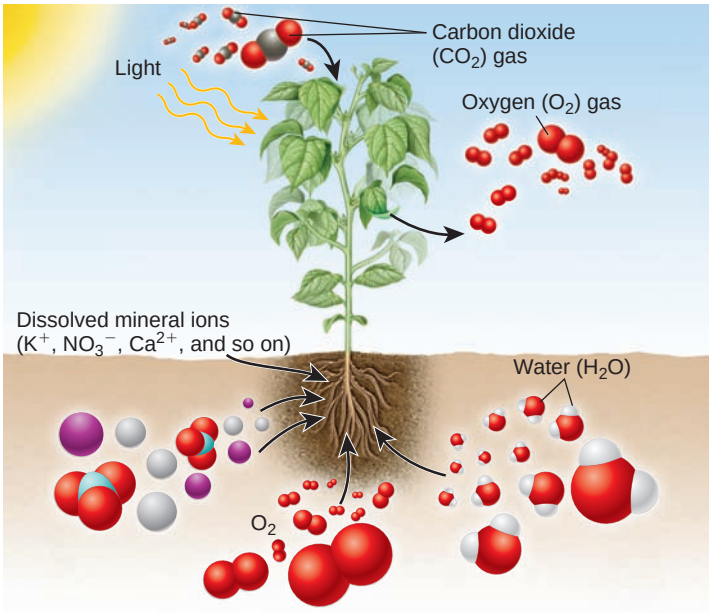

Figure 37.1 The major types of plant nutrients and their sources.

plant growth, these resources are known as **limiting factors**. In this section, we will take a closer look at the factors that can foster or limit plant growth, beginning with light energy.

Light Is an Essential Resource for the Growth of Green Plants

All photosynthetic plants require light for the formation of the covalent bonds of organic compounds that make up the plant body. Green plants' use of light energy as an essential resource parallels animals' nutritional requirements for organic food as a source of chemical energy. For the several hundred species of plants that have lost their photosynthetic capacity, such as the Indian pipe (*Monotropa uniflora*), essential nutrients include organic compounds that replace light as a source of energy (Figure 37.2).

Light-deprived plants display deficiency symptoms, as do plants that receive too little carbon dioxide, water, or other minerals. For example, if houseplants receive too little light, they must use stored carbohydrates for cellular respiration. As a result, the leaves may die and fall off, a symptom of light deficiency. When reserves are exhausted, the plant will die. Even if a plant is able to obtain enough light to survive, it may not absorb enough light to reproduce.

In nature, plants must adapt to environments with varying amounts of light and shade. For example, in forests, light availability limits the growth of tree seedlings and other small plants that are shaded by the leafy tree canopy overhead. But if a canopy tree dies from disease or is blown over by wind, creating a hole in the canopy called a light gap, the plants growing beneath it receive more sunlight and may be able to grow taller. Conversely, plants growing in deserts or on mountains often experience light that is so intense that it can damage the photosynthetic components. We now consider some of the adaptations that help plants cope with environments that have too little or too much light.

Table 37.1 Plant Essential Nutrients

Element (chemical symbol)	Percent of plant dry mass	Major source	Form taken up by plants	Function(s)
Macronutrients				
Carbon (C)	45	Air	CO_2	Component of all organic molecules
Oxygen (O)	45	Air, soil, water	CO_2, O_2, H_2O	Component of all organic molecules
Hydrogen (H)	6	Water	H_2O	Component of all organic molecules; protons used in chemiosmosis and cotransport
Nitrogen (N)	1.5	Soil	NO_3^-, NH_4^+	Component of proteins, nucleic acids, chlorophyll, coenzymes, and alkaloids
Potassium (K)	1.0	Soil	K^+	Has essential role in cell ionic balance
Calcium (Ca)	0.5	Soil	Ca^{2+}	Component of cell walls; messenger in signal transduction
Magnesium (Mg)	0.2	Soil	Mg^{2+}	Component of chlorophyll; activates some enzymes
Phosphorus (P)	0.2	Soil	HPO_4^{2-}	Component of nucleic acids, ATP, phospholipids, and some coenzymes
Sulfur (S)	0.1	Soil	SO_4^{2-}	Component of proteins, some coenzymes, and defense compounds
Micronutrients				
Chlorine (Cl)	0.01	Soil	Cl^-	Required for water splitting in photosystem cell ion balance
Iron (Fe)	0.01	Soil	Fe^{3+}, Fe^{2+}	Enzyme cofactor; component of cytochromes
Manganese (Mn)	0.005	Soil	Mn^{2+}	Enzyme cofactor
Boron (B)	0.002	Soil	$B(OH)_3$	Enzyme cofactor; component of cell walls
Zinc (Zn)	0.002	Soil	Zn^{2+}	Enzyme cofactor
Sodium (Na)	0.001	Soil	Na^+	Required to generate PEP in C4 and CAM plants
Copper (Cu)	0.0006	Soil	Cu^+, Cu^{2+}	Enzyme cofactor
Molybdenum (Mo)	0.00001	Soil	MoO_4^{2-}	Enzyme cofactor
Nickel (Ni)	0.000005	Soil	Ni^{2+}	Enzyme cofactor

Figure 37.2 **The heterotrophic flowering plant, Indian pipe (*Monotropa uniflora*).** This plant lacks photosynthetic capacity and therefore must absorb organic compounds for use as an energy source. In contrast, nearby autotrophic green plants use sunlight as a source of energy.

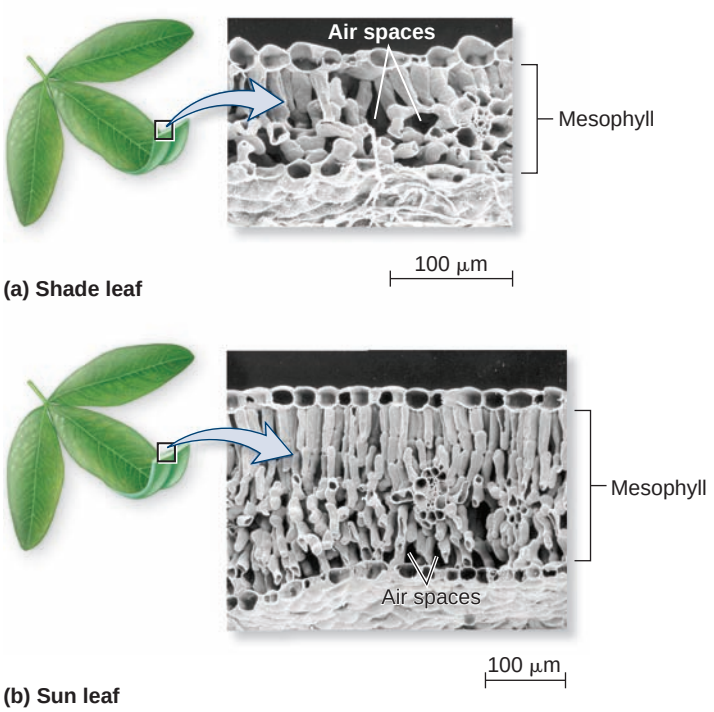

Figure 37.3 **Shade and sun leaves.** These scanning electron micrographs of cut leaves reveal the thinner mesophyll and greater amount of air spaces in **(a)** shade leaves as compared to **(b)** sun leaves.

Adaptations to Shade One way in which plants adapt to shading is by producing thin leaves that allow some light to pass through to other leaves. In a shady environment, a plant or leaf may also produce more total chlorophyll, thereby maximizing the amount of light absorbed. In addition, many plants produce distinctive sun and shade leaves (Figure 37.3). Sun leaves have a thicker layer of chlorophyll-containing mesophyll and are able to harvest more of the bright sunlight that penetrates deeply into the leaf. In contrast, shade leaves have a thinner mesophyll layer, with more air spaces than do sun leaves.

Most epidermal cells at leaf surfaces are transparent because their plastids lack chlorophyll, allowing light to penetrate to green mesophyll. In some plants, these epidermal cells are shaped like lenses that focus more light into the green tissue. The arrangement of leaves on plants and stem branching patterns can also reflect adaptations that reduce shading. For example, many tropical forest trees that must compete for light with closely crowded neighbors are extremely tall, and they produce branches and leaves only at their very tops. Shorter plants native to the shady interiors of tropical rain forests are so well adapted to these moist but dim conditions that they make excellent houseplants (Figure 37.4). One example of an adaptation by shade-tolerant plants is that their epidermal cells may contain green, photosynthetically active plastids that aid in collecting light.

Adaptations to Excessive Light Too much light can damage the photosynthetic machinery of plants by destroying an essential photosynthetic protein, called the D1 protein. As an adaptation to excess light, chloroplasts can change position so that they

Figure 37.4 **The tropical houseplant *Monstera deliciosa*.** Houseplants can survive indoors because they have evolved in dimly lit natural habitats. *M. deliciosa* makes an attractive houseplant because its large, deep green leaves are adapted to the moist and shady conditions present in the interiors of tropical forests.

Concept check: *How do the epidermal cells of plants adapted to deep shade sometimes differ from epidermal cells of plants adapted to sunnier habitats?*

are less likely to be damaged. In addition, specific xanthophyll pigments in the chloroplast absorb some of the light energy and dissipate it as harmless heat. Xanthophylls are carotenoids that contain oxygen. These protective pigments can be produced from a precursor xanthophyll within minutes of a plant's exposure to excess light. Other adaptations prevent UV damage. Harmful amounts of UV radiation are absorbed by the plant's surface cuticle, as well as by carotenoid and flavonoid compounds located within leaf cells. These protective compounds are often brightly colored and, when present in large amounts, explain the attractive red or purple colors of some leaves.

Carbon Dioxide Concentration Influences Plant Growth

Although light provides the energy for plant photosynthesis, most plant dry mass originates from carbon dioxide (CO_2). Most plants obtain CO_2 gas from the atmosphere, by absorption through stomatal pores. As CO_2 dissolves in water on the surfaces of leaf mesophyll cells, it combines with water to form carbonic acid, which can dissociate into bicarbonate ion and H^+.

$$H_2O + CO_2 \longleftrightarrow \underset{\text{Carbonic acid}}{H_2CO_3} \longleftrightarrow \underset{\text{Bicarbonate ion}}{HCO_3^-} + H^+$$

Leaf mesophyll cells then absorb the carbonic acid and bicarbonate ions. Under experimental conditions, plant photosynthetic rates increase with CO_2 concentration until the Calvin cycle enzyme rubisco has become fully supplied, that is, saturated with CO_2. (To review the role of rubisco and the Calvin cycle in photosynthesis, see Chapter 8.)

CO_2 Limitation In nature, plants are often unable to obtain enough CO_2 for maximal photosynthesis. As a result, CO_2 limits agricultural crop productivity. This is partly because the modern atmospheric concentration of CO_2 is only 350 μL/L (0.035% of atmospheric content), whereas 1,000 μL/L of CO_2 would be required to saturate photosynthesis in most plants. In addition, oxygen can compete with carbon dioxide for the active site in rubisco, causing a reduction in photosynthetic productivity known as photorespiration (see Chapter 8).

Evidence that plant photosynthesis can be limited by CO_2 availability is provided by studies of crops grown in greenhouses where atmospheric gas content can be controlled. When supplied with air enriched with CO_2, tomatoes, cucumbers, leafy vegetables, and some other crops can double their growth rate.

In nature, plants that experience hot, dry conditions are particularly vulnerable to low CO_2 levels when their stomata close to conserve water. When stomata are closed, plants cannot absorb CO_2, which limits photosynthesis. Many plants possess structural and biochemical adaptations that help them cope with CO_2 limitation by improving CO_2 absorption. Such adaptations may be helpful in genetic engineering efforts to improve crop productivity.

Engineering CO_2-Absorption Adaptations into Crop Plants Many plants that evolved in arid or hot environments display an adaptation known as C_4 photosynthesis, which improves productivity by aiding CO_2 absorption (see Chapter 8). About 30,000 plant species utilize C_4 photosynthesis, which is thought to have evolved on as many as 70 separate occasions. In addition, 7,500 other plant species possess a variation of C_4 photosynthesis known as CAM (crassulacean acid metabolism; see Chapter 8). However, many other plants that grow in hot environments lack C_4 photosynthesis. Rice, a staple crop for much of the world's population, is a prominent example. Agricultural scientists envision using genetic engineering techniques to endow rice with C_4 photosynthesis with the goal of increasing this crop's productivity.

To understand how this valuable crop modification might be accomplished, a review of C_4 photosynthesis may be useful. Both C_4 and CAM photosynthesis rely on the leaf mesophyll enzyme phosphoenolpyruvate (PEP) carboxylase. PEP carboxylase binds CO_2 more readily than does rubisco, thereby effectively trapping scarce CO_2 within four-carbon compounds. You may recall that this process is the basis for the term C_4 plants. In the leaves of most C_4 plants, such as maize (corn), the four-carbon compounds move through intracellular connections from mesophyll cells into specialized bundle-sheath cells that surround leaf veins. Within the bundle-sheath cells, enzymes release CO_2 from the C_4 compounds, and the CO_2 is incorporated into organic carbon during the Calvin cycle (see Chapter 8).

Molecular biologists have succeeded in transferring maize genes encoding PEP carboxylase and other C_4 enzymes into the rice genome. However, this procedure primarily improved plant stress tolerance rather than photosynthetic performance, which was the primary goal. Because bundle-sheath cells are often central to C_4 photosynthesis, an alternative strategy is to transform rice with the genes that control development of these specialized cells.

Some other plants accomplish C_4 photosynthesis without specialized bundle-sheath cells, offering additional strategies for crop genetic engineering. For example, PEP carboxylase and rubisco occupy the same mesophyll cells in the aquatic plant *Hydrilla verticillata*. In this case, PEP carboxylase is localized within the cytoplasm, while rubisco occurs within plastids. *Borszczowia aralocaspica*, a plant native to salty, near-desert regions of central Asia, and *Bienertia cycloptera*, native to Iranian deserts, are likewise remarkable for single-cell C_4 photosynthesis. Plant biologists Elena Voznesenskaya, Gerald Edwards, and colleagues discovered that *B. aralocaspica* and *B. cycloptera* achieve C_4 photosynthesis within a single photosynthetic cell by producing two types of plastids, one type containing PEP carboxylase and the other containing rubisco (**Figure 37.5**). These and other recent discoveries reveal that wild plants have acquired diverse adaptations that improve CO_2 absorption and show that both basic and applied research are essential to efforts to improve food crops.

Water Is an Essential Plant Resource

Water is essential to plants for several reasons. As a nutrient, water is the source of most of the hydrogen atoms and some of the oxygen atoms in organic compounds (see Table 37.1). You

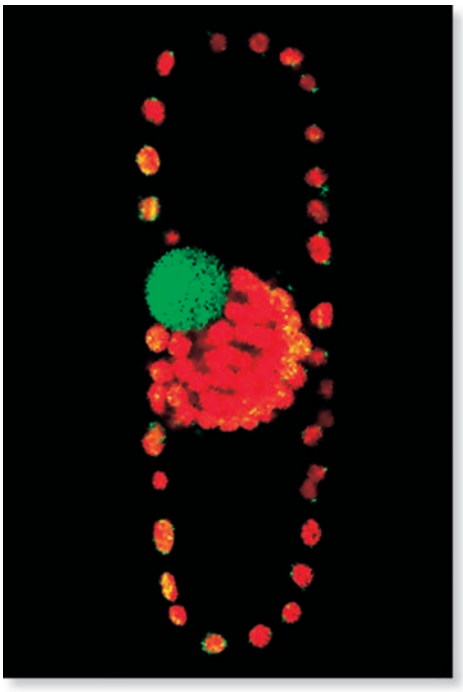

Figure 37.5 **A CO_2-acquisition adaptation.** In contrast to most C_4 plants, *Bienertia cycloptera* is able to conduct C_4 photosynthesis within the confines of a single cell. In this fluorescence photograph of a *B. cycloptera* cell, the red plastids at the cell periphery function like the mesophyll cells of most C_4 plants. In contrast, the red plastids clustered near the green nucleus function much like the bundle-sheath cells of most C_4 plants. The plastids appear red because chlorophyll emits red light when it fluoresces.

Concept check: *Which plastids should have more rubisco enzyme in them, plastids at the cell periphery or those clustered near the nucleus?*

may recall that hydrogen is incorporated as CO_2 is reduced during the process of photosynthesis, and oxygen is incorporated during hydrolysis reactions. Water is also the solvent for other mineral nutrients and is the main transport medium in plants, allowing movement of minerals and other solutes throughout the plant body via the vascular tissues. Cytoplasmic and vacuolar water also help to support plants by maintaining hydrostatic pressure on the cell wall.

Though plants vary in water content, water typically makes up about 90% of the weight of living plants. Most plants die when their water content falls below half of the amount normal for that particular species. While many types of desiccation-resistant plants display adaptations that allow them to survive for extended periods in nearly dry conditions, all plants require an adequate supply of water for active metabolism and growth.

Soil Water Provides Additional Plant Nutrients

In addition to light, CO_2, and water, plants require additional elements. Macronutrients—the elements required in relatively large amounts—include nitrogen, potassium, calcium, magnesium, phosphorus, and sulfur (see Table 37.1). Nitrogen and phosphorus play many important roles in plants, and potassium helps to maintain or alter plant cell water content. Calcium is used in the construction of cell walls and as a cellular signal, and magnesium is an essential component of chlorophyll. Sulfur occurs in the amino acids cysteine and methionine, as well as other cell constituents. In addition, the distinctive flavors of onions, garlic, broccoli, mustard, and horseradish result from plant defense compounds that contain sulfur. Micronutrients—essential elements that plants require in relatively small (trace) amounts—include chlorine, iron, manganese, boron, zinc, sodium, copper, molybdenum, and nickel (see Table 37.1). Terrestrial plants obtain both macronutrients and micronutrients in the form of ions dissolved in soil water (see Figure 37.1).

Plant biologists have quantitatively analyzed the mineral ion requirements of plants by growing them hydroponically, that is, by bathing plant roots in a water solution to which minerals are added in various combinations and amounts. Hydroponic studies reveal that when plants lack an adequate supply of an essential mineral nutrient, they display characteristic deficiency symptoms. Such symptoms include failure to reproduce, tissue death, and changes in leaf color. Yellowing of leaves, known as **chlorosis**, is a common mineral deficiency symptom, because many nutrients are needed for chlorophyll production (Figure 37.6). Deficiency symptoms are often specific to particular plants. For example, zinc deficiency causes chlorosis in corn, but causes smaller than normal leaves in fruit trees. Such deficiency symptoms provide clues that crop, garden, or houseplant soils are deficient in one or more essential minerals. Farmers commonly have their soil analyzed for mineral content, and if the soil is deficient, they may amend it with **fertilizers**, soil additions that enhance plant growth by providing essential elements. Fertilizers are also sold for use in enriching garden soil and growing houseplants.

Figure 37.6 **Chlorosis as a symptom of mineral deficiency.** This camellia plant is suffering from an iron deficiency, as revealed by the yellow leaves, a symptom known as chlorosis.

Concept check: *Does chlorosis always indicate iron deficiency?*

37.2 The Role of Soil in Plant Nutrition

Soil is an essential resource for most wild and cultivated plants, providing water and other essential nutrients. For this reason, extensive loss of soil by wind and water erosion is of wide concern. Soils vary greatly in fertility, that is, their ability to support plant growth. Thus, plants of many types have had to adapt to the challenges of obtaining nutrients from poor soils. In this section, we explore soil structure and chemistry from the perspective of plant growth and examine how plants take up nutrients from the soil.

The Physical Structure of Soils Affects Their Aeration, Water-Holding Capacity, and Fertility

Natural soils display layers, known as **soil horizons** (Figure 37.7a). The remains of dead plants and other organisms form a layer of litter above the topsoil, the topmost layer of soil. Many of the inorganic minerals and organic materials that enrich high-quality topsoil arise from the activities of microorganisms that decompose the litter. In this way, the minerals contained in living plants are eventually recycled to subsequent generations. Beneath the topsoil lie layers called subsoil and soil base, which are largely composed of mineral materials. Bedrock is the bottom layer that supports the soil horizons. Plant roots play an important role in conveying deep-lying minerals to the surface, thereby helping to enrich topsoil.

Soil horizons vary in composition and thickness, depending on various factors—including climate, vegetation, and bedrock type—and the history of human impact. For example, natural grasslands produce deep, rich topsoil that is used for cropland in many regions of the world (Figure 37.7b). In dramatic contrast, tropical rain forests often have only thin layers of topsoil; their soils are composed mostly of inorganic materials that are not useful to plants (Figure 37.7c). However, certain Amazonian soils, known as "terra preta," are rich and black with organic materials, because ancient inhabitants fertilized extensive gardens with large amounts of decayed plant material dredged from nearby riverbanks. In other parts of the world, however, human activities have increased topsoil loss by wind or water erosion, a worldwide agricultural concern.

These examples illustrate that soils are composed of both organic materials and inorganic minerals. The proportions of organic to inorganic materials and the sizes of inorganic particles are used to classify soils into different types. Soils also display variation in amount of aeration, water-holding capacity, pH, and mineral content. All of these soil properties affect plant growth. For this reason, we will take a closer look at the organic and inorganic constituents of soils and the role of fertilizers.

Organic Soil Constituents The organic constituents of soils are collectively known as **humus**. Humus is largely derived from plant detritus, the dead and decaying remains of plants, although animal wastes and decayed animal bodies also contribute to the organic content of soils. Organic soil constituents derived from plants include chemically stable lignin and cutin, as well as organic acids containing phenolic groups that are known as humic acids. These organic compounds give many soils their characteristic brown to black coloration. Soils that contain less than 1% organic materials are said to be humus-poor, whereas soils containing more than 8% are considered to be humus-rich. Though some plants are adapted to humus-poor soils, optimal growth generally requires soil that has an organic content close to 8%, because humus helps soils hold more water and ions. Humus particles accomplish this by electrostatically binding positively charged ions, cations such as K^+, to negative charges at their surfaces. In this way, humus helps to prevent ions from washing out of soils, thereby maintaining soil fertility. Humus also gives most soils their soft consistency, a property that fosters root growth.

(a) Soil structure (b) Thick layer of topsoil in cropland (c) Thin layer of topsoil in rain forest

Figure 37.7 **Soil horizons, the structural layers of soil.** **(a)** Diagram showing general soil structure. **(b)** A vertical view of an agricultural soil, showing a relatively deep layer of dark topsoil. **(c)** A vertical view of a tropical rain forest soil, showing a thin layer of dark topsoil.

Figure 37.8 **Composting.** Gardeners produce compost by layering small amounts of soil with vegetable waste from the kitchen and yard waste and periodically turning the pile to introduce the oxygen needed for decomposition. Compost can be used to increase the humus and mineral content of garden soils.

The benefits of humus explain why farmers often plow manure and plant residues left after crop harvesting into agricultural soils. Garden soils that are low in organic materials can be amended with peat moss or with composted (partially decomposed) manure, which is available at garden stores. Gardeners often produce their own humus-rich compost by layering vegetable waste from the kitchen and yard waste with soil, and turning the pile occasionally to introduce the oxygen necessary for decomposition (Figure 37.8).

Inorganic Soil Constituents Inorganic materials in soil are derived from the physical and chemical breakdown of rock, a process known as **weathering**. Rock, which is an aggregate of two or more minerals, is physically weathered by changes such as cycles of freezing and thawing. Lichens and plant roots may produce organic acids that contribute to chemical weathering of rocks. During chemical weathering, soluble salts are washed out, and minerals are hydrolyzed or oxidized. **Leaching** is the dissolution and removal of inorganic ions as water percolates through materials. Heavy rainfall can reduce the fertility of soils by leaching large amounts of nutrients from them. The leached minerals often end up in natural bodies of water, where they can foster the growth of cyanobacteria, algae, and aquatic plants.

Inorganic soil materials occur as particles that can be categorized according to their size as gravel, coarse sand, fine sand, silt, or clay (Figure 37.9). Coarse sand grains range from 200 to 2,000 μm (micrometers) in diameter, whereas fine sand particles can be as small as 20 μm. Particles of silt range from 2 to 20 μm in diameter, and clay particles are less than 2 μm in size. Soils can be classified according to their relative content of coarse and fine materials. For example, soils that contain 45% or more sand and 35% or less clay are classified as sandy soils. The other main types of soil are silty, clay, and loam soils. Loam soil contains a mixture of sand, silt, and clay.

Because of their size differences, sand, silt, and clay particles confer different properties on soils. The relatively large size and irregular shapes of sand particles allow air and water to

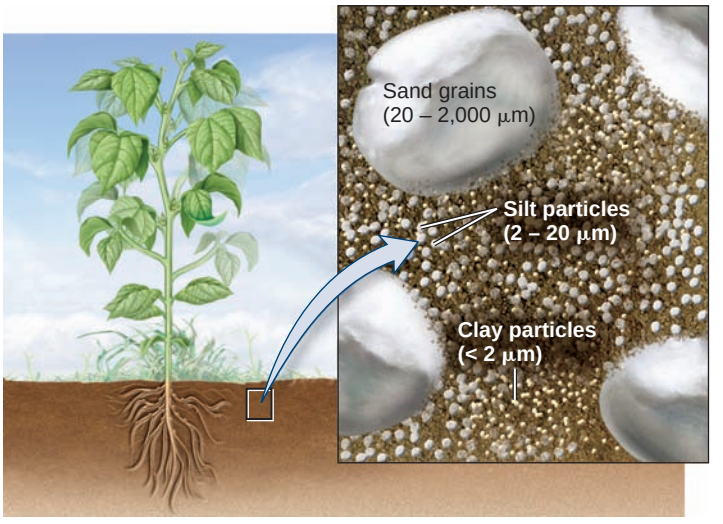

Figure 37.9 **The relative sizes of inorganic soil components.**

move rapidly through sandy soils, which are said to be porous (Figure 37.10). Sandy soils are well aerated, which is favorable to the growth of plant roots, because they require oxygen for cellular respiration. However, sandy soils hold less water than the same volume of clay, and rapid percolation of water through sandy soils both reduces the amount of water available to the roots and leaches minerals from the soil.

Silt and clay particles fit closely together, so soils containing larger amounts of these materials are less porous than sandy

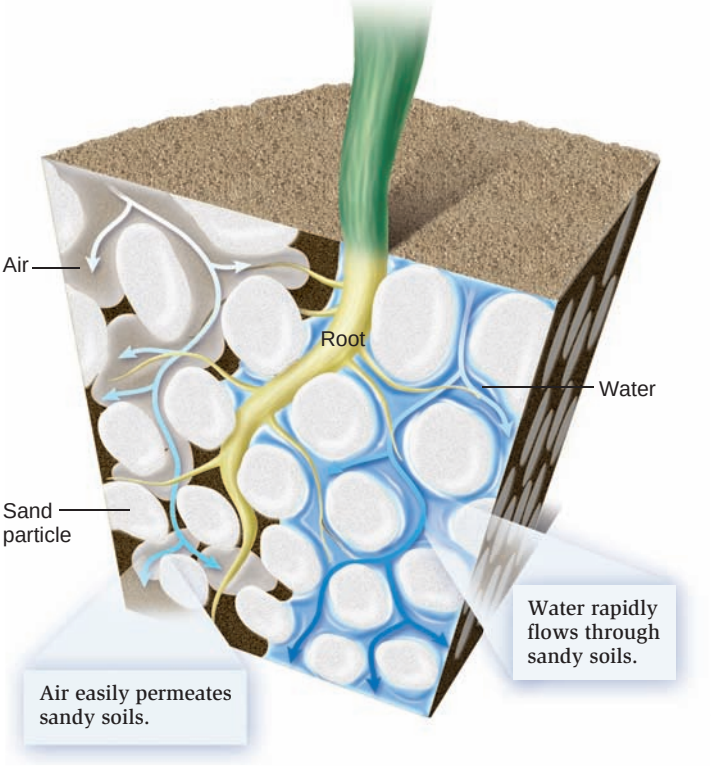

Figure 37.10 **The movement of air and water in sandy soil.**

Concept check: *In which type of soil is nutrient leaching a more common problem, sandy or clay soils?*

soils. Water percolates less easily through silty and clay soils, which therefore retain more ionic mineral nutrients than do sandy soils. Like humus, clay particles have negative charges on their surfaces that electrostatically bind cations (such as NH_4^+, Ca^{2+}, and Fe^{2+}) (Figure 37.11a). Cations having higher valence numbers (such as Fe^{2+}) are bound more tightly than ions having lower valence numbers (NH_4^+). Hydrogen ions (H^+, protons) are able to replace mineral cations on the surfaces of humus or clay particles, a process known as **cation exchange** (Figure 37.11b). Cation exchange releases cations to soil water, making them more available for uptake by plant roots. However, free ions are also more easily washed out of soil. If the H^+ concentration becomes too high, large numbers of mineral ions are released and can be leached from soil by heavy rainfall. Such leached minerals may include heavy metals such as aluminum that would otherwise be bound in soil. Cation exchange is the mechanism by which acid rain, which adds H^+ to soil, causes loss of soil fertility and the pollution of streams with toxic substances, such as aluminum, that can harm human health.

Despite their water- and mineral-retention features, silt- and clay-rich soils may be poorly aerated and therefore unfavorable to root growth. Gardeners often mix organic materials and sand into silt or clay-rich soils to improve their aeration properties. A loam soil is the preferred soil for agriculture because it combines the aeration provided by sand with the mineral and water retention capacity of silt and clay.

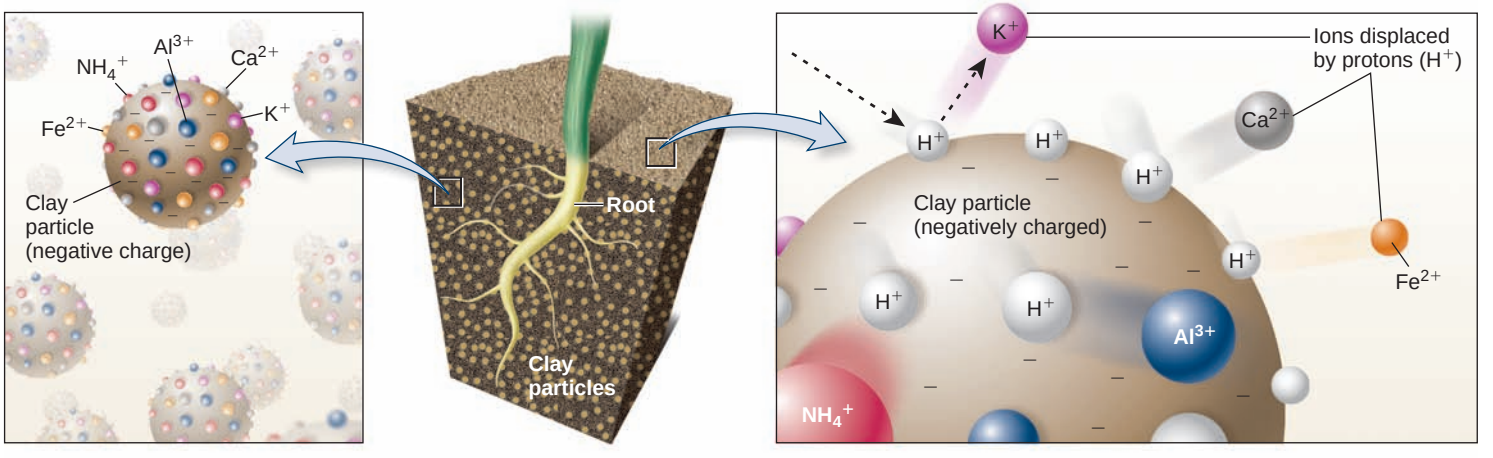
The Role of Fertilizers The addition of fertilizer to soils can compensate for deficiencies in soil humus or mineral content and thus improve soil fertility. Fertilizers occur in organic and inorganic forms. Organic fertilizers are those in which most of the minerals are bound to organic molecules and are thus released relatively slowly. They play an important role in **organic farming**, the production of crops without the use of inorganic fertilizers, growth substances, and pesticides. Manure and compost are examples of organic fertilizers.

In contrast, inorganic fertilizers consist of inorganic minerals, which are immediately useful to plants but are more easily leached from soils by heavy rainfall. Nitrogen (N), phosphorus (P), and potassium (K) are the mineral nutrients that most frequently limit crop growth. For this reason, these minerals are the main components of the most common type of commercial inorganic fertilizers, known as NPK fertilizers. Such fertilizers are available in different ratios of minerals, which are optimal for different types of plants.

Excessive application of fertilizers to farm fields and lawns is undesirable because minerals not taken up by plant roots are easily washed by rain into waterways. In aquatic habitats, excess mineral nutrients fuel large growths of cyanobacteria, algae, and aquatic plants that can harm other aquatic lifeforms. For example, large areas of the Gulf of Mexico and other coastal regions are known as "dead zones" because microbial decomposition of large algal populations has depleted oxygen from the water, suffocating the animal life. These large populations of algae are fostered by fertilizers that wash from farm soils into rivers, such as the Mississippi River, that drain into coastal oceans. More careful application of fertilizers and planting stream and river edges with vegetation that helps to absorb mineral nutrients are actions that can reduce or prevent dead zones.

Plants Require Fixed Nitrogen

Nitrogen is frequently limiting to plant growth in nature and in crop fields, because large amounts of it are required for plant



(a) Electrostatic attraction between clay particles and mineral ions

(b) Cation exchange

Figure 37.11 **Cation binding and exchange.** **(a)** Clay and humus particles display negative electrostatic surface charges that bind cations. Bound cations include not only plant mineral nutrients such as NH_4^+ but also cations that are not plant nutrients, such as Al^{3+}. **(b)** Cation exchange occurs when protons (H^+) displace other cations, releasing them to soil water. This process makes cations more available for uptake by plant roots, but it also increases the potential for cations to leach away during rains or floods. Protons in acid soils or arising from acid rain displace so many cations from soil that its fertility decreases, and toxic ions such as Al^{3+} more readily damage plants.

Concept check: *In what parts of the world do acidic soils tend to occur?*

synthesis of amino acids, nucleotides, and alkaloids, among many other cellular constituents. Nitrogen is the largest component of plants by mass after carbon, oxygen, and hydrogen. Although the Earth's atmosphere is 78% nitrogen gas (N_2), plants cannot utilize nitrogen in this form.

To be of use to plants, soil nitrogen must occur in a combined form, such as ammonia (NH_3), ammonium ion (NH_4^+), or nitrate ion (NO_3^-). Combined forms of nitrogen are also known as **fixed nitrogen**. Ammonia and its dissolved form—ammonium ion—can be used directly for amino acid production by plants, explaining why ammonia is often applied as a fertilizer to farm fields in springtime. However, in oxygen-rich soils, microorganisms oxidize much of the ammonium ion to nitrate, so nitrate may be the form in which fixed nitrogen enters most plants.

Nitrate is imported into root cells by means of plasma membrane transporter proteins (Figure 37.12). Once inside the plants, the nitrate can be transported in the xylem for use elsewhere, stored for later use, or assimilated for immediate use. Cells store nitrate by transporting it into vacuoles. To assimilate nitrate, plant cells must reduce it to ammonium ion in a two-step process. First, the cytosolic enzyme nitrate reductase reduces nitrate (NO_3^-) to nitrite (NO_2^-). Second, in plastids, nitrite is reduced to ammonium ion (NH_4^+) by nitrite reductase. Another plastid enzyme, glutamine synthetase, uses ammonium ion to produce the amino acid glutamine.

Atmospheric Nitrogen Is Fixed by Natural and Industrial Processes

Much of the fixed nitrogen in soils has been recycled from compounds previously utilized by other organisms. New fixed nitrogen can be added to soils by the action of lightning, fire, and air pollution, as well as biological and industrial nitrogen fixation. **Nitrogen fixation** is the process by which atmospheric nitrogen gas is combined with hydrogen to produce ammonia. Most of the fixed nitrogen in soils is produced by **biological nitrogen fixation**, which is performed in nature only by certain prokaryotes. Nitrogen fertilizers applied to crops are produced by **industrial nitrogen fixation**, a human activity.

Biological Nitrogen Fixation by Bacteria Nitrogen-fixing prokaryotes include many types of cyanobacteria, which are

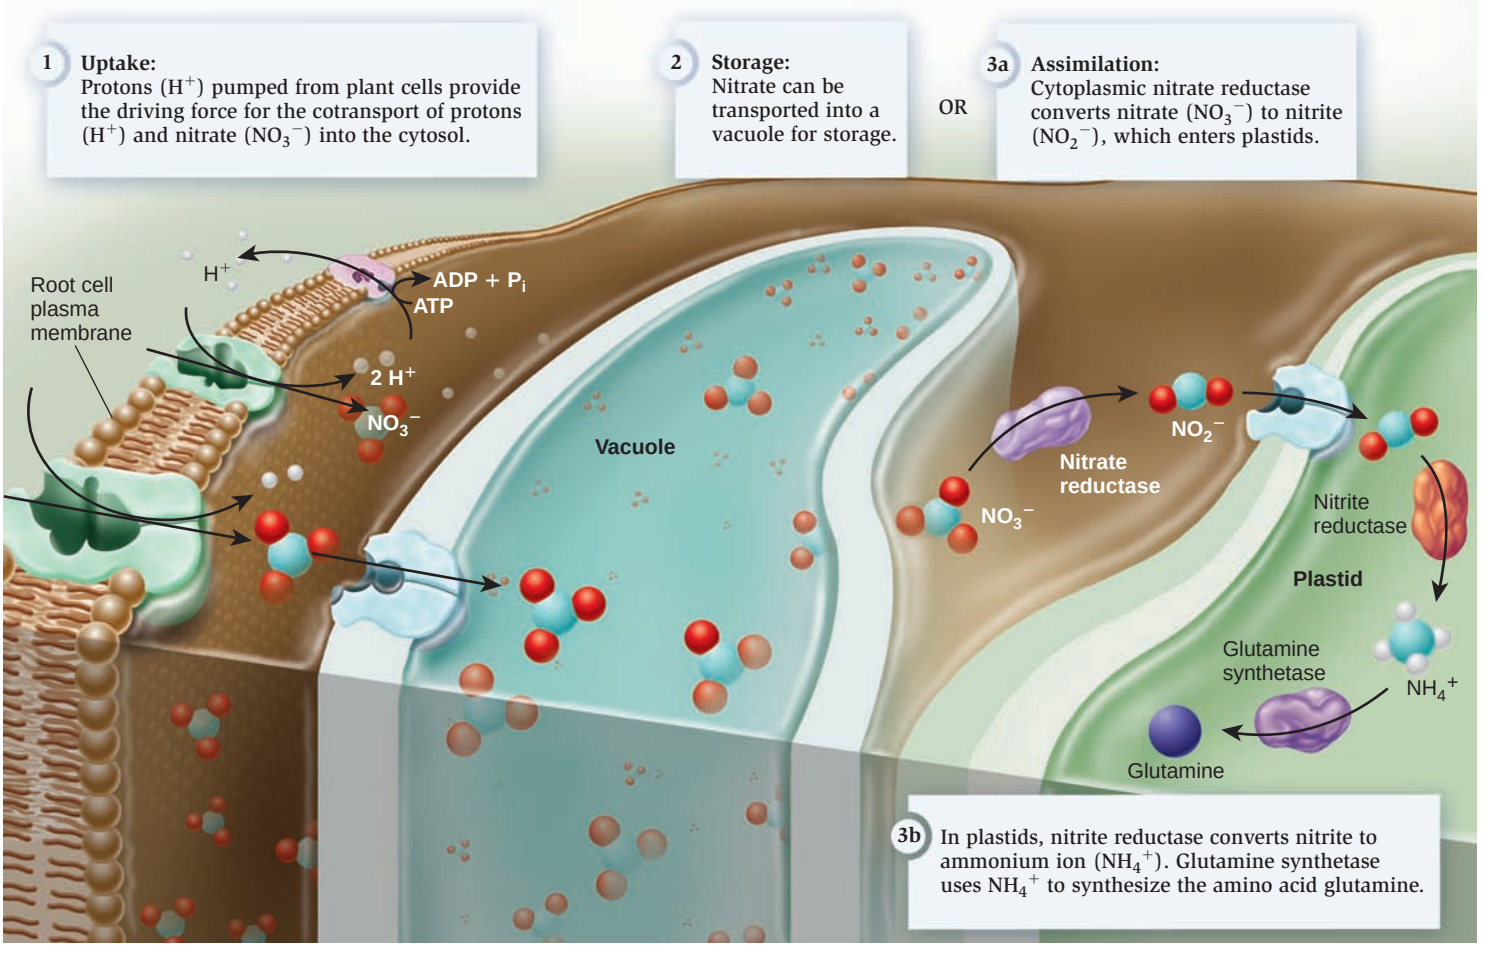


Figure 37.12 How plant cells take up, store, and assimilate nitrate.

Concept check: *List at least five organic compounds essential to photosynthesis whose biosynthesis requires a supply of fixed nitrogen such as nitrate.*

Figure 37.13 **A soil surface crust that includes nitrogen-fixing, soil-enriching cyanobacteria.** Such crusts are widespread in grasslands and other arid regions.

Concept check: *How might soil crusts influence the ecology and economy of regions in which grazing is important?*

photosynthetic organisms that occur in oceans, lakes, and other aquatic systems, as well as in surface soil crusts (Figure 37.13). Various types of nonphotosynthetic bacteria living in water and soil are also able to fix nitrogen; actinobacteria and the genera *Clostridium*, *Klebsiella*, and *Azotobacter* are examples. Nitrogen-fixing prokaryotes often excrete a substantial amount of fixed nitrogen, and their death makes still more fixed nitrogen available to plants. Many plants have nitrogen-fixing, prokaryotic symbionts that transfer fixed nitrogen directly to plant cells. Nitrogen-fixation symbioses are so important in nature and in agriculture that they are discussed in more detail in Section 37.3.

All nitrogen-fixing prokaryotes utilize relatively large amounts of ATP and an enzyme known as **nitrogenase** to fix nitrogen (Figure 37.14). This process occurs in three steps. In the first step, a molecule of nitrogen gas (N_2) binds to nitrogenase. In the second step, the bound nitrogen is reduced by the addition of two hydrogen atoms (2 H), a reaction powered by the breakdown of ATP. Such a reduction occurs three times, with the addition of a total of three hydrogen atoms to each nitrogen atom. In a third and final step, two molecules of ammonia (NH_3) are released and dissolve in cell water to form ammonium ions. The nitrogenase enzyme is then free to bind more nitrogen gas.

Because the O_2 molecule resembles N_2, oxygen can bind to the active site of nitrogenase. Oxygen-binding disables nitrogenase, thereby stopping nitrogen fixation. Many of the genes involved in prokaryotic nitrogen fixation are known, and crop scientists are working to genetically engineer nitrogen fixation capacity into crop plants such as rice and maize (corn). However, the vulnerability of nitrogenase to oxygen means that this enzyme may need to be altered so that it binds oxygen less readily, or plants must be engineered with some mechanism that protects nitrogenase from oxygen.

Industrial Nitrogen Fixation Worldwide, farmers apply more than 80 million metric tons of nitrogen fertilizer per year. The fixed nitrogen found in fertilizer is produced industrially from nitrogen gas by means of a procedure invented by German chemists Fritz Haber and Carl Bosch in 1909. The reduction of N_2 gas to NH_3 is energetically favorable at room temperature, but the activation energy is very high, so the reaction occurs extremely slowly. Using an iron catalyst, temperatures

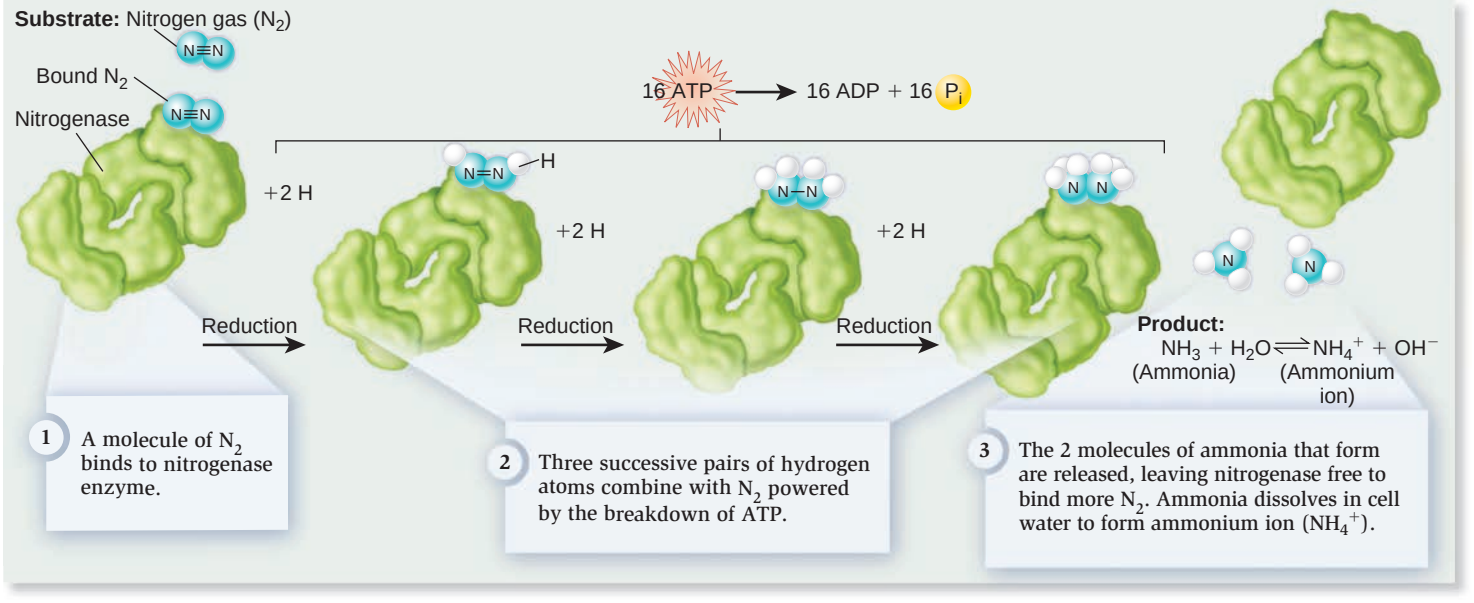

Figure 37.14 **The biological process of nitrogen fixation.**

Concept check: *What common substance inactivates nitrogenase enzyme by binding to its active site?*

of 400–650°C (752–1,202°F), and high pressures (150–400 atmospheres), the Haber–Bosch process generates NH_3 rapidly. However, because of its high energy requirements, industrial nitrogen fixation can be costly from the perspective of many of the world's farmers. The high cost of fertilizers helps to explain why agricultural scientists are so interested in the possibility of genetically engineering nitrogen fixation into crop plants.

Plants Display Adaptations for Acquiring Phosphorus

Phosphorus (P) is another soil mineral that often limits plant growth. Plants obtain phosphorus from the ion known as phosphate (PO_4^{3-}), which occurs in the soil in three dissolved forms: H_3PO_4, $H_2PO_4^-$, and HPO_4^{2-}. HPO_4^{2-} (called hydrogen phosphate ion) is the form most commonly absorbed by plants. Phosphate uptake involves ATP-requiring proton cotransport, as is the case for other anions such as nitrate and sulfate. The uptake of minerals at the root hair surface is discussed further in Chapter 38.

Although phosphorus is abundant in soil, it is often unavailable to plants. One reason is that phosphate forms tightly bound complexes with clay, iron and aluminum oxides, and calcium carbonate in soils. In addition, soil microbes convert phosphate ions into organic compounds that are not taken up by plants.

Because plants need large supplies of phosphorus for a variety of cell processes, they have evolved various adaptations that increase their ability to obtain phosphate from soil. A common adaptation for acquiring phosphate is the symbiotic association of plant roots with various types of fungi (see Section 37.3). In addition, plants that grow in soils having low phosphorous content may produce more highly branched roots and more and longer root hairs. Plant roots also secrete protons and organic acids such as citrate and malate into the soil, which help release phosphorus from inorganic complexes. For example, the plant *Lupinus alba* releases as much as 25% of its total photosynthetic carbon into the soil as organic acids—a high price to pay but apparently one that is essential for the plant to obtain sufficient phosphorus. Plants may also secrete phosphatase enzymes from roots. These enzymes release phosphorus from organic compounds in the soil. The general process by which phosphorus, nitrogen, CO_2, and other minerals are released from organic compounds is called **mineralization**.

Farmers and gardeners apply phosphate-rich fertilizers to crop fields and gardens as a way of preventing phosphorous deficiencies, which reduce yields. Phosphorous fertilizers are obtained from phosphate-rich mineral deposits, but experts have warned that inexpensive sources of phosphate will be exhausted within the next 90 years. Consequently, there is much interest in devising ways to maximize the efficiency by which plants are able to take up and use phosphorus. Genetic engineering to produce "smart plants" that can sense the levels of nutrients in the soil may offer some options.

Feature Investigation

Hammond and Colleagues Engineered Smart Plants That Can Communicate Their Phosphate Needs

If farmers could apply fertilizer to crops in the precise amounts needed by plants, not only would they save money, but also less fertilizer would run off fields into aquatic habitats, where it can lead to harmful ecological effects. Plant biologists have used genetic engineering to produce smart plants that signal impending nutrient deficiency via a visible marker. Such plants could serve as sentinels, warning farmers of the conditions of an entire field. With this information, farmers could apply just enough mineral nutrients to prevent deficiency, thereby avoiding overapplication of fertilizers.

In 2003, working with the model plant *Arabidopsis*, John Hammond, Philip White, and their associates grew plants hydroponically, which means their roots were in a water solution rather than soil. They then used microarray technology (see Chapter 20) to identify some of the genes whose expression changes when plants are transferred from nutrient solutions containing sufficient phosphorus to solutions lacking phosphorus. They found that some genes were turned on quickly after phosphorus removal, while others took much longer, such as 100 hours or more. This timing is important because genes expressed between 24 and 72 hours after phosphate removal are considered useful as phosphorous monitors. During this window of time, plant tissue levels of phosphate decreased but had not yet affected plant growth. One gene that met this timing criterion was *SQD1*, which is required for the synthesis of sulfur-containing lipids. Expression of *SQD1* allows plants to respond to low phosphorous levels by replacing plastid phospholipids with sulfur-containing lipids, thereby reducing their phosphorous requirement. This evidence suggested that smart plants could be engineered to communicate impending phosphate deficiency when they express *SQD1*.

To make smart plants, the researchers first placed the reporter gene *GUS* under the control of the *SQD1* promoter and transformed this gene into *Arabidopsis* plants (Figure 37.15). The researchers then grew these genetically engineered plants for various time periods in hydroponic solutions of differing phosphate levels. After different time periods, they removed leaves and chemically treated them with a compound that produces a blue color when the *GUS* gene is expressed. Some leaves were removed before transfer to the phosphate-deficient solution and served as controls. Because the *GUS* gene was under the control of the *SQD1* promoter, leaves from plants that were developing phosphate deficiency turned blue! These smart plants were able to communicate impending phosphorous deficiency in time for a farmer to apply fertilizer.

In a later and more extensive study of gene expression in *Arabidopsis*, molecular biologists Julie Misson, Marie-Christine Thibaud, and associates discovered that phosphate induces 612 genes and represses 254 genes. Some of these genes may

Figure 37.15 **The experiment of Hammond and colleagues showed that plants can be engineered to communicate changes in the level of nutrients.**

GOAL To determine if plants can be engineered to signal impending phosphate deficiency.

KEY MATERIALS *Arabidopsis* plants, mineral nutrient solutions.

	Experimental level	Conceptual level
1 Construct DNA with promoter of *SQD1* linked to *GUS* (blue color–producing gene), using methods described in Chapter 20.		Plants are genetically engineered with a reporter system (*GUS*).
2 Transform new DNA into *Arabidopsis* (see Chapter 20).		
3 Remove some leaves 20 hours before transfer to phosphate-deficient media, and 24, 100, and 220 hours after transfer.		Leaves removed 20 hours before transfer to phosphate-deficient media serve as negative (untreated) controls.
4 After each time point, add a reagent that produces blue color when the *GUS* (and *SQD1*) gene is expressed from the *SQD1* promoter. (See the data.)		Leaves removed at increasingly longer times after transfer to phosphate-deficient media reveal how quickly the reporter system works.

5 THE DATA

6 CONCLUSION Plants can be genetically engineered to express color signals in time for farmers to apply fertilizer sufficient to prevent nutrient deficiency.

7 SOURCE Hammond, John P. et al. June 2003. Changes in gene expression in *Arabidopsis* shoots during phosphate starvation and the potential for developing smart plants. *Plant Physiology* 132:578–596.

encode proteins useful in monitoring plant phosphorous status. If smart plant technology can be developed for crop plants, farmers may be able to monitor and fertilize fields with much greater precision.

Experimental Questions

1. Why did Hammond and colleagues seek to identify genes whose expression changed between 24 and 72 hours after plants experience phosphorous limitation?
2. What advantage do plants obtain when the *SQD1* gene is expressed?
3. How were the investigators able to identify potential sentinel plants that were starting to experience phosphorous deficiency?

Some Common Soil Minerals Can Be Toxic to Plants

Some soil minerals, including certain micronutrients, inhibit plant growth when present at high concentrations and therefore are considered toxic to plants. Minerals that may occur in toxic concentrations in soils include aluminum, lead, cadmium, chromium, mercury, and uranium and the micronutrients boron, copper, and nickel. These minerals enter plant roots through water-soaked cell walls and intercellular spaces. Boron is an example of an element that functions as a micronutrient when present in low levels but that is toxic at higher concentrations. Aluminum is not known to be an essential element, but has important ecological effects on plants even in very low concentrations.

Boron Toxicity At concentrations less than 0.01 g/kg of plant tissue, boron (B) is an essential micronutrient, required for cross-linking polysaccharides in plant cell walls (see Table 37.1). However, boron is toxic to wheat plants, for example, in concentrations of 0.01 g/kg or higher. Boron is easily taken up by plant tissues because this mineral occurs as uncharged boric acid, $B(OH)_3$, which readily crosses membranes. When applying fertilizer to relieve boron deficiency, farmers must take care not to add too much.

Plant scientists Junpei Takano, Toru Fujiwara, and their associates reported in 2005 that the model flowering plant *Arabidopsis* has cellular adaptations that regulate the concentration of boron. These investigators demonstrated that when boron is present in small amounts, a boron transporter protein (BOR1) is expressed in the plasma membranes of root pericycle tissue. In this case, BOR1 moves boric acid into root xylem for transport to shoots, where boron can be used in producing new cell walls. However, when potentially harmful amounts of boric acid are applied to roots, endocytotic vesicles move the BOR1 protein to the cell vacuole for degradation. This process prevents too much boric acid from moving into shoots. Together, these processes protect plants from boron deficiency and toxicity.

Aluminum Toxicity Aluminum, in the form of Al^{3+}, is one of the most common minerals in soil, so small amounts may seep into plant tissues. However, aluminum is not known to be an essential element and is toxic to plants even at micromolar concentrations. Aluminum binds to cellular carbohydrates, phosphates such as ATP, and sulfates, thereby inhibiting root elongation and uptake of minerals and water. Aluminum toxicity is primarily a problem for plants rooted in acidic soils, which are common in the tropics and subtropics, including at least 12% of cultivated land. In addition, aluminum toxicity can occur in temperate regions that receive acid rain. In the cation exchange process, the abundant protons in acidic soils or acid rain can replace aluminum ions bound to soil particles (see Figure 37.11) and allow the released aluminum ions to enter plant roots more easily.

Some plants defend themselves against aluminum toxicity by secreting organic acids such as citrate, oxalate, and malate from their root tips. In the soil, these acids form complexes with Al^{3+}, which helps to prevent aluminum from entering roots. Within plant cells, certain proteins also bind aluminum and other metals, thereby protecting cell components. Some plants accumulate aluminum or other toxic metals in their tissues, often sequestering the metals in cell vacuoles, where they do little harm. For example, when hydrangea plants are grown in acid soil, aluminum accumulations in vacuoles cause the showy sepals of the flowers to change from pink to blue (Figure 37.16). Many other kinds of plants protect themselves from toxic metals by storing them in plant tissues.

Figure 37.16 An adaptation protecting against aluminum toxicity. The showy sepals of hydrangea (*Hydrangea macrophylla*) flowers turn from pink to blue when soil conditions become more acidic. The sepals shown here are in the process of undergoing the transition from pink to blue.

Concept check: Explain the processes by which the color change occurs in hydrangea sepals.

Hyperaccumulators and Phytoremediation Some plants are known as hyperaccumulators because they accumulate and safely bind high concentrations of toxic metal minerals within their tissues, an adaptation that allows such plants to grow on metal-rich soils. Some 400 different plant species are hyperaccumulators. Examples include the alpine pennycress (*Thlaspi caerulescens*), which accumulates zinc and cadmium, and the brake fern (*Pteris vittata*), which accumulates arsenic. These plant adaptations can be usefully applied to remove pollutants such as harmful metals from soils, a process known as **phytoremediation**. In this process, hyperaccumulator plants are grown on metal-contaminated soils, harvested, and burned to ashes for disposal and/or metal recovery.

37.3 Biological Sources of Plant Nutrients

This section focuses on several fascinating ways in which plants use other organisms as sources of nutrients. Biological sources of plant nutrients include symbiotic fungi or bacteria, the animal prey of carnivorous plants, and green plants that serve as hosts for nonphotosynthetic plant parasites.

Mycorrhizal Associations Help Most Plants Obtain Mineral Nutrients

About 90% of seed plants have symbiotic associations with fungi that live within the tissues of plant roots or that envelop root surfaces (see Chapter 31). These associations are termed **mycorrhizae**; the prefix *myco* refers to fungi, and *rhiza* means root, so the term literally means "fungus root."

In mycorrhizal associations, soil fungi obtain organic food from the roots of a photosynthetic plant host, while the fungal partner supplies the plant with water and mineral nutrients. Due to the extensive mycelia that fungi produce within the soil, these fungal-root associations provide an exceptionally efficient way for plants to harvest water and minerals, especially phosphate, from a much larger volume of soil than is available to roots by themselves. The presence of lush vegetation on thin, infertile tropical rain forest soils is largely due to the ability of mycorrhizae to rapidly absorb mineral nutrients released by decaying organisms and transmit the nutrients directly to plant roots (Figure 37.17). In many tropical rain forests, mineral nutrients occur within the bodies of living organisms, rather than accumulating in the soil where they could easily be leached away by heavy, frequent rains.

Various species of ghostly pale plants have lost their photosynthetic pigments (see Figure 37.2) and have thus become dependent on organic compounds supplied by fungi that form mycorrhizal associations with a photosynthetic host, such as a nearby tree. In this process, known as mycoheterotrophy, the fungus serves as an underground conduit for the flow of organic nutrients from a green, photosynthetic plant to a heterotrophic plant. Many plant seedlings that grow in the shade of taller plants also use mycoheterotrophy to survive until they are able to obtain enough light for photosynthesis.

Plant–Prokaryote Symbioses Provide Some Plants with Fixed Nitrogen

Some kinds of plants have symbiotic relationships with bacteria that provide them with fixed nitrogen. Though many nitrogen-fixing bacteria live freely within the soil, some form nitrogen-fixing partnerships with plants, actually living within plant cells or tissues. Such symbioses are advantageous to both partners. The plants provide organic nutrients to the bacteria, while the bacteria supply the plants with a much higher supply of fixed nitrogen than the plants could obtain from most soils. Representatives of three types of prokaryotes—cyanobacteria, actinobacteria, and proteobacteria—are symbiotically associated with specific types of plants. (For more information about the characteristics of these bacterial groups, see Chapter 27.)

Plant–Cyanobacteria Symbioses Although cyanobacteria are themselves photosynthetic, organic compounds supplied by plant partners subsidize the high energy costs of nitrogen fixation. This allows the cyanobacteria to fix more nitrogen than they require, secreting the excess to plant partners. Nitrogen-fixing cyanobacteria form symbioses with some bryophytes, ferns, and gymnosperms, as well as the flowering plant *Gunnera*. This plant, commonly known as the giant rhubarb or prickly rhubarb, can produce leaves almost 3 m across (Figure 37.18). Nitrogen-fixing symbionts are advantageous to *Gunnera* because this large plant grows in nitrogen-poor habitats, such as volcanic slopes in Hawaii. *Gunnera* harbors cyanobacteria within stems and leaf petioles. In these locations, the cyanobacteria can use cyclic electron flow to transform light energy into ATP, needed to produce fixed nitrogen. The presence of nitrogen-fixing cyanobacteria helps to explain why *Gunnera* can grow to dramatic size on poor soils.

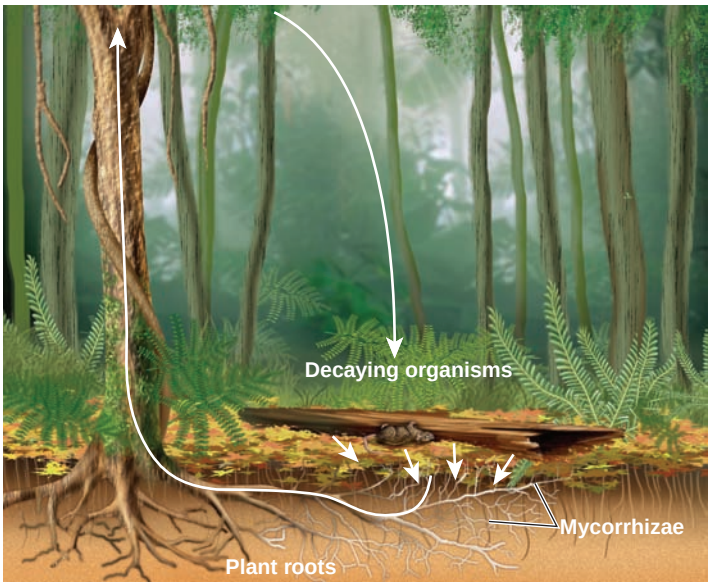

Figure 37.17 **Nutrient acquisition via mycorrhizae.** In all forests, but particularly those of tropical regions, mycorrhizal fungi rapidly collect soil minerals released from decaying organisms and transport them directly to plant roots. Such efficient nutrient cycling bypasses the soil, from which mineral ions can be easily leached by heavy rainfall. This process explains how lush forests can grow on thin, infertile soils.

Woody Plant–Actinobacteria Symbioses In contrast to cyanobacteria, actinobacteria are heterotrophic, nitrogen-fixing bacteria. Actinobacteria known as *Frankia* occur in nodules formed on the underground roots of certain shrubs or trees, such as alder (*Alnus*) and myrtle (*Myrica*). These plants receive fixed nitrogen from their bacterial partners, which, in turn, obtain organic nutrients. Woody plants, such as *Ceanothus* shrubs, that have *Frankia* symbionts are able to grow abundantly even in places where soil nitrogen is low. This symbiosis helps to explain why *Ceanothus* covers extensive areas in mountainous chaparral regions of the western U.S.

Legume–Rhizobia Symbioses The nitrogen-fixation symbioses most important in nature and to agriculture involve certain proteobacteria that are collectively known as **rhizobia** (from the Greek *rhiza*, meaning root). Rhizobia live within root cells of wild and cultivated legumes, forming legume–rhizobia symbioses. In nature, legume plants are important sources of fixed nitrogen for other plants. When legumes die, they generate humus that is enriched with fixed nitrogen. Consequently,

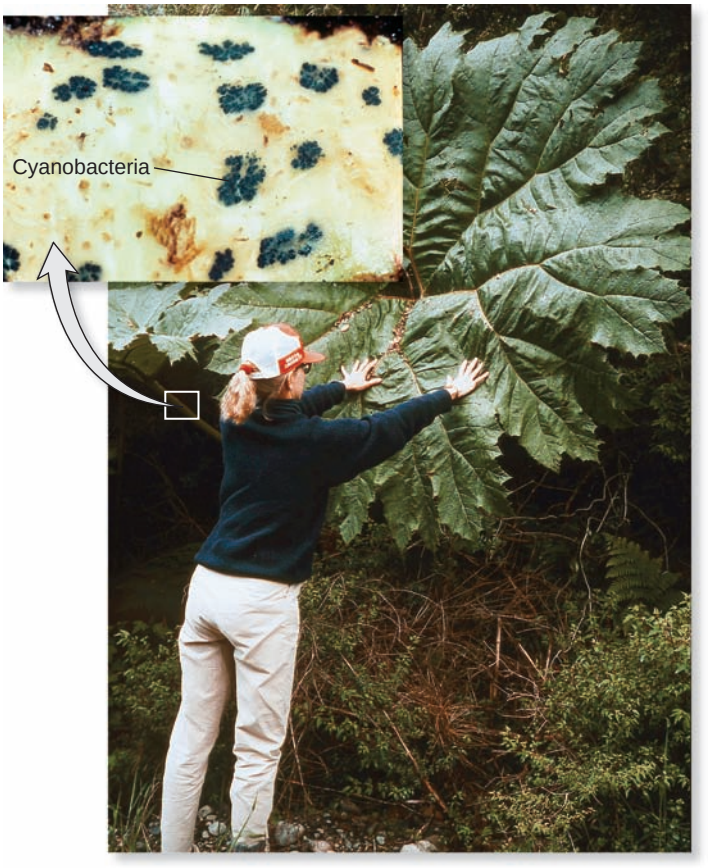

Figure 37.18 *Gunnera* growing on nitrogen-poor soil. Nitrogen-fixing cyanobacteria that live within cavities in this plant's leaf petioles provide the plant with fixed nitrogen, which explains how such a large plant can grow on infertile soils.

wild legumes are regarded as particularly valuable members of natural plant communities. For example, plant conservationists are concerned about the survival of a rare Appalachian legume known as running buffalo clover (*Trifolium stoloniferum*), because it is a valuable source of environmental fixed nitrogen.

Important legume crops include soybeans, peas, beans, peanuts, clover, and alfalfa. Foods produced from soybeans, peas, beans, and peanuts are valued for their high protein content. Clover and alfalfa are used for animal food and to enrich fields with the fixed nitrogen needed by subsequent food crops. The value of these crops arises from their fixed-nitrogen content. The amount of ammonia produced by legume–rhizobia symbioses nearly equals the world's entire industrial production.

Genomes & Proteomes Connection

Development of Legume–Rhizobia Symbioses

Rhizobia can live independently in the soil, but they fix nitrogen only when they occur within lumpy **nodules** that form on legume roots (Figure 37.19). Different species of rhizobia preferentially form symbioses with particular plant species. Because of their agricultural importance, these legume–rhizobia symbioses have been extensively studied, and a great deal is now known about the molecular basis of their development. This information is potentially useful in efforts to genetically engineer nitrogen-fixation capacity into nonlegume crops.

Nodule development involves a series of chemical signals sent back and forth between rhizobia and their host plants (Figure 37.20). Legumes start this exchange by secreting particular flavonoid compounds from their roots. Recall that flavonoids are phenolic secondary metabolites that play essential roles in plant structure, reproduction, and protection (see Chapter 30). These flavonoids bind to receptors in the plasma membranes of compatible soil rhizobia (Figure 37.20, step 1). In response, the rhizobia typically secrete **Nod factors** (nodulation factors). Each rhizobial species produces Nod factors with distinctive structural variations that can be recognized by the preferred host species. These Nod factors function something like keys that unlock doors, allowing bacteria to enter roots via root hairs. These factors bind to receptors in the membranes of root hair cells in the host plant (step 2).

Within minutes after its membrane receptors bind Nod factors, the root hair plasma membrane allows an influx of calcium ions, and a few minutes later, root hair calcium concentrations start oscillating rapidly. Root hairs respond to these calcium changes by swelling at their tips and curling around the rhizobia (step 3). The rhizobia then inject infection proteins into root hairs. In response, the cell wall at the root hair tip changes in a way that allows bacterial enzymes to erode a small hole in the wall, allowing bacterial cells to enter. The plasma membrane forms a tubular infection thread through which rhizobia

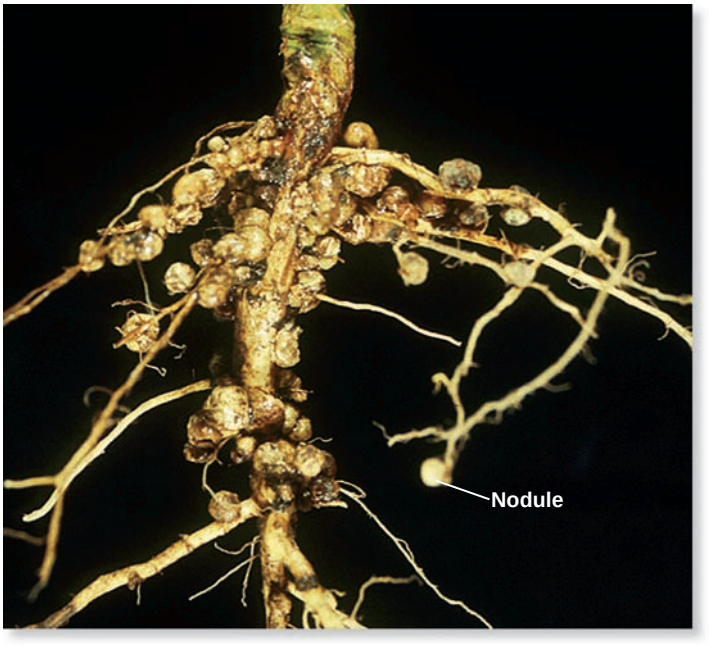

Figure 37.19 Legume root nodules. The cells of nodules on the roots of this soybean plant (*Glycine max*) and other legumes contain nitrogen-fixing bacteria known as rhizobia.

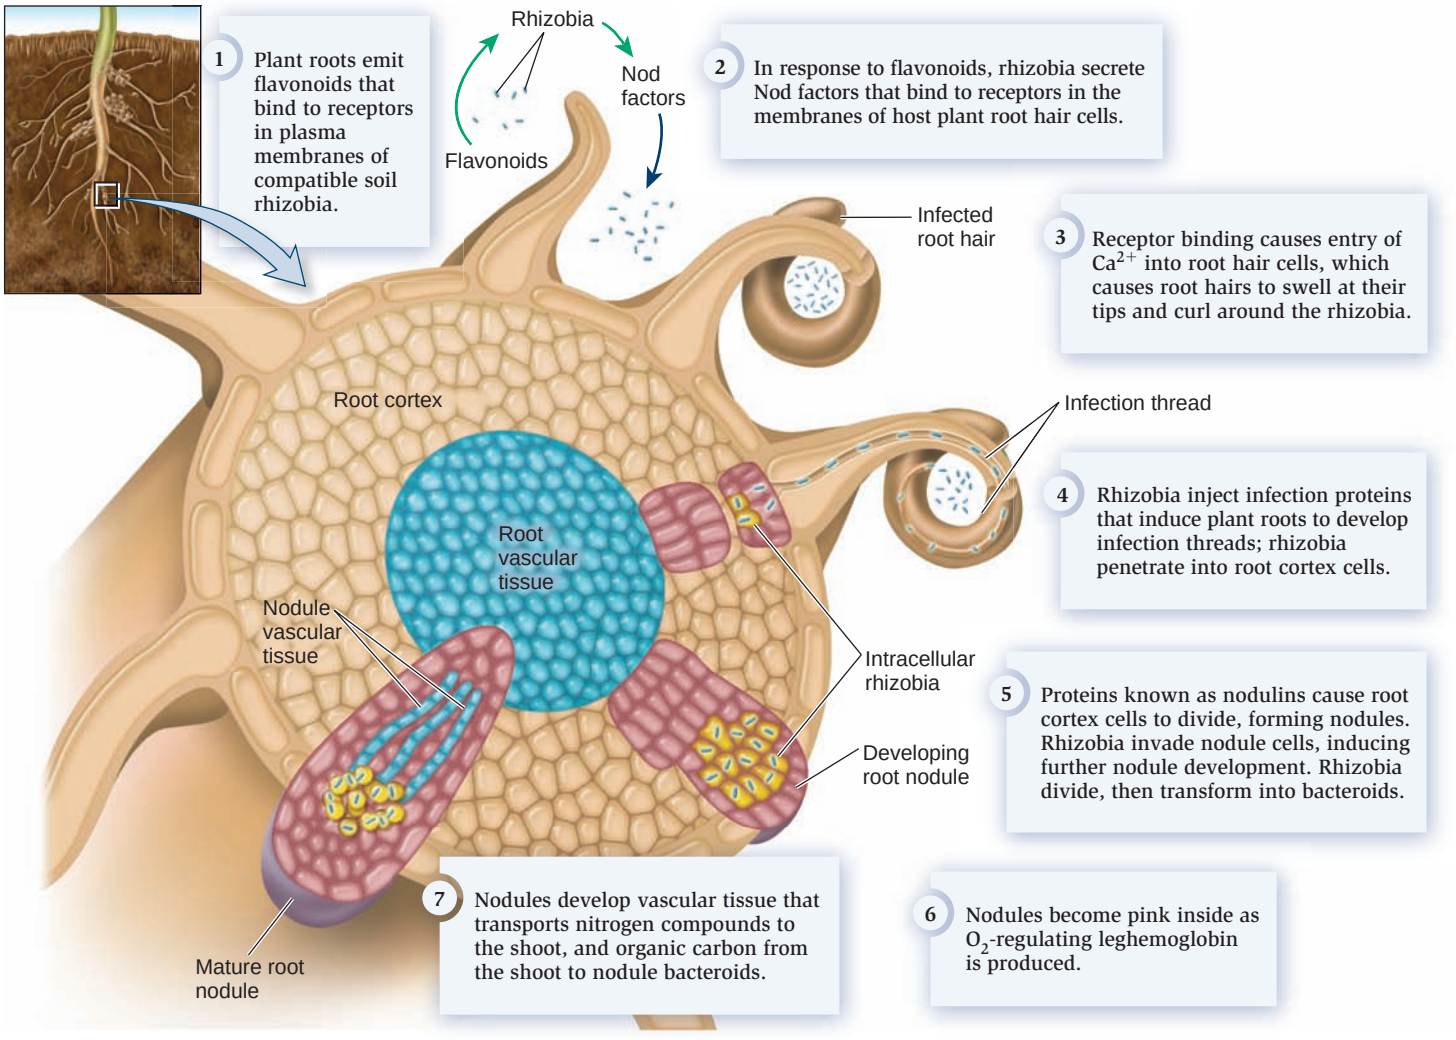

Figure 37.20 Root nodule development.

move into the root cortex. The tip of the infection thread fuses with the plasma membrane of a cortex cell, then the rhizobia are released into the cortex cell cytoplasm, each bacterial cell enclosed by the host membrane (step 4).

Meanwhile, plants produce proteins known as **nodulins** that foster nodule development. Within 18–30 hours after the initial infection, root cortex cells start to divide to form root nodules. Environmental conditions in developing nodules cause rhizobia to undergo changes in their structure and gene expression patterns. The modified rhizobia present in mature nodules are known as **bacteroids** (step 5). Legume nodules typically produce **leghemoglobin** (legume hemoglobin), a pink protein that helps regulate local oxygen concentrations (step 6). By so doing, leghemoglobin prevents oxygen from poisoning nitrogenase, while still allowing bacteroids to accomplish aerobic respiration. Bacteroid respiration provides the large amounts of ATP that are necessary for nitrogen fixation. Mature nodules also produce vascular tissue that moves nitrogen fixed by bacteroids to the root vascular system for transport throughout the plant. These nodule vascular tissues also supply organic food produced by the legume to their bacteroid partners (step 7).

In 2004, plant molecular biologists Melanie Barnett, Sharon Long, and their colleagues produced a type of a DNA microarray chip (see Chapter 20) called a symbiosis chip that contains the genomes of both a legume plant host, *Medicago truncatula*, and its rhizobial symbiont, *Sinorhizobium meliloti*. This chip allows investigators to study gene expression in both partners simultaneously, revealing that nearly 5,000 gene expression changes are associated with the legume–rhizobia symbiosis.

Carnivorous Plants Are Autotrophs That Obtain Mineral Nutrients from Animals

About 600 species of flowering plants have adapted to low-nitrogen environments by evolving mechanisms for trapping and digesting animals and are therefore known as carnivorous plants. Their leaves are modified in ways that allow them to

capture animal prey, primarily insects, though larger animals are sometimes snared as well. (Despite the popular play and movie *Little Shop of Horrors*, there are no wild or cultivated carnivorous plants that, like Audrey II, are large enough to consume humans!) Carnivorous plants are photosynthetic autotrophs that supply their own organic compounds; prey animals are primarily sources of nitrogen. The experimental use of radioactively labeled prey insects has revealed that carnivorous plants obtain as much as 87% of their nitrogen from animals.

The trapping mechanisms used by carnivorous plants are classified as passive or active. Plants with passive trapping mechanisms depend on the prey to fall or wander into the trap. For example, tropical pitcher plants (genus *Nepenthes*) have leaves that are folded and partially fused to form tubes that collect rainwater (Figure 37.21a). The interior walls of these pitchers are slippery and have downward-pointing hairs. Insects and other small animals such as lizards and frogs that fall into the pitchers are unable to climb out. Eventually, the trapped animals drown and are digested by microbes living within the pitchers.

Plants with active mechanisms, such as Venus flytraps and sundews, have traps that are stimulated by touch. Charles Darwin, who was fascinated by carnivorous plants, was one of the first to study the trapping mechanisms of Venus flytraps and sundews. The Venus flytrap (*Dionaea muscipula*) has an active trap formed by two-lobed leaves that are edged with lance-shaped teeth (Figure 37.21b). The leaf surface has glands that secrete carbohydrates, which lure prey, as well as glands that secrete digestive enzymes after prey has been trapped. Also present on leaf surfaces are modified hairs, usually three per leaf lobe. If a single hair is touched—perhaps by wind or rain, or debris—and another touch does not occur soon thereafter, nothing happens. But when a fly or similar prey lands on the leaf and brushes against the same hair twice, or touches a second hair within 20–40 seconds, the leaf lobes snap shut around it. Experimental studies indicate that an action potential develops in the stimulated hairs and then travels along plasma membranes, via plasmodesmata, at about 10 cm per second. This signal causes leaf cells to take up ions and water so that the leaf enlarges and changes shape, springing the trap. Digestion of the prey is typically finished within 10 days, whereupon the trap may reopen. Trap leaves can go through three or four digestive cycles during their lifetime.

Sundews (such as *Drosera rotundifolia*) have leaves bearing glandular hairs whose sticky tips glisten in the sunlight. Insects that land on sundew leaves get mired in the sticky mucilage exuded by these hairs, as shown in the chapter-opening photo. As the insects struggle to get away, they become covered with more mucilage and eventually smother as their breathing pores become clogged. Darwin discovered that sundew leaves bend after being touched and that glandular hairs not originally in contact with the insects also bend, folding over the prey as you would fold your fingers over an object in your palm. Later, investigators discovered that this bending involves the plant hormone auxin. In response to touch, auxin accumulates in sundew leaf tips and then flows downward, stimulating the cell expansion that causes the leaf bending. The glandular hairs also produce enzymes that digest the prey.

Parasitic Plants Obtain Nutrients from Photosynthetic Plants

More than 4,500 species of plants live as complete or partial **parasites**, organisms that obtain all or much of their water, minerals, and organic compounds from another organism. Dodder and witchweed are prominent examples of plants that are completely parasitic.

Dodder (*Cuscuta pentagona*) lacks roots and does not grow from the soil. Instead, all of the 150 species of this parasite live aboveground (Figure 37.22). These parasites twine their yellow or orange stems around green plant hosts, into which they sink peg-shaped, absorptive structures known as haustoria. These haustoria tap into the host plant's vascular system, stealing water, minerals, and sugar, which the parasite uses for growth and reproduction. The long, flexible stems of dodder often loop from one plant to another, such that an individual dodder plant

(a) This pitcher plant (genus *Nepenthes*) passively captures animals that accidentally fall into its water-filled pitcher.

(b) The Venus flytrap (*Dionaea muscipula*) has an active trap that is stimulated by the touch of its prey, in this case, a fly.

Figure 37.21 Carnivorous plants.

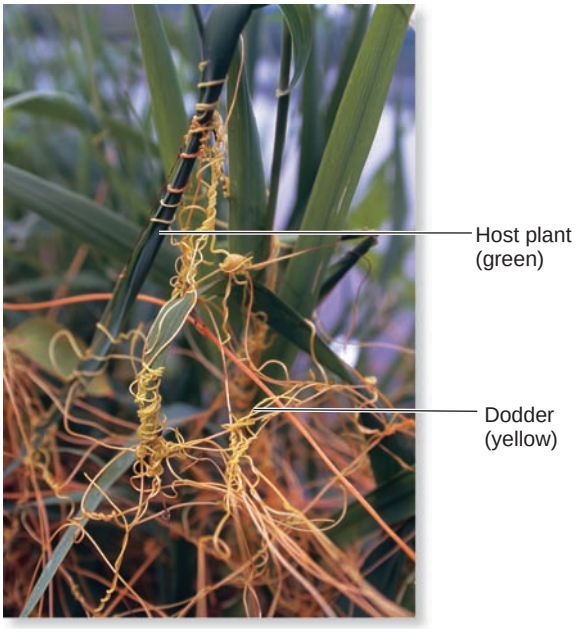

Figure 37.22 **A parasitic plant.** Dodder (*Cuscuta pentagona*) is an example of a parasitic plant that obtains all of its water, minerals, and organic compounds from one or more green plant hosts.

can tap into many different plants at the same time. Dodder reproduces very rapidly by means of broken-off stem fragments and seeds. A single dodder plant can produce more than 16,000 seeds. In consequence, dodder is a widespread agricultural pest that attacks citrus, tomatoes, and many other fruit, vegetable, forage, and flower crops.

Another group of parasitic plants, the witchweeds (genus *Striga*), are serious problems for African agriculture, because these parasites attack the major cereal crops: corn, sorghum, and millet. Witchweed seeds lie dormant in soil until secretions from host plant roots stimulate their germination. Genetic engineers are working to find ways to protect crops from the debilitating effects of these crop parasites.

Summary of Key Concepts

37.1 Plant Nutritional Requirements

- In addition to light, green plants require CO_2, absorbed from the air, water, and several types of minerals absorbed from water in the soil. (Figure 37.1, Table 37.1)
- Green plants are autotrophs that use light as the energy source for producing organic compounds. Flowering plants that have lost photosynthetic capacity must obtain energy by metabolizing organic compounds absorbed from their environment. (Figure 37.2)
- Plants display many adaptations that allow them to cope with insufficient or excess amounts of light and inadequate CO_2. Some of these adaptations may be usefully engineered into crop plants as a way of improving food production. (Figures 37.3, 37.4, 37.5)
- Nutrients can limit plant growth and cause nutrient-deficiency symptoms. (Figure 37.6)

37.2 The Role of Soil in Plant Nutrition

- Soil structure affects aeration, water-holding capacity, and fertility, factors that influence root and plant growth. Soil structure depends largely on particle sizes of inorganic soil components (sand, silt, and clay) and the amount of organic material that is present. (Figures 37.7, 37.8, 37.9, 37.10)
- Organic soil components, collectively known as humus, help soil hold water and mineral nutrients and provide the soil's soft consistency.
- Inorganic soil components include mineral nutrients dissolved in soil water. Clay particles electrostatically bind cations, which can be released by ion exchange. (Figure 37.11)
- The addition of organic fertilizers, which release minerals relatively slowly, can compensate for humus and mineral deficiencies in the soil. Inorganic fertilizers are washed more rapidly from soils and can contaminate natural waters when excessively applied. In aquatic habitats, excess mineral nutrients washed from agricultural fields can cause excessive growths of cyanobacteria, algae, and plants that harm other organisms.
- Plants take up fixed nitrogen in the form of ammonium ion or nitrate. To utilize nitrate, plant cells must convert it to ammonium ion. (Figure 37.12)
- Biological or industrial processes can convert atmospheric nitrogen gas into fixed nitrogen. Biological nitrogen fixation can be performed only by certain prokaryotes. (Figures 37.13, 37.14)
- Plants display several types of adaptations to cope with phosphate deficiency. Genetically modified smart plants can signal impending phosphate deficiency. (Figure 37.15)
- Some soil minerals inhibit plant growth, and some plants, called hyperaccumulators, are adapted to cope with high concentrations of toxic soil minerals. Such plants can be used to remove harmful minerals from soil in the process known as phytoremediation. (Figure 37.16)

37.3 Biological Sources of Plant Nutrients

- Mycorrhizal fungi, which are associated with the roots of most plants, provide plants with water, phosphorus, and other minerals. (Figure 37.17)
- Nitrogen-fixing prokaryotes living within the tissues of some plants provide them with fixed nitrogen. Legume–rhizobia associations are particularly important in nature and in agriculture. (Figures 37.18, 37.19, 37.20)
- Carnivorous plants obtain mineral nutrients from the digested bodies of trapped animals. (Figure 37.21)
- Parasitic plants obtain water, mineral ions, and organic compounds from green plant hosts. (Figure 37.22)

Assess and Discuss

Test Yourself

1. Which of the following substances can limit plant growth in nature?
   a. sunlight
   b. water
   c. carbon dioxide
   d. fixed nitrogen
   e. all of the above
2. In what form do plants take up most soil minerals?
   a. as ions dissolved in water
   b. as neutral salts
   c. as mineral–clay complexes
   d. linked to humus particles
   e. none of the above
3. Why do plants need sulfur?
   a. for the construction of cell walls
   b. as an essential component of chlorophyll
   c. to produce the amino acids cysteine and methionine
   d. all of the above
   e. none of the above
4. Humus is
   a. a food produced from garbanzo beans.
   b. the organic constituents of soils.
   c. the inorganic constituents of soils.
   d. the bedrock layer of soils.
   e. none of the above.
5. Which environments are conducive to heavy leaching of minerals from soils?
   a. those having soils that are composed primarily of sand particles
   b. those having acidic soils
   c. those impacted by acid rain
   d. regions characterized by heavy rainfall
   e. all of the above
6. Which property is not characteristic of clay-rich soils?
   a. high mineral nutrient retention
   b. high water retention
   c. high aeration
   d. lower amounts of sand than clay
   e. all of the above
7. Which of the substances listed is toxic to plants?
   a. carbon dioxide
   b. oxygen
   c. atmospheric nitrogen gas
   d. aluminum
   e. none of the above
8. What kinds of organisms occur in nitrogen-fixing symbioses with plants?
   a. cyanobacteria
   b. actinobacteria
   c. rhizobia bacteria
   d. all of the above
   e. none of the above
9. How do legume roots attract rhizobia?
   a. They secrete flavonoids.
   b. They secrete carotenoids.
   c. They secrete alkaloids.
   d. They secrete Nod factors.
   e. none of the above
10. Which plant uses a passive trap to obtain animal prey as a source of mineral nutrients?
    a. the Indian pipe (*Monotropa uniflora*)
    b. the tropical pitcher plant (*Nepenthes* spp.)
    c. the Venus flytrap (*Dionaea muscipula*)
    d. dodder (*Cuscuta* spp.)
    e. all of the above

Conceptual Questions

1. Why are agricultural experts and ecologists alike concerned about overfertilization of crop fields?
2. Describe how plant roots acquire enough boron to serve essential needs without transporting toxic amounts of this mineral to shoots.
3. Draw a diagram showing how rhizobia and legume roots communicate chemically during nodule formation.

Collaborative Questions

1. Imagine that you have bought a farm and want to start growing a crop to sell at a local market. How could you go about determining if the soil needs to be fertilized and with what mineral nutrients?
2. Imagine that you own a large farm with a trout stream running through it. How would you protect the water quality of the stream?

Flowering Plants: Transport

38

A shade tree. The evaporation of water from plant leaves cools them and us, and even affects local and global climate.

On hot days, people naturally gravitate to the cool shade beneath trees, as shown in the chapter-opening photo. But most people do not realize that trees are not only sun umbrellas. Plants actually cool the air around them as water evaporates from their surfaces. That's why grass feels cool when you walk barefoot on it, even on a hot day.

Plants benefit from this evaporation process—known as transpiration—because it cools their surfaces and enables the movement of a continuous stream of water from the soil, through roots and stems, to leaves. This evaporation process not only helps to distribute water throughout the plant body, it also aids the movement of dissolved minerals and organic compounds such as sugars, hormones, and other organic materials over long distances within plants. Transport is therefore crucial for the functions of plant growth, behavior, and nutrition, which were described in the preceding three chapters.

In addition, plant transport plays a critical role in Earth's global climate. On a worldwide basis, plant transpiration moves huge amounts of water from the soil into the atmosphere as water vapor. Together with water evaporated from the surfaces of oceans and freshwater bodies, plant-produced water vapor is a source of rain. Along with other atmospheric gases (including carbon dioxide and methane), water vapor also works as a greenhouse gas that helps to warm Earth's climate by absorbing the sun's heat. Plant transport processes are also relevant to agriculture, as humans seek to improve crop productivity and the efficiency of water and nutrient use.

To comprehend plant transport more fully, in this chapter, we will first survey the materials that move through plants and the general directions of material movements. Next, we will focus more closely on water and solute uptake by plant cells. We will then examine how these materials are moved within plants over short and long distances and explore some of the plant adaptations that allow such transport to be as efficient as possible in a variety of environments. In the process, we will learn why plants are so cool!

Chapter Outline

38.1 Overview of Plant Transport

Our previous studies of angiosperm plant structure and nutrition described the interdependence of plant root and shoot systems (see Chapters 35 and 37). We have observed that in most plants, the root system absorbs water and dissolved minerals from the soil and that the shoot system takes up carbon dioxide (CO_2) from the atmosphere (Figure 38.1). Carbon dioxide enters plants via stomata, pores that occur in the surfaces of leaves and other aboveground structures. Photosynthetic cells use these materials to produce sugar and other organic compounds needed for overall plant growth and reproduction. Nonphotosynthetic plant cells, such as those of roots and flowers, depend upon organic food produced by green tissues. Therefore, plants must transport water and minerals upward from roots to shoots and transport organic food from photosynthetic to nonphotosynthetic parts. Since plants can grow to sizeable heights, the tallest trees being over 100 meters tall, transport of materials often occurs over long distances.

The long-distance transport of water, dissolved minerals, and sugar throughout the plant body occurs within a continuous system of conducting tissues. Recall that the complex tissues of vascular plants that primarily conduct water and dissolved minerals are known as the xylem, and those that conduct organic substances in a watery sap are termed the phloem. These conducting tissues are key to the ability of vascular plants to thrive in terrestrial habitats, which can sometimes be quite arid. To

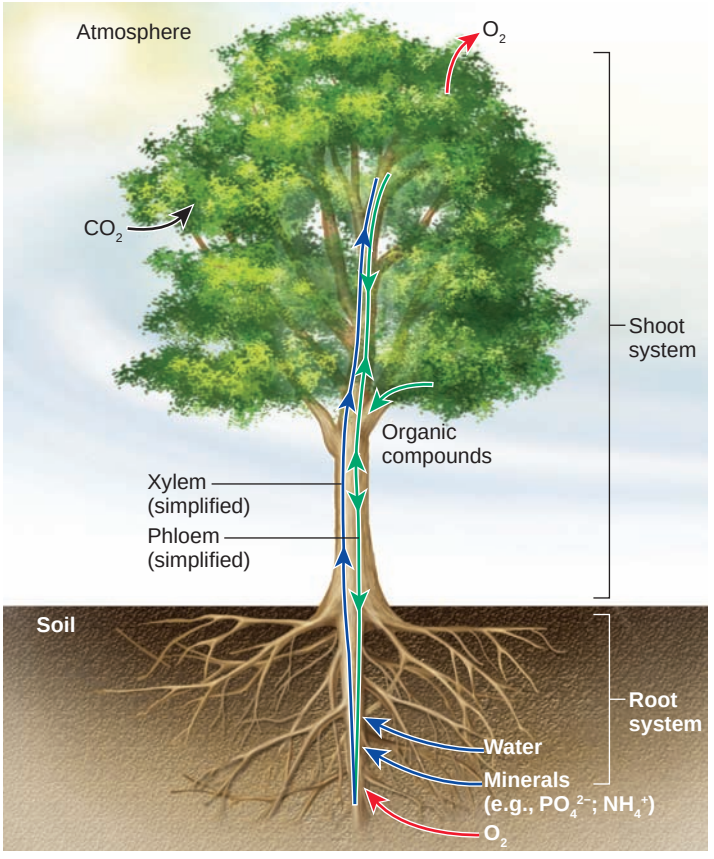

Figure 38.1 Overview of material uptake and long-distance transport processes in plants.

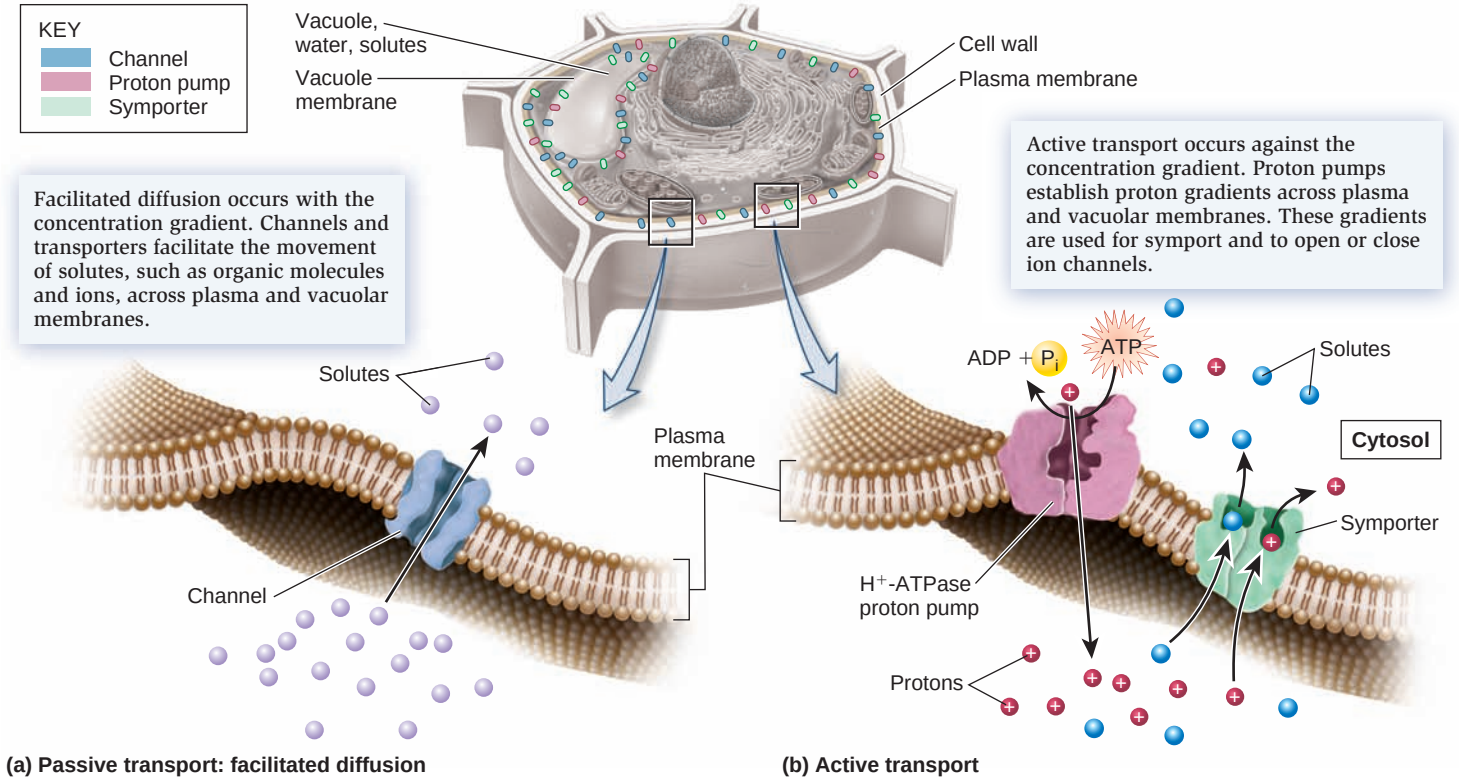
fully understand how plants accomplish long-distance transport, we will begin by reviewing the processes by which minerals, organic compounds, and water are taken up and move at the cellular level.

38.2 Uptake and Movement of Materials at the Cellular Level

Chapter 5 described how cells use both passive and active processes to import or export materials. Here, we briefly review these processes, describing and contrasting them and illustrating how they work in flowering plants.

Passive Transport Does Not Require the Input of Energy

Recall from your earlier studies of plasma membranes that water, gases, and certain small, uncharged compounds can diffuse across membranes in the direction of their concentration gradients. **Passive transport** is the movement of materials into or out of cells down a concentration gradient without the expenditure of energy in the form of ATP. Passive transport across plasma membranes occurs in two ways: by passive diffusion or facilitated diffusion. **Passive diffusion** into or out of cells is the movement of molecules through a phospholipid bilayer down a concentration gradient. **Facilitated diffusion** is the transport of molecules across plasma membranes down a concentration gradient with the aid of membrane transport proteins (Figure 38.2a; see also Chapter 5).



(a) Passive transport: facilitated diffusion

(b) Active transport

Figure 38.2 Passive and active transport.

The two main types of membrane transport proteins that function in facilitated diffusion are channels and transporters. **Channels** are membrane pores formed by proteins that allow movement of ions and molecules across membranes (refer back to Figure 5.21). **Transporters** are proteins that transport molecules by binding them on one side of the membrane and then changing conformation so that the molecule is released to the other side of the membrane (refer back to Figure 5.22). Transporters increase the rate at which specific mineral ions and organic molecules are able to enter or leave plant cells and vacuoles.

Recall that osmosis is the diffusion of water across a selectively permeable membrane in response to differences in solute concentrations. In the case of plants, water moves from a solution that has a lower solute concentration (soil) to one of higher solute concentration (root cells). Osmotic water uptake into living plant cells is essential to photosynthesis, as well as to cell expansion and structural support. However, the passive diffusion of water does not occur rapidly enough to supply the water needs of rapidly expanding plant cells. In this case, facilitated diffusion of water occurs through protein channels known as **aquaporins**, which occur widely in living things (refer back to Figure 5.20). Thirty-five distinct aquaporin genes have been identified in the genome of the model plant *Arabidopsis*. Aquaporins increase the rate at which water flows into expanding plant cells and their vacuoles. In the same way, many other types of plasma membrane protein channels and transporters facilitate the diffusion of specific mineral ions and organic molecules into and out of plant cells and vacuoles. If a substance must be transported across a plasma membrane against its concentration gradient, however, work must be performed in the process known as active transport.

ATP Hydrolysis Powers Active Transport

During **active transport**, membrane transporter proteins use energy to move substances against their concentration gradients. An example is the H^+-ATPase proton pump, found in the plasma membranes of plant cells, which uses ATP to pump H^+, which are protons, against a gradient (Figure 38.2b). This proton gradient generates an electrical difference across the membrane, which is known as a **membrane potential**. Energy is released when protons pass back across the plasma membrane, in the direction of their electrochemical gradient. This energy can then be used to power other active transport processes. For example, it might be used to open or close ion channels or in the functioning of a proton **symporter** (a protein that transports two substances in the same direction across a membrane) that is needed for the uptake of organic materials such as sugars, amino acids, and nucleotide bases.

Proton pumps occur in vast numbers in the vacuolar membrane as well as in the plasma membrane. The large vacuole present in many plant cells serves as a storage site for ions and other substances that move in or out via active transport. For example, vacuoles store calcium ions until they are needed in signal transduction processes, and they store reserves of nitrate (see Chapter 37). Active transport proteins are particularly abundant in root cell membranes (Figure 38.3), allowing root cells to concentrate dissolved mineral nutrients to more than 75 times their abundance in soil. As a result, soil water flows into root cells by osmosis. We next take a closer look at osmotic water movement into and out of plant cells.

Cellular Water Content Is Influenced by Solute Content and Turgor Pressure

The water content of plant cells depends on osmosis, and osmosis depends on two factors: solute content and turgor pressure. **Turgor pressure** is the hydrostatic pressure that increases as water enters plant cells, because their cell walls restrict the extent to which the cells can swell.

A plant cell whose cytosol is so full of water that the plasma membrane presses right up against the cell wall is said to be **turgid** (Figure 38.4a). The pressure relationship between the cytosol and cell wall recalls the way that a soccer ball's leather skin presses inward upon the air within, while at the same time the internal air presses on the ball's cover. If you add more air to a limp ball, the ball will stiffen. In the same way, if a nonturgid cell absorbs more water, it will become more rigid as the water exerts pressure on the cell wall. By contrast, a plasmolyzed cell is one that has lost so much water by osmosis

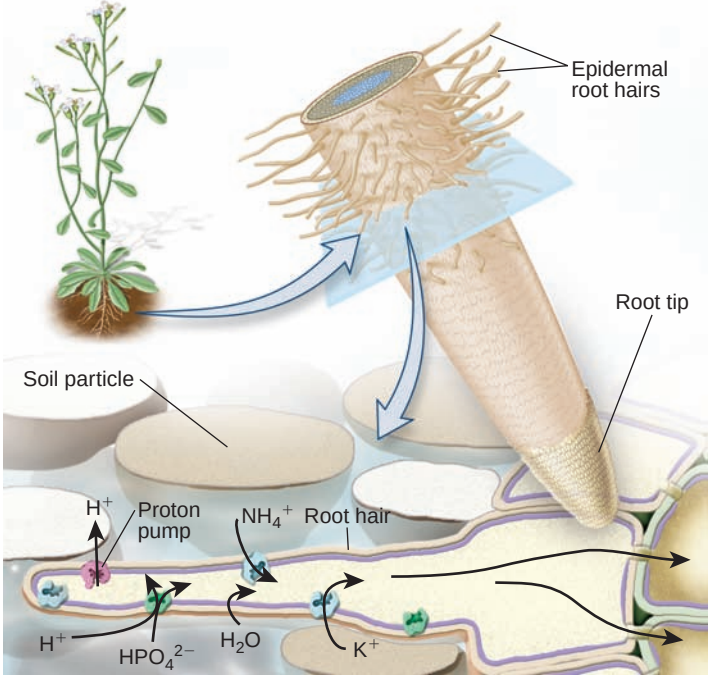


Figure 38.3 **Ion uptake at root-hair membranes.** When soil mineral ion concentrations are lower than those within cells, root-hair plasma membranes take up nutrient ions by active transport. The H^+-ATPase establishes an electrochemical gradient that drives the active uptake of solutes. The resulting increase in intracellular solute concentration also drives the osmotic diffusion of water into the cell.

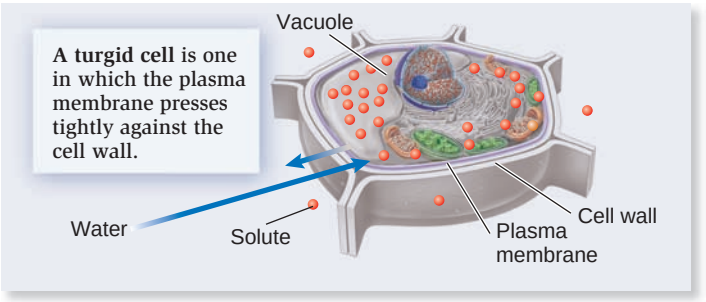
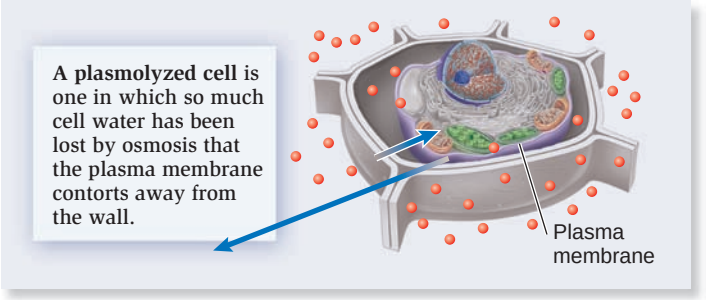
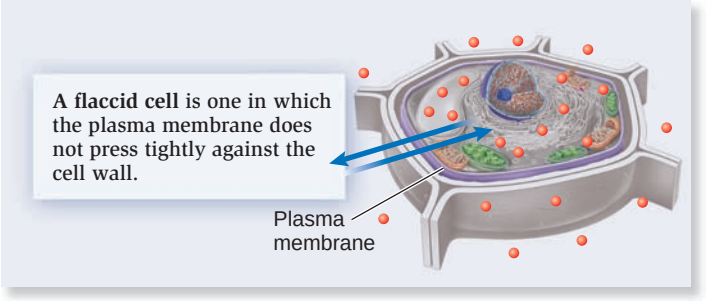


(a) Turgid cell in a hypotonic solution



(b) Plasmolyzed cell in a hypertonic solution



(c) Flaccid cell in an isotonic solution

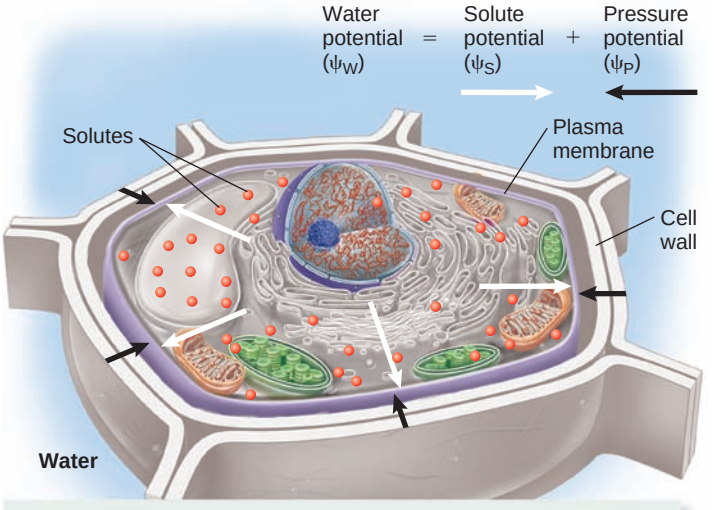
Figure 38.4 **Turgid, plasmolyzed, and flaccid plant cells.** **(a)** When the concentration of solutes inside a cell is higher than that outside (the cell is surrounded by a hypotonic solution), more water will enter the cell than will leave it. As a result, a plant cell will become swollen, or turgid. **(b)** When the concentration of solutes outside a cell is greater than within it (the cell is surrounded by a hypertonic solution), more water will leave the cell than will enter it. As a result, a plant cell will become plasmolyzed. **(c)** When the concentration of solutes is the same outside and inside a plant cell (the cell is bathed in an isotonic solution), it will be flaccid.

that turgor pressure has also been lost. **Plasmolysis** is the condition in which the plasma membrane no longer presses on the cell wall (Figure 38.4b). A cell having a water content between these two extremes is termed a flaccid cell (Figure 38.4c).

Together, solute concentration and turgor influence an important plant cell property known as water potential. What is water potential? Recall that potential energy is the stored energy of a material or system, with the capacity to perform work. **Water potential** is the potential energy of water. A waterfall analogy illustrates that water moves from a region of higher water potential to a region of lower water potential, in this case, as the result of gravity. Pressure also influences water potential; a waterfall would flow upward if pressure greater than the force of gravity were applied. Solutes and some other factors also affect water potential. Water potential is measured in pressure units known as megapascals (MPa) (a pascal is equal to 1 newton per square meter). One MPa is equal to 10 times the average air pressure at sea level. As another reference point, 1 MPa is several times the pressure in typical home plumbing pipes, which you experience when turning on a water faucet.

In the study of plants, the concept of water potential is used in two ways: to understand the movement of water into and out of cells (cellular water potential) and to understand the water status of entire plants or organs (relative water content). We begin by considering the water potential of cells.

Cellular Water Potential A water potential equation can be used to predict the direction of cellular water movement, given information about the solute concentrations inside and outside of plant cells, and a measure of pressure at the cell wall–membrane interface (Figure 38.5). In this equation, cellular water potential is symbolized by the Greek letter psi (ψ) with the subscript W for water: ψ_W. In its simplest form, total



Examples of ψ_W calculations:

Turgid cell	Plasmolyzed cell	Flaccid cell
$\psi_S = -0.1$	$\psi_S = -1.0$	$\psi_S = -0.5$
$\psi_P = +0.1$	$\psi_P = 0.0$	$\psi_P = 0.0$
$\psi_W = 0.0$ MPa	$\psi_W = -1.0$ MPa	$\psi_W = -0.5$ MPa

Figure 38.5 **Plant-cell water potential.** The water potential of a plant cell, which predicts the direction of water movement into or out of a cell, can be simplified as the sum of the solute potential and the pressure potential resulting from pressure exerted by the cell wall–plasma membrane complex. Examples of water potential calculations are shown for a turgid cell, a plasmolyzed cell, and a flaccid cell.

Concept check: *Make a drawing that shows the direction of water movement when a cell of each of these types is placed into a solution of pure water (whose water potential, ψ_W, is defined as 0 MPa).*

ψ_W is calculated as the sum of the **solute potential** (ψ_S), also known as the osmotic potential, and the **pressure potential** (ψ_P). A simple form of the water potential equation is

$$\psi_W = \psi_S + \psi_P$$

Solute potential is the component of water potential due to the presence of solute molecules. As you might expect, solute potential is proportional to the concentration of solutes in a solution. The solute potential of pure water open to the air, at sea level and room temperature, is defined as zero. When solutes are added, they interact with water molecules, thereby diluting the water and affecting its disorder. As a result, fewer free water molecules are present, which reduces the potential energy of water. Thus, in the absence of a pressure potential, water that contains solutes always has a negative solute potential. The higher the concentration of dissolved solutes, the lower (more negative) the solute potential.

Pressure potential is the component of water potential due to hydrostatic pressure. In plant cells, the hydrostatic pressure is determined in part by the resistance provided by the cell wall. Because of this resistance, the value for pressure potential can be either positive or negative. For example, a turgid cell has a positive pressure potential, which typically measures about 1 MPa. This high pressure inside turgid plant cells is a testimony to the strength of their cellulose-rich plant cell walls. In contrast to turgid cells, both flaccid and plasmolyzed cells have a pressure potential of zero. Plants or plant organs having many cells with low turgor pressure will appear wilted. If your houseplants become wilted, watering will enable the cells to increase their pressure potential, restoring cell turgor and normal plant appearance. Therefore, the water content of an entire organ or plant is influenced by the water potential of its component cells.

Relative Water Content The property known as **relative water content** (**RWC**) is often used to gauge the water content of a plant organ or entire plant. RWC integrates the water potential of all cells within an organ or plant and is thus a measure of relative turgidity. Measurements of RWC can be used to predict a plant's ability to recover from the wilted condition. An RWC of less than 50% spells death for most plants, but some plants can tolerate lower water content for substantial time periods.

A standard method for determining RWC was developed by plant biologists H. D. Barrs and Paul E. Weatherley in 1962. This process involves three simple weight measurements: fresh weight, turgid weight, and dry weight. Sample tissue taken from a plant under a given set of conditions is first weighed to obtain the fresh weight. Then it is completely hydrated in water within an enclosed, lighted chamber until constant turgid weight is achieved. Finally, the sample is dried to a constant dry weight. Researchers use these measurements to calculate RWC using the equation

$$\text{RWC} = \frac{(\text{fresh weight} - \text{dry weight})}{(\text{turgid weight} - \text{dry weight})} \times 100$$

RWC measurements have been very useful in ecological studies of natural plant adaptation to cold, drought, or salt stress and in agricultural research for developing drought-tolerant crops. Agricultural research reported by R. Chandra Babu, Henry Nguyen, and colleagues in 2004 provides an example. These investigators used measurements of leaf RWC to evaluate rice crops that had been genetically engineered with a barley gene that confers dehydration tolerance. Developing new crops that are better able to withstand water stress requires an understanding of not only water potential but also how plant cells cope with cellular osmotic stress, which leads to water stress.

Plant Adaptations to Cellular Osmotic Stress Plants native to cold, dry, or saline environments have evolved many different adaptations that allow them to cope with low water content. For example, plants often increase the solute concentrations of their cell cytosol, a process known as **osmotic adjustment**. Increased amounts of the amino acid proline, sugars, or sugar alcohols such as mannitol decrease the cells' water potential, thus drawing water into cells. By increasing the concentration of solutes inside cells, cold-resistant plants prevent water from moving out of their cells when ice crystal formation in intercellular spaces lowers the water potential outside cells. The additional solutes also lower the freezing point of the cytosol, for the same reason that adding antifreeze to a car's radiator in winter keeps the radiator fluid from freezing.

Plants of arid lands often possess adaptations that help them survive water stress. Many can survive in a nearly dry state for as much as 10 months of the year, growing and reproducing only after the rains come. The cytosol of such desiccation-tolerant plants is typically rich in sugars that bind to phospholipids to form a glasslike structure. This helps to stabilize the cellular membranes, preventing them from becoming damaged during plasmolysis (see Figure 38.4b). Plant cells under water stress may also increase the number of plasma membrane aquaporins. These additional protein channels increase the rate of water uptake, allowing cells to recover turgor more quickly when water becomes available.

Halophytes are plants that are able to grow in salty habitats, including coastal salt marshes. Plant cells cannot readily absorb salty water because of its highly negative water potential. Halophytes have therefore acquired adaptations to help them cope with osmotic stress. Some halophytes accumulate inorganic salts in their vacuoles and organic solutes in their cytosol. Such storages balance solute concentrations inside and outside cells, preventing osmotic water loss. Halophytes also display adaptations that help rid their bodies of excess salt. Some halophytes excrete salt from root surfaces, while others transport excess salt to their leaf epidermal cells, where it forms crystals (look ahead to Figure 54.16). Some halophytes accumulate salt within multicellular surface glands that break off or burst harmlessly. The water potential adaptations of desiccation-tolerant plants and halophytes are of special interest to agricultural scientists seeking to develop crops that are able to grow in arid lands or in places where the soil or water used for irrigation is salty.

38.3 Tissue-Level Transport

Now that we have learned more about how water, dissolved minerals, and organic compounds enter or leave plant cells, we are prepared to consider short-distance transport within and among nearby tissues. Tissue-level transport occurs in three forms: transmembrane transport, symplastic transport, and apoplastic transport (Figure 38.6).

Transmembrane transport involves the export of a material from one cell, followed by import of the same substance by an adjacent cell (Figure 38.6a). One prominent example of transmembrane transport is the movement of the plant hormone auxin downward in shoots. Auxin travels from one phloem parenchyma cell to another in a linear series (Chapter 36). This process explains how auxin produced in one part of the plant body can influence more distant tissues.

Symplastic transport is the movement of a substance from the cytosol of one cell to the cytosol of an adjacent cell via membrane-lined channels called plasmodesmata (Figure 38.6b). Plasmodesmata also have a central tubule called a desmotubule that connects endoplasmic reticulum of adjoining cells (refer back to Figure 10.14). Plasmodesmata are large enough in diameter to allow transport of proteins and nucleic acids, as well as smaller molecules. These molecules primarily move by diffusion, though in some cases, special movement proteins facilitate transport through plasmodesmata. Together, all of a plant's protoplasts (the cell contents without the cell walls) and plasmodesmata form the **symplast**. Symplastic transport has the potential to move molecules widely among the cells and tissues of the plant body.

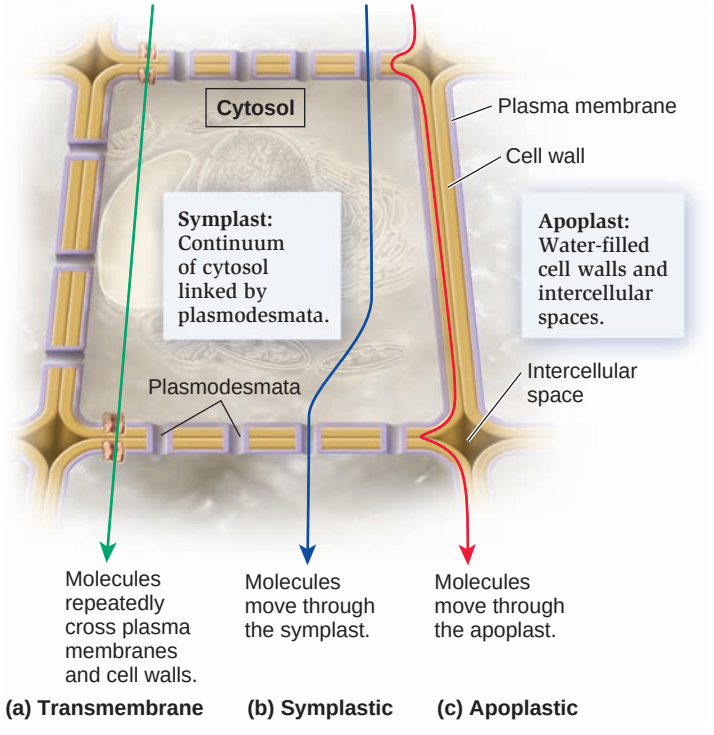


Figure 38.6 Three routes of tissue-level transport in plants: (a) transmembrane, (b) symplastic, and (c) apoplastic.

In contrast to the symplast, the **apoplast** refers to the continuum of water-soaked cell walls and intercellular spaces (Figure 38.6c). **Apoplastic transport** is the movement of solutes along cell walls and the spaces between cells. Water and dissolved minerals often move through plant tissues for short distances by apoplastic transport.

Both symplastic and apoplastic transport play important roles in mineral nutrient transport through the outer tissues of roots (Figure 38.7). As we have noted, the plasma membrane of epidermal root hair cells is rich in channels and transporters that selectively absorb essential mineral ions from soil water. Absorbed ions can move symplastically from the cytosol of root hairs, cortex, and endodermis directly to xylem parenchyma cells. Plasmodesmata make such cell-to-cell, tissue-level transport possible.

Apoplastic transport can also move water and dissolved minerals into root epidermal and cortex tissues. However, apoplastic movement of water and minerals stops at the **endodermis**, a term meaning "inside skin." In roots, the endodermis is a thin cylinder of tissue whose close-fitting cells and specialized cell walls form a barrier between the cortex and the central core of vascular tissue. Materials in the root apoplast cannot penetrate farther into the root unless endodermal cells transport them into their cytosol, a process that requires specific transporter proteins.

Root endodermal cell walls possess ribbon-like strips of waterproof suberin, composed of wax and phenolic polymers. These suberin ribbons, known as **Casparian strips**, prevent apoplastic transport through endodermal cell walls and into the root vascular tissues (Figure 38.8). The root endodermis prevents harmful solutes (such as toxic metal ions) from moving through the apoplast to vascular tissues and being transported to the shoot. For example, recall that aluminum ions (Al^{3+}) are commonly dissolved in soil water, but they are not plant nutrients and are highly toxic to plants (see Chapter 37). Aluminum ions can penetrate the root epidermis and cortex by moving through the apoplast, but they stop at the endodermis because they are unable to enter the cytosol of endodermal cells. Keep in mind, however, that while the endodermis is effective in reducing the entry of toxic metal ions, these substances can enter roots at root tips, which lack a mature endodermis, and in places where a branch root has broken through the endodermis (refer back to Figure 35.26).

Endodermal plasma membranes possess specific channels and transporters for essential mineral nutrients (such as K^+), which are thereby able to enter the cytosol of root endodermal cells. By moving through endodermal cytosol, symplastically transported essential minerals are able to bypass the endodermal barrier that limits apoplastic transport. Therefore, the root endodermis functions as a molecular filter that allows the passage of beneficial solutes that have entered from the symplast or have been specifically transported into endodermal cytosol. Once solutes have passed the endodermal barrier, they are transported out of xylem parenchyma cells and into

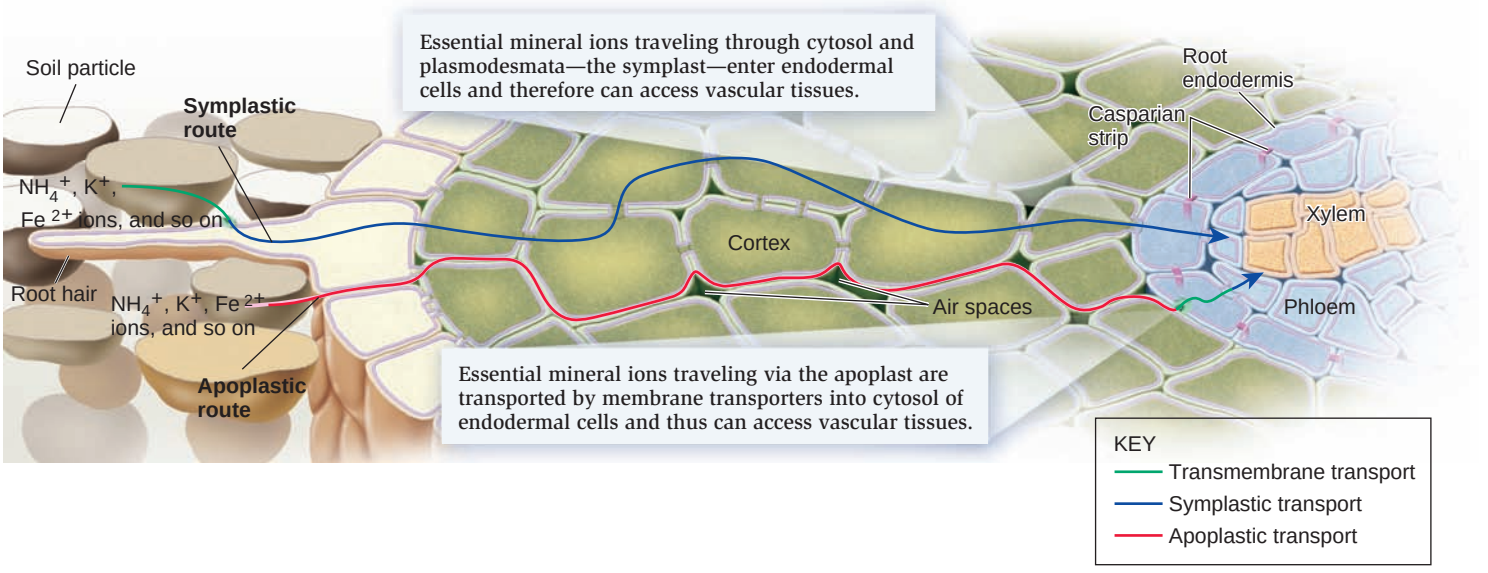

Figure 38.7 Symplastic and apoplastic transport of mineral ions in roots.

the apoplast of the vascular system, which includes conducting cells of the xylem (Figure 38.8). The endodermis prevents solutes from returning to outer root tissues or the soil, so the solute concentrations of xylem parenchyma cells rise, decreasing their cellular water potential. As a result, water flows into vascular tissues from outer root tissues and the soil. In the process known as **xylem loading**, large amounts of water and dissolved solutes enter the long-distance conducting cells of the xylem. In the next section, we will see how water and solutes are transported for long distances through the plant.

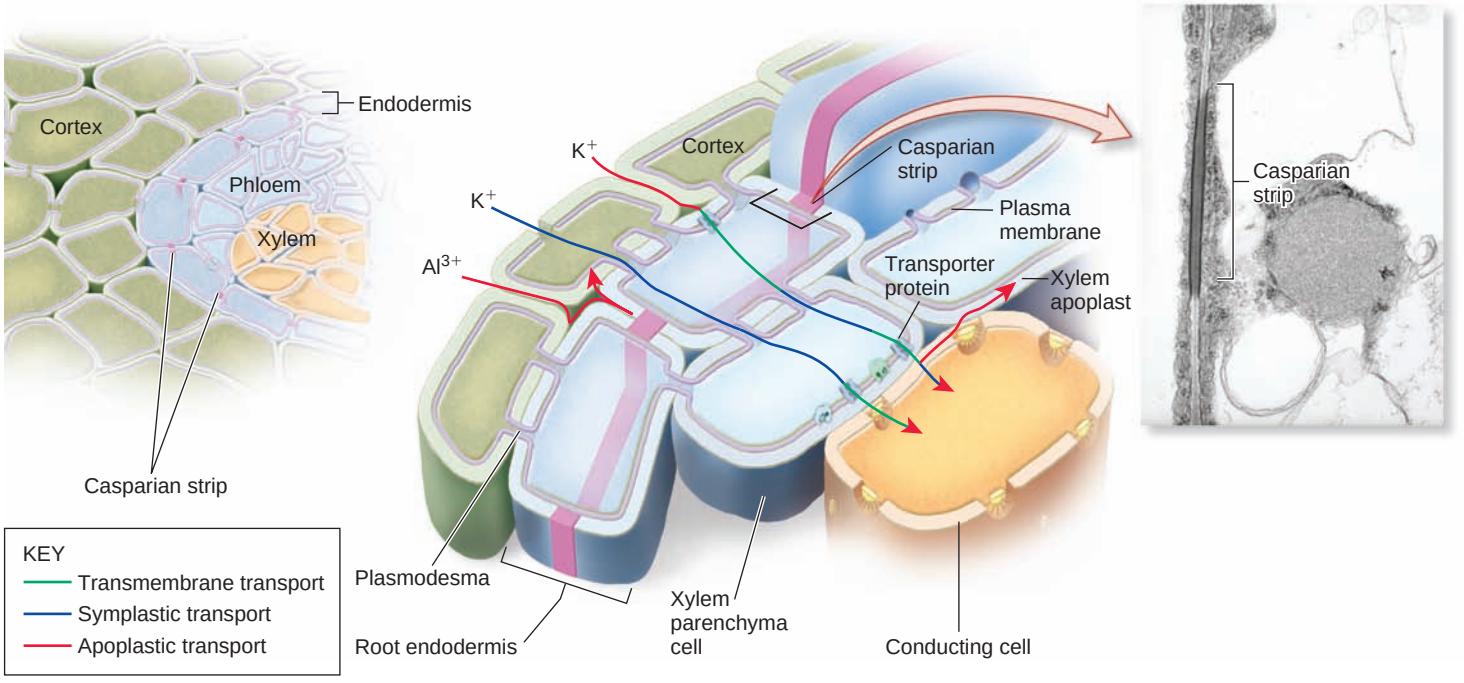

Figure 38.8 **Ion transport pathways across the root endodermis.** Casparian strips in endodermal cell walls prevent apoplastic transport across the root endodermis, limiting entry of harmful soil minerals such as Al^{3+} and exit of useful minerals. Mineral nutrients that are transported into the cytosol of endodermal cells are able to pass through the endodermal barrier to xylem parenchyma cells via plasmodesmata. Once past the endodermis, nutrient ions such as K^+ are moved across plasma membranes to the apoplast of the vascular tissue and are thus able to enter xylem. Inset shows a transmission electron micrograph (TEM) of a Casparian strip in the wall of an endodermal cell.

Concept check: *Where in most plants would you expect to find the highest concentration of Al^{3+}?*

38.4 Long-Distance Transport

Plants rely on long-distance transport to move water and dissolved materials from roots to shoots and among organs. Tall trees are able to transport water and minerals to astounding heights, more than 110 m in some cases. This is possible because plants possess an extensive, branched, long-distance vascular system composed of xylem and phloem tissues. Watery solutions move through these tissues by **bulk flow**, the mass movement of liquid caused by pressure, gravity, or both. Plant-conducting tissues are specialized in ways that foster bulk flow and aid plants in adapting to water stress. The evaporation of water at plant surfaces, the cohesion of water molecules to each other, the adhesion of water to the walls of conducting cells, and the tension that pulls water through those cells all are important physical forces that influence long-distance water transport. Gravity, though of negligible effect for shorter plants, must also be considered in the case of water transport in tall trees. In this section, we will take a closer look at bulk flow and the major factors involved in long-distance transport by this process.

Bulk Flow Is Water Movement Under the Influence of Pressure and Gravity

Bulk flow (also known as mass flow) occurs when molecules of liquid all move together from one place to another as the result of differences in pressure. One example of bulk flow is leaching, the movement of water and dissolved minerals downward through soil layers as the result of gravity. Bulk flow is one way in which mineral ions can move through soil toward plant roots. Likewise, once inside the plant, minerals and other dissolved solutes can move through xylem and phloem conducting tissues via bulk flow, which is much faster than diffusion.

Phloem sap, which contains sugars and other dissolved solutes, moves by bulk flow up to 1 m per hour. Bulk flow within xylem moves water from the roots to the uppermost leaves of 100-m-tall trees.

In plants, water and dissolved materials move by bulk flow through xylem tissues as the result of differences in root and shoot water pressure. The water pressure is lower in upper parts of plants than in lower parts because water diffuses through stomata into the atmosphere (Figure 38.9). In the phloem, bulk flow occurs because a high pressure builds up in leaves, which have relatively high solute concentrations. The pressure causes the water to flow to other regions having lower solute concentrations, such as developing fruit. Bulk flow is impeded by obstructions such as cytoplasm. This explains why xylem-conducting cells are devoid of cytoplasm and why phloem-conducting cells have reduced amounts of cytoplasm. Xylem and phloem share additional features related to bulk flow, which we will discuss later in this chapter.

Although xylem serves as the primary transport system for water and minerals, and phloem for organic compounds dissolved in water, the transport functions of xylem and phloem overlap somewhat. Phloem can aid in the distribution of certain minerals, and xylem sometimes transports organic compounds. For example, in early spring, trees convert starch stored in stem parenchyma cells into sugars that are used during bud expansion and flower development. These sugars are transported in xylem sap. Maple trees produce such a copious flow of sugar-rich xylem sap that people have long tapped them for making maple syrup (Figure 38.10).

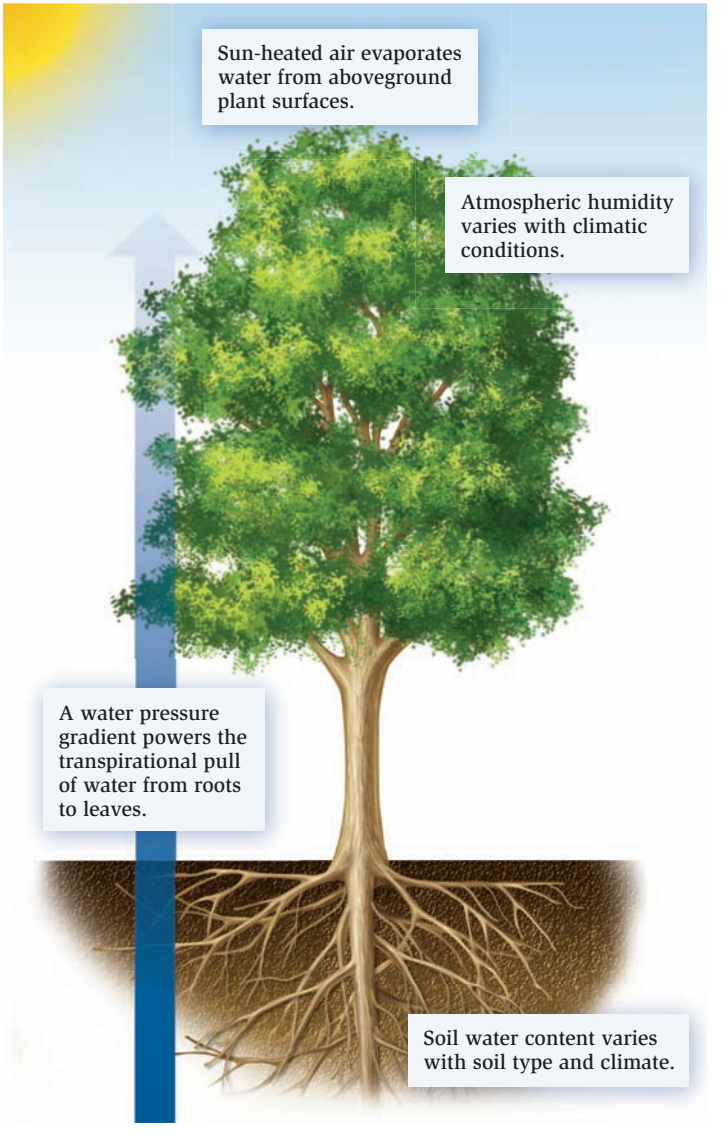

Figure 38.9 **Upward transport of water in xylem.** Water pressure differences between moist soil and drier air drive the upward movement of water in plants.

Long-Distance Transport of Water and Minerals Occurs in the Xylem

Xylem structure plays an essential role in its transport function. The xylem of flowering plants contains several types of specialized cells, some of which remain alive at maturity, and some

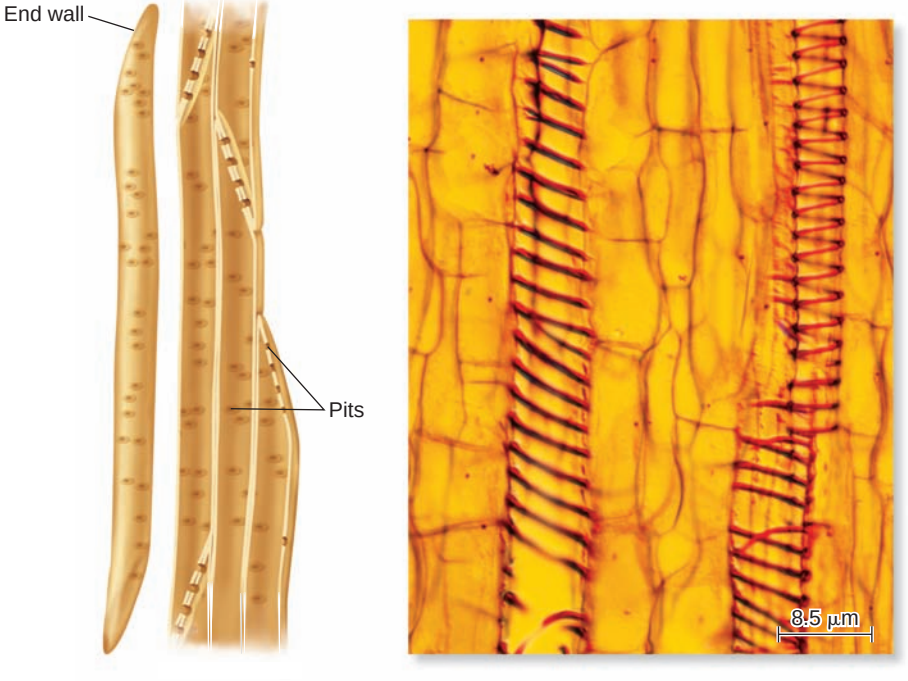
Figure 38.10 **Maple-sugar tapping.** In early spring, xylem transports sugar from storage sites to the shoot buds of woody plants such as this sugar maple. We use the xylem sap of sugar maples to produce maple syrup.

of which are dead when they are fully functional. Xylem parenchyma cells are alive, while thick-walled supportive fibers may be alive or dead at maturity. Two types of specialized water-conducting cells are always dead and empty of cytosol when mature: tracheids and vessel elements. Together, tracheids and vessel elements are known as **tracheary elements**. During the development of tracheary elements, a secondary wall is deposited in patterns on the inside of the primary cell wall. This secondary wall is rich in a plastic-like polymer known as lignin. Because lignin is resistant to compression, microbial decay, and water infiltration, it confers strength, durability, and waterproofing. Like the plumbing pipes of a building, tracheary elements do not readily collapse as water moves through them under tension. These characteristics explain why tracheary elements contribute to structural support of the plant body as well as transport.

Tracheids Long and narrow in shape, **tracheids** typically have slanted end walls that fit together to form long tubes (Figure 38.11a). The end walls of tracheids are not lignified, nor are large areas of the side walls of tracheids that occur in plant tissues that are still growing. Such tracheids are extensible because they have rings or spirals of lignin that allow tracheids to continue elongating (Figure 38.11b). In contrast, tracheids that develop in tissues that have already expanded have more lignin, which makes them rigid and unable to elongate any more. Tracheid walls that are extensively lignified display numerous small, lignin-free cell-wall regions known as **pits**. At such pits, the thin primary wall of the tracheid remains readily permeable to water. Water moves from one tracheid to another both vertically and laterally through pits.

Vessels and Vessel Elements Mature **vessel elements** are a second type of water-conducting cell present in xylem tissue. Vessel elements are aligned in pipeline-like files known as **vessels** (Figure 38.12a). Flowering plants are distinguished from other plant groups by the abundance of vessels; nonflowering plants primarily rely on tracheids for water conduction. Vessel elements are larger in diameter than tracheids, conferring greater capacity for bulk flow and therefore represent one of the many ways in which flowering plants are particularly well adapted to life on land.

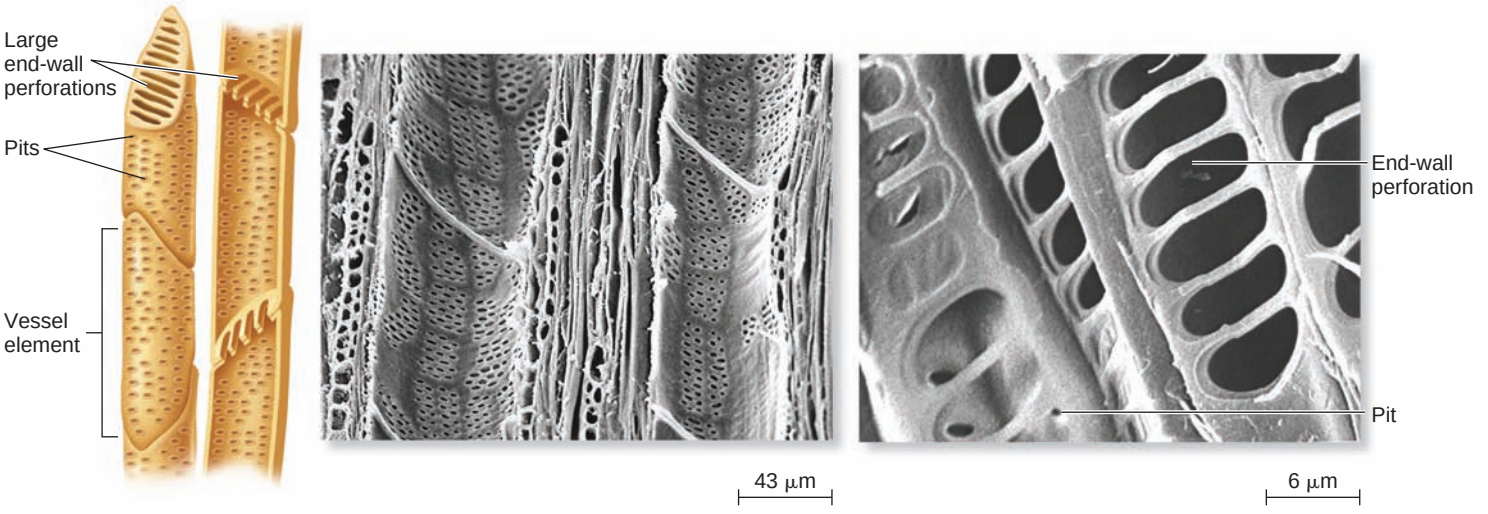
Development of vessel elements resembles that of tracheids in some ways. For example, lignified secondary walls are deposited in spirals or sheets on the inside of the primary cell



(a) Tracheids (b) Extensible tracheids

Figure 38.11 **Tracheid cells in xylem tissue.** **(a)** Tracheids are long, tubular cells with slanted end walls. Water and ions move from cell to cell through the pits. **(b)** Light micrograph of extensible tracheids from the xylem of pumpkin.

Concept check: *If you applied a stain specific for lignin to tracheids present in a longitudinal slice of a plant stem that is still growing in length, then observed the cells with a light microscope, what portions of the tracheids would be stained, and what parts would not be stained?*



(a) Vessels made up of vessel elements **(b) Vessel elements in a walnut tree** **(c) Perforations in a vessel element end wall**

Figure 38.12 **Vessels composed of vessel elements in xylem tissue.** **(a)** This illustration shows the wide diameter of vessel elements with many pits and end-wall perforations. **(b)** SEM of vessels in the wood of the walnut tree (genus *Juglans*). **(c)** SEM of a perforated vessel element end wall from the tulip tree (*Liriodendron tulipifera*).

Concept check: *Which structural features of vessel elements explain the vulnerability of vessels to embolism, that is, blockage by air bubbles?*

wall. Vessel elements also have numerous pits in their side walls. In contrast to tracheids, the end walls and some side walls of vessel elements are extensively perforated, meaning that all cell-wall material is removed from some areas (Figure 38.12b,c). This allows water to flow faster from one vessel element to another than it can flow from one tracheid to another.

Because the perforated end walls and large diameter of vessels allow them to transport more water at a faster rate than tracheids, you might wonder why vessels have not completely replaced tracheids in flowering plants. The answer is that vessels are more vulnerable than tracheids to embolism, meaning blockage by air bubbles. Once an embolism forms in a vessel element, it can extend through the large end-wall perforations into many elements, thereby blocking a vessel. Just as air bubbles can cause disruption of blood circulation in people, sometimes leading to death, such bubbles also disrupt water transport in plants, sometimes severely. An embolism can form within a vessel as the result of physical damage, drought, or repeated cycles of freezing and thawing. Air bubbles form frequently during winter, because air does not dissolve in ice. By the end of a cold winter, the functional vessels of many woody plants have become almost completely blocked by air. Blocked vessels in trees often cease to function in water transport and must be replaced by new growth in the spring. Fortunately, even if vessels become blocked, water conduction can still occur via tracheids. This is because tracheid pits are so small that they do not allow air bubbles to move to other tracheids. Thus, an air bubble is confined to the single tracheid in which it first formed, and water continues to flow through nearby tracheids. Tracheids thereby provide a fail-safe conduction route when vessels have become disabled by embolisms.

Figure 38.13 **Guttation, the result of root pressure.**

Concept check: *What functions can root pressure serve in plants?*

Some plants are able to refill embolized vessels by means of a process known as **root pressure**. At night, the xylem of roots may accumulate high concentrations of ions that are not immediately transported upward to shoots. In this case, the root acts much like a cell rich in solutes, with the result that water gushes in so rapidly that it pushes upward to leaves. Evidence of this process can be observed in the early morning as droplets of water at the edges of leaves, a phenomenon known as **guttation** (Figure 38.13). As the water rushes upward, it can dislodge air bubbles or dissolve them, thereby reversing an embolism. Root pressure refilling has been observed to occur in nonwoody plants such as corn (*Zea mays*) and in some woody plants, including the sugar maple (*Acer saccharum*).

Feature Investigation

Holbrook and Associates Revealed the Dynamic Role of Xylem in Transport

Plant biologists once thought that xylem sap moved from one conducting cell to another at a uniform rate, unless blocked by an embolism. After all, botanists hypothesized, the cells are dead and thus lack cytoplasmic components that might influence sap flow rates. However, recent experiments have revealed that xylem sap actually moves more readily from one vessel to another through pits when the solute concentration of xylem sap is relatively high. These studies suggest that this variation results from dynamic changes in pit-wall microstructure.

More than 20 years ago, plant biologists noticed that tap water moved more rapidly through cut pieces of stem than did pure water. This observation suggested that ions present in the tap water might have influenced bulk flow rates. However, this hypothesis remained untested until 2001, when N. Michelle Holbrook and colleagues conducted experiments designed to explore this phenomenon, as shown in Figure 38.14. These investigators compared the flow rate of pure water with that of artificial sap, pure water to which they had added various levels of potassium chloride (KCl) or other salts that normally occur in xylem sap. The artificial sap and pure water were introduced into the same experimental tobacco plant through

Figure 38.14 The Holbrook team's dynamic xylem experiment.

HYPOTHESIS Dissolved minerals increase water flow through microchannels in xylem vessel pit walls.

KEY MATERIALS Plants with split stems.

		Experimental level		Conceptual level	
1	Initially, supply both stem flaps with pure water. After 500 seconds, supply flap A with artificial sap and flap B with pure water. Measure the rate of flow into the stem with a flowmeter.			 With artificial sap, pectins shrink, micropores widen.	With pure water, pectins swell, micropores narrow.
2	At 1,500 seconds, apply pure water to both stem flaps.	 Flow decreases.	 Flow remains constant and low.	 Pectins swell, micropores narrow.	
3	Substitute solutions of other salts (NaCl, KNO_3, or $CaCl_2$) or organic molecules (sucrose or ethanol). These solutions are alternated with pure water.	 Flow for dissolved salts increases; rate depends on solute.	 Flow for organic molecules remains constant and low.	 With salts, pectins shrink, micropores widen.	 With organic molecules and pure water, pectins swell, micropores narrow.
4	Flush stems with boiling water for several hours; then treat as in step 3.	A Same as in step 3	B Same as in step 3	Same as in step 3	Same as in step 3

separate flaps cut into the stem. (Using different flaps on the same plant helps to remove experimental variation that might have resulted if investigators had compared results from separate plants.)

These researchers observed that the xylem flow rate was higher when the flap received artificial sap than when it was receiving pure water. Then the investigators supplied pure water to both stem flaps, with the result that the flow rate equalized (see step 2 in Figure 38.14 and also The Data, part a). The investigators then provided artificial sap containing various types of solutes to one flap, along with alternating additions of pure water. The flow rate increased for artificial sap containing dissolved salts, but not for artificial sap containing the organic compounds sucrose or ethanol (see The Data, part b).

Next, the scientists performed experiments designed to determine if living cells in the xylem tissue were causing these effects. They flushed the stems with boiling water or froze the stems in liquid nitrogen before treating them with artificial sap or water as in step 3. These treatments kill living cells. They found that flow rates through the boiled or frozen stems yielded the same results: The flow rate was higher when the flap received sap containing dissolved salts rather than pure water or organic solutes. These results indicated that living cells did not cause the effect.

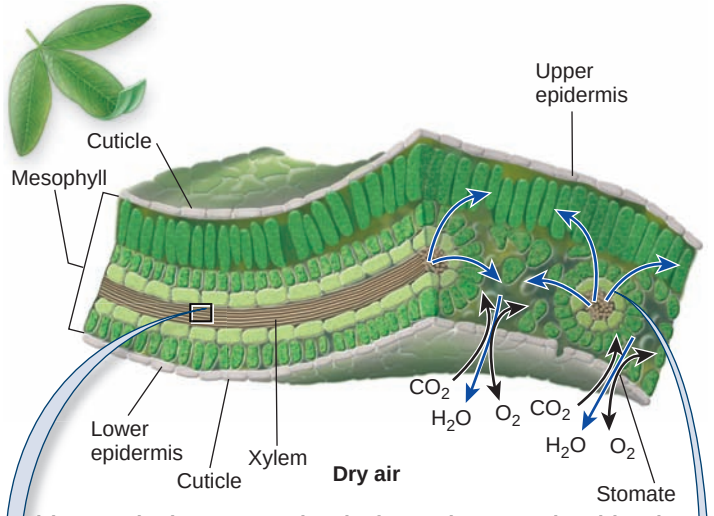
The investigators suspected that ions change vessel element structure in some way that allows greater flow through them. In later experiments not shown here, the scientists devised an apparatus for measuring the flow of sap through individual xylem vessels versus sap flow through groups of vessels. They found that flow through an isolated vessel did not respond to changes in sap ion content, whereas flow between adjacent vessels responded. The researchers interpreted these results as evidence that small pores called micropores in the thin pit walls between adjacent vessel elements play a role in the change in flow rates. These micropores occur within a mesh of cellulose microfibrils and pectins. The pectins, which are water-rich gels known as hydrogels, shrink in response to sap ions and swell in response to pure water. As a result, micropores widen in response to sap ions, increasing flow rates, but narrow in response to pure water (Figure 38.14, step 1, Conceptual level). Researchers speculated that this process hastens the delivery of ion-rich sap to transpiring tissues. Investigators also proposed that this process, which increases sap flow, may help plants compensate for partial loss of xylem sap flow when an air embolism occurs.

Experimental Questions

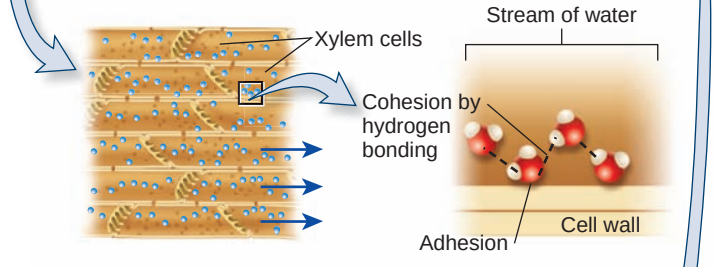
1. Why did the Holbrook team use the same plant to examine the effect of a pure-water control and an experimental, artificial xylem sap?
2. What caused water to flow from the source of artificial sap (or pure water) into the xylem of the plants used in the experiment conducted by Holbrook and associates?
3. Why were sap flow rates the same in living and dead plants in the experiment conducted by the Holbrook team?

Cohesion-Tension Theory Explains the Role of Transpiration in Long-Distance Water Transport

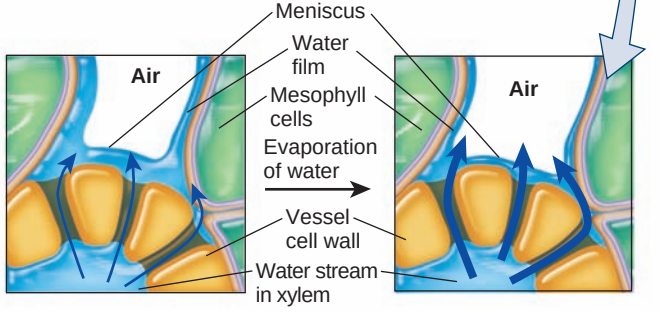
In warm, dry air, water evaporates from plant surfaces. This evaporation process is known as **transpiration** (from the French *transpirer*, meaning to perspire) (Figure 38.15a). Transpiration is capable of pulling water by bulk flow up to the tops of the tallest trees and is the primary way in which water is transported for long distances in plants. Plants expend no energy to transport water and minerals by transpiration. Rather, the sun's energy indirectly powers this process by generating a water pressure difference between moist soil and drier air (see Figure 38.9).



(a) Transpiration occurs when leaf water is exposed to drier air.



(b) Cohesion in xylem causes water to form a continuous stream.



(c) When water evaporates, the surface tension increases in the intercellular spaces of cells, pulling on the water stream in xylem.

Figure 38.15 The roles of transpiration, cohesion, adhesion, and tension in long-distance water transport.

How does evaporation at plant surfaces influence long-distance water transport in the xylem? To answer this question, we must consider the unique physical properties of water. Liquid water molecules are linked by hydrogen bonds (see Chapter 2). As a result, liquid water is amazingly cohesive, explaining why water tends to form continuous streams (Figure 38.15b). Consequently, when water molecules evaporate from plants, water films present in leaves display high surface tension. This tension causes a curved water surface known as a meniscus to form (Figure 38.15c) that pulls on neighboring liquid water molecules and eventually on water in the nearest vein, which is connected to the plant's entire water supply. As the result of water's cohesion and the tension exerted on water at the plant's surface, a continuous stream of water can be pulled up through the plant body from the soil, into roots, through stems, and into leaves. This explanation for long-distance water movement in plants is known as the **cohesion-tension theory**. (Recall that a scientific theory is a well-established concept, not just a hypothesis.) Considerable experimental data support the cohesion-tension concept. For example, in 2008, Tobias Wheeler and Abraham Stroock constructed a synthetic tree and watched the movement of water through it; their observations were consistent with the cohesion-tension theory. Even so, some experts think that additional factors might be important in long-distance water transport. These factors include adhesion of water (its tendency to stick) to the lignified walls of xylem conducting cells (Figure 38.15b) and a squeezing effect exerted by nonconducting tissues on conducting tissues.

Plant transpiration moves huge amounts of water from the soil to the atmosphere. About 99% of the water that enters plants via roots is generally lost as water vapor during transpiration. Each crop season, a single corn plant (*Zea mays*) loses more than 200 L of water, which is more than 100 times the corn plant's mass. A typical tree loses 400 L of water per day! On a regional and global basis, plant transpiration has enormous climate effects. For example, an estimated one-half to three-quarters of rainfall received by the Amazon tropical rain forest actually originates from plant-transpired water vapor, often visible as mist (Figure 38.16). Furthermore, about half of the solar heat received by Amazonian plants is dispersed to the atmosphere during transpiration. This heat dispersal has a cooling effect on regional ground temperature, which would be much higher in the absence of plant transpiration. Such cooling effects result from water's unusually high heat of vaporization, the amount of heat needed to isolate water molecules from the liquid phase and move them to the vapor phase. Most of this energy is needed to break the large numbers of hydrogen bonds that occur in liquid water. The evaporation of large amounts of water from plant surfaces effectively dissipates heat, explaining how plants cool themselves and their environments.

Although evaporation of water from plant surfaces plays an essential role in bulk flow through xylem, if plants lose too much water, they will die. Plant surfaces, including those of leaves, typically produce a cuticle, a wax-containing layer that retards water loss. Only about 5% of water evaporated from

plant surfaces emerges through the cuticle. More than 90% of the water that evaporates from plants is lost through stomata, surface pores that can be closed to retain water or opened to allow the entry of CO_2 needed for photosynthesis. When the stomata are open, oxygen also exits the plant, as does water vapor when the atmospheric humidity is relatively low. Stomata are often abundantly located on the lower surfaces of leaves. Tobacco leaves, for example, possess an estimated 12,000 stomata per square centimeter of leaf surface! Plants face a constant dilemma: whether to open their stomata for CO_2 intake and suffer the impact of reduced water content or to close stomata to retain water, thereby preventing CO_2 uptake. For this reason, plants have acquired many adaptations to cope with transpirational water loss.

Plant Adaptations Help to Reduce Transpirational Water Loss

Under some conditions, almost all plants experience water stress, which is an inadequate amount of water. Water stress is common for plants of the world's arid regions, and their growth is often limited by water availability. Even plants of moist, forested regions of the world experience water stress during drier or colder seasons or under windy conditions. The leaves at the tops of tall trees are generally under considerable water stress because gravity has a substantial impact on their water potential. Earlier, we considered examples of plant cellular adaptations to deal with osmotic stress. Plants have evolved two additional ways to prevent excessive loss of water by transpiration: regulation of stomata opening and leaf drop.

Stomatal Opening and Closing Plant stomata close to conserve water under conditions of water stress and open when the stress has been relieved, allowing air exchange with the leaf's spongy mesophyll. Stomata are bordered by a pair of **guard cells**, which are sausage-shaped chloroplast-containing cells attached at their ends (Figure 38.17a). The distinctive structural features of guard cells explain how they are able to open and close a pore. As guard cells become fully turgid, their volume expands by 40–100%. This expansion does not occur evenly, however, because the innermost cell walls are thicker and less extensible than are other parts of the guard cell walls. In addition, the cells expand primarily in the lengthwise direction because bands of radially oriented cellulose microfibrils prevent the guard cells from expanding laterally (Figure 38.17b). Thus, when guard cells are turgid, a stomatal pore opens between them, allowing air exchange with the leaf's spongy mesophyll. Conversely, when the guard cells lose their turgor, their volume decreases, and the stomatal pore closes.

What causes the change in turgor? Stomata often open early in the morning, in response to sunlight. This response makes sense, given that light, water, and carbon dioxide are all required for photosynthesis. Blue light stimulates H^+-ATPase proton pumps, leading to guard cell uptake of ions, especially potassium (K^+), and other solutes. As a result of increases in solute concentrations inside guard cells, osmotic water uptake occurs via plasma membrane aquaporins, resulting in cell expansion and stomatal opening (Figure 38.18a).

Figure 38.16 **Plant-transpired water vapor mist rising from a tropical rain forest.** This mist visually illustrates the enormous amount of water that is transpired from the surfaces of plants into the atmosphere. Water vapor derived from plant transpiration is an important source of rainfall, and the process of evaporation cools plant surfaces as well as affecting the local and global climate.

Concept check: Why does evaporation of water have such a powerful cooling effect?

At night, the reverse process closes stomata. Potassium and other solutes are pumped out of guard cells, causing water to exit and deflate guard cells, resulting in pore closure. Plants also close stomata during the daytime under conditions of water stress, a process mediated by the stress hormone abscisic acid (ABA). Water stress causes a 50-fold increase in ABA, which is transported in the xylem sap to guard cells. ABA then binds to a receptor, which elicits a Ca^{2+} second messenger, causing the guard cells to lose solutes and deflate (Figure 38.18b).

Leaf Abscission Angiosperm trees and shrubs of seasonally cold habitats experience water stress every winter, when evaporation from plant surfaces occurs, yet soil water is frozen and therefore unavailable for uptake by roots. Desert plants experience water stress conditions at less predictable times and for much of the year. Both types of plants are adapted to cope with water stress by dropping their leaves, a process known as **leaf abscission**. Dropping leaves lets these plants avoid very low leaf water potentials and the consequent danger of xylem embolism. Leaf abscission also reduces the amount of root mass that plants must produce to obtain water under arid conditions. The ocotillo (*Fouquieria splendens*) of North American deserts can produce leaves after sporadic rains and then drop all of its

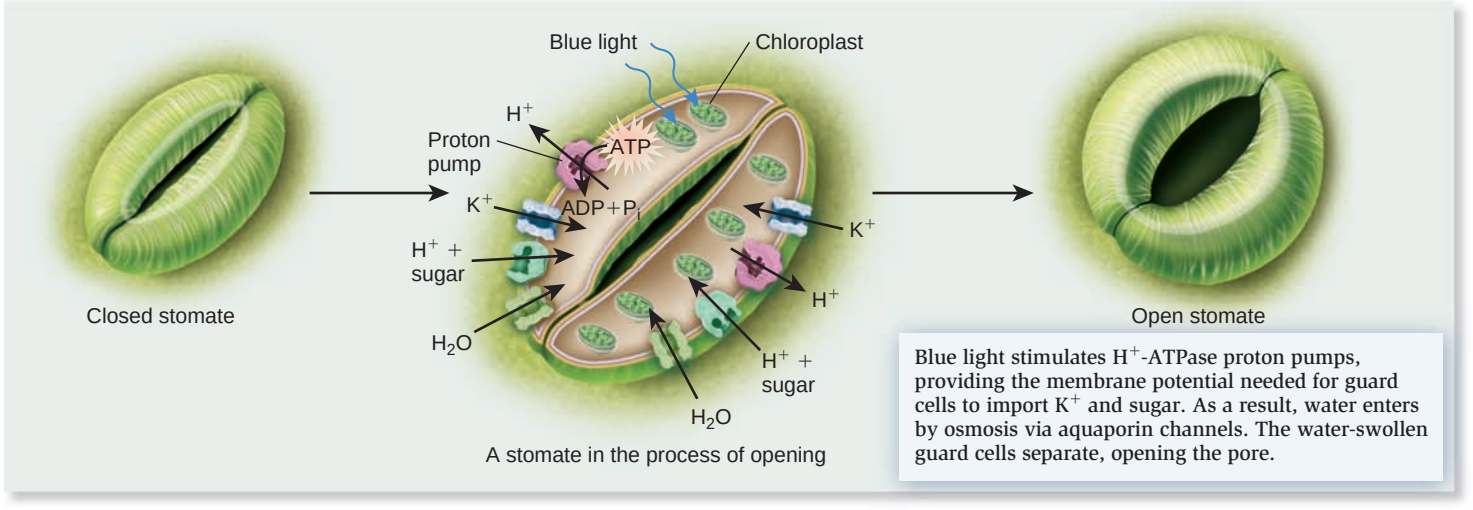
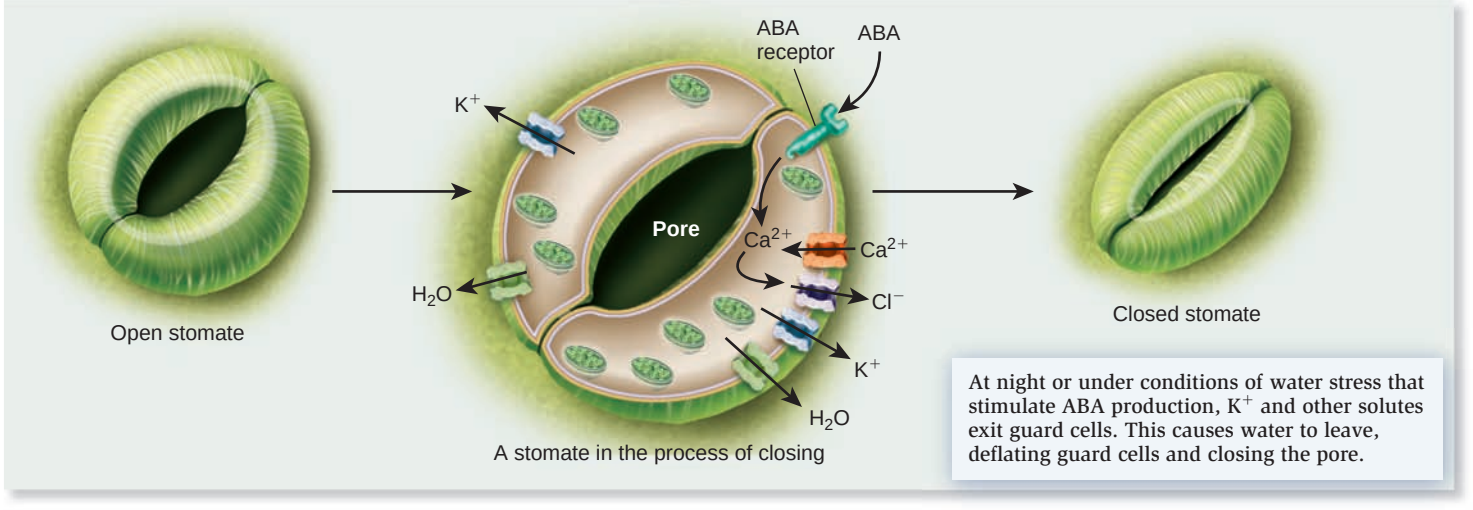
Figure 38.17 **The structure of stomatal guard cells.** When flaccid, guard cells close stomatal pores. Turgid guard cells produce a stomatal opening. **(a)** An SEM of a stomate in a rose leaf, showing the two guard cells bordering a partly open pore. **(b)** Thickened inner cell walls and radial orientation of cellulose microfibrils in the guard cell walls explain why they separate when turgid, forming a pore.

Concept check: *How could you make a physical model that would illustrate how guard cell structure affects its function?*



(a) The process of stomate opening



(b) The process of stomate closing

Figure 38.18 **How stomatal pores open and close.** **(a)** Stomata usually open in response to the blue light of sunlight. **(b)** Stomata usually close in response to lack of sunlight. They can also close during the day under conditions of water stress, which induces plants to produce more of the hormone abscisic acid (ABA). Stomatal guard cell plasma membranes possess ABA receptors, which receive the drought signal.

(a) Ocotillo with leaves (b) Ocotillo without leaves

Figure 38.19 Leaf abscission as a drought adaptation. The ocotillo (*Fouquieria splendens*), a plant native to North American deserts, is known for its ability to respond to intermittent rain and drought by producing and dropping leaves multiple times within a year.

Concept check: *Why does the ocotillo not drop its leaves at a single predictable time each year, as do temperate angiosperm trees and shrubs?*

leaves as a direct response to drought as many as six times a year (Figure 38.19).

The sugar maple (*Acer saccharum*) is an example of the many types of temperate forest trees or shrubs that drop their leaves each autumn and are thus known as deciduous plants. Deciduous plants contrast with evergreen conifers, whose needle- or scale-shaped leaves are adapted to help these gymnosperms cope with water stress during the cold season (Chapter 30). By contrast, the broader, thinner leaves produced by many angiosperms are well adapted for efficient light-capture, but more vulnerable to the stresses caused by cold. During their evolution, temperate zone angiosperm trees and shrubs have acquired the genetic capacity to predict the onset of cold, dry winter conditions and respond with preemptive leaf abscission. In contrast to the case of ocotillo, autumn leaf drop in temperate angiosperms is not directly induced by drought.

Leaf abscission is a highly coordinated developmental process. The hormone ethylene stimulates an abscission zone to develop at the bases of leaf petioles (Figure 38.20a). The abscission zone contains two types of tissues: a separation layer of short, thin-walled cells and an underlying protective layer of suberin-impregnated cork cells (Figure 38.20b). Suberin contains both waterproofing wax and phenolic polymers that retard microbial attack. As the abscission layer develops across the vein linking the petiole with the stem, it eventually cuts off the water supply to the leaf. Chlorophyll in the leaves degrades, revealing colorful orange and yellow carotenoid and xanthophyll pigments that were hidden beneath. In addition, some plants synthesize red and reddish blue pigments in response to changing environmental conditions. The presence of these pigments explains colorful autumn vegetation in temperate zones.

(b) Tissues involved in leaf abscission

Figure 38.20 Leaf abscission.

Enzymes eventually break down the cell-wall components of the separation layer, causing the petiole to break off the stem. The underlying protective layer forms a leaf scar that seals the wound, helping to protect the plant stem from water loss and pathogen attack.

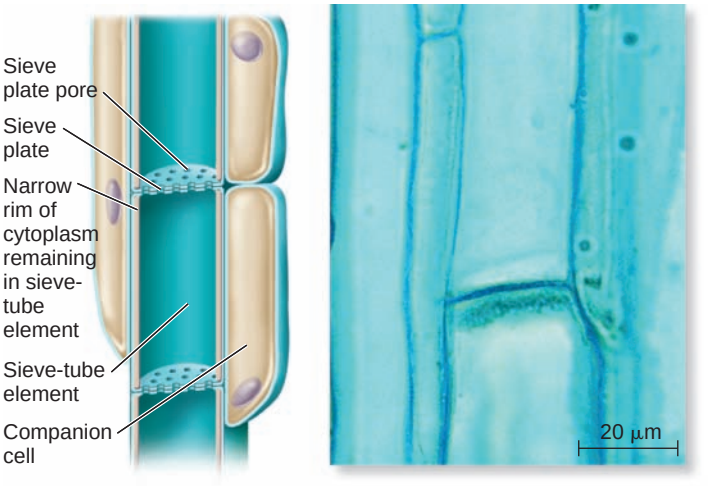
Long-Distance Transport of Organic Molecules Occurs in the Phloem

Our examination of xylem structure and function provides the background needed to understand phloem structure and function. As we have noted, phloem plays an essential role in long-distance transport of organic molecules and some minerals in the plant body. Phloem often transports sugars from where they are produced to other sites where they are also used. Recall that primary phloem occurs in the vascular bundles of herbaceous plants and secondary phloem occurs as the inner portion of bark of woody plants. In contrast to xylem, whose transport tissues are dead and empty of cytoplasm at maturity, mature phloem tissues remain alive and retain at least some cytoplasmic components. A closer look at phloem structure and function will help to illuminate these differences.

Phloem Structure Phloem tissues of flowering plants include supporting fibers, parenchyma cells, sieve-tube elements, and adjacent companion cells. **Sieve-tube elements** are arranged end to end to form transport pipes (Figure 38.21), analogous to the way that the xylem's vessel elements are aligned to form longitudinal vessels. Together, the sieve-tube elements and companion cells form a transport system whose structure explains its function.

Each sieve-tube element and companion cell pair has a common origin. They are produced by an unequal division of a single precursor cell and are therefore linked by plasmodesmata formed at cytokinesis. The smaller of the two cells develops into a companion cell, whose name reflects its life-support function, and the larger of the two cells develops into a sieve-tube element. The sieve-tube element loses its nucleus and most of its cytoplasm as an adaptation that reduces obstruction to bulk flow. Mature sieve-tube elements retain only a thin film of peripheral cytoplasm that includes some endoplasmic reticulum, plastids, and mitochondria. The end walls of developing sieve-tube elements become perforated by the action of wall-digesting enzymes that enlarge existing plasmodesmata. The perforated end walls of mature sieve-tube elements are known as **sieve plates**, and the numerous perforations are known as **sieve plate pores**. Phloem sap passes through these plates from one sieve-tube element to another.

Mature sieve-tube elements are not dead. However, because they lack a nucleus, they are dependent on their neighboring companion cell for messenger RNA (mRNA) and proteins, which are supplied via plasmodesmata. For example, when a plant's conducting system is damaged, a short-term wound response occurs that involves a protein known as **P protein** (for phloem protein). Masses of this protein accumulate along sieve plates, preventing loss of phloem sap (Figure 38.22). This mass functions much like a clot that helps reduce blood loss from wounded animals. P protein also binds to the cell walls of pathogens, thereby helping to prevent infection at wounds. However, sieve-tube elements cannot produce P protein by themselves. Their companion cells provide either P protein mRNA or the protein itself to sieve-tube elements. In the longer term, plants deposit the carbohydrate callose at the wound site.



(a) Sieve-tube elements and companion cells

(b) Light micrograph of phloem stained with blue dye, showing sieve-tube elements

Figure 38.21 Sieve-tube elements and companion cells.

Phloem Loading Companion cells also play an essential role in moving sugars into sieve-tube elements for long-distance transport, a process known as **phloem loading**. Although glucose and some other sugars can occur in phloem, the disaccharide sucrose is the main form in which most plants transport

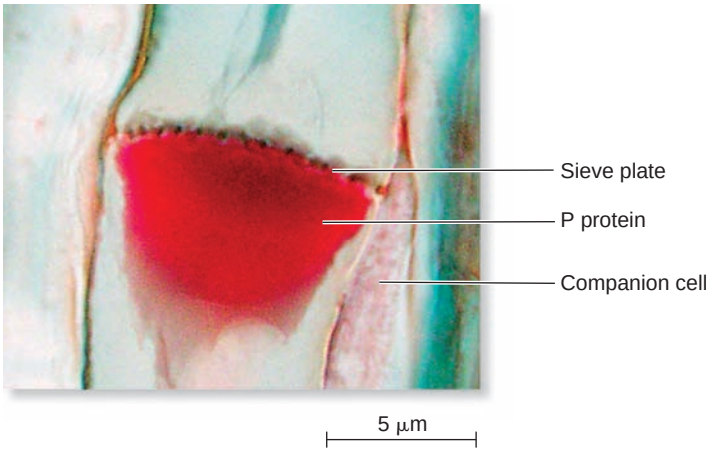


Figure 38.22 **Phloem wound response.** When phloem is damaged, the cytoplasm of a sieve-tube element surges toward the sieve plate, depositing P protein, stained red in this light micrograph. In this location, P protein helps to prevent infection and leakage of solutes.

sugar over long distances. Plant biologists think that sucrose is less vulnerable to metabolic breakdown en route than are monosaccharides.

Two types of phloem loading occur, symplastic and partly apoplastic. Many woody plants transport sucrose from sugar-producing cells of the leaf mesophyll to companion cells and then to sieve-tube elements via plasmodesmata, a process known as symplastic phloem loading (Figure 38.23a). The advantage of symplastic loading is that it does not require ATP; by moving through plasmodesmata, sugar does not have to cross plasma membranes.

In contrast, most herbaceous plants, including important crop plants and the model plant *Arabidopsis*, load sugar into sieve-tube elements or companion cells from intercellular spaces, often against a concentration gradient. ATP must be used to move the sugar across a plasma membrane into a companion cell or sieve-tube element (Figure 38.23b). Therefore, this second type of phloem loading is partly apoplastic and partly a transmembrane process.

The Pressure-Flow Hypothesis Explains Transport in Phloem Tissues

We have learned that transpiration, driven by the sun's energy, moves water in plant xylem by the processes of cohesion and tension. Once sugar has been loaded into phloem sieve-tube elements, how does it move within the plant? The most common explanation is that phloem transport is driven by differences in turgor pressure that occur between cells of a **sugar source**, where sugar is produced, and those of a **sugar sink**, where sugar is consumed. Photosynthetic leaf mesophyll is the main sugar source. Roots and developing leaves, seeds, and fruits are examples of sugar sinks. In the process known as **translocation**, phloem transports substances from source to sink. The direction of phloem movement can be horizontal as well as vertical, depending on the relative positions of the sources and sinks.

Because sieve-tube elements near source tissues have higher solute contents than surrounding tissues, water tends to rush into them from nearby xylem, thereby building turgor pressure. In contrast, sieve-tube elements near sink tissues have lower solute concentration. The resulting water pressure difference drives the bulk flow of phloem sap from source to sink tissues. This explanation for phloem transport is known as the **pressure-flow hypothesis** (Figure 38.24). German plant physiologist Ernst Münch first proposed this hypothesis in 1927, though later investigators have modified it. The pressure-flow hypothesis is supported by studies that show relatively high solute concentrations in phloem samples taken from tree leaves (source) and relatively low solute concentrations in samples taken from a tree trunk (sink). The production of turgor pressure requires an intact plasma membrane. This explains why mature phloem sieve-tube elements must be alive in order to function, in contrast to xylem tracheary elements.

At sink tissues, sugar is typically unloaded through plasmodesmata (Figure 38.24). Because plasmodesmata are very narrow in comparison to sieve-tube elements, they slow the flow of phloem sap from sieve-tube elements into sink tissues. This reduction in flow rate helps to equalize the distribution of phloem sap, preventing delivery of too much sap to any single sink. When the solute concentration of phloem sap has been sufficiently reduced, water flows from the phloem back into the xylem, where upward transport occurs. The reliance of phloem bulk flow on water supplied by the xylem explains the close proximity of phloem and xylem tissues in vascular bundles and woody stems.

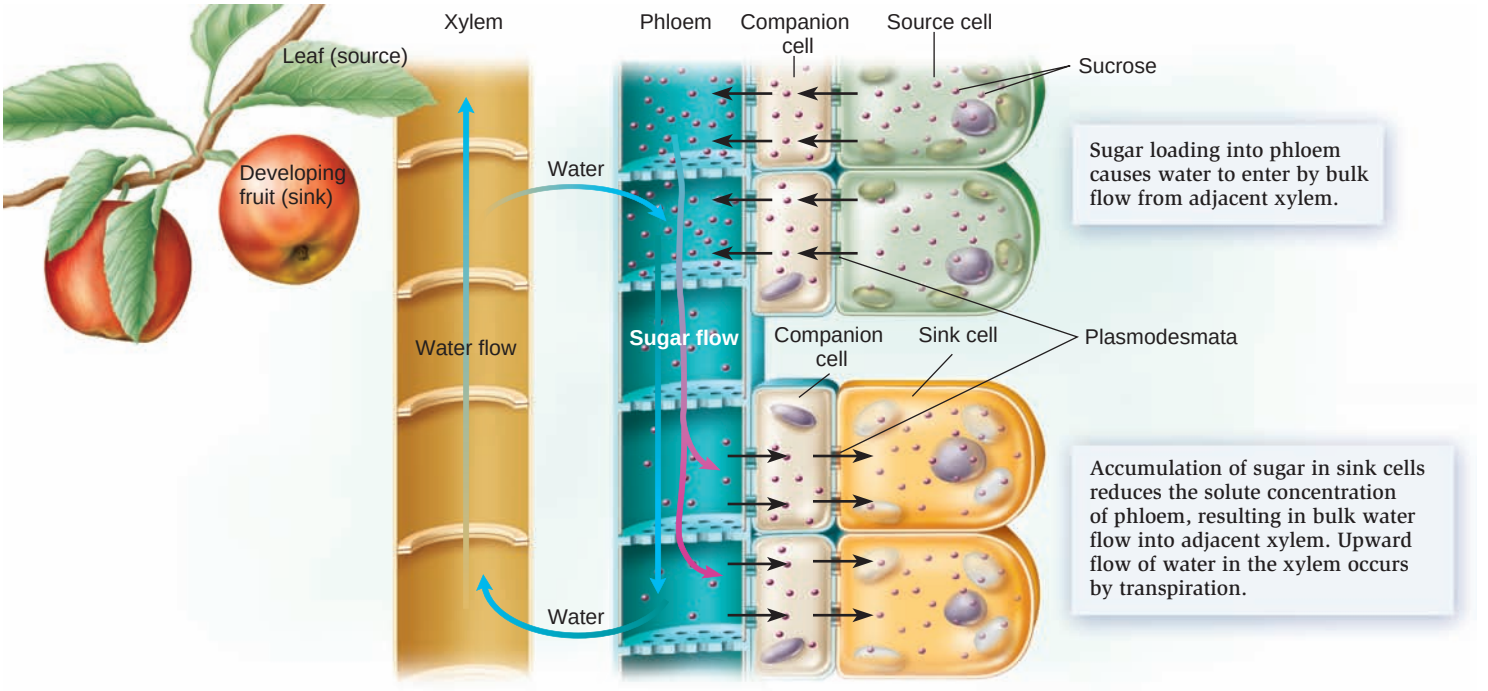

Figure 38.24 Pressure-flow hypothesis for phloem transport.

Genomes & Proteomes Connection

Microarray Studies of Gene Transcription Reveal Xylem- and Phloem-Specific Genes

Xylem and phloem tissues have important economic, agricultural, and ecological roles. For example, secondary xylem produced by the vascular cambium, otherwise known as wood, forms the basis of our forest products industry. The ability of plants to respond to environmental factors also relies on vascular tissues to transport hormones. Seeking increased fundamental understanding and enhanced ability to engineer plants, molecular biologists have tried to identify the genes involved in xylem and phloem development. The use of microarrays, also known as gene chips, is providing a genomewide view of gene expression related to xylem and phloem.

Chengsong Zhao, Eric Beers, and their coworkers recently compared gene expression in immature xylem (X), phloem plus vascular cambium (PC), and nonvascular (NV) tissues dissected from young *Arabidopsis* plants. Recall that the vascular cambium is the meristematic tissue that produces secondary phloem (inner bark) and secondary xylem (wood; see Chapter 35). The investigators used a dissecting microscope to view 1-cm-long pieces of tissue and a razor blade to make a longitudinal cut into nonvascular tissues and phloem, isolating the immature xylem. Then they peeled the nonvascular tissue away from the phloem. They ensured that their tissue samples were pure and authentic by checking for the expression of marker genes already known to be tissue specific. The investigators ascertained that their X and NV tissue samples had very low expression of certain PC genes and that their PC samples had very low expression of certain X and NV genes. They then extracted RNA from the three separate tissues and used it to make labeled nucleic acid for hybridization to gene microarrays containing about 90% of the *Arabidopsis* genome (refer back to Figure 20.9).

Binding of labeled nucleic acid revealed which genes were expressed. By comparing the binding patterns on different chips hybridized with nucleic acid from distinct tissues, the researchers were able to determine the genes that were preferentially expressed in X, PC, and/or NV tissues. These differences are revealed by a "triangle plot" that reflects the proportions of genes expressed in the three tested tissues (Figure 38.25). Genes expressed primarily in only one tissue type cluster at the trian-

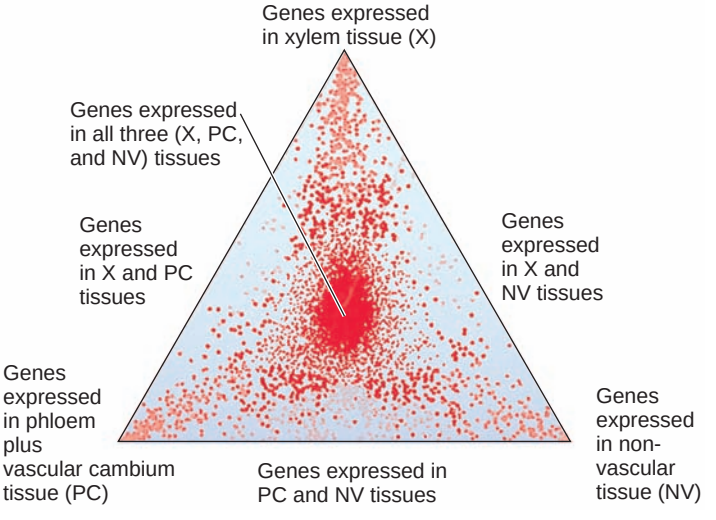

Figure 38.25 Triangle plot showing gene expression related to immature xylem, phloem, and nonvascular tissue in *Arabidopsis*.

Concept check: Suppose you are interested in identifying proteins that are involved in the development of both xylem and phloem. How might results illustrated here help you?

gle corners, and genes expressed in two tissues but not the third are plotted at the triangle edges. Genes expressed in all three tissues lie in the center. The researchers identified 319 X-biased genes, 211 PC-biased genes, and 154 NV-biased genes. Not surprisingly, 17% of the X-expressed genes were related to cell-wall biosynthesis, including lignin production. The investigators then confirmed, via microscopy, that several proteins predicted by microarray data to be located in X, PC, or NV tissues were actually made in these tissues. This study is an essential first step toward determining the function, timing of expression, and cellular locations of xylem- and phloem-specific proteins.

Summary of Key Concepts

38.1 Overview of Plant Transport

- The root system takes up water and minerals, and the shoot system absorbs carbon dioxide from the air. Photosynthetic cells use these materials to produce organic compounds. The vascular system xylem transports water and minerals from root to shoot, while the phloem transports organic compounds to roots and other nonphotosynthetic tissues. (Figure 38.1)

38.2 Uptake and Movement of Materials at the Cellular Level

- Passive transport of substances along a concentration gradient does not require ATP. Simple diffusion of water, gases, and other small, uncharged molecules across plasma membranes may occur in the absence of transport proteins. Facilitated diffusion involves plasma membrane and vacuolar protein channels and transporters. (Figure 38.2)
- Transport of materials across plasma membranes against concentration gradients is known as active transport and usually requires ATP. Plasma membrane proton pumps use the energy released by ATP hydrolysis to move protons from the cytosol into the intercellular space, thereby generating a membrane potential. Potential energy released by the flow of protons back into the cell can be coupled to the transport of ions and organic compounds into and out of cells, a process known as cotransport. (Figure 38.3)
- Turgor pressure arises when the cell wall restricts the extent to which plant cells can swell when water enters as the result of osmosis. A cell that is so full of water that the plasma membrane presses closely against the cell wall is turgid. By contrast, a cell that is not swollen with water is flaccid, and a cell that contains so little water that the plasma membrane pulls away from the cell wall is plasmolyzed. (Figure 38.4)
- Solute potential and pressure potential arising from the presence of a cell wall are major factors affecting cellular water potential. The relative water content (RWC) is a measure of relative turgidity that integrates the water potential of all cells in a plant or an organ. (Figure 38.5)
- Plants display a variety of adaptations that help them cope with osmotic stress. In osmotic adjustment, high solute concentrations accumulate in the cytosol, a process that helps cells retain their water. Halophytes are plants adapted to very saline conditions, which impose extreme osmotic stress.

38.3 Tissue-Level Transport

- Transmembrane transport involves the movement of materials from one cell to another from intercellular spaces, across plasma membranes, and into the cytosol. The symplast is the continuum of all plant cytosolic compartments linked by plasmodesmata. Symplastic transport allows materials to move from one cell to another without crossing plasma membranes. In apoplastic transport, water and solutes move through the apoplast, the water-filled cell walls and intercellular spaces of tissues. (Figures 38.6, 38.7)
- In roots, waxy Casparian strips on cell walls of endodermal tissue act as filters that reduce the movement of toxic ions and concentrate useful minerals into the plant vascular system. (Figure 38.8)

38.4 Long-Distance Transport

- Water and solutes move for long distances by bulk flow within the xylem and phloem. Plant vascular tissues are adapted in ways that reduce resistance to bulk flow. Bulk flow of water upward in xylem is powered by the water pressure difference between moist soil and drier air, the latter resulting from solar heating. (Figure 38.9)
- Xylem is the main conduit for water and dissolved mineral nutrients, but it may also transport certain organic compounds. At maturity, tracheids and vessel elements, together known as tracheary elements, are dead and empty of cytoplasm, and have lignified cell walls. Pits in tracheary element walls allow water entry and exit. Experiments reveal that pits narrow or constrict in response to xylem sap solute content. Narrow tracheids fit together in long cell files. Vessel elements are wider but are more vulnerable than tracheids to blockage by air bubbles or embolisms. Root pressure, the effects of which include the morning water drops on leaf tips known as guttation, helps some plants to refill embolized vessels. (Figures 38.10, 38.11, 38.12, 38.13, 38.14)
- Transpiration is the evaporative loss of water from plant surfaces into sun-heated air. Plant transpiration has extensive local, regional, and global effects on climate. The cohesion-tension theory explains long-distance water transport as the combined effect of the cohesive forces of water and evaporative tension. (Figures 38.15, 38.16)
- Expansion of guard cells causes stomatal pores to open, allowing CO_2 intake. Guard cell deflation causes pores to close, an adaptation that helps to prevent excess water loss. Plants under existing or predicted water stress often drop their leaves in a process known as abscission, an adaptive response that lets plants avoid very low water potentials and the consequent threat of embolism. (Figures 38.17, 38.18, 38.19, 38.20)
- Organic solutes and minerals are transported in phloem sap as the result of osmosis. Phloem sap moves within sieve-tube elements that are living when mature, but lack a nucleus and are thus dependent on companion cells. Phloem loading occurs by symplastic or partly apoplastic transport. The pressure-flow hypothesis explains sugar translocation as a process driven by differences in turgor pressure that occur between a sugar source (for example, leaves) and a sugar sink (for example, developing fruit). (Figures 38.21, 38.22, 38.23, 38.24, 38.25)

Assess and Discuss

Test Yourself

1. An aquaporin is
   a. a channel protein that allows the influx of K^+ into cells, causing water to also flow in between the phospholipids of a plasma membrane.
   b. a type of blue-colored pore in the epidermal surfaces of plants.
   c. a protein channel in plasma membranes that facilitates the diffusion of water.
   d. a protein transporter in plasma membranes that uses protons to cotransport water.
   e. none of the above.
2. Why is turgor pressure a property of plant cells?
   a. Plant cells possess the necessary chloroplasts.
   b. Plant cells possess a cell wall, necessary for formation of turgor.
   c. Plant cells possess mitochondria, which provide the ATP needed for turgor.
   d. all of the above
   e. none of the above
3. How might plant cells avoid losing too much water in very cold, dry, or saline habitats?
   a. They may balance the osmotic condition of their cytosol with that of the environment.
   b. Their epidermal cells may be coated with waxy cuticle.
   c. They may stabilize their membranes with sugars.
   d. They may produce more aquaporin water channels to take maximum advantage of available moisture.
   e. All of the above are possible.
4. What are ways in which plants accomplish tissue-level transport?
   a. transmembrane transport of solutes from one cell to another
   b. symplastic transport of materials from one cell to another via plasmodesmata
   c. apoplastic transport of water and dissolved solutes through cell walls and intercellular spaces
   d. all of the above
   e. none of the above
5. A root endodermis is
   a. an innermost layer of cortex cells that each display characteristic Casparian strips.
   b. a layer of cells just inside the epidermis of a root.
   c. a layer of cells just outside the epidermis of a root.
   d. a group of specialized cells that occur within the root epidermis.
   e. none of the above.
6. Xylem loading is
   a. the process by which water from the air enters vascular tissues of the leaf.
   b. the process by which sugar is transported via plasmodesmata directly into vessel elements.
   c. the process by which sugar is transported directly into sieve-tube elements.
   d. the process in which ions are transported across the membranes of root xylem parenchyma into the xylem apoplast, followed by water.
   e. none of the above.
7. What features of water explain how it can be drawn up a tall tree from roots to leaves?
   a. cohesion, the result of extensive hydrogen bonding
   b. adhesion, water's tendency to stick to surfaces such as the inner walls of tracheid and vessels
   c. high surface tension that develops when water evaporates from intercellular leaf spaces
   d. all of the above
   e. none of the above
8. What feature of vascular plants contributes to their ability to maintain relatively stable internal water content?
   a. a waxy surface cuticle
   b. an extensive root system that mines water from soil
   c. specialized water-conducting tracheary elements composed of dead cells
   d. epidermal pores that open and close
   e. all of the above
9. What structural features of stomatal guard cells foster their ability to form an open pore in plant epidermal surfaces?
   a. thickened inner cell walls and radially oriented microfibrils
   b. thickened outer cell walls and radially oriented microfibrils
   c. thickened inner cell walls and longitudinal microfibrils
   d. thickened outer cell walls and longitudinal microfibrils
   e. uniform thickness of cell walls and randomly arranged microfibrils
10. What substances plug wounded sieve-tube elements, thereby preventing the leakage of phloem sap?
    a. X protein and callose
    b. C protein and callose
    c. P protein and callose
    d. P protein and sucrose
    e. none of the previously listed choices

Conceptual Questions

1. Why is it a bad idea to overfertilize your houseplants? If the amount recommended on the package is good, wouldn't more be better?
2. Why is it a bad idea for subsistence farmers (those barely able to grow enough crops to feed themselves) to allow livestock to graze natural vegetation to the point that it disappears?
3. In the desert southwestern U.S., the ocotillo plant is often used as a landscaping plant, thanks to its interesting shape and beautiful floral displays. Imagine that you are responsible for property landscaped with ocotillo but find the plants bare of leaves. Can you assume that the plants are dead and need to be replaced?

Collaborative Questions

1. Imagine that you are part of a team assigned to determine what environmental conditions best suit a new crop so that the crop can be recommended to farmers in appropriate climate regions. What features of the crop plants might you investigate?
2. Take a look outside or imagine a forest or grassland. What can you deduce about the availability of soil water from the types of plants that occur?

Chapter Outline

Flowering Plants: Reproduction

39

The reproductive success of dandelions.

Dandelions sometimes seem to be taking over the world, growing abundantly in open, sunny areas. Cheerful, bright yellow flower heads, as shown in the chapter-opening photo, are one of the secrets of dandelions' success. If you pull a dandelion flower head apart, you can see that it is actually a bouquet of 200 or so small flowers. Each flower produces a tiny, one-seeded fruit equipped with a "parachute" for effective long-distance dispersal by wind. Each dandelion plant can produce up to 5,000 fruits during its lifetime, which explains how dandelions can spread so rapidly across a landscape.

Though most flowering plants produce seeds by means of sexual reproduction, dandelions and some other plants are able to produce seeds by a type of asexual reproduction, a process that does not involve meiosis and fusion of gametes. As a result, the traits of asexually reproducing dandelion parents and their progeny are uniform. Asexual reproduction could be very usefully applied in agriculture, because most crops reproduce only sexually. Each year many U.S. farmers buy and plant hybrid seeds that develop into mature plants having uniform and desirable trait combinations. Such farmers typically do not use seed from one year's crop to plant the next, because sexual reproduction mixes genes into diverse combinations present among the resulting seeds. For this reason, plants that grow from sexually produced seeds do not uniformly express the desirable trait combinations present in their hybrid parents. But if hybrid crop plants could be engineered to produce seed asexually, as dandelions do, farmers might be able to use seed from one crop to plant the next and still harvest uniformly desirable crops. Because reproduction is so important to agriculture, plant biologists aim to better understand both sexual and asexual reproduction in flowering plants.

Flowers, fruits, and seeds are not just important in agriculture but are essential reproductive features of the diverse types of flowering plants found in nature. This chapter begins with an overview of the reproductive cycle of flowering plants that describes how flowers, fruits, and seeds function. This overview provides essential background for a closer look at flower structure and development and some of the genes that control flower production and appearance. We will also examine the sexual reproductive processes by which plants produce gametes and accomplish fertilization, thereby producing zygotes and embryos. We will explore how seeds, fruits, and seedlings develop. Finally, we will take a closer look at the ways in which dandelions and some other plants reproduce without using the sexual process.

39.1 An Overview of Flowering Plant Reproduction

Most flowering plants display **sexual reproduction**, the process by which two gametes fuse to produce offspring that have unique combinations of genes. Flowering plants, also known as angiosperms, inherited their sexual life cycle, known as alternation of generations, from ancestors extending back to the earliest land plants (as we explored in Chapters 29 and 30). Though all plants share the same basic life cycle, flowering plants display unique reproductive features. In this section, we first review the general features of alternation of generations and then consider more specific features of the angiosperm life cycle.

Flowering Plants Display Alternation of Generations

All groups of land plants produce two multicellular life cycle stages, in essence, two distinct plants. These two life cycle stages

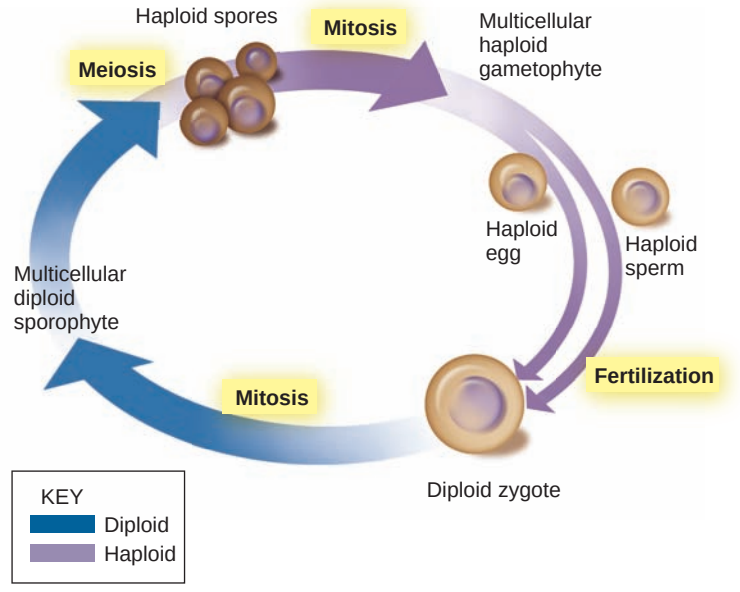

Figure 39.1 Alternation of generations, the plant life cycle.

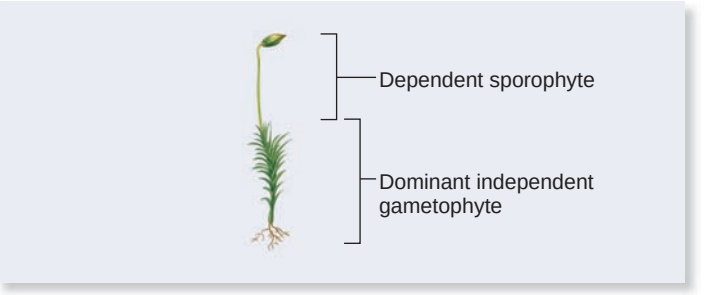
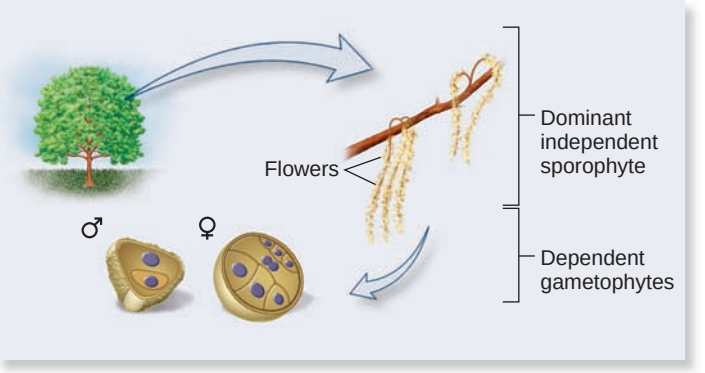
are the diploid, spore-producing **sporophyte** and the haploid, gamete-producing **gametophyte**. In all groups of plants, haploid spores are typically produced by diploid sporophytes as the result of meiosis. These spores undergo mitotic cell divisions to produce multicellular gametophytes. Certain cells within the gametophytes differentiate into gametes. Thus, meiosis does not directly generate the gametes of plants. The processes of meiosis and fertilization form the transitions between the sporophyte and gametophyte life stages and link them in a cycle (Figure 39.1). The land plant life cycle is known as **alternation of generations** because it involves the cycling between distinct sporophyte and gametophyte generations.

During the evolutionary diversification of land plants, the sporophyte generation has become larger and more complex, while the gametophyte generation has become smaller and less complex. To illustrate this, let's compare the life cycle stages of mosses to those of angiosperms. Mosses diverged early in the history of land plants, whereas angiosperms appeared much later. During the intervening time, the relative sizes and dependence of the sporophyte and gametophyte generations changed dramatically. Moss sporophytes are small structures that always grow attached to larger, photosynthetic gametophytes, because moss sporophytes are incapable of independent life (Figure 39.2a). Moss sporophytes are dependent on gametophytes, because the gametophytes supply the sporophytes with essential nutrients.

In contrast, flowering plant sporophytes are notably larger and more complex than gametophytes. A tall oak tree, for example, is a single sporophyte. However, oak gametophytes are few-celled, microscopic structures that develop and grow within flowers (Figure 39.2b). In addition, photosynthetic oak seedlings and trees grow independently, but nonphotosynthetic oak gametophytes are completely dependent on the sporophyte generation for their nutrition. A closer look at flower structure



(a) Gametophyte-dominant bryophyte (moss)



(b) Sporophyte-dominant flowering plant (oak)

Figure 39.2 Evolutionary shift in plant life cycle stage dominance. **(a)** In mosses, the gametophyte is the dominant life cycle stage, and the sporophyte is dependent on the gametophyte for resources. **(b)** In flowering plants such as oak trees, the sporophyte life cycle stage is dominant. Microscopic flowering plant gametophytes develop and grow within sporophytic flower tissues and are completely dependent on sporophytes.

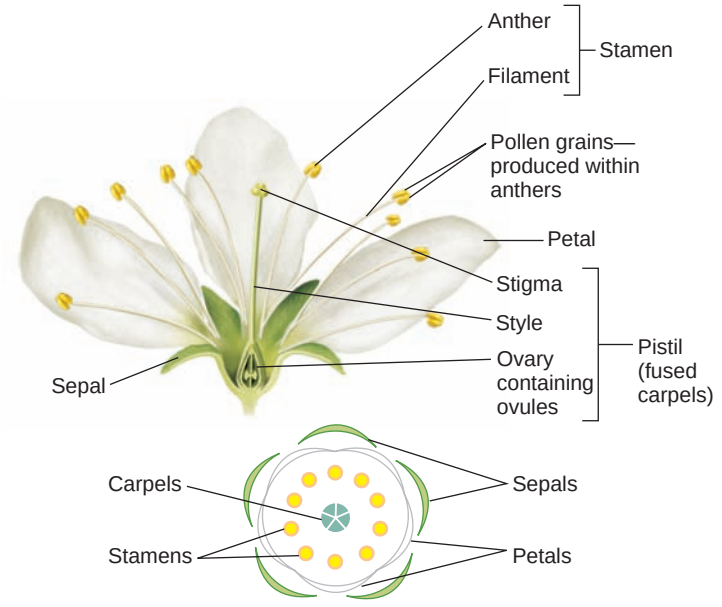
Concept check: What advantages do flowering plants obtain by having such small and dependent gametophytes?

will help us to gain a more complete view of angiosperm gametophyte structure and function.

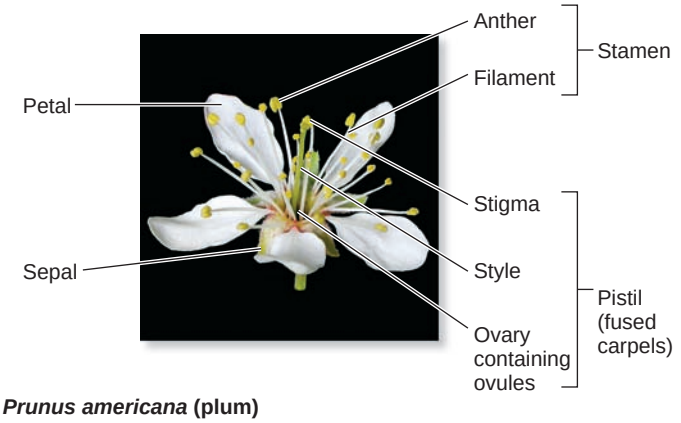
Flowers Produce and Nurture Male and Female Gametophytes

The literary wit Gertrude Stein famously paraphrased Shakespeare when she wrote, "A rose is a rose is a rose." Everyone knows that a rose is a flower, but what, exactly, is a flower? A **flower** is defined as a reproductive shoot, a stem branch that produces reproductive organs instead of leaves. Flower organs are thought to have evolved from leaflike structures by descent with modification (refer back to Figure 30.15). Flower organs are produced by shoot apical meristems much like those that generate leaves.

A flower shoot generally produces four types of organs: sepals, petals, stamens, and carpels (Figure 39.3). **Sepals** often function to protect the unopened flower bud. **Petals** usually serve to attract insects or other animals for pollen transport (refer back to Figures 30.19 and 30.20). **Stamens** and **carpels**



(a) Flower parts



(b) *Prunus americana* (plum)

Figure 39.3 The structure of a typical flower.

Concept check: *Do all flowers have all of the structures illustrated here?*

each produce distinctive types of spores by the process of meiosis. From these spores, multicellular gametophytes develop, and certain gametophytic cells become specialized gametes. Nutritive tissues of stamens and carpels channel organic food, mineral ions, and water from the adult sporophyte into dependent gametophytes.

Stamens Stamens produce **male gametophytes** and foster their early development. Most stamens display an elongate stalk, known as a **filament**, which is topped by an anther (Figure 39.3). Filaments contain vascular tissue that delivers nutrients from the parental sporophyte to the anthers. Each **anther** is a group of four sporangia, structures in which spores are produced. Within the anther's sporangia, many diploid cells undergo meiosis, each producing four tiny, haploid spores. Because they are so small, generally 25–50 µm in diameter, the spores produced within anthers are known as **microspores**. Immature male gametophytes, known as **pollen grains**, develop from microspores. The term pollen comes from a Latin word meaning "fine flour," reflecting the small size of pollen grains. Pollen grains are eventually dispersed through pores or slits in the anthers. At the time of dispersal, the pollen grain is a two- or three-celled immature male gametophyte produced by mitotic division. During a later phase of development, a mature male gametophyte produces **sperm cells**.

Carpels Carpels are vase-shaped structures that produce, enclose, and nurture **female gametophytes**. Carpels contain veins of vascular tissue that deliver nutrients from the parent sporophyte to the developing gametophytes. The term **pistil** (named for its resemblance to the pestle used to grind materials to a powder) refers to a single carpel or several fused carpels (Figure 39.3). The topmost portion of a pistil, known as a **stigma** (Greek, meaning mark), receives pollen grains. The **style** is the middle portion of the pistil, and an ovary is at the bottom of the pistil. As described later in Section 39.3, the **ovary** produces and nourishes one or more ovules. An **ovule** consists of a spore-producing structure (a sporangium) and enclosing tissues consisting of modified leaves known as **integument**. Within an ovule, a diploid cell produces four haploid **megaspores** by meiosis, three of which die. The surviving megaspore generates a female gametophyte by mitosis. The female gametophytes of flowering plants typically consist of seven cells, one of which is the female gamete, the **egg cell**. This basic information about male and female gametophytes will help us to understand how they function to produce a young sporophyte within a seed.

Fertilization Triggers the Development of Embryonic Sporophytes, Seeds, and Fruits

In flowering plants, fertilization leads to the production of a young sporophyte that lies within a seed, completing the life cycle (Figure 39.4). Prior to fertilization, pollen grains released from anthers first find their way to the stigma of a compatible flower, a process known as **pollination**. Some plants display **self-pollination**, in which pollen from the anthers of a flower is transferred to the stigma of the same flower or between flowers of the same plant. **Cross-pollination**, which occurs when a stigma receives pollen from a different plant of the same species, is also common. Many flowers are attractive to insects or other animals that transport pollen, but oak flowers and those of some other angiosperms are adapted for pollen transport by wind. A few plants move pollen by means of water currents. The diverse ways that flowers are adapted for pollination are described and illustrated in Chapter 30.

Development of a Mature Male Gametophyte When pollen grains land on the stigma, the stigma functions as a gatekeeper, allowing only pollen of appropriate genotype to germinate. During germination, a pollen grain produces a long, thin **pollen tube** that contains two sperm cells. The pollen tube grows through the style toward the ovary. Upon reaching the ovules, the pollen tube grows through the **micropyle**, an opening in the

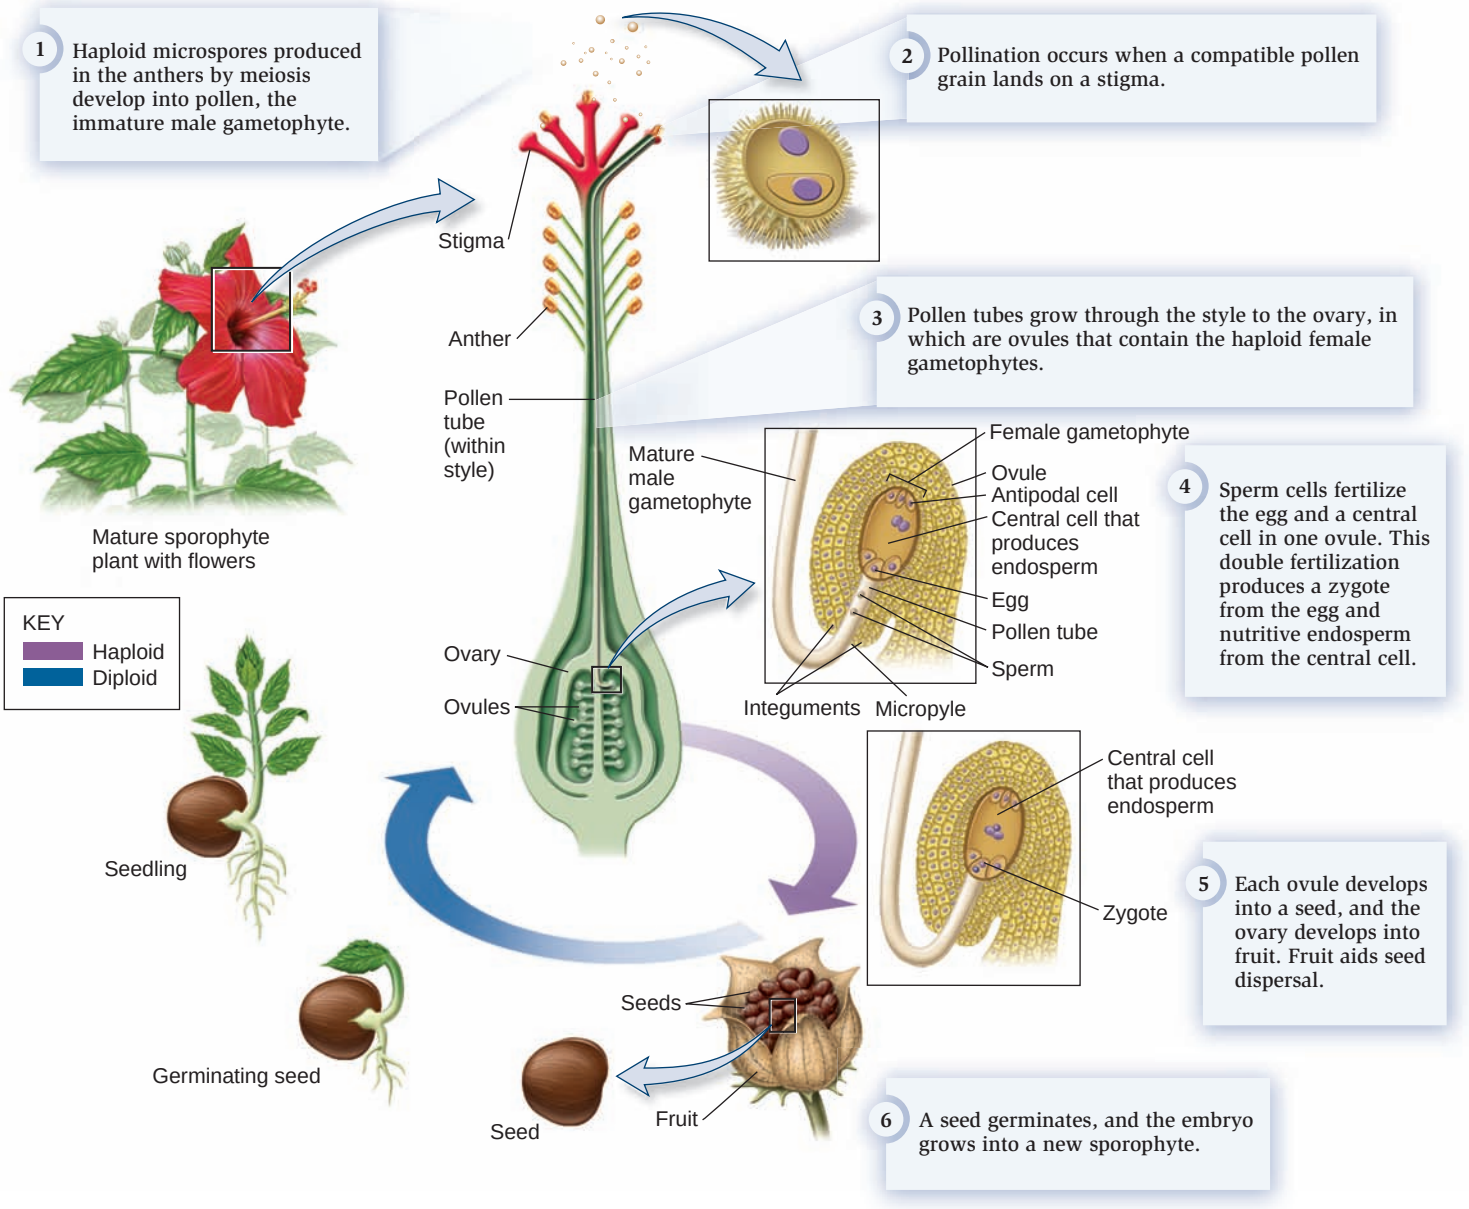


Figure 39.4 **The life cycle of a flowering plant.** The plant reproductive cycle is illustrated here by hibiscus.

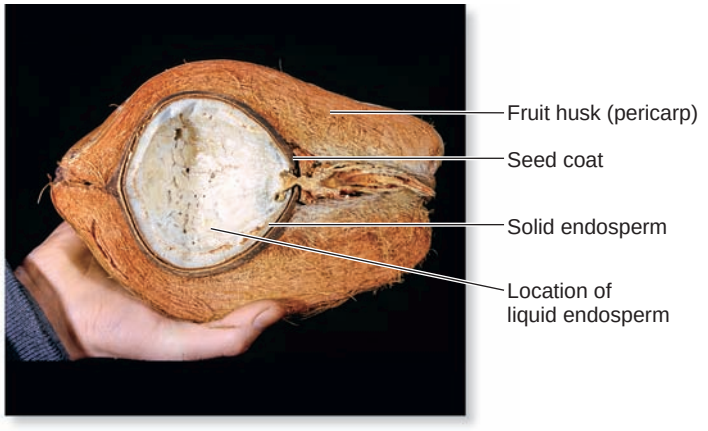
Concept check: *What advantage does the hibiscus flower gain by clustering its stamens around the pistil?*

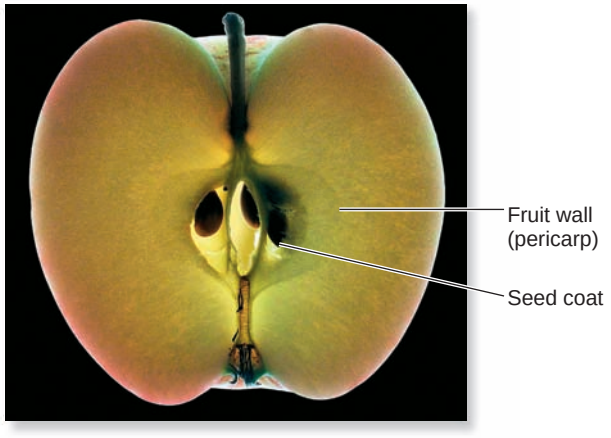
ovule, and delivers sperm to the female gametophyte (Figure 39.4). These sperm unite with haploid cells of the female gametophyte in the process of **fertilization**. Note that pollination and fertilization are distinct processes in flowering plants.

Double Fertilization Angiosperms display an amazing phenomenon known as **double fertilization**. In this process, two different fertilization events occur. One of the two sperm cells delivered by a pollen tube fertilizes the egg cell, thereby forming a diploid **zygote**. This zygote may develop by mitotic division into a young sporophyte, known as an **embryo**. Fertilization thus begins a new cycle of alternation between sporophyte and gametophyte generations. The other sperm delivered by the same pollen tube fuses with the two nuclei of the central cell of the female gametophyte. The cell formed by this second fertilization undergoes mitosis, eventually producing a nutritive tissue known as the **endosperm**. The embryo and the endosperm are essential parts of maturing seeds. Fertilization not only starts the development of zygotes into embryos but also triggers the transformation of ovules into seeds and ovaries into fruits. Embryo, seed, and fruit development occur at the same time.

Embryos and Seeds An embryo is a young, multicellular, diploid sporophyte that develops from a single-celled zygote by mitosis. Because they are not yet capable of photosynthesis,



(a) Coconut fruit and seed



(b) Apple fruit and seed

Figure 39.5 **The structure of fruits as adaptations for seed dispersal.** **(a)** The coconut fruit's outer wall, called a husk, allows the fruit to float and thus disperse its seed among tropical shores. **(b)** The apple is a juicy, sweet fruit that attracts animals to consume it, thereby helping to disperse its seed.

embryos depend on organic food and other materials supplied by sporophytes. Therefore, embryo development occurs within developing seeds located in a flower ovary. Seeds develop from fertilized ovules. Each developing seed contains an embryo and nutritive endosperm tissue, enclosed and protected by a **seed coat** that develops from the ovule integuments. When embryos and the seed coat have fully matured, they undergo drying, and the seed enters a phase of metabolic slowdown known as **dormancy**. Fully mature, dormant seeds are ready to be dispersed.

Fruit and Seed Dispersal A **fruit** is a structure that encloses and helps to disperse seeds (Figure 39.4). Seed dispersal benefits plants by reducing competition for resources among seedlings and parental plants, and it allows plants to colonize new sites.

Fruits develop from the flower's ovary and sometimes include other flower parts. Young fruits bearing immature seeds are typically small and green. During the time that embryos and seeds are developing, the fruit also matures. The ovary wall changes into a fruit wall known as a **pericarp** (from the Greek, meaning surrounding the fruit). Mature fruits vary greatly among plant species in size, shape, color, and water content. These variations represent adaptations for seed dispersal in different ways. For example, single-seeded dandelion fruits are dry and lightweight and bear a fluffy "parachute" derived from the flower's sepals (see the chapter-opening photo). These features foster dispersal by wind. In contrast, coconut fruits feature an airy husk (the pericarp) that keeps them afloat in ocean currents that carry coconuts from one tropical shore to another. Inside the coconut fruit is a single, large seed loaded with liquid and solid endosperm, which people use as coconut milk and coconut meat, respectively (Figure 39.5a). These large amounts of endosperm provide nutrients that sustain coconut seedling growth on infertile, sandy shores. Fruit variation is also extremely important to wild animals and in human agriculture. For example, most fruit crops are juicy and sweet, with relatively small seeds (Figure 39.5b). In nature, these features foster dispersal by birds and other animals that feed on such fruits.

Seed Germination and Seedlings If a dispersed seed encounters favorable conditions, including sufficient sunlight and water, it will undergo seed **germination**. During seed germination, the embryo absorbs water, becomes metabolically active, and grows out of the seed coat, producing a seedling. If the seedling obtains sufficient nutrients from the environment, it grows into a mature sporophyte capable of producing flowers. In the next section, we focus on flower production, structure, and development.

39.2 Flower Production, Structure, and Development

Flowers are essential sources of food for many animals that help to disperse pollen. As the result of coevolutionary relationships with such animals, flowers occur in a spectacular array of colors and forms that attract particular pollinators (refer back to Table 30.1). Flowers also attract humans because we possess sensory systems much like those of animal pollinators. We give bouquets to show love and appreciation; decorate homes, workplaces, and objects with flowers; display flower arrangements on ceremonial occasions; and make perfume from flowers. Consequently, many types of flowers are grown for the florist and perfume industries. Humans also associate flowers with the eventual presence of fruits, which are a source of our food. Flowers are necessary for the production of grain and other crops. Flower development is controlled by both environmental signals and changes in gene expression.

Environmental Signals Interact with Genes to Control Flower Production

Flowering time is controlled by the integration of environmental information such as temperature and day length (photoperiod) with hormonal influences (see Chapter 36). These stimuli are perceived and integrated by leaves, which then signal shoot

meristems to produce flowers. Experiments performed in the 1970s revealed that leaves transmit a flowering signal to the shoot apical meristem via phloem. Based on these results, plant scientists hypothesized the existence of a flowering hormone, which they named **florigen**, meaning "flower generator." However, the chemical nature of florigen remained unknown until recently. In 2007, several groups of plant researchers demonstrated that a protein known as FT (flowering time), produced in leaves, is transported to the shoot tip. In this location, FT protein binds to a transcription factor called FD, and together these proteins stimulate another protein known as LEAFY, which activates many floral-identity genes. As the result, a leaf-producing apical meristem transforms into a reproductive meristem. FT protein is probably the long-sought florigen molecule.

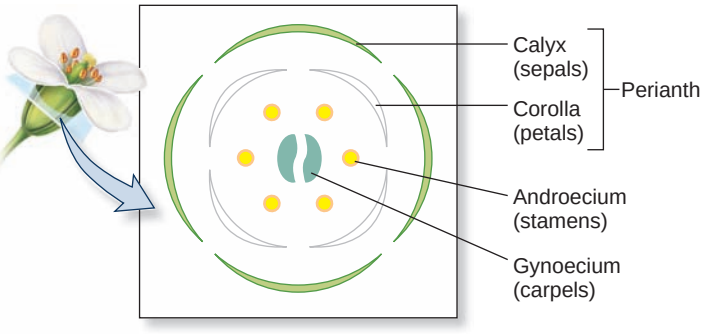


Figure 39.6 The occurrence of flower parts in whorls.

Developmental Genes Control Flower Structure

Organ identity genes specify the four basic flower organs—sepals, petals, stamens, and carpels. Other genes determine flower shape, color, odor, or grouping into bunches known as inflorescences.

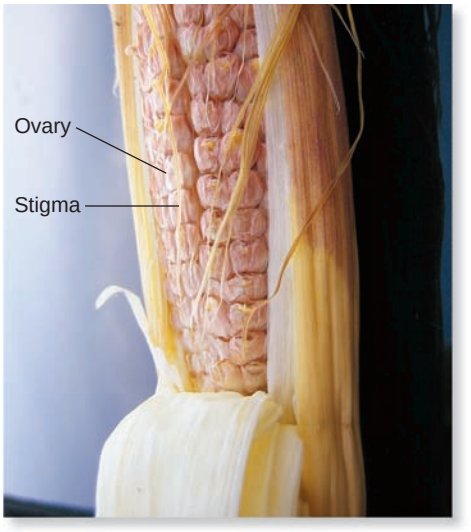
The Genetic Basis of Flower Organ Identity Sepals, petals, stamens, and carpels occur in four concentric rings known as **whorls**. Sepals (collectively known as the **calyx**) form the outermost whorl, and petals (together known as the **corolla**) form an adjacent whorl type. Stamens (the **androecium**) create a third type of whorl, and carpels (the **gynoecium**) form the innermost whorl (Figure 39.6). The **perianth** consists of the calyx plus the corolla.

You may recall that *A*, *B*, *C*, and *E* genes encode transcription factors that control the production and arrangement of these whorls (refer back to Figure 19.24). Class *A* genes control the development of sepals and petals, class *B* genes specify petal and stamen formation, and class *C* genes determine the identities of the stamen and carpels. *E* gene expression distinguishes the sepals from the other whorls. However, not all flowers produce all four types of organs.

Variation in Number of Whorls Flowers that possess all four types of flower whorls—calyx, corolla, androecium, and gynoecium—are known as **complete flowers**. In contrast, flowers that lack one or more flower whorls are described as **incomplete flowers**. Flowers having both stamens and carpels are said to be **perfect**, whereas flowers lacking stamens or carpels are described as **imperfect**. An imperfect flower that produces only carpels is known as a carpellate flower (or pistillate flower). Imperfect flowers that produce only stamens are described as staminate flowers.

Corn is a plant that produces both imperfect staminate and carpellate flowers (Figure 39.7). The flowers of corn start to develop as perfect flowers, but in carpellate flowers, the stamens stop developing. After pollination and fertilization, each carpellate flower produces one of the kernels on a cob of corn. In contrast, staminate flowers of corn, which are found in corn tassels, produce the pollen. Corn is termed **monoecious** (meaning "one house") because it produces staminate and carpellate

(a) Staminate flowers of *Zea mays* (corn)



(b) Carpellate flowers of *Zea mays* (corn)

Figure 39.7 **Imperfect flowers of corn, a monoecious plant.** **(a)** Staminate flowers lack carpels, and **(b)** carpellate flowers lack stamens, but both types of flowers occur on a single corn plant. In contrast, dioecious plants produce staminate and carpellate flowers on separate plants.

Concept check: *What inference can you make from the observation that corn flowers lack showy petals?*

flowers on the same plant. Holly and willow also produce staminate and carpellate flowers, though on separate plants, and are thus described as **dioecious** (meaning "two houses").

Variation in Flower Organ Number In addition to variation in whorls, flowers vary in number of organs. You may recall that flowering plants occur in two major groups differing in flower structure and other features: the eudicots and the monocots (see Chapter 35). Eudicot flower organs often occur in fours or fives or a multiple of these numbers. By contrast, monocot flower organs often occur in threes or a multiple of three. Many plants sold for use in gardens have been bred so that the flowers produce multiple organs. Garden roses, for example, typically have many more whorls of petals than do wild roses. This change results from a mutation that causes organs that would have become stamens to instead develop into additional petals. Other flowers possess relatively few organs. For example, the miniscule flowers of the tiny aquatic flowering plant *Lemna gibba* produce no perianths and only two stamens.

Variation in Flower Color Different flower parts may vary in color. The calyx and corolla of monocot flowers such as tulip are often similar in appearance and attractive function. In contrast, eudicot flowers tend to have green, leaflike sepals that are quite distinct from petals, which are often colorful and fragrant. For example, the sepals of petunia (*Petunia hybrida*) resemble leaves in having numerous stomata on both epidermal surfaces, and internal parenchyma tissue rich in chloroplasts. Petunia petal epidermis lacks stomata, and the parenchyma tissue usually lacks chlorophyll. Instead, the cell vacuoles of petals are often colored by **flavonoids**, a type of secondary metabolite (see Chapter 30). Among the pigments responsible for pink, red, blue, violet, purple, or yellow colors of petals and other flower parts, flavonoids are the most important. Color variations arise from differences in gene action that influence pigment biosynthesis pathways. Petunia has become an important model system for understanding the evolution of genes and proteins that control petal color.

Interestingly, research involving flower color has led to important discoveries in genetics. In 1990, plant molecular biologist Rich Jorgensen and colleagues reported one of the first cases of gene silencing in plants. You may recall that gene silencing is one of the ways in which gene expression is controlled (see Chapter 13). In an attempt to produce flowers of deeper color, the researchers introduced an extra copy of a pigment-producing gene into petunia plants. To their surprise, the extra copy of the gene sometimes produced flowers whose petals had white patches or were completely white (Figure 39.8). Adding the extra gene caused the plants to produce siRNA that not only silenced the expression of the extra gene, but also the natural pigment-producing genes, causing white patches on the petals.

Variation in Flower Fragrance The fragrances of flowers result from secondary metabolites that diffuse into the air from petals and other flower organs. One example is the terpene known as geraniol, which is alluded to in Shakespeare's famous phrase, "A rose by any other name would smell as sweet." Diverse fragrances function to attract particular types of animal pollinators. Because humans possess sensory systems similar to those of many pollinators, we are also attracted to many of these fragrances. Genetic variation in the synthesis of different types of secondary metabolites is responsible for the many types of flower scents.

Flower Shape Variation Resulting from Organ Fusion During their development, many flowers undergo genetically controlled fusion between whorls or fusion of the organs within a whorl. Stamen filaments often partially fuse with the carpel or form a tube surrounding the pistil, a feature displayed by hibiscus flowers (see Figure 39.4). Each small dandelion flower has five petals that are fused at their sides to form a single

strap-shaped structure. Some flowers have petals that are fused together to form a tube that holds nectar consumed by animal pollinators (refer back to Figure 30.20).

As we have seen, pistils are often composed of two or more fused carpels. The rosy periwinkle (*Cantharanthus roseus*), the original source of widely used leukemia drugs, provides an example. This plant's flowers each have two carpels, whose surfaces fuse together during flower development. In 1995, plant developmental biologist Judy Verbeke and colleagues reported that when the two young carpels first come into contact with each other, epidermal cells change their pattern of differentiation. This re-differentiation is necessary for carpel fusion. When the investigators experimentally removed one of the carpels or inserted a nonporous barrier between the two carpels, cells did not redifferentiate and carpels did not fuse. If they inserted a porous barrier, however, normal differentiation and carpel fusion occurred. These experiments indicate that carpels communicate with each other by means of diffusible chemical signals that foster the cellular changes necessary for fusion.

Variations in Flower Symmetry and Aggregation Flower shape variation can also result from changes in symmetry. Flowers that possess radial symmetry are described as regular, actinomorphic, or polysymmetric flowers. Flowers having radial symmetry can be divided into two equal parts by more than one plane inserted through the center of the flower. In contrast, flowers that display bilateral symmetry are known as irregular, zygomorphic, or monosymmetric flowers. Flowers having bilateral symmetry can be divided into two equal parts by only a single plane inserted through the center. The evolution of bilateral symmetry in flowers can often be linked to insect pollination.

Symmetry, like other flower features, is under genetic control. The production of flowers having bilateral symmetry is controlled by transcription factors such those encoded by the *CYCLOIDEA* gene. For example, snapdragon (*Antirrhinum majus*) flowers are normally bilaterally symmetrical, but a loss-of-function mutation in the *CYCLOIDEA* gene causes these flowers to display radial symmetry (Figure 39.9). Another interesting example is the cut-flower crop plant *Gerbera hybrida*, whose "flowers" are actually **inflorescences**, structures composed of many flowers. While many flowers occur singly, many others occur in inflorescences of diverse types that are adapted to particular pollination circumstances. As in the case of sunflowers (refer back to Figure 30.20b), *Gerbera* flowers occur in more than one structural type having distinctive functions. During inflorescence development, a *CYCLOIDEA*-like transcription factor is expressed more strongly at the margins so flowers in that position become bilaterally symmetrical, while the centermost flowers of *Gerbera* are more radially symmetrical (Figure 39.10). These central flowers produce stamens and therefore

Figure 39.10 **An inflorescence.** The clustering of flowers into a type of inflorescence known as a head, displayed here by a Gerbera daisy, is an adaptation that fosters pollination by insects.

Concept check: *List several ways in which the flowers at the rim of the Gerbera inflorescence differ from those at the center.*

function to supply pollen. In contrast, stamens do not develop in the marginal flowers, and their petals fuse to form larger colorful structures that attract pollinators.

39.3 Male and Female Gametophytes and Double Fertilization

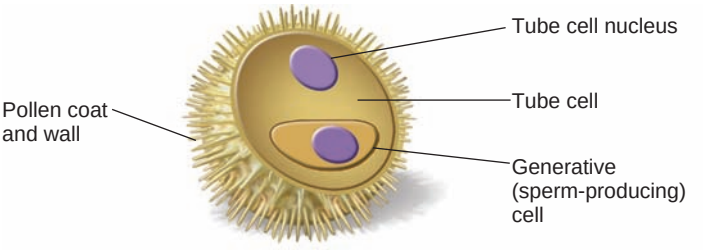
Mature male gametophytes are pollen tubes that deliver sperm cells, the male gametes. Mature female gametophytes are located within ovules and produce egg cells, the female gametes. In this section, we will begin by examining male and female gametophyte development and how stamens and carpels aid this process. Gametes participate in fertilization, a process we consider next. We will also take an in-depth look at how scientists first achieved the technique of in vitro fertilization, which has applications in producing transgenic crops and allowing plant biologists to gain a better understanding of plant fertilization processes.

Pollen Grains Are Immature Male Gametophytes

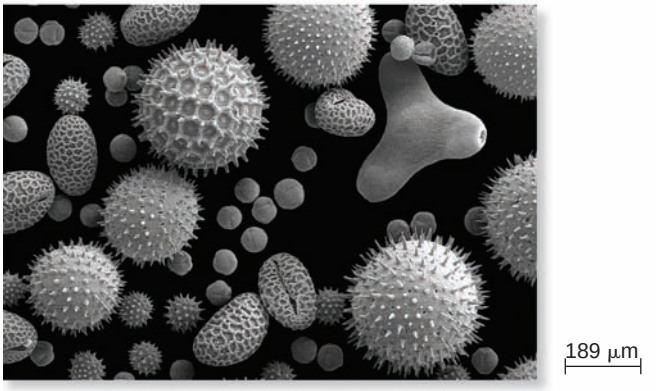
As we have earlier noted, pollen grains are immature male gametophytes that are adapted for transport through air from one flower to another. Pollen grains develop within the sporangia of anthers. Inside these sporangia, diploid cells undergo meiosis and cytokinesis. As a result, each diploid cell gives rise to a cluster of four haploid microspores, each having a thin cellulose cell wall. The development of microspores into pollen grains involves two processes that occur at the same time: (1) the microspore divides within its cell wall, producing a two- or three-celled young male gametophyte, and (2) each male gametophyte develops a tough pollen wall that protects the gametophyte during pollen transport. Both of these processes are completed before anthers release pollen.

Early Male Gametophyte Development Each microspore nucleus undergoes one or two mitotic divisions to form a young male gametophyte. The first division gives rise to two specialized cells: a tube cell and a generative cell suspended within the tube cell (Figure 39.11a). The **generative cell** divides to produce two sperm cells, either before or (more commonly) after pollination. The **tube cell** produces the pollen tube, which delivers sperm to the female gametophyte.

Pollen Wall Development A mature pollen grain has a tough wall, and each plant species produces pollen whose wall has a distinctive sculptural shape (Figure 39.11b). The **pollen wall**, which surrounds the plasma membrane of the tube cell, is composed largely of a nearly indestructible polymer known as **sporopollenin**. Sporopollenin is so chemically inert that its biochemical composition is still uncertain. Named for its presence on the surfaces of mature spores and pollen, sporopollenin confers physical strength, chemical inertness, and resistance to microbial attack. Sporopollenin protects spores and pollen from damage. It also is responsible for the occurrence of intact fossil pollen grains in deposits that are millions of years old.



(a) A cut pollen grain showing immature male gametophyte



(b) SEM of whole pollen grains showing distinctive pollen wall ornamentation

Figure 39.11 **Pollen grains.** **(a)** Diagram of cut pollen grain. **(b)** SEM of whole pollen grains of different species.

Concept check: *What is the maximum number of cells in a mature male gametophyte of a flowering plant?*

Development of the pollen wall starts with deposition of a blanket of the carbohydrate **callose** around each cluster of four microspores after they form by meiosis. The callose blanket seals microspores off from the influences of adjacent sporophyte tissues, thereby aiding pollen differentiation. Callose also provides a surface pattern for sporopollenin deposition and holds microspores together until an anther enzyme degrades the callose, freeing developing pollen grains from each other.

As pollen grains develop, anther cells secrete a **pollen coat**, a layer of material that covers the sporopollenin-rich pollen wall. Coat materials include additional sporopollenin and pigments that give pollen its typically yellow, orange, or brown coloration, and lipids and proteins that aid in pollen attachment to carpels. Certain of these pollen coat compounds are responsible for allergic reactions in people exposed to particular types of airborne pollen. It is no wonder that pollen allergies are common, because about 10% of flowering plants are wind-pollinated, and such plants produce copious amounts of pollen. For example, ragweed plants (genus *Ambrosia*), which are commonly associated with allergies, each produce an estimated 1 billion pollen grains during a year.

The production and dispersal of pollen grains is just the first phase of male gametophyte development. We will learn more about the second phase of male gametophyte development, the

production of a pollen tube, after focusing on female gametophyte development.

A Female Gametophyte Develops Within Each Ovule

Each ovule produces a single female gametophyte (Figure 39.12). Although flowering plant female gametophytes vary somewhat in size and structure, many possess seven cells and eight nuclei. One of these cells is an egg cell, which lies wedged between two cells known as **synergids**. These synergids have characteristic cell-wall ingrowths that increase the area of the plasma membrane, thereby helping to move nutrients from the larger sporophyte to the nonphotosynthetic female gametophyte. The other four cells of the angiosperm female gametophyte consist of three antipodal cells, whose functions are not well understood, and a large **central cell**. The central cell contains two nuclei, which accounts for the extra nucleus in the female gametophyte.

After Pollination, the Pistil Controls Pollen Germination

Pollen grains adhere to the surfaces of the stigma, which provides a receptive surface. The stigma and the style determine whether or not pollen grains germinate and pollen tubes grow. In some plants, pistils allow pollen from the same plant to germinate, but in many cases, pistils prevent the germination of pollen from different species and pollen that is genetically too similar, such as pollen from the same flower.

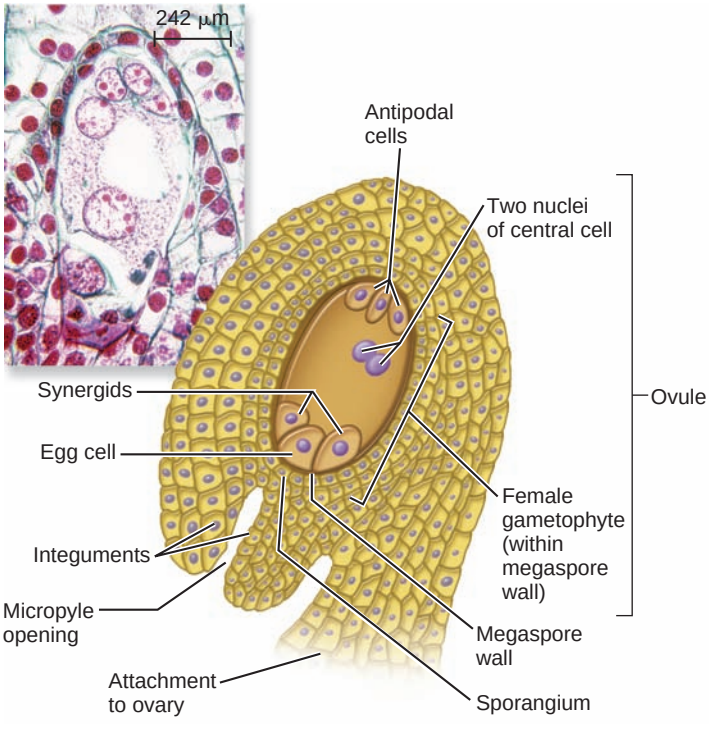


Figure 39.12 Female gametophyte within an ovule.

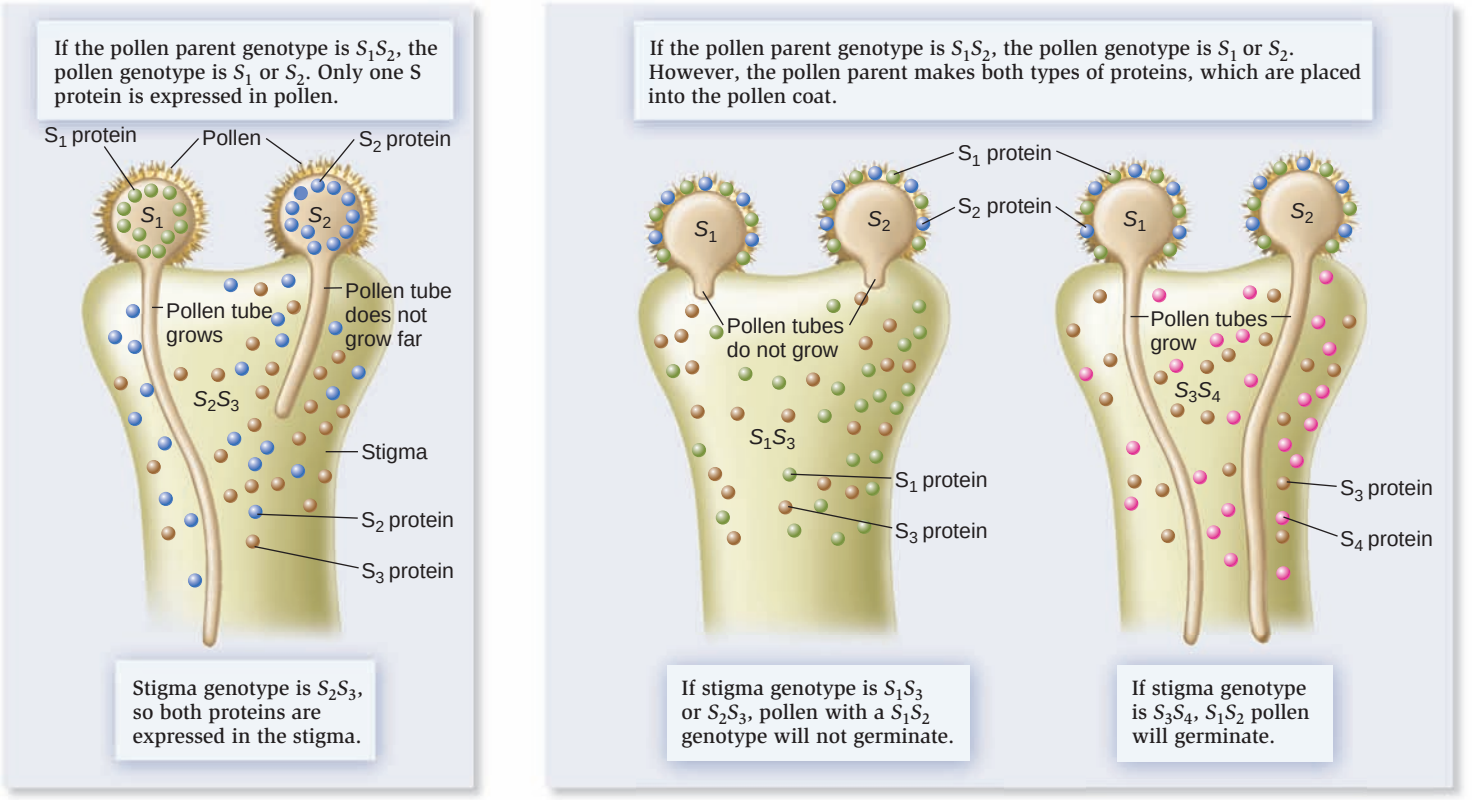
Concept check: *How do female gametophytes obtain nutrients?*

Rejection of pollen that is genetically too similar to the pistil is a phenomenon known as **self-incompatibility** (**SI**). This feature helps to decrease the likelihood of recessive disorders in offspring. In the absence of self-incompatibility, self-fertilization and matings between closely related parent plants are more likely to produce progeny that are homozygous for recessive deleterious alleles, which would then be expressed. How then do pistils recognize compatible pollen grains of the appropriate species that are genetically distinct? Recognition involves interactions between proteins of pollen and pistil cells. These interactions influence the ability of pollen to take up water, a process known as rehydration. Pollen is nearly dry when it reaches the stigma, and incompatible pollen will not rehydrate and will eventually die. In contrast, compatible pollen rehydrates, a process that activates pollen metabolism and allows it to germinate. Pollen–stigma interactions thus form an important part of a flowering plant's mate recognition and selection system.

A closer look at SI systems explains how they work. In many plants, SI involves the *S* gene locus, which encodes S proteins. Each locus contains two genes, one that determines pollen compatibility traits and another that determines pistil compatibility traits. Multiple *S* alleles for both genes occur in plant populations. Two major types of SI are known—gametophytic SI and sporophytic SI. Gametophytic SI occurs when an *S* gene within a pollen grain itself determines compatibility. Because pollen is a haploid gametophyte, the pollen genome contains only one pollen-compatibility allele. This allele encodes a specific S protein that is located in the pollen cytosol. When the gametophyte controls compatibility, tubes may start to grow from incompatible pollen, but the same specific S protein encoded by pistil cells enters the tubes and destroys the pollen tube RNA. This halts tube growth. In contrast, S protein within genetically compatible pollen binds the pistil-produced protein, thereby preventing destruction of pollen tube RNA and allowing tube growth to continue (Figure 39.13a).

Sporophytic SI occurs when pollen compatibility is determined by the sporophyte that produces the pollen. This control is exerted when anthers deposit proteins into the pollen coat. Because anther cells belong to the sporophyte generation, they possess two *S* genes, and therefore, heterozygotes will produce two different pollen coat S proteins. When the sporophyte controls compatibility, pollen cannot germinate when S proteins in the plasma membranes of stigma cells recognize (bind) the S proteins of incompatible pollen. In this case, protein binding leads to signal transduction processes that prevent pollen germination. However, pollen can germinate if stigma proteins are unable to bind genetically distinct S proteins in its coat (Figure 39.13b).

If the SI system becomes inactivated by mutation, a plant species can become self-pollinating. This has occurred during the evolution of self-pollinating lines of the model plant *Arabidopsis* from an ancestor that possessed SI. An estimated 20–50% of all modern plant species, including many crop plants, display self-pollination. The ability to self-pollinate



(a) Gametophytic SI: If pollen *S* allele does not match either stigma allele, pollen will germinate.

(b) Sporophytic SI: If pollen coat S proteins do not match either stigma S protein, pollen tubes will grow.

Figure 39.13 Self-incompatibility. Self-incompatibility helps plants to avoid the combination of gametes that are too genetically similar. It is controlled by interactions between proteins of pollen and the pistil. **(a)** In gametophytic self-incompatibility, compatibility between pollen and pistil is determined by the haploid genotype of the pollen. In this case, S protein is located in the pollen cytosol. **(b)** In sporophytic self-incompatibility, compatibility between pollen and pistil is determined by the sporophyte that produced the pollen and contributed S proteins to its coat.

can be advantageous to plants as they colonize new habitats, and it is a common characteristic of weedy and invasive plant species. Self-pollination is also useful to scientists performing genetic experiments with *Arabidopsis*. Pea plants are also self-pollinating, a feature that was useful to Mendel in performing his classic experiments on inheritance (see Chapter 16).

During Pollen Germination, the Pollen Tube Grows, and Double Fertilization Occurs

As we have seen, a pollen grain germinates by taking up water, and when this occurs, the pollen generative nucleus usually divides by mitosis to produce two sperm cells. Upon rehydration, it takes a few minutes to an hour or so for the tube cell to produce a pollen tube. Pollen tubes extend from a thin region in the grain's wall into the spaces between cells of the style. To deliver sperm to egg cells, the tube must grow from the stigma, through the style, to reach the ovule (Figure 39.14).

The Role of the Style In some flowers, the style plays a role in mate selection by nourishing or inhibiting pollen tube growth. The style also guides pollen tube growth. For example, in 2005, Elizabeth Lord and associates reported that the *Arabidopsis* style produces a blue copper-containing protein known as plantacyanin. These investigators also noted that the concentration of plantacyanin is normally low at the stigma but gradually increases in the style, with highest levels occurring near the ovary. Their observation suggested that plantacyanin might guide pollen tube growth toward ovules. Lord and associates tested this hypothesis by producing transgenic plants that expressed abnormally high levels of plantacyanin in the stigma. This change disrupted normal pollen tube behavior, causing pollen tubes to grow in circles around stigma cells or, in rare cases, up into the air, away from the style! This experimental evidence supports the concept that a gradient of plantacyanin in the style likely guides *Arabidopsis* pollen tubes toward ovules.

Tip Growth and Sperm Delivery A pollen tube transports two sperm cells to a female gametophyte in an ovule. A pollen tube does this by a process called tip growth, which is controlled by the tube cell nucleus. During tip growth, new cytoplasm and cell-wall material are added to the tip of an elongating cell (Figure 39.15). Golgi vesicles continuously deliver the carbohydrate

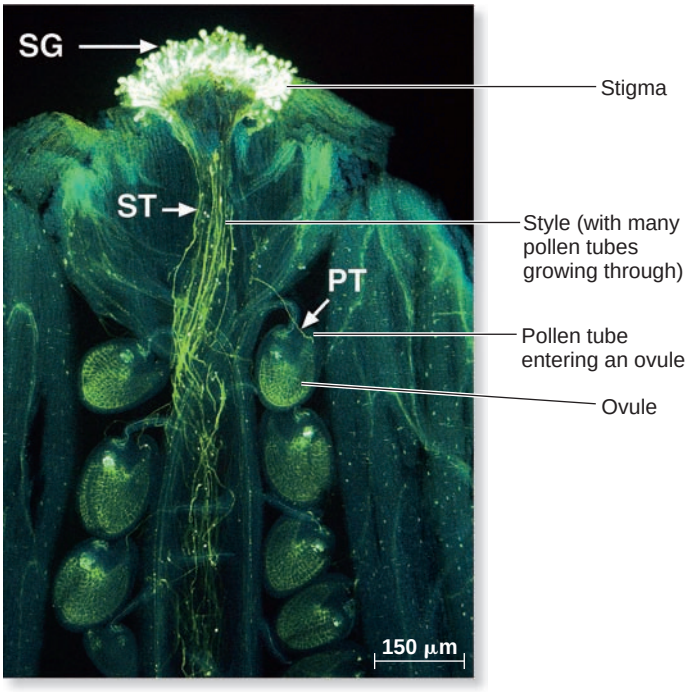


Figure 39.14 **Pollen tubes delivering sperm to ovules.** This fluorescence microscopic view shows pollen grains (the pale objects) germinating on the stigma surface (SG) and pollen tubes (PT) growing through the style (ST) toward ovules.

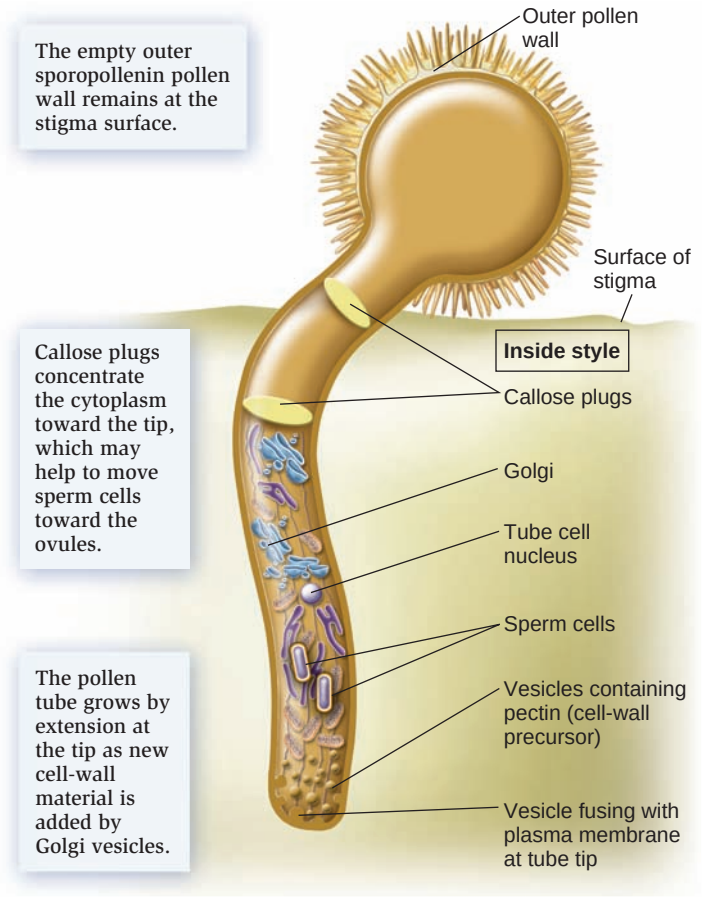

Figure 39.15 **Tip growth by a pollen tube.**

pectin to the tube tip, whose thin cell wall is largely composed of pectin. As a pollen tube grows, callose plugs are commonly deposited in the older parts of the tubes. These plugs concentrate the tube cytoplasm at the tip, which may help to maintain the turgor pressure necessary for continued tip growth.

In some plants, pollen tubes have been observed to grow toward ovules at about 0.5 mm per hour, commonly taking from 1 hour to 2 days to reach their destination. When a pollen tube encounters an ovule, it enters through the micropyle. Attracted by secretions from a synergid, the pollen tube penetrates the synergid. The thin tube tip wall then bursts, releasing the sperm into the female gametophyte. Plant biologists used to think that these two sperm cells were identical, but now it is known that in at least some plants, the sperm differ in structure and role. For example, plant reproductive biologist Scott Russell reported in 1985 that pollen tubes of leadwort (*Plumbago zeylanica*) contain a smaller sperm cell that is destined to fuse with the egg and a larger sperm that participates in endosperm formation.

Double Fertilization During the process of double fertilization, one sperm nucleus fuses with the egg cell to produce a zygote, the first cell of a new sporophyte generation (see steps 4 and 5 in Figure 39.4). The other sperm fuses with the two nuclei of the central cell to form the first endosperm cell. As the zygote develops into an embryo, the endosperm develops into a nutritive tissue that is usually triploid. We will next see how plant biologists first achieved plant fertilization in the laboratory using isolated gametes, a process known as in vitro fertilization.

Feature Investigation

Kranz and Lörz First Achieved Plant in Vitro Fertilization

In vitro fertilization (IVF) is a widely practiced technology in human medicine and in agriculture. The term in vitro is Latin, meaning "in glass," referring to lab dishes. In past decades, plant biologists had only been able to perform in vitro pollination. To do this, they removed ovules from plant carpels and applied pollen to them in laboratory dishes. Pollen tubes were able to deliver sperm cells to female gametophytes, resulting in fertilization and seed development. This process was useful in overcoming mating barriers to hybridization that occur because stigmas and styles usually prevent interspecies matings. Therefore, in vitro pollination allowed agricultural scientists to produce new interspecies hybrids that would otherwise not be possible.

Crop scientists realized that IVF, the direct union between egg and sperm cell, would allow plant biologists to gain a better

understanding of plant fertilization processes and might ultimately be useful in producing hybrid crops. However, plant gametes are so deeply buried within gametophytic and sporophytic tissues that scientists found it difficult to isolate and manipulate them. As a result, plant IVF was not accomplished until 1993. In that year, German researchers Erhard Kranz and Horst Lörz reported that they had used isolated gametes to produce mature hybrid corn (maize) plants, as shown in Figure 39.16.

The development of a method for plant IVF required several research steps. First, by conducting many experiments, Kranz and Lörz developed procedures for isolating and handling single eggs and sperm. They also designed a process for using electrical current to induce gamete fusion. Further, they defined the optimal chemical and physical conditions necessary for in vitro development of zygotes into mature plants. For example, the researchers discovered that "nurse" cells grown from excised natural embryos were critical to the survival of

Figure 39.16 Kranz and Lörz first achieved plant in vitro fertilization.

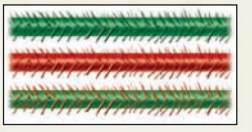
GOAL To demonstrate in vitro plant fertilization using isolated gametes.

KEY MATERIALS Maize egg cell donor plants with green stigmas and hairs, and maize sperm cell donor plants with red stigmas and hairs.

	Experimental level	Conceptual level
1 Isolate sperm cells from pollen ruptured by osmotic shock. Isolate egg cells from ovules by microdissection of female gametophytes with a glass needle, using an enzyme solution that degrades cell walls.		
2 Under a light microscope, use a micromanipulator to line up egg and sperm on electrode surface.		Sperm and egg are aligned.
3 Fuse gametes with electrical pulses.		
4 Culture zygotes on porous membrane over a suspension of maize "nurse" cells in a solution of minerals and glucose at pH 5.5, on a rotary shaker, at 25°C, with 16-hour light/day.		Maize "nurse" cells allow a sustained growth of zygotes into embryos.
5 Transfer embryos to solid media containing various concentrations of sucrose and plant hormones.		Embryos develop into young plants.
6 Transplant young plants to soil. When plants flower, examine plants to see if their stigmas and stigma hairs were those expected of a hybrid.		

7 THE DATA

Plants donating the egg cells (step 1) had green stigma and hairs.
Plants donating the sperm cells (step 1) had red stigma and hairs.
Plants produced by in vitro fertilization (step 6) had green stigma, red hairs.



8 CONCLUSION Under the appropriate conditions, plant in vitro fertilization can occur.

9 SOURCE Kranz, E., and Lörz, H. 1993. In vitro fertilization with isolated, single gametes results in zygotic embryogenesis and fertile maize plants. *Plant Cell* 5:739–746.

zygotes and embryos produced in vitro. The IVF corn embryos displayed normal development and grew into normal seedlings and reproductive adults. These investigators demonstrated their accomplishment by showing the hybrid origin of traits in progeny plants (see The Data in Figure 39.16). The hybrid progeny plants had flower pistils with green stigmas coated by red hairs. These traits were inherited from different parents: The green stigmas were inherited from the female parent, and the red hairs were inherited from the male parent. This work provided a foundation for additional IVF work with plants and also enabled more detailed investigations of plant embryo development, our next subject.

Experimental Questions

1. Why had in vitro plant fertilization been so difficult for plant biologists to accomplish before the work of Kranz and Lörz?
2. What procedure did Kranz and Lörz use to accomplish fertilization of isolated eggs by sperm cells?
3. How did Kranz and Lörz demonstrate that their plants were actually hybrids arising from in vitro fertilization involving specific genetic parents?

39.4 Embryo, Seed, Fruit, and Seedling Development

Seeds and fruits are major components of plant reproduction. Seeds contain dormant plant embryos that may develop into seedlings under favorable conditions. As noted earlier, fruits aid seed dispersal, which allows plants to colonize new sites. Embryos, seeds, and fruits mature simultaneously, and their development is coordinated by hormonal signals. Seedling development is also hormonally regulated.

Endosperm Provides Nutrients for Developing Embryos Within Seeds

Endosperm is a tissue present in developing angiosperm seeds and also occurs in the mature seeds of many plants. Rich in protein, lipid, carbohydrate, vitamins, and minerals, endosperm supplies the nutritional needs of developing embryos and often seedlings as well. We have already noted how humans use the coconut's liquid and solid endosperm as food (see Figure 39.5a). In fact, a large percentage of human and animal food protein comes from seed endosperm of grain crops. Corn, wheat, rice, and other grain crops generate more than 380 billion pounds of endosperm per year in the U.S. alone.

How does this valuable tissue develop? Recall that the first cell of the endosperm tissue arises by the fusion of a sperm nucleus with the two nuclei of the female gametophyte's central cell. The resulting nucleus is typically triploid, combining one set of chromosomes from the male parent with two sets from the female parent. Mitotic division of the triploid cell generates endosperm tissue. The food stored in endosperm comes from the parent sporophyte by diffusing through moist cell walls and intercellular spaces.

As the embryo develops, it uses food stored in the endosperm, but food storage differs in eudicots and monocots. By the time that most eudicot seeds are mature, they contain little or no endosperm because such embryos store organic food in two embryonic leaves, the cotyledons. The seeds of legumes such as beans, peas, and peanuts are valued as food because of their protein-rich cotyledons. In contrast, many mature monocot seeds retain considerable endosperm, explaining the food value of grain crops.

Embryos Develop from Zygotes Within Seeds

Embryos develop from single-celled zygotes by mitotic divisions, in the process known as **embryogenesis**. This process begins with an unequal cell division and proceeds through several distinctive stages, as illustrated by the model eudicot plant *Arabidopsis* (Figure 39.17).

Early Embryogenesis Sometime within a period of days to several weeks following fertilization, a zygote begins to divide.

At this point, a zygote is blanketed with a layer of callose, which helps to seal it off from the environment, thereby fostering embryo-specific gene expression. The zygote's first cell division is unequal, producing a smaller cell and a larger cell (Figure 39.17, step 1). These two cells differ in cytoplasmic contents, which Kranz and Lörz observed in IVF corn embryos. This unequal division helps to establish the apical-basal (top-bottom) polarity of the embryo, which persists through the life of the plant. The smaller cell develops into the embryo, whose radial symmetry is established at this point and continues in adult plants. The larger cell develops into a **suspensor**, a short chain of cells anchored near the micropyle at the ovule entrance (Figure 39.17, step 2). The suspensor channels nutrients and hormones from the parent sporophyte into the young embryo, which absorbs them at its surfaces.

Researchers have found that the functional loss of a gene called *TWN* (twin) transforms the suspensor into a second, twin embryo. This indicates that when TWN protein is active, it prevents the suspensor from developing into an embryo, thereby maintaining normal suspensor attachment and nutrient transport functions. The suspensor usually disappears by controlled cell death during embryo development. Older embryos rely on nutrients supplied by the endosperm.

Later Embryogenesis Young eudicot embryos are spherical, but they soon become heart-shaped as the seedling leaves, called **cotyledons**, start to develop. At this point, auxin and cytokinins are involved in establishing the young shoot and root at the apical and basal poles, respectively. This process is also influenced by the TOPLESS protein, which helps to repress auxin-response genes that would otherwise promote root development at the apical pole. (Mutants that have lost normal *TOPLESS* function have roots at both apical and basal poles, but no shoots, and are thus topless.) Eudicot embryos such as *Arabidopsis* then become torpedo-shaped, and as the cotyledons grow, they often curl to fit within the developing seed (Figure 39.17, step 4). In contrast, mature monocot embryos are cylindrical, with a single cotyledon and a side notch where the apical meristem forms. Mature embryos then become dormant as seeds mature.

Mature Seeds Contain Dormant Embryos

The structure of mature monocot and eudicot seeds differs. Within eudicot seeds, mature embryos often display an **epicotyl**, the portion of an embryonic stem with two tiny leaves in a first bud that is located above the point of attachment of the cotyledons (Figure 39.18a). The **hypocotyl** is the portion of an embryonic stem located below the point of attachment of the cotyledons. An embryonic root, the **radicle**, extends from the hypocotyl. Much of the endosperm has been absorbed into the large cotyledons.

In contrast, mature monocot embryos, such as those of corn, feature an epicotyl with a first bud enclosed in a protective sheath known as the **coleoptile**. The young monocot root is enclosed within a protective envelope known as the **coleorhiza** (Figure 39.18b).

As seeds mature, they undergo changes leading to dormancy, an adaptation that prevents them from germinating when environmental conditions are not suitable for seedling

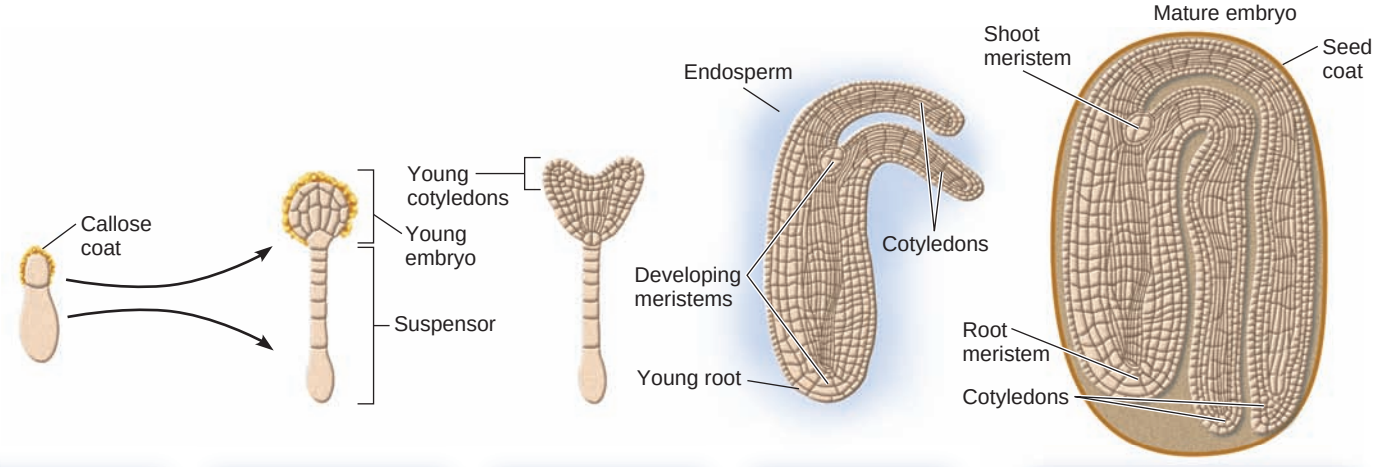


Figure 39.17 Embryogenesis in the eudicot *Arabidopsis*.

Concept check: *How would this embryo differ if its TOPLESS genes were nonfunctional?*

Concept check: *Why do mature seeds of eudicots lack extensive amounts of endosperm?*

growth. During this process, embryos become dry and thus able to survive in the absence of water. Seed maturation includes transformation of the ovule's integuments into a tough seed coat (see Figure 39.17, step 5). The seed coat restrains seedlings from growing and prevents the entry of water and oxygen, which maintains low seed metabolism. In addition, the coats of some seeds are darkly colored with pigments that may help to prevent damage by UV radiation or microbial attack. Another change leading to seed dormancy is gradual, controlled loss of water from the embryo and other seed tissues. As the result, the water content of dispersed seeds is only 5–15%. Abscisic acid (ABA) is a hormone that induces the activity of genes that help embryo tissues to survive the drying process. Some of these desiccation-tolerance genes encode proteins that form loose coils enclosing cell contents, thereby preventing damage as the cytoplasm becomes almost completely dry. When the seeds of flowering plants are dry and ready for dispersal, they are released from the plant while enclosed in a fruit or released when the fruit breaks open.

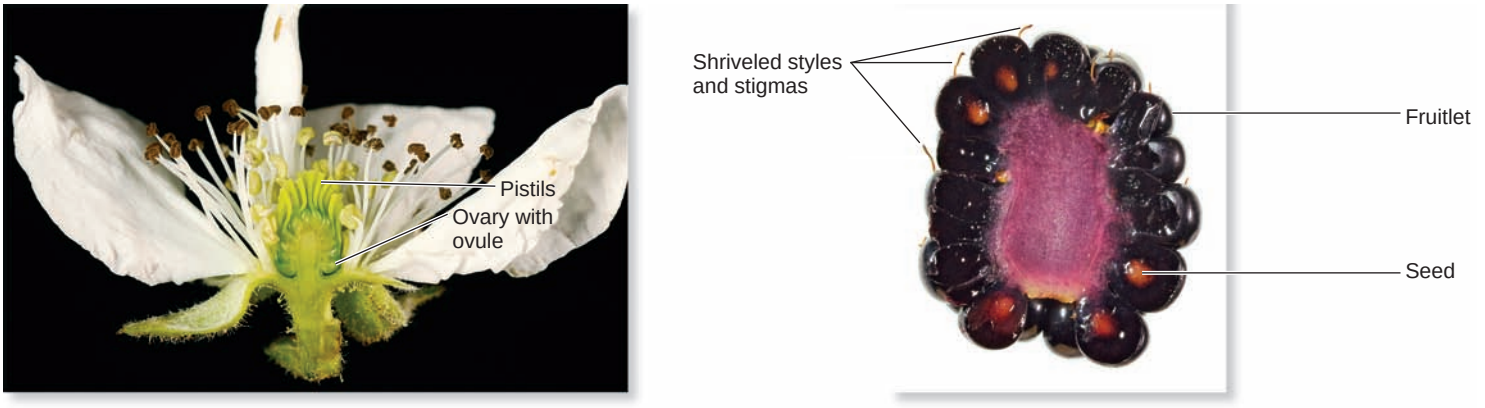
Fruits Develop from Ovaries and Other Flower Parts

All fruits develop from ovaries and sometimes other flower parts. They occur in diverse forms that aid seed dispersal. Some fruits are dry, whereas others are moist and juicy; some open to release seeds, and others do not. Fruits also display a wide variety of sizes, colors, and fragrances. These variations result from differences in the process of fruit development. Plant hormones, including auxin, gibberellic acid, and cytokinins, control this transformation. Abscisic acid stimulates cell expansion, and ethylene influences fruit ripening. For instance, ethylene helps to ripen nuts, a type of dry fruit, by inducing plasma membranes to rupture, causing water loss. Under the influence of plant hormones, the pericarp (ripened ovary wall) of peaches, plums, and related fruits swells and softens, while orange or red chromoplasts replace green chloroplasts. As fruits mature, the outer protective cuticle often becomes very thick, contributing to peel toughness, which helps to prevent microbe attack. In addition, many maturing fruits increase their sugar and acid content, which produces the distinctive tastes of ripe fruit. Many fruits also produce fragrant volatile compounds.

Differences in the shape, color, fragrance, and moisture content of wild fruits reflect evolutionary adaptation for effective seed dispersal. Though many fruits and seeds are dispersed by wind or water or by attaching to animal fur, others are consumed by fruit-eating animals that are attracted by fruit color and fragrance. Blackberries provide a good example of fruits adapted for animal dispersal. Blackberry flowers produce many separate pistils, each containing a single ovule (Figure 39.19a). Following pollination and fertilization, the ovary of each pistil develops into a sweet, juicy fruitlet containing a single seed. As the individual fruitlets develop, they fuse together at the sides. Consequently, the many fruitlets produced by a single blackberry flower are dispersed together, in a structure known as an aggregate fruit (Figure 39.19b). Attracted by the color, birds consume the whole aggregate and excrete the seeds, thereby dispersing many at a time. Many other types of fruits occur and these likewise represent adaptations that foster seed dispersal (refer back to Figure 30.21). Although a fruit is usually defined as a mature ovary containing seeds, commercial seedless fruits such as watermelon are produced by genetic modification or treatment with artificial auxin.

Environmental and Internal Factors Influence Seed Germination

Seeds vary greatly in their ability to germinate after dispersal. Small seeds such as those of dandelions and lettuces germinate quickly if light is available. Other seeds require a period of dormancy before germination occurs. Some seeds can remain dormant for amazingly long time periods. For example, a lotus (*Nelumbo nucifera*) seed collected from a lake bed in China germinated at the age of 1,300 years, as determined by radiocarbon dating. In 2005, plant scientists germinated a 2,000-year-old date seed found in Israel.



(a) ***Rubus allegheniensis*** **(common blackberry) flower** **(b) Blackberry fruit**

Figure 39.19 **Blackberry flower and fruit.** **(a)** Each of the many separate pistils in a blackberry flower is able to produce a single one-seed fruit (called a fruitlet) if fertilization occurs. **(b)** Together, the individual fruitlets of the blackberry compose an aggregate fruit. A shriveled style with a stigma is attached to each fruitlet.

Water is generally required to rehydrate seeds so that embryos can resume their metabolic activity. Water absorption also swells seeds, helping to break the seed coat and allowing embryonic organs to emerge. In some cases, rainfall of sufficient duration to leach germination-inhibiting compounds out of seeds is required. The optimal temperature for germination of most seeds lies between 25 and 30.25°C (77 and 86.25°F). This explains why gardeners wait until the soil is warm before planting seeds outdoors in spring. However, some seeds need a period of cold treatment or seed coat abrasion before they will germinate.

Such physical stimuli induce the activity of more than 2,000 genes associated with seed germination. In *Arabidopsis*, several phases of cell division occur after dry seeds have been moistened. Cell division in the radicle, the embryonic root, occurs first. As a result, the radicle is the first organ to emerge from a germinating seed, which allows seedlings to take up water even more rapidly. Next, cell division rates rise in the cotyledons and then in the shoot apical meristem, which increases the size of the embryonic shoot.

When grass seeds rehydrate, the young shoot secretes the hormone gibberellic acid from the seed cotyledon into the outermost endosperm layer, known as the aleurone. In response, the aleurone secretes digestive enzymes into the central endosperm, releasing sugars from stored starch (Figure 39.20). The seedling uses these sugars for growth. This highly coordinated process allows grass seeds to quickly germinate when it rains, an advantage in arid grassland habitats.

Humans also use this basic process to make beer. In the process known as malting, beer brewers apply gibberellic acid to barley seeds to induce them to germinate simultaneously. The barley seeds are then baked at a high temperature to stop germination, a process that produces malt. Baking also caramelizes sugars, contributing to the distinctive flavors and color of beer. To make beer, brewers treat malt with water and heat, add the dried flowers of the hop plant (the genus *Humulus*), and add yeasts to ferment the plant sugars to alcohol.

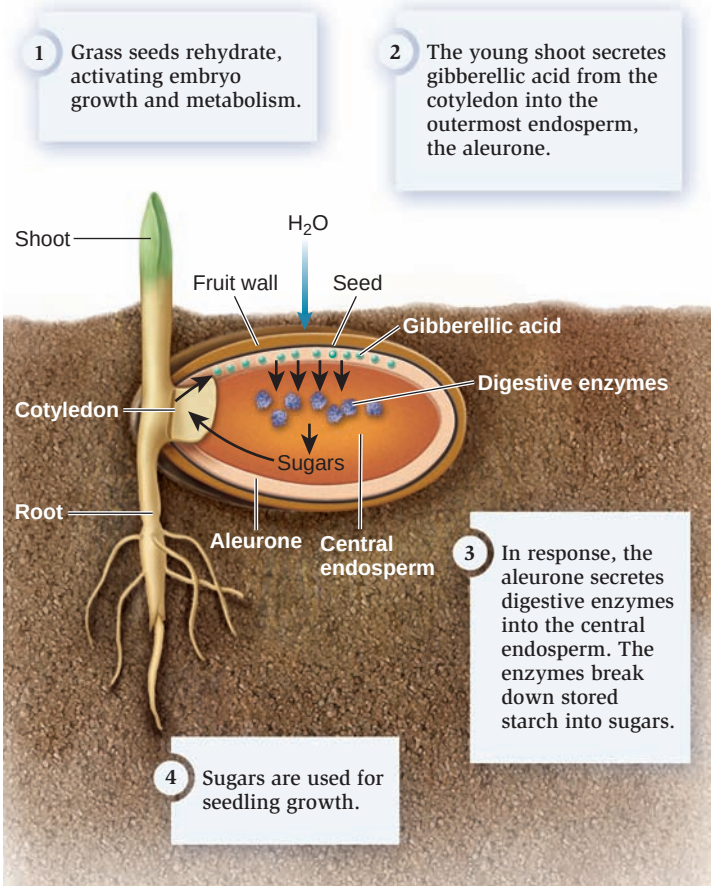


Figure 39.20 **Germination of grass seeds.**

Once seeds have germinated, plants vary in the process by which the embryonic shoot emerges. When bean and onion seeds germinate, the hypocotyl forms a hook that first breaches the soil surface and then straightens, thereby pulling the rest of the seedling and cotyledons aboveground (Figure 39.21a,b). In contrast, when pea seeds germinate, the epicotyl forms a hook that pulls the shoot tip out of the ground, leaving the

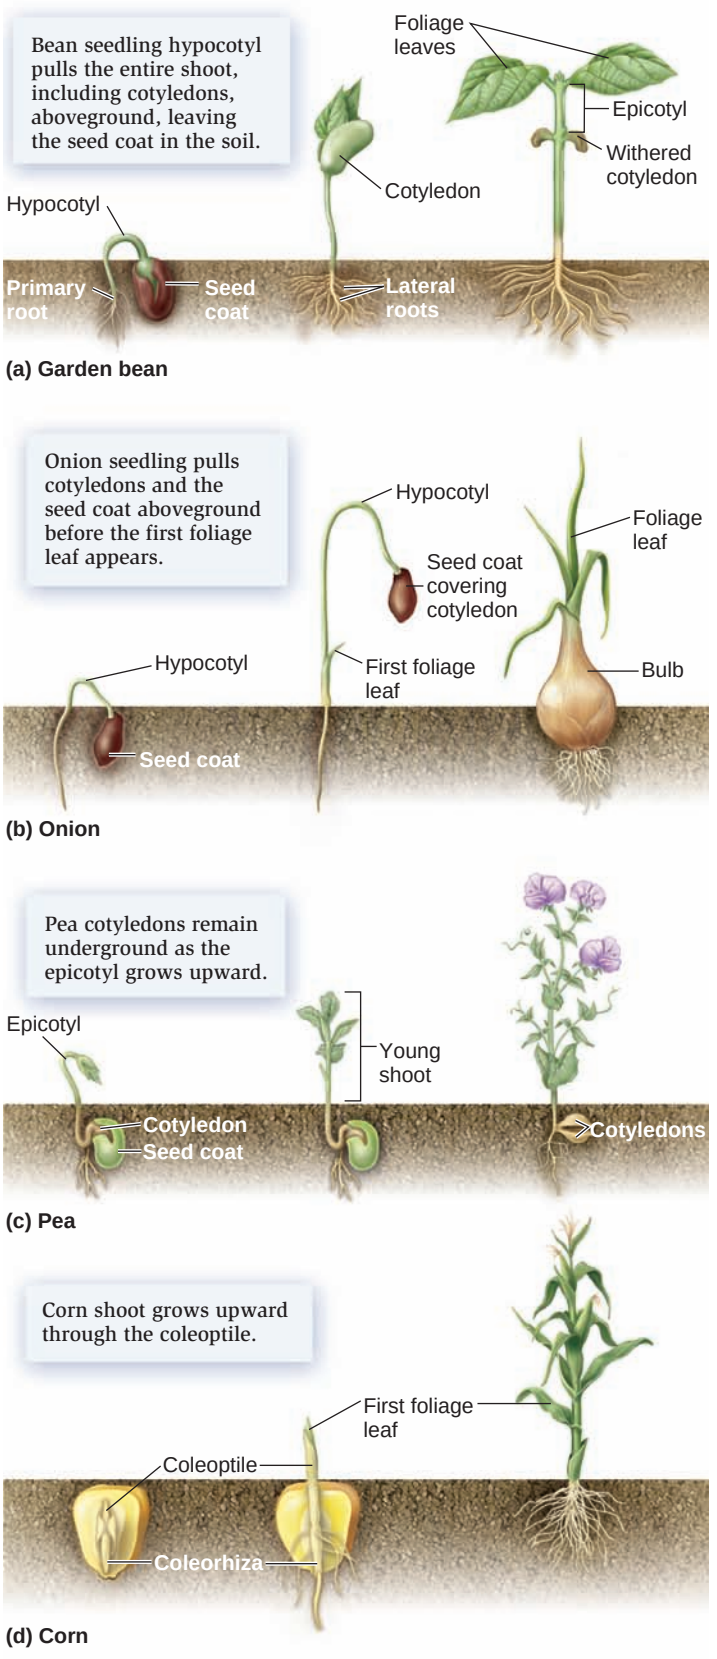

Figure 39.21 Variations in seed germination and seedling growth patterns.

cotyledons beneath the soil surface (Figure 39.21c). In both cases, the tough hook cells bear the brunt of passage through hard surface soil crusts, thereby protecting the delicate shoot tips. The plant hormone ethylene controls seedling hook formation, as described in Chapter 36. However, not all seedlings form hooks. For example, as they grow through the soil, the shoot tips of corn seedlings and those of other grasses are protected by the coleoptile, which functions as a protective tube for the first foliage leaves (Figure 39.21d).

39.5 Asexual Reproduction in Flowering Plants

Many plants rely on sexual reproduction. However, a wide variety of other angiosperms reproduce primarily by asexual means, and other plants commonly utilize both sexual and asexual reproduction. **Asexual reproduction** is the production of new individuals from a single parent without the occurrence of fertilization. Although sexual reproduction provides beneficial genetic variation, asexual reproduction can be advantageous in other ways. For example, asexual reproduction maintains favorable gene combinations that allow faster population growth in stable environments. Asexual reproduction is also advantageous in stressful habitats where pollinators or mates can be rare, because it allows a single individual to start a new population. Finally, asexual reproduction allows some plants to persist for very long periods of time. Among the oldest known plants are creosote bushes that are asexual clones of a parent that grew from a seed about 12,000 years ago!

The artificial vegetative propagation of plants from cuttings is a form of asexual reproduction that is widely used commercially and by home gardeners. In this section, we will explore the three main mechanisms of plant asexual reproduction: specialized reproductive structures, apomixis, and somatic embryogenesis.

Vegetative Asexual Reproduction Generates Plant Clones from Organs

Roots, stems, and leaves are vegetative plant organs that can function as asexual reproductive structures. For example, root sprouts, such as those produced by aspens, can generate entire groves of genetically identical trees. Sucker shoots, such as those appearing at the bases of banana plants and date palms, and the pieces of tuber-bearing "eyes" (which are buds) that develop into potato plants are examples of vegetative plant organs that have agricultural importance. Attractive horticultural varieties of African violets and other plants can be propagated from leaf cuttings. Such asexual offspring grow into adult plants that have the same valued properties as their parent plant. In contrast, these crops grown from seed would produce diverse progeny, not all of which would have economically prized properties.

Somatic embryogenesis is the production of plant embryos from body (somatic) cells. Embryos can develop from many

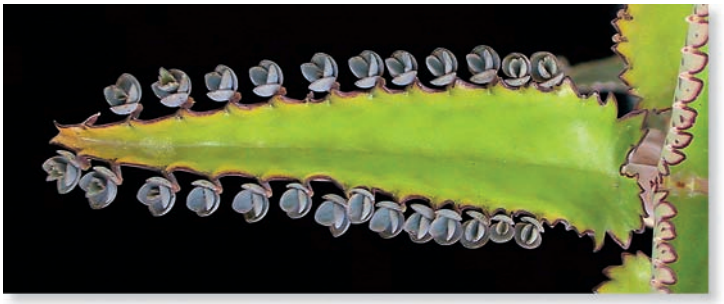

Figure 39.22 **Asexual reproduction via vegetative structures.** The leaves of this *Kalanchoë* plant bear small plantlets around the edges. When mature, these plantlets drop off and under the right conditions, grow into new plants.

types of plant cells. Somatic embryos develop normally to the torpedo stage but do not dehydrate and become dormant, as is normal for zygotic embryos. Rather, somatic embryos produce root and shoot systems and develop into mature plants. Somatic embryogenesis occurs naturally in citrus, mango, onion, and tobacco plants, but agricultural scientists have made use of it as well.

In the 1950s, plant biologist F. C. Steward and associates were the first researchers to successfully clone a complex organism, carrot plants, by means of somatic embryogenesis. They used differentiated cells from carrot roots, grew the cells in conditions that caused some cells to lose their specialized properties and develop into embryos, and then cultivated each embryo in conditions that favored development into a mature carrot plant. Many types of plants are now cloned by somatic embryogenesis, which allows commercial growers to produce large numbers of genetically identical individuals.

The common houseplant *Kalanchoë daigremontiana* has leaves bearing many tiny plantlets at their edges. When these detach, they are able to take root and grow into new individuals (Figure 39.22). Recent molecular studies have revealed that embryogenesis genes are involved in this process and its evolution.

Genomes & Proteomes Connection

The Evolution of Plantlet Production in *Kalanchoë*

Kalanchoë daigremontiana is informally known as mother of thousands because it produces many plantlets at the edges of leaves. Helena Garces, Neelima Sinha, and their colleagues investigated the evolution of this type of asexual reproduction by studying genes that are involved in the development of organs and embryos in four species of *Kalanchoë*. In addition to *K. daigremontiana*, they investigated *K. marmorata*, which does not produce plantlets; *K. pinnata*, which produces plantlets only under certain stressful conditions; and *K. gastonis-bonnieri*, which produces plantlets both normally and when stressed. In leaves of these species, the biologists looked for expression of the gene *STM*, which encodes a key regulator of leaf production at the shoot meristem. They found that *STM* is expressed in cells at the leaf margins of all *Kalanchoë* species that produce leaf plantlets, but not the species that do not produce plantlets. Then the investigators checked for the expression in leaves of two genes that are involved in embryo development (*LEC1* and *FUS3*). They discovered that these embryo-linked genes were expressed only in the leaf margins of species that normally form plantlets, not the species in which plantlet formation is induced by stress.

In a survey of a larger number of species, these investigators also discovered that *Kalanchoë* species that normally produce plantlets have an altered LEC1 protein. The normal form of LEC1 protein is essential to the process by which embryos become dry and thus tolerant to arid conditions. LEC1 is therefore necessary for the production of viable seeds, those able to germinate. *Kalanchoë* species that produce plantlets only under stressful conditions and those that do not produce plantlets at all were able to produce viable seeds. By contrast, the seeds of plantlet-producing species were not viable.

Together, these data allowed the investigators to infer that the evolution of plantlet formation began when certain leaf cells of some species gained the ability to function like a shoot meristem, thereby producing structures resembling small shoots. In some of the descendents of these species, normal LEC1 function in seeds was lost, as was the ability to produce viable seeds. Some species adapted by expressing the embryo-development process in leaf margin cells, a process that allowed them to produce plantlets. Such plantlets are not affected by loss of LEC1 function because, unlike seeds, they do not undergo a drying process during development.

Apomixis Is Seed Production Without Fertilization

Apomixis (from the Greek, meaning away from mixing, that is, genetic mixing) is a natural asexual reproductive process in which fruits and seeds are produced in the absence of fertilization. More than 300 species of flowering plants, including hawkweeds, dandelions, and some types of citrus, are able to reproduce asexually by apomixis. Dandelions and some other apomictic plants require pollination to stimulate seed development, but others do not. Some weedy plant species are apomictic; this process allows them to reproduce quickly, a characteristic of weeds. In addition to their concern about weeds, agricultural scientists are interested in apomixis as a potential method for producing genetically uniform seeds, propagating hybrids, and removing the need for fertilization in crop plants.

Most studies of apomixis have been carried out with dandelions, because they are widespread and locally abundant. Dandelions are herbaceous perennials that flower in their first year. Although some European dandelion populations contain individuals that reproduce sexually, many dandelion populations are composed mainly of individuals that reproduce by apomixis. In apomictic plants, meiosis produces diploid megaspores because homologous chromosomes do not pair and meiosis II does not occur. These diploid megaspores

produce diploid female gametophytes, which generate diploid eggs. These eggs develop into normal embryos without fertilization, a process known as parthenogenesis. In apomictic dandelions, the endosperm develops from diploid central cells. Though such plants produce microspores via meiosis, most pollen grains have abnormal numbers of chromosomes and can produce pollen tubes, but not sperm cells. Hence, fertilization does not occur. However, pollination stimulates dandelions to produce their single-seeded fruits. Fruit that develops in the absence of fertilization is known as parthenocarpic fruit.

Summary of Key Concepts

39.1 An Overview of Flowering Plant Reproduction

- Flowering plants display a sexual life cycle known as alternation of generations, as do all plant groups. The gamete-producing male and female gametophytes of flowering plants are very small and entirely dependent on nurturing sporophytic tissues. Plant gametes arise by the process of mitosis. (Figures 39.1, 39.2)
- Flowers are reproductive shoots that develop from a shoot apical meristem. The role of flowers is to promote seed production. A flower shoot generally produces four types of organs: sepals, petals, stamens, and carpels. Stamens produce pollen, otherwise known as immature male gametophytes. Carpels produce ovules, which contain female gametophytes. (Figure 39.3)
- Mature male gametophytes, or pollen tubes, each produce two sperm and deliver them to ovules. Flowering plants display double fertilization: One of the two sperm released from a pollen tube combines with an egg cell to form a zygote, while the other fuses with two nuclei located in a central cell of the female gametophyte, producing the first cell of endosperm tissue. Endosperm is a nutritive tissue that supports development of an embryonic sporophyte. (Figure 39.4)
- Seeds are reproductive structures that contain a dormant embryo enclosed by a protective seed coat that develops from ovule integuments. Fruits are structures that contain seeds and foster seed dispersal. Like flowers and endosperm, fruits are unique features of flowering plants. (Figure 39.5)

39.2 Flower Production, Structure, and Development

- Plants flower in response to environmental stimuli, such as temperature and day length, by the conversion of a leaf-producing shoot into a flowering shoot.
- Flowers vary in the type of whorls present, the number of flower organs, color, fragrance, organ fusion, symmetry, and arrangement (whether single or in inflorescences). These variations are related to pollination mechanisms and are genetically controlled. (Figures 39.6, 39.7, 39.8, 39.9, 39.10)

39.3 Male and Female Gametophytes and Double Fertilization

- Pollen grains are immature male gametophytes protected by a tough sporopollenin wall. Female gametophyte development occurs within an ovule. Mature female gametophytes include an egg, a central cell with two nuclei, and a few additional cells. (Figures 39.11, 39.12)
- After pollination, interactions between proteins of pistil cells and those of pollen determine pollen germination. (Figure 39.13)
- Germinated pollen delivers two sperm to female gametophytes by means of a long pollen tube. The style plays a role in the guidance, nutrition, and fate of the pollen tube. Pollen tubes that enter female gametophytes burst at their tip, releasing sperm. One sperm nucleus fuses with the egg to produce a zygote, the first cell of a new sporophyte generation; the other sperm nucleus fuses with the two nuclei of the central cell, generating the first cell of the nutritive endosperm tissue. (Figures 39.14, 39.15, 39.16)

39.4 Embryo, Seed, Fruit, and Seedling Development

- Unequal division of a zygote leads to development of a nutritive suspensor and an embryo. Young eudicot embryos are heart-shaped as two embryonic leaves (cotyledons) develop, and the embryo assumes a torpedo shape as the embryonic root forms. Monocot embryos produce only a single cotyledon. (Figures 39.17, 39.18)
- Mature seeds contain embryos that become dry and are protected by desiccation-resistance proteins and a tough seed coat. These adaptations enable seeds to withstand long periods of dormancy, germinating only when conditions are favorable for seedling survival. Mature fruits develop from ovaries and aid in seed dispersal. (Figure 39.19)
- Seed germination is influenced by environmental and internal factors. The embryonic root (radicle) is the first organ to emerge, an adaptation that allows rapid water uptake, essential for seedling development. (Figures 39.20, 39.21)

39.5 Asexual Reproduction in Flowering Plants

- Asexual reproduction is the production of new individuals from a single parent without the occurrence of fertilization. Vegetative reproduction is the development of whole plants from nonreproductive organs. Somatic embryogenesis is the production of embryos from individual body cells. Apomixis is a mechanism by which some plants produce seeds from flowers without fertilization. (Figure 39.22)

Assess and Discuss

Test Yourself

1. Where do the pollen grains of flowering plants develop?
   a. in the anthers of a flower
   b. in the carpels of a flower
   c. while being dispersed by wind, water, or animals
   d. within ovules
   e. within pistils
2. Where do mature male gametophytes of flowering plants primarily develop?
   a. in the anthers of a flower
   b. in the carpels of a flower

c. while being dispersed in wind, water, or by animals
d. within ovules
e. on the surfaces of leaves

3. Where would you find female gametophytes of a flowering plant?
a. in the anthers of a flower
b. at the stigma of a pistil
c. in the style
d. within ovules in a flower's ovary
e. in structures that are dispersed by wind, water, or animals

4. How does double fertilization occur in flowering plants?
a. The two sperm in a pollen tube fertilize the two egg cells present in each female gametophyte.
b. One of the two sperm in a pollen tube fertilizes the single egg in a female gametophyte, while the other fuses with the two nuclei present in the central cell.
c. Two sperm, one contributed by each of two different pollen tubes, fertilize the two egg cells in a single female gametophyte.
d. Two sperm contributed by separate pollen tubes enter a single female gametophyte; one of the sperm fertilizes the egg cell, while the other fertilizes the central cell.
e. None of the above is correct.

5. A seed is
a. an embryo produced by the fertilization of an egg, which is protected by a seed coat.
b. a structure that germinates to form a seedling under the right conditions.
c. an embryo produced by parthenogenesis that is enclosed by a seed coat.
d. all of the above.
e. none of the above.

6. What is the likely chemical composition of florigen, the long-sought chemical stimulus of flowering?
a. the hormone auxin
b. the protein STM
c. the carbohydrate callose
d. the mineral ion K^+
e. none of the listed choices

7. How many whorls of organs occur in complete flowers?
a. two
b. four
c. six
d. eight
e. ten

8. If an ovary contains eight ovules, how many seeds could potentially result if pollen tubes reach all eight ovules?
a. one
b. four
c. eight
d. more than 20
e. none of the listed choices

9. What function(s) does the polysaccharide callose have in the reproduction of flowering plants?
a. Callose forms a coat that isolates young embryos during their early development.
b. Callose forms a coat that isolates groups of four microspores during their early development into pollen grains.
c. Callose helps to pattern the sculptured sporopollenin walls of pollen grains.
d. all of the above
e. none of the above

10. From what structure does a fruit pericarp primarily develop?
a. the style
b. a stamen filament
c. the ovary wall
d. a group of fused sepals
e. the stigma

Conceptual Questions

1. Why are pollen grain walls composed of sporopollenin?
2. Why are seed coats often tough?
3. Why do flowers occur in such a diversity of shapes and colors?

Collaborative Questions

1. Observe or think of orchid flowers. Are these flowers bilaterally symmetrical or radially symmetrical? Are these flowers more likely to be wind-pollinated or pollinated by animals? What gene might be involved in the production of orchid flower shape?
2. How do plants prevent the production of many offspring expressing deleterious recessive traits?

Animal Bodies and Homeostasis

40

Chapter Outline

Perspiring and drinking water are both mechanisms that help achieve homeostasis, a stable internal body environment.

In Chapters 32–34, we considered the diversity of animal life. Yet, despite the obvious differences between a worm and a human, or an insect and a fish, fundamental similarities link the millions of animal species together. We will introduce some of these similarities in this chapter and explore them throughout this unit. For example, all animals must obtain energy to survive, and they must have the ability to cope with or adapt to changes in their environment. Furthermore, all animals are composed of similar types of cells. In this chapter, we will look at some of the characteristics common to all animals and the link between structure and function. We will also see how animals maintain internal conditions within normal limits (homeostasis) despite fluctuations in their external environments. **Anatomy** is the study of an animal's structure, and **physiology** is the study of how those structures function. Collectively, anatomy and physiology form the foundation of animal biology. We begin, therefore, with an examination of the physical structure and organization of animal bodies.

40.1 Organization of Animal Bodies

All animal cells share similarities in the ways in which they exchange materials with their surroundings, obtain energy from organic nutrients, synthesize complex molecules, reproduce themselves, and detect and respond to signals in their immediate environment. Animals usually begin life as a single cell—most commonly a fertilized egg—which divides to create two cells, each of which divides in turn, resulting in four cells, and so on. If cell multiplication were the only event occurring, the end result would be a spherical mass of identical cells. As we will see in Chapter 52, however, cells become specialized during development to perform a particular function (that is, they differentiate). Examples of differentiated cells are muscle and blood cells. Cells also migrate to new locations within the developing organism and form clusters with other cells. In this way, the cells of an animal's body are arranged in various combinations to form organized, multicellular structures (Figure 40.1). Cells with similar properties group to form tissues (for example, muscle tissue), which combine with other types of tissues to form organs (for example, a urinary bladder). Organs are anatomically or functionally linked to form organ systems (for example, the urinary system).

Specialized Cells Are Organized into Tissues

Specialized cells of a given type often cluster together to form **tissues**. The tissues in a typical animal's body can be classified into four categories, according to their locations and the types of functions they perform: muscle, nervous, epithelial, and connective tissues. Most structures in an animal's body contain at least two types of tissues; many of these structures contain all four. Within each of these functional categories, subtypes of tissues perform variations of that function, as described next for the three types of muscle tissue.

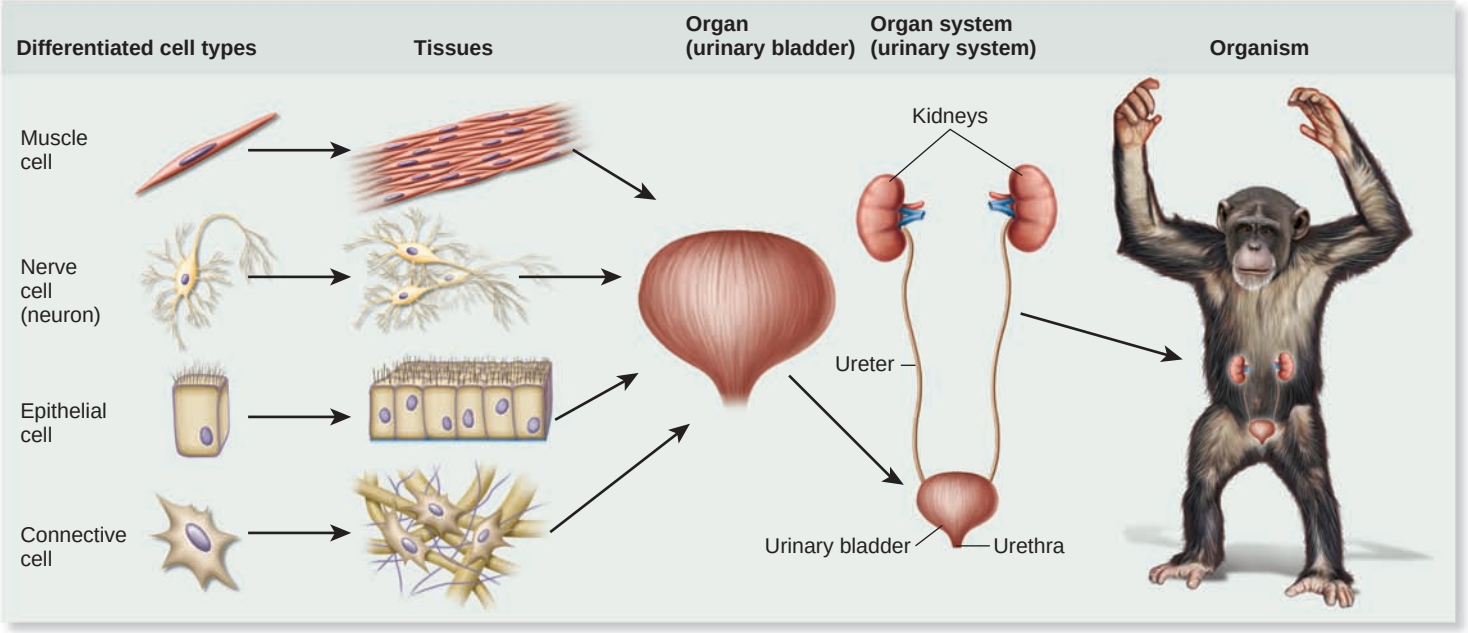

Figure 40.1 **The internal organization of cells, tissues, organs, and organ systems in a mammal.** Most animals share the same four tissue types.

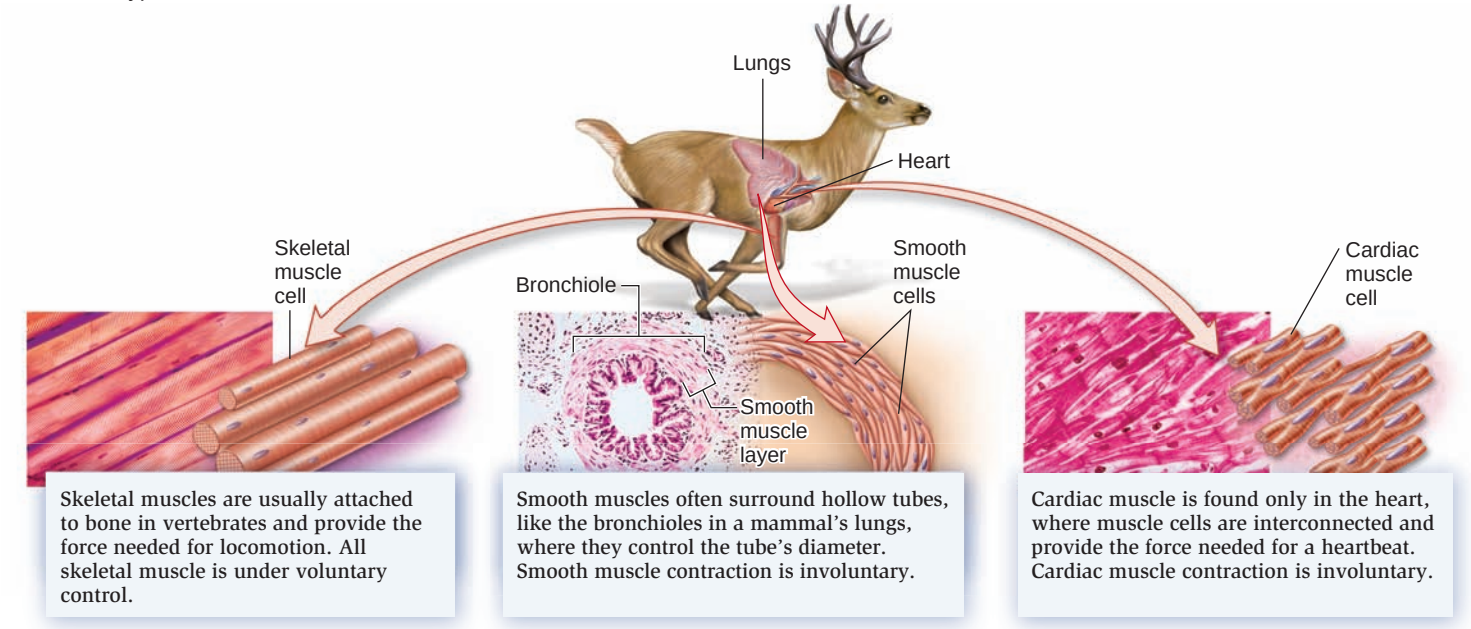

Figure 40.2 **Three types of muscle tissue: skeletal, smooth, and cardiac.** All three types produce force, but they differ in their appearance and in their locations within animals' bodies. (Right inset: © Dr. Richard Kessel & Dr. Gene Shih/Visuals Unlimited)

Concept check: *All muscles produce movement, but only skeletal muscle produces locomotion. What is meant by this statement?*

Muscle Tissues **Muscle tissues** consist of cells specialized to shorten, or contract, generating the mechanical forces that produce body movement, decrease the diameter of a tube, or exert pressure on a fluid-filled cavity. Three types of muscle tissue may be found in animals: skeletal, smooth, and cardiac (Figure 40.2). **Skeletal muscles** are generally linked to bones in vertebrates via bundles of collagen fibers called tendons, and to the exoskeleton of invertebrates. When skeletal muscles are stimulated by signals from the nervous system, they generate force that leads to the contraction of the muscle (see Chapter 44). Contraction of these muscles may be under voluntary control and can produce the types of movements required for locomotion, such as extending limbs or flapping wings. Skeletal muscles may also attach to skin, such as the muscles producing facial expressions. **Smooth muscles** surround hollow tubes and cavities inside the body's organs, such that their contraction can propel the contents of those organs. For example, the contraction of smooth muscle in the stomach wall propels partially

digested food into the intestines, where it can be digested fully. Smooth muscle also surrounds and forms part of small blood vessels and airway tubes (bronchioles). Contraction in those regions reduces blood flow or movement of air, respectively. Contraction of all smooth muscle is involuntary—that is, it occurs automatically without conscious control. In the third type, **cardiac muscle**, physical and electrical connections between individual cells enable many of the cells to contract almost simultaneously. Like smooth muscle, cardiac muscle is involuntary. It is found only in the heart, however, where it provides the force that generates pressure sufficient to pump blood through an animal's body.

Nervous Tissues **Nervous tissues** initiate and conduct electrical signals from one part of an animal's body to another part (Figure 40.3). A single nerve cell, called a **neuron**, may connect two or more other neurons and be only a few micrometers long. Such neurons are found widely throughout the vertebrate brain. In contrast, other neurons located in the brain may send extensions along the length of the spinal cord; in a large animal like a giraffe, this distance may extend over 2 meters! Depending on where it is generated in an animal's body, an electrical signal produced in one neuron may stimulate or inhibit other neurons to initiate new electrical signals, stimulate muscle tissue to contract, or stimulate glandular cells to release chemicals into the animal's body fluids. Thus, nervous tissue provides a critical means of controlling many diverse activities of body cells.

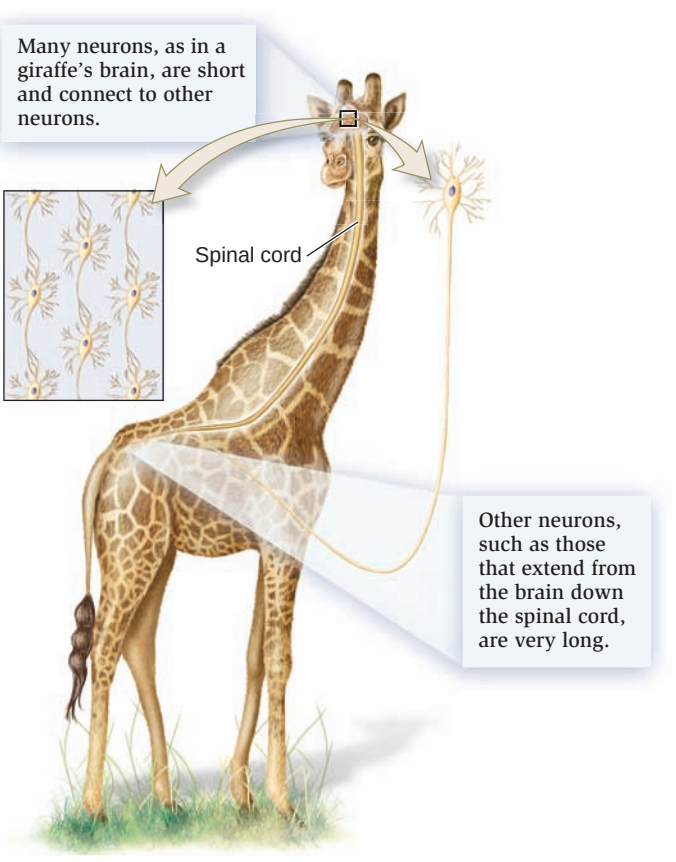

Figure 40.3 Variation in shape and length of neurons.

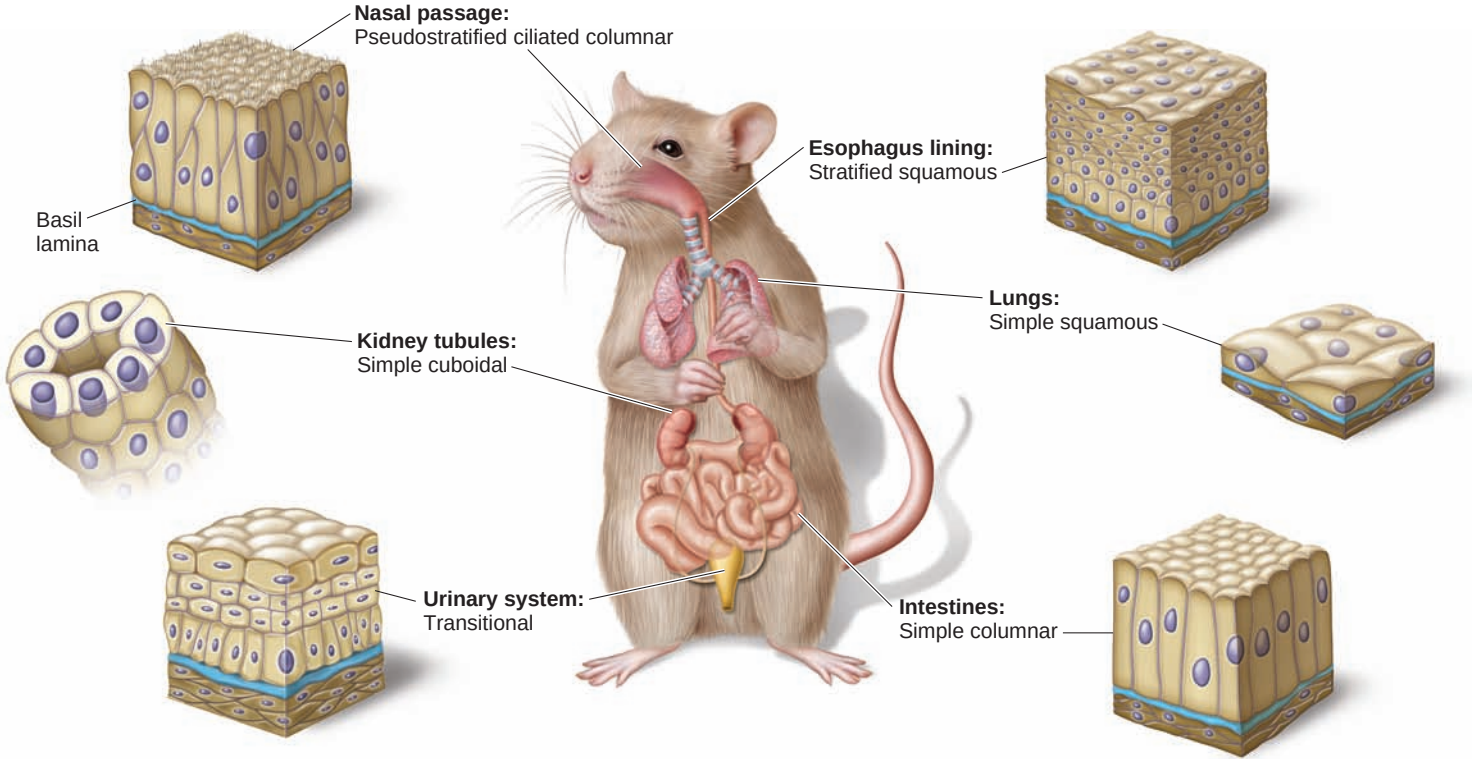

Figure 40.4 **Examples of epithelial tissue.** There are several types of epithelial tissue, distinguished by their appearance. Epithelial tissue is used to construct body coverings and the protective sheets that line and cover hollow tubes and cavities.

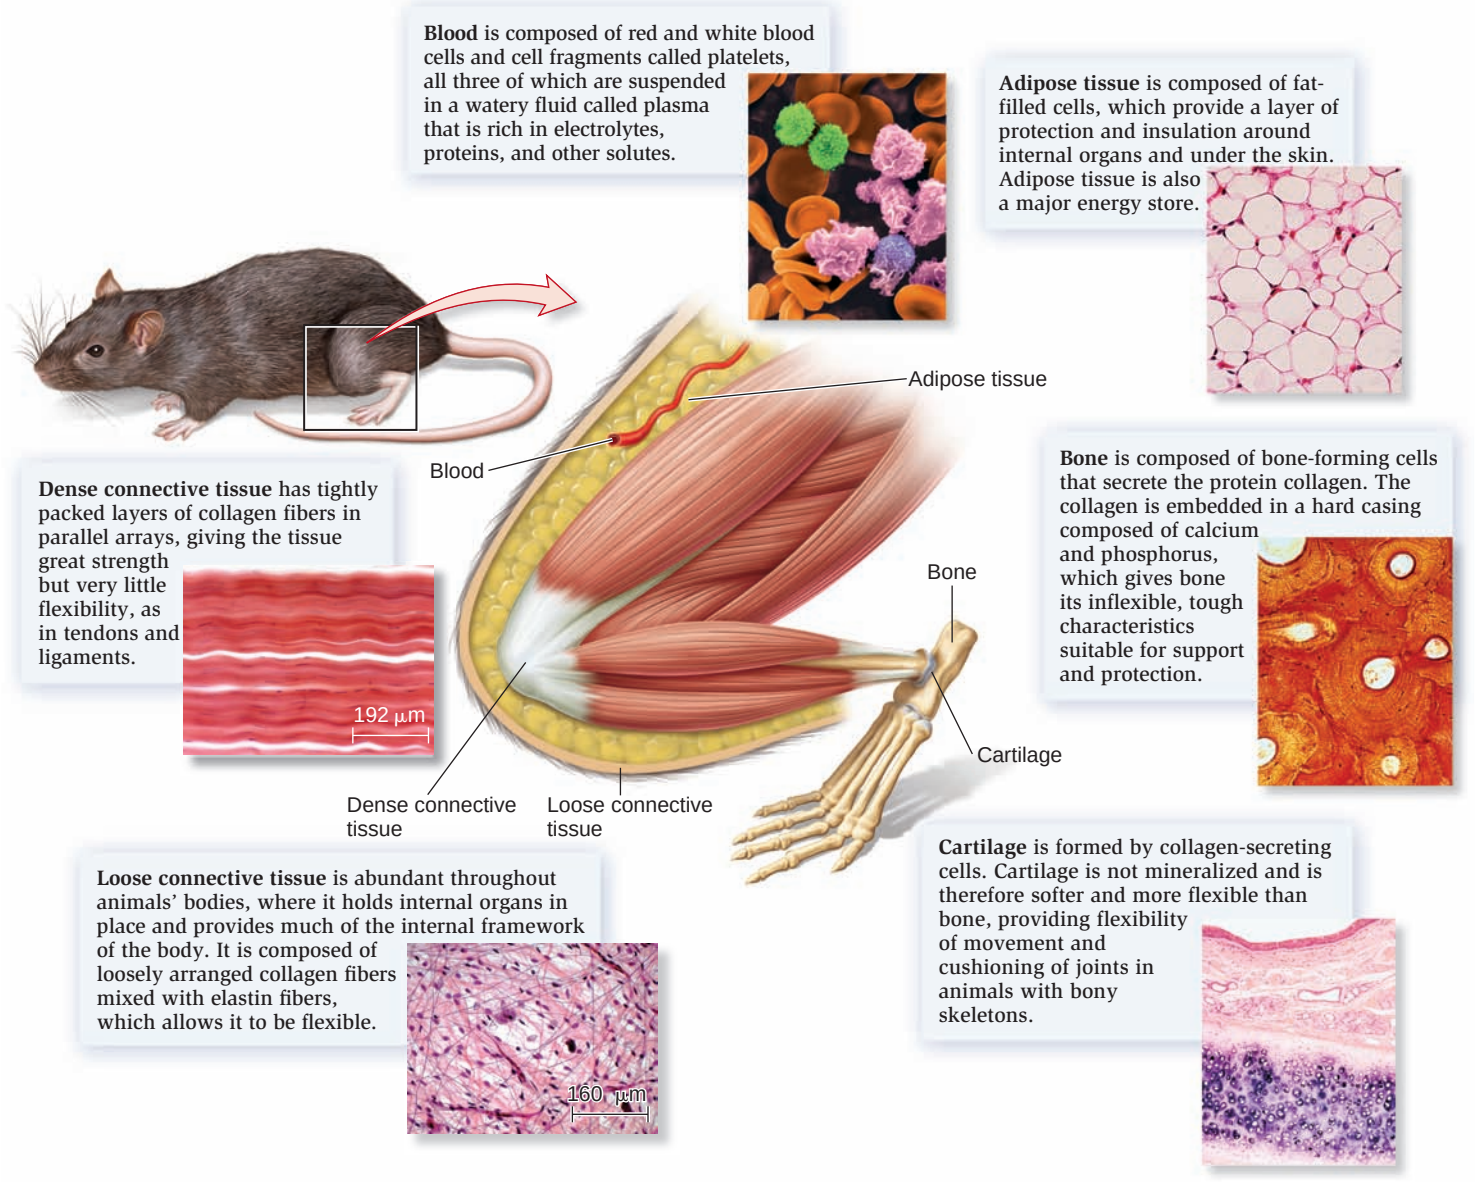

Figure 40.5 **Examples of connective tissue in mammals.** Connective tissue connects, surrounds, anchors, and supports other tissues and may exist as isolated cells (blood), clumps of cells (fat), or tough, rigid material (bone and cartilage). The samples have been stained or the micrographs have been computer-colorized to reveal connective tissue.

Epithelial Tissues **Epithelial tissues** are sheets of densely packed cells that cover the body or individual organs or line the walls of various cavities inside the body. Epithelial cells (see Chapter 10) are specialized to protect structures and to secrete and absorb ions and organic molecules. For example, epithelial tissue can invaginate (fold inward) to form sweat glands that secrete water and ions onto the surface of an animal's skin. Epithelial cells come in a variety of shapes, such as cuboidal (cube-shaped), squamous (flattened), and columnar (elongated), and are arranged in epithelial tissues as simple (one layer), stratified (multiple layers), or pseudostratified (one layer, but with nuclei located in such a way that it appears stratified) (Figure 40.4). Regardless of their location or function, all epithelial cells are asymmetrical, or polarized. This means that one side of such a cell is anchored to an extracellular matrix called the basal lamina, or basement membrane (see Chapter 10). The other side faces the internal or external environment of the animal. Thus, epithelial cells form boundaries between different body compartments, as discussed later in this chapter. In this way, epithelial tissues can function as selective barriers that regulate the exchange of molecules between compartments. For example, epithelial tissues in an animal's skin help to form a barrier that prevents most substances in the external environment from entering the body.

Connective Tissues As their name implies, **connective tissues** connect, surround, anchor, and support the structures of an animal's body. Connective tissues include blood, adipose (fat-storing) tissue, bone, cartilage, loose connective tissue, and dense connective tissue (Figure 40.5).

An important function of some types of connective tissue cells is to form part of the extracellular matrix around cells by secreting a mixture of fibrous proteins and carbohydrates, such

as glycosaminoglycans. These carbohydrates may covalently attach to proteins to form proteoglycans. In some cases, the extracellular matrix is rich in minerals. The final characteristics of any type of connective tissue are determined in part by the relative proportions and types of proteins, proteoglycans, and minerals secreted into the extracellular matrix. The matrix serves several general functions, which include (1) providing a scaffold to which cells attach, (2) protecting and cushioning parts of the body, (3) providing mechanical strength, and (4) transmitting information to the cells that helps regulate their activity, migration, growth, and differentiation.

The proteins of the extracellular matrix of a tissue consist mainly of two types. The first type is insoluble fiber-like proteins such as **collagen** and the rubber band-like protein **elastin**; these proteins are often referred to as fibers. A second category is adhesive proteins (fibronectin and laminin) that serve to organize the protein and carbohydrate components of the extracellular matrix (refer back to Tables 10.1 and 10.2, and Figures 10.1–10.4).

Different Tissue Types Combine to Form Organs and Organ Systems

An **organ** is composed of two or more kinds of tissues arranged in various proportions and patterns, such as sheets, tubes, layers, bundles, or strips. For example, the vertebrate stomach (Figure 40.6) consists of the following layers:

- an outer covering of simple squamous epithelial tissue;
- connective tissue layers covering and cementing the organ together;
- layers of smooth muscle tissue whose contraction propels food through the stomach;
- nervous tissue that comes in close contact with the smooth muscle tissues and helps regulate their activity;
- an inner lining of simple columnar epithelial tissue that secretes hormones (long-distance signaling molecules), enzymes and acid (important in the digestive process), and protective mucus.

In an **organ system**, different organs work together to perform an overall function. In the example just described, the stomach is part of the digestive system, along with other structures, such as the mouth, esophagus, small and large intestines, and anus. In another familiar example, the kidneys, the urinary bladder, the tubes leading from the kidneys to the bladder, and the tube leading from the bladder to the exterior of the body constitute the urinary system in mammals (see Figure 40.1). This system helps regulate the composition of body fluids and removes waste products from the blood, which are then excreted in the urine. The organ systems found in animals are listed in Table 40.1. Some organ systems may be rudimentary in some animals (such as the simple nervous systems of worms and other early-diverging groups of animals).

Organ systems frequently work together. For example, signals from the nervous system and endocrine system strongly influence how much water the mammalian kidney retains as it forms urine, an adaptation that can be lifesaving under certain circumstances. Likewise, nerve signals from the urinary bladder relay information to the cells of the brain when the bladder is full and needs to be emptied.

The spatial arrangement of organs into organ systems is part of the overall body plan of animals. Organ systems develop at specific times and locations within the body and along the anteroposterior body axis, as do other structures, such as

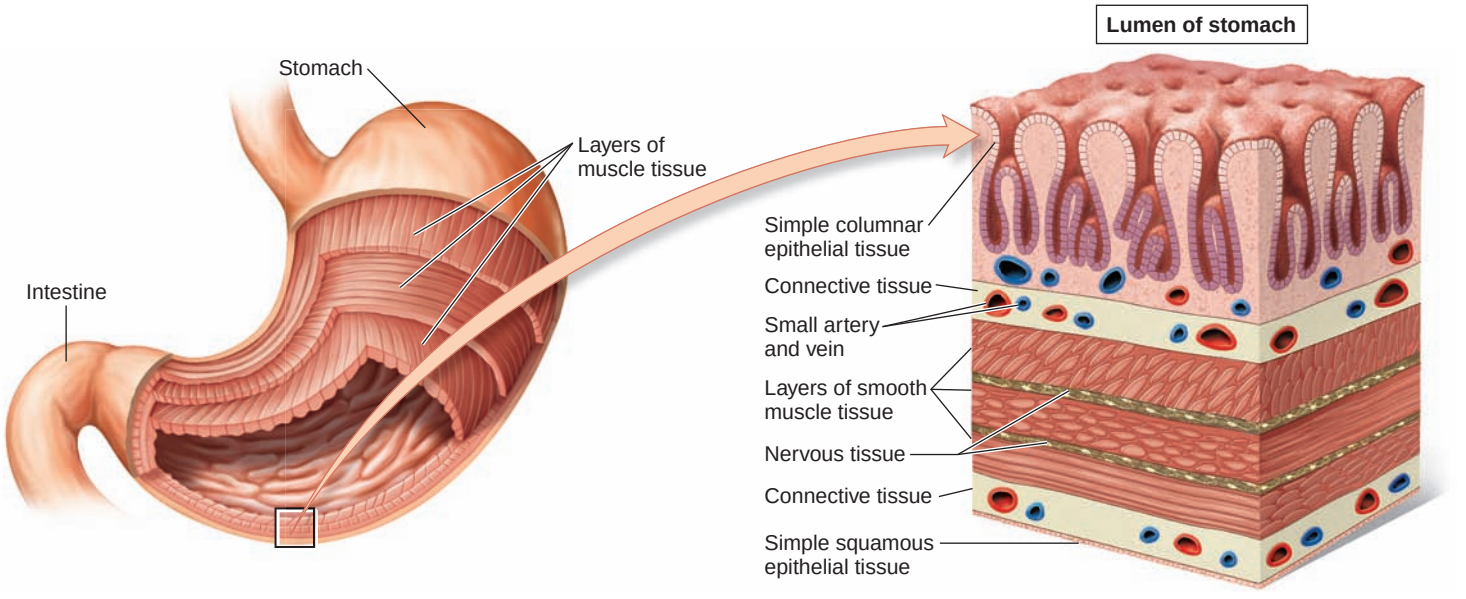

Figure 40.6 The vertebrate stomach as an example of an organ composed of all four tissue types. In this illustration, the thickness and appearance of the layers of nervous tissue have been considerably exaggerated for visual clarity.

Concept check: Do all animal organs contain all four tissue types? Can you think of an example that does not?

Table 40.1 Organ Systems Found in Animals

Organ system	Major components*	Major functions
Circulatory	Contractile element (heart or vessel); distribution network (blood vessels); blood or hemolymph	Transports and distributes solutes (nutrients, gases, wastes, and so on) to and from all parts of an animal's body
Digestive	Ingestion structures (mouth or mouthparts); storage structures (crop, stomach); digestive and absorptive structures (stomach, intestines); elimination structures (rectum, anus); accessory structures (pancreas, gallbladder)	Breaks complex foods into smaller, absorbable units; absorbs organic nutrients, salts, and water; eliminates solid wastes
Endocrine	All glands, organs, or tissues that secrete hormones; examples include the pituitary and thyroid glands	Regulates and coordinates processes such as growth, development, metabolism, mineral balance, and reproduction
Excretory	Filtration system (kidneys or comparable structures); storage sites for soluble wastes (bladder); tubes connecting kidneys and bladder, and bladder to external environment	Eliminates soluble metabolic wastes; regulates body fluid volume and solute concentrations
Immune and lymphatic	Circulating white blood cells; lymph vessels and nodes	Defends against pathogens
Integumentary	Body surfaces (skin)	Protects from dehydration and injury; defends against pathogens; regulates body temperature; in some animals, transports gases and fluids
Muscular-skeletal	Force-producing structures (muscles); support structures (bones, cartilage, exoskeleton); connective structures (tendons, ligaments)	Produces locomotion; generates force; propels materials through body organs; supports body
Nervous	Processing (brain); signal delivery (spinal cord, peripheral nerves and ganglia, sense organs)	Regulates and coordinates many body activities, such as movement, sensation, and learning
Reproductive	Gonads and associated structures	Produces gametes (sperm and egg); in some animals, provides nutritive environment for embryo and fetus
Respiratory	Gas exchange sites (gills, skin, trachea, lungs)	Exchanges oxygen and carbon dioxide with environment; regulates blood pH

*Selected examples only; these do not necessarily pertain to all animals.

limbs, tentacles, antennae, and other animal appendages. Scientists have long wondered how the layout of animal bodies is determined during the period when an embryo is developing. Remarkably, the body plan of animals appears to be under the control of a highly conserved family of genes with homologs in all animals, as described next.

Genomes & Proteomes Connection

Organ Development and Function Are Controlled by Homeotic Genes

In previous chapters, you have learned about a family of ancient, highly conserved genes called homeotic genes that are found in all animals. These genes determine the timing and spatial patterning of the anteroposterior body axis during development. For example, we saw in Chapter 19 how homeotic genes determine the number and position of legs and wings in *Drosophila*. In vertebrates, the homeotic genes are known as *Hox* genes, and they play a similar role in determining the spatial patterning of the vertebrate body and appendages. Recently, scientists have begun exploring the role of *Hox* genes in the development and spatial patterning of the organs that make up animals' organ systems.

By generating mutant mice that fail to express one or more *Hox* genes (the genes are said to have been knocked out; see Chapter 20), researchers have discovered the important role these genes play in determining where within the vertebrate body particular organs form. Recall from Chapter 19 (refer back to Figures 19.16 and 19.17) that mouse *Hox* genes are arranged in four clusters, designated A–D, with multiple genes per cluster. Because these homologous genes (for example, *HoxA-3*, *HoxB-3*, and *HoxD-3*) are found within a single species, they are considered paralogous genes. Such paralogous genes typically act in concert to regulate similar developmental processes. For example, *HoxA-3* is important for development of anterior parts of the body, including the neck. When this gene is knocked out, mouse embryos show defects in neck structure, such as abnormal blood vessels. Also, the organs within the neck—including the thymus, thyroid, and parathyroid glands—do not develop normally. When two or more paralogs of this group are knocked out, certain neck organs fail to form at all. Experimental deletion of *Hox* genes associated with other body segments does not affect the development and function of neck glands and organs. Likewise, investigators have uncovered vital roles of different *Hox* genes in lung development within the thorax and the proper positioning and development of the vertebrate kidneys in the abdomen.

Of particular interest is the discovery that *Hox* genes are important in vertebrates not only for spatial patterning of organs

but also for their growth, development, and function. Genes in the *Hox* 1 and 3 groups, for instance, help determine the final branching patterns of the airways of the lungs, the final size of the lungs, and the ability of the lungs to produce secretions that are important for breathing air after birth. Other *Hox* genes have been shown to control cell proliferation, shape changes, apoptosis, cell migration, and cell-cell adhesion within various organs. This is also true in invertebrates, such as the leech, where homeotic genes are first expressed during organ formation, and in *Drosophila*, where the final shape and size of the heart are partly controlled by homeotic genes.

Chapter 52 will describe in greater detail how organs form. *Hox* genes in vertebrates and their homologs in invertebrates are important in organ positioning, development, and function. This explains in part why the thyroid gland forms in the neck region of vertebrates and not in the legs or tail, for example. Interestingly, *Hox* genes continue to be expressed long after embryonic development has ceased, and scientists believe that they play roles in organ function even in adult animals. Researchers have hypothesized that the expression of abnormal *Hox* genes in a mature organ is a contributing factor in organ disease, such as lung disorders and leukemia (cancer of the white blood cells).

Body Fluids Are Distributed into Compartments

All animal bodies are composed primarily of water. Indeed, even terrestrial animals can be thought of as "living in water," because all the cells of an animal's tissues and organs are filled with and surrounded by water.

Most of the water in an animal's body is contained inside its cells and therefore is called **intracellular fluid** (from the Latin *intra*, meaning inside of). The rest of the water in its body exists outside of the cells and is therefore called **extracellular fluid** (from the Latin *extra*, meaning outside of). Extracellular fluid is composed of the fluid part of blood, called **plasma**, and the fluid-filled spaces that surround cells, called **interstitial fluid** (from the Latin *inter*, meaning between) (Figure 40.7). In vertebrates and some invertebrates, plasma and interstitial fluid are kept separate within a closed circulatory system. In many invertebrates with open circulatory systems (see Chapter 47), however, plasma and interstitial fluid are intermingled into a single fluid called hemolymph.

The fluids depicted in Figure 40.7 are said to be enclosed in compartments. In a typical vertebrate, the total water volume in the three compartments (intracellular fluid, plasma, and interstitial fluid) accounts for about two-thirds of body weight, with solids comprising the rest. Of the total body water, up to two-thirds is intracellular and one-third extracellular, the majority of which is located in the interstitial compartment.

Plasma membranes separate the intracellular fluid from the extracellular fluid. The two components of extracellular fluid in vertebrates and some invertebrates—the interstitial fluid and the plasma—are separated by the walls of the blood vessels (for example, arteries, capillaries, and veins).

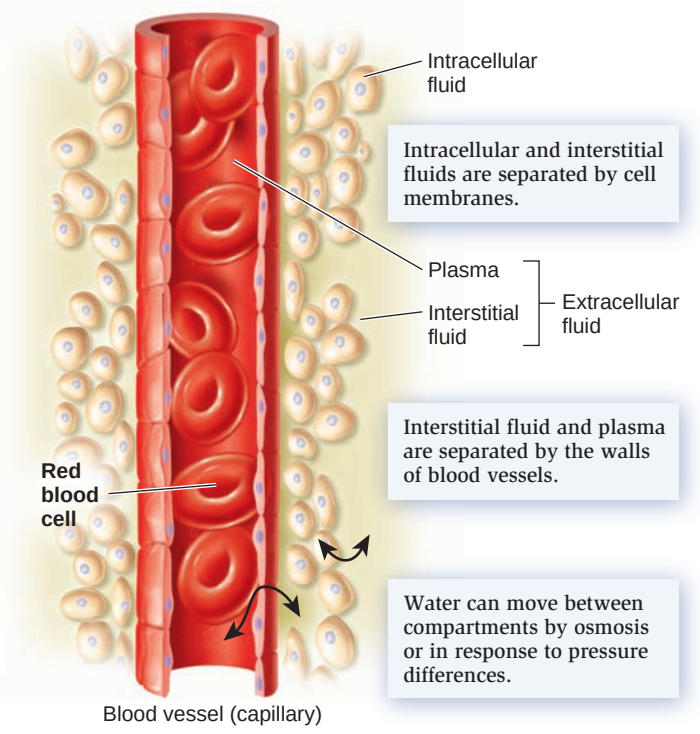

Figure 40.7 **Fluid compartments in a typical vertebrate.** Most of the fluid within an animal's body exists within cells (intracellular fluid). Extracellular fluid is that portion of the body's fluid that lies outside cells (interstitial fluid) and within blood vessels (plasma), such as the capillary shown here. Arrows indicate directions of water movement between adjacent compartments.

Concept check: *What would happen to the distribution of water in the fluid compartments of an animal's body if a blood vessel were damaged such that it leaked its contents?*

The solute composition of the extracellular fluid is very different from that of the intracellular fluid. Maintaining differences in fluid composition across the plasma membrane is an important way in which animal cells regulate their own activity. For example, many different proteins that are important in regulating cellular events such as mitosis, cytokinesis, and metabolism are confined to intracellular fluid.

Movement of Solutes Between Compartments Solutes must move between body fluid compartments in order for cells in an animal's body to maintain concentrations of ions, nutrients, and gases such as oxygen within their normal ranges. Barriers separating adjacent fluid compartments determine which solutes can move between them. Solute movement, in turn, accounts for the differences in composition of the different compartments. We discussed the mechanisms by which solutes move in Chapter 5. Let's summarize those mechanisms, which apply to all animal cells.

Simple diffusion is the movement of a solute down its concentration gradient without the aid of a transport protein or hydrolysis of ATP. Simple diffusion is one way in which cells gain and lose solutes. Molecules that can cross lipid bilayers are able to passively diffuse into or out of a cell. Examples include nonpolar solutes such as lipids and CO_2, and extremely small

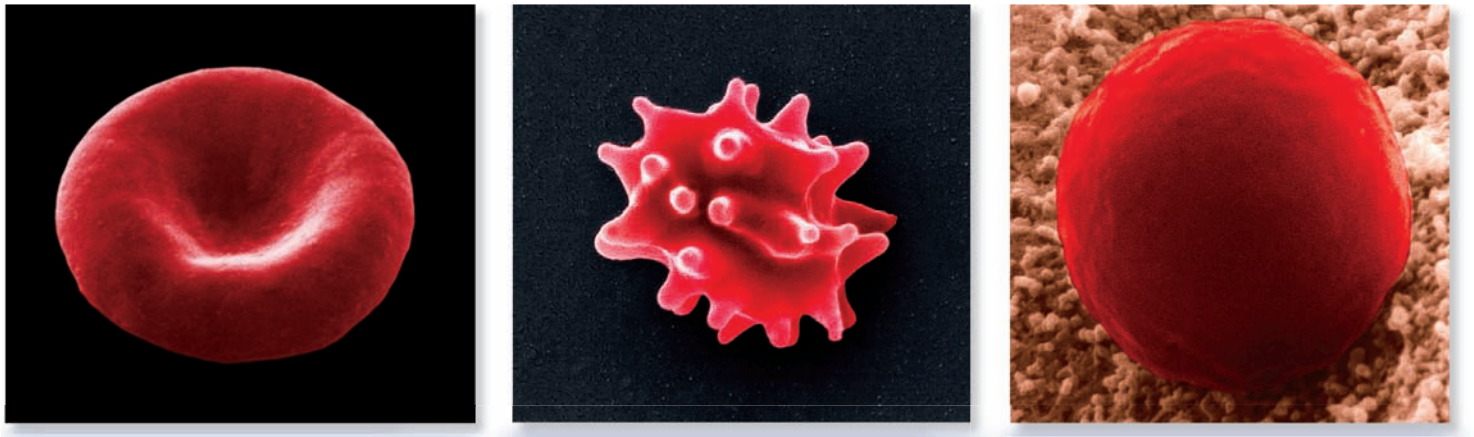
polar solutes such as ethyl alcohol. Most polar molecules and ions, however, can diffuse through a plasma membrane only if the membrane has pores or channels of some type that permit the molecule to pass through the bilayer. The rate of diffusion of any solute depends on several factors, notably the concentration gradient of the solute and the area across which it is diffusing. The rate of diffusion of a solute across a membrane of given thickness can be calculated by the Fick diffusion equation, shown here in simplified form:

$$J = KA\ (C_1 - C_2)$$

where J is the rate of diffusion, K is a constant that includes temperature, A is the cross-sectional area of the barrier across which diffusion is occurring, and C_1 and C_2 are the concentrations of the solute at two locations (for example, inside and outside a cell). This equation makes it possible to determine how changes in solute concentrations, temperature, or area can influence the rate at which a substance moves across a plasma membrane. For example, breathing a gas mixture from a tank that is enriched in oxygen will increase the amount of oxygen entering the blood in a mountain climber at high altitude, where oxygen is limited. According to the Fick equation, the difference between C_1 (inhaled oxygen) and C_2 (oxygen in the blood) will be increased by this procedure. Therefore, we can predict that J, the rate of diffusion of oxygen into the blood, will also be increased, an important survival mechanism at very high altitudes.

The movement of most solutes between compartments or across plasma membranes is mediated by transport proteins via facilitated diffusion or active transport (see Chapter 5). Each of these processes is critical to regulation of intracellular and extracellular fluid composition in animal cells. In Chapter 45, we will discuss one example, the mechanism by which cells obtain their most important energy source, glucose. Because glucose is a relatively large and polar molecule, it cannot diffuse through lipid bilayers. Instead, it is transported from the interstitial fluid into cells by membrane-bound proteins.

Movement of Water Between Compartments Water can readily move between adjacent compartments in an animal's body, because barriers such as plasma membranes tend to be highly permeable to water. This movement depends on pressure differences in the fluids of each compartment and on osmosis (see Chapter 5), in which water moves from a compartment of lower solute concentration to one of higher solute concentration. For cells to function properly, they require a relatively stable internal composition, including ion and protein concentrations, cellular volume, and pH. A decrease in solute concentration outside a cell, for example, would cause water to move by osmosis from outside the cell to inside. In this case, osmosis redistributes fluid from the interstitial to the intracellular compartment. This would cause a cell to become deformed as it swells due to the influx of water. In contrast, an increase in extracellular solute concentration would lead to osmosis of water from inside the cell to outside, causing the cell to shrink. In either case, a swollen or shrunken animal cell generally is more fragile than a normal cell and will die if its membrane ruptures. Figure 40.8 shows examples of mammalian red blood cells in which intracellular fluid levels have been altered. This could occur, for example, if the blood cells were exposed to extracellular fluids that were either more dilute (hypoosmotic or hypotonic; see Chapter 5) or more concentrated (hyperosmotic or hypertonic) than the fluid inside the blood cell. When red blood cells swell, they may burst, a phenomenon called hemolysis; shrinkage of red blood cells is called crenation (Figure 40.8, middle panel).



Red blood cell in a solution of normal osmolarity (an isotonic solution)

Red blood cell that has lost intracellular fluid when placed in a solution of higher than normal osmolarity (a hypertonic solution)

Red blood cell that has gained intracellular fluid when placed in a solution of lower than normal osmolarity (a hypotonic solution)

Figure 40.8 **Changes in cell shape due to alterations in intracellular fluid volume.** Alterations in intracellular fluid volume can have drastic effects on cell shape, as shown by these scanning electron micrographs of red blood cells. Each cell is approximately 7 μm in diameter. Dramatic changes in shape like these are usually lethal for cells.

Concept check: *What effect would changes in intracellular fluid volume have on intracellular solute concentration?*

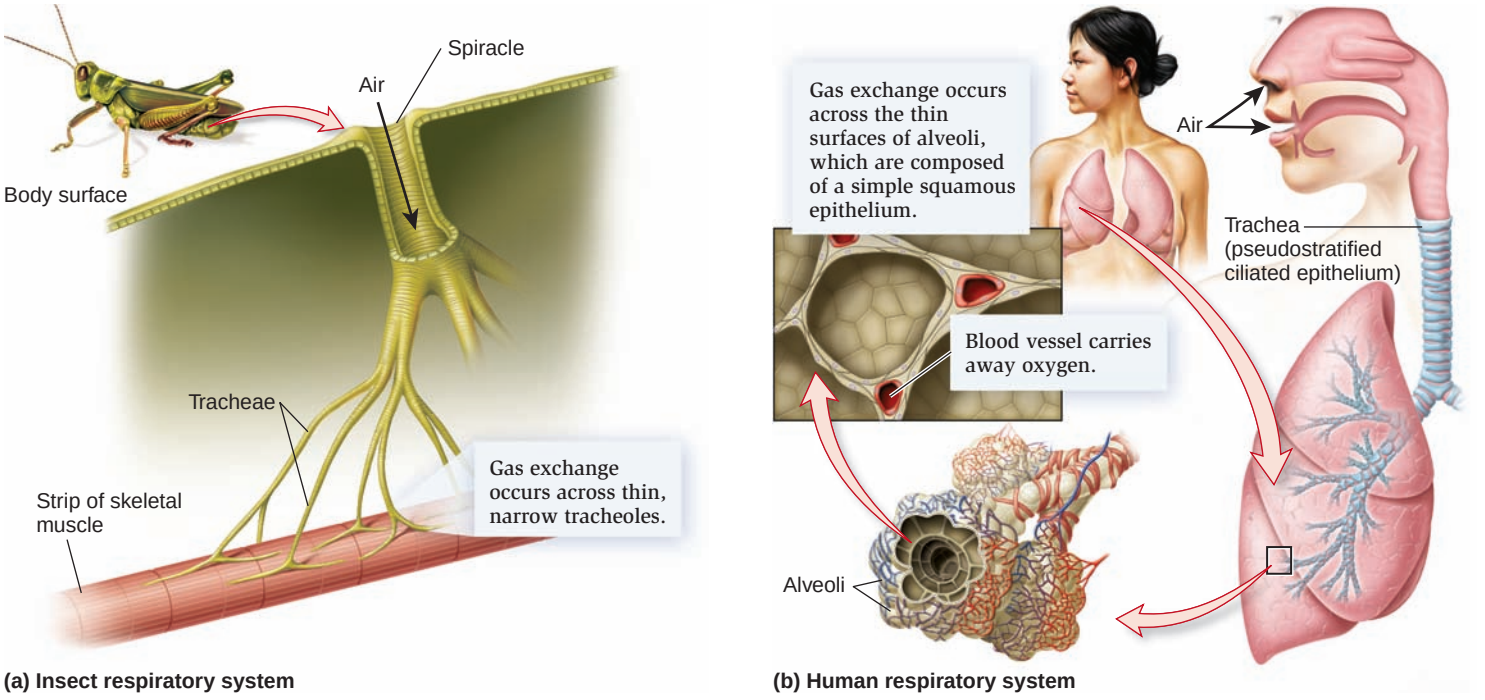
40.2 The Relationship Between Form and Function

A key theme throughout this unit is that form (structure) and function are closely related. The appearance or structure of an animal's tissues and organs can often help us predict the function of those structures. For example, let's compare the respiratory systems of an insect and a mammal (Figure 40.9). The respiratory systems of animals exchange oxygen from the environment with carbon dioxide generated by the body. Although many important differences exist between the respiratory systems of insects and mammals, notably the absence of lungs in insects, certain structural similarities suggest that both systems serve similar functions. In both cases, for example, a series of internal branching tubes composed of epithelial and connective tissues arises from one or more openings that connect with the outside environment (the mouth and nose in the mammal, and the spiracles in the insect). These tubes become smaller and smaller as they continue to branch, eventually terminating in narrow structures that are only one cell thick.

Without knowing anything else about the respiratory systems of these two animals, we can surmise that in both cases these branching tubes serve as conduits for air to flow back and forth between the environment and the internal spaces of the animal. In the insect, the ends of the branching tubes called tracheoles are where oxygen diffuses from the air to the fluid around individual cells (and from there to intracellular fluid) (Figure 40.9a). In the mammal, the ends of the tubes form saclike structures called alveoli across which oxygen diffuses into the bloodstream.

If we examine the mammalian lung in greater detail (Figure 40.9b), we see that the alveoli are composed of extremely thin, squamous epithelial cells. The shape of the cells provides a clue to their function. Their thinness permits diffusion of gases across the cells as rapidly and efficiently as possible. Imagine the resistance to oxygen diffusion if the cells were thick or scaly, like the cells of the body surface of many animals, for example. Therefore, both the gross and microscopic anatomy of the gas-exchange surfaces of respiratory systems facilitates their functions.

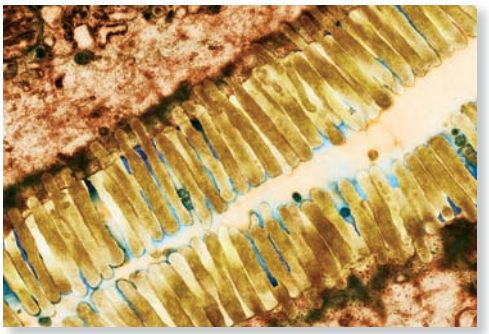
An additional structural similarity found in essentially all respiratory surfaces, including gills, is an extensive surface area. In fact, we can expand our discussion to include all cells, tissues, and organs that mediate diffusion or absorption of a solute from one compartment to another, or which require extensive cell-to-cell contacts. Consider, for instance, the finger-like projections of the small intestine of a human, the skin folds of some high-altitude frogs, the cellular extensions on the surface of neurons of a mouse, and the feathery antennae of a moth (Figure 40.10). What do these structures have in common? They all display a large surface area, which maximizes the ability of a tissue or organ to absorb solutes (intestine), obtain oxygen from the environment (frog skin), communicate with other cells (neurons), or sense airborne molecules (moth antennae). Increasing surface area of a structure, however, comes at the expense of greatly increasing volume if the shape of the structure is not changed. This is because as an object enlarges, its volume grows relatively more than its surface area; surface area increases by the power of two, while volume increases by the power of three as an object enlarges. For example, if an animal's height, length, and width are increased by a factor of 10, its surface area is



(a) Insect respiratory system

(b) Human respiratory system

Figure 40.9 **Comparison of the branching air tubes in (a) an insect and (b) a mammal.** Note the similar features of highly branching, internalized hollow tubules that connect to the outside air, suggesting that these systems perform similar functions.



(a) Human intestine

(b) Frog skin

(d) Moth antennae

Figure 40.10 **Examples of structures in which extensive surface area is important for function.**
A large surface area allows **(a)** high rates of transport of digested foods across the intestine of a human, **(b)** increased diffusion of oxygen across the folds of skin of a frog living at high altitude, where O_2 is less available, **(c)** extensive communication between neurons in a mouse's brain, and **(d)** detection of airborne chemicals by moth antennae.

Concept check: *Is surface area important only for animals, or could it also provide advantages to other living organisms?*

increased 100 times, but its volume is increased 1,000 times. This relationship is also true when considering an animal's organs and other structures, and could create certain disadvantages. For example, the ability to obtain sufficient oxygen from water requires a great amount of surface area within the fine structure of a fish's gills. Were the gills to increase their volume in the expected proportion just described, they would become far too unwieldy to allow the normal behaviors required for survival of a fish. The challenge of packaging an extensive surface area into a confined space is overcome by changes in shape (see, for example, the way the inner surface of the intestines in Figure 40.10a folds inward to form finger-like extensions). In a fish gill, numerous thin, flat, platelike structures are packed together, one on another, forming a dense array of surfaces available for oxygen diffusion. The ratio between a structure's surface area and the volume in which the structure is contained is called the **surface area/volume (SA/V) ratio**. This concept will appear throughout this unit as we explore the ways in which animals obtain energy, regulate their metabolism and body temperature, obtain oxygen, and eliminate wastes.

When all of an animal's organ systems operate correctly and body fluid levels and solute composition are maintained within normal limits, the animal is generally considered to be in a healthy condition. In the rest of this chapter, we will examine the process of achieving and maintaining this condition, which is known as homeostasis.

40.3 Homeostasis

The environmental conditions in which organisms—including all animals—live are rarely, if ever, constant. Animals are exposed to fluctuations in air and water temperatures, food and water supplies, pH, and, in some cases, oxygen availability. Any one of these environmental changes could be harmful or even fatal if an organism is unable to respond appropriately. However, as you might expect from the incredible diversity of environments in which they exist, animals can adjust in many ways to their surroundings and thrive.

The process of maintaining a relatively stable internal environment despite changes in the external surroundings is known as **homeostasis** (from the Greek *homoios*, meaning similar, and *stasis*, meaning to stand still). The term was coined in the 20th century by the American physician and physiologist Walter Cannon, but the concept itself originated in the 19th century with the French physician and physiologist Claude Bernard, who postulated that a constant *milieu interieur* (internal environment) was a prerequisite for good health. The ability to maintain homeostasis can impart a selection advantage for animals (as well as other organisms), because many of the fundamental processes of life—for example, enzyme activity—operate most efficiently within narrow limits of such variables as temperature and intracellular pH.

Some Animals Conform to External Environments; Others Regulate Their Internal Environments

Generally speaking, animals use two mechanisms to maintain homeostasis: conforming and regulating. Some animals conform to their environments so that some feature of their internal body composition matches their external surroundings. A marine crab, for example, has about the same solute concentration in its body fluids as is found in seawater. Likewise, the body temperatures of many fishes and aquatic invertebrates match the temperatures of the surrounding waters. Energetically

speaking, conforming is a cheap strategy for survival. It would take a great deal of energy for a small fish to maintain its body temperature at, say, 37°C when swimming in the waters of Antarctica. However, because they do not actively adjust their internal body composition, conformers are generally restricted to living in environments that are relatively stable.

Other animals regulate the internal composition of their fluids and solutes at levels that are different from those of the external environment. Most vertebrates are regulators, but as just noted for fishes, exceptions exist. A single animal may be both a conformer and a regulator with respect to different physiological variables. A fish may conform its body temperature to the environment but regulate its internal solute concentrations at levels different from that of fresh or salt water. Regulating the internal environment requires considerable energy in the form of ATP. For this reason, homeostasis for regulators comes with a high price tag. However, the energetic price paid by regulators makes it possible for them to exploit environments that fluctuate significantly, something that is difficult for conformers.

Vertebrates Maintain Most Physiological Variables Within a Narrow Range

In vertebrates, the common physiological variables—levels of bloodborne factors such as minerals, glucose, and oxygen, for example—are usually maintained within a certain range despite fluctuating external environmental conditions (Table 40.2). At first glance, homeostasis may appear to be a state of stable balance of physiological variables. However, this simple idea cannot capture the scope of homeostasis. For example, no physiological function is constant for very long, which is why we call them variables. Some variables may fluctuate around an average value during the course of a single day yet still be considered in balance. Homeostasis is a dynamic process, not a static one.

Consider an example in your own body. Normally, blood sugar (glucose) remains at fairly steady and predictable levels in any healthy individual. After a meal, however, the level of glucose in your blood can increase quickly, especially if you have just eaten something sweet. Conversely, if you skip a few meals, your blood sugar level may drop slightly (Figure 40.11). Such fluctuations above and below the normal value might suggest that blood glucose levels are not homeostatic, but this is incorrect. Once blood glucose increases or decreases, homeostatic mechanisms restore glucose levels back toward normal. In the case of glucose, the endocrine system is primarily responsible for this quick adjustment, but in other examples, a wide variety of control systems may be initiated. In later chapters, we will see how every organ and tissue of an animal's body contributes to homeostasis, sometimes in multiple ways, and usually in concert with each other.

Homeostasis, then, does not imply that a given physiological function is rigidly constant. Instead, homeostasis means

Table 40.2 Selected Examples of Homeostatic Variables in Animals

Variable	Factors that influence homeostasis	Examples of functions
Minerals	Eating food; excreting wastes	
Na^+ and K^+		Establish resting membrane potentials across plasma membranes in all cells and are responsible for transmitting electrical signals in excitable tissues (muscles and nervous tissue).
Ca^{2+}		Important for muscle contraction; neuron function; skeleton and shell formation
Fe^{2+}		Binds and transports oxygen in blood or body fluids (some invertebrates use copper instead of iron)
Fuel sources	Eating food; expending energy	
Glucose		Broken down to provide energy for use by all cells, especially brain cells
Fat		Provides an alternate source of energy, particularly for cells not in the nervous system; major component of plasma membranes
ATP		Provides energy to drive most chemical reactions and body functions; modifies function of many proteins by transferring its terminal phosphate group to proteins
Body temperature	Changing rates of energy expenditure; environmental temperature; behavioral mechanisms (see Chapter 46)	Determines the rate of chemical reactions in an animal's body
pH of body fluids	Hydrogen ion pumps in cells; buffers in body fluids; rates of energy expenditure; breathing rate	Affects enzymatic activity in all cells
Other variables		
Oxygen and carbon dioxide	Movement of air or water across respiratory surfaces (for example, lungs and gills); rates of energy expenditure	Oxygen circulates in body fluids and enters cells, where it is used during the production of ATP; carbon dioxide is a waste product that is eliminated to the environment, but it is also a key factor that regulates the rate of breathing air or water
Water	Drinking, eating, excretion of wastes, perspiration, osmosis across body surface (for example, skin or gills)	Numerous biological functions including participating in chemical reactions, helping to regulate body temperature, and acting as a solvent for biologically important molecules (see Chapter 2)

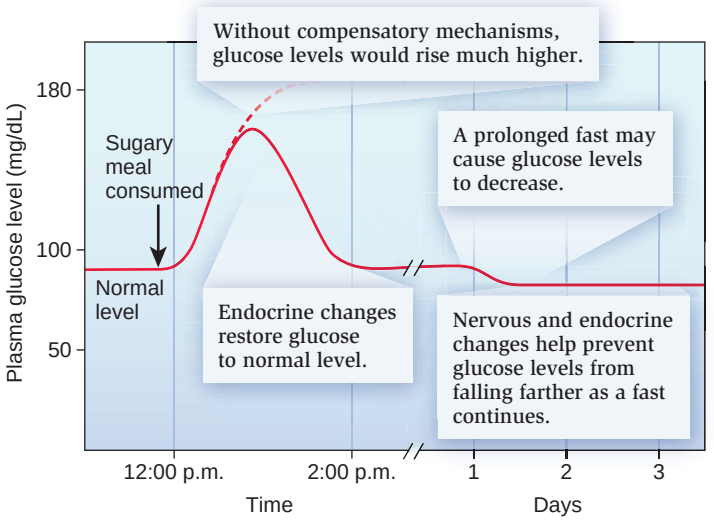

Figure 40.11 **An example of a homeostatically controlled variable, glucose levels in human blood.** Note that glucose levels in the plasma may rise or fall depending on whether an animal has recently eaten. However, even after a sugary meal or a prolonged fast, homeostatic mechanisms either return glucose levels to normal or enable those levels to remain within the range required for survival. Traditional units for glucose used in the U.S. are given on the y-axis; as a reference, a value of 100 mg/dL is equal to 5.5 mM.

that a variable fluctuates within a certain range and that once disturbed from that range, compensatory mechanisms restore the variable toward normal levels.

Homeostatic Control Systems Maintain the Internal Environment

The activities of cells, tissues, and organs must be regulated and coordinated with each other so that any change in the extracellular fluid—the internal environment—initiates a response to correct the change. These compensating regulatory responses are performed by homeostatic control systems. A **homeostatic control system** must have several components, including:

- a **set point**—the normal value for a controlled variable;
- a **sensor**, which monitors the level or activity of a particular variable;
- an **integrator**, which compares signals from the sensor to the set point; and
- an **effector**, which compensates for any deviation between the actual value and the set point.

Figure 40.12 shows an example of a homeostatic control system that regulates body temperature in mammals. This system is somewhat analogous to the heating system of a home. In that case, a sensor and integrator within the thermostat compare the actual room temperature to the set point temperature that was determined by setting the thermostat to a given temperature. If the room temperature becomes cooler than the thermostat setting, the effector (furnace) is activated and adds heat to the room. In a mammal, the sensors are temperature-sensitive neurons in the skin and brain, whereas the integrator is within the brain. Signals from the brain are sent along nerves to the effectors, which include skeletal muscles. The muscles contract vigorously in response to these signals, resulting in shivering—a key way in which mammals' bodies generate heat. We will discuss other heat-conserving and heat-generating mechanisms that contribute to this homeostatic control system in Chapter 46.

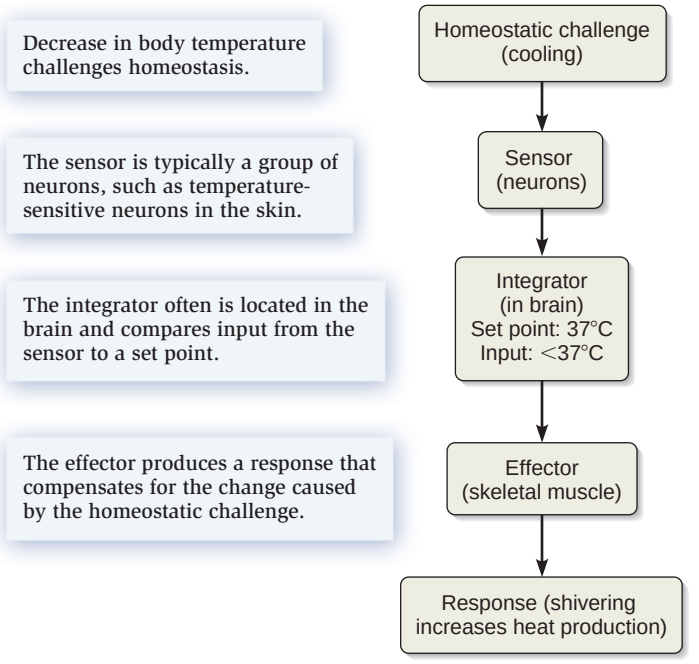

Figure 40.12 **An example of a homeostatic control system.** The sensor and effector for responding to a decrease in body temperature are shown. Different homeostatic control systems have different sensors and effectors.

Concept check: Would you expect all animals to have similar set points for a given homeostatic variable?

There are instances where animals make excursions far outside of their homeostatic ranges. For example, the high body temperature associated with a fever or the low body temperature associated with hibernation are temporary resettings of physiological set points.

When a homeostatic control system operates normally, changes in a physiological variable are kept to a minimum. These changes are limited by the process of feedback, as we will now see.

Feedback Is a Key Feature of Homeostasis

Feedback is a fundamental feature of homeostasis and a major way in which disturbances to a physiological variable are minimized. The temperature regulation system just described is an example of a **negative feedback loop**, in which a change in

the variable being regulated brings about responses that move the variable in the opposite direction. Thus, a decrease in body temperature leads to responses that increase body temperature—that is, move it back toward its original value.

Negative feedback also prevents homeostatic responses from overcompensating. When the blood pressure of a bleeding animal falls as more and more blood is lost, for example, pressure sensors in the heart and certain blood vessels detect the change in pressure and send the information to the integrator—the brain (Figure 40.13). In the brain, the signal is compared to the normal set point for blood pressure. The brain responds to this sharp deviation from the blood pressure set point in two ways. First, signals are sent along nerves to the effectors—in this case, the kidneys, heart, and blood vessels. Second, the brain stimulates the release of certain hormones into the blood; these hormones act with the nervous system on the effectors. The result is that the heart beats more rapidly and forcefully, the kidneys produce less urine and thereby retain more body fluid, and the blood vessels preferentially direct blood to the most vital organs such as the brain. These responses raise the animal's blood pressure back toward the set point. Restoring the blood pressure removes the stimulus from the sensor, and this, in turn, shuts off further production of the hormonal and neural responses (negative feedback). If feedback inhibition did not occur, the blood pressure would not only rebound back to the set point but might rise to abnormally high and possibly dangerous levels.

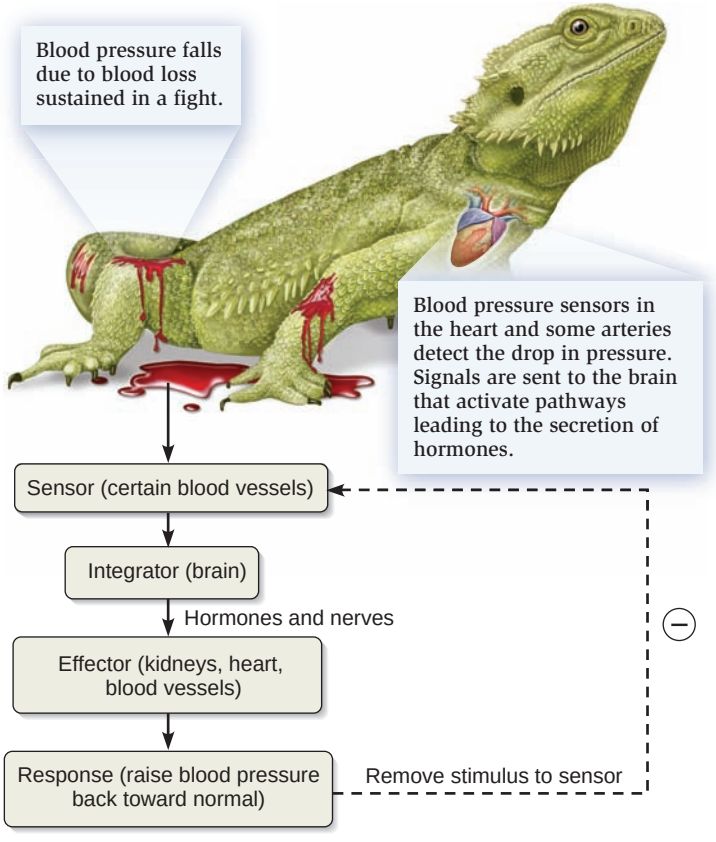

Figure 40.13 **Negative feedback as a mechanism by which homeostatic control systems operate.** In this example, loss of blood results in a drop in blood pressure, which could be life-threatening if not corrected. Effectors such as the kidneys, heart, and blood vessels help restore blood pressure toward normal. They do not raise blood pressure above normal, however, because of negative feedback (as denoted by the minus sign).

Negative feedback may occur at the organ, cellular, or molecular level. For instance, feedback mechanisms regulate many enzymatic processes. In one example, ATP regulates the rate of its own formation in cells by inhibiting certain intracellular enzymes that catalyze the breakdown of glucose molecules, a key event in the production of ATP.

Not all forms of feedback contribute to homeostasis. In some cases, a **positive feedback loop** may accelerate a process, leading to what is sometimes called an explosive system (think of an avalanche that begins with a small snowball rolling down a steep hill). This is contrary to the principle of homeostasis, in which large fluctuations in a variable are minimized and reversed. Not surprisingly, perhaps, positive feedback is far less common than negative feedback in animals. Nonetheless, positive feedback is crucial to some processes in animal biology. One example is the process of birth in mammals (Figure 40.14). Birth is triggered by a positive feedback loop between nerve signals arising from smooth muscle cells of the cervix (the connection between the vagina and the uterus) and the mother's brain and pituitary gland (a component of the endocrine system). As the uterus pushes the baby's head against the cervix in late pregnancy, nerve signals from the cervix send information

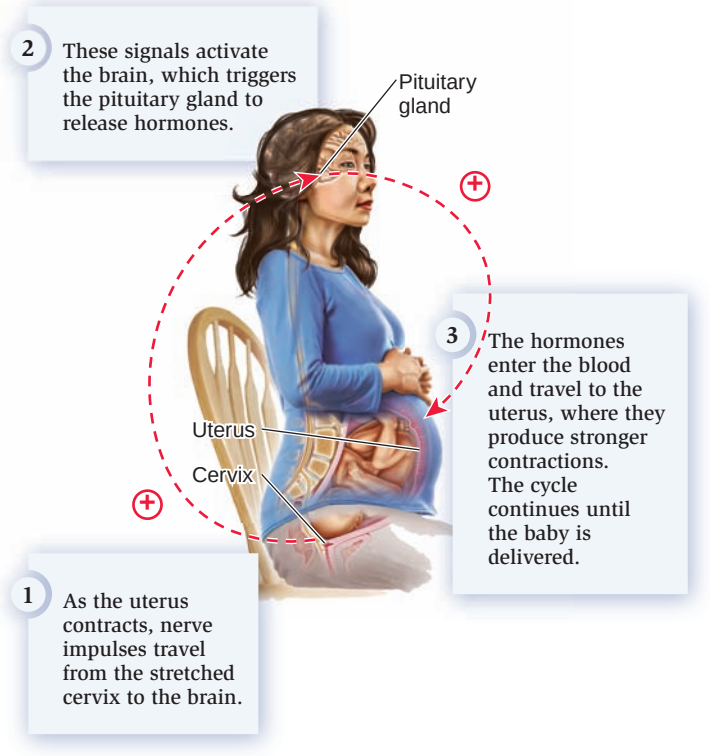

Figure 40.14 **The human birth process as an example of positive feedback.**

to the brain, which triggers the pituitary gland to release certain hormones. These hormones stimulate the uterus to contract with more force, which in turn sends additional nerve signals to the brain, and so on. Eventually, the uterus contracts strongly enough to deliver the baby, which stops the signals from the cervix to the brain and allows the uterus to gradually relax.

Feedforward Regulation Prepares for an Upcoming Challenge to Homeostasis

Built into the homeostatic mechanisms of many animals, particularly those with well-developed nervous systems, is another feature designed to minimize large swings in physiological variables. In **feedforward regulation**, an animal's body begins preparing for a change in some variable (for example, blood glucose levels) before it even occurs. Consider the anticipatory changes that occur when a hungry dog smells or sees food; indeed, the same phenomenon happens in humans. First, the animal starts to salivate, and its stomach begins to churn. Salivation and movements of the stomach are important components of the digestive process, yet at this stage, the animal has not actually eaten any food. Instead, its digestive system is already preparing for the arrival of food in order to maximize digestive efficiency, speed the flow of nutrients into the blood, and minimize the time required for active cells to replenish energy stores. Therefore, feedforward regulation speeds up the body's homeostatic responses and minimizes fluctuations in the variable being regulated—that is, it reduces the amount of deviation from the set point.

In the preceding example, feedforward control uses sensory detectors that recognize odors and sights. Many examples of feedforward control, however, result from, or are modified by, the phenomenon called learning. The result of this process is that the nervous system learns to anticipate a homeostatic challenge. Familiar examples are the increased heart rate and breathing rate that occur just before an athletic competition—for example, in trained racehorses before the start of a race (Figure 40.15). The process of training, in which the horses' bodies learn to prepare for the exertion of the race, allows there to be no delay between the start of exercise and the flow of blood and nutrients to skeletal muscle. The most famous example of feedforward control was first demonstrated in the early 20th century by Russian physiologist Ivan Pavlov, as described next.

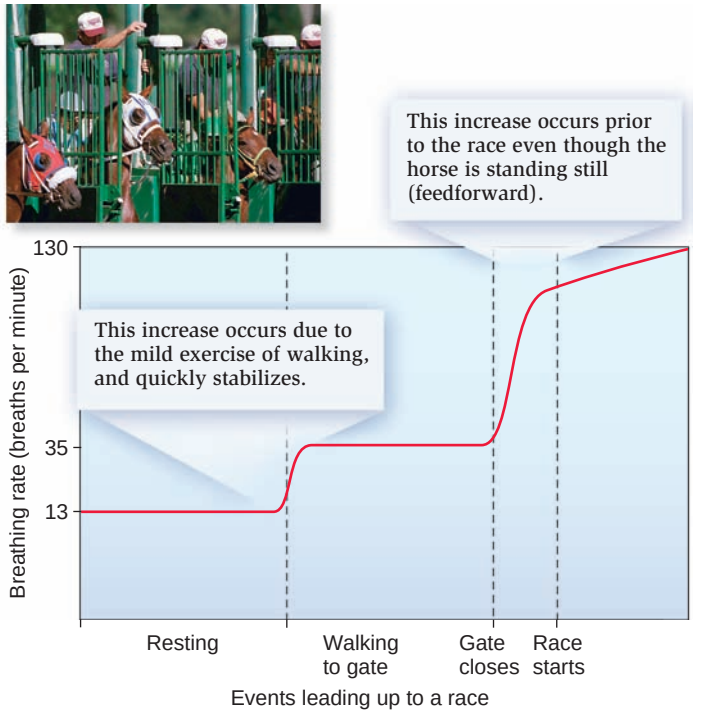

Figure 40.15 **Feedforward control of breathing rate in an animal trained for athletic exercise.** Feedforward processes prepare the body for an ensuing challenge or event, such as the race shown here.

Concept check: What kind of similar feedforward response might occur in nature?

Feature Investigation

Pavlov Demonstrated the Relationship Between Learning and Feedforward Processes

Ivan Pavlov made numerous contributions to our understanding of the digestive processes in mammals, for which he earned a Nobel Prize in Physiology and Medicine in 1904. Today, however, Pavlov is best remembered for work he did later in his career, when he demonstrated that feedforward processes associated with digestion could be conditioned to an irrelevant stimulus, that is, one that normally is not associated with digestive processes.

Pavlov was interested in the factors that increase production of saliva in a hungry animal. Saliva is an important secretion made by glands in the mouth, because among other things it aids in swallowing and contains enzymes that kill pathogens and begin the process of digesting starches in food. Pavlov discovered that dogs accustomed to being fed by the same researcher each day would begin to salivate any time they saw the researcher approaching, even without receiving, seeing, or smelling any food. In other words, the dogs had become conditioned to associate the researcher with food. This did not happen in dogs that were not yet accustomed to the regular feeding schedule of the laboratory. Pavlov hypothesized that any stimulus could elicit the feedforward process of salivation, even an irrelevant one that is not normally associated with feeding, so long as that stimulus was somehow paired with feeding.

To test this hypothesis, Pavlov presented two groups of dogs with either food (the control group) or food plus an irrelevant stimulus (the experimental group) (Figure 40.16). Each dog was isolated in a room so that it could not see, hear, or smell the

researcher or sense any other cues that might interfere with the experiment. Contrary to popular belief, the first stimulus Pavlov used was not the ringing of a bell, but the ticking of a metronome. Pavlov reasoned that after some period of time, the experimental dogs would become conditioned to the auditory stimulus and would learn to associate it with the arrival of food. If this was correct, the metronome by itself should eventually be sufficient to elicit the feedforward process of salivation.

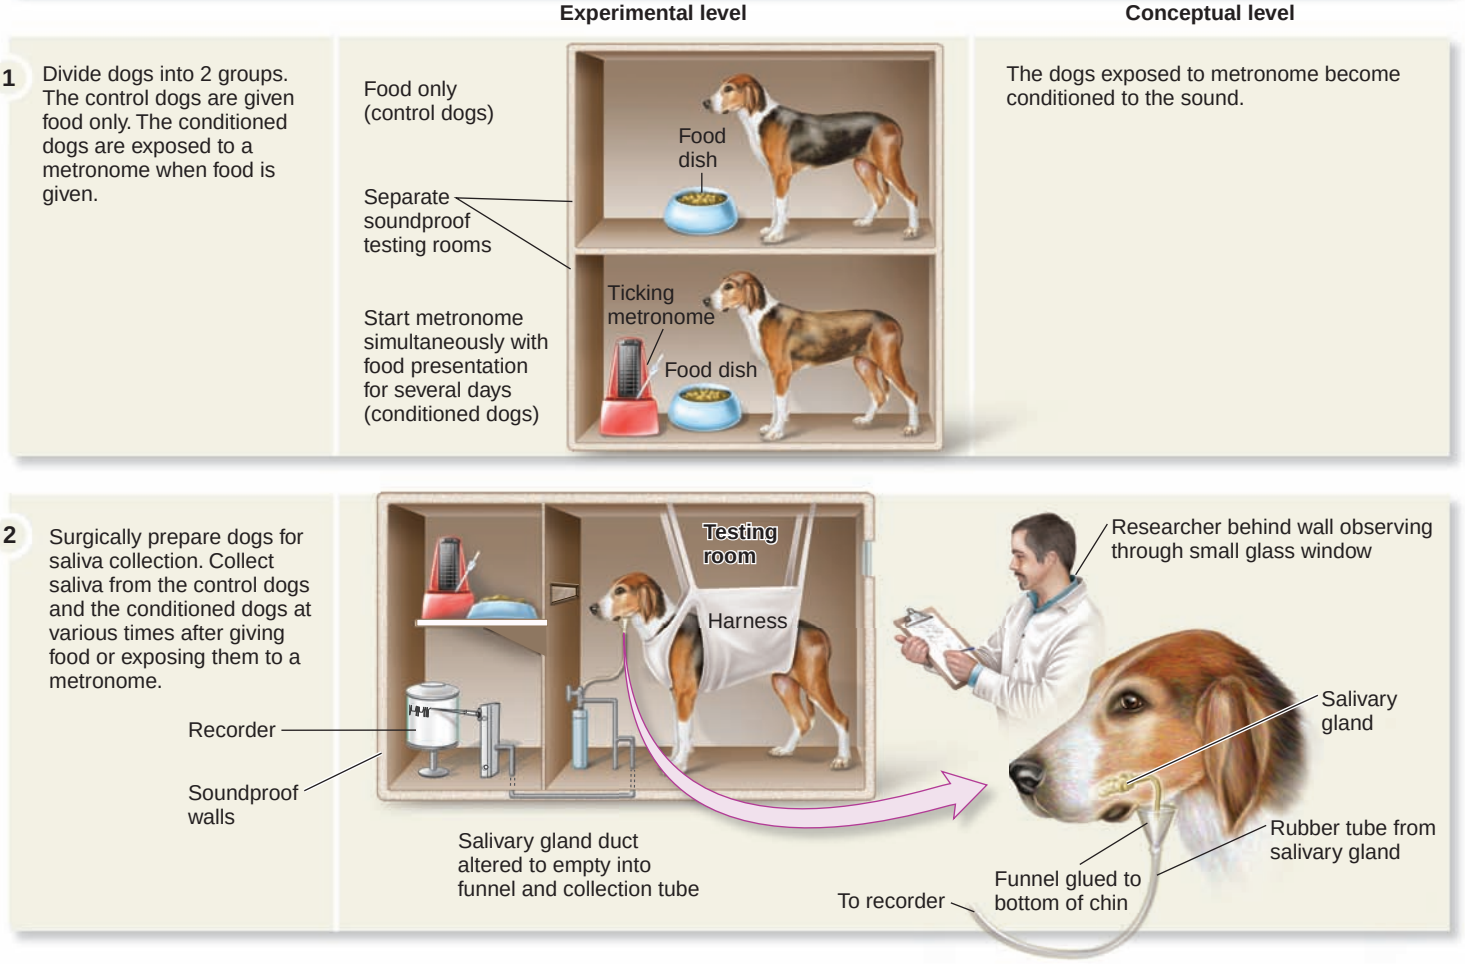
To measure salivary production rates, Pavlov surgically altered the ducts leading from the salivary glands located under the dogs' tongues such that the ducts opened up outside the dog's chin. A glass funnel was then glued beneath the chin. In Pavlov's initial experiments, the amount of saliva was quantified simply by counting the number of drops coming from a tube leading from the funnel. This was achieved by allowing the saliva to settle onto a mechanical device attached to a rocker arm that caused a deflection on a rotating electrical recorder. Each time a drop was collected, the arm moved and registered a hatch mark on the recorder. The number of hatch marks was equal to the total number of drops of saliva collected in any given period. Pavlov's hypothesis was confirmed when, after a conditioning period of several days, the conditioned stimulus by itself elicited increased salivation in the conditioned dogs in under 10 seconds. The control dogs responded slightly sooner to the appearance of food than the conditioned dogs did to the metronome, but the amount of saliva produced was roughly comparable in both groups of dogs.

In later experiments, Pavlov demonstrated that other stimuli, such as touch, produced the same phenomenon he observed with sound. He also showed that the conditioned response was not permanent. If a dog that was already conditioned to the sound of a metronome was then repeatedly exposed to that sound without the simultaneous presentation of food, the salivary response to the sound would eventually cease. These experiments demonstrated that certain feedforward processes can be modulated by experience and learning and suggested

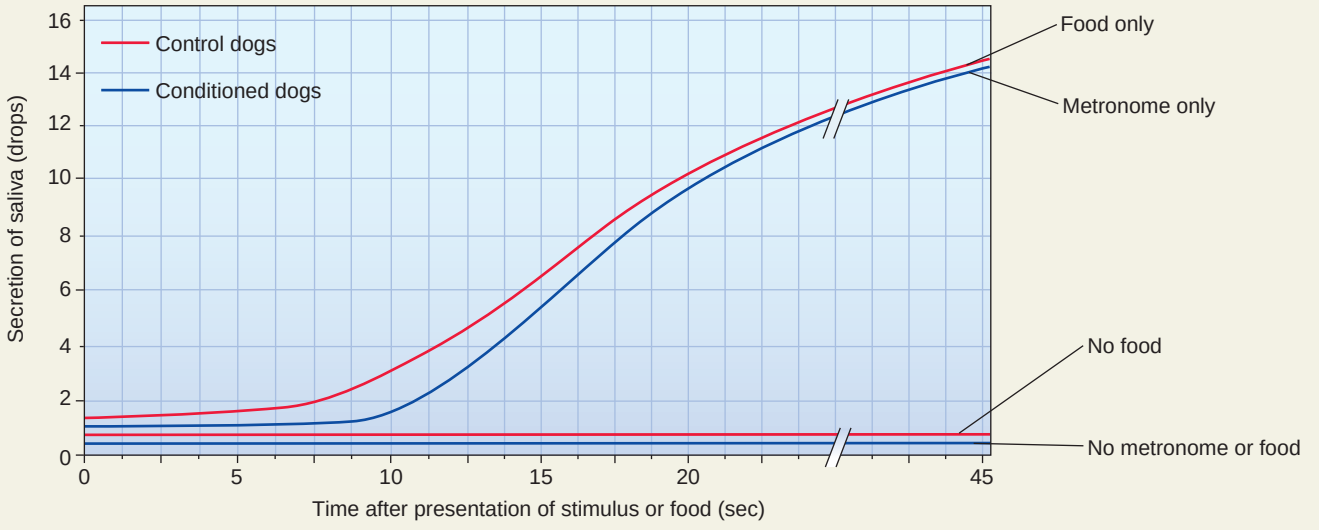
Figure 40.16 Feedforward events can be conditioned to external stimuli.

HYPOTHESIS It is possible to condition a feedforward response to an irrelevant stimulus through learning.

KEY MATERIALS Experimental animals (dogs), metronome, collection ports for saliva, food, soundproof testing rooms.



3 THE DATA



4 CONCLUSION The feedforward response of salivation can be modulated by experience and learning, demonstrating the adaptability of animals' physiological responses.

5 SOURCE These are idealized data compiled from several of the original published experiments performed by Pavlov and coworkers. The original experiments were reported in Pawlow, J. 1903. Sur la sécrétion psychique des glandes salivares. *Archives Internationales Physiologie* 1:119–135. (Note the alternate spelling of Pavlov's name.)

that animals have a much greater ability to recognize and adapt to changes in their environment than previously thought.

Experimental Questions

1. What process did Pavlov study in his experimental animals, and what was his hypothesis?
2. How did Pavlov control for the possibility that other stimuli, such as the smell of the investigator, were somehow causing the feedforward response?
3. What did Pavlov measure, and what was his major finding?

Local and Long-Distance Chemical Signals Coordinate Homeostatic Responses

A common thread that links all homeostatic processes together is communication between cells, whether cells are close to each other or in different parts of an animal's body. Some homeostatic responses may be highly localized, occurring only in the area of a disturbance. For example, damage to an area of skin causes cells in the injured area to release molecules that help contain the injury, prevent infections, and promote tissue repair in the immediate vicinity (see Chapter 53). Local responses provide areas of the body with mechanisms for local self-regulation. It would be of no benefit to an animal to promote tissue repair in regions of the body that are not injured. This type of cellular communication—in which molecules are released into the interstitial fluid and act on nearby cells—is called **paracrine** signaling (refer back to Figure 9.3).

Another example of extremely localized paracrine signaling occurs between neurons. Most neurons communicate through the release of **neurotransmitters**, small signaling molecules that are synthesized and stored in neurons. When a neuron releases these neurotransmitters, they diffuse to combine with receptor proteins on a single, adjacent neuron (or in some cases a muscle or gland cell), altering the activity of that cell. This type of cell-to-cell communication is typically very rapid, finishing within milliseconds. Consequently, neurotransmitter responses can make immediate homeostatic adjustments, like those associated with reflexes. These are just two of the many types of paracrine signaling that occur in animals' bodies and that will be described in subsequent chapters in this unit.

In addition to localized paracrine signaling, cells can communicate over long distances by releasing chemical messenger molecules. This type of signaling is mediated by the endocrine systems of animals. As introduced in Chapter 9, a hormone is a chemical messenger produced in a gland or other structure that when secreted into the blood acts on distant target cells that have the appropriate receptor for that particular hormone. A hormone released in response to a homeostatic disturbance, such as the drop in blood pressure described earlier, can influence the activities of many different cells, tissues, and organs simultaneously because the hormone is carried throughout the entire blood circulation. Some hormones act quickly—within seconds—while others take minutes or even hours for their effects to occur. In subsequent chapters, we will see that hormones are a key part of the regulatory processes that govern the functions of every organ system in a vertebrate's body, and they play key roles in growth, development, and reproduction in invertebrates.

Summary of Key Concepts

40.1 Organization of Animal Bodies

- In an animal's body, differentiated cells with similar properties group to form tissues, which combine with other types of tissues to form organs. Organs are functionally linked to form organ systems. (Figure 40.1)
- Muscle tissues consist of cells specialized to contract, generating the mechanical forces that produce movement, decrease the diameter of a tube, or exert pressure on a fluid-filled cavity. There are three categories of muscle tissue: skeletal, smooth, and cardiac. Nervous tissues initiate and conduct electrical signals from one part of an animal's body to another part. Epithelial tissues are specialized to protect structures and to secrete and absorb ions and organic molecules. Connective tissues connect, surround, anchor, and support the structures of an animal's body. Connective tissues include blood, adipose (fat-storing) tissue, bone, cartilage, loose connective tissue, and dense connective tissue. (Figures 40.2, 40.3, 40.4, 40.5)
- An organ is composed of two or more kinds of tissues. In an organ system, different organs work together to perform an overall function. (Figure 40.6, Table 40.1)
- The development, spatial positioning, and function of many body organs are under the control of highly conserved homeotic genes, such as *Hox* genes in vertebrates.
- An animal's body fluids are distributed into three compartments (intracellular fluid, plasma, and interstitial fluid). The properties of the barriers between the compartments determine which substances can move between them. (Figures 40.7, 40.8)

40.2 The Relationship Between Form and Function

- Similarities in structure are often associated with similarities in function. (Figure 40.9)
- Extensive surface area maximizes the ability of a tissue or organ to absorb solutes, exchange oxygen and carbon dioxide with the environment, communicate with other cells, and receive sensory information from the environment. The high surface area/volume (SA/V) ratio principle applies to many structures and across all animal taxa. (Figure 40.10)

40.3 Homeostasis

- Homeostasis is the process of maintaining a relatively stable internal environment and adapting to changes in the external environment. Some animals are conformers; others are regulators. Within an animal, some systems may conform while others regulate.
- Vertebrates maintain most physiological variables within a certain range despite variations in external environmental conditions. (Figure 40.11, Table 40.2)
- Homeostatic control mechanisms regulate the internal environments of organisms. A sensor monitors a variable, an integrator compares signals from the sensor to a set point, and an effector compensates for any deviations from the set point. Negative feedback minimizes changes in a variable and prevents homeostatic responses from overcompensating. (Figures 40.12, 40.13)
- Negative feedback is far more common in animals than positive feedback. Feedforward regulation prepares the body for an upcoming challenge to homeostasis. (Figures 40.14, 40.15)
- Pavlov's experiments with dogs demonstrated that certain feedforward responses such as salivation could be conditioned to irrelevant stimuli, such as the ticking of a metronome. (Figure 40.16)
- Chemical communication between cells is essential to homeostasis. Types of chemical messengers include paracrine signals, such as neurotransmitters, and long-distance signals, such as hormones.

Assess and Discuss

Test Yourself

1. Tissue that is specialized to conduct electrical signals from one structure in the body to another structure is _____ tissue.
   a. epithelial
   b. connective
   c. nervous
   d. muscle
2. Structures composed of two or more tissue types arranged in various proportions and patterns are
   a. cells.
   b. tissues.
   c. organs.
   d. organ systems.
   e. organisms.
3. The extracellular matrix of connective tissue
   a. contains different proteins that provide structural support to cells.

b. provides a scaffolding for the cells of the tissue.
c. plays a role in cellular communication.
d. does all of the above.
e. does a and b only.

4. When examining the structure of many animal organs,
   a. it is apparent that all organ systems are fully functional in all animals.
   b. the function can be predicted based on the structural adaptations.
   c. the function of the structure is difficult to determine because of the lack of variation among the different structures of the body.
   d. all four tissues are equally represented in all organs.
   e. None of the above are correct.
5. Most of the water in an animal's body
   a. lacks any type of ions or other solutes.
   b. is found in the spaces between cells.
   c. is contained inside the cells.
   d. is located in the extracellular fluid.
   e. is unable to move between body compartments.
6. The folds, convolutions, or extensions found in many structures of animals results in
   a. decreased level of activity in that particular structure.
   b. interruption in the normal functioning of the structure.
   c. increased surface area for absorption, communication, or exchange.
   d. higher susceptibility to infection.
   e. none of the above.
7. Adapting to changes in the external environment and maintaining internal variables within physiological ranges is
   a. natural selection.
   b. evolution.
   c. positive feedback.
   d. homeostasis.
   e. both c and d.
8. Which of the following statements regarding negative feedback is not correct?
   a. It helps regulate variables such as body temperature and blood pressure.
   b. It is the mechanism by which birth occurs in mammals.
   c. It is a major feature of homeostatic control systems.
   d. It prevents homeostatic responses from overcompensating.
   e. It may occur at the organ, cellular, or molecular level.
9. The ability of an animal's body to prepare for a change in some variable before the change occurs is called
   a. positive feedback.
   b. negative feedback.
   c. homeostasis.
   d. feedforward regulation.
   e. autoregulation.
10. A hormone differs from a neurotransmitter in that
    a. hormones act extracellularly; neurotransmitters act within the cell that synthesized them.
    b. hormones are released only by neurons; neurotransmitters are released by many different types of cells.
    c. hormones only cause fast responses (seconds or less) to stimuli; neurotransmitters cause slow responses (minutes to hours) to stimuli.
    d. hormones affect only epithelial cells; neurotransmitters affect only muscle cells.
    e. hormones are released into the bloodstream and can activate many cells in many parts of the body; neurotransmitters are released by neurons and affect adjacent cells.

Conceptual Questions

1. Define anatomy and physiology.
2. Describe the relationship between structure and function in animals, and describe how surface area and volume are related.
3. Define homeostasis, and give examples of homeostatic variables.

Collaborative Questions

1. Describe the terms negative feedback loop and positive feedback loop, and describe how they differ.
2. Discuss the organization of animal bodies from the cellular to the organ system level.

Neuroscience I: Cells of the Nervous System

41

Chapter Outline

A fluorescently stained human neuron. These types of cells are responsible for sending signals throughout the nervous systems of animals.

As you begin reading, stop and think. Can you describe everything you are doing right now? Your eyes are sensing light reflected off this page, and your brain is interpreting the meanings of the words you are reading. You may be hearing sounds and, in some cases, choosing to ignore them as you concentrate on reading. Your digestive system may be sending signals about hunger, or perhaps if you've just eaten, you feel full and are digesting what you ate. You are breathing, perspiring, feeling the chair on which you're sitting, and your heart is beating. All of these processes and many others are under the control of the **nervous system**, coordinated circuits of cells that sense internal and environmental changes and transmit signals that enable us and other animals to respond in an appropriate way. Nervous systems help us to exert control over our bodies. They also allow animals such as ourselves to sense what is going on in the outside world, initiate actions that influence events and respond to demands, and regulate internal processes—all while maintaining homeostasis (see Chapter 40). You are conscious of some of these functions, such as reading this text or feeling hungry. Many others, however, such as maintaining your body temperature and controlling your heart rate, occur without your awareness.

Neuroscience is the scientific study of nervous systems. Neuroscientists are interested in topics such as the structure and function of the brain and the biological basis of consciousness, memory, learning, and behavior. Neuroscience is now experiencing an unprecedented level of new discoveries and rapid growth. It interfaces with other disciplines such as cell and molecular biology, psychology, and behavioral biology.

In this chapter, our focus on neuroscience will be at the cellular level. Nervous systems are composed of circuits of **neurons**, highly specialized cells that communicate with each other and with other types of cells by electrical or chemical signals (see chapter-opening photo). In many animals, such as ourselves, neurons become organized into **nuclei** (singular, nucleus), clusters of cells that carry out a particular function. Nuclei typically form in a central processing area of the nervous system called a **brain**. The brain sends commands to various parts of the body through **nerves**—bundles of neuronal cell extensions projecting to and from various tissues and organs.

In this chapter, we will investigate the special features of neurons that make them suited for rapid communication between cells. Chapters 42 and 43 will explore how nervous systems are organized, how the brain functions, and how animals use their nervous systems to sense the world around them.

41.1 Cellular Components of Nervous Systems

The organization of nervous systems permits extremely rapid responses to changes in an animal's external or internal environment. In complex animals, the **central nervous system** (**CNS**) consists of a brain and a nerve cord, which in vertebrates extends from the brain through the vertebral column and is called the **spinal cord**. The **peripheral nervous system** (**PNS**) consists of all neurons and projections of their plasma membranes that are outside of but connect with the CNS, such as projections that end on muscle and gland cells. In certain invertebrates with simple nervous systems, the distinction

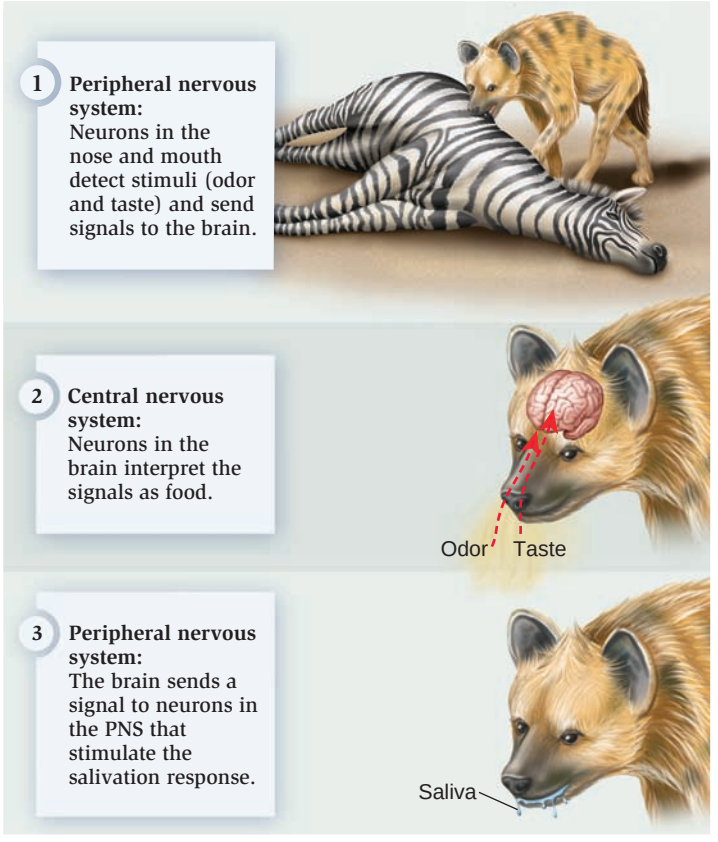

Figure 41.1 Roles of the central and peripheral nervous systems. In this example, a hungry hyena senses a smell and taste, which the brain interprets as a potential food source. This initiates a biological response (salivation) that prepares the hyena for eating.

Concept check: As you learned in Chapter 40, what type of response is demonstrated by the production of saliva in this figure? Note that saliva is being produced before the animal has begun eating.

between central and peripheral nervous systems is less clear or not present.

The evolution of nervous systems has allowed animals to receive information about the environment via their PNS, transmit that information along nerves to a CNS, interpret that information in a CNS, and, if necessary, initiate a behavioral response via their PNS (Figure 41.1). For example, if a hungry hyena receives stimuli such as the smell and taste of food, odor-sensing cells in the nose and taste-sensing cells in the tongue act as receptors for the stimuli and then send signals along nerves to the brain. There, the signals are interpreted and recognized. The brain then sends a signal via nerves that stimulate gland cells in the mouth, which respond by producing saliva in preparation for the arrival of food. In this section, we will survey the general properties of the cells of the CNS and PNS.

Cells of the Nervous System Are Specialized to Transfer Signals

Nervous systems transfer signals from one part of the body to another and direct the activities of cells, tissues, organs, and glands. Although these are complex tasks, nervous systems have only two unique classes of cells: neurons and glia.

Neurons As mentioned, neurons are cells that send and receive electrical and chemical signals to and from other neurons or other cells throughout the body. All animals except sponges have neurons. The number of neurons in the nervous systems of different species varies widely, partly as a function of the size of an animal's head and brain, but also as a function of the complexity of its behavior. As a comparison, the tiny, short-lived nematode *C. elegans* has 302 neurons in its nervous system, compared with several thousand in a wasp, several hundred thousand in a salamander, 300 million in an octopus, and over 100 billion in a human!

Regardless of the total number, neurons in one animal species look and act much like neurons from any other species. A neuron is composed of a **cell body**, or **soma**, which contains the cell nucleus and other organelles (Figure 41.2a,b). There are two types of extensions or projections that arise from the cell body: the dendrites and the axon. **Dendrites** (from the Greek word *dendron*, meaning tree) may be single projections of the plasma membrane but more commonly are elaborate treelike structures with numerous branching extensions. Electrical and chemical messages from other neurons are received by the dendrites, and electrical signals move toward the cell body (Figure 41.2c). The cell body processes these signals along with some signals that are received directly by the cell body and produces an outgoing signal to a structure called an axon. An **axon** is an extension of the plasma membrane that is involved in sending signals from a neuron to neighboring cells. An axon may be only a few micrometers long or as long as 2 m, such as in a giraffe's neck. A typical neuron has a single axon, which may have branches. The part of the axon closest to the cell body is named the **axon hillock**, also known as the initial segment. As we will see later, the axon hillock is important in the generation of the electrical signals that travel along an axon. At the other end of the axon are **axon terminals** that convey electrical or chemical messages to other cells, such as neurons or muscle cells.

Within an animal's body, many axons tend to run in parallel bundles to form nerves, which are covered by a protective layer of connective tissue. Nerves enter and leave the CNS and transmit signals between the PNS and the CNS. Along the way, the axon terminals of axons communicate with particular cells of the body.

Glia Surrounding the neurons are cells called the **glia** (from the Greek, meaning glue). Glial cells perform various functions and are many times more numerous than neurons, depending on the species. In the human brain, for example, glial cells outnumber neurons by about 50 to 1. Glial cells perform numerous important roles. One type of glia, called astrocytes, provides metabolic support for neurons and also is involved in forming the blood-brain barrier, which is a physical barrier between blood vessels and most parts of the central nervous system. This barrier protects the CNS by preventing the passage of toxins and other damaging chemicals from the blood into the

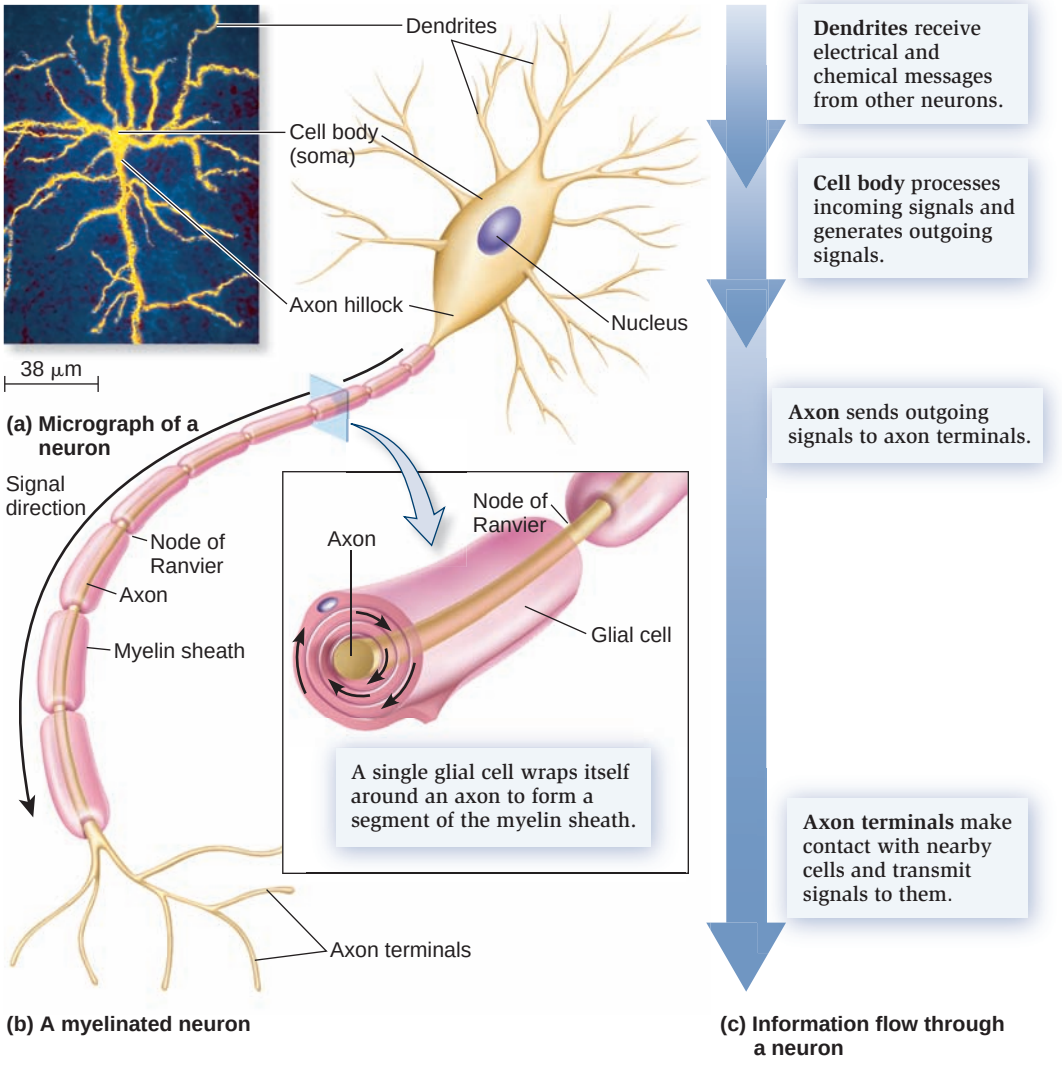

Figure 41.2 **Structure and basic function of a typical vertebrate neuron and associated glial cells.** **(a)** A stained neuron seen at high magnification (confocal microscopy). **(b)** A diagrammatic representation of a peripheral neuron with glial cells—in this instance, a type of glia called Schwann cells. The Schwann cells wrap their membranes around the axon at regular intervals, creating a myelin sheath that is interrupted by nodes of Ranvier. **(c)** The structures involved in the processing of information by a neuron; information flows in the direction shown.

CNS. Astrocytes also help to maintain a constant concentration of ions in the extracellular fluid. Other glia, called microglia, remove cellular debris produced by damaged or dying cells. In developing embryos, glia form tracks along which neurons migrate to form the nervous system. In addition, some glia function as stem cells to produce more glial cells and neurons.

In vertebrates, specialized glial cells wrap around the axons at regular intervals to form an insulating layer called a **myelin sheath** (Figure 41.2). The sheath is periodically interrupted by noninsulated regions called **nodes of Ranvier**. In the human brain and spinal cord, the myelin-producing glial cells are called **oligodendrocytes**. **Schwann cells** are the glial cells that form myelin on axons that travel outside the brain and spinal cord. As we will see later, myelin and the nodes of Ranvier increase the speed with which electrical signals pass down the axon.

Sensory and Motor Neurons as Well as Interneurons Form Pathways in a Nervous System

Neurons can be categorized into three main types: sensory neurons, motor neurons, and interneurons. The structures of each type reflect their specialized functions (Figure 41.3).

Sensory Neurons As their name suggests, **sensory neurons** detect or sense information from the outside world, such as light, odors, touch, or heat. In addition, sensory neurons detect internal body conditions such as blood pressure or body temperature. Sensory neurons are also called afferent (from the Latin, meaning to bring toward) neurons because they transmit information to the CNS. Many sensory neurons have a long, single axon that branches into a peripheral process and a central process, with the cell body in between (Figure 41.3a). This arrangement allows for the rapid transmission of a sensory signal to the CNS.

Motor Neurons **Motor neurons** send signals away from the CNS and elicit some type of response. They are so named because one type of response they cause is movement. In addition, motor neurons may cause other effects such as the secretion of hormones from endocrine glands. Because they send signals away from the CNS, motor neurons are also called efferent (from the Latin, meaning to carry from) neurons. Like sensory neurons, motor neurons tend to have long axons (Figure 41.3b), but do not branch into two main processes.

Interneurons A third type of neuron, called the **interneuron** (or association neuron), forms interconnections between other

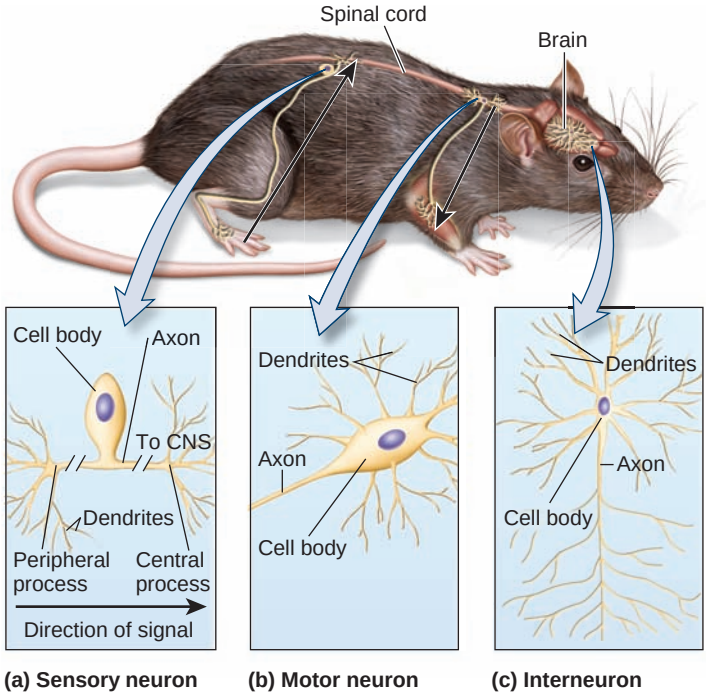

Figure 41.3 **Types of neurons.** **(a)** The vertebrate sensory neurons are afferent neurons with an axon that bypasses the cell body and projects to the CNS. **(b)** Motor neurons are efferent neurons that leave the CNS and usually have long axons that enable them to act on distant cells. **(c)** Interneurons are usually short neurons that connect two or more other neurons within the CNS. Although short, the axons and dendrites may have extensive branches, allowing them to receive many inputs and transmit signals to many neurons.

neurons in the CNS. The greatest complexity of nervous systems occurs among interneurons, such as those found in the brain. The signals sent between interneurons are critical in the interpretation of information that the CNS receives, as well as the response that it may elicit. Interneurons tend to have many dendrites, and their axons are typically short and highly branched (Figure 41.3c). This arrangement allows interneurons to form complex connections with many other cells.

Reflex Circuits As a way to understand the interplay between sensory neurons, interneurons, and motor neurons, let's consider a simple example in which these types of neurons form interconnections with each other. Neurons transmit information to each other through a series of connections that form a circuit. An example of a simple circuit is a **reflex arc**, which allows an organism to respond rapidly to inputs from sensory neurons and consists of only a few neurons (Figure 41.4). The stimulus from sensory neurons is sent to the CNS, but there is little or no interpretation of the signal; typically there are very few, if any, interneurons involved, as in the example shown in Figure 41.4. The signal is then transmitted to motor neurons, which elicit a response, such as a knee jerk. Such a response is very quick and automatic.

Reflexes are among the evolutionarily oldest and most important features of nervous systems, because they allow animals to respond quickly to potentially dangerous events. For instance, many vertebrates will immediately cringe, jump, leap, or take flight in response to a loud noise, which could represent sudden danger. Some animals that live in the water

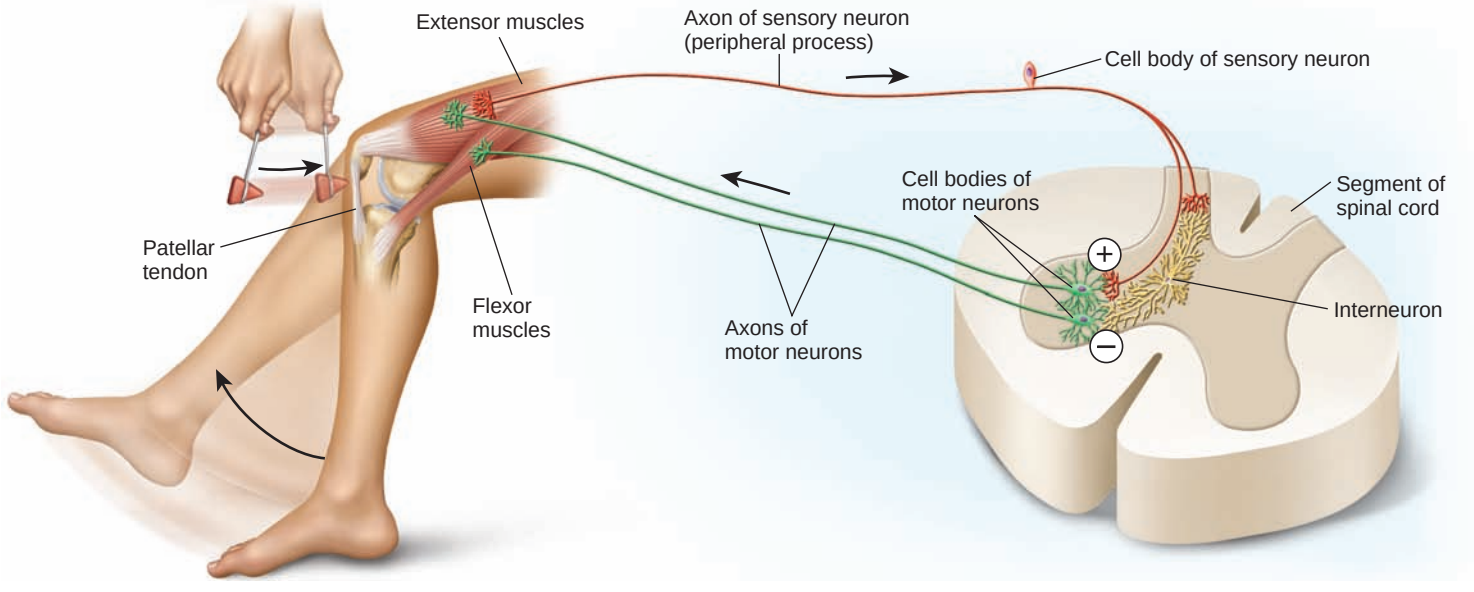

Figure 41.4 **A reflex arc.** The knee-jerk response is an example of a reflex arc. A tap below the kneecap (also known as the patella) stretches the patellar tendon, which acts as a stimulus. This stimulus initiates a reflex arc that activates (+) a motor neuron that causes the extensor muscle on top of the thigh to contract. At the same time, an interneuron inhibits (−) the motor neuron of the flexor muscle, causing it to relax.

Concept check: *Animals have many types of reflexes. Once initiated, must all reflexes occur to completion, or do you think that in some cases they may be overridden or partially suppressed?*

will reflexively dive deeper in response to a shadow overhead, which could represent a passing shark or other predator. Infant primates have strong grasping reflexes that help them hold onto their mothers as they move about. Countless examples of useful reflexes are found in animals, and their importance is evident from the observation that they arose early in evolution and exist in nearly all animals.

41.2 Electrical Properties of Neurons

In the late 18th century, Italian scientists Luigi Galvani and Alessandro Volta experimented with ways to stimulate the contraction of frog leg muscles that had been dissected and placed in saline (NaCl) solutions. The saline solutions approximated the ion concentrations in plasma, kept the muscles alive, and also conducted electricity. They discovered that the stimulation of the nerve that led to the muscle or the stimulation of the muscle itself with any source of electric current caused the muscle to contract. Eventually, Galvani postulated that electric current could somehow be generated by the tissue itself, something he called "animal electricity."

Today, we know that Galvani's animal electricity comes from neurons, which use electrical signals to communicate with other neurons, muscles, or glands. These signals, or nerve impulses, involve changes in the amount of electric charge across a cell's plasma membrane. In this section, we first examine the electrical and chemical gradients across the plasma membrane of neurons. Later, we explore how such gradients provide a way for neurons to conduct signals.

Neurons Establish Differences in Ion Concentration and Electric Charge Across Their Membranes

Like all cell membranes, the plasma membrane of a neuron acts as a barrier that separates charges. Ion concentrations differ between the interior and exterior of the cell. Such differences in charge act as an electrical force measured in **volts** (V), named after Alessandro Volta. Analogous to a battery, there are negative and positive poles, but these are the inside and outside surfaces of the plasma membrane. For this reason, a neuron is said to be electrically **polarized**. The difference between the electric charges along the inside and outside surfaces of a cell membrane is called a potential difference, or **membrane potential**. The **resting potential** refers to the membrane potential of a cell that is not sending nerve impulses.

How do scientists measure electrical changes in a structure as tiny as a neuron? Several invertebrates, such as squids, lobsters, and earthworms, have large neurons that have been used successfully to measure membrane potentials. The squid giant axon, for example, has a diameter up to 1 mm. This makes it relatively easy to impale the axon with a microelectrode, which is a recording instrument constructed of a glass pipette with an extremely thin tip of less than 1 μm in diameter. Within the microelectrode is a salt solution that can conduct electric charge (ions). The squid giant axon has been used extensively since the mid-20th century to determine the mechanisms by which neurons generate electrical signals (Figure 41.5). A neuron is dissected from the squid and placed in a solution that has ionic concentrations similar to that of normal extracellular fluid. A microelectrode is pushed through the axon membrane to record from inside the cell, and another microelectrode is placed within the solution bathing the neuron outside the cell. A voltmeter records the voltage difference between the two microelectrodes, which is a measure of the membrane potential.

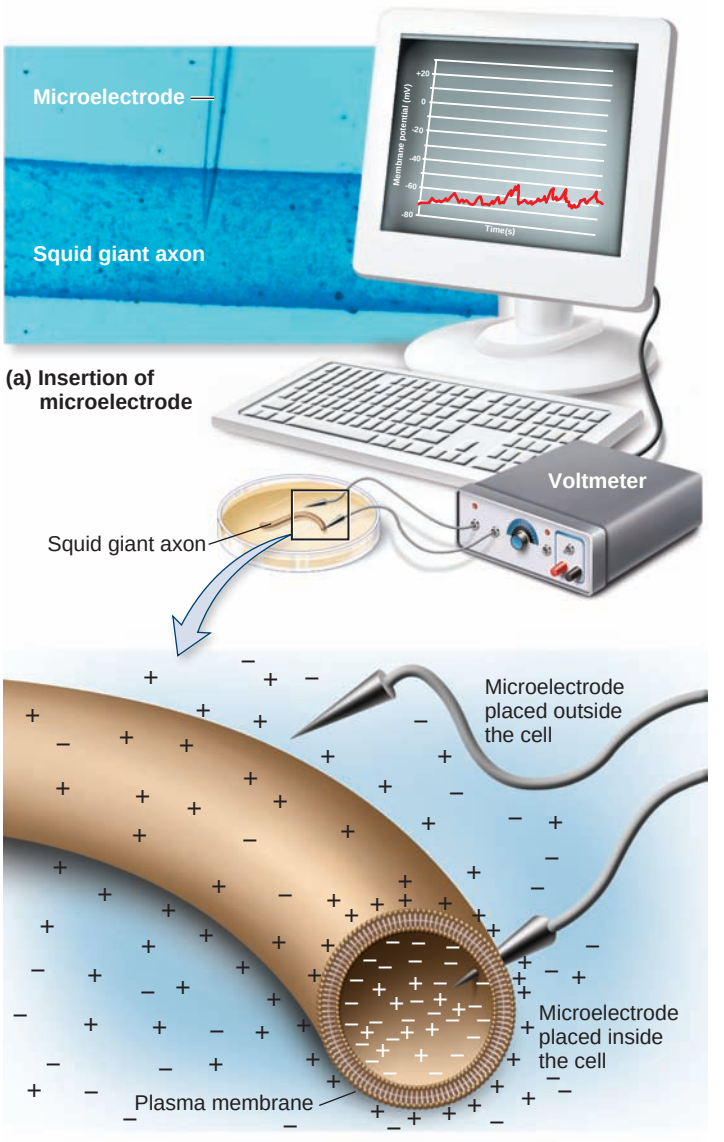

Figure 41.5 Recording the membrane potential of neurons. **(a)** A microelectrode, seen here under a microscope, impales the giant axon from a squid. **(b)** The potential difference across the membrane of the axon is recorded by comparing the electric charge inside and outside the axon. The membrane potential (measured in millivolts, mV) is steady at times and fluctuates at other times, depending on experimental conditions.

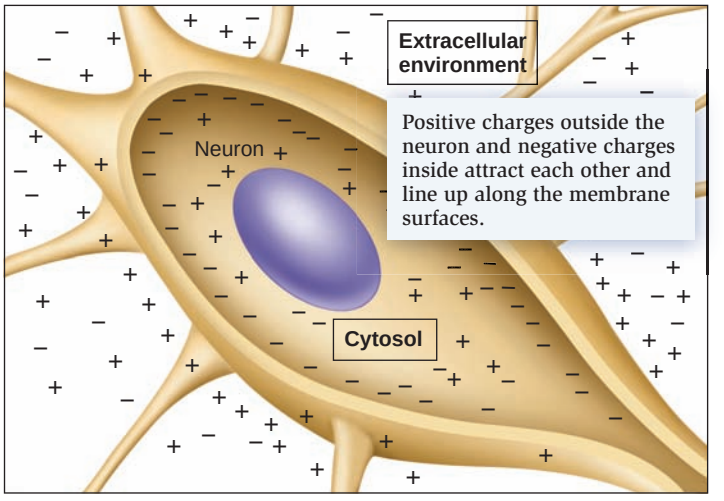
Concept check: What obvious difference (besides its size) can you see between the giant axon of the squid, as illustrated here, and the illustration of the vertebrate axon depicted in Figure 41.2?

This measurement is made as a function of time and displayed on a computer screen.

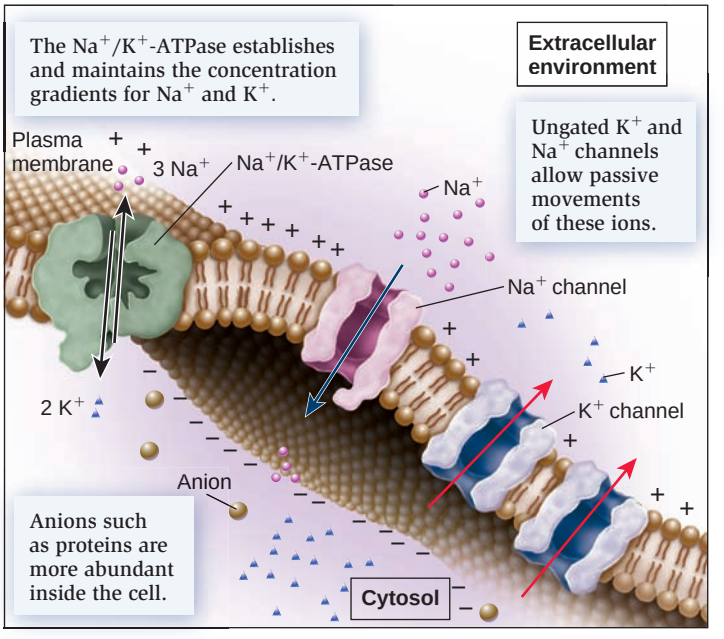
Let's begin our discussion of electrical signaling by examining how the resting potential is established and maintained. The plasma membrane is not very permeable to cations and anions, so it separates charge by keeping different ions largely inside or outside the cell. When investigators first measured the resting potential of a squid giant axon, they registered a voltage that read about −70 millivolts (mV) inside the cell with respect to the outside bathing medium. This means that the interior of the cell had a more negative charge than the exterior, which turns out to be true of all animal cells in their resting state. A resting potential of −70 mV is tiny compared to the voltages used to provide electric current in a home (approximately 120 V), or even that of a small 1.5-V battery. Nonetheless, this tiny difference in charge across the membrane of a neuron is sufficient to generate a nerve impulse, or action potential, that can travel from one end of a neuron to the other, as we will see later in this chapter.

The resting potential is determined by the ions located along the inner and outer surfaces of the plasma membrane (Figure 41.6a). Ions of opposite charges align on either side of the membrane because they are drawn to each other due to electrical forces. Negative ions within the cell are drawn to the positive ions arrayed on the outer surface of the plasma membrane. Although there are more positive charges along the outside surface of a neuron and more negative charges inside, the actual number of ions that contribute to the resting membrane potential is extremely small compared to the total number of ions inside and outside the cell. Table 41.1 lists the ions that are important in maintaining the resting potential and their intracellular and extracellular concentrations. The ions that are most critical for establishing the resting potential are Na^+ and K^+ and, to a lesser extent, Cl^-, and intracellular anions such as negatively charged proteins.

Three factors are primarily responsible for the resting membrane potential (Figure 41.6b). First, the sodium-potassium pump (Na^+/K^+-ATPase) within the plasma membrane continually moves sodium ions out of the cell and potassium ions into the cytosol (see Chapter 5). The sodium-potassium pump uses the energy of ATP to transport three Na^+ out of the cell for every two K^+ it moves into the cell. Consequently, the pump contributes modestly to a charge difference across the plasma membrane; more importantly, it establishes concentration gradients for Na^+ and K^+ by continually transporting them across the membrane in one direction. Second, the plasma membrane contains ion-specific channels that affect the permeability of Na^+ and K^+ across the membrane. Ungated channels that are specific for Na^+ or K^+ influence the resting potential by allowing the passive movement of these ions. An ungated channel is one that is open at rest and that does not respond to other stimuli, such as voltage, ligand binding, or mechanical stimulation. Ungated ion channels are sometimes referred to as "leak" channels. In most neurons, there are about 50 times more ungated K^+ channels than ungated Na^+ channels, so at rest, the membrane is more permeable to K^+ than to Na^+. As you will learn shortly, Na^+ tends to diffuse into cells, and K^+ diffuses



(a) Distribution of charges across the neuronal plasma membrane



(b) Three factors that influence the resting potential

Figure 41.6 The resting membrane potential.

Table 41.1 Extracellular and Intracellular Concentrations of Ions for a Typical Mammalian Neuron

	Concentration (mM)	
Ion	**Extracellular**	**Intracellular**
Na^+	145	15
K^+	5	150
Cl^-	110	7
Anions found in macromolecules	<1	65

out of cells when the cell is at rest. The greater number of leak channels for K^+, therefore, means that excess positive charges exit the cell. Finally, a third contribution to resting potential is the presence of negatively charged molecules such as proteins that are more abundant inside the cell. These anions do not readily move through the plasma membrane, so they contribute some negative electric charge to the interior of the cell.

An Electrochemical Gradient Governs the Movement of Ions Across a Membrane

Both the membrane potential and the chemical concentration of ions influence the direction of ion movement across a membrane. The direction that an ion will move depends on the **electrochemical gradient** for that ion, which is the combined effect of both an electrical and chemical gradient. Figure 41.7 considers the concept of an electrochemical gradient for K^+. This hypothetical drawing illustrates two compartments separated by a semipermeable membrane that permits the diffusion of K^+. Figure 41.7a illustrates an electrical gradient. In this case, the chemical concentration of K^+ is equal on both sides of the membrane, but the concentrations of other ions such as Na^+ and Cl^- are unequal on both sides of the membrane and thereby produce an electrical gradient. Because K^+ is positively charged, it will be attracted to the side of the membrane with more negative charge. Figure 41.7b shows a chemical gradient in which K^+ concentration is higher on one side compared to the other. In this scenario, K^+ will diffuse from a region of high to low concentration. Finally, Figure 41.7c shows a situation in which an electrical gradient is balanced by a chemical gradient. The electrical gradient would favor the movement of K^+ from left to right, while the chemical gradient would favor movement from right to left. These opposing forces can create an equilibrium in which there is no net diffusion of K^+ in either direction. The membrane potential at which this occurs for a particular ion is referred to as that ion's **equilibrium potential**.

With two different forces—electrical and chemical gradients—acting on a given ion, is it possible to predict the direction that an ion will move across a membrane at any concentration gradient? In other words, can we compare the relative strengths of the electrical and chemical gradients and predict their net effect? By measuring the membrane potential of isolated neurons in the presence of changing concentrations of extracellular ions, scientists have deduced a mathematical formula that relates electrical and chemical gradients to each other. This formula, named the **Nernst equation** after the Nobel laureate Walther Nernst, gives the equilibrium potential for an ion at any given concentration gradient. For monovalent cations such as Na^+ and K^+, the Nernst equation can be expressed as

$$E = 60 \text{ mV} \log_{10} ([X_{extracellular}]/[X_{intracellular}])$$

where E is the equilibrium potential; [X] is the concentration of an ion, outside or inside the cell; and 60 mV is a value that depends on temperature, valence of the ion, and other factors. (For anions, the value would be −60 mV.)

The Nernst equation allows neuroscientists to predict when an ion is or is not in equilibrium. To understand the usefulness

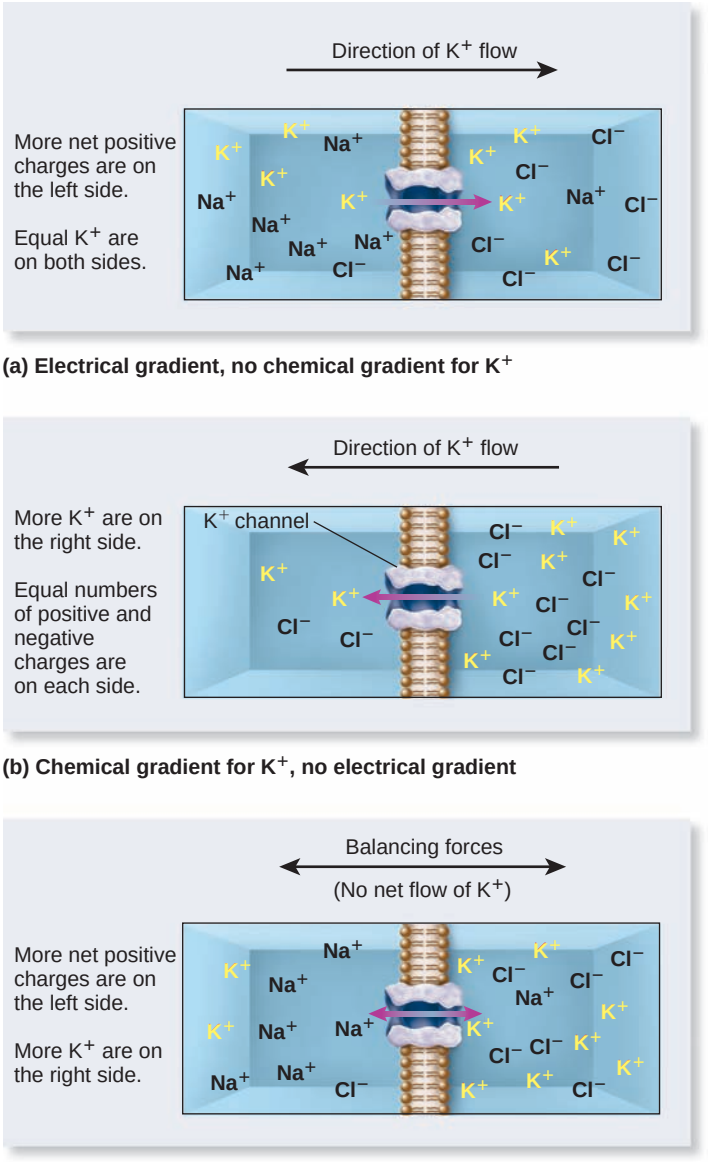


Figure 41.7 Electrical and chemical gradients. This hypothetical example depicts two chambers separated by a membrane that is permeable to K^+. **(a)** In this example, the compartments initially contain equal concentrations of K^+, but an electrical gradient exists due to an unequal distribution of Na^+ and Cl^-. Potassium ions are attracted to the higher amount of negative charge on the right side of the membrane. **(b)** In this case, there is initially no electrical gradient across the membrane, and the left compartment contains a lower concentration of KCl compared to the right compartment. In water, the KCl dissociates to K^+ and Cl^-. Under these conditions, K^+ diffuses down its chemical concentration gradient from right to left. **(c)** This example illustrates opposing electrical and chemical gradients. The right compartment contains a higher chemical concentration of K^+, while the left side has a higher net amount of positive charge. These gradients balance each other, so no net movement of K^+ occurs.

Concept check: In part (b), does the diffusion of K^+ down its chemical gradient result in an electrical gradient? What will eventually stop the net diffusion of K^+?

of this equation, consider two examples. First, let's suppose the membrane potential is −88.6 mV and the K^+ concentration is 5 mM outside and 150 mM inside a neuron. If we plug these chemical concentrations into the Nernst equation,

$$E = 60 \text{ mV } \log_{10} (5/150) = 60 \text{ mV } (-1.48)$$

$$E = -88.6 \text{ mV}$$

Under these conditions, where the K^+ equilibrium potential equals the membrane potential, K^+ is in equilibrium, and no net diffusion of K^+ will occur, even when many K^+ channels are open.

As a second example, let's suppose that the membrane potential is at the typical resting potential of −70 mV and the Na^+ concentration is 100 mM outside and 10 mM inside. If we plug these chemical concentrations into the Nernst equation,

$$E = 60 \text{ mV } \log_{10} (100/10) = 60 \text{ mV } (1)$$

$$E = 60 \text{ mV}$$

At a resting potential of –70 mV, the value of +60 mV tells us that Na^+ is not in equilibrium. When the equilibrium potential for a given ion—calculated by the Nernst equation—and the resting membrane potential do not match, there will be a driving force for that ion to diffuse across the membrane. In this example, Na^+ will diffuse into the cell, because both the electrical and chemical gradients favor an inward flow. However, if the membrane potential was +60 mV instead of −70 mV, Na^+ would be in equilibrium at these concentrations, and therefore, there would be no net diffusion of Na^+ in any direction.

By establishing electrochemical gradients and maintaining them with the sodium-potassium pump, neurons have the ability to suddenly allow ions to move across the plasma membrane by opening additional channels that were previously closed. The movement of a charged ion down its gradient results in an electric current. This current is different from the type of current that runs through electrical wires and is much smaller in amplitude. Even so, this small current provides the electrical signal that neurons use to communicate with one another, as we will see next.

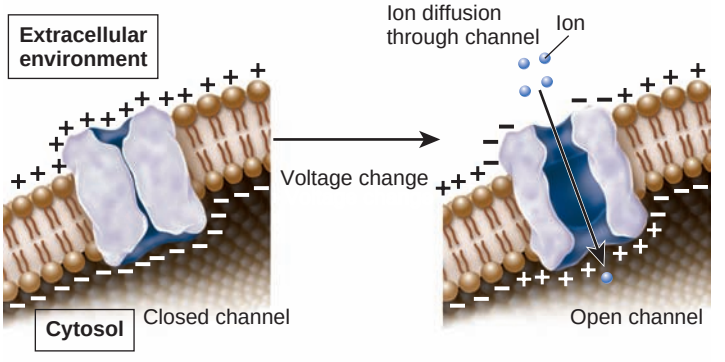
41.3 Communication Between Neurons

Communication between neurons begins when one cell receives a stimulus and sends an electrical signal along its plasma membrane via currents generated by ion movements. This signal will then influence the next neuron in a circuit. Each signal is brief (only a few milliseconds), but a neuron may receive and transmit millions of signals in its lifetime. In this section, we will survey the ability of neurons to send brief signals with amazing speed.

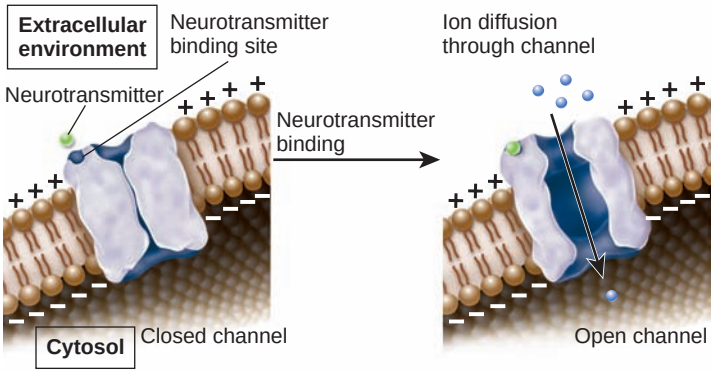
Signaling by a Neuron Occurs Through Changes in the Membrane Potential

Recall that a cell is polarized because of the separation of charge across its membrane. The resting potential of the membrane is more negative inside than outside. Changes in the membrane potential, therefore, are changes in the degree of polarization. **Depolarization** occurs when the cell membrane becomes less polarized, that is, less negative inside the cell relative to the surrounding fluid. As described later, when a neuron is stimulated by an electrical or chemical stimulus, one or more types of gated membrane channels open, and sodium ions may move into the cell, bringing with them their positive charge. This changes the membrane potential to a level somewhat less negative than the resting membrane potential. Consequently, the membrane potential is said to be depolarized. In contrast, **hyperpolarization** occurs when the cell membrane becomes more polarized, that is, more negative relative to the extracellular fluid. For example, increased movement of K^+ out of the cell would make the internal charge of the cell membrane more negative than the resting potential.

Though all cells in an animal's body have a membrane potential, neurons and muscle cells are called **excitable cells** because they can generate electrical signals. For a cell to communicate using electrical signals, it must be able to change its membrane potential very rapidly. This is accomplished by gated ion channels, so called because they open and close in a manner analogous to a gate in a fence (Figure 41.8; also refer back to Chapter 5). **Voltage-gated ion channels** open and close in



(a) Voltage-gated ion channel



(b) Ligand-gated ion channel

Figure 41.8 **Examples of gated ion channels.** (a) A voltage-gated ion channel allows ions to diffuse into the cell. These channels open or close depending on changes in charge (voltage) across the membrane. (b) A ligand-gated ion channel opens or closes in response to ligand binding. In the example here, the binding of a neurotransmitter opens the channel.

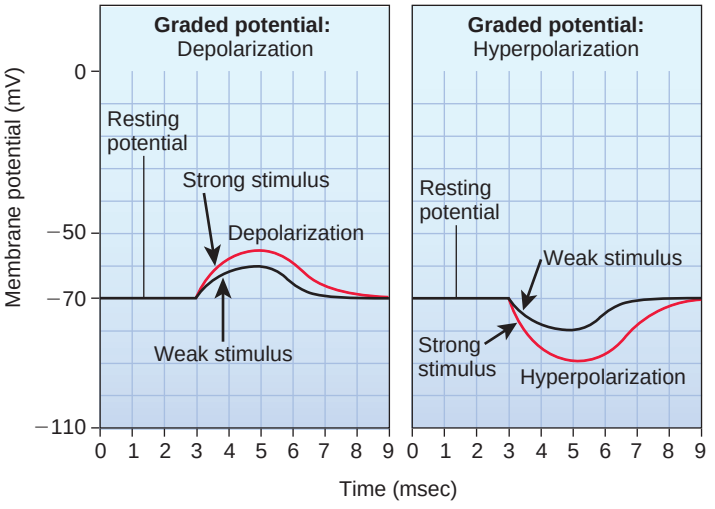


Figure 41.9 **Graded membrane potentials.** Within a limited range, the change in the membrane potential occurs in proportion to the intensity of the stimulus. If the membrane potential becomes less negative, the resulting change is called a depolarization. Hyperpolarization results from the membrane potential becoming more negative following a stimulus.

response to changes in voltage across the membrane. **Ligand-gated ion channels**, also known as chemically-gated ion channels, open or close when ligands, such as neurotransmitters, bind to them. The opening and closing of ligand-gated and voltage-gated channels are responsible for two types of changes in the neuron's membrane potential, called graded potentials and action potentials.

Graded Potentials A **graded potential** is a depolarization or hyperpolarization that varies depending on the strength of the stimulus. A large change in membrane potential will occur when a strong stimulus opens many channels, whereas a weak stimulus causes a small change because only a few channels are opened (Figure 41.9).

Graded potentials occur locally on a particular area of the plasma membrane, such as dendrites or the cell body, where an electrical or chemical stimulus opens ion channels. From this area, a graded potential spreads a small distance across a region of the plasma membrane. In a short time, the membrane potential returns to the resting potential because ion pumps restore the ion concentration gradients, and the ion channels close again.

Graded potentials occur on all neurons and are particularly important for the function of sensory neurons, which must distinguish between strong and weak stimuli coming into the organism from the environment. In addition, though, graded potentials can act as triggers for the second type of electrical signal, the action potential.

Action Potentials **Action potentials** are the nerve impulses that carry an electrical signal along an axon. In contrast to a graded potential, an action potential is always a large depolarization; all action potentials in a given neuron have very similar amplitudes, which is the degree to which an action potential changes the membrane potential away from its resting state. Once an action potential has been triggered, it occurs in an all-or-none fashion. In other words, it cannot be graded. Unlike a graded potential, an action potential is actively propagated along the axon, regenerating itself as it travels. Action potentials travel rapidly down the axon to the axon terminal, where they initiate a response at the junction with the next cell.

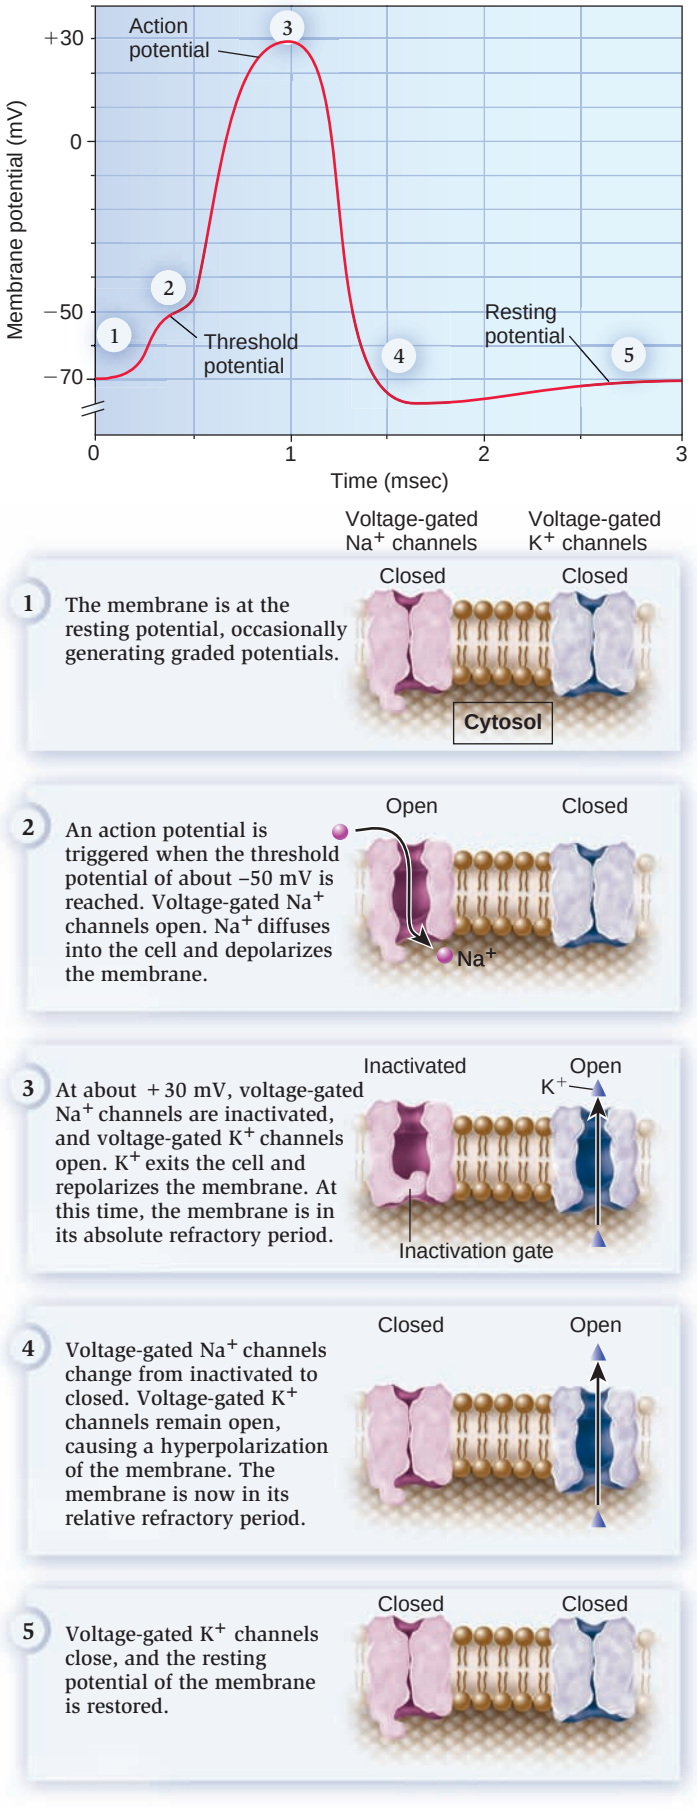
Figure 41.10 shows the electrical changes that happen in a localized region of an axon when an action potential is occurring. Voltage-gated Na^+ channels and K^+ channels are present in very high numbers from the axon hillock to the axon terminus. An action potential begins when a graded potential is large enough to spread to the axon hillock and depolarizes the membrane to a value called the threshold potential. The **threshold potential** is the membrane potential, typically around −50 mV, which is sufficient to open voltage-gated Na^+ channels and trigger an action potential.

Voltage-gated Na^+ channels open rapidly when the membrane potential changes from the resting potential (−70 mV) to the threshold potential (−50 mV). The opening of Na^+ channels involves a change in the conformation of the membrane-spanning region of the channel (Figure 41.10). When the protein changes shape, the central pore opens, and Na^+ rapidly diffuses into the cell down its electrochemical gradient. This further depolarizes the cell, causing even more voltage-gated Na^+ channels to open, resulting in the spike in membrane potential that characterizes the action potential. This positive feedback process is so rapid that the membrane potential reaches its peak positive value in less than 1 millisecond (msec)!

When the membrane potential becomes sufficiently positively polarized, a conformational change in the Na^+ channel blocks the continued flow of Na^+ into the cell. The conformational change involves the **inactivation gate**, a string of amino acids that juts out from the channel protein into the cytosol (Figure 41.10). The inactivation gate swings into the channel, thereby preventing the movement of Na^+ into the cell. Under these conditions, the Na^+ channel is said to be inactivated. The inactivation gate does not swing out of the channel until the membrane potential returns to a value that is close to the resting potential.

Voltage-gated K^+ channels are also triggered to open by the change in voltage to the threshold potential, but they open about 1 msec later than Na^+ channels. When K^+ channels open, some potassium ions leave the cell down their electrochemical gradient, and the membrane potential becomes more negative again. The membrane shows a brief period of hyperpolarization because the K^+ channels remain open and the electrical gradient approaches the equilibrium potential for K^+, which is slightly more negative than the resting potential. When the voltage-gated K^+ channels close, the membrane returns to the resting potential. At this stage, both the Na^+ and K^+ voltage-gated channels are closed, and they have the ability to reopen if the resting potential increases again to the threshold potential.

The evolution of K^+ channels with a slightly slower opening time than Na^+ channels was a key event that led to the formation of nervous systems. Imagine what would happen if



the voltage-gated Na^+ and K^+ channels opened simultaneously: As Na^+ entered the cell down its electrochemical gradient, K^+ would leave the cell down its electrochemical gradient, and they would negate each other's effects on membrane potential.

While the inactivation gate of the Na^+ channel is closed, the membrane is in its **absolute refractory period** (Figure 41.10), during which time that portion of membrane is unresponsive to another stimulus. A change in voltage will not open the Na^+ channels while they are inactivated. Once the voltage-gated Na^+ channels change to the closed state, but while the voltage-gated K^+ channels are still open, the membrane enters a brief **relative refractory period** (Figure 41.10). During this time, when the membrane is hyperpolarized, a new action potential may be generated but only in response to an unusually large stimulus. Therefore, the refractory periods place limits on the frequency with which a neuron can generate and transmit action potentials. As we will see, this also ensures that the action potential does not "retrace its steps" by moving backward toward the cell body.

Many natural toxins work by blocking the actions of Na^+ and K^+ channels. Some animals use these toxins as defensive mechanisms or for capturing prey, and they can be deadly. For instance, tetrodotoxin, a chemical produced by pufferfish, blocks voltage-gated Na^+ channels and, therefore, nerve activity. An animal that eats a pufferfish dies because the poison paralyzes muscles, including those that depend on nerve stimulation to control breathing and movement. Animals that avoid pufferfish, therefore, have a selection advantage. Eating even a small amount can paralyze or kill a human. Other toxins from wasps, bees, and scorpions can block the action of voltage-gated K^+ channels, resulting in abnormal action potentials and loss of normal muscle responses.

Our present understanding of action potentials began with experiments carried out in the 1940s by two British physiologists, Alan Hodgkin and Andrew Huxley. They noted that Na^+ channels are involved in the initiation and early phase of the action potential, while K^+ channels control the duration and termination of the action potential. Since those early studies, we have learned a great deal about the structure and function of voltage-gated Na^+ and K^+ channels. Modern studies have largely involved selectively mutating amino acids within these proteins and observing whether changes occur in the function of the channels. The Na^+ channel consists of one long protein that crosses or spans the membrane 24 times. The K^+ channel consists of four separate protein subunits that each span the membrane six times. The pores of the Na^+ and K^+ channels are composed of different amino acids and have different properties,

Figure 41.10 Changes that occur during an action potential. The electrical gradient across the plasma membrane of an axon first depolarizes and then repolarizes the cell. The values given for membrane potential are representative and not necessarily the same in all neurons. These changes in the membrane potential are caused by the opening and closing of voltage-gated Na^+ and K^+ channels.

Concept check: How would the curve in part (a) be affected if the Na^+ channels were missing their inactivation gate?

which results in each ion being able to specifically pass through its own channel. Researchers have identified 10 different Na^+ channel genes in mammals alone and as many as 100 types of K^+ channel genes, each encoding channels with slightly different properties, such as how quickly they open or close.

Action Potentials Are Conducted Down the Axon with Great Speed

Thus far we have considered the electrical changes that happen when an action potential is initiated. We will now consider how such potentials are conducted down an axon from the axon hillock to the axon terminal (Figure 41.11). Let's begin at the axon hillock. When the neuron receives stimuli from other cells, this causes a graded potential that reaches the axon hillock. If the change in membrane potential is sufficient to reach threshold, an action potential will be triggered. The action potential starts with the abrupt opening of several voltage-gated Na^+ channels just beyond the axon hillock, where many Na^+ channels are found. This action potential, in turn, triggers the opening of nearby Na^+ channels farther along the axon, which allows even more Na^+ to flow into the neuron and depolarize a region closer to the axon terminal, leading to another action potential. In this way, the sequential opening of Na^+ channels along the axon membrane conducts a wave of depolarization from the axon hillock to the axon terminal.

Why doesn't the action potential move backward from the terminal to the hillock? Experimentally, if an axon is stimulated in its middle, action potentials can travel in both directions, toward the cell body and the terminal. The key reason why this doesn't ordinarily happen is the inactivation state of the Na^+ channel, which contributes to the absolute refractory period. Again, let's begin at the hillock. When these voltage-gated Na^+ channels open for 1 msec, they allow Na^+ to rapidly enter the cell, and then they become inactivated. This inactivation prevents the action potential from moving backward (Figure 41.11). While the Na^+ channels are inactivated, K^+ channels open, and the resting potential is restored. At the resting potential, the Na^+ channels switch from the inactivated to the closed state. The opening of K^+ channels also travels from the axon hillock to the axon terminal, but it causes a wave of hyperpolarization that helps to reestablish the resting potential.

An action potential can be conducted down the axon as fast as 100 m/sec or as slow as a centimeter or two per second. The speed is determined by two factors: the axon diameter and the presence or absence of myelin.

The axon diameter influences the rate at which incoming ions can spread along the inner surface of the plasma membrane. The flow of ions meets less resistance in a wide axon than it does in a thin axon, just as water moves more easily through a wide hose than a narrow one. Therefore, in a wider axon the action potential will move faster. The large axons of the squid or lobster conduct action potentials very rapidly, allowing the animals to move quickly when threatened.

Myelination also influences the speed of an action potential. Myelinated axons conduct action potentials at a faster rate than unmyelinated axons. Invertebrate neurons lack myelin, whereas

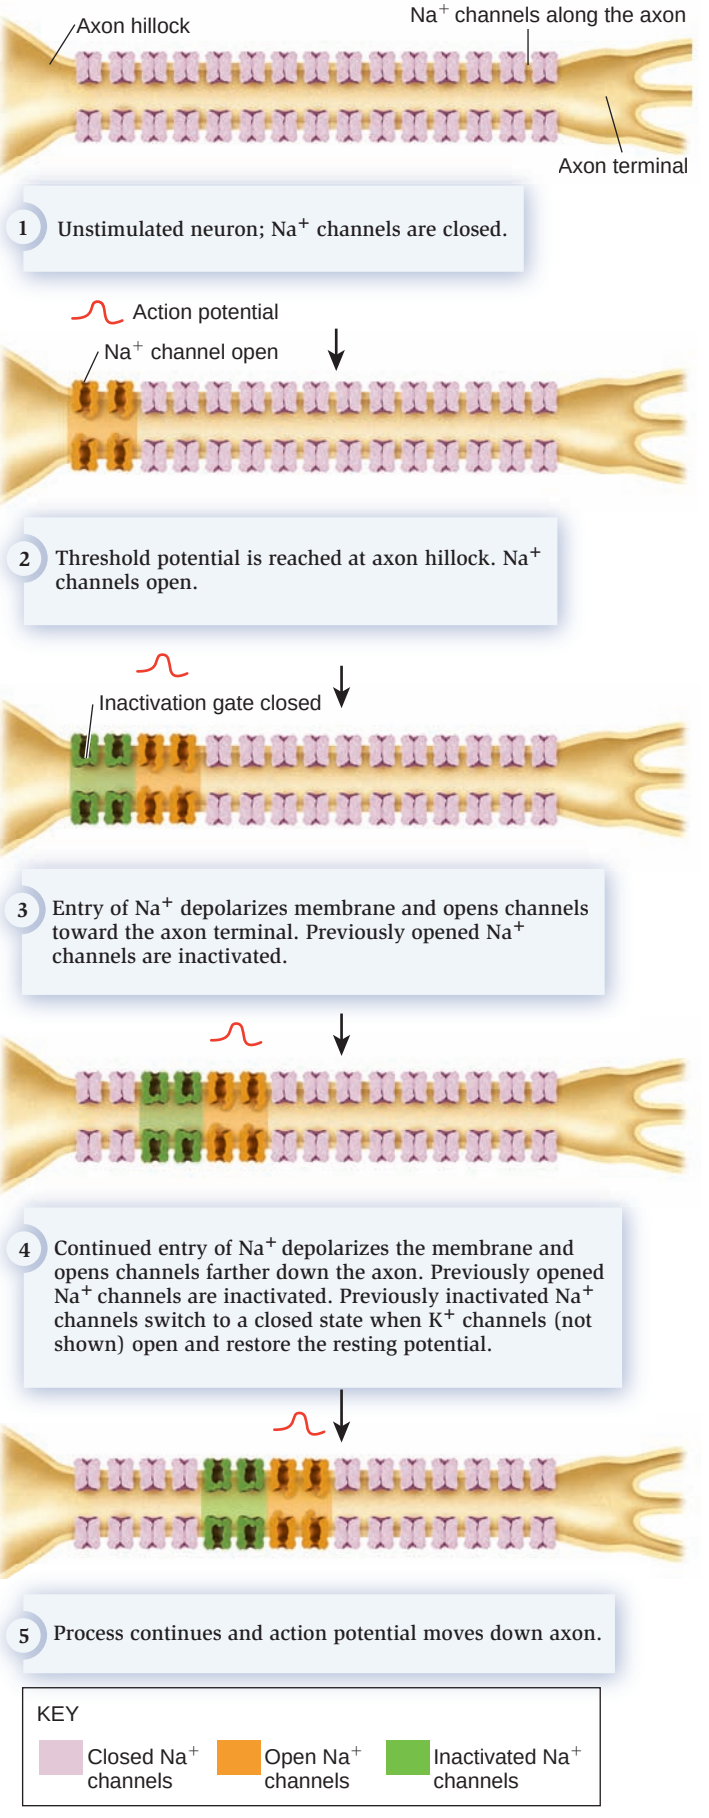


Figure 41.11 **Conduction of the action potential along an axon.** All Na^+ channels shown refer to voltage-gated channels.

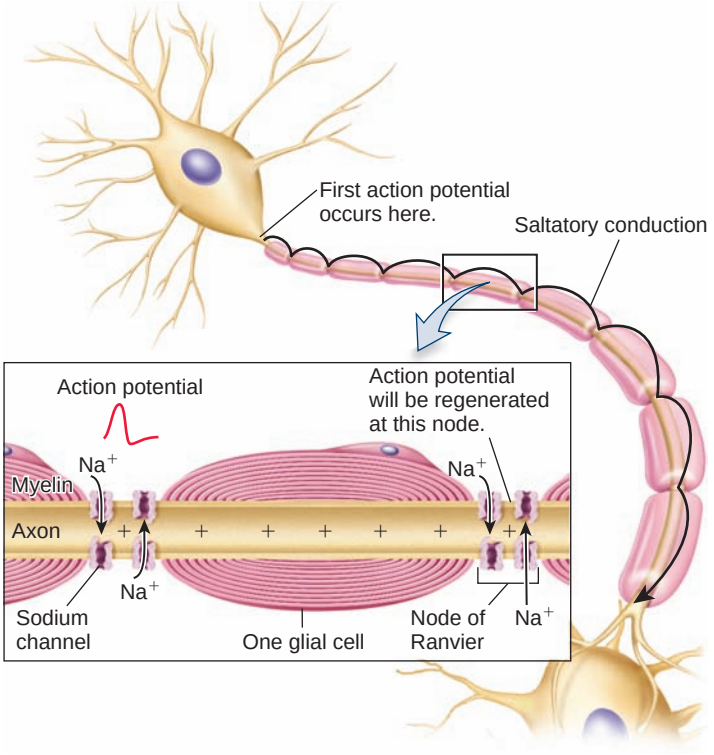

Figure 41.12 **Saltatory conduction along a myelinated axon.** Action potentials are generated only at the nodes of Ranvier, which lack a surrounding sheath of myelin.

Concept check: *What is the main advantage of saltatory conduction?*

vertebrate neurons may be myelinated or unmyelinated. Recall that glial cells (oligodendrocytes and Schwann cells) wrap around vertebrate axons to form an insulating sheath of membrane. The insulating layer of myelin reduces charge leakage across the membrane of the axon. However, this myelin sheath is not continuous (Figure 41.12). As described earlier (see Figure 41.2), the axons of myelinated neurons have exposed areas known as the nodes of Ranvier; these nonmyelinated regions are characterized by having many voltage-gated Na^+ channels. The nodes of Ranvier are the only areas of myelinated axons that have enough Na^+ channels to elicit an action potential. When sodium ions diffuse into the cell at one node, the charge spreads through the cytosol and causes the opening of Na^+ channels at the next node, where an action potential is regenerated. This type of conduction is called **saltatory conduction** (from the Latin *saltare,* meaning to leap) because the action potential seems to "jump" from one node to the next. In reality, action potentials do not jump from place to place; saltatory conduction speeds up the conduction process because it takes less time for changes in membrane potential to travel from node to node, eliciting action potentials only at the nodes, than it would if each tiny strip of membrane generated action potentials all along the length of the axon.

Neurons Communicate Electrically or Chemically at Synapses

Neurons communicate with other cells at a **synapse**, which is a junction where an axon terminal meets a target neuron, muscle cell, or gland. At a synapse, an electrical or chemical signal passes from the axon terminal to the next cell. A synapse includes the axon terminal of the neuron that is sending the message, the nearby plasma membrane of the receiving cell, and the **synaptic cleft**, or extracellular space between the two cells. The **presynaptic cell** sends the signal, and the **postsynaptic cell** receives it (Figure 41.13).

By studying neurons from both invertebrates and vertebrates, researchers have identified two types of synapses, electrical and chemical. The first type, the **electrical synapse**, directly passes electric current from the presynaptic to the postsynaptic cell. The electrical signal passes through this type of synapse extremely rapidly, because the plasma membranes of adjacent cells are connected by gap junctions that can move electric charge freely from one cell to the other (see Chapter 10). Recent research indicates that electrical synapses are more widespread among taxa than originally thought, including vertebrates. The most well-studied examples, however, occur in some aquatic invertebrates such as leeches. In those animals, electrical synapses occur where a group of neurons must fire rapidly and synchronously, such as when an animal must coordinate a number of muscles to swim or escape danger. The second type of synapse is a **chemical synapse**, in which a chemical called a **neurotransmitter** is released from the axon terminal and acts as a signal from the presynaptic to the postsynaptic cell. Chemical synapses are more common, particularly in vertebrates. Some neurons release only one type of neurotransmitter, and some neurons can release two or more different ones.

Figure 41.14 describes the steps that occur when two cells communicate via a chemical synapse. The presynaptic axon terminal of a chemical synapse contains vesicles—small,

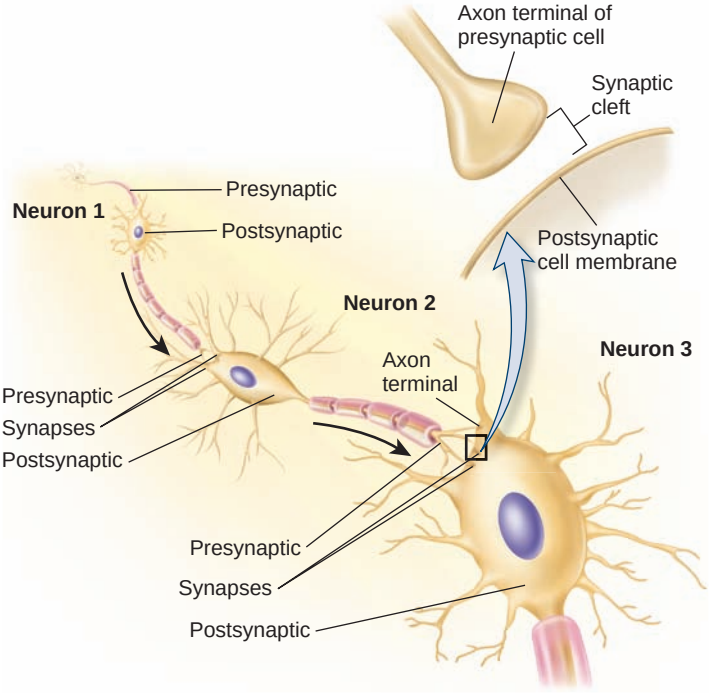

Figure 41.13 **Presynaptic and postsynaptic cells.** The arrows show the direction of signal transmission from one neuron to the next. Note that neuron 2 is postsynaptic with respect to neuron 1 and presynaptic with respect to neuron 3.

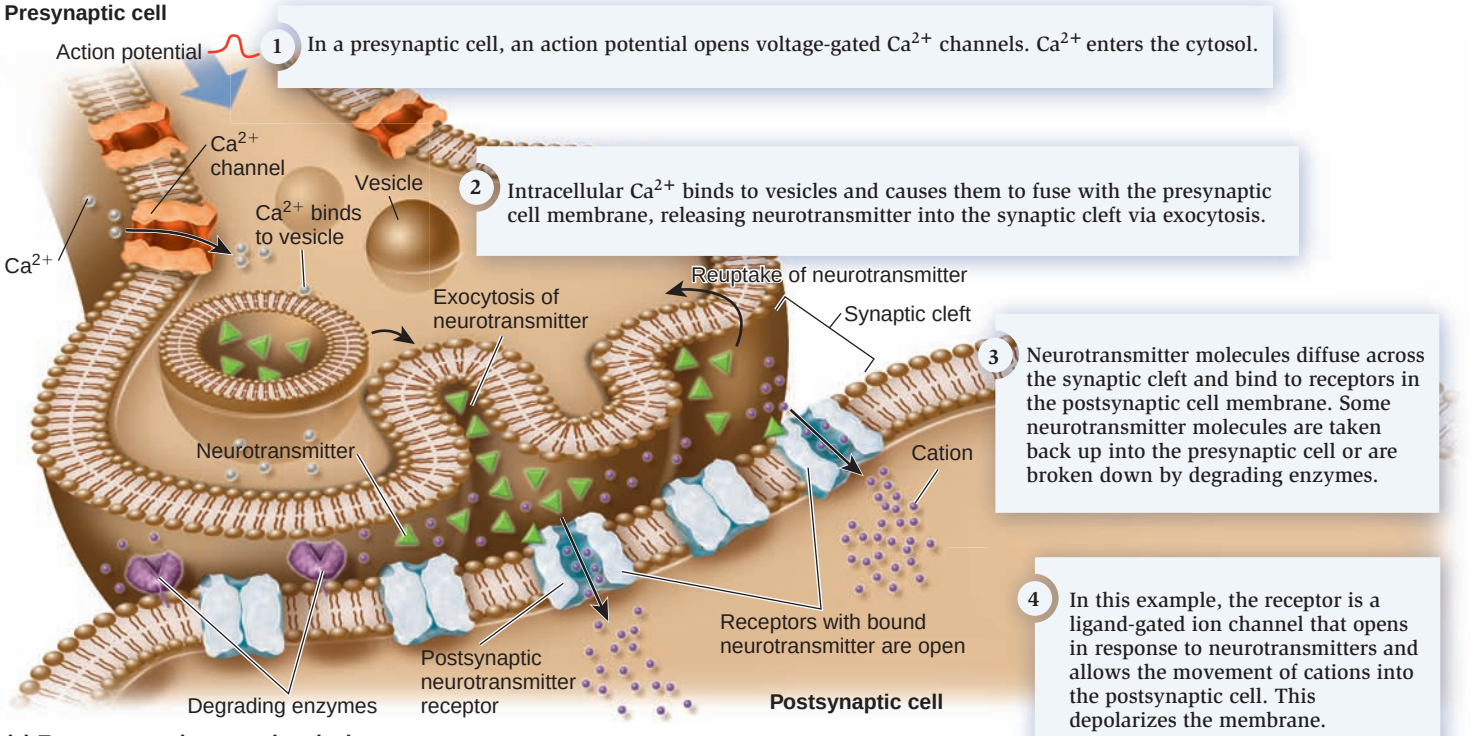
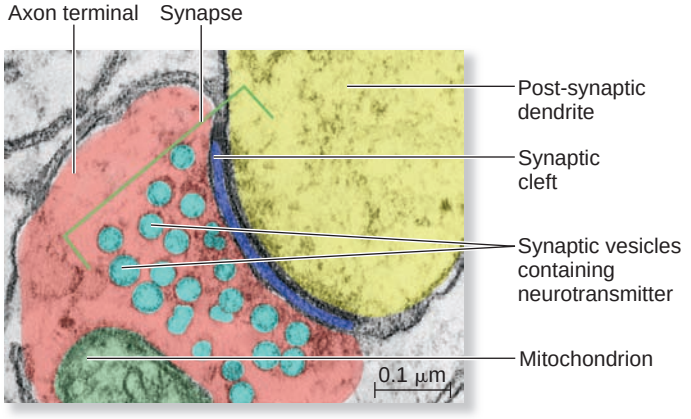
membrane-enclosed packets, each containing thousands of molecules of neurotransmitter. The membranes of axon terminals contain another type of ion channel localized primarily to the terminal, namely, voltage-gated Ca^{2+} channels. When an action potential arrives at the axon terminal, these channels open, allowing calcium ions to diffuse down their electrochemical gradient into the cell. Calcium binds to a protein associated with the vesicle membrane. This triggers exocytosis, in which the vesicle fuses with the presynaptic membrane, thereby releasing its neurotransmitter molecules into the synaptic cleft. The neurotransmitter molecules diffuse across the 10–20-nm-wide synaptic cleft and bind to receptors which are ion channels or other receptor proteins in the postsynaptic cell membrane.

The binding of neurotransmitter molecules opens or closes ion channels and thereby changes the membrane potential of the postsynaptic cell. In some cases, neurotransmitters directly bind to ion channels and cause the channels to open or close. Others bind to receptor proteins on the neuronal membrane and induce the formation of second messengers in the cell (see Chapter 9), which, in turn, open or close ion channels by any of several mechanisms. Some neurotransmitters are called excitatory, because they depolarize the postsynaptic membrane; the response is an **excitatory postsynaptic potential** (**EPSP**). This response is called excitatory because the depolarization of the membrane brings the membrane potential closer to the threshold potential that would trigger an action potential. An EPSP can be caused by the opening of Na^+ channels in a neuronal membrane or by the closing of K^+ channels. In both cases, positive charges would accumulate inside the cell. Conversely, an inhibitory neurotransmitter usually hyperpolarizes the postsynaptic



(a) Events occurring at a chemical synapse



(b) False-colored electron micrograph of a chemical synapse

Figure 41.14 **Structure and function of a chemical synapse.** **(a)** In response to an action potential, Ca^{2+} enters the presynaptic neuron axon terminal. This results in vesicle fusion with the plasma membrane, which releases neurotransmitter molecules into the synaptic cleft. The neurotransmitter molecules then bind to receptors in the plasma membrane of the postsynaptic cell. This causes ion channels to open (in this example) or close, which, in turn, changes the membrane potential of the postsynaptic cell. **(b)** Transmission electron micrograph of a chemical synapse from rat brain (magnification 170,000x).

Concept check: *What is the benefit of having synaptic enzymes break down neurotransmitter molecules?*

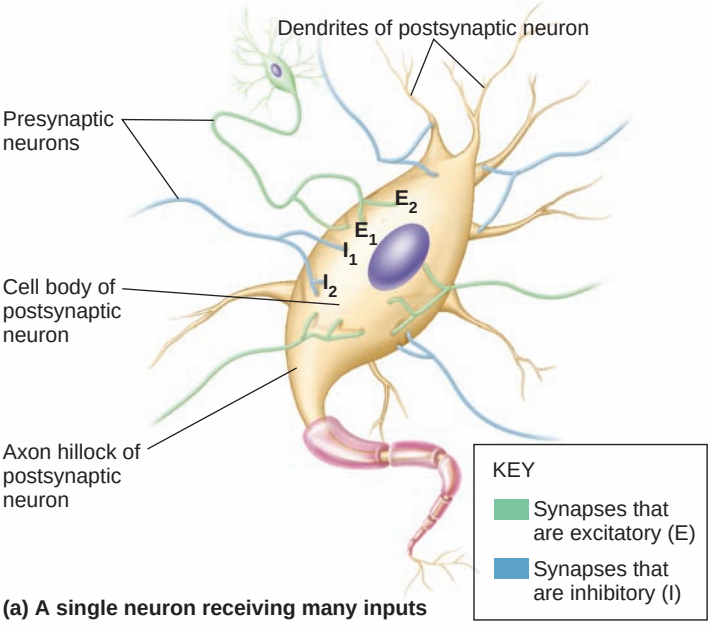
membrane, producing an **inhibitory postsynaptic potential** (**IPSP**), which reduces the likelihood of an action potential. An IPSP can be caused by, for example, the opening of Cl^- channels. The equilibrium potential for Cl^- is typically between the resting potential and that of K^+. Therefore, when Cl^- channels are opened, Cl^- moves into cells, bringing them closer to the equilibrium potential for Cl^-.

To end the synaptic signal, neurotransmitter molecules in the synaptic cleft are broken down by enzymes or transported back into the presynaptic terminal and repackaged into vesicles for reuse. The latter event is called reuptake and is an efficient mechanism for recapturing unused neurotransmitters that were released into the synaptic cleft. As we will see at the end of this chapter, drugs that prevent the reuptake process can sometimes be used to treat people with disorders of neurotransmission.

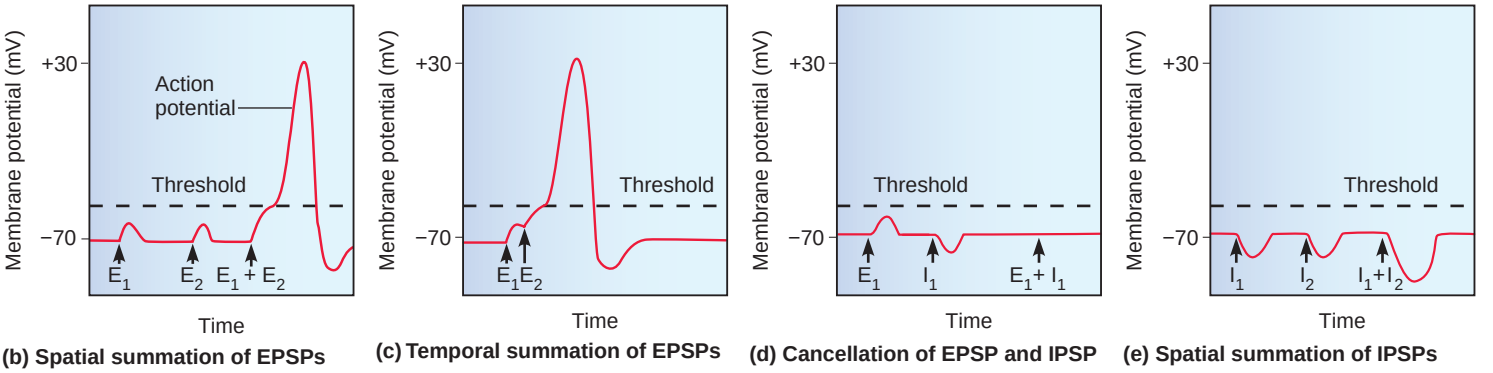
We can appreciate the power of neurotransmitters when we consider the effects of toxins that are known to affect neurotransmitter release. For example, the venom of black widow spiders (genus *Latrodectus*), α-latrotoxin, acts on presynaptic proteins involved in exocytosis to cause massive release of neurotransmitter from motor neurons that act on skeletal muscle. Correspondingly, the symptoms of black widow spider bites in humans are painful muscle cramping and rigidity due to overstimulation of the muscle. Researchers have also demonstrated the function of several proteins involved in vesicle membrane fusion and exocytosis by experimenting with certain toxins that decrease neurotransmitter release. For instance, the toxin secreted by the *Clostridium botulinum* bacterium prevents exocytosis of motor neuron vesicles containing neurotransmitter. If ingested in food, the toxin causes botulism, a sometimes fatal form of food poisoning characterized by weak muscles, trouble focusing the eyes, and difficulty swallowing. As you may know, researchers have discovered several cosmetic and medical uses for this toxin. For example, when injected into a chronically stimulated muscle, it blocks contraction of the muscle by preventing the motor neurons from releasing neurotransmitter, resulting in muscle relaxation. Clinicians may also administer a synthetic form of the toxin (called BOTOX) to patients who wish to reduce facial wrinkles. The effect is to reduce the contractions of the facial muscles that cause frown lines. The procedure is not without risk, however, as the toxin may diffuse from the site of the injection and affect other targets.

Neurons Respond to Multiple Synaptic Inputs

A neuron may receive inputs from many synapses occurring on its dendrites or cell body (Figure 41.15a), and some of these synapses may release their neurotransmitter onto the neuron at the same or nearly the same time. Certain neurotransmitters are excitatory, while others are inhibitory. When do these different inputs lead to an action potential? The effect of a single synapse is usually far too weak to elicit an action potential in the postsynaptic neuron (though a single synapse can cause a muscle cell to contract). However, when two or more EPSPs are generated at one time along different regions of the dendrites and cell body, their depolarizations sum together. The resulting larger depolarization may bring the membrane potential at the axon hillock to the threshold potential, initiating an action potential. This is called **spatial summation** and is a type of neuronal processing known as synaptic integration (Figure 41.15b). In another example of synaptic integration, two or more EPSPs may arrive at the same location in quick succession, such that the first EPSP has not yet decayed away when the next EPSP arrives. In that case, the depolarizations sum and may reach



(a) A single neuron receiving many inputs



(b) Spatial summation of EPSPs **(c) Temporal summation of EPSPs** **(d) Cancellation of EPSP and IPSP** **(e) Spatial summation of IPSPs**

Figure 41.15 Integration of synaptic inputs.

threshold upon arrival at the axon hillock. This is called **temporal summation** (Figure 41.15c). Finally, if EPSPs and IPSPs arrive together at a postsynaptic cell, the two types of signals may cancel each other out, and no action potential is elicited (Figure 41.15d). From this discussion, you might deduce that when two or more IPSPs arrive together, their hyperpolarizations might sum, too. That is exactly what happens. In that case, the membrane potential of the cell receiving multiple IPSPs moves farther away from threshold (Figure 41.15e).

In addition to the number of synapses that stimulate the postsynaptic membrane, the location of the synapses is also important. Synapses initially cause a graded potential in the postsynaptic membrane that spreads only a short distance. If two excitatory synapses are close together and activated at the same time, the resulting depolarization will be larger and will spread farther. This spread increases the chances that the depolarization will reach the axon hillock, where the high concentration of Na^+ channels can trigger an action potential. Synapses that occur far from the axon hillock are less effective than synapses on the cell body nearer the axon hillock.

Several Classes of Neurotransmitters Elicit Responses in Postsynaptic Cells

Neuroscientists have identified more than 100 different neurotransmitters in animals. Generally, neurotransmitters are categorized by size or structure (Table 41.2). The changing balance between excitatory and inhibitory neurotransmission controls the state of nervous system circuits at any one time. To understand how neurotransmitters work, imagine driving a car with one foot on the accelerator and one foot on the brake. To speed up, you could press down on the accelerator, ease up on the brake, or both, whereas to slow down, you could do the opposite. All nervous systems operate in this way, with combined excitatory and inhibitory actions of neurotransmitters.

Next, we highlight major features of the different chemical classes of neurotransmitters found in animals, which include acetylcholine, biogenic amines, amino acids, neuropeptides, and gaseous neurotransmitters. With the exception of acetylcholine, all of these classes contain several different neurotransmitters that are similar in chemical structure but may have different functions in nervous systems.

Acetylcholine Acetylcholine, one of the most widespread neurotransmitters in animals, is released at the synapses of **neuromuscular junctions** in vertebrates, where a neuron contacts skeletal or cardiac muscle. It is also released at synapses within the brain and elsewhere. Acetylcholine acts as an excitatory neurotransmitter in the brain and on skeletal muscle cells, but it is inhibitory when released from neurons that control cardiac muscle contraction. Therefore, it stimulates skeletal muscle but inhibits cardiac muscle. As we will see later, the same neurotransmitter can exert both excitatory and inhibitory effects depending on the type of receptor to which it binds.

Biogenic Amines The biogenic amines are compounds containing amine groups that are formed from amino acids or their precursors. Common biogenic amines include the catecholamines—dopamine, norepinephrine, and epinephrine—and serotonin and histamine. The catecholamines are formed from the amino acid tyrosine. Dopamine and epinephrine are primarily active in the brain, while norepinephrine acts in the brain and at synapses in the peripheral nervous system. Serotonin is formed from the amino acid tryptophan. In addition to widespread physiological effects such as control of heart and lung function, catecholamines and serotonin are psychoactive; that is, they affect mood, attention, behavior, and learning. In humans, for example, abnormally high or low levels of the biogenic amines have been associated with a variety of mental illnesses, including schizophrenia and depression. Histamine is formed from the amino acid histidine and has several functions in the body. As a neurotransmitter, it is important in modulating sleep. In the brain, neurons that produce histamine are most active during waking and are nearly inactive during sleep. This explains why certain antihistamines (drugs that block the ability of histamine to bind to its receptor, thereby inhibiting its action) used to treat colds and allergies also induce drowsiness.

Table 41.2 Classes of Neurotransmitters and Some Representative Examples and Functions

Transmitter	Some major functions
Acetylcholine	CNS: Stimulates the brain; important in memory, motor control, and many other functions
	PNS: Stimulates skeletal muscle at neuromuscular junctions; inhibits cardiac muscle; promotes digestion
Biogenic amines	
Catecholamines: dopamine, norepinephrine, epinephrine	CNS: Regulate mood, attention, learning, behavior
Serotonin	PNS: Stimulates cardiac muscle; improves lung function; helps animals respond to stressful situations
Histamine	CNS: Helps to maintain awake state
Amino acids	
Excitatory amino acids: glutamate, aspartate	CNS: Widespread mediators of activity in all areas of CNS; the major "on" signal of the CNS
Inhibitory amino acids: gamma-aminobutyric acid (GABA), glycine	CNS: Hyperpolarize neurons; act as a "brake" on the nervous system
Neuropeptides	
Opiate peptides: endorphin	CNS: Modulate postsynaptic cell response to neurotransmitters; play a role in mood, behavior, appetite, pain perception, and many other areas
Gases	
Nitric oxide, carbon monoxide	CNS: Possible role in memory and odor sensation
	PNS: Relax smooth muscle, especially in blood vessels

Amino Acids In addition to their role in the formation of proteins, the amino acids glutamate, aspartate, and glycine function as neurotransmitters. Glutamate is the most widespread excitatory neurotransmitter found in animal nervous systems. Though not involved in protein formation, another amino acid, gamma-aminobutyric acid (GABA), is the most common inhibitory neurotransmitter. GABA hyperpolarizes the postsynaptic membrane by opening chloride channels, allowing chloride ions to move into the cell (see Table 41.1), and acting as the major "brake" on the central nervous system.

Neuropeptides Neuropeptides are short chains of 2 to about 15 amino acids. They remained largely unknown until the 1970s, when it became clear that perhaps 100 or so peptides can act as neurotransmitters. Like the other neurotransmitters discussed, neuropeptides can be excitatory or inhibitory. They are produced within the neuron cell body, packaged in vesicles in the Golgi apparatus, and transported to the axon terminal, from where they are released. Neuropeptides are often called **neuromodulators**, because they can alter or modulate the response of the postsynaptic neuron to other neurotransmitters. For example, a cell exposed to a neuropeptide may increase the number of receptors for another neurotransmitter, which makes the cell more responsive to that neurotransmitter. One group of neuropeptides is called the opiate peptides because opium-like drugs, such as morphine, bind to their receptors. Opiate peptides include the endorphins, a group of peptides that decrease pain and cause natural feelings of euphoria (extreme happiness and feeling of invulnerability). Endorphins may also be important in helping animals deal with stress.

Gaseous Neurotransmitters Certain gaseous molecules such as nitric oxide (NO) and carbon monoxide (CO) act locally in many tissues and sometimes function as neurotransmitters. Unlike other neurotransmitters, they are not sequestered into vesicles and are produced locally as required. Gaseous neurotransmitters are short-acting and influence other cells by diffusion. In humans, NO is responsible for relaxing the smooth muscle surrounding blood vessels, including those in the penis. When a male becomes sexually aroused, NO levels increase in this tissue, dilating the vessels and increasing blood flow into the penis, producing an erection. Several drugs used for male sexual dysfunction enhance erections by increasing or mimicking the action of NO on smooth muscle. The functions of CO are still uncertain, but scientists think it may act as a neurotransmitter in the sense of smell in some animals, such as the terrestrial mollusk *Limax maximus*.

The discovery that the actions of neurons are mediated in large part by neurotransmitters was one of the most significant discoveries in the history of neuroscience. That discovery laid the foundation for our understanding of the nervous system and of many human diseases. Amazingly, the existence of neurotransmitters was demonstrated in a remarkably simple experiment that arose from a dream, as we see next.

Feature Investigation

Otto Loewi Discovered Acetylcholine

German physiologist Otto Loewi was interested in how neurons communicate with skeletal muscle. He already knew that the electrical stimulation of a nerve in a frog's leg would result in muscle contraction, so it appeared that neurons communicate with the muscle by electrical signals. In 1921, he turned his studies to another type of muscle, the heart. As we will see in Chapter 47, all vertebrate and some invertebrate hearts receive both excitatory and inhibitory signals from different nerves that regulate the rhythm and intensity of the heartbeat. Loewi hypothesized that because different nerves produced opposite effects on the heart, the effects of the nerves could not be a direct electrical action on heart muscle, because there would be no way for the heart muscle to discern between the same type of signal from different nerves. Instead, perhaps the neurons in each nerve released different chemicals of some type, and it was these chemicals that exerted opposite actions on the heart.

As shown in Figure 41.16, Loewi removed the hearts from two frogs and placed the hearts in baths containing saline (an isotonic NaCl solution). As long as a frog's heart is kept in this solution, it will continue to beat for several hours before eventually dying.

Initially, Loewi began by examining the major inhibitory nerve of the vertebrate heart, called the vagus nerve. When Loewi dissected the hearts from the two frogs, he left the vagus nerve intact in one heart, but removed it from the other. Next, Loewi used an electrode to electrically stimulate the vagus nerve attached to the first frog's heart. As expected, this resulted in a decrease in the rate at which the first heart contracted. He then removed some of the saline solution from within and around the first heart and transferred it to the solution that was bathing the second (unstimulated) heart. The rate and force of beating of the second heart quickly decreased, even though it had no vagus nerve and was not exposed to any electrical stimulation. Loewi concluded that a chemical substance was released from the nerve of the first heart into the surrounding fluid and that when this chemical was added to the second heart, it reproduced the effects of electrical stimulation that were observed on the first heart.

Loewi initially named this substance vagusstoff (vagus substance), after the vagus nerve he stimulated. It was later renamed acetylcholine when its chemical nature (acetic acid bonded to choline) was determined. Acetylcholine was the first neurotransmitter discovered. Loewi's research opened the door for what we now know about chemical transmission at synapses, and the enormous pharmaceutical industry, which builds on this knowledge to treat neurological disorders (diseases of the nervous system).

Interestingly, as Loewi described later, the idea for his experiment, which would be largely responsible for his earning a share of a Nobel Prize, came to him in a dream. He woke in the middle of the night, scribbled down his idea, and returned

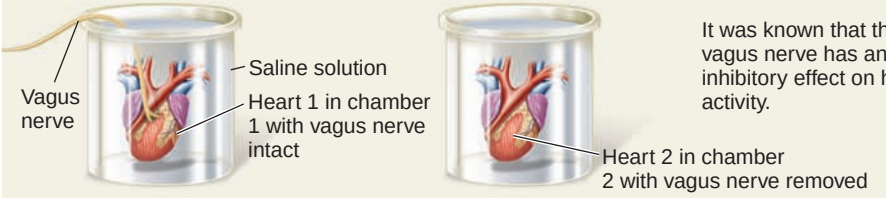
Figure 41.16 Loewi's experimental discovery of chemical neurotransmission.

HYPOTHESIS Neurons release chemical substances that influence the activity of the heart.

KEY MATERIALS Two frog hearts, saline solution, and stimulating and recording electrodes.

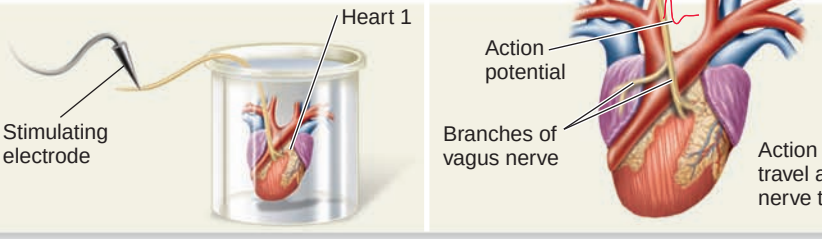
Experimental level | **Conceptual level**

1 Dissect hearts from 2 frogs and place in chambers with a saline solution. Heart 1 still has its vagus nerve attached.



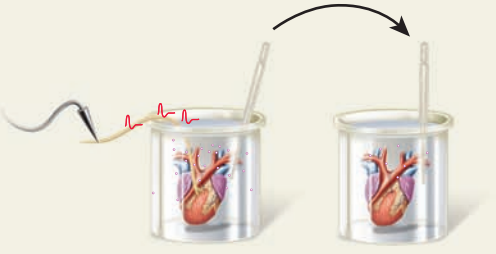
It was known that the vagus nerve has an inhibitory effect on heart activity.

2 Electrically stimulate vagus nerve of heart 1.



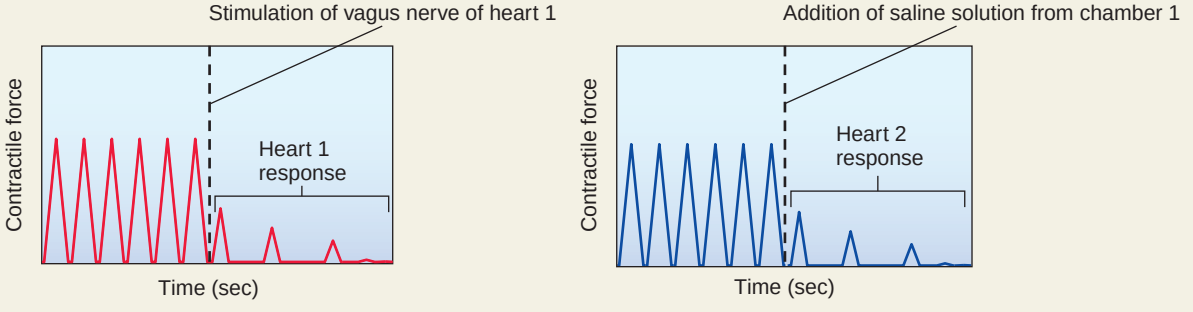
Action potentials travel along vagus nerve to heart 1.

3 Record strength and number of beats in heart 1 before and after electrical stimulation of vagus nerve. Next, remove a sample of the saline solution in and around heart 1, and transfer to heart 2. Record activity of heart 2. This was done using mercury manometers that were connected to each heart. The manometers measure pressure, which is due to the contractile force of the heart beating.



If stimulation of vagus nerve resulted in the release of chemicals onto heart 1, then these same chemicals (some of which may diffuse into the saline solution) should have an identical effect on heart 2.

4 THE DATA



5 CONCLUSION Electrical stimulation causes the vagus nerve to secrete chemicals that decrease heart contractions.

6 SOURCE Loewi, O. 1921. On humoral transmission of the action of heart nerves. Pflügers archives. *European Journal of Physiology* 189:239–242.

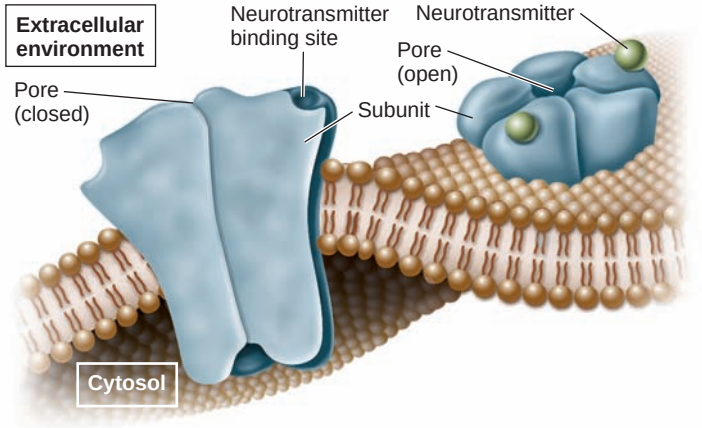
to sleep. The next morning, he despaired to find that he couldn't read his sleepy scribblings! Incredibly, he had the dream again the following night and, not taking any chances, got up and went directly to his laboratory.

Experimental Questions

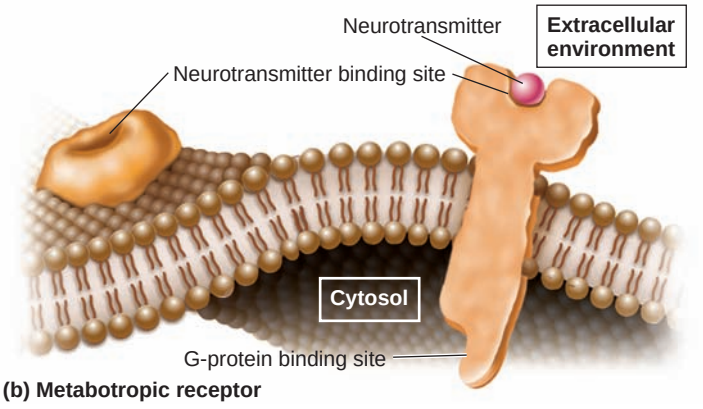
1. What observations led Loewi to develop his hypothesis of how nerves stimulate or inhibit heart muscle contractions?
2. Describe Loewi's experimental design to test his hypothesis.
3. What were the results of Loewi's experiment? Did the results support his hypothesis?

Postsynaptic Receptors Determine the Response to Neurotransmitters

As we have seen, in some cases the same neurotransmitter can have both excitatory and inhibitory effects. The response of the postsynaptic neuron depends on the type of receptor present in the postsynaptic membrane. The two major types of postsynaptic receptors are ionotropic and metabotropic, and many neurotransmitters, such as acetylcholine, act on both (Figure 41.17). Neurotransmitter molecules bind to the extracellular portion of these receptors.



(a) Ionotropic receptor



(b) Metabotropic receptor

Figure 41.17 **The two major categories of postsynaptic receptors.** **(a)** Ionotropic receptors have several subunits. Neurotransmitters bind to ionotropic receptors and directly open ion channels in the membrane. **(b)** Metabotropic receptors are G-protein-coupled receptors, which are discussed in Chapter 9. Neurotransmitters bind to metabotropic receptors and initiate a signaling pathway that typically opens or closes ion channels.

Ionotropic receptors are ligand-gated ion channels that open in response to neurotransmitter binding (Figure 41.17a). When neurotransmitter molecules bind to these receptors, ions flow through the channels to cause an EPSP or IPSP. Acetylcholine and amino acids bind to ionotropic receptors. Ionotropic receptors are composed of multiple subunits that associate in a ring to form the receptor's channel.

Metabotropic receptors are G-protein-coupled receptors (GPCRs) (described in Chapter 9). They do not form a channel but instead are coupled to an intracellular signaling pathway that initiates changes in the postsynaptic cell (Figure 41.17b). A common type of response is the phosphorylation of ion channels for sodium, potassium, or calcium ions, which are present in the plasma membrane. In Chapter 43, we will see that metabotropic receptors are important in activating sensory cells that respond to visual and other stimuli.

As mentioned earlier, many neurotransmitters bind to more than one type of receptor. In addition, receptors that are composed of subunits may exist in multiple forms made up of different combinations of subunits. What benefit is there to an organism to express such a variety of receptor types for a given neurotransmitter? One helpful way of understanding this diversity and its importance is illustrated by the amazing complexity of one well-studied receptor family, that of the widespread amino acid neurotransmitter GABA, as we see next.

Genomes & Proteomes Connection

Varied Subunit Compositions of Neurotransmitter Receptors Allow Precise Control of Neuronal Regulation

As mentioned earlier, gamma-aminobutyric acid (GABA) is an inhibitory neurotransmitter that opens Cl^- channels. Though cells can possess different types of GABA receptors, we will focus here on one type, which functions as a ligand-gated ion channel. This ionotropic receptor, which we will simply refer to as the GABA-A receptor, binds GABA and thereby opens the channel. This event allows Cl^- to diffuse into the cell, causing a hyperpolarization of the plasma membrane and shifting the membrane potential toward the equilibrium potential for Cl^- (usually between about −70 to −90 mV) (Figure 41.18). In this way, GABA binding to this receptor decreases the likelihood that a neuron will generate an action potential.

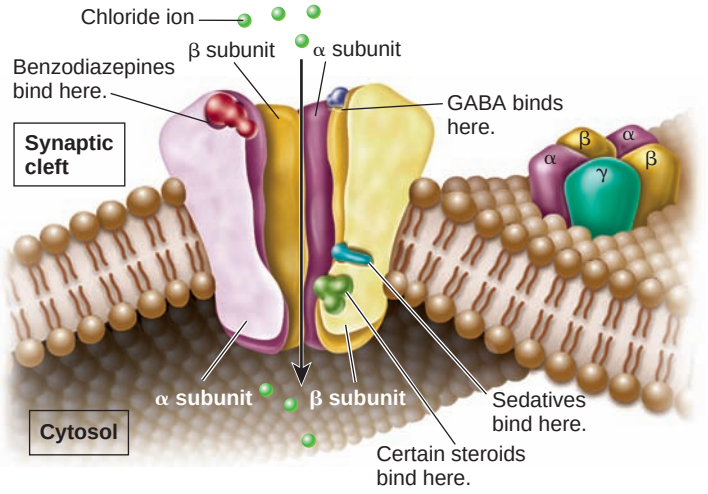


Figure 41.18 The structure and function of the GABA-A receptor. Each type of GABA-A receptor has five subunits that form an anion channel allowing the passage of chloride ions. When GABA binds to the receptor, chloride ions move through the open channel and hyperpolarize the cell. Various other molecules bind to different sites on the receptor. These include molecules that naturally occur in animals' bodies, such as certain steroid hormones, and drugs, such as sedatives and benzodiazepines, used to treat anxiety and other disorders.

The GABA-A receptor is a good example of how receptor subunits can influence a postsynaptic response to a neurotransmitter. GABA-A receptor proteins are usually composed of five subunits (designated α, β, and so on). The genomes of humans and other mammals have a group of homologous genes that encode at least 19 different GABA-A receptor subunits. In addition, subunit variation can be further increased by alternative splicing (see Chapter 13). This amazing variety in subunits allows cells to express dozens of different kinds of GABA-A receptors.

What are the benefits of having such a variety of different GABA-A receptor subunits? Though the answer is not entirely understood, each type of subunit has its own unique properties that can fine-tune the function of the GABA-A receptor so that it works optimally in the neuron in which it is expressed. The various subunits may differ in their affinity for GABA and the rate of Cl^- movement through the channel.

In addition, neuroscientists have been particularly interested in whether the various subunits differ in their ability to recognize molecules other than GABA (Figure 41.18). This work has shown that the subunits of the GABA receptor bind a variety of other molecules, including naturally occurring ones such as certain steroid hormones. Presumably, the binding of these molecules enhances or reduces the effectiveness of GABA in activating the receptor. This knowledge has proven beneficial in understanding how certain drugs exert their actions. For example, ethanol—found in alcoholic drinks—binds to one of the GABA-A receptor subunits expressed in brain and motor neurons and enhances the actions of GABA. This may explain in part why alcohol depresses the activity of the brain and impairs motor coordination, among other effects. Other subunits of the GABA-A receptor bind drugs, such as benzodiazepines (for example, Xanax), which are used to treat chronic or severe anxiety. Apparently, the inhibitory effects of GABA are part of the mechanism for achieving a balance between alertness, anxiety, and calmness. The ability of the receptor to bind numerous ligands, and the many different combinations of subunits in the receptor, provide an enormous degree of control over precisely how this neurotransmitter system regulates the activity of the brain.

41.4 Impact on Public Health

When neurons fail to develop properly or their function is impaired, the consequences can be devastating, affecting mood, behavior, and even the ability to think or move. Over 100 neurological disorders have been identified in humans, and drugs to treat them are among the most widely prescribed medicines today (Table 41.3). All recreational drugs also exert their effects by altering neurotransmission. The use of these drugs, therefore, can result in symptoms similar to those of neurological disorders.

Disorders of Neurotransmission Can Impact Mood

Several neurological disorders result from disrupted neurotransmission between cells. Genetic processes involved in the production of neurotransmitters or malfunction of synaptic events can increase or decrease activity at synapses, which, in turn, affects emotions and behavior. One mood disorder is **bipolar disorder**, previously called manic depression, in which individuals experience shifts between periods of euphoria and despair.

The most common mood disorder is **major depressive disorder**, also called unipolar depression or, simply, depression. This illness results in prolonged periods of sadness, despair, and lack of interest in daily activities without alternating episodes of euphoria. Depression affects 5–12% of men and 10–25% of women at some point in their lifetime. This condition is thought to result from decreased activity of synapses that release biogenic amines, such as serotonin, which changes neuronal activity within specific areas in the brain involved in processing emotion. Drugs used to treat major depression include the **selective serotonin reuptake inhibitors**, such as Prozac, Zoloft, and Paxil, which reduce the reuptake of serotonin into the presynaptic terminal after it is released. This allows serotonin to accumulate in the synaptic cleft, counteracting the deficit that causes the alteration in mood.

In many respects, the use of such drugs to treat depression reflects a profound change in the public's attitude toward mental illness. Historical attitudes toward mood disorders held that individuals who were depressed lacked the ability to cope with stressful events in their lives. Only recently has it become accepted that mood disorders can be caused by changes in the balance of neurotransmitters in the brain. Perhaps the best

Table 41.3 Representative Effects of Common Therapeutic or Recreational Drugs on Neurotransmitter Action and Mood

Name of drug	Actions on neurotransmission	Effects on mood	Effects of abuse or overdose
Alcohol (ethanol)	Enhances inhibitory GABA transmission; increases dopamine transmission; inhibits glutamate transmission	Relaxation; euphoria; sleepiness	Liver damage; brain damage
Amphetamines *"uppers," "crystal meth," "pep pills"*	Stimulate the release of dopamine and norepinephrine	Euphoria; increased activity	High blood pressure; psychosis
Antidepressants *Tricyclic antidepressants*; for example, *Elavil*, *Anafranil*	Block the reuptake of norepinephrine from synapses	Relieve depression and obsessive-compulsive disorder	Drowsiness; confusion
Selective serotonin reuptake inhibitors; for example, *Prozac*, *Zoloft*, *Paxil*, *Lexapro*	Block the reuptake of serotonin from synapses	Relieve depression and obsessive-compulsive disorder	Insomnia; anxiety; headache
Monoamine oxidase inhibitors; for example, *Parnate*, *Nardil*	Block the breakdown of biogenic amine neurotransmitters	Relieve depression	Liver damage; hyperexcitability
Antianxiety drugs *Benzodiazepines*; for example, *Xanax*, *Valium*, *Librium*, *Rohypnol* (*"date rape drug," "roofies"*)	Bind to GABA receptors and increase inhibitory neurotransmission	Relieve anxiety; cause sleepiness and in some cases amnesia	Drowsiness; memory loss in some cases
Antipsychotic drugs *Phenothiazines*; for example, *Thorazine*, *Mellaril*, *Stelazine*, *Abilify*, *Risperdal*	Block dopamine receptors	Ease schizophrenic symptoms	Decreased control of movement
Cocaine	Blocks norepinephrine and dopamine reuptake	Intense euphoria followed by depression	Convulsions; hallucinations; death from overdose
LSD (lysergic acid diethylamine)	Binds to serotonin receptors	Hallucinations; sensory distortions	Unpredictable and irrational behavior
Marijuana (tetrahydrocannibinol)	Binds to receptors for natural cannabinoids	Increased sense of well-being; decreased short-term memory; decreased goal-directed behavior; increased appetite	Delusions; paranoia; confusion
Narcotics *Heroin*, *morphine*, *Demerol*, *codeine*	Bind to opiate receptors	Pain relief; euphoria; sedation	Slowed breathing; death from overdose
Nicotine	Initially stimulates but then depresses activity in adrenal medulla and neurons in the peripheral nervous system; increases dopamine in brain	Increased attention; decreased irritability	Heart disease and lung disease
PCP (phencyclidine) *"angel dust," "ozone"*	Blocks channel for excitatory amino acid neurotransmitters; increases dopamine activity	Violent behavior; feelings of power; numbness; disorganized thoughts	Psychosis; convulsions; coma; death

evidence of a physiological basis for depression is that mood disorders occur more frequently in certain families, suggesting a genetic component. Drugs can be very effective in treating these disorders. Patients taking selective serotonin reuptake inhibitors often report decreased sadness, increased energy, and a greater interest in daily activities.

Recreational Drugs Disrupt Normal Neurotransmission

Most so-called recreational drugs work at the synapse to either enhance or interfere with the normal mechanisms of neurotransmission (Table 41.3). In the presynaptic terminal, such drugs can decrease neurotransmitter release by reducing Ca^{2+} entry into the cell or by preventing the exocytosis of vesicles containing stored neurotransmitters. In the synaptic cleft, drugs can slow the rate at which the neurotransmitter is broken down into an inactive form or taken back up into the presynaptic neuron, thereby prolonging the action of the neurotransmitter in the synaptic cleft. Some substances act on the postsynaptic membrane by either preventing the neurotransmitter from binding to its receptor or by acting as a substitute for the neurotransmitter by stimulating the receptor.

In effect, these drugs produce changes or imbalances in neurotransmission similar to those observed in some neurological disorders. These substances can induce euphoria, increase activity, alter mood, and produce hallucinations. They can also have potentially life-threatening effects and may be highly addictive.

Some drugs, such as cocaine, block the removal of dopamine and norepinephrine from the synaptic cleft by preventing their reuptake into the presynaptic terminal. Morphine and marijuana mimic the actions of biological substances already in the brain, binding to receptors on the postsynaptic membrane. With these drugs, the resulting effects are much stronger than are the effects of natural neurotransmitters. It is no surprise that recreational drugs are mind altering. They do, after all, change the ways in which neurons communicate with each other.

Disorders of Conduction May Result in Motor Problems and Abnormal Neuronal Development

Some human diseases are caused by the inability of the axon to properly conduct an action potential. This occurs most commonly because an axon fails to become myelinated or because a myelinated axon becomes demyelinated.

In **congenital hypothyroidism** (formerly called cretinism), axons fail to become wrapped with myelin during fetal development, which leads to slow conduction speeds and abnormal connections between brain neurons. This results in profound mental defects that cannot be reversed unless treatment begins immediately after birth. Congenital hypothyroidism is caused by insufficient levels of thyroid hormones in the fetus. Among their many actions, thyroid hormones stimulate the formation of myelin during fetal development. However, thyroid hormones cannot be synthesized without the element iodine, which is part of the structure of the hormones. The iodine in the fetus comes from the mother's diet. If a mother's dietary intake of iodine is too low, the fetus will not have enough iodine to make its own thyroid hormones, and therefore, the fetus will not be able to make normal amounts of myelin. Although iodine is not an abundant element in most diets, congenital hypothyroidism is rare in the U.S. and many other countries since the advent of iodized table salt; however, it is not uncommon in many parts of the world.

Unlike congenital hypothyroidism, **multiple sclerosis** (**MS**) usually begins between the ages of 20 and 50 in individuals with apparently healthy nervous systems. With MS, the patient's own immune system, for reasons unknown, attacks and destroys myelin as if it were a foreign substance. Eventually, these repeated attacks leave multiple scarred (sclerotic) areas of tissue in the nervous system and impair the function of myelinated neurons that control movement, speech, memory, and emotion. Multiple sclerosis is a serious and unpredictable disease, characterized by flare-ups followed by periods of remission in which symptoms are reduced or absent. No cure is currently available, but certain drugs may slow its progression and reduce the severity of symptoms. This disease affects roughly 2.5 million people worldwide, 60–75% percent of them women.

Summary of Key Concepts

41.1 Cellular Components of Nervous Systems

- The central nervous system (CNS) is composed of a brain and a nerve cord. The peripheral nervous system (PNS) consists of all neurons and their projections that are outside of and connect with the CNS. Nerves transmit signals between the PNS and CNS. (Figure 41.1)
- The two major classes of cells in nervous systems are neurons and glia. In neurons, information flows from dendrites to the cell body and then to the axon and axon terminal. (Figure 41.2)
- Types of neurons include sensory neurons, motor neurons, and interneurons. A neuron's structure is a reflection of its function. (Figure 41.3)
- The most basic circuit is a reflex arc, which occurs rapidly in response to inputs from sensory neurons and consists of only one or a few afferent and efferent cells. (Figure 41.4)

41.2 Electrical Properties of Neurons

- Neuronal membranes are electrically polarized. The membrane potential is determined by the differential distribution and differential permeability of ions across the plasma membrane. The resting potential is the membrane potential of a cell that is not sending electrical signals. (Figures 41.5, 41.6, Table 41.1)
- Neurons use electrical signals to communicate with other neurons, muscles, or glands. These signals involve changes in the amount of electric charge across a cell's plasma membrane.
- Diffusion of ions through membrane channels occurs as a result of the concentration gradient of an ion across the membrane and the electric charge across the membrane. Ions move in response to an electrochemical gradient. (Figure 41.7)
- The Nernst equation gives the equilibrium potential for an ion at any given concentration gradient.

41.3 Communication Between Neurons

- Gated ion channels enable a cell to communicate by changing its membrane potential rapidly. The opening and closing of voltage-gated and ligand-gated ion channels cause two types of changes in the neuron's membrane potential—graded potentials and action potentials. (Figures 41.8, 41.9)
- When a graded potential is large enough to spread to the axon hillock and depolarize the membrane to its threshold potential, this causes an action potential that carries an electrical signal from the axon hillock to the axon terminal. (Figures 41.10, 41.11)
- Axon diameter and myelination influence the speed of an action potential. (Figure 41.12)
- Electrical synapses are connected via gap junctions. Most vertebrate neurons communicate via chemical synapses, in which a neurotransmitter carries the signal from the presynaptic to the postsynaptic cell. Many EPSPs generated at one time can sum together and bring the membrane potential to the threshold potential, initiating an action potential. (Figures 41.13, 41.14, 41.15)
- Chemical classes of neurotransmitters found in animals include acetylcholine, biogenic amines, amino acids, neuropeptides, and gaseous neurotransmitters. (Table 41.2)
- The discovery that the actions of neurons are mediated in large part by neurotransmitters was one of the most significant discoveries in the history of neuroscience. (Figure 41.16)

- The receptors of the postsynaptic neuron determines the types of signals that pass from one neuron to the other. The two major types of postsynaptic receptors are ionotropic and metabotropic. (Figures 41.17, 41.18)

41.4 Impact on Public Health

- Most neurological conditions can be classified as disorders of either neurotransmission or conduction. Mood disorders caused by disrupted neurotransmission include bipolar disorder and major depressive disorder. Drugs used in the treatment of neurological disorders and recreational drugs usually alter neurotransmission. (Table 41.3)
- Some neurological conditions are caused by the inability of the axon to conduct an action potential. This occurs most commonly because axons fail to become myelinated (congenital hypothyroidism) or because myelinated axons become demyelinated (multiple sclerosis).

Assess and Discuss

Test Yourself

1. In vertebrates, the brain and the spinal cord are parts of
   a. the peripheral nervous system.
   b. the enteric nervous system.
   c. the central nervous system.
   d. the autonomic nervous system.
   e. the endocrine system.
2. The structures of a neuron that function mainly in receiving signals from other neurons are
   a. the myelin sheaths.
   b. the axons.
   c. the axon terminals.
   d. the dendrites.
   e. the K^+ channels.
3. The glial cells that form the myelin sheath in the peripheral nervous system are called
   a. astrocytes.
   b. oligodendrocytes.
   c. microglia.
   d. neurons.
   e. Schwann cells.
4. Neurons that function mainly in connecting other neurons in the central nervous system are
   a. sensory neurons.
   b. efferent neurons.
   c. motor neurons.
   d. afferent neurons.
   e. interneurons.
5. The difference in charges across the plasma membrane of an unstimulated neuron is called
   a. the membrane potential.
   b. the resting membrane potential.
   c. homeostasis.
   d. the graded potential.
   e. the action potential.
6. Which of the following contributes to the resting membrane potential?
   a. negatively charged ions inside and outside of the cell
   b. active transport of ions across the membrane
   c. concentration of Na^+ and K^+ inside and outside of the cell
   d. all of the above
   e. b and c only
7. A neuron has reached a threshold potential when it has depolarized to the point where
   a. most voltage-gated K^+ channels open.
   b. sufficient numbers of voltage-gated Na^+ channels open to initiate a positive feedback cycle, contributing to further depolarization.
   c. voltage-gated K^+ channels close.
   d. voltage-gated Na^+ channels close.
   e. both b and c occur.
8. The speed of transmission of an action potential along an axon is influenced by
   a. the presence of myelin.
   b. an increased concentration of Ca^{2+}.
   c. the diameter of the axon.
   d. all of the above.
   e. a and c only.
9. Gap junctions are characteristic of
   a. electrical synapses.
   b. chemical synapses.
   c. acetylcholine synapses.
   d. GABA synapses.
   e. synapses between motor neurons and muscle cells.
10. The response of the postsynaptic cell is determined by
    a. the type of neurotransmitter released at the synapse.
    b. the type of receptors the postsynaptic cell has.
    c. the number of Na^+ channels in the postsynaptic membrane.
    d. the number of K^+ channels in the postsynaptic membrane.
    e. all of the above.

Conceptual Questions

1. Distinguish between neurons and glial cells, and give an example of a glial cell.
2. Describe the difference between graded and action potentials.
3. In certain diseases, such as kidney failure, the Na^+ concentration in the body's extracellular fluid can become altered. What effect would a high extracellular Na^+ concentration have on neurons?

Collaborative Questions

1. Discuss how nervous systems are organized into central and peripheral nervous systems in animals.
2. Name the parts of a neuron, and give a brief description of their major characteristics.

Neuroscience II: Evolution and Function of the Brain and Nervous Systems

42

Chapter Outline

Three-dimensional reconstruction of the brain of a fruit fly. The brains of animals are organized into anatomic structures with specialized functions.

It will take you approximately 2–3 seconds to read this sentence. During that time, many of the 100 billion or so neurons of your brain will have fired off millions of action potentials. Some of those signals will help process the visual information reaching your eyes as you scan the page. Others will activate centers of learning and memory to help you understand the meanings of the words you've read. Still other signals will help filter out extraneous inputs—such as background noise—that might distract you from your task. The complexity of the seemingly simple task of reading a single sentence emphasizes the enormous level of activity that goes on continually in the brain, even at rest.

The beauty of the brain lies in its incredible complexity. The human brain, for example, has several thousand miles of interconnected neurons and hundreds of trillions of synapses, resulting in a total surface area that if spread out, would cover more than four soccer fields. The brain allows us to move, think, and experience sensation and emotion. Groups of neurons also coordinate homeostatic functions such as breathing, blood circulation, and body temperature. When we examine the way that groups of neurons communicate, we begin to understand the complex mental functions of nervous systems, including learning, memory, and motivation.

Neuroscience—the study of nervous systems—is an area of intense research activity worldwide. For example, at one annual scientific meeting, more than 30,000 neuroscientists from dozens of countries meet to present their research and learn about the latest developments in this dynamic field. The challenge of neuroscience is to transform the astounding complexity of nervous systems into manageable proportions. For this reason, most neuroscientists do not study the human nervous system, because of its great complexity and the difficulties inherent in doing research on humans. Many animals, however—including the nematode *Caenorhabditis elegans*, the sea slug *Aplysia californica*, the fruit fly *Drosophila melanogaster* (see chapter-opening photo), the zebrafish *Danio rerio*, and the mouse *Mus musculus*—provide excellent opportunities to study how neurons work and how groups of neurons cooperate to produce animal behavior. The genomes of most of these animals have been sequenced, and neuroscientists are identifying genes that are critical for the structure and function of nervous systems. Many of the relevant genes are homologous to human genes, so the study of the molecular control of the nervous system in these model animals has the potential to reveal new treatments for many genetically inherited neurological diseases in humans.

In this chapter, we will first survey a variety of nervous systems, which allow animals to sense and respond to environmental changes. We will then examine the complex nervous system of humans. However, keep in mind that we still have much to learn about the organization, connectivity, and functions of nervous system structures. Our nervous system is fascinating and mysterious, and the study of how it functions will ultimately tell us much about what makes us human.

42.1 The Evolution and Development of Nervous Systems

The nervous systems of animals are the products of hundreds of millions of years of evolution. They provide advantages to animals that promote reproductive success. For example, nervous

systems allow animals to keenly sense their environment and respond to changes in an appropriate way. In addition, nervous systems form connections with muscle systems and facilitate movement, which has allowed animals to travel across distances to obtain food. Likewise, nervous systems help animals to avoid predation and other environmental dangers.

Studying the evolution and development of nervous systems helps us understand how particular nervous systems are adapted to different functions. At the structural level, the organization of nervous systems ranges from a relatively simple network of a few cells to the marvelous complexity of the human brain. The characteristics of an animal's nervous system determine the behaviors that it displays. In this section, we will survey the nervous systems of invertebrates and vertebrates and also examine the brains of vertebrates in greater detail.

Nervous Systems Evolved to Sense and Respond to Changes in the Environment

Precisely when nervous systems first arose and whether or not the nervous systems of most or all animals can be traced back to a common ancestor are questions of active investigation by neuroscientists. For example, recent genetic studies have uncovered remarkable similarities in the expression and activation of genes coding for proteins that regulate neuronal development across taxa in bilaterians. Those studies suggest that the patterning of nervous system development in such animals may be traced to a common ancestor that lived more than 500 million years ago!

Today, all animals except sponges have a nervous system. Interestingly, though, researchers have recently discovered that sponges express about 25 genes with similarity to genes expressed in human neurons, specifically those that code for proteins that regulate synaptic function. The functions of the sponge genes are uncertain, but the proteins coded for by the genes interact in ways that are reminiscent of human synaptic proteins. Thus, the origin of nervous systems almost certainly can be traced to genes of evolutionarily ancient organisms; as animals evolved, these genes were modified and formed the basis of all future nervous systems. The simplest nervous system is the **nerve net** of the radially symmetrical cnidarians (jellyfish, hydras, and anemones) (Figure 42.1a). In these organisms, no single group of neurons controls all the others the way a brain does in other animals, as we'll see shortly. Instead, the neurons are arranged in a network of connections between the inner and outer body layers of the animals. A characteristic feature of nerve nets is that activation of neurons in any one region leads to activation of most or all other neurons, with the excitation spreading in all directions at once. Many of these neurons stimulate contractile cells to contract. This allows the organism to move large areas of its body simultaneously, thereby coordinating simple movements such as swimming. Recent research has identified regions of specialized function in the nerve nets of some cnidarians, such as local sensory neurons in the outer body wall. Some cnidarians, such as the jellyfish, have two nerve nets, one for moving tentacles and one for swimming. By contrast, sea stars and other echinoderms have a slightly more

Figure 42.1 Representative nervous systems throughout the animal kingdom.

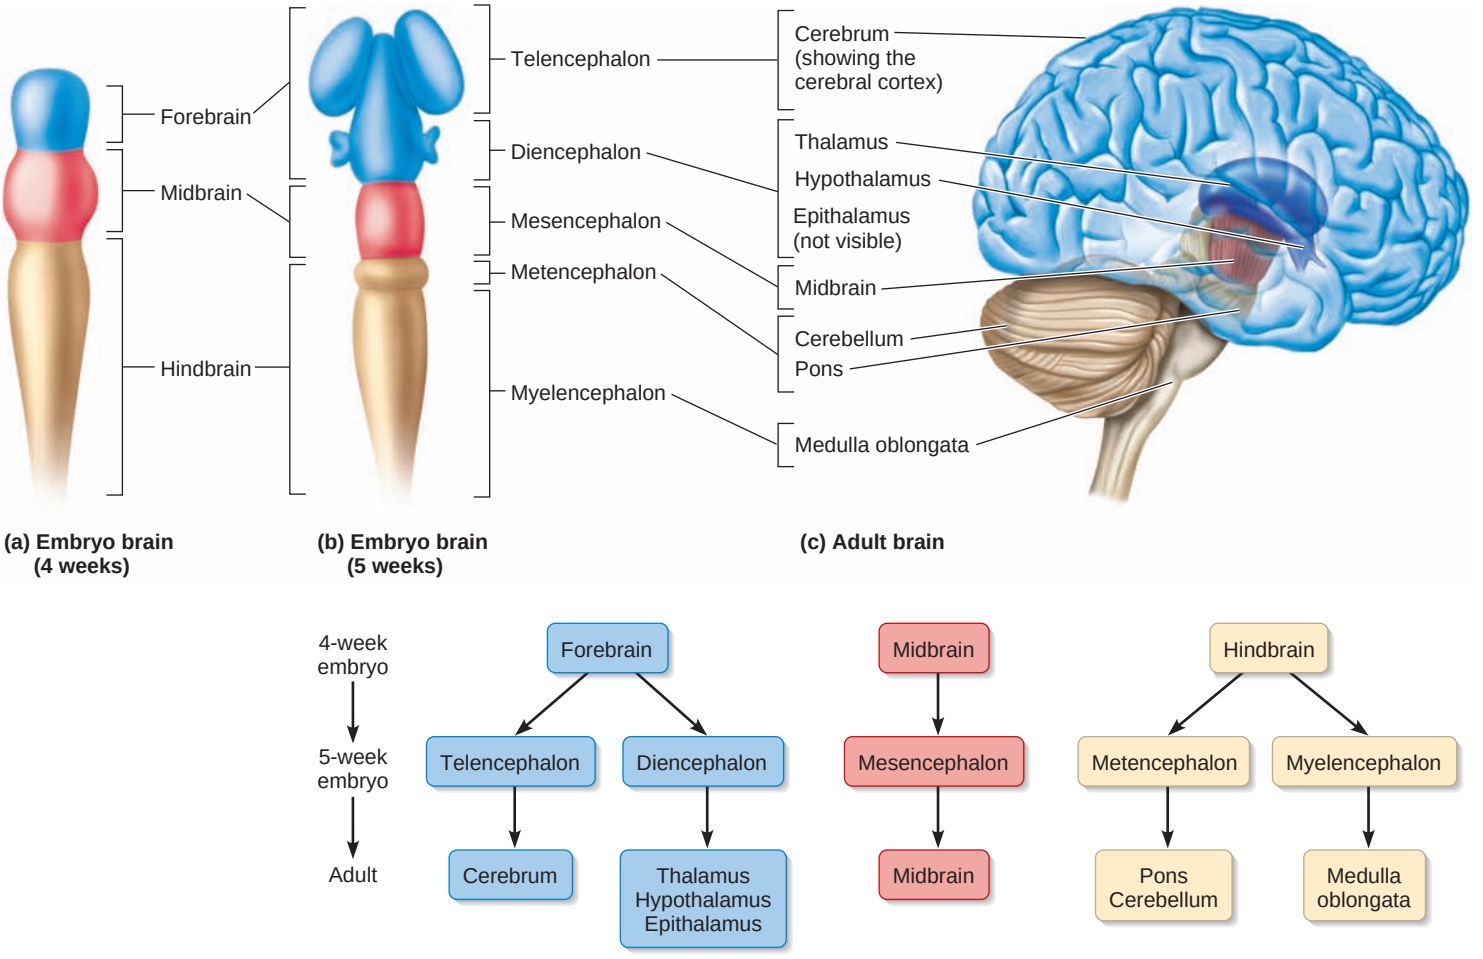

Figure 42.2 **Development of the human brain.** The structures shown here that occur during embryonic development at **(a)** 4 weeks and **(b)** 5 weeks are compared to **(c)** how they appear in the adult. Most structures beneath the cerebrum are not shown. **(d)** This flowchart gives an overview of the development of the three brain divisions.

complex nervous system with a nerve ring around the mouth that is connected to larger radial nerves extending into the arms (Figure 42.1b). This arrangement allows the mouth and arms to operate independently.

More complex invertebrate nervous systems usually consist of one or two **nerve cords** that extend from the anterior end to the posterior end. In the flatworm (genus *Planaria*), collections of neurons in the animal's head form **cerebral ganglia** (singular, ganglion). These are groups of neuronal cell bodies that perform the basic functions of integrating inputs from sense organs, such as the eyes, and controlling motor outputs such as those involved in swimming (Figure 42.1c). Two lateral nerve cords extend along the ventral surface of the animal into the tail and are connected to each other by transverse nerves. In annelids (segmented worms), the basic structure is similar, except that more neurons are present and the single ventral nerve cord has ganglia located in each body segment (Figure 42.1d). In the head, cerebral ganglia form an integrative center, which functions as a rudimentary brain to control body movements. The other ventral ganglia along the nerve cord receive sensory information from a particular body segment and control local movements. In the simpler types of mollusks, such as the snail, the nervous system is very similar to that of the annelids. The head contains a pair of anterior ganglia; paired nerve cords extend from these ganglia to the eyes, muscular foot, and gut.

During the evolution of animals, more complex body types have been associated with **cephalization** (from the Greek *cephalo*, meaning head), which is the formation in the head of an increasingly complex **brain** that controls sensory and motor functions of the entire body. Within the brain, neuronal pathways provide the integrative functions necessary for an animal to make more sophisticated responses to its environment. Brains are found in all vertebrates and most invertebrates, and they are usually composed of more than one anatomical and functional region. For instance, in *Drosophila* (Figure 42.1e and the chapter-opening photo), the brain has several subdivisions with separate functions, such as a region devoted to learning and memory. Some complex mollusks, such as the squid and octopus, have brains with well-developed subdivisions that allow these animals to coordinate the complex visual and motor behaviors necessary for their predatory lifestyle (Figure 42.1f). In all chordates, the brain is connected to a dorsally located **spinal cord**; together, the brain and spinal cord constitute the **central nervous system** (Figure 42.1g). As discussed later, nerves from the **peripheral nervous system** route information into and out of the central nervous system at separate regions along the

spinal cord. The organization of the vertebrate spinal cord and bony vertebrae shares similarities with that of the segmented nervous system of invertebrates.

Brains of Vertebrates Have Three Basic Divisions

Development of the vertebrate brain begins with the formation of a central fold in the embryo called the **neural tube**. This hollow tube is the structure from which the entire nervous system develops. Increased cell proliferation leads to bending and folding of the neural tube during embryonic development, resulting in bulges that become separate divisions of the nervous system. The anterior end develops into the brain, while the posterior portion becomes the spinal cord.

In vertebrates, the brain has three major divisions, the **hindbrain**, **midbrain**, and **forebrain** (Figure 42.2). Fossils of agnathan fishes that lived 400 million years ago show that their brains were already organized into the three basic divisions that have been retained in all modern vertebrates.

Let's look at the development of the human brain, which goes through these forms before it reaches its adult structure. At 4 weeks, the human embryo exhibits just hindbrain, midbrain, and forebrain (Figure 42.2a). Just a week later, the hindbrain and forebrain have each formed two separate divisions (Figure 42.2b). The hindbrain subdivides into the metencephalon and the myelencephalon. The forebrain subdivides into the telencephalon and the diencephalon. The midbrain, by contrast, does not subdivide and is termed the mesencephalon. By the time the human brain is fully developed, some of these structures have further divided and specialized (Figure 42.2c). The metencephalon, from the hindbrain, subdivides into the **pons** and **cerebellum**. Also from the hindbrain, the myelencephalon develops into the **medulla oblongata**. In the forebrain, the telencephalon develops into the **cerebrum**, and the diencephalon develops into the **thalamus**, **hypothalamus**, and **epithalamus**. The development of brain subdivisions provides additional specialization and increases the capacity of the brain to perform complex functions.

Hindbrain The hindbrain includes the medulla oblongata, pons, and cerebellum (Figure 42.2c). The medulla oblongata coordinates many basic reflexes and bodily functions, such as breathing, that maintain the normal homeostatic processes of the animal. The pons and cerebellum are responsible for monitoring and coordinating body movements.

Midbrain The midbrain processes several types of sensory inputs, including vision, olfaction (smell), and audition (hearing). It controls sophisticated tasks such as coordinating eye movement with visual inspection of the environment and also plays a role in alertness.

Forebrain The forebrain initiates motor functions and processes sensory inputs. In humans and other mammals, it consists of a group of structures that are responsible for the higher functions of conscious thought, planning, and emotion. Many of these functions are attributed to the cerebrum. The surface layer of the cerebrum, which is only a few millimeters thick, is called the **cerebral cortex**. As we will learn later, this thin area is critical to thought, learning, and movement, among other functions. Other structures of the forebrain are beneath the cerebrum. These include the thalamus, hypothalamus, and epithalamus, which we will discuss later in this chapter.

The relative sizes of the brain divisions vary in different animals. Usually, a larger area plays a greater role in an animal's life. In addition, the functions performed by these divisions have changed over the course of evolution. For instance, the midbrain in fishes is relatively large compared to the other two areas, and it plays a key role in vision. By comparison, the forebrain is the largest division in birds and mammals and is the primary area responsible for vision.

Increased Brain Complexity Involves a Larger, Highly Folded Cerebrum

As evolution produced animals with more complex nervous systems, the size of the cerebrum also increased, making up a greater proportion of the brain. As mentioned, many of the important functions of the cerebrum are carried out by neurons along its outer surface in the cerebral cortex. Therefore, increased complexity of the brain is also correlated with an increased surface area of the cerebral cortex. During the evolution of mammals, this increase in surface area occurred more rapidly than an expansion in the size of the skull. How could this occur? The answer is that the external surface of the cerebrum in animals with increasingly complex brains is highly convoluted, forming many folds called gyri (singular, gyrus), separated by grooves called sulci (singular, sulcus). Compare the relatively smooth-looking surface of the cerebrum of a rat with the highly folded one of a human in Figure 42.3.

As body size increases across the animal kingdom, you might expect that brain mass would increase proportionately—that the brain of an elephant would be larger than that of a bat, for instance. That is generally the case, with a few important exceptions (Figure 42.4). In particular, the masses of the human

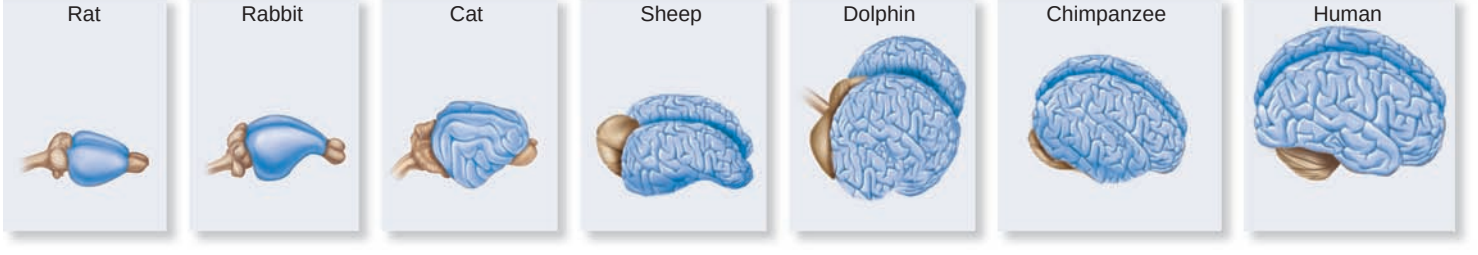

Figure 42.3 **The degree of cerebral cortex folding in different mammalian species.** The brains are not shown to scale.

	Bat	Elephant
Body mass	20 g	3,000 kg
Brain mass	0.9 g	2.5 kg

Figure 42.4 **Brain mass as a function of body mass in mammals.** For most mammals, brain weight is in proportion to body mass. However, humans and dolphins have a much higher brain mass relative to their body mass than do other mammals.

Concept check: *Scientists have determined that the brain mass of Homo neanderthalensis (Neanderthal man) was greater than that of our own. Does this mean that Neanderthals were more intelligent and capable of more complex behaviors than we are?*

and dolphin brains are greater than would be expected on the basis of body mass.

Brain mass and the amount of folding are correlated with more complex behaviors. Why is this so? As we've indicated, the outer surface of the brain, the cerebral cortex, plays a key role in conscious thought, reasoning, and learning. Greater size and folding provide a larger number of neurons and synapses and more surface area, which allows greater processing and interpretation of information. Even so, evidence does not suggest that people with small differences in brain size differ in intelligence. Also, it would be wrong to assume that an animal with a small brain is profoundly limited in its behavioral repertoire. A bat with a 0.9-gram brain and an elephant with a 2,500-gram brain can both perform a great variety of interesting and complex behaviors, such as navigating across great distances and interacting with fellow members of their species.

42.2 Structure and Function of the Human Nervous System

The nervous system of the human is wonderfully complex—the brain alone has over 100 billion neurons and many more billions of glia cells. Moreover, complexity is defined by more than just numbers of cells. Within the human brain, for example, are enormous numbers of connections between neurons—a single neuron in the cerebellum may have as many as 100,000 synapses with other cells! In this section, we will examine the human nervous system, with an emphasis on the functions of the major parts of the brain and spinal cord.

The Nervous System Is Composed of the Central and Peripheral Nervous Systems

The brain and spinal cord constitute the central nervous system (CNS) of vertebrates (Figure 42.5). The peripheral nervous system (PNS) is composed of neurons and axons of neurons that are outside the CNS and communicate with it. The CNS

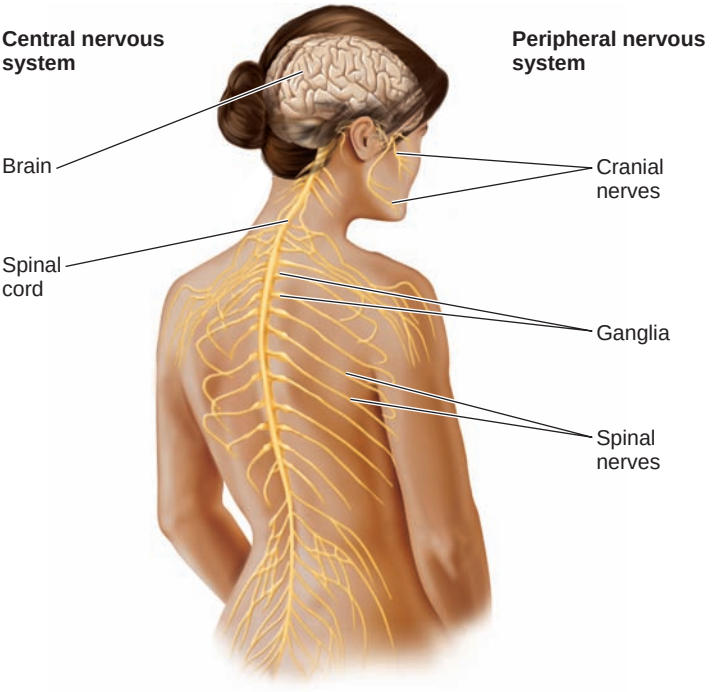

Figure 42.5 **Organization of the human nervous system.** The central nervous system consists of the brain and spinal cord, both of which are encased in bone (not shown). The peripheral nervous system includes cranial nerves, ganglia, and spinal nerves, which carry information to and from the CNS, and many other neurons throughout the body.

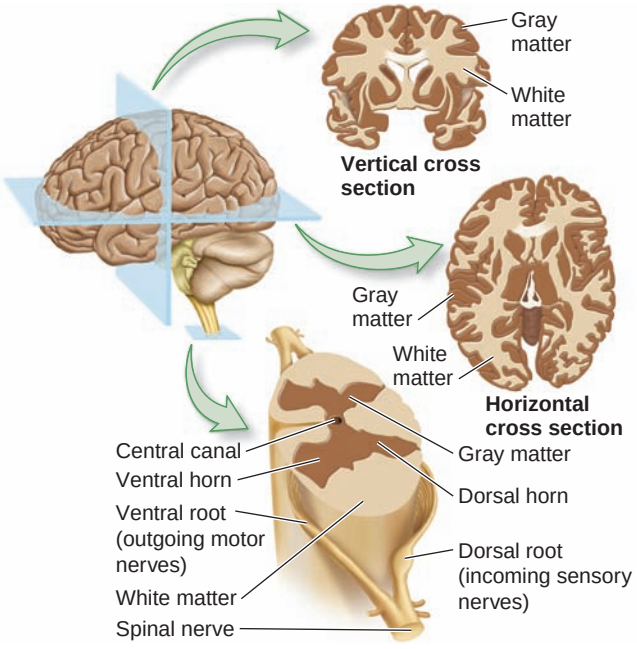
and PNS are connected anatomically and functionally. The CNS receives information about the internal or external environment from the PNS. The CNS interprets that information and may initiate a response that is then carried out by the PNS. For example, suppose you accidentally lean against a newly painted fence. Neuronal endings in your skin, which are part of the PNS, would transmit tactile (touch) information through axons that bring information directly into the spinal cord. From there, the information travels to your brain, where the sensation is



(a) Gray and white matter in the brain and spinal cord

Figure 42.6 **Gray matter and white matter in the CNS.** **(a)** The gray matter is composed of groups of cell bodies, dendrites, and unmyelinated axons. The white matter consists of tracks of myelinated axons. **(b)** Photograph of a vertical cross section through an adult human brain.

Concept check: *Is a spinal nerve composed of axons from afferent or efferent neurons, or both?*

analyzed and identified as something sticky. Signals are sent from your brain, down your spinal cord, and through the neurons of the PNS to your muscles, causing you to move away.

Within the nervous system, groups of neurons may associate with each other and perform a particular function. In the CNS, the cell bodies of neurons that are involved in a similar function may be grouped into a structure called a **nucleus** (plural, nuclei), which may include thousands of cells. For instance, cell bodies that regulate body temperature and those that recognize visual information are located in separate nuclei in the brain. In the context of the vertebrate nervous system, the term **ganglion** is used to refer to a group of neuronal cell bodies located in the PNS (Figure 42.5).

Within the vertebrate nervous system, many myelinated axons may run in parallel bundles. (Myelination is described in Chapter 41.) Such a structure is called a **tract** when it is found in the CNS. Tracts convey information from region to region within the brain and between the brain and the spinal cord. Bundles of myelinated axons also form outside the CNS, in the PNS, in which case they are called **nerves**. The cell bodies that give rise to the axons of nerves may be within the PNS or the CNS; in other words, nerves may carry information from outside the CNS into the CNS, from the CNS to structures outside the CNS, or even both. Connections between the PNS and the CNS occur at the brain or spinal cord. **Cranial nerves** are directly connected to the brain, primarily to sites within the hindbrain and midbrain. By comparison, **spinal nerves** are connections between the PNS and spinal cord (Figure 42.5).

One of the most obvious characteristics of the CNS is that some parts look white, and others appear gray (Figure 42.6). The **white matter** gets its color from myelin; it consists of myelinated axons bundled together in large numbers to form tracts. The **gray matter** consists of neuronal cell bodies, dendrites, and some unmyelinated axons. The cerebral cortex is composed of gray matter that sits on top of a large collection of white matter pathways. In the spinal cord, the gray matter is located in the center and forms two dorsal horns and two ventral horns (Figure 42.6a). Each dorsal horn connects to a dorsal root, which is part of a spinal nerve. Dorsal roots receive incoming information from sensory (afferent) nerves of the PNS. The ventral horn connects to the ventral root, which is also part of a spinal nerve that transmits outgoing information to motor (efferent) nerves. A central canal runs through the spinal cord, carrying a nutritive and protective fluid called cerebrospinal fluid, as described shortly.

Unlike the PNS, the CNS is encased in protective structures including bone (the skull and backbone) and three layers of sheathlike membranes called **meninges** (Figure 42.7). The outermost membrane, the dura mater (from the Latin, meaning hard mother), is a thick protective layer that lies just inside the skull and vertebrae. The middle membrane is called the arachnoid mater (from the Latin, meaning spidery mother) because it has numerous weblike tissue connections to the innermost membrane, the pia mater (from the Latin, meaning thin mother). The pia mater is a very thin membrane that lies on the surface of the brain and spinal cord, folding with the brain's surface.

Between the arachnoid mater and pia mater is the subarachnoid space. This space is filled with **cerebrospinal fluid**, which surrounds the exterior of the brain and spinal cord and absorbs physical shocks to the brain resulting from sudden movements or blows to the head. The cerebrospinal fluid contains nutrients, hormones, and other substances that are taken up by cells of the brain. The fluid is also a reservoir for metabolic waste products that are then carried away by the circulatory system. In addition to the subarachnoid space, the cerebrospinal fluid also fills a

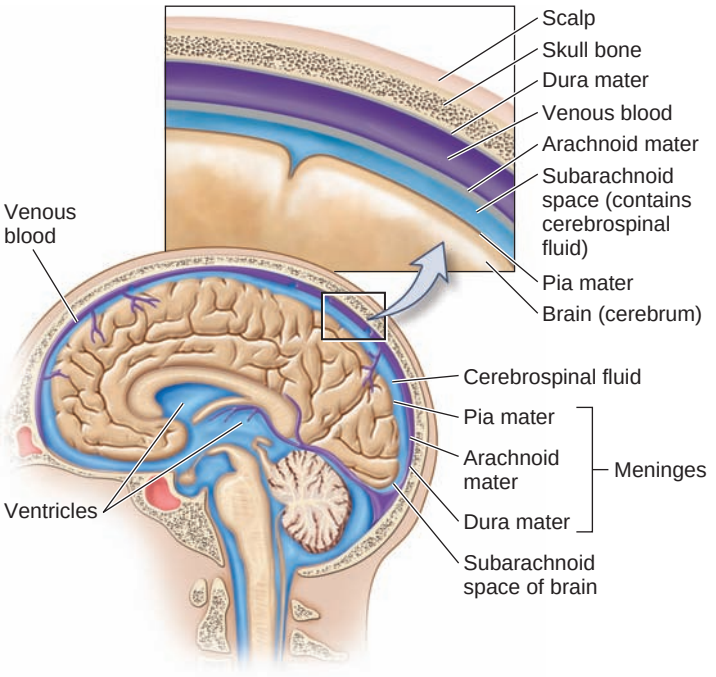

Figure 42.7 **The meninges and ventricles of the CNS.** The thickness of the meninges are exaggerated for illustration purposes. Note that the cerebrospinal fluid encases the entire CNS and also fills the ventricles.

Concept check: In a procedure known as a lumbar puncture (commonly referred to as a spinal tap), physicians use a needle to withdraw a small portion of cerebrospinal fluid from the bottom of the spine to help diagnose specific illnesses. What effects might this procedure have on a patient?

series of connected cavities called the ventricles that lie deep within the brain and connect to the central canal that extends the length of the spinal cord (see Figure 42.6). These fluid-filled structures provide a cushion of support and protection for the CNS.

The PNS Carries Information to and from the CNS

The PNS of vertebrates is subdivided into two major functional and anatomical components: the somatic nervous system and the autonomic nervous system. Both divisions have sensory (afferent) nerves and motor (efferent) nerves.

Somatic Nervous System The primary function of the **somatic nervous system** is to sense the external environment and control skeletal muscles. The sensory neurons of the somatic nervous system receive stimuli, such as heat, light, odors, chemicals (in food), sounds, and touch, and transmit signals to the CNS. The motor neurons of the somatic nervous system control skeletal muscles. The cell bodies of these motor neurons are actually located within the CNS. The axons from these cells leave the spinal cord and project directly onto skeletal muscle without any intermediary synapses along the way.

The somatic nervous system is said to be voluntary because many of the responses can be controlled consciously. For example, we use our somatic nervous system to walk and hold a pencil. However, not all responses are voluntary. An example is a reflex arc, such as the knee-jerk response, which is automatic (refer back to Figure 41.4).

Autonomic Nervous System The **autonomic nervous system** regulates homeostasis and organ function. For example, it is involved in regulating the rate of heart contractions, blood pressure, and the amount of stomach acid secreted. Though the autonomic nervous system is predominantly composed of motor neurons, it also has sensory neurons that detect internal body conditions. For example, baroreceptors are sensory neurons that detect blood pressure. For the most part, the autonomic nervous system is not subject to voluntary control. We usually cannot consciously change our heart rate or blood pressure.

The efferent pathways of the autonomic nervous system involve two motor neurons. The cell body of the first neuron is within the CNS and synapses on a second neuron in ganglia outside the spinal cord; these ganglia, therefore, are part of the PNS. This second neuron sends its axon to an effector cell, where it alters that cell's function. These neurons control smooth muscles, cardiac muscle, and glands.

The efferent nerves of the autonomic system are subdivided into the sympathetic and parasympathetic divisions (Figure 42.8). Both divisions of the autonomic system act on the same organs and usually have opposing actions. The **sympathetic division** is responsible for rapidly activating systems that prepare the body for danger or stress. Imagine, for example, the physiological responses that would occur if a person was hiking and came upon a grizzly bear. This is the **fight-or-flight** response, which is characterized by increased heart rate, stronger pumping action of the heart, relaxed (opened) airways and faster breathing, inhibition of digestive activity, increased blood flow to skeletal muscles, and increased secretion of energy-supplying substances such as glucose and fats into the blood by the liver and adipose tissue. These features prepare us to confront (fight) or avoid (flight) a perceived threat.

The **parasympathetic division** of the autonomic nervous system is involved in maintaining and restoring body functions. It is active during restful periods or after a meal, which is why it is sometimes said to mediate the **rest-or-digest** response. Neurons of the parasympathetic division promote digestion and absorption of food from the gut, slow the heart rate, and decrease the amount of fuel supplied to the blood from the liver and adipose tissue. A summary of these and other major functions of the two divisions of the autonomic nervous system can be found in Figure 42.8.

The Hindbrain Is Important for Homeostasis and Coordination of Bodily Functions

Let's now turn our attention to the structure and function of the human brain (Figure 42.9). We will begin with the evolutionarily oldest structures of the brain, some of which are located in the hindbrain and control the basic processes that sustain life.

Medulla Oblongata The medulla oblongata is located between the pons and the anterior part of the spinal cord. It

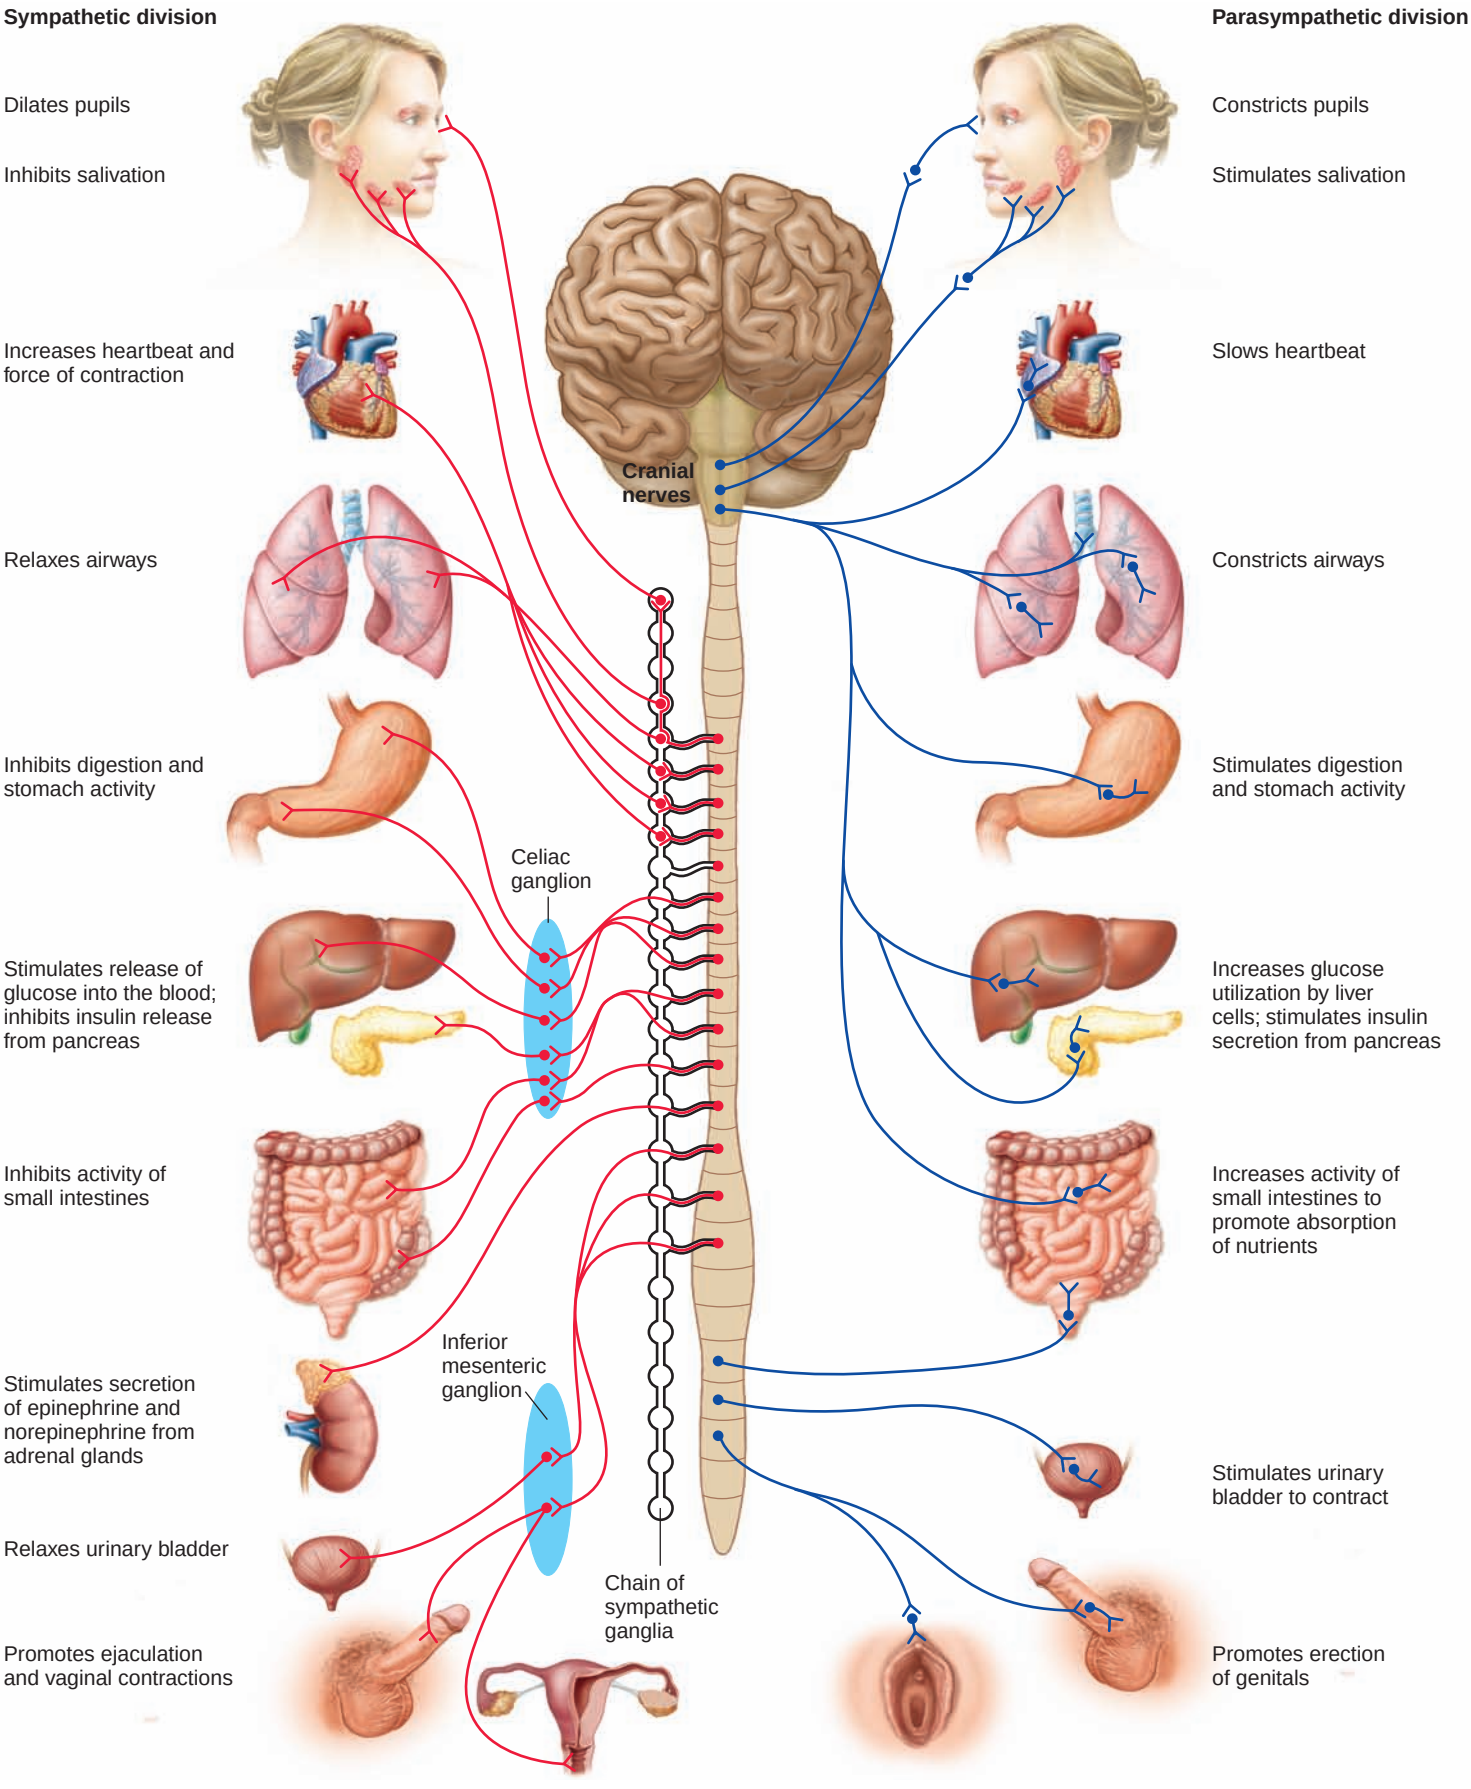

Figure 42.8 **Sympathetic and parasympathetic divisions of the autonomic nervous system.** For simplicity, only some of the major functions of each division are shown in this figure. The sympathetic and parasympathetic systems tend to have opposite effects, and most parts of the body receive inputs from both divisions. Nerves from the sympathetic division make connections with a chain of ganglia, most but not all of which are alongside the spinal cord. Nerves from the parasympathetic division make connections in ganglia near or in their targets (for clarity, the ganglia are only shown near the targets).

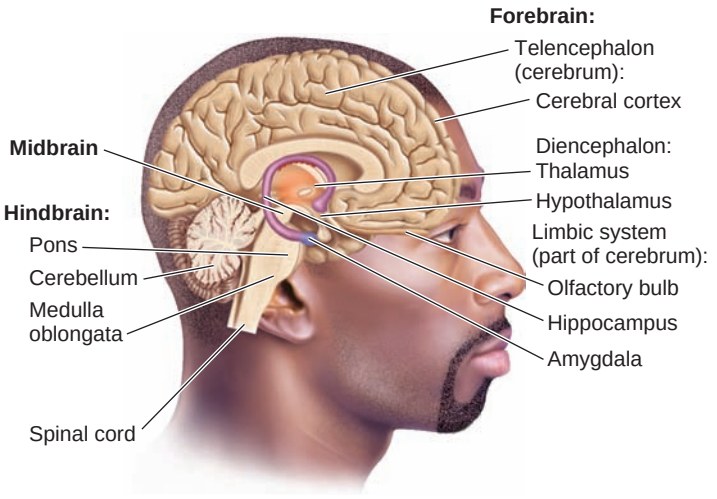

Figure 42.9 **Major structures of the human brain.** An overview of the brain, showing many internal structures (not all structures are visible in this plane, such as the basal nuclei). The limbic system consists of the olfactory bulbs, amygdala, and hippocampus, which are part of the telencephalon (many neuroscientists consider parts of the thalamus and hypothalamus as part of the limbic system). The midbrain, pons, and medulla oblongata collectively comprise the brainstem.

Concept check: *If a person received an injury to the cerebellum, how would that affect his or her behavior?*

coordinates many basic reflexes and bodily functions that maintain the normal homeostatic processes of a person. It is involved in the control of heart rate, breathing, cardiovascular function, digestion, swallowing, and vomiting, and gives rise to several of the cranial nerves.

Cerebellum and Pons The cerebellum, a large structure that sits dorsal to the medulla oblongata, receives sensory inputs from the cerebral cortex and the auditory and visual areas of the brain. It also receives inputs from the spinal cord that convey information about the position of joints and the contraction or relaxation of muscles. The overall function of the cerebellum is to maintain balance and coordinate hand-eye movements. The cerebellum controls the use of multiple muscles at one time and synchronizes motor activities such as typing, making a jump shot in basketball, or touching the fingers to the tip of the nose with your eyes closed. When the cerebellum is damaged, such as in an accident, people find it difficult to maintain balance and fine-tune motor functions. Reaching for a glass filled with water, for example, might result in spilling some of the water while bringing the glass to the mouth. Although historically scientists have thought that the cerebellum does not play a role in learning, memory, and conscious thought, recent evidence has strongly suggested that the cerebellum may indeed have significant cognitive functions, the full extent of which remains to be discovered.

The pons sits anterior to the medulla oblongata and beneath the cerebellum. Major tracts pass through the pons into and out of the cerebellum, so the pons serves as a relay between the cerebellum and other areas of the brain. In addition to this integrative motor function, the pons contains nuclei that play a very important role in regulating the rate and depth of breathing. The pons also gives rise to some of the cranial nerves.

The Midbrain Processes Sensory Inputs

The midbrain lies anterior to the pons. It processes several types of sensory inputs, including vision, olfaction, and audition. It has tracts that pass this information to other parts of the brain for further processing and interpretation. As one example, the midbrain is responsible for activating neural pathways that change the diameter of the pupil of the eye in response to a change in the amount of ambient light. If the midbrain were damaged, this pupilary reflex would not occur normally or at all.

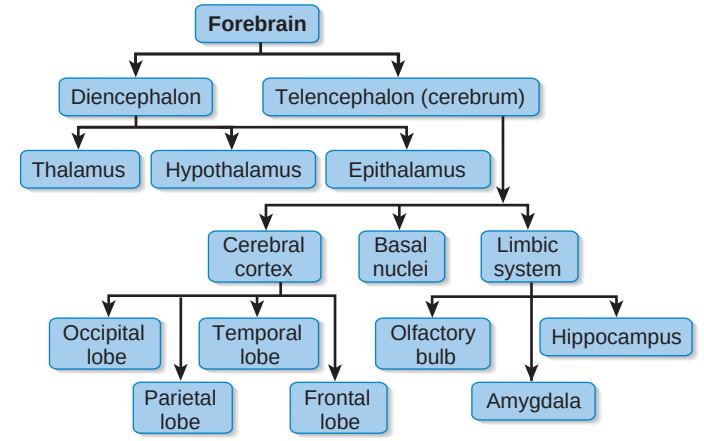
The medulla oblongata, the pons, and the midbrain collectively comprise the **brainstem**. In addition to the functions just described, all three major parts of the brainstem contain additional nuclei that together form the **reticular formation**. This is a network-like pathway that extends throughout much of the brainstem and that maintains and controls alertness and sleep, plus essential functions such as regulation of the respiratory and cardiovascular systems. Because of the importance of the brainstem's functions, damage to it is catastrophic and may result in coma or death.

The Forebrain Is Responsible for Movement, Sensory Function, and Higher Functions of Thought, Learning, and Emotion

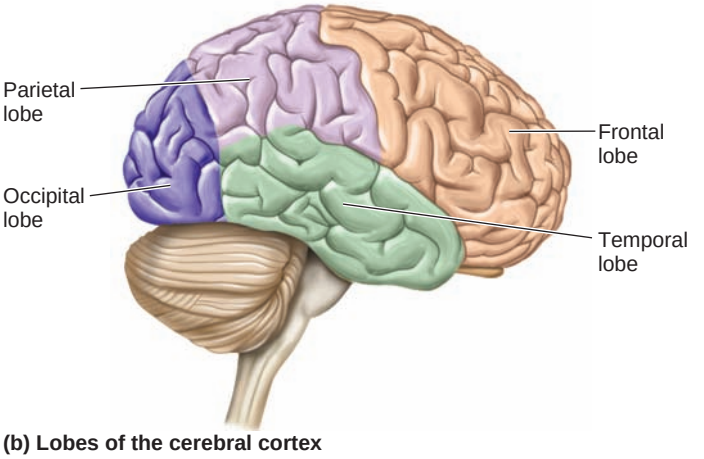
As mentioned, the diencephalon and the telencephalon (cerebrum) comprise the forebrain (Figure 42.10a). The diencephalon is made up of the thalamus, hypothalamus, and epithalamus. The cerebrum consists of the basal nuclei, limbic system, and cerebral cortex.

Diencephalon In vertebrates, the thalamus plays a major role in relaying sensory information to appropriate parts of the cerebrum and, in turn, sending outputs from the cerebrum to other parts of the brain. It receives input from all sensory systems except olfaction. The thalamus is organized according to the type of sensation. For example, certain parts of the thalamus process visual inputs, while other parts process sounds. One type of processing performed by neurons in the thalamus is that of filtering out sensory information in a way that allows us to pay attention to important cues while temporarily ignoring less important ones. A good example of this occurs when you focus on what someone is saying to you in a crowded room, with background sounds, sights, and activities that could otherwise be distracting. The thalamus also directs outgoing motor instructions that it receives from the cerebral cortex, sending directions to the spinal cord to generate voluntary movements, and is involved in the perception of pain and the degree of mental arousal in the cerebral cortex.

The hypothalamus, located below the thalamus at the floor of the forebrain, controls functions of the gastrointestinal and reproductive systems, body temperature (thermoregulation), and many basic behaviors such as eating and drinking. This area has



(a) Forebrain hierarchy



(b) Lobes of the cerebral cortex

Figure 42.10 The human forebrain. (a) Relationships of the various parts of the forebrain. (b) The four lobes of the cerebral cortex as seen on the right hemisphere.

great importance for homeostasis of the body and the control of behavior. Though small in size, it is composed of many nuclei, each with its own vital function. A major role of the hypothalamus is the production of hormones, which travel to the pituitary gland located just beneath the brain. The pituitary gland, in turn, regulates hormone secretion from other glands in the body, including the thyroid, gonads, and adrenal glands. In addition to producing hormones, the hypothalamus is sensitive to their actions. For example, certain hormones produced by cells in the stomach, intestine, adipose tissue, gonads, and elsewhere act within the hypothalamus to facilitate the expression of feeding, drinking, sexual, and aggressive behaviors. Finally, a small pair of hypothalamic nuclei called the suprachiasmatic nuclei acts as the "master clock" of the CNS, establishing circadian rhythms, which control the expression of behavioral, physiological, and hormonal rhythms over the 24-hour day.

The epithalamus is a collection of structures that have various roles in the production of cerebrospinal fluid, control of food and water intake, and rhythmic and seasonal behaviors in some vertebrates. One of these structures, the pineal gland, is located in the center of the brain and secretes a hormone called **melatonin** into the blood. Production of melatonin is regulated by the length of the light period in each day, and, partly for this reason, melatonin is believed to be a key factor in determining seasonal reproductive behaviors in certain mammals (for example, sheep and hamsters). The function of melatonin in humans in still debated but has been suggested to play a role in daily cycles such as our sleep/wake rhythm.

Telencephalon (Cerebrum) As mentioned, the cerebrum consists of the basal nuclei, limbic system, and cerebral cortex. For historical reasons, the **basal nuclei** are also called the basal ganglia, though the term ganglia in vertebrates normally refers to structures in the PNS. The basal nuclei are a group of nuclei that surround the thalamus and lie beneath the cerebral cortex. Like the cerebellum, the basal nuclei are involved in planning, learning, and fine-tuning movements. They also function via a complex circuitry to initiate or inhibit movements.

Parkinson disease (formerly called Parkinson's disease), a common neurological disorder that affects the basal nuclei, provides a good illustration of the function of these nuclei. People with Parkinson disease have trouble initiating movement, such as beginning to move their legs when they wish to walk. They are capable of walking once movement has begun, but they move slowly with muscle tremors and a shuffling, jerky gait. These symptoms result from the gradual deterioration of dopamine-releasing neurons in an area of the midbrain called the substantia nigra, the neurons of which send axons to the basal nuclei. People in the early stages of Parkinson disease can be treated with L-dopa, a molecule that enters the blood and travels to the basal nuclei. There, axon terminals from cells originating in the substantia nigra take up the L-dopa and convert it into dopamine, which is then released onto cells of the basal nuclei. L-dopa, therefore, substitutes for dopamine and reduces the Parkinson symptoms.

The **limbic system** refers to a collection of evolutionarily older structures that form an inner layer at the base of the forebrain. These include structures such as the **olfactory bulbs** (which process information about smells), **amygdala**, and **hippocampus**. Many neuroscientists also consider parts of the diencephalon as part of the limbic system, because of the extensive connections between these regions. The limbic system is primarily involved in the formation and expression of emotions, and it plays an important role in learning, memory, and the perception of smells. The expression of emotions occurs early in childhood before the more advanced functions of the cerebral cortex are evident. Thus, even very young babies can express fear, distress, and anger as well as bond emotionally with their parents.

Deep within the ventral part of the brain, the amygdala is one of the areas critical for understanding and remembering emotional situations. This area also is involved in the ability to recognize emotional expression in others. Emotions are not unique to humans, however, and are clearly present in other primates and mammals. Being able to express and detect emotions imparts a selective advantage by enabling animals to establish and maintain relationships. Emotions such as fear help an animal defend itself against danger by avoiding conflict. Likewise, anger is associated with aggression, a key behavior by which many animals defend themselves or their territories.

Adjacent to the amygdala and forming a loop within the medial regions within the brain, the hippocampus is composed of

several layers of cells that are connected together in a circuit. Its main function appears to be establishing memories for spatial locations, facts, and sequences of events. Damage to certain parts of the hippocampus in humans results in an inability to form new memories, a devastating condition that prevents recognition of other people or even an awareness of daily events. Experiments with laboratory animals have also demonstrated the importance of the hippocampus for memory and learning in other mammals. In a particularly well-studied example, rats are placed into a pool of milky water containing a hidden platform. The animals swim until they find the platform, on which they can safely stand. The time it takes to find the platform in subsequent trials is shorter as they learn and remember its whereabouts. This type of spatial learning depends on activity in the hippocampus. Rats with parts of their hippocampus destroyed fail to improve their times with repeated trials. The hippocampus also receives extensive inputs from the olfactory bulbs, which may explain why smells are such potent triggers of memory in humans and why many animals use their sense of smell as a major way to learn and remember aspects of their environments.

As mentioned earlier, the cerebral cortex is the surface layer of gray matter that covers the cerebrum (see Figure 42.6). The **neocortex** (from the Greek, meaning new cortex), the layer that evolved most recently in mammals, has six layers of cells organized in rows and columns. Neurons within and between layers are connected to form circuits, which integrate information from other nervous system structures and create outgoing signals that reflect that integration. Evolutionarily older parts of the cerebral cortex, including areas involved in processing the sense of smell, have fewer layers. Although the cerebral cortex is only a few millimeters thick, it contains about 10% of all the neurons in the human brain.

The brain has two halves, or **hemispheres**. The cerebral cortex is divided into four lobes in each hemisphere: the frontal, parietal, occipital, and temporal lobes (Figure 42.10b). Each lobe has a number of functions, many of which are still being actively investigated by researchers. Among other things, the **frontal lobe** is important for voluntary initiation of movement, decision making, controlling impulses, making plans, and exhibiting judgment and for conscious thought and social awareness. The **parietal lobe** receives and interprets sensory input from visual pathways and somatic pathways, including those from the surface of the body. In addition, the parietal lobe plays an important role in spatial awareness, that is, our ability to use visual cues to orient ourselves in space. The **occipital lobe** controls many aspects of vision and color recognition. The **temporal lobe** is necessary for language, hearing, and some types of memory.

One particularly interesting aspect of temporal lobe activity that illustrates the subtle functions of the various lobes is the recognition of objects and people. One area of the temporal lobe contains neurons known as face cells that are activated specifically in response to seeing faces. Electrical activity of individual cells within the temporal lobe of rhesus monkeys increases when the monkey views human and monkey faces, though not when looking at other images. Humans who have damage to that area are unable to recognize other people by their faces even if they knew them before the brain damage occurred. Fortunately, these patients can recognize other traits such as gait or tone of voice, which they use to identify the people in their lives. Scientists do not know whether face cells are active in nonprimate mammalian species.

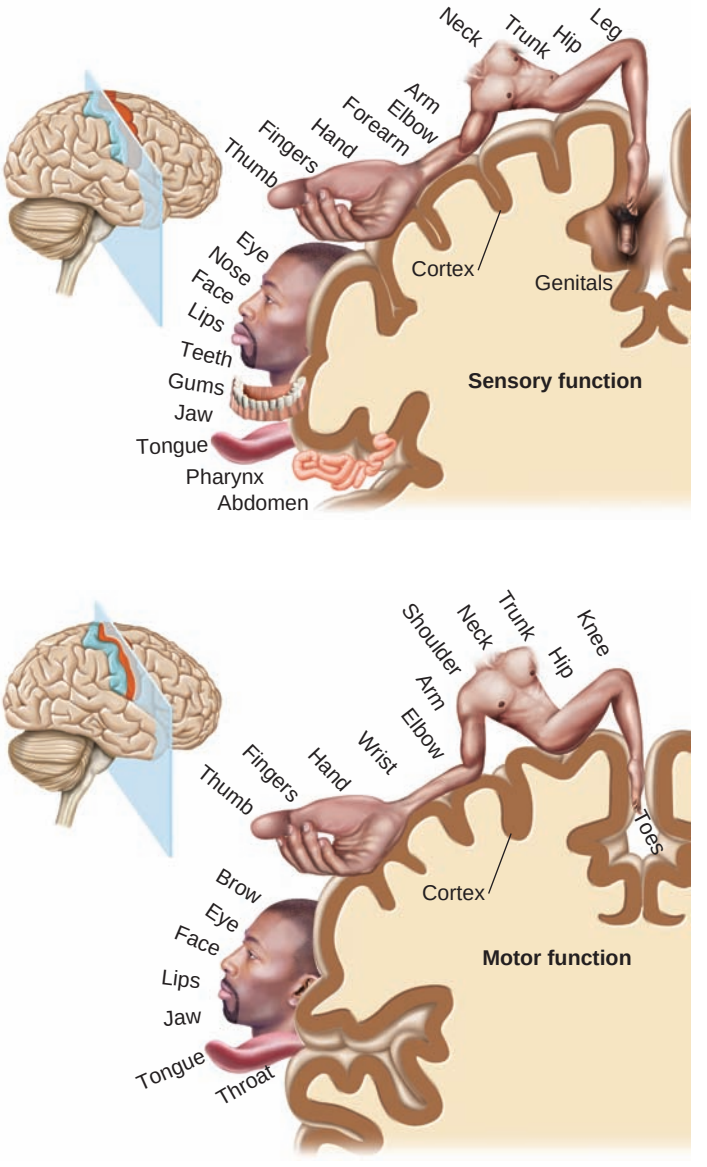


Figure 42.11 Homunculus maps of human body parts along the cerebral cortex. These maps represent how the cortex interprets sensory information from these body parts and controls body movements of these parts (motor function). The relative sizes of body parts reflect the relative amount of cortex devoted to them.

An amazing finding is that sensory inputs enter and motor outputs exit the cerebral cortex in a pattern that forms a sort of map of the body, often depicted as a homunculus (from the Latin, meaning little man) (Figure 42.11). The amount of space in the cerebral cortex assigned to a particular part of the body is proportional to either the degree of sensory sensitivity of that body part or the number of muscles required for its movement. For instance, a larger part of the cerebral cortex is devoted to the lips than to other areas of the face. The lips have more nerve endings and are more sensitive to touch than these other areas. Other cortical functions are also mapped in this way; for example, a map that reflects different sound frequencies (the pitch of

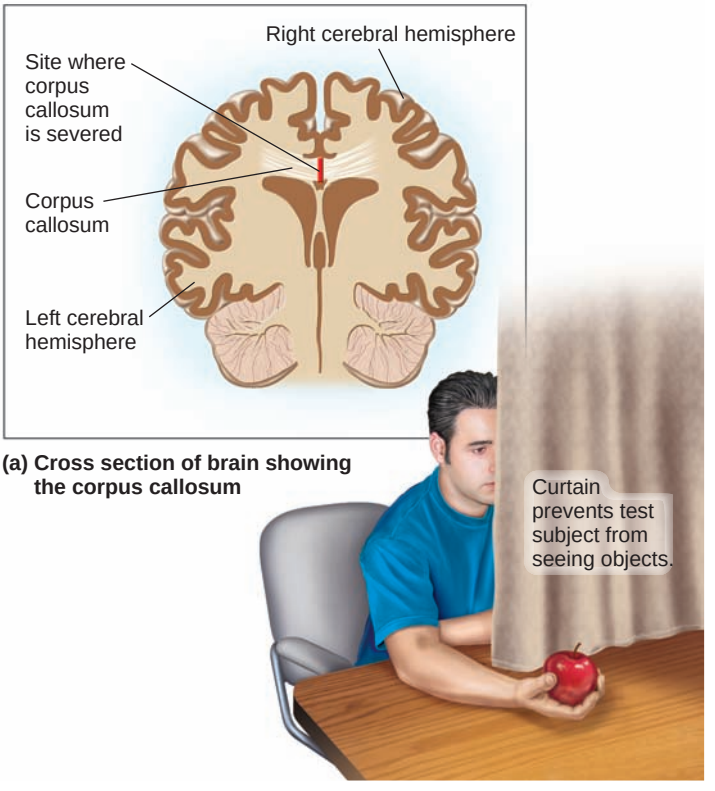
Table 42.1 Major Functions of Brain Regions in Humans

Region		Major Functions
Hindbrain		
	Medulla oblongata and pons	Coordinate homeostatic functions such as breathing, heart rate, digestion; form part of reticular formation that controls sleep and alertness; give rise to cranial nerves
	Cerebellum	Fine tuning of complex body movements; maintenance of balance
Midbrain		Processes visual, auditory, and olfactory sensory inputs; forms part of reticular formation
Forebrain		
	Thalamus	Routes sensory information (except olfaction) to discrete parts of cerebrum; filters irrelevant sensory information; directs outgoing motor information from cerebral cortex to spinal cord; involved in pain perception and mental arousal
	Hypothalamus	Regulates activities of gastrointestinal and reproductive systems; controls function of pituitary gland; regulates body temperature, appetite, thirst, aggressive behavior, sexual behavior, and body rhythms
	Epithalamus	Produces cerebrospinal fluid; plays a role in food and water intake; contains the pineal gland, which may regulate sleep/wake and body rhythms
	Basal nuclei	Planning, fine-tuning, initiating, inhibiting and learning movements
	Limbic system	Formation and expression of emotions; perception of odors; learning and memory
	Cerebral cortex	Voluntary motor control; perception of sensory inputs; attention; integration of sensory and motor information; generation of speech; decision-making, impulse control, judgment, and planning; conscious thought; learning, memory, and emotion

sound) exists in the temporal lobes. The organization of the cerebral cortex may not be permanent, however, because the map may change depending on the amount of use or disuse of a given part of the body, as discussed in the Feature Investigation later in this chapter. Some of the major functions of the hindbrain, midbrain, and forebrain are summarized in Table 42.1.

Cerebral Hemispheres As mentioned, one of the most recognizable features of the surface of the cerebrum is its division into two hemispheres. Each hemisphere is connected to the other by a major tract called the **corpus callosum** (Figure 42.12a). In the 1950s, American neuroscientists Roger Sperry and Ronald Meyers examined the separate functions of the hemispheres in laboratory animals by performing split-brain surgeries in which they severed the corpus callosum. The animals that underwent such surgery maintained their overall health and functioning; therefore, the surgery was considered safe for humans. This became important in 1961, when the procedure was used for the first time to treat patients with severe epilepsy, a disorder characterized by uncontrolled electrical activity that begins in one place in the brain and can spread via the corpus callosum to the other side. Cutting the connection between the hemispheres reduced the severity of epileptic seizures.

Split-brain surgery also provided an opportunity for the researchers to make critical observations that could not be made in laboratory animals. Split-brain humans generally show normal behavior and intellectual function, because both hemispheres can function fairly independently. However, psychological tests revealed that the two sides of the brain process different types of information. One study demonstrated that the



(a) Cross section of brain showing the corpus callosum

(b) Testing of split-brain patient

Figure 42.12 **The hemispheres of the human brain.** **(a)** The cerebral hemispheres and their connection by the corpus callosum. (Note: The left hemisphere controls the right side of the body, and the right hemisphere controls the left side.) **(b)** Split-brain patient being tested for hemispheric dominance. By using this apparatus, Roger Sperry and his collaborators showed that the left and right cerebral hemispheres have different capabilities. When a split-brain patient held an object in his right hand but could not see it or touch it with his left hand, he could give it a name (for example, an apple). When he held another object in his left hand, he could describe it (for example, smooth), but could not name it.

Concept check: *With her eyes closed, a split-brain patient was given a rock to hold, and she described it as a rock. Which hand was it in?*

left hemisphere produces a descriptive word for an object but does not identify certain characteristics of that object, such as its shape and texture (Figure 42.12b). The right hemisphere, in contrast, cannot use words to name the object but can identify other qualities. The studies of Sperry, Meyers, and other neuroscientists have concluded that the left hemisphere is involved in understanding language and producing speech in most people. Therefore, the left hemisphere is said to be dominant for those functions. The right hemisphere is dominant for nonverbal memories, recognizing faces, and interpreting emotions. In 1981, Sperry received the Nobel Prize for his insight regarding specialization in each hemisphere of the brain.

Although not unique to humans, the cerebral cortex is one of the defining features of the human brain, because it is responsible for much of what we call our individual personalities. Researchers are now beginning to understand the molecular mechanisms by which this important brain structure develops, as we see next.

Genomes & Proteomes Connection

Several Genes Have Been Important in the Evolution of the Cerebral Cortex

A number of genes are known to be involved in the development of the cerebral cortex. Some have been identified by examining genetic mutations in developmentally disabled individuals, and others by comparing human genes with genes known to be involved in brain development in other species such as *Drosophila*. Researchers have also compared these genes in many species that show notable differences in cerebral structure. This last approach can determine whether a relationship exists between the expression of a particular gene and the organization of the cerebral cortex.

One inherited disorder that involves abnormal development of the cerebral cortex is polymicrogyria (from the Greek, meaning many small folds), which results in mental impairment as well as disrupted gait and language production. In people with this disorder, the cerebral cortex is characterized by multiple abnormal surface folds and fewer layers of cells. One type of polymicrogyria is a recessively inherited condition for which eight different mutations of a single gene are known. This gene, called *GPR56*, encodes a G-protein-coupled receptor (described in Chapter 9), which has large extracellular loops. All eight mutations that produce polymicrogyria alter these extracellular loops of the receptor, and scientists think that this alters the ability of the G-protein-coupled receptor to bind its ligand.

Two other genes, called microcephalin or *MCPH1* (from the Greek, meaning small head) and *ASPM* (*abnormal spindle-like microcephaly-associated gene*), have been shown to be determinants of brain size and thus are possibly involved in the evolution of brain size. For example, mutations of these genes in the human population produce individuals with much smaller frontal lobes. Interestingly, the sequences of these genes in several primates, including humans, as well as in other mammals such as dogs and sheep, have shown that the proteins produced by the normal *MCPH1* and *ASPM* genes have undergone greater changes in humans and great apes than in other species. Therefore, these genes may have been under greater selection pressure in animals with larger cerebral cortexes, suggesting that the genes play a key role in cerebral cortex development.

42.3 Cellular Basis of Learning and Memory

In the past few decades, an exciting advance in neuroscience has occurred—researchers have begun to understand complex behaviors, such as learning and memory, at the cellular level. Though it is difficult to separate the two concepts, **learning** can be defined as the process by which new information is acquired. Learning is an evolutionary adaptation that allows past experiences to affect ongoing and future behavior. **Memory** is the ability to retain, retrieve, and use information that was previously learned. Memory connects our experiences throughout life. Our behavior is largely controlled by what we have learned and remember from past experiences. Neuroscientists want to understand how the brain learns and how it captures memories. In this section, we will examine some current ideas about how this may be achieved at the cellular level and consider experimental approaches that neuroscientists follow when investigating such complicated phenomena.

Learning and Memory Occur via Changes Within Neurons and Their Connections with Each Other

Beginning in the 1960s, research along two fronts led to key insights regarding the cellular basis of memory. Norwegian neuroscientist Terje Lomo and British researcher Timothy Bliss focused their efforts on the hippocampus. As described earlier, this is a key region of the brain involved with learning and memory. Lomo and Bliss conducted experiments on anesthetized rabbits in which they monitored signal transmission across particular regions of the hippocampus. Their key discovery involved the effects of multiple stimuli. Experimentally, a series of short, electrical stimulations to a neuron was shown to strengthen, or potentiate, its communication at a synapse with an adjacent cell for minutes or hours. Such multiple stimuli caused neurons to communicate more readily; responses were stronger and more prolonged. This phenomenon was termed **long-term potentiation** (**LTP**). LTP is the long-lasting strengthening of the connection between neurons. Later work showed that LTP occurs naturally in the hippocampus and can last from hours to days, and even years.

Austrian neuroscientist Eric Kandel also was interested in learning and memory, and some of his early studies involved the hippocampus. In the 1960s, however, he took a different approach by studying learning and memory in a simpler organism called the California sea slug or sea hare (*Aplysia californica*). He chose this organism for several key reasons. First, it has only about 20,000 neurons, making it easier to identify pathways that are

involved in specific types of behavior. Second, some of the neurons in this organism are extremely large, allowing the study of action potentials via microelectrodes (as described in Chapter 41). In addition, the large size of the neurons made it possible to inject substances into them and study their effects. Finally, another major advantage is that Kandel and colleagues could isolate proteins and mRNA from these large neurons and identify the biochemical and genetic changes that occur when the animal learns about its outside world and retains memory.

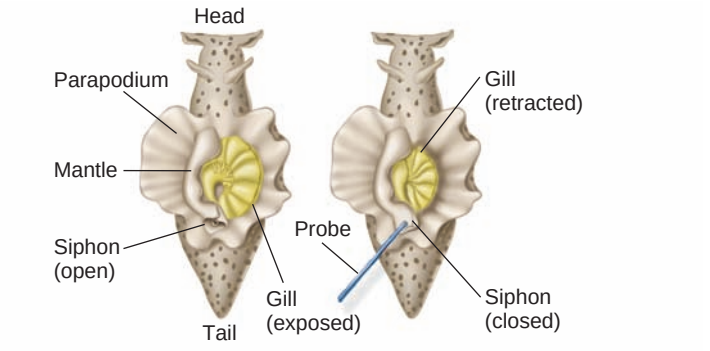
Much of Kandel's work focused on one type of learning involving the gill-withdrawal reflex, which is thought to involve less than 100 neurons in the CNS. The gill and siphon are organs involved in respiration, located in the animal's mantle cavity and protected by muscular appendages called parapodia (Figure 42.13a). When the siphon is gently touched with a fine probe, the sea slug closes the siphon and retracts its gills into the mantle cavity for protection (Figure 42.13b). Though called a reflex, this behavior is subject to learning. For example, if the touching of the siphon is accompanied with a brief electrical shock to the tail, the sea slug can learn to withdraw its gill in response to a subsequent shock without the siphon being touched. This is similar in some ways to the famous conditioning experiments of Ivan Pavlov, described in Chapter 40. Interestingly, a single tail shock paired with a touch of the siphon will result in conditioning that lasts for a few minutes. Amazingly, though, multiple trials over several days result in a lasting memory—a shock given three weeks later (without siphon touch) still results in the gill-withdrawal reflex!

Over the course of many years, the work of Kandel and colleagues revealed many clues regarding the cellular basis of learning and memory. As in vertebrates, these processes in the sea slug occur in two phases, short-term and then long-term memory (Figure 42.14). Short-term memory lasts for minutes or hours. This type of memory is typically caused by a single stimulus. Kandel found that short-term memory does not require the synthesis of new proteins. Rather, a single stimulus activates intracellular second messenger pathways that make it easier for neurons involved in a particular behavior to communicate with each other. For example, as shown in Figure 42.14a, a single stimulus may lead to the activation of protein kinases such as protein kinase A in the presynaptic (sensory) cell. Protein kinase A, in turn, can phosphorylate proteins such as ion channels and proteins involved with the release of neurotransmitter. These changes enhance the transmission of a signal between the presynaptic and postsynaptic cells.

Kandel and colleagues also discovered that repeated stimuli result in long-term memory, which lasts days or weeks. Such repeated stimuli require the synthesis of new proteins (Figure 42.14b). Long-term memory involves the activation of genes in the presynaptic cell, which leads to the synthesis of mRNA and the translation of the encoded proteins. Once made, such proteins cause the formation of additional synaptic connections. These connections also allow the presynaptic and postsynaptic cells to communicate with each other more readily. Such a change in synapses, which occurs as a result of learning, is termed **synaptic plasticity**.

Kandel's work provides a foundation for our ability to understand how learning and memory may occur at the cellular level. Short-term memory may involve changes in pre-existing cellular proteins that make it easier for neurons to communicate. Long-term memory results in protein synthesis that causes physical changes in the synapse itself, also affecting communication. Later studies by Kandel and others showed that such changes also occur in vertebrates such as the mouse. For his work on learning and memory, Kandel was awarded the Nobel Prize in Physiology or Medicine in 2000.

(a) Sea slug



(b) Gill-withdrawal reflex

Figure 42.13 **The gill-withdrawal reflex in the sea slug.** **(a)** Photo of *Aplysia californica* in its natural habitat; note the parapodium and tail. **(b)** When touched with a probe, the siphon closes and the gill retracts. In this drawing, the parapodia are moved apart for a better view of the gill.

Neurogenesis May Also Contribute to Learning and Memory

Until fairly recently, neuroscientists had thought that the adult brain of vertebrates was incapable of **neurogenesis**—the production of new neurons by cell division. In 1983, a study showing neurogenesis in an adult vertebrate was carried out by Fernando Nottebohm and colleagues. Their research revealed an increase in the number of neurons in certain brain areas of the canary arose during mating season. In the late 1990s, evidence also showed that the primate and human CNS, like other parts of the body, contain stem cells (see Chapter 19). American researchers Elizabeth Gould and Bruce McEwen have demonstrated the appearance of new neurons in the hippocampus and olfactory bulbs of adult marmosets and rhesus monkeys. In 1998, American researcher Fred Gage and Swedish physician Peter Eriksson made a key discovery: They found new hippocampal cells in the brains of recently deceased adult cancer patients. Those patients

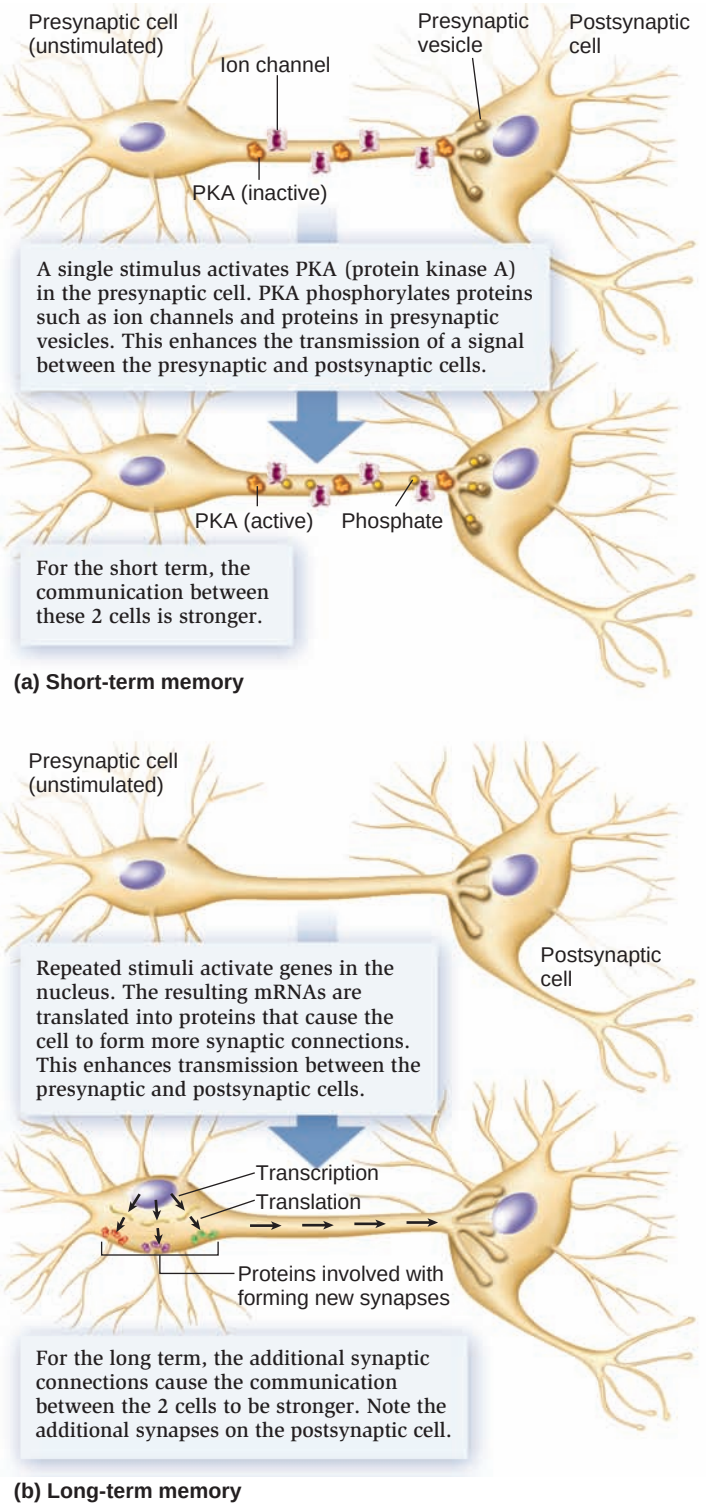


Figure 42.14 Cellular changes associated with short-term and long-term memory in the sea slug.

had previously been treated with bromodeoxyuridine (BrdU) to combat their cancer. BrdU is also taken up by noncancerous cells, but only those that are actively dividing. Its presence in cells can be detected with special stains on sections of brain and other tissue. Gage conducted such staining procedures on the brains of the deceased patients and observed the presence of BrdU in the hippocampus, demonstrating recent neurogenesis.

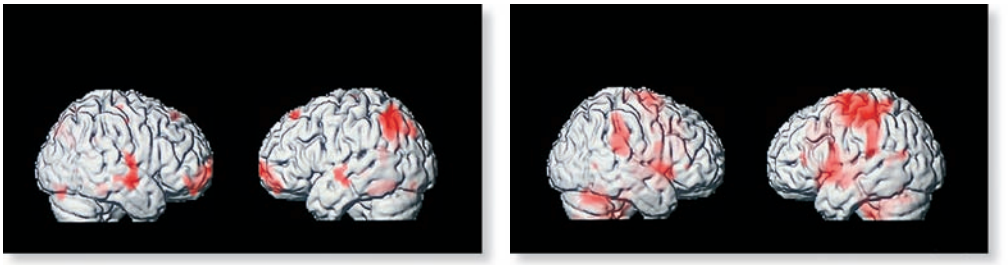
A key question is whether the neurogenesis observed in adult brains is involved in learning and memory. This question is hotly debated and not resolved. However, some evidence suggests that it could play a role. For example, McEwen and coworkers have shown that the hippocampus of adult rhesus monkeys grows new neurons when the animals are placed in enriching environments, and the formation of these neurons slows when animals are chronically stressed. Also, studies in the rat by Gould and colleagues suggested that new neurons are retained in the hippocampus in response to training in particular tasks that require hippocampus function.

Brain Images Are Used to Assess Brain Structure and Function

Because of the enormous number of neurons and connections between neurons in the vertebrate brain, a key challenge in neuroscience is to understand how such complexity results in sophisticated forms of learning, memory, and responses to environmental conditions. Several imaging techniques allow doctors and researchers to examine the structure and activity level of the brain without anesthesia or surgery. The earliest technique to be developed was computerized tomography (from the Greek *tomas*, meaning a cutting). A **CT scan** involves the use of an X-ray beam and a series of detectors that rotate around the head, producing slices of images that are reconstructed into three-dimensional images based on differences in the density of brain tissue. CT scans can easily visualize the ventricles and differences between white and gray matter, but they cannot examine the brain in great detail.

A more sensitive method, called **magnetic resonance imaging** (**MRI**), was developed in the 1980s. The patient's head is placed in a device that contains a magnet powerful enough to generate a magnetic field many thousands of times greater than that of the Earth. This stabilizes the spinning, or resonance, of atomic nuclei (usually hydrogen atoms in water molecules) so that most of the nuclei align with the magnetic field. When body tissue is stimulated with a beam of radio waves, its atoms absorb the energy of the waves and the resonance of their nuclei changes, thereby altering their alignment with the magnetic field. When the radio wave pulse stops, the atoms release their energy, which is recorded by a detector. This information is analyzed by a computer, and an image is produced. MRI images allow detection of structures as small as one-tenth of a millimeter. For example, they can provide information about abnormal tissue, such as brain tumors, which respond to magnetic and radio frequency pulses differently than normal tissue. MRIs are widely used in medicine to check for injured tissue, cancers, and other abnormalities throughout the body. In 2003, Paul Lauterbur and Peter Mansfield received the Nobel Prize in Medicine for their work in developing this method.

With certain modifications, MRI can be used to assess the functional activity of areas within the brain. This technique, which is widely used by neuroscientists, is called **functional MRI** (**fMRI**). It takes advantage of the observation that blood flow, and therefore oxygen delivery, increases to areas where neurons are more active. This increase in oxygenation is detected via



(a) Brain activity of a person thinking about a task that requires finger movements

(b) Brain activity when the same person is performing this task

Figure 42.15 **Exploring the functional activity of brain regions using fMRI scans.** Red color indicates higher O_2 use.

Concept check: *What can we conclude from part (a) about the metabolic cost of thinking?*

fMRI. In this way, fMRI determines which neurons in particular areas of the brain are active when an individual performs certain intellectual or motor tasks (Figure 42.15). The principle is similar to the standard MRI, except that the higher oxygen content of active tissue alters the resonance of local hydrogen atoms.

The use of fMRI has revealed many fascinating aspects of the activities of different brain regions, notably in people who have suffered brain damage or loss of sensory inputs. For example, individuals who are blind from birth might be predicted to have occipital lobes that are less functional or active than are those in sighted persons (recall that the occipital lobes play the major role in visual processing). However, the work of American researcher Harold Burton and others has revealed with fMRI that the occipital lobes of blind persons are active but have become adapted to other sensory functions such as tactile signals from the fingers, including those arising from Braille reading. Amazingly, this reassignment of occipital function occurs to some extent even in individuals who have lost their vision later in life. Most likely, this does not represent a brand new function of the occipital lobes, but rather an expanded ability of an existing function that remains relatively minor in sighted persons.

The plasticity of the brain revealed by the work of Burton and coworkers is not restricted to clinical situations, as just described. MRI and fMRI are also revealing differences in brain structure and function in individuals due to the types of activities in which they engage, as described next.

Feature Investigation

Gaser and Schlaug Showed That the Sizes of Certain Brain Structures Differ Between Musicians and Nonmusicians

MRI and fMRI have been extremely useful in revealing which brain areas are involved in a particular function. They have also shown that the human brain is surprisingly adaptable. A number of studies have been carried out on musicians, because they practice extensively throughout their lives, enabling researchers to study the effects of repeated use on brain function.

American neuroscientist Christian Gaser and German neuroscientist Gottfried Schlaug used MRI to examine the sizes of brain structures in three groups of people—professional musicians, amateur musicians, and nonmusicians (Figure 42.16). Individuals were assigned to each group based on their reported history of musical training: professional musicians with over 2 hours of musical practice time each day, amateur musicians who played a musical instrument regularly but not professionally (practicing about 1 hour/day), and those who never played a musical instrument regularly. The researchers hypothesized that repeated exposure to musical training would increase the size of brain areas associated with visual, motor, and auditory skills, because each of these activities is used to read, make, and interpret music. The results showed that brain areas

Figure 42.16 **Gaser and Schlaug's study of the size of visual, motor, and auditory nuclei in the brains of musicians and nonmusicians.**

HYPOTHESIS Musical training is associated with structural differences in the brain.

KEY MATERIALS Volunteer subjects with different degrees of musical training.

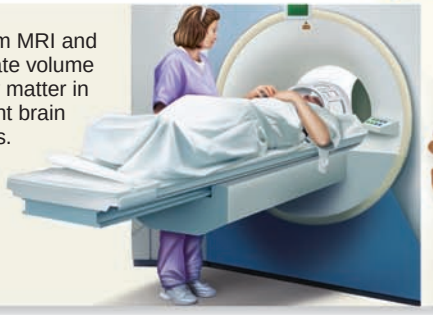
	Experimental level	Conceptual level
1 Establish 3 groups of subjects with different musical backgrounds.	Interview subjects for musical history and assign to 1 of 3 groups. 	**Controls (nonmusicians)** No musical training. **Amateur musicians** Play an instrument about 1 hr/day and are not employed as musicians. **Professional musicians** Employed as musicians and practice their instrument > 2 hr/day.

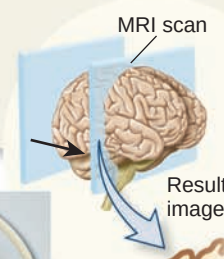
2 Control for possible factors that might affect results.

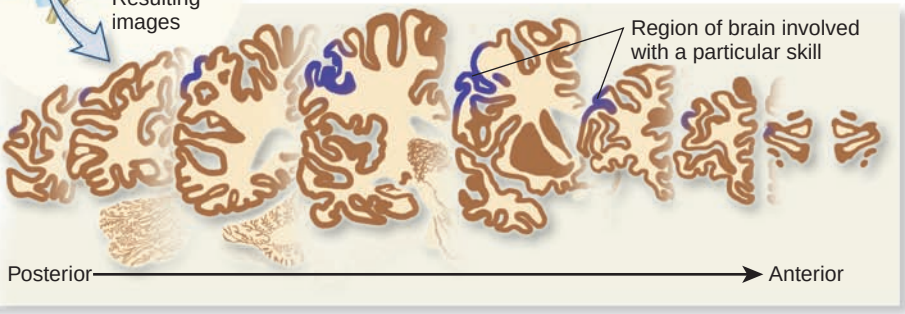
Make group assignments in a way that matches subjects' age and other characteristics.

	Controls	Amateurs	Professionals
Age (average)	23	26	27
Type of instrument	None	Keyboard	Keyboard
Mental IQ	119	123	118
Sex	Male	Male	Male

3 Perform MRI and calculate volume of gray matter in different brain regions.

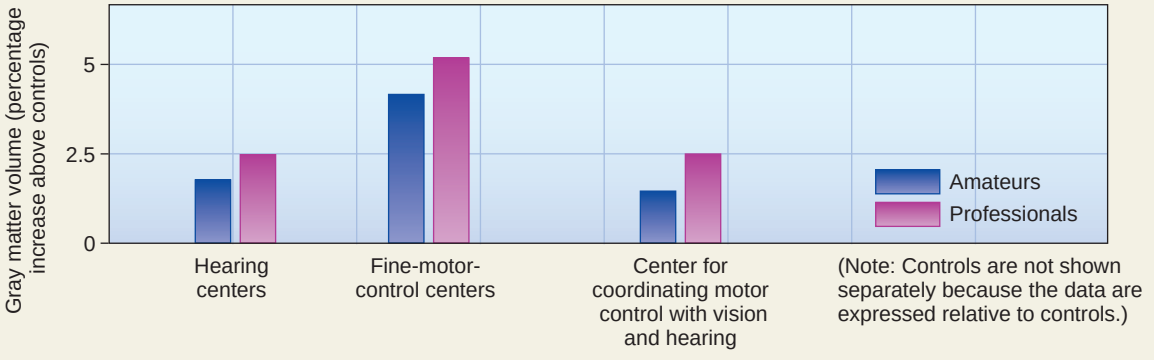






4 THE DATA

Results from step 3:



5 CONCLUSION Musical training is associated with increased volumes of brain regions involved in hearing, fine-motor control, and the coordination of motor and sensory information.

6 SOURCE Gaser, C., and Schlaug, G. 2003. Brain structures differ between musicians and non-musicians. *Journal of Neuroscience* 23:9240–9245.

involved in hearing, moving the fingers, and coordinating movements with vision and hearing were larger in professionals than in amateur musicians, and larger in amateurs than in nonmusicians. The region of the brain that controls finger movements was particularly well developed in the professional musicians, an interesting finding because all of the musicians in this study played keyboard instruments such as the piano.

In another study, American researchers Vincent Schmithorst and Scott Holland used fMRI to determine if musicians' brains were activated differently than nonmusicians' brains when they heard music. They found that one area of the cerebral cortex was selectively activated by melodies only in musicians. This study differed from that of Gaser and Schlaug, because Schmithorst and Holland examined the activity of brain areas as well as their sizes. Their results showed that listening to music activates certain neurons and pathways in the brains of musicians but not in nonmusicians.

The human studies of Gaser, Schlaug, Schmithorst, and Holland have not determined the underlying reason(s) for increased brain size. One possibility is that people with increased brain

size in these regions are more likely to become musicians. Alternatively, musical training may actually cause certain regions of the brain to grow larger and alter their neuronal pathways. In other research studies involving experimental animals, groups of animals have been randomly separated into those learning a task versus controls, which do not learn the task. Such experiments have shown increases in the size of brain regions that are associated with learning and memory. The increased size may result from formation of new synapses, growth of blood vessels to the region, and/or production of more glial cells.

Experimental Questions

1. What was the hypothesis proposed by Gaser and Schlaug?
2. How did Gaser and Schlaug test this hypothesis? What were the results of their experiment?
3. How did the research of Schmithorst and Holland impact the findings of Gaser and Schlaug? How did their experiments differ from that of Gaser and Schlaug?

42.4 Impact on Public Health

Most neurological disorders can be classified into several broad groups (Table 42.2). These disorders collectively affect hundreds of millions of people around the world. In addition to the conditions already discussed in this chapter and Chapter 41, we will consider two of these disorders, meningitis and Alzheimer disease, that result from very different causes and impact millions of individuals worldwide.

Table 42.2 Categories of Diseases Affecting the Human Central Nervous System

Category	Examples
Infectious diseases	Meningitis (discussed in this section), encephalitis
Neurodegenerative disorders	Alzheimer disease (discussed in this section)
Movement disorders	Parkinson disease (described in Section 42.2)
Seizure disorders	Epilepsy (described in Section 42.2)
Sleep disorders	Sleep apnea (brain fails to regulate breathing during sleep)
Tumors	Glioma (a tumor arising from glial cells)
Headache disorders	Migraines
Mood disorders	Major depressive disorder; bipolar depression (see Chapter 41)
Demyelinating disorders	Multiple sclerosis (see Chapter 41)
Injury-related disorders	Brain and spinal cord injuries due to accidents

Meningitis Is an Infectious Disease That Attacks the Meninges

An essential nonspecific response to infection is inflammation. This response increases the permeability of blood vessels in infected areas, allowing immune cells to be delivered to the site of an infection. When that infection occurs within the meninges (causing **meningitis**), fluid accumulates in the subarachnoid space. This accumulation compresses the underlying brain tissue, interrupting oxygen flow to the neurons of the cerebral cortex. If not corrected, the resulting loss of oxygen (and nutrients) cause neuronal death and the loss of function of brain regions associated with those neurons.

The initial symptoms of meningitis include severe headaches, fever, or seizures. Many patients with meningitis also develop a stiff neck because the inflammation proceeds down the spinal cord. If the infection progresses untreated, it may lead to unconsciousness and even death within hours.

Several different viruses or bacterial species can cause meningitis. It usually results from an untreated infection in neighboring regions, such as the sinuses behind the eyes, nose, or ears. Meningitis can be confirmed by using a long needle to sample the cerebrospinal fluid in the spinal cord and analyzing the pressure and contents of the fluid. Large numbers of white blood cells, which are the body's chief infection-fighting cells, indicate infection in the cerebrospinal fluid and meninges. If the infection is the result of bacterial invasion, meningitis can be treated with bacterial-killing agents such as antibiotics. Antibiotics do not kill viruses, but fortunately the viral form of meningitis is usually less serious than the bacterial form and runs its course after several days or weeks.

Meningitis strikes roughly 25,000 people a year in the U.S. and can affect people of any age. Its incidence in children has greatly declined since the widespread use of a vaccine against the bacterium *Haemophilus influenzae* began in the U.S. in the early 1990s. Despite the vaccine, meningitis is still a dangerous and prevalent disease worldwide, and it tends to occur in individuals living in close quarters, where infections may spread rapidly. Occasionally, meningitis can become epidemic. For example, 250,000 people in sub-Saharan Africa were infected and 25,000 died in 1996, and nearly 75,000 people in Southeast Asia died of meningitis in 2004.

Alzheimer Disease Impairs Memory, Thought, and Language

Alzheimer disease (**AD**) (formerly called Alzheimer's disease) is the leading cause of dementia worldwide. It is characterized by a loss of memory and intellectual and emotional function. AD is a progressive disease that begins with small memory lapses, leading in later stages to problems with language and abstract thinking, and finally to loss of normal motor control. The disease usually appears after age 65, though some inherited forms can strike people in their 30s and 40s.

Although psychological testing can help to diagnose AD, historically a definitive diagnosis is possible only after death when the brain is examined microscopically. Brains of Alzheimer

patients show two noticeable changes: senile plaques and neurofibrillary tangles (Figure 42.17). Senile plaques are extracellular deposits of an abnormal protein, β-amyloid, that forms large, sticky aggregates. These plaques were first noted in 1906 by German physician Alois Alzheimer, after whom the disease was named. Neurofibrillary tangles are intracellular, twisted accumulations of cytoskeletal fibers. Scientists are unsure how these changes influence intellectual function and memory. AD is also associated with the degeneration and death of neurons, particularly in the hippocampus and parietal lobes, which is why it is considered a neurodegenerative disease.

Researchers have identified variation in a few genes whose products are associated with the likelihood of developing AD later in life, but the underlying changes that result in the expression of these and other possible AD-related genes are still the subject of considerable research. Although genetics undoubtedly plays a role in AD, it is not the only possible cause. For example, when one identical twin develops AD, the other appears to be at increased risk but does not always develop the disease, even if he or she survives to very old age. Moreover, evidence suggests that severe head injuries, metabolic diseases such as diabetes, and heart and blood vessel disease may predispose a person to AD in later life.

Currently, AD cannot be prevented or cured. However, three major clinical approaches are currently being tested to prevent or slow down its progression. These approaches are designed to (1) induce a person's immune system to destroy β-amyloid as soon as it is formed, (2) prevent the formation of β-amyloid with drugs that block its synthesis, or (3) prevent the accumulation of β-amyloid into large aggregates using antiaggregation drugs. Each of these approaches holds great promise but is still unproven.

Until a cure for AD is found, its impact on public health remains enormous. Currently, about 4–5 million Americans have AD, and this number is expected to grow to nearly 16 million by 2050. The prevalence of the disease is about 3% for people between the ages of 65 and 74, and 25–50% for people over 85. Estimated costs associated with providing health care and housing for AD patients (30% of whom live in nursing homes), as well as lost productivity in the workplace, total a staggering $100 billion in the U.S. per year. This number will rise substantially as the population spike known as the baby boomer generation approaches age 65.

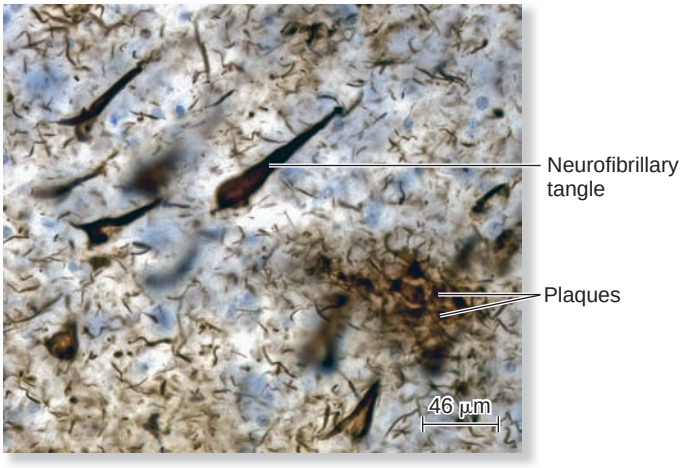


Figure 42.17 **Cellular section from the brain of a person who died from Alzheimer disease.** The section has been stained by immunohistochemistry for visualization of proteins found in plaques and neurofibrillary tangles.

Summary of Key Concepts

42.1 The Evolution and Development of Nervous Systems

- All multicellular animals except sponges have a nervous system. Simpler nervous systems include the nerve net of cnidarians and cerebral ganglia, which integrate inputs from sense organs. As animal bodies become more complex, the integrative center in the head becomes a brain that is larger and capable of more functions. (Figure 42.1)
- In all vertebrates, the three major divisions of the brain are the hindbrain, midbrain, and forebrain. Human embryos develop these divisions by 4 weeks. (Figure 42.2)
- Additional folding of the brain and increased mass allow for expansion of regions associated with conscious thought, reasoning, and learning. (Figures 42.3, 42.4)

42.2 Structure and Function of the Human Nervous System

- In humans and other vertebrates, the brain and spinal cord are the central nervous system (CNS). The neurons and all axons outside the CNS, including the cranial and spinal nerves, constitute the peripheral nervous system (PNS). The CNS relies on the PNS for sensory input, and the PNS relies on commands from the CNS. (Figure 42.5)
- The gray matter of the CNS is composed of dendrites, cell bodies, and unmyelinated axons. The white matter consists of tracts of myelinated axons. (Figure 42.6)
- The meninges are protective coverings of the CNS. Cerebrospinal fluid fills the subarachnoid space and ventricles. (Figure 42.7)
- The PNS can be subdivided into the somatic and autonomic nervous systems. The somatic nervous system senses external environmental conditions and controls skeletal muscles and skin. The autonomic nervous system senses internal body conditions and controls homeostasis.
- The efferent part of the autonomic nervous system is divided into two components: sympathetic (fight or flight) and parasympathetic (rest or digest). (Figure 42.8)
- The evolutionarily oldest structures of the brain, some of which are located in the hindbrain, control the basic processes that sustain life. These structures include the medulla oblongata, cerebellum, and pons. (Figure 42.9)
- In addition to forming part of the reticular formation, the midbrain processes several types of sensory inputs, including vision, olfaction, and audition. (Figure 42.9)
- The forebrain is made of the thalamus, hypothalamus, and epithalamus (diencephalon) and the cerebrum (telencephalon), which consists of the basal nuclei, limbic system, and cerebral cortex. Each side of the human cerebral cortex is divided into four lobes, each of which has a number of functions. (Figures 42.9, 42.10, 42.11, Table 42.1)

- The cerebrum is divided into two hemispheres. Each hemisphere is specialized to perform certain aspects of behavior and can operate independently. (Figure 42.12)

42.3 Cellular Basis of Learning and Memory

- Learning is the process by which new information is acquired; memory involves the retention of that information.
- Repeated stimuli result in long-term potentiation, in which the connections between adjacent neurons become stronger.
- Studies of the sea slug indicate that short-term memory is caused by a single stimulus that activates second messenger pathways. Long-term memory is caused by repeated stimuli that activate genes, which results in more synaptic connections, a phenomenon called synaptic plasticity. (Figures 42.13, 42.14)
- Imaging techniques such as CT scans, MRI, and fMRI allow us to examine the structure and activity of the brain. (Figures 42.15, 42.16)

42.4 Impact on Public Health

- Disorders of the human central nervous system can be placed into several broad categories. (Table 42.2)
- Meningitis is a potentially life-threatening infectious disease in which the meninges become inflamed.
- Alzheimer disease, the leading cause of dementia worldwide, is a progressive disorder characterized by the formation of senile plaques and neurofibrillary tangles in brain tissue. (Figure 42.17)

Assess and Discuss

Test Yourself

1. A nerve net consists of
   a. bilateral neurons that extend from the head of the animal to the tail.
   b. a group of neurons that are interconnected and are activated all at once.
   c. a single nerve cord with ganglia in each body segment.
   d. a central nervous system with peripheral nerves associated with different body structures.
   e. none of the above.
2. The division of the vertebrate brain that includes the cerebellum is
   a. the hindbrain.
   b. the telencephalon.
   c. the midbrain.
   d. the forebrain.
   e. the diencephalon.
3. In general, the brains of more complex vertebrates
   a. are larger.
   b. have fewer neurons.
   c. have more folds in the cerebral cortex.
   d. use less oxygen.
   e. both a and c
4. The white matter of the CNS is composed of
   a. dendrites.
   b. unmyelinated axons.
   c. myelinated axons.
   d. cell bodies.
   e. a and b only.
5. The division of the nervous system that controls voluntary muscle movement is
   a. the autonomic nervous system.
   b. the sensory division.
   c. the somatic nervous system.
   d. the parasympathetic division.
   e. the sympathetic division.
6. Which of the following is <u>not</u> a response to activation of the sympathetic division of the autonomic nervous system?
   a. increased breathing rate
   b. decreased heart rate
   c. increased blood flow to the skeletal muscles
   d. increased blood glucose levels
   e. All of the above are characteristic responses to activation of the sympathetic division of the autonomic nervous system.
7. The ___ acts as a relay for the cerebrum.
   a. medulla
   b. pons
   c. hypothalamus
   d. midbrain
   e. thalamus
8. The _____ is a portion of the limbic system that is important for memory formation.
   a. amygdala
   b. hippocampus
   c. pons
   d. thalamus
   e. mesencephalon
9. In humans, the _____ hemisphere of the cerebrum is dominant in nonverbal processing.
   a. right
   b. left
   c. both a and b
10. _____ is a progressive disease that causes a loss of memory and intellectual and emotional function.
    a. Meningitis
    b. Parkinson disease
    c. Amnesia
    d. Alzheimer disease
    e. Stroke

Conceptual Questions

1. One of the most important and fundamental features of all nervous systems is the reflex. Describe why reflexes are adaptive.
2. Explain the differences between white matter and gray matter.
3. What are the two subdivisions of the efferent pathways of the autonomic nervous system, and what are their functions?

Collaborative Questions

1. Describe the basic features of two different types of nervous systems found in animals.
2. List the three major divisions of the brain of vertebrates and briefly describe the function of each in humans.

Neuroscience III: Sensory Systems

43

Vision in the dark. As with many animals that are active at night, a cat's eye contains a reflective layer of tissue called a tapetum lucidum. This increases their ability to see in the dark.

Chapter Outline

As complex as our sensory environment seems, there exists, in other animals, a world of sensory abilities that differ radically from our own. We do not see the color patterns of flowers produced by the reflection of ultraviolet light the way honeybees do, or hear the very low frequency sounds (such as those produced by earthquakes) that elephants, whales, and alligators hear. We cannot use echoes of our own sounds to locate flying insects the way some bats do. We cannot smell the odor given off by one female Emperor moth from a distance of hundreds of meters the way a male moth can, nor can we detect the presence of chemicals (food) using our entire body surface, the way an earthworm can. We have a sensitive ability to detect touch, but we cannot detect the electric field generated by the muscles and hearts of marine animals, although many sharks and catfish can.

What does the world look, sound, smell, and feel like to other animals? We can never know exactly how an animal perceives its environments. Biologists can perform experiments, however, to determine the capabilities of an animal's sensory systems. For instance, we can examine the structure of a cat's eye, conduct behavioral studies to determine if cats can discriminate between different colors, and measure the electrical responses of neurons in the feline visual system to different visual stimuli. From such research, we know that cats sense color very poorly, if at all, but can see exceptionally well even in the dark (see the chapter-opening photo).

Animals with nervous systems often have acute senses, such as the ability to detect light, touch, and sound. Senses allow living organisms to perceive their environments. In neuroscience, a broad definition of a **sense** is a system that consists of specialized cells that respond to a specific type of chemical, energy, or physical stimulus (also known as a modality) and send signals to the central nervous system, where the signals are received and interpreted. The senses allow animals to detect subtle and complex aspects of their environments. They are the windows through which animals experience the world around them. The nervous systems of most animals also have the ability to sense signals arising from within an animal's body, such as hunger or pain. However, neuroscientists do not always agree on the actual number of different senses. Common examples include sight, smell, taste, touch, hearing, balance, and the ability to sense heat, cold, and pain.

In this chapter, we will examine how nervous systems collect incoming sensory information and how membrane potentials of specialized neurons change in response to sensory inputs. We will learn that other structures of the nervous system may modify or enhance this neural activity before sending it to the brain, where it is interpreted. Finally, we will discuss how problems with sensory systems can affect human health.

43.1 An Introduction to Sensory Receptors

Sensory systems convert chemical or physical stimuli from an animal's body or the external environment into a signal that causes a change in the membrane potential of sensory neurons. **Sensory transduction** is the process by which incoming stimuli are converted into neural signals. Sensory transduction involves cellular changes, such as opening of ion channels, which cause either graded potentials or action potentials in neurons.

Perception is an awareness of the sensations that are experienced. For instance, touching a hot object generates a thermal sensation, which initiates a neuronal response, giving us the perception that this stimulus is hot. Not all sensations are consciously perceived by an organism. Most of the time, for example, we are not aware of the touch of our clothing. The brain also processes sensory information in areas that do not generate conscious thought. For instance, certain neurons constantly monitor blood pressure and the blood levels of oxygen, glucose, and other substances, but we are not aware that this is occurring.

We will begin our study of sensory systems by examining the specialized cells—called sensory receptors—that receive sensory inputs. A **sensory receptor** recognizes an internal or external (environmental) stimulus and initiates sensory transduction by creating graded potentials (described in Chapter 41) in itself or an adjacent cell. Sensory receptor is a term that neuroscientists use to describe certain types of cells, which are either neurons or specialized epithelial cells that respond to internal or environmental stimuli (Figure 43.1). When a response is strong enough, sensory receptors initiate electrical responses to stimuli, such as chemicals, light, heat, and sound, which lead to action potentials that are sent to the CNS.

An Intense Stimulus Generates More Frequent Action Potentials

How do sensory receptors pass along the intensity of a stimulus? Let's consider an example involving weak and strong stimuli to the sense of touch (Figure 43.2). Sensory transduction begins when the specialized endings of a sensory receptor, such as dendrites, respond to a stimulus such as the touch of a glass rod. Such a stimulus opens ion channels that allow sodium ions to diffuse down their electrochemical gradient into the cell, depolarizing the sensory receptor. The amount of depolarization is directly related to the intensity of the stimulus, because a stronger stimulus will open more ion channels.

The first response of a sensory receptor is usually a graded change in the membrane potential of the cell body that is proportional to the intensity of the stimulus (Figure 43.2). The membrane potential, known as the **receptor potential** in these cells, becomes more and more positive as the strength of the stimulus increases. When a stimulus is strong enough, it will depolarize the membrane to the threshold potential at the axon hillock and produce an action potential in a sensory neuron (see Chapter 41).

Recall from Chapter 41 that action potentials proceed in an all-or-none fashion, regardless of the nature of the stimulus that elicits them. How, then, can action potentials provide information about the intensity of a stimulus? The answer is that the strength of the stimulus is indicated by the frequency of action potentials generated. A particularly strong stimulus will generate many action potentials in a short period of time. As a result, the frequency of action potentials is higher when the stimulus is strong than when it is weak. The action potentials are transmitted into the CNS and carried to the brain for interpretation.

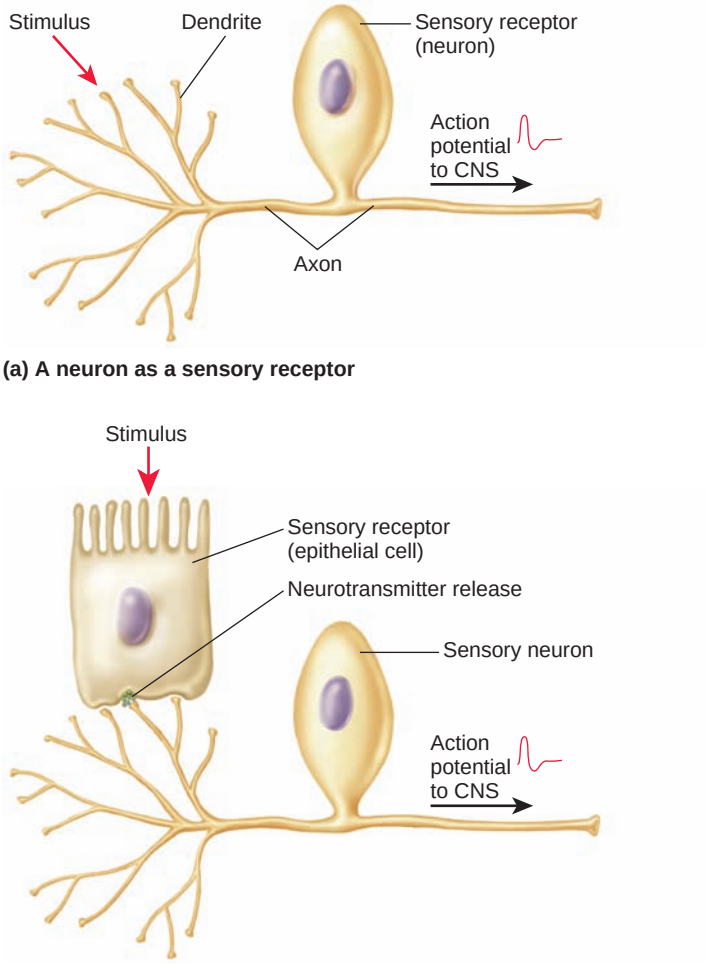

Figure 43.1 **Sensory receptors.** **(a)** Many sensory receptors are neurons that directly sense stimuli. **(b)** Others are specialized epithelial cells that sense stimuli and secrete neurotransmitter that stimulates nearby sensory neurons. In both cases, when stimulated, the neurons send action potentials to the CNS, where the signals are interpreted.

Concept check: *What is the difference between the sensory receptor described in this chapter and the membrane receptors described in Chapter 9?*

The brain interprets a higher frequency of action potentials as a more intense stimulus.

The CNS Processes Each Sense Within Its Own Pathway

Different stimuli produce different sensations because they activate specific neural pathways that are dedicated to processing only that type of stimulus. We know that we are seeing light because the signals generated by visual sensory receptors in the eye are transmitted along a neural pathway that sends action potentials into areas of the brain that are devoted to processing vision. For this reason, the brain interprets such signals as

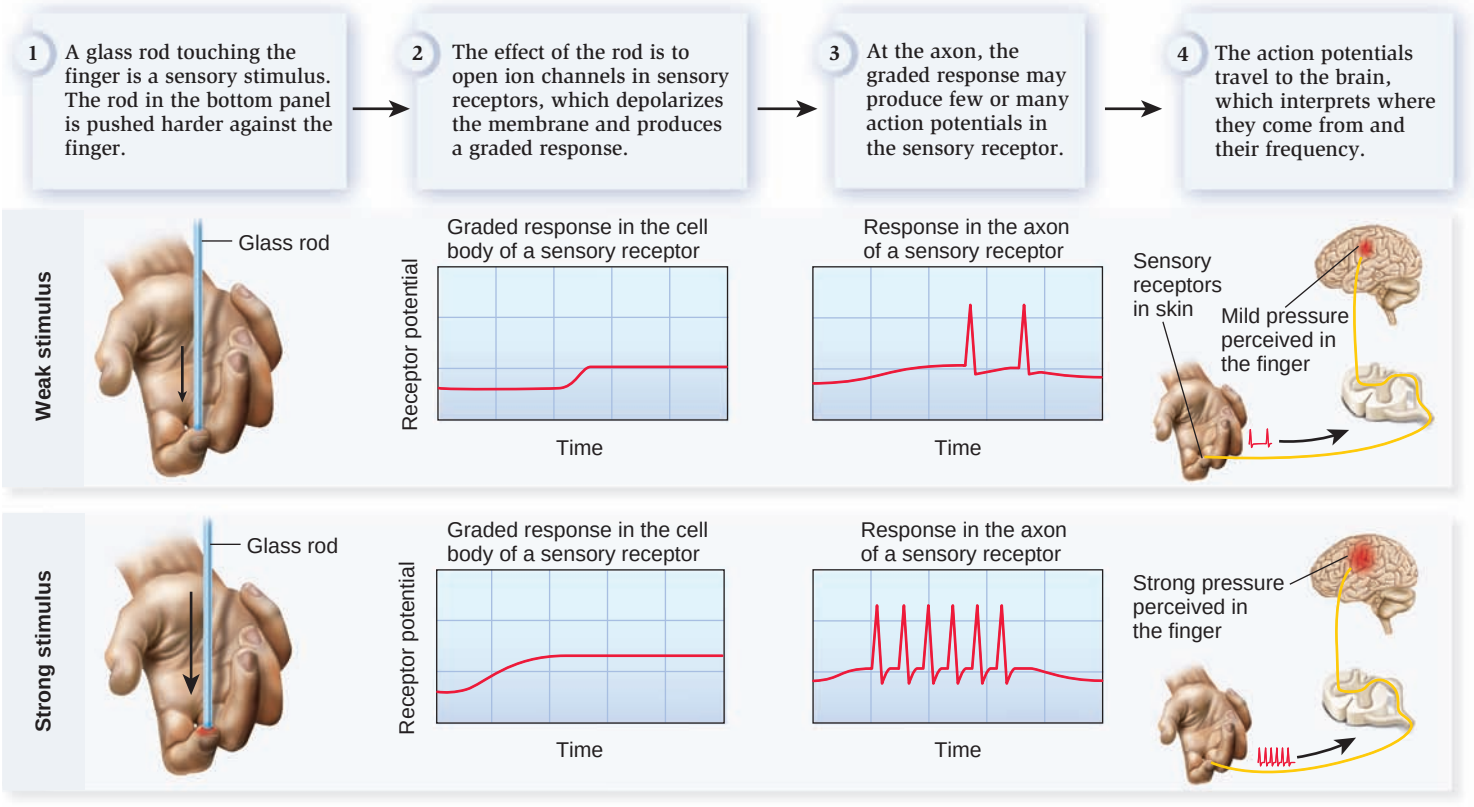

Figure 43.2 **Transduction of a sensory stimulus of two different intensities.** In this example, the sensory receptor is a neuron. Note the faster and larger graded response following the stronger stimulus.

visual stimuli. The brain can separate and identify each sense because each one uses its own dedicated pathway.

We can divide sensory receptors into general classes, based on the type of stimulus or modality to which they respond. Each type uses a different mechanism to detect stimuli and to transmit the information to different regions of the CNS. **Mechanoreceptors** transduce mechanical energy such as touch, pressure, stretch, movement, and sound. **Thermoreceptors** detect cold and heat. **Nociceptors**, or pain receptors, detect extreme heat, cold, and pressure, as well as certain molecules such as acids. **Electromagnetic receptors** sense radiation within a wide range of the electromagnetic spectrum, including visible, ultraviolet, and infrared light, as well as electrical and magnetic fields in some animals. **Photoreceptors** are electromagnetic receptors that detect visible light energy. **Chemoreceptors** recognize specific chemical compounds such as odor molecules or blood-borne compounds. Most of the remaining sections of this chapter will examine the structures and functions of these types of sensory receptors and the organs in which they are found.

43.2 Mechanoreception

As mentioned, mechanoreceptors are cells that detect physical stimuli such as touch, pressure, stretch, movement, and sound. Physically touching or deforming a mechanoreceptor cell opens ion channels in its plasma membrane. As discussed in this section, some mechanoreceptors are neurons that send action potentials to the CNS in response to physical stimuli. Other mechanoreceptors are specialized epithelial cells that contain hairlike structures that bend in response to mechanical forces.

Skin Receptors Detect Touch and Pressure

Several types of receptors in the skin detect touch, deep pressure, or the bending of hairs on the skin. Some of these specialized receptors consist of neuronal dendrites covered in dense connective tissue. In mammals, these receptors are located at different depths below the surface of the skin, which makes them suitable for responding to different types of stimuli (Figure 43.3). For example, **Meissner's corpuscles** (also called tactile corpuscles) sense touch and light pressure and lie just beneath the skin surface. They are found throughout the skin but are concentrated in areas sensitive to light touch, such as the fingertips, lips, eyelids, and genitals. In contrast, **Pacinian corpuscles** (also called lamellated corpuscles) and **Ruffini corpuscles** are located much deeper beneath the surface, particularly in the soles of the feet and the palms of the hands. These corpuscles respond best to deep pressure or vibration. All the skin corpuscles contain sensory receptor neurons that generate action potentials when the structure of the corpuscle is deformed. Other skin mechanoreceptors located in the hair follicles respond to movements of hairs and whiskers.

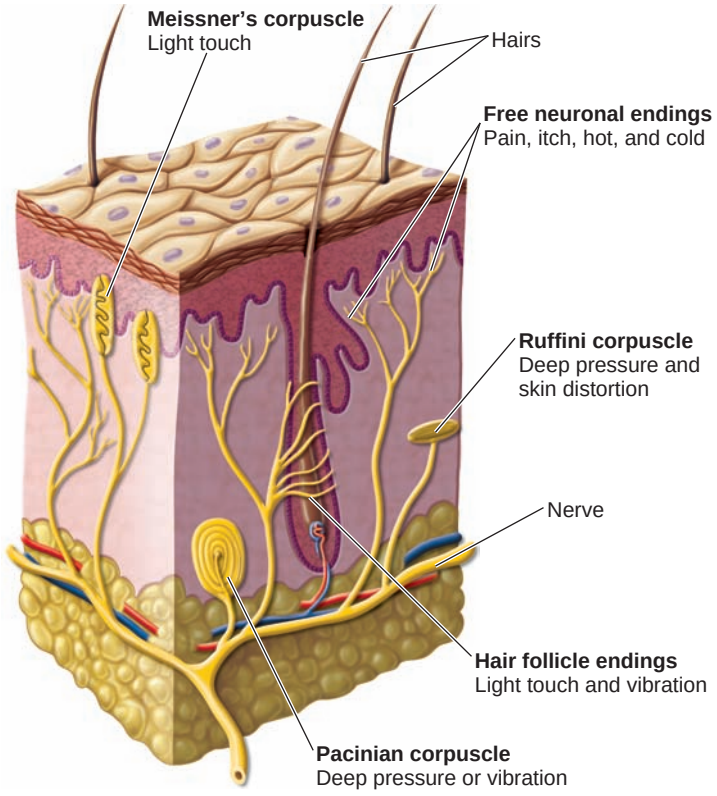

Figure 43.3 **Examples of sensory receptors in the skin of mammals.**

Concept check: *There are several types of touch receptors in the skin that respond to different stimuli. What different qualities of touch are you aware of?*

Stretch Receptors Detect Expansion

Mechanoreceptors called **stretch receptors** are neuron endings commonly found in the walls of organs that can be distended. They occur in organs such as the stomach and urinary bladder and also in skeletal muscles. Although stretch receptors are probably found throughout the animal kingdom, they have been best studied in crustaceans and mammals. In decapod crustaceans, for example, stretch receptors in muscles of the tail, abdomen, and thorax relay signals to the brain regarding the position in space of the different body parts. This information allows the animal to perform complex motor functions, such as walking backward or sideways. In another example, when the mammalian stomach stretches after a meal, the stretch receptors in the stomach are deformed, causing them to become depolarized and send action potentials to the brain. The brain interprets the signals as fullness, which reduces appetite.

Hair Cells Are Mechanoreceptors with Deformable Stereocilia

Thus far, we have considered skin and stretch receptors, which are neurons that detect physical stimuli. Other mechanoreceptors are specialized epithelial cells called **hair cells**, which have deformable projections called **stereocilia** that resemble hairs under the microscope. The stereocilia, which are different from true cilia (see Chapter 4), are bent by movements of fluid or other physical stimuli (Figure 43.4).

Many types of hair cells contain ion channels that open or close when the stereocilia bend and thereby change the cell's membrane potential. When the plasma membrane depolarizes, this opens voltage-gated Ca^{2+} channels and results in the release of neurotransmitter molecules from the hair cells (refer back to

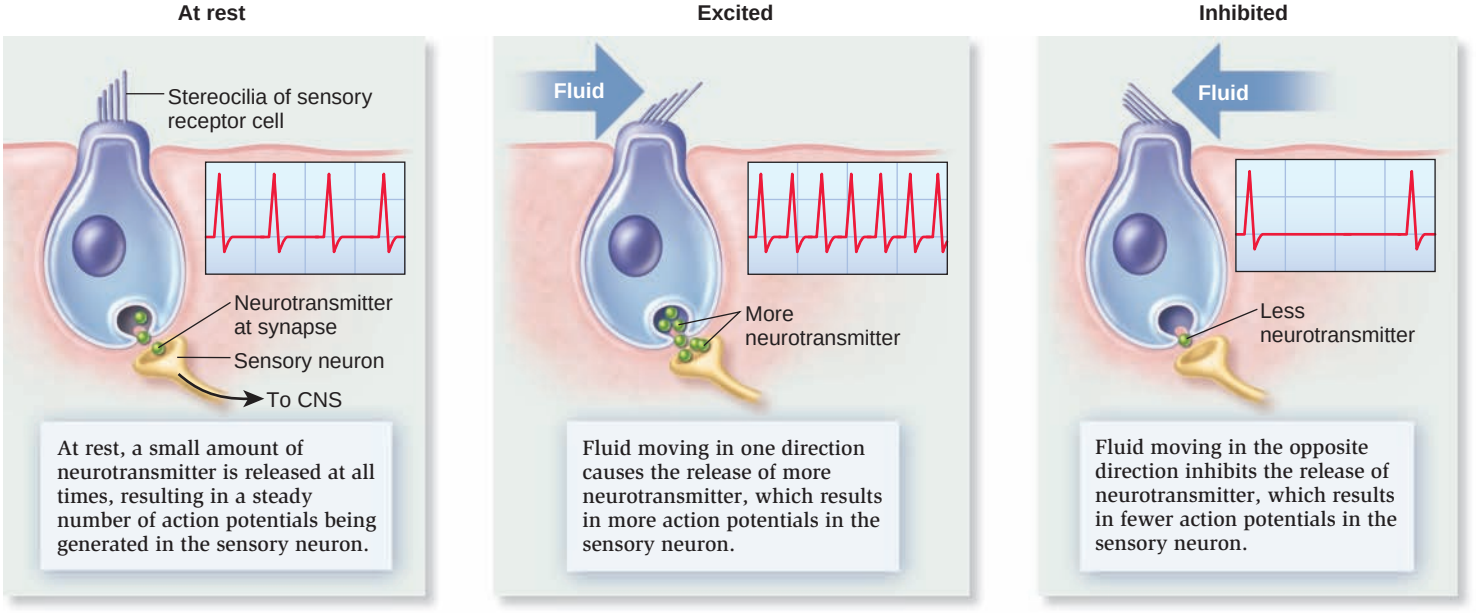

Figure 43.4 **The response of hair cells to mechanical stimulation.** Note: The stereocilia inside these hair cells are hairlike projections of the plasma membrane that contain actin filaments. They are structurally different from cilia, which are described in Chapter 4.

Figure 41.14). The neurotransmitter then binds to protein receptors in adjacent sensory neurons and can result in action potentials being sent to the CNS. Even when unstimulated, hair cells usually release a small amount of neurotransmitter onto nearby sensory neurons, resulting in a resting level of action potentials in the sensory neurons. In the example shown in Figure 43.4, bending of the stereocilia in one direction in response to fluid movement increases the release of neurotransmitter from the hair cell, whereas bending in the other direction decreases the release of the same neurotransmitter. The result is an increase or decrease, respectively, in the number of action potentials produced in the sensory neurons.

Hair cells are found in the ear and equilibrium (balance) organs of many invertebrates and vertebrates, where they detect sound or changes in head position. They are also found along the body surface of fishes and some amphibians, where they detect external water currents, as described next.

Mechanoreceptors in the Lateral Line System Detect Movements in Water

Fishes and some toads detect changes in their environment through a **lateral line system** (Figure 43.5). This sensory system has hair cells that detect changes in water currents brought about by waves, nearby moving objects, and low-frequency sounds traveling through the water. The lateral line organ runs along both sides of the body and the head of the animal. Small pores let water enter into a lateral line canal. The stereocilia of hair cells protrude into a gelatinous structure called a **cupula** within the lateral line organ. When the cupula is moved by the water, the stereocilia bend, causing the release of neurotransmitter from the hair cell. This stimulates a response in sensory neurons at the base of the hair cells. The response provides information to the brain about changes in water movement, such as the approach of a predator.

Hearing Involves the Reception of Sound Waves

The sense of hearing, called **audition**, is the ability to detect and interpret sound waves. This sense is critical for the survival of many types of animals. For example, a mother seal locates her pup by hearing its calls, and a male bird sings an elaborate song to attract a mate. Hearing is also important for detecting the approach of danger—a predator, a thunderstorm, an automobile—and locating its source.

Sound travels through air or water in waves. The distance from the peak of one wave to the next is a **wavelength**. The number of complete wavelengths that occur in 1 second is called the **frequency** of the sound, measured in number of waves per second, or Hertz (Hz), after the German physicist and pioneer of radio wave research, Heinrich Hertz. The length and frequency of sound waves impart certain characteristics to the stimulus. Short wavelengths have high frequencies that are perceived as a high **pitch** or tone, while long wavelengths have lower frequencies and a lower pitch.

The sense of hearing is present in vertebrates and arthropods, but not in other phyla. Arthropods do not appear to have more than a general sensitivity to sound, although some exceptions exist. For example, some species of moths have sound-sensitive membranes that detect the high frequencies emitted by their chief predators, bats. The sense of hearing, however, is especially well developed in vertebrates (notably birds and mammals); we turn now to a detailed discussion of the mammalian ear and the mechanism by which it detects sound.

Structure of the Mammalian Ear The mammalian ear has three main compartments: the outer, middle, and inner ears (Figure 43.6). The **outer ear** consists of the external ear, or pinna (plural pinnae), and the auditory canal. Mammals have a wide variety of shapes and sizes of the external ear, which reflects their different abilities to capture sound waves. The outer ear is separated from the **middle ear** by the tympanic

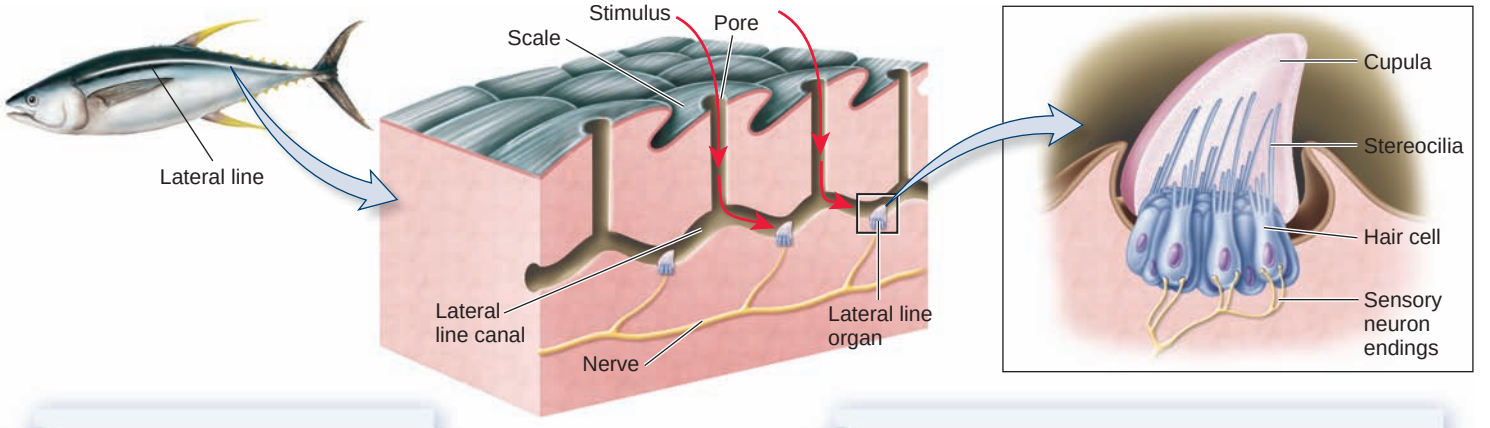

Figure 43.5 Mechanoreceptors in the lateral line system that detect changes in water movement.

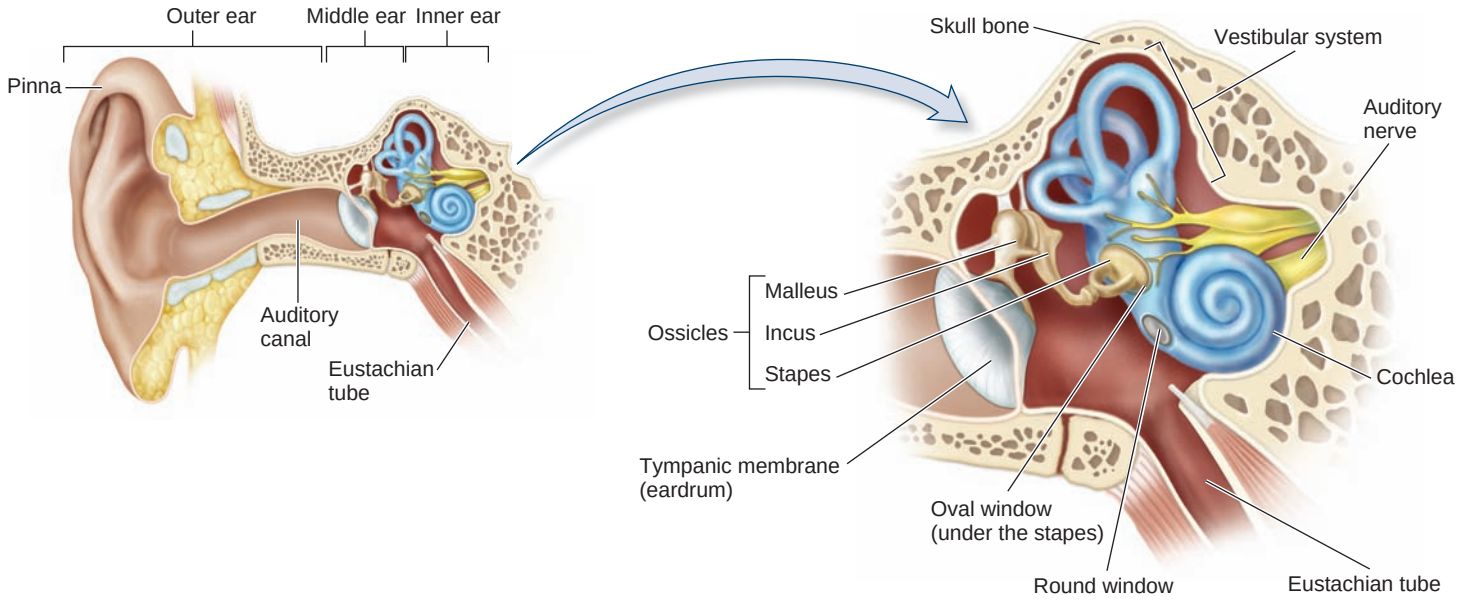

Figure 43.6 **The structure of the human ear.** The three main compartments are the outer, middle, and inner ear.

membrane (eardrum). The middle ear contains three small bones called ossicles (named the malleus, incus, and stapes) that link movements of the eardrum with the oval window. The oval window is another membrane similar to the eardrum that separates the middle ear from the **inner ear**. The inner ear is composed of the **cochlea** (from the Latin, meaning snail)—a coiled chamber of bone containing the hair cells and the membrane-like round window—and the vestibular system, which plays a role in balance, as described later. These structures in the inner ear generate the signals that travel via the auditory nerve to the brain.

Both the tympanic membrane and the oval window must be able to vibrate when sound waves meet the eardrum. For this to occur properly, the air pressure in the outer and middle ear compartments must be equal. The pressure in the outer ear is the atmospheric pressure. The **Eustachian** (or **Auditory**) **tube**, which connects the middle ear to the pharynx, maintains atmospheric pressure in the middle ear. If you change altitude quickly, as during a plane takeoff, the pressure in your outer ear changes because atmospheric pressure decreases with altitude. After awhile, the pressures in the outer and middle ear equalize. However, if the pressure in your outer ear becomes greater than the pressure in your middle ear, which would occur when the plane descends, your eardrum will be pushed or bowed inward. The eardrum is less able to vibrate in response to sounds when it is deformed under pressure, and thus your hearing becomes muffled. Swallowing or yawning will open the Eustachian tube and equalize the pressure in the middle ear with atmospheric pressure. The popping sound you hear when the plane ascends or descends is the sudden return of the eardrum to its normal position.

Generation of Electrical Signals in the Mammalian Ear

To understand how we hear, let's first consider how mechanical forces move through the ear. Sound waves entering the outer ear cause the tympanic membrane to vibrate back and forth (Figure 43.7). The ossicles transfer the vibration of the tympanic membrane to the oval window, causing it to vibrate against the cochlea. This sends pressure waves, which also travel in a back-and-forth manner, through a fluid called perilymph. Perilymph is found within two narrow passages in the cochlea called the vestibular and tympanic canals. The waves travel from the vestibular canal to the tympanic canal and eventually strike the round window, where they dissipate. Along the way, the waves cause the vibration of a membrane called the **basilar membrane**, which as you will see shortly is a key part of the mechanism by which different frequency sounds are sensed. Sounds of very low frequency create pressure waves that take the complete route through the vestibular and tympanic canals (see green arrows in Figure 43.7). Sounds of higher frequency produce pressure waves that follow a different route, passing from the vestibular canal through a tube between the canals called the cochlear duct (as shown by the blue arrows in Figure 43.7). They then pass through the basilar membrane, before reaching the tympanic canal.

Mechanical vibrations are changed, or transduced, into electrical signals within the cochlea. This happens in a structure called the organ of Corti (named after the Italian anatomist Alfonso Corti), which rests on top of the basilar membrane. To understand how this works, we need to look at a cross section through the cochlea (Figure 43.8). The organ of Corti contains supporting cells and rows of hair cells. The stereocilia of the hair cells are embedded in a gelatinous tectorial membrane. The back-and-forth vibration of the basilar membrane bends the stereocilia in one direction and then the other. When bent in one direction, the hair cells depolarize and release neurotransmitter, which activates adjacent sensory neurons that then send action potentials to the CNS via the auditory nerve. When bent in the

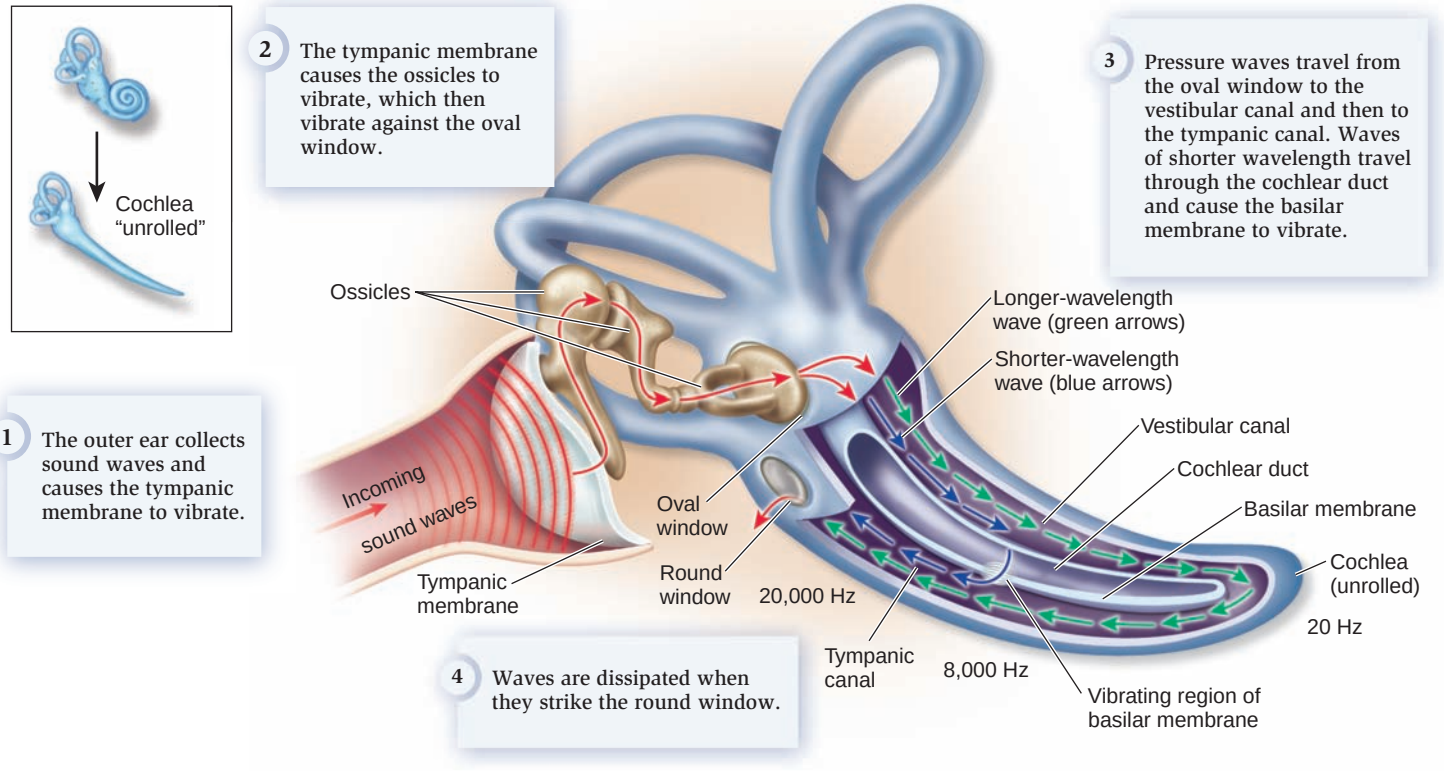

Figure 43.7 Movement of sound waves through the human ear.

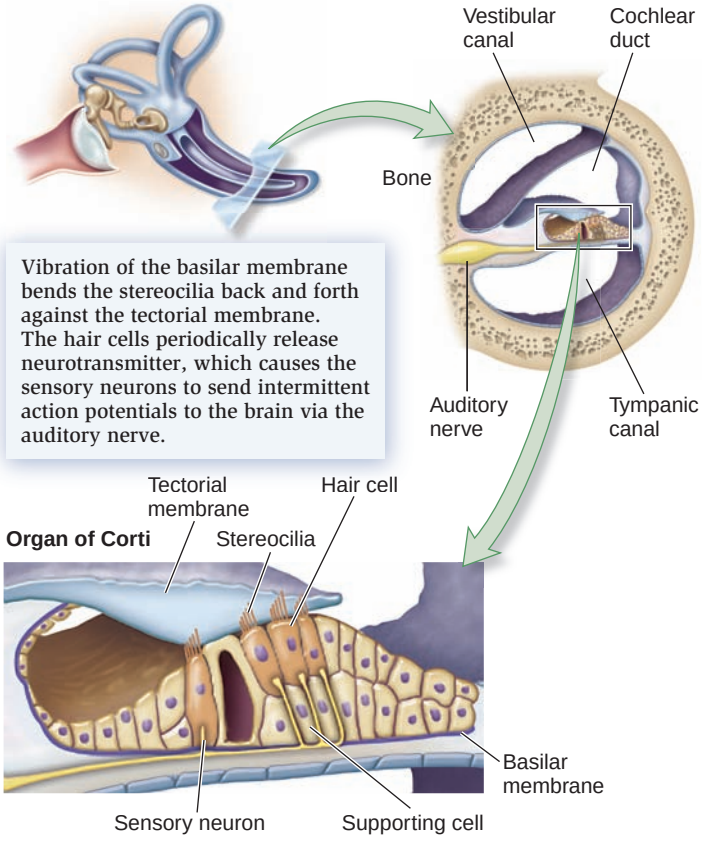

Figure 43.8 Transduction of mechanical vibrations to electrical signals in the organ of Corti.

other direction, the hair cells hyperpolarize and shut off the release of neurotransmitter. In this way, the frequency of action potentials generated by the sensory neurons is determined by the up-and-down vibration of the basilar membrane.

The basilar membrane is lined with protein fibers that span its width. These fibers function much like the strings of a guitar. The fibers near the oval and round windows at the base of the cochlea are short and rigid, and they vibrate in response to high-frequency waves. Longer and more resilient fibers are near the other end of the cochlea and vibrate to lower-frequency waves. For this reason, hair cells closer to the oval and round windows respond to high-pitched sounds, whereas those at the opposite end are triggered by lower-pitched sounds. When we hear a great number of sound frequencies at once, such as at a musical concert, the waves traveling through the cochlea activate hair cells all along the basilar membrane in a physical representation of the music! These cells stimulate sensory neurons, which send multiple action potentials to the auditory areas of the brain for processing. The most incredible feature of this process, however, is that the mammalian ear and brain can "tune in" to all of these frequencies simultaneously.

Adaptations for Hearing Allow Animals to Live in a Wide Range of Habitats

Different animals are capable of hearing sounds of different pitches. For example, humans can hear between 20 and 20,000 Hz (conversation averages 90–300 Hz). Insectivorous

bats, toothed whales, and some species of moths may have the highest-frequency range, while baleen whales and elephants may have the lowest-frequency range. These adaptations increase the animals' ability to communicate and survive. For instance, high-pitched sounds are useful to animals that need to locate small prey such as flying insects, while low-pitched sounds carry great distances through water or air and are especially useful for animals with large territories.

Locating a Sound A vital feature of hearing is the ability to locate the origin of a sound. For example, this ability makes the difference between a successful and an unsuccessful hunter. How does an animal locate a sound? Under most circumstances, sound does not arrive at both ears simultaneously. Sound waves coming from the right, for example, may excite the sensory receptors in the right ear first and the left ear some milliseconds later, and therefore, the brain receives action potentials from the auditory nerves of each ear at slightly different times. The brain interprets the time difference to determine the origin of the sound.

Animals such as owls that rely on hearing to locate prey tend to be extremely good at localizing the source of a sound. An interesting experiment demonstrated this by outfitting owls in a dark room with small headphones. Just as in a human hearing test, sounds could be sent to either headphone or to both. If the investigator sent a high-pitched noise that mimicked the sounds of a mouse first to the left headphone, and then a single millisecond later to the right headphone, the owl turned its head to the left, because the owl's brain perceived the sound to be coming from that direction. If the noises reached both headphones simultaneously, the owl interpreted the signal as coming from directly in front of its head.

Hearing in Air and Water Amphibians have the special challenge of hearing both on land and underwater, their two natural environments. The ears of amphibians have several interesting specializations that are adapted to these requirements. First, they do not have external ears. The tympanic membrane is located on the outer surface of the head behind the eye (Figure 43.9). This arrangement allows them to swim through the water without being impeded by pinnae and to receive sound waves from any direction. Amphibians also have unusually wide Eustachian tubes. When they are on land, sound waves can pass from one ear through the Eustachian tube to the pharynx and then travel up the Eustachian tube of the other ear, where they hit the backside of the tympanic membrane. Air from the lungs also can pass into each ear in this manner. When a male bullfrog emits its loud call, pressure coming through the Eustachian tubes and from the outside of the head prevents his own eardrum from vibrating and being injured by the loud sound.

Echolocation Bats in the air, whales and dolphins in the sea, and shrews in underground tunnels generate high-frequency sound waves to determine the location of an object. This phenomenon is called **echolocation**, because the sound waves bounce off a distant object, like an echo, and return to the animal. The time it takes for the sound to return indicates the distance of the object. Echolocation can be useful in situations where vision is limited, such as in the dark. Although the sound of an echo may be familiar to you, it is hard to imagine how other animals can use echoes to locate objects with such precision. To get a feel for how this works, imagine shouting "hello" across a canyon. After a few seconds, you would hear the echo return to you. Now imagine that you knew the speed of sound in air (approximately 344 m/sec at sea level) and had a stopwatch that measured the length of time it took for the echo to return. From this, you could calculate the distance across the canyon (accounting for the fact that sound first traveled in one direction, then back again, so you would have to divide your result by two). Bats and other echolocating animals perform this feat instantly, without the aid of mathematics or calculators, and can do it while they and the object they are tracking are both in motion!

Figure 43.9 The tympanic membrane of a frog.

The Sense of Balance Is Mediated by Statocysts in Invertebrates and the Vestibular System in Vertebrates

Let's now turn our attention to the sense of balance, also called equilibrium. Balance is part of a broader sense called proprioception, which is the ability to sense the position, orientation, and movement of the body. Being able to sense body position is vital for the survival of animals. This is how a lobster, for example, rights itself when flipped over by a predator or how a bird maintains its balance while flying rapidly through the air.

Many aquatic invertebrates have sensory organs called **statocysts** that send information to the brain about the position of the animal in space (Figure 43.10). Statocysts are small round structures made of an outer sphere of hair cells and **statoliths**, which are tiny granules of sand or other dense objects. When the animal moves, gravity alters the statoliths' position. If the animal turns on its left side, for example, the movement of statoliths stimulates a new set of hair cells to release

neurotransmitter, generating action potentials in sensory neurons that inform the brain of the change in body position.

Several experiments have demonstrated the importance of statoliths. In one particularly dramatic example, researchers replaced the statoliths of crayfish with iron filings. Moving a magnet to different positions around the animal displaced the filings, causing the animal to change its position, and even to swim upside down when the magnet was placed directly above its head.

The organ of balance in vertebrates, known as the **vestibular system**, is located in the inner ear next to the cochlea (Figure 43.11). The vestibular system is composed of a series of fluid-filled sacs and tubules, which provide information about either linear or rotational movements. The utricle and saccule, the two sacs nearest the cochlea, detect linear movements of the head (Figure 43.11a), such as those that occur when an animal runs and jumps or changes from lying down to sitting up. The hair cells within these structures are embedded in a gelatinous substance that contains granules of calcium carbonate called **otoliths** (from the Latin, meaning ear stones), which are analogous to statoliths. When the head moves forward, the heavy otoliths are temporarily "left behind" as they are dragged forward more slowly, and the weight of the otoliths bends the

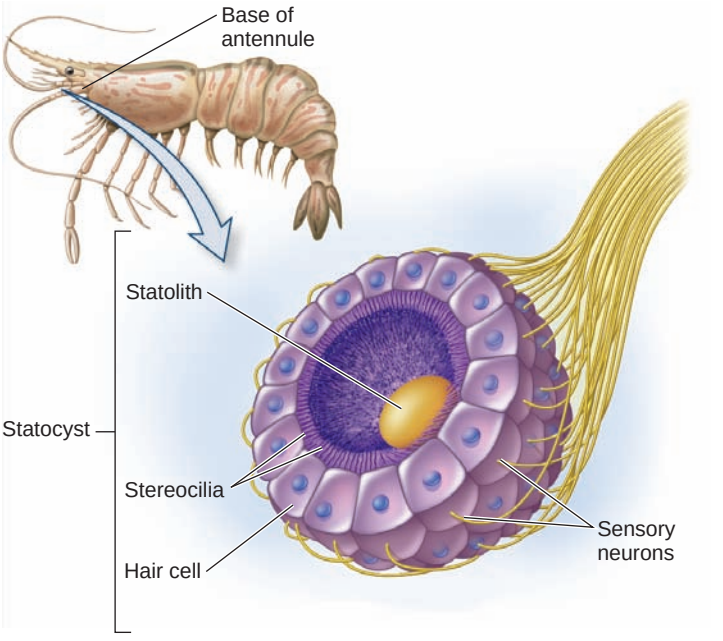

Figure 43.10 **Sensing of balance in aquatic invertebrates.** Statocysts located near the antennae consist of a sphere of sensory hair cells surrounding a stony statolith. When the animal moves, gravity shifts the statolith and stimulates the hair cells beneath it.

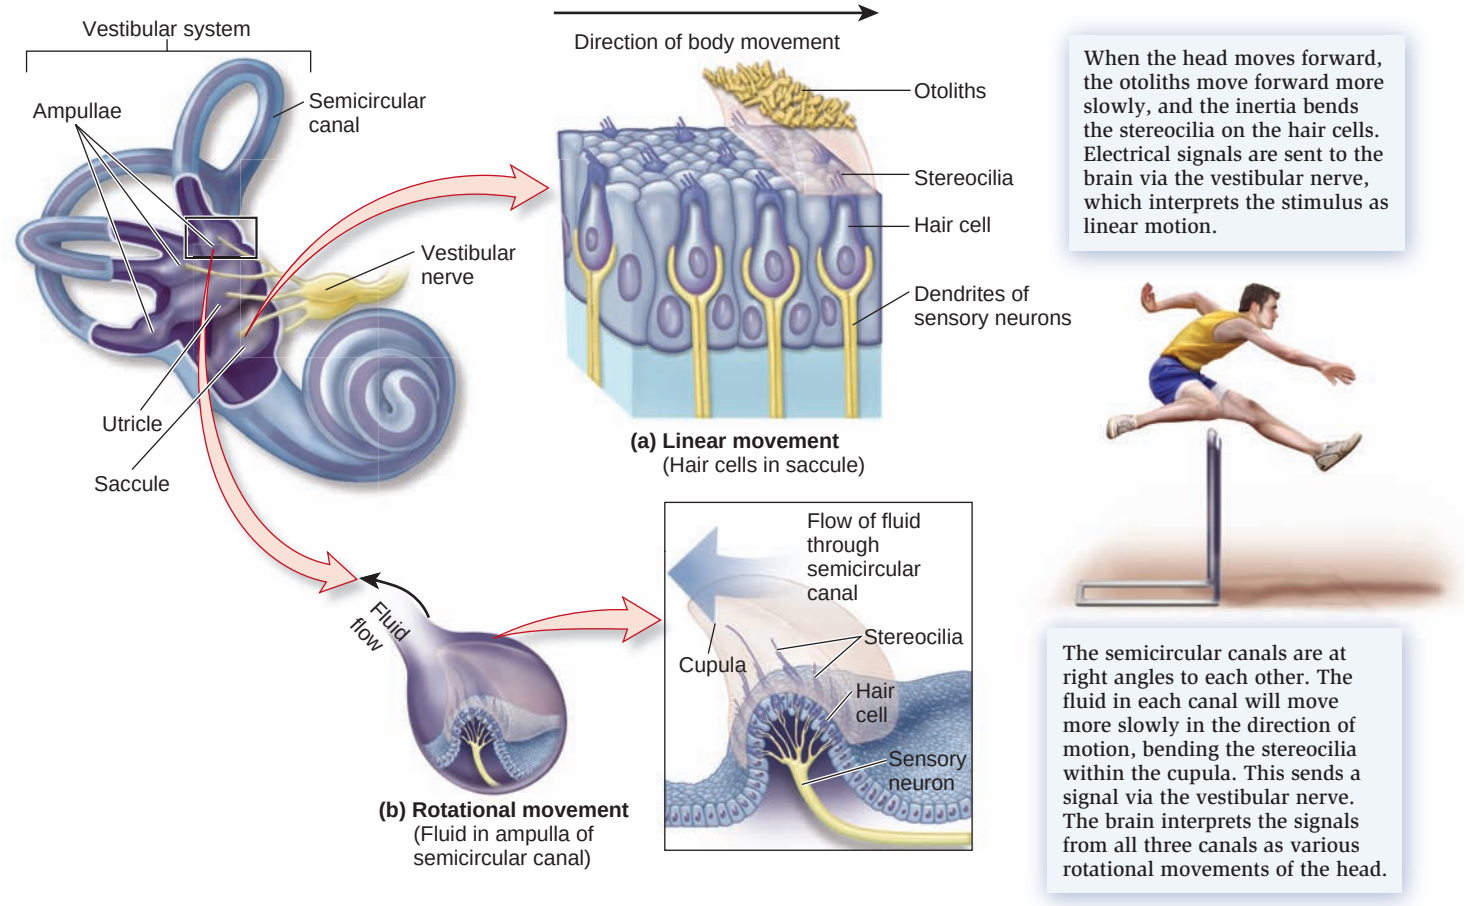

Figure 43.11 **The vertebrate vestibular system.**

Concept check: *Note the orientation of the three semicircular canals with respect to each other. Why are the canals oriented in three different planes?*

stereocilia of the hair cells in the direction opposite that of the linear movement. This changes the membrane potential of the hair cells and alters the electrical responses of nearby sensory neurons. These signals are sent to the brain, which uses them to interpret how the head has moved. (Interestingly, gravity detection by statolith-containing organs is not unique to animals; as described in Chapter 36, the upward growth of many types of plants also depends on the presence of statoliths!)

Three **semicircular canals** connect to the utricle at bulbous regions called the **ampullae**. The function of the semicircular canals is to detect rotational motions of the head (Figure 43.11b). The hair cells in the semicircular canals are embedded in the ampullae in a gelatinous cone called the cupula (similar to the cupula of the fish lateral line). When the head moves, the fluid in the canal shifts in the opposite direction. This movement of fluid pushes on the cupula and bends the stereocilia of the hair cells in the direction of the fluid flow, which is opposite that of the motion. The three canals are oriented at right angles to each other, and each canal is maximally sensitive to motion in its own plane. For example, the canal that is oriented horizontally would respond most to rotations such as shaking the head "no," whereas the other canals respond to "yes" motions and to tipping the ear to the shoulder. Overall, by comparing the signals from the three canals, the brain can interpret the motion of the head in three dimensions.

The vestibular system of vertebrates provides conscious information about body position and movement. It also supplies unconscious information for reflexes that maintain normal posture, control head and eye movements, and assist in locomotion. Motion sickness in humans results when the vestibular system has not adapted to unfamiliar patterns of movement, such as spinning around or sailing aboard a ship. In these cases, the sense from your vestibular system conflicts with information coming from your vision. Vertigo, an illusion of movement or spinning, can result from malfunction of the vestibular system.

43.3 Thermoreception and Nociception

The perception of temperature and pain enables animals to respond effectively to their environments. As described in this section, these sensory stimuli are related in that their receptors are located in some of the same areas (skin), share similar physical features, and under certain conditions result in similar perceptions.

Thermoreceptors Detect Temperature

Sensing the outside temperature is important for animals because their body temperature is affected by the external temperature, particularly in ectotherms. Animals can survive at body temperatures only within certain limits, because the proteins in their cells function optimally within a particular temperature range. Thermoreceptors respond to cold or hot temperatures by activating or inhibiting enzymes within their plasma membranes, which alters membrane channels. There are two types of thermoreceptors: those that respond to hot and those that respond to cold. Both of these types of receptors are free neuronal endings. Thermoreceptors are often linked with reflexive behaviors, such as when an animal steps on a hot surface and pulls its foot away.

In addition to skin receptors that sense the outside temperature, thermoreceptors in the brain also detect changes in core body temperature. Activation of skin or brain thermoreceptors triggers physiological and behavioral adjustments that help maintain body temperature. These changes, described in Chapter 46, include changes in blood flow, shivering, and behaviors such as seeking shade or sunlight.

Nociceptors Warn of Pain

The sense of pain is one of the most important of all the senses. It tells an animal whether it has been injured and triggers behavioral responses that protect it from further danger. Although in many cases we cannot know whether or how animals perceive pain, nociceptors have been identified in mammals and birds. Their existence and physiological significance in other phyla are likely but are still being investigated.

Nociceptors, the receptors for pain, are free neuronal endings in the skin and internal organs (see Figure 43.3). They respond to tissue damage or to stimuli that are about to cause tissue damage. Nociceptors are unusual because they can respond not only to external stimuli, such as extreme temperatures, but also to internal stimuli, such as molecules released into the extracellular space from injured cells. Damaged cells release a number of substances, including acids and prostaglandins, that cause inflammation and make nociceptors more sensitive to painful stimuli. Aspirin and ibuprofen reduce pain by preventing the production of prostaglandins.

Signals arising from nociceptors travel to the CNS and reach the cerebrum, where the type or cause of the pain is interpreted. The signals are also sent to the limbic system, which holds memories and emotions associated with pain, and to the reticular formation, which increases alertness and arousal—an important response to a painful stimulus.

43.4 Electromagnetic Sensing

As mentioned earlier, electromagnetic receptors detect radiation within a wide range of the electromagnetic spectrum, including those wavelengths that correspond to visible light, ultraviolet light, and infrared light, as well as electrical and magnetic stimuli. Photoreceptors are specialized electromagnetic receptors that respond to light and are covered in Section 43.5. Here, we will examine the ability of some animals to sense electrical and magnetic fields and also heat in the form of infrared radiation.

The ability to detect the presence of nearby prey or predators is an important adaptation in certain animals that inhabit low-light environments. The more ways that an animal has to detect other animals, the better it can avoid danger or obtain a meal. Many fishes living in dark waters can detect weak

electrical signals given off by other fishes, and sharks and rays can even detect the tiny electrical signals generated by the heartbeats of their prey. Similarly, the platypus, which lives in the murky waters of streams and ponds, has receptors on the skin of its bill that can detect very small electrical currents produced by its prey.

Homing pigeons use one type of electromagnetic sensing to return to their starting points from as far away as 1,500 km. This navigational feat is made possible by small particles of magnetite (iron oxide) in their beaks that indicate direction by acting as a compass. The magnetic particles respond to the Earth's magnetic field and alter the activity of neurons that project to the brain. In one experiment, pigeons were placed individually in large tubes and trained that food was present in only one end of the tube. When the tube was placed in a changeable magnetic field, pigeons readily learned which end contained food based solely on the magnetic polarity of the tube. In another experiment, the pigeons lost this ability when their beaks were anesthetized or cooled down, procedures that block action potentials from being sent to the brain. This demonstrates that their magnetic sensing ability is located in the beak and communicated by nerves to the brain.

Magnetic field sensing is not unique to birds. Magnetite has also been found in the heads of migratory fishes such as rainbow trout. However, this probably does not entirely explain the extraordinary ability of migratory animals to navigate great distances, because other cues, such as smell and visual recognition of landmarks, also appear to play roles in this process.

Venomous snakes known as pit vipers (a group that includes copperheads and rattlesnakes) can localize prey in the dark with detectors that sense the heat emitted from animals as infrared radiation. These detectors are located in pits on each side of the head between the eyes and nostrils (Figure 43.12). Within the pit, a thin, nerve-rich, temperature-sensitive membrane becomes activated in response to infrared waves emitted by live animals. When the snake detects the heat of the animal, it localizes its prey by moving its head back and forth until both pits detect the same intensity of radiation. This indicates that the prey is centered in front of the snake, and then the snake is ready to strike.

Electrical, magnetic, and infrared sensing are adaptations for long-distance migration or low-light environments. When light is available, however, photoreception becomes a dominant sensory ability in many animals, as described next.

43.5 Photoreception

Although it is a form of electromagnetic reception, photoreception is such an important and widespread sense that we will cover it separately here. Visual systems employ specialized neurons called **photoreceptors**, which detect photons of light arriving from the sun or other light sources, or reflecting off an object. A photon is the fundamental unit of electromagnetic radiation and has the properties of both a particle and a wave. The properties of light are described in Chapter 8. In this section, we will examine the organs found in animals, usually called **eyes**, that detect light and send signals to the brain. The amazing features of these organs reflect the importance of vision in the animal world.

Figure 43.12 **Infrared sensing.** Sensory pits enable a white-lipped pit viper to detect the heat given off by its prey.

Eyecups and Compound Eyes Are Found in Certain Invertebrates

One of the simplest visual organs is found in the flatworm (*Planaria*); it is a concave structure called an **eyecup**, or eyespot (Figure 43.13). The eyecup contains the endings of photoreceptor cells and a layer of pigment cells that shields the

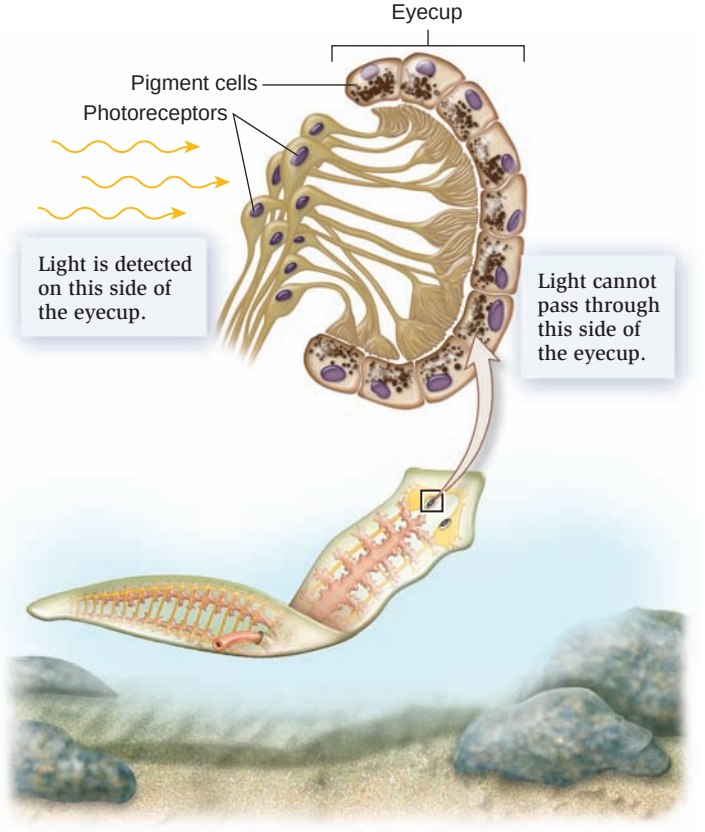

Figure 43.13 **The eyecup of a flatworm.** The orientation of the eyecup allows light to stimulate photoreceptors from only one direction. This type of eye senses only the presence or absence of light and does not form visual images.

photoreceptors from one side. The left and right eyecups receive light from different directions. This allows the eyecups to detect the direction as well as the presence or absence of light. The nervous system compares the amount of light detected by each eyecup, and the flatworm moves toward darkness, a behavior that protects it from predators. This type of photoreceptor does not form visual images of the environment.

In contrast, arthropods and some annelids have image-forming **compound eyes** (Figure 43.14a), which consist of several hundred to more than 10,000 light detectors called ommatidia (Figure 43.14b). Each ommatidium makes up one facet of the eye. Within the ommatidium, a **lens** composed of the cornea and the crystalline cone focuses light onto a long central structure called a rhabdom (Figure 43.14c). The rhabdom is a column of light-sensitive microvilli that project from the cell membranes of the photoreceptor (retinula) cells of the ommatidium (Figure 43.14d). The light-sensitive molecules required for vision are located in the microvilli; the extensive surface area imparted by the microvilli provides the animal with increased sensitivity to light. Pigmented cells surrounding the photoreceptor cells absorb excess light and thereby isolate each ommatidium from its neighbors.

Each ommatidium senses the intensity and color of light. Combined with the different inputs from neighboring ommatidia, the compound eye forms an image that the brain interprets. Animals such as bees and fruit flies, with large numbers of ommatidia, presumably have sharper vision than those with fewer sensory cells, such as grasshoppers.

As anyone who has tried to swat a fly knows, the compound eye is extremely sensitive to movement and helps flying insects evade birds and other predators. Behavioral studies have shown, however, that the resolving power of even the best compound eye is considerably less than that of the single-lens eye, which we will consider next.

Vertebrates and Some Invertebrates Have a More Complex Single-Lens Eye

Single-lens eyes are found in vertebrates and also in some mollusks, such as squid, octopus, and some snails, and in some annelids. In such eyes, different patterns of light emitted from images in the animal's field of view are transmitted through a small opening, or **pupil**, through the lens, to a sheetlike layer of photoreceptors called the **retina** at the back of the eye (Figure 43.15a). This forms a visual image of the environment on the retina. The activation of these photoreceptors triggers electrical changes in neurons that pass out of the eye through the **optic nerves**, carrying the signals to the brain. The brain then interprets the visual image that was transmitted.

As illustrated in Figure 43.15a, the vertebrate eye has a strong outer sheath called the **sclera** (the white of the eye). Between the sclera and the retina is a layer of blood vessels called the choroid. At the front of the eye, the sclera is continuous with a thin, clear layer known as the **cornea**. Within the eye are two cavities, the anterior and posterior cavities. The anterior cavity is the part of the eye between the lens and the cornea. It is subdivided into the anterior chamber and posterior chamber. The anterior chamber is located between the cornea and the **iris**—the circle of pigmented smooth muscle responsible for eye color. This chamber is filled with a thin liquid called the **aqueous humor**. The posterior chamber is the space between the single lens and the iris. The larger posterior cavity between the lens and the retina contains the thicker **vitreous humor**, which helps maintain the shape of the eye.

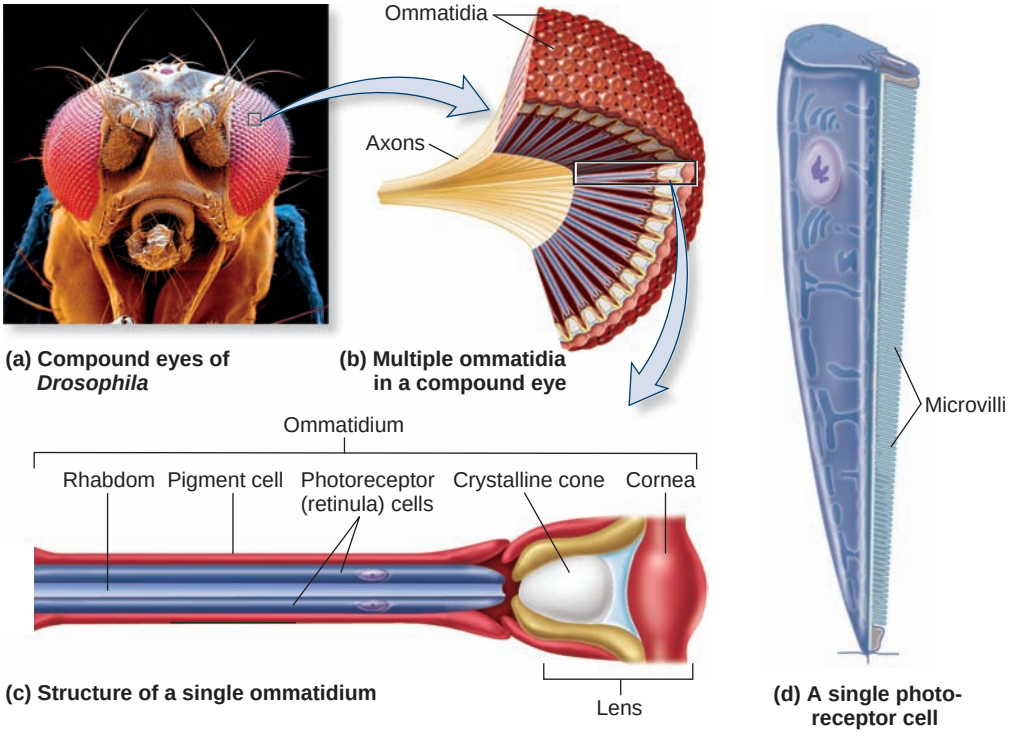

Figure 43.14 **The compound eye of insects.** **(a)** Close-up of the eyes of a fruit fly (*Drosophila melanogaster*). **(b)** Each eye has approximately 1,000 ommatidia, which form a sheet on the surface of the eye. **(c)** Each ommatidium has a lens that directs light to the photosensitive rhabdom. **(d)** Extending from each photoreceptor cell are many light-sensitive microvilli.

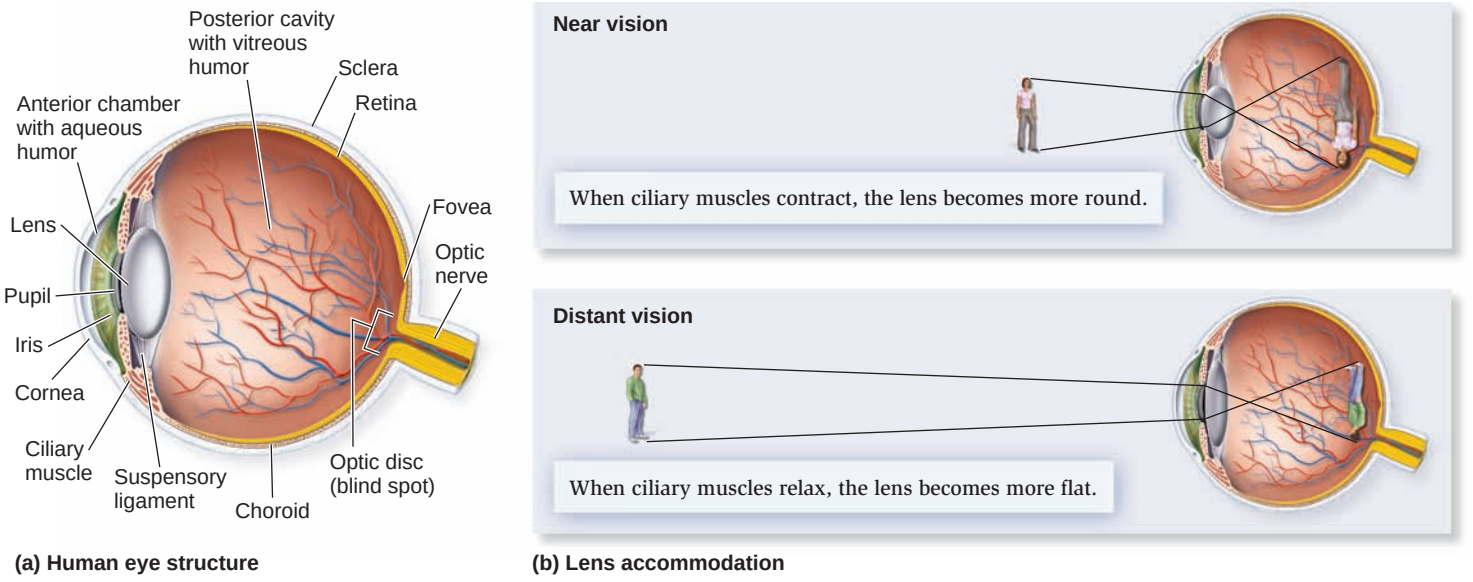
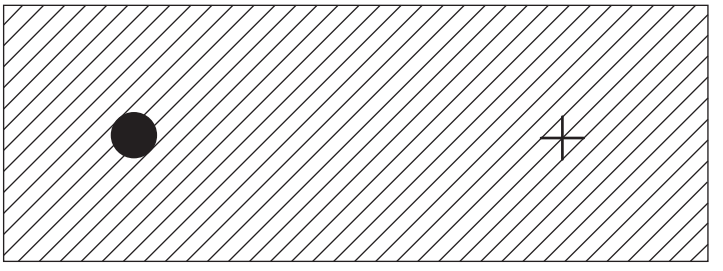


(a) Human eye structure

(b) Lens accommodation



(c) Demonstration of blind spot

Figure 43.15 **The vertebrate single-lens eye.** **(a)** The structure of the human eye. **(b)** Changes in lens shape during accommodation. When an object is near, the ciliary muscles contract and the lens becomes rounder, causing light to bend more. When the object is far away, the ciliary muscles relax and the lens flattens. **(c)** Demonstration of the blind spot. First, hold this picture up in front of your face, or place the book on a table and stand over it. Next, close your left eye and stare at the black spot with your right eye while you move the picture toward and away from your face. At some point, light reflecting off the plus (+) sign will fall directly on your blind spot, and it will seem to disappear.

The hole in the center of the iris is the pupil. The size of the pupil changes when the muscles of the iris reflexively relax or contract to allow more or less light to enter the eye.

Because light radiates in all directions from a light source, light must be bent (refracted) inward toward the photoreceptors at the back of the eye. This is accomplished by the cornea and the lens. Whenever light passes from one medium to another medium of a different density, light waves will bend (try looking at a pencil in a glass partly filled with water). The cornea, which is at the interface between the air and the aqueous humor, initially refracts the light. The light then passes through the thick lens, where it is refracted again and focused onto the layer of photoreceptors, the retina, at the back of the posterior chamber. The bending of the incoming light results in an upside-down and laterally inverted image on the retina, but the brain adjusts for this, and the image is perceived correctly.

The lens is adjusted to focus light that comes from different distances. In fishes and amphibians, the lens is moved forward or backward. In the avian and mammalian eye, the lens remains stationary but changes shape to become more or less round. When the lens is stretched, it flattens, and light passing through it bends less than when it is round. Contraction and relaxation of the ciliary muscles adjust the lens according to the angle at which light enters the eye, a process called **accommodation** (Figure 43.15b).

The single-lens eye is often compared to a film camera. Like the aperture mechanism of a camera, the iris regulates the amount of light that enters the eye. Just as the lens of a camera bends light and directs it toward the light-sensitive film, the lens of the eye bends and directs light toward the photoreceptor cells on the surface of the retina. Both the retina and a piece of film can be thought of as sheetlike structures across which different intensities and colors of light imprint an image.

How does the retina form such sharp images? The region on the retina directly in line with the pupil and lens is called the macula. The center of the macula, the **fovea**, contains the highest density of photoreceptors for color. The fovea is responsible for the sharpness with which we and many other animals see in daylight. However, the retina also has limitations in forming images. In the eye, as mentioned, the image initiates signals that travel from the retina to the brain through neurons that exit the eye in the optic nerve. In vertebrates, the point on the retina where the optic nerve leaves the eye is called the **optic disc**. The optic disc does not have any photoreceptors, forming a "blind spot" where light does not activate a response (Figure 43.15c). Invertebrates with single-lens eyes do not have a blind spot, because the photoreceptors in their eyes are at the front of the retina; consequently, the optic nerve does not pass through the layer of photoreceptors before leaving the eye. How do photoreceptors respond to light to form these images?

Rods and Cones Are Photoreceptor Cells

The two types of photoreceptors have names that are derived from their shapes: rods and cones (Figure 43.16). **Rods** are very sensitive to low-intensity light and can respond to as little as one photon, but they do not discriminate different colors. Rods are used mostly at night, and they send signals to the brain that generate a black-and-white visual image. **Cones** are less sensitive to low levels of light but, unlike rods, can detect color. Cones are used in daylight by most diurnal (active by day) vertebrate species and by some insects such as the honeybee, which can detect the yellow color of pollen. Compared to rods, the human retina has fewer cones, which are clustered in and around the fovea. Cones provide sharp images because of their density at the fovea. Although they are less sensitive to light than rods, this is less critical in daylight because the amount of light reaching the eyes at this time far exceeds what is needed to stimulate any photoreceptor cell. Because the two types of photoreceptor are specialized for either night or day vision, neither rods nor cones function at peak efficiency at twilight. This accounts for our relatively poor vision at this time.

Rods and cones are cells with three functional parts: the outer segment, inner segment, and synaptic terminal. The **outer segment** of the cell contains folds of membranes that form stacks like discs (Figure 43.17). These discs contain the pigment molecules that absorb light. The **inner segment** of the cell contains the cell nucleus and other cytoplasmic organelles. Rods and cones do not have axons but have synaptic terminals with neurotransmitter-containing vesicles, which synapse with other neurons within the retina.

Nocturnal animals (those active at night) rely predominantly on rod vision, though some have limited color vision, too. In diurnal animals with both rods and cones, such as humans, the rods are located around the periphery of the retina away from the fovea. Therefore, it is easiest to see low-intensity light if it comes into the eye at an angle. You can easily test this. In early evening, before many stars are visible, look at the sky until you notice a star out of the corner of your eye. Now shift your gaze to where you thought you saw the star. You will probably not be able to locate it anymore. When you look away again so that light from the dim star enters your eye at an angle, it will reappear. This demonstrates that under low-light conditions, your vision is better when the light is directed to the part of the retina that contains only rods.

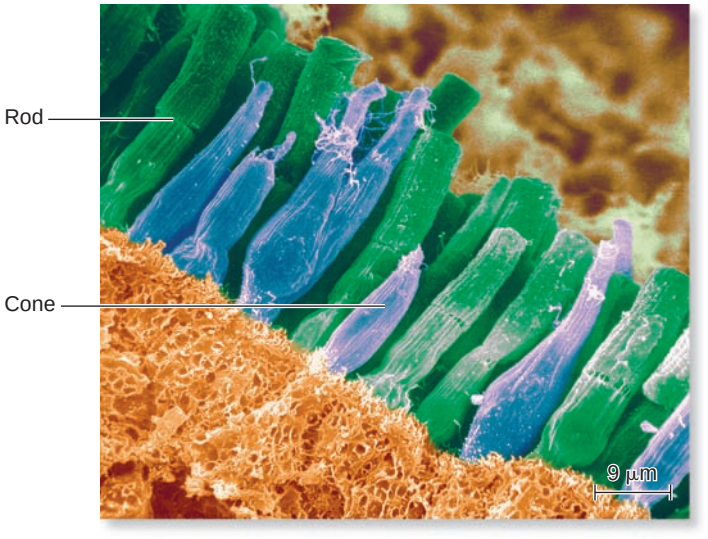


Figure 43.16 **Rod and cone photoreceptors.** Rods are shown as green and cones as blue in this false-color image (SEM).

Rods and Cones Contain Visual Pigments That Detect Light

Visual pigments are molecules that absorb light; they are found embedded in the disc membranes of the outer segment of rods and cones. In the mid-20th century, American biologist and Nobel Prize winner George Wald discovered that these pigments consist of two components bonded together. The first is **retinal**, a derivative of vitamin A that is capable of absorbing light energy. The discovery of retinal in the visual pigment explains the need for vitamin A in the diet and its importance in vision. The second component of visual pigments is a protein called **opsin**, of which there are several types. Opsins are examples of G-protein-coupled receptors (see Chapter 9), which trigger a biochemical cascade that changes the permeability of membrane channels to ions.

Rods and cones have visual pigments containing different types of opsin protein. These pigments are named according to the type of opsin they contain. In rods, the visual pigment is

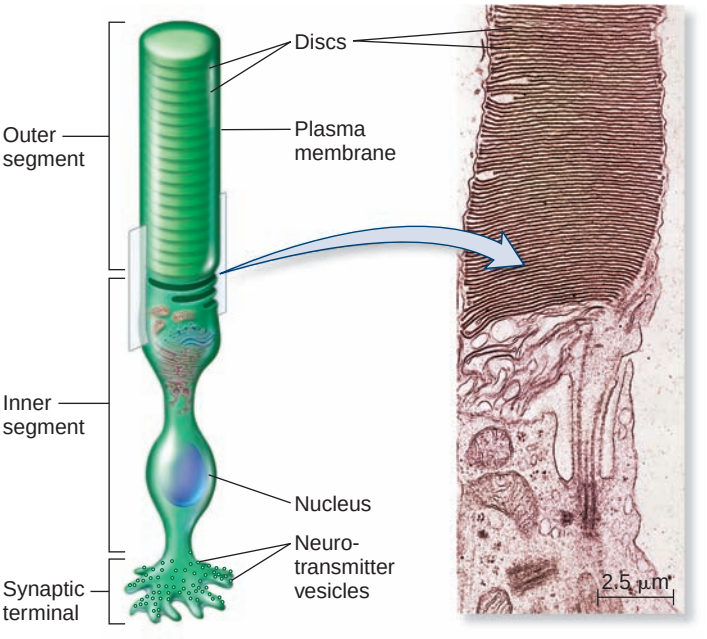

Figure 43.17 **Structure of a photoreceptor.** The illustration shows the structure of a rod photoreceptor and its appearance in a transmission electron micrograph. Note the multiple stacks of membranous discs in the outer segment of the cell.

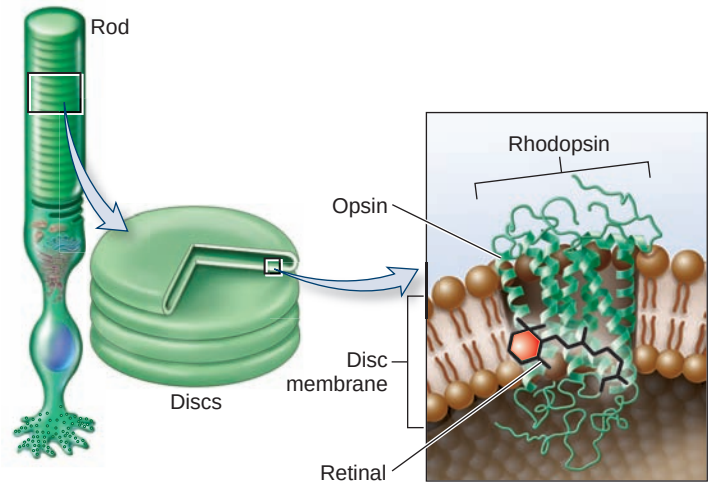

Figure 43.18 **A visual pigment.** The visual pigment rhodopsin is found within the membrane of the rod photoreceptor discs. It is composed of a transmembrane protein, opsin, that is bonded to a molecule of retinal, a derivative of vitamin A that is capable of absorbing light energy.

Concept check: *What is the adaptive value of the convolutions and discs of photoreceptors?*

named **rhodopsin** (Figure 43.18). Cones contain several types of visual pigments called **cone pigments**, or photopsins.

In humans, cone pigments are composed of retinal plus one of three possible opsin proteins. Each type of opsin protein determines the wavelength of light that the retinal in a cone can absorb. For this reason, each cone pigment can respond to either red, green, or blue light. Any given cone cell makes only one type of cone pigment. Many different shades of these colors can be perceived, however, because the brain uses information about the proportion of each type of cone that was stimulated to generate all other colors. Red, green, and blue opsins are not present in all species, and many species have only one or two opsins. Presumably, the more types of cones an animal has, the more shades of color it perceives. It is intriguing, therefore, to imagine how birds see the world, because they have up to five cones of overlapping wavelength sensitivity. What happens, however, if some cones are defective?

Concept check: *Why is red-green color blindness rare in females?*

Genomes & Proteomes Connection

Mutations in Cone Pigments Cause Color Blindness

In daylight, about 92% of human males and over 99% of females have normal color vision. However, problems in color vision may result from defects in the cone pigments arising from mutations in the opsin genes. The most common is red-green color blindness, which occurs predominantly in men (1 in 12 males compared with 1 in 200 females). Individuals with red-green color blindness either lack the red or green cone pigments entirely or, more commonly, have one or both of them in an abnormal form. In one form, for example, an abnormal green pigment responds to red light as well as green, making it difficult to discriminate between the two colors.

Color blindness was first described in the scientific literature in 1794 by John Dalton, the chemist mentioned in Chapter 2 after whom units of molecular mass are named. Dalton was himself color blind and willed that his eyes be preserved so that careful examination of them might help to determine the cause of the defect. He hypothesized that it arose because his aqueous humor was filled with a blue-colored medium of some type, but this was proven wrong after his death.

Instead, discovering the cause of color blindness had to wait until the development of genetics. As geneticists determined, color blindness results from a recessive mutation in one or more genes encoding the opsins. Genes encoding the red and green opsins are located very close to each other on the X chromosome, while the gene encoding the blue opsin is located on a different chromosome. In males, the presence of only one X chromosome means that a single recessive allele from the mother will result in red-green color blindness, even though the mother herself is not color blind (Figure 43.19). In 1994, DNA testing of John Dalton's retina confirmed that he had classic red-green color blindness.

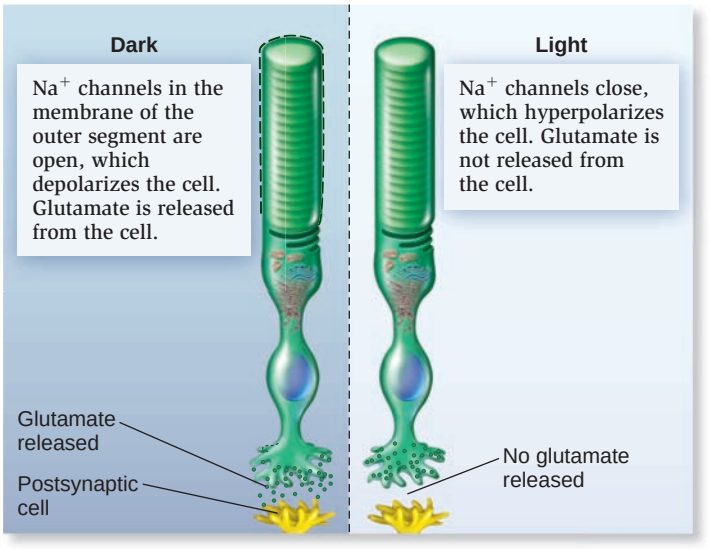

Figure 43.20 Membrane potential response of photoreceptors to dark and light.

Photons Change Photoreceptor Activity by Altering the Conformation of Visual Pigments

Photoreceptors differ from other sensory receptor cells because at rest in the dark their membrane potential is slightly depolarized, whereas in response to a light stimulus, it is hyperpolarized rather than depolarized (Figure 43.20). In the dark, the cell membranes of the outer segments of resting cells are highly permeable to sodium ions. Sodium ions flow into the cytosol of the cell through open Na^+ channels in this membrane, depolarizing the cell. This depolarization results in a continuous release of the neurotransmitter glutamate from the synaptic terminal of the photoreceptor. The photoreceptor synapses with a postsynaptic cell that is the next neuron in the visual pathway. This initiates a series of events within the retina that is interpreted by the brain as an absence of light. In contrast, when exposed to light, the Na^+ channels in the outer segment membranes of the photoreceptor close. The resulting reduction in sodium concentrations leads to a hyperpolarization of the cell. In response, the release of glutamate is stopped. This results in a series of cellular activations within the retina and brain that is interpreted as a visual image.

Let's take a more detailed look at the mechanism that allows a photoreceptor to respond to light (Figure 43.21). When the photoreceptor is exposed to light, the retinal within the visual pigment absorbs a photon. The energy of the photon alters the retinal from *cis*-retinal to *trans*-retinal, an isomer with a slightly different conformation due to a rotation at one of the molecule's double bonds (Figure 43.21). This change results in retinal briefly dissociating from the opsin protein, causing the opsin to change its three-dimensional shape and activate a G protein called transducin, located in the disc membrane. The activated transducin, in turn, activates another disc protein, the enzyme phosphodiesterase.

The action of phosphodiesterase results in the closure of Na^+ channels in the outer segment membrane. Remember that

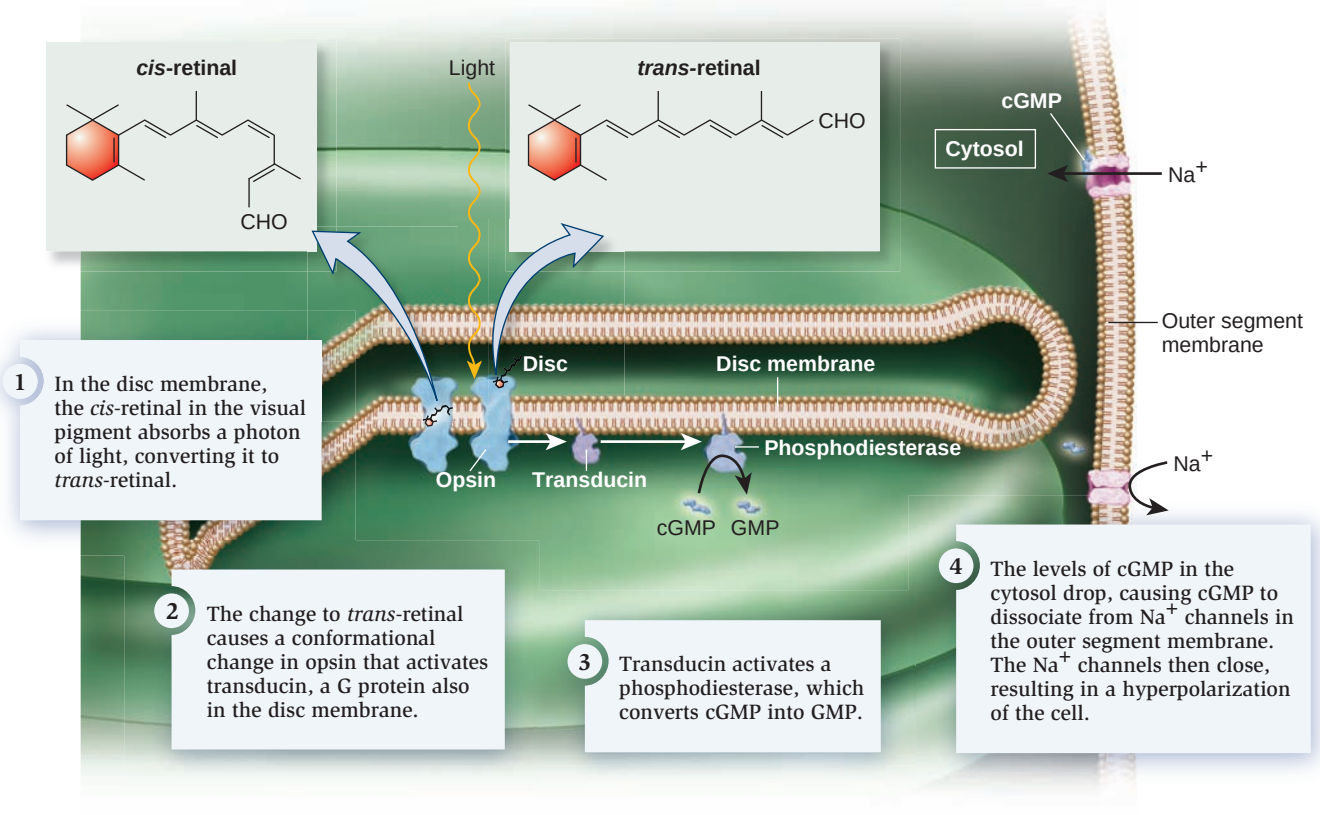

Figure 43.21 Signal transduction in photoreceptor (rod) cells in response to light.

in the dark, these channels are open. Sodium ions flow in and are pumped back out of the cell by Na^+/K^+-ATPase pumps in the cell membrane of the inner segment. The Na^+ channels are gated by intracellular cGMP. In the dark, cytosolic concentrations of cGMP are high, keeping sodium channels open. However, when phosphodiesterase is activated, it reduces the amount of cytosolic cGMP by converting it to GMP. GMP molecules cannot hold the sodium channels of the outer segment membrane open, so the channels close, and sodium ions stop moving into the cell. The membrane potential of the cell becomes less positive than it was in the dark. Therefore, the response of the cell is a hyperpolarization that is proportional to the intensity of the light. The final result is a decrease in glutamate release from the photoreceptor (see Figure 43.20), ultimately leading to a visual image. The sequential activation of enzymes following activation of a single photoreceptor results in an amplification of the original signal (see Chapter 9 for a description of signal amplification). Because of this property, we are able to detect extremely low levels of light.

The Visual Image Is Refined in the Retina

Thus far, we have considered the structure of the vertebrate eye and how photoreceptors transduce light. We will now turn our attention to the neural pathways through which the visual signal travels to reach the brain. To do so, we must consider the cellular organization of the retina. The vertebrate retina has three layers of cells (Figure 43.22). The rods and cones form the deepest layer, closest to the inside of the sclera. Immediately behind the photoreceptors is a pigmented epithelium that absorbs light that missed the photoreceptors; this prevents scattering of light within the retina, which could degrade the sharpness of vision. Because the photoreceptors are positioned at the back of the retina, light must pass through two transparent layers of cells before it reaches them. The middle layer contains **bipolar cells**, so named because one end (or "pole") of the cell synapses with the photoreceptors, and the other end relays responses to a top layer of cells, the **ganglion cells**. The ganglion cells send their axons out of the eye into the optic nerve. In addition to these three layers, two other types of cells, horizontal and amacrine cells, are interspersed across the retina.

The pathway for light reception begins at the photoreceptor cells (rods and cones). These photoreceptor cells release neurotransmitter molecules that affect the membrane potential of bipolar cells. The membrane potential of the bipolar cells determines the amount of neurotransmitter that they release, which, in turn, controls the membrane potential of ganglion cells. When a threshold potential is reached in ganglion cells, action potentials are sent out of the eye via the optic nerve to the brain. These signals travel along pathways that include the thalamus, brainstem, cerebellum, and the visual cortex (the occipital lobe of the cerebral cortex). Visual information is further refined and interpreted within the visual cortex. The visual cortex responds to such characteristics of the visual scene as whether something is moving, how far away it is, how one color compares to another, and the nature of the image (for example, a face). The cortex does not form a picture in the brain, but forms a spatial and temporal pattern of electrical activity that is perceived as an image.

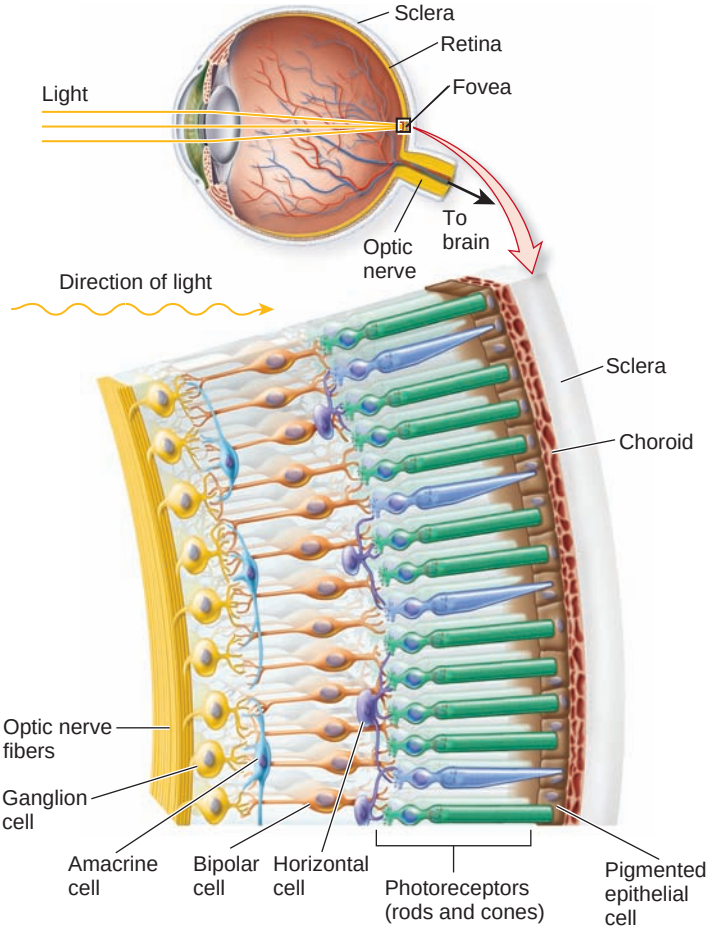

Figure 43.22 **The arrangement of cells in the retina.** Light passes through two layers of cells before it reaches the photoreceptors. Amacrine and horizontal cells integrate the responses of the bipolar and ganglion cells. The ganglion cells generate action potentials to carry the information to the brain.

Horizontal and amacrine cells modify electrical signals as they pass from the photoreceptors to the ganglion cells. These cells adjust the signal significantly, enhancing an animal's ability to visualize a scene by emphasizing the differences between images. Horizontal cells make connections between photoreceptors and help to define the boundaries of an image. Amacrine cells are important in adjusting the eye to different light intensities and increasing the sensitivity of the eye to moving images. The ability of the retina to refine the image is especially well developed in birds and reptiles. These animals have complex retinas that process the image extensively before it is interpreted in the brain.

Vertebrate Eyes Are Adapted to Environmental Conditions and Life Histories

Many vertebrates show unique modifications of their visual systems that are the result of evolutionary adaptations to environmental conditions. Other adaptations have occurred as a

result of behavioral requirements for obtaining food or attracting a mate.

Variation in Light Intensity Over the course of a day, the amount of light that stimulates the eye varies widely. The vertebrate eye can adjust to the differences in illumination in part by adjusting the diameter of the pupil. In addition, the eye can adapt to light differences by changing the relative amounts of *cis*- and *trans*-retinal. Such changes can alter the light sensitivity of the eye by as much as a million-fold!

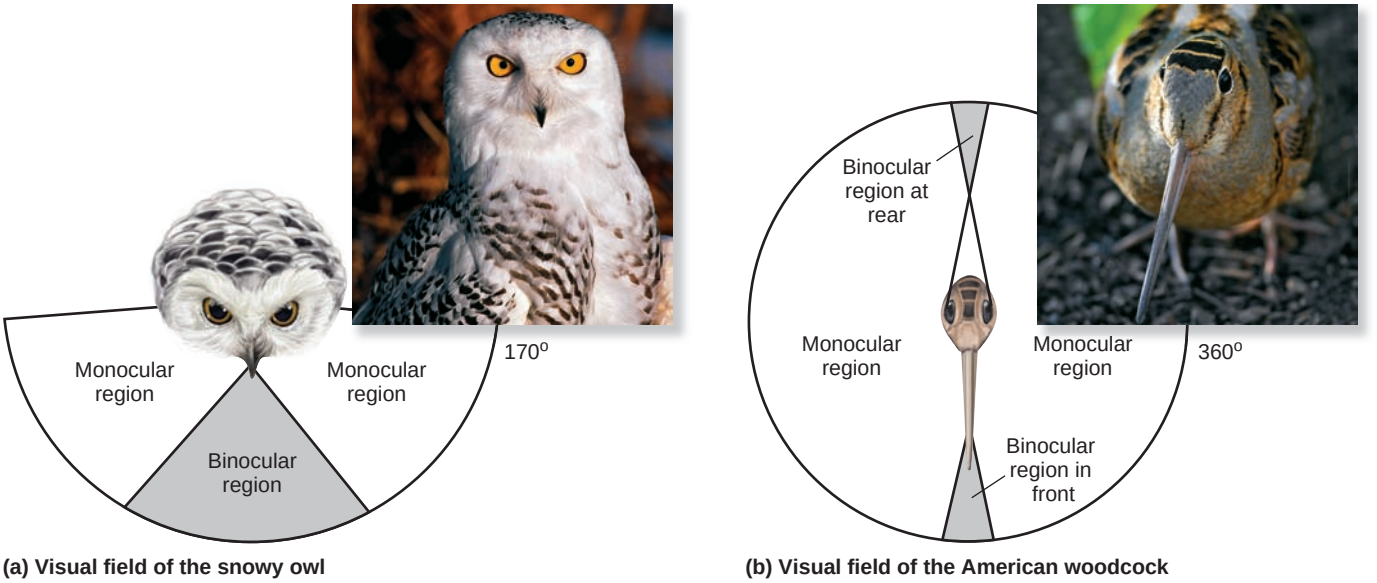
In a dark environment, a large amount of *cis*-retinal is available for light absorption. When light stimulates *cis*-retinal to change into *trans*-retinal, the visual pigment no longer responds to additional light and is said to be bleached. Bleaching makes the eye less sensitive to low levels of light. When you enter a dark movie theater on a bright day, for example, most of your visual pigments have been bleached by the sunlight and are temporarily unavailable for use. For a few minutes, you are unable to detect low levels of light. This process of adjusting to dim light, called dark adaptation, involves the gradual reconversion of *trans*-retinal to *cis*-retinal.

Conversely, when you move from a dark room into bright sunlight, as when you leave the theater after the matinee, the large amount of *cis*-retinal makes your eyes extremely sensitive to light and temporarily overwhelms your ability to see colors and shapes. In light adaptation, the bright light stimulates bleaching of the visual pigments, converting *cis*-retinal back to *trans*-retinal, which reduces the response to bright light.

Differences in Eye Placement Except for some of the ray-finned fishes, blunt-headed cetaceans, and most amphibians, vertebrate animals have some degree of **binocular** (or stereoscopic) **vision**. Animals with both eyes located at or near the front of the head, such as primates and raptors, have greater binocular vision, because the overlapping images coming into both eyes are processed together in the brain to form one perception (Figure 43.23). Binocular vision provides excellent depth perception because the images come into each eye from slightly different angles. The brain processes those tiny differences to determine where an object is relative to other objects in its environment. Predators benefit from binocular vision because it helps them judge distance and determine the location of their prey. Binocular vision is present in predatory birds such as the snowy owl (Figure 43.23a) and mammals (as well as in predatory insects such as Mantids), and also in arboreal animals that must judge distances between tree limbs.

In contrast, animals with eyes on the sides of the head, such as most fishes, blunt-headed cetaceans, amphibians, herbivorous mammals, and insects, have strictly or primarily **monocular vision**. Monocular vision allows an animal to see a wide area at one time, at the cost of reduced depth perception. Many prey species have monocular vision, perhaps because it helps them scan for predators across a wide field of vision. The placement of the eyes in the American woodcock (*Scolopax minor*) actually permits a field of vision of 360°, most of which is monocular (Figure 43.23b); in other words, these and similar birds can see directly behind themselves, even when digging in the dirt for earthworms!

Vision in the Deep Sea Fishes and other deep-sea vertebrates have color vision that is limited primarily to the color blue. Light with longer wavelengths that would be seen as red or orange does not usually penetrate more than 6 m into the water, whereas the higher-energy, shorter-wavelength light, which is seen as blue, can penetrate to greater depths. Aquatic animals that live in the deep sea are usually capable of seeing only blue, because they generally have only one opsin, which



(a) Visual field of the snowy owl **(b) Visual field of the American woodcock**

Figure 43.23 **Examples of binocular and monocular fields of vision.** Visual fields are shown for **(a)** the snowy owl (*Bubo scandiacus*) and **(b)** the American woodcock (*Scolopax minor*). Monocular regions are white; binocular regions are shaded.

is responsive to blue light. Deep-dwelling fishes tend to be drab colors, because most wavelengths of light do not penetrate that far and therefore could not reflect off the surface of the fishes. In those deep-dwelling fishes with more than one type of opsin, the additional visual pigments detect the bioluminescence (self-generated light, like that of a firefly) produced by their own or other species.

By contrast, fishes that live near the water's surface sometimes have four or five different opsins, giving them excellent color vision. Not surprisingly, shallow water and surface-dwelling fishes are often very colorful, because light of all wavelengths penetrates shallow water. These fishes have adapted by using coloration for protection (camouflage) or for identification.

Vision with Speed Peregrine falcons, like other raptors, have exceptionally good eyesight. They dive at speeds up to 150 to 200 miles per hour to capture prey, and their visual system is specialized to maintain great sensitivity during the dive. The retina of a falcon has two foveas, one deep and one shallow. The deep fovea has a central pit and provides the highest visual accuracy when objects are far away and to the side. However, when the falcon uses the deep fovea, it does not have good depth perception. The shallow fovea provides the best images of nearby objects and good depth perception. When the falcon dives, it first uses the deep fovea to locate the prey and steer toward it. When the falcon gets closer, it switches to the shallow fovea. Some details of the image are sacrificed, but the improved depth perception allows it to gauge when it will reach its prey.

Vision in the Dark: The Tapetum Lucidum Did you ever wonder why cats' eyes seem to glow in photographs, as in the chapter-opening photo? What you see is light being reflected off the tapetum lucidum, a reflective layer of tissue located beneath the photoreceptors at the back of the eye in some animals. When light enters the retina, some of it passes into the layer containing the photoreceptors, but some light also passes through this layer. Normally, the pigmented epithelium at the back of the eye absorbs this light. However, in animals with a tapetum lucidum, the light reflects off this structure and back to the photoreceptors. This gives the photoreceptors a "second chance" to capture light, making it easier to detect low levels of light. Many nocturnal animals, both vertebrate and invertebrate, have a tapetum lucidum, which increases their ability to see in the dark.

43.6 Chemoreception

Chemoreception includes the senses of smell (**olfaction**) and taste (**gustation**), both of which involve detecting chemicals in air, water, or food. These chemicals bind to chemoreceptors, which, in turn, initiate electrical responses in other neurons that pass into the brain. Amazingly, the binding of a single molecule to a receptor cell can sometimes be perceived as an odor! Airborne molecules that bind to olfactory receptors must be small enough to be carried in the air and into the nose. Taste molecules can be heavier because they are conveyed in food and liquid.

Taste and smell are closely related. In fact, the distinction is largely meaningless for aquatic animals, because for them all chemoreception comes through the water. Even in terrestrial animals, about 80% of the perception of taste is actually due to activation of olfactory receptors. (This is why food loses its flavor when the sense of smell is impaired, such as when you have a cold.) In this section, we explore chemoreception in insects and then in mammals.

Olfaction and Taste in Insects Involve Chemoreceptors in Sensory Hairs

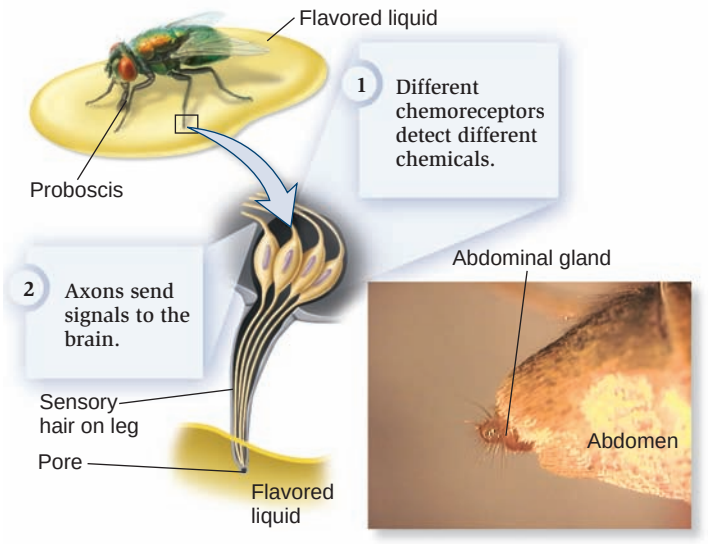
Insects are highly dependent on odor and taste for finding food and mates. In insects, chemoreceptors are neurons that are located on sensory hairs on the proboscis, legs, feet, and antennae. Each sensory hair on the proboscis and feet has a pore at the tip through which the substance passes. As the example in Figure 43.24a shows, the blowfly has four separate chemoreceptors within each hair, and each of these neurons responds to different molecules. Dendrites of the chemoreceptor cells inside the pore bind to the molecules and initiate a sensory transduction pathway that opens ion channels in the membrane. This depolarizes the plasma membrane of the chemoreceptor cell and generates action potentials, which are sent to the brain for interpretation.

In certain moths, males have elaborate antennae that can sense pheromones, extremely potent signaling molecules given off by a female. The female secretes a sexual-attractant pheromone into the air from an abdominal gland (Figure 43.24b), and the chemosensory hairs on the male's antennae (Figure 43.24c) can detect extremely low concentrations of it from several kilometers away. This highly sensitive detection system enables the male to locate the female in the dark.

Mammalian Olfactory Receptors Respond to the Binding of Odor Molecules

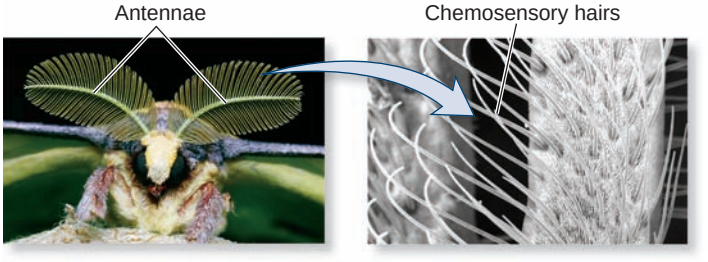
The olfactory sensitivity of mammals varies widely depending on their supply of olfactory receptor cells, which ranges from 5 or 6 million in humans to 100 million in rabbits and 220 million in dogs. Olfactory receptors are neurons that are located in the epithelial tissue at the upper part of the nasal cavity in mammals (Figure 43.25a). These cells are surrounded by two additional cell types: supporting cells and basal cells. Supporting cells are located between the receptor cells and provide physical support for the olfactory receptors. The basal cells differentiate into new olfactory receptors every 30–60 days, replacing those that have died after prolonged exposure of their cell endings.

Olfactory receptors have dendrites from which long, thin extensions called cilia emerge into a mucous layer that covers the epithelium. Despite the similarity in structure, these cells do not function like the mechanoreceptor hair cells of the auditory and vestibular systems; these cilia are different from stereocilia that bend. Instead, olfactory receptor cells have receptor proteins within the plasma membranes of the cilia (Figure 43.25b).



(a) Chemoreception in the blowfly

(b) Abdominal gland of the female moth secretes a pheromone.

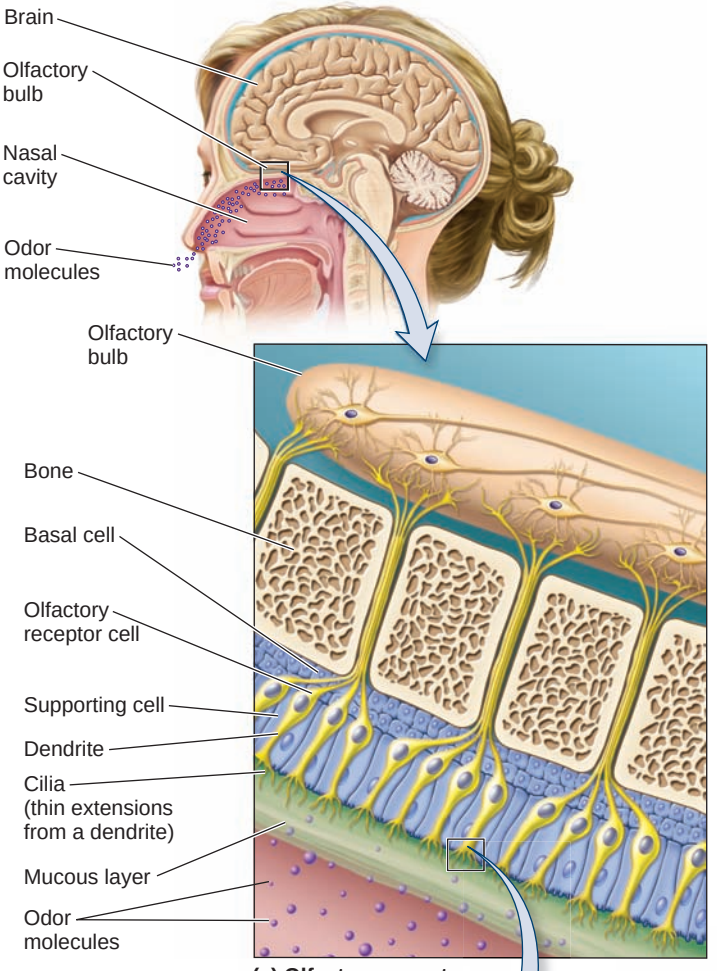


(c) Chemosensory hairs on antennae of the male moth detect the pheromone.

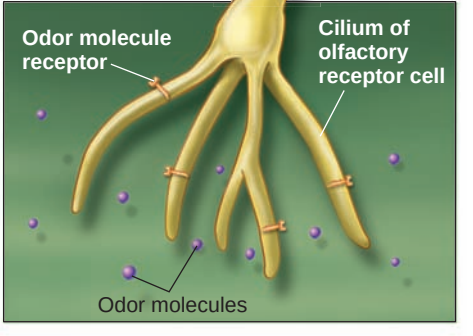
Figure 43.24 **Chemoreception in insects.**
(a) Chemosensory cells of the blowfly located on the proboscis, legs, and feet sense different chemicals. **(b)** Female moths secrete a pheromone from abdominal glands, which is detected by **(c)** chemosensory hairs in a male's antennae (shown enlarged in this scanning electron micrograph) that bind odor molecules.

Airborne molecules dissolve in the mucus and bind to these olfactory receptor proteins. When an odor molecule binds to its receptor protein, it initiates a signal transduction pathway that ultimately opens sodium channels in the plasma membrane. The subsequent depolarization results in action potentials being transmitted to the next series of cells in the olfactory bulbs, which are located at the base of the brain, one on each side. The olfactory bulbs are a collection of neurons that act as an initial processing center of olfactory information and as a relay center to the cerebral cortex and limbic system for further processing and interpretation.

The relative size of the olfactory bulbs indicates the importance of olfaction to an animal. In humans, the olfactory bulbs make up only about 5% of the weight of the brain, whereas in nocturnal animals like rats and mice, they can comprise as much as 20%. Even with their relatively limited olfactory sensitivity, however, humans have the capacity to detect up to 10,000 different odors, and other mammals are thought to respond to many more. Exactly how this is possible remained a mystery until 1991, when two scientists uncovered the molecular basis of olfaction.



(a) Olfactory receptor cells in olfactory epithelium



(b) Cilia from dendrite with odor molecule receptors

Figure 43.25 **Olfactory structures in the human nose.**
Odor molecules dissolve in a layer of mucus that coats the olfactory receptor cells. The molecules bind to protein receptors in the membrane of cilia that extend from the olfactory receptor cells. Action potentials in the olfactory receptor cells are conducted to cells in the olfactory bulb, and from there to the brain for interpretation. Basal cells periodically replace dead or damaged olfactory receptor cells.

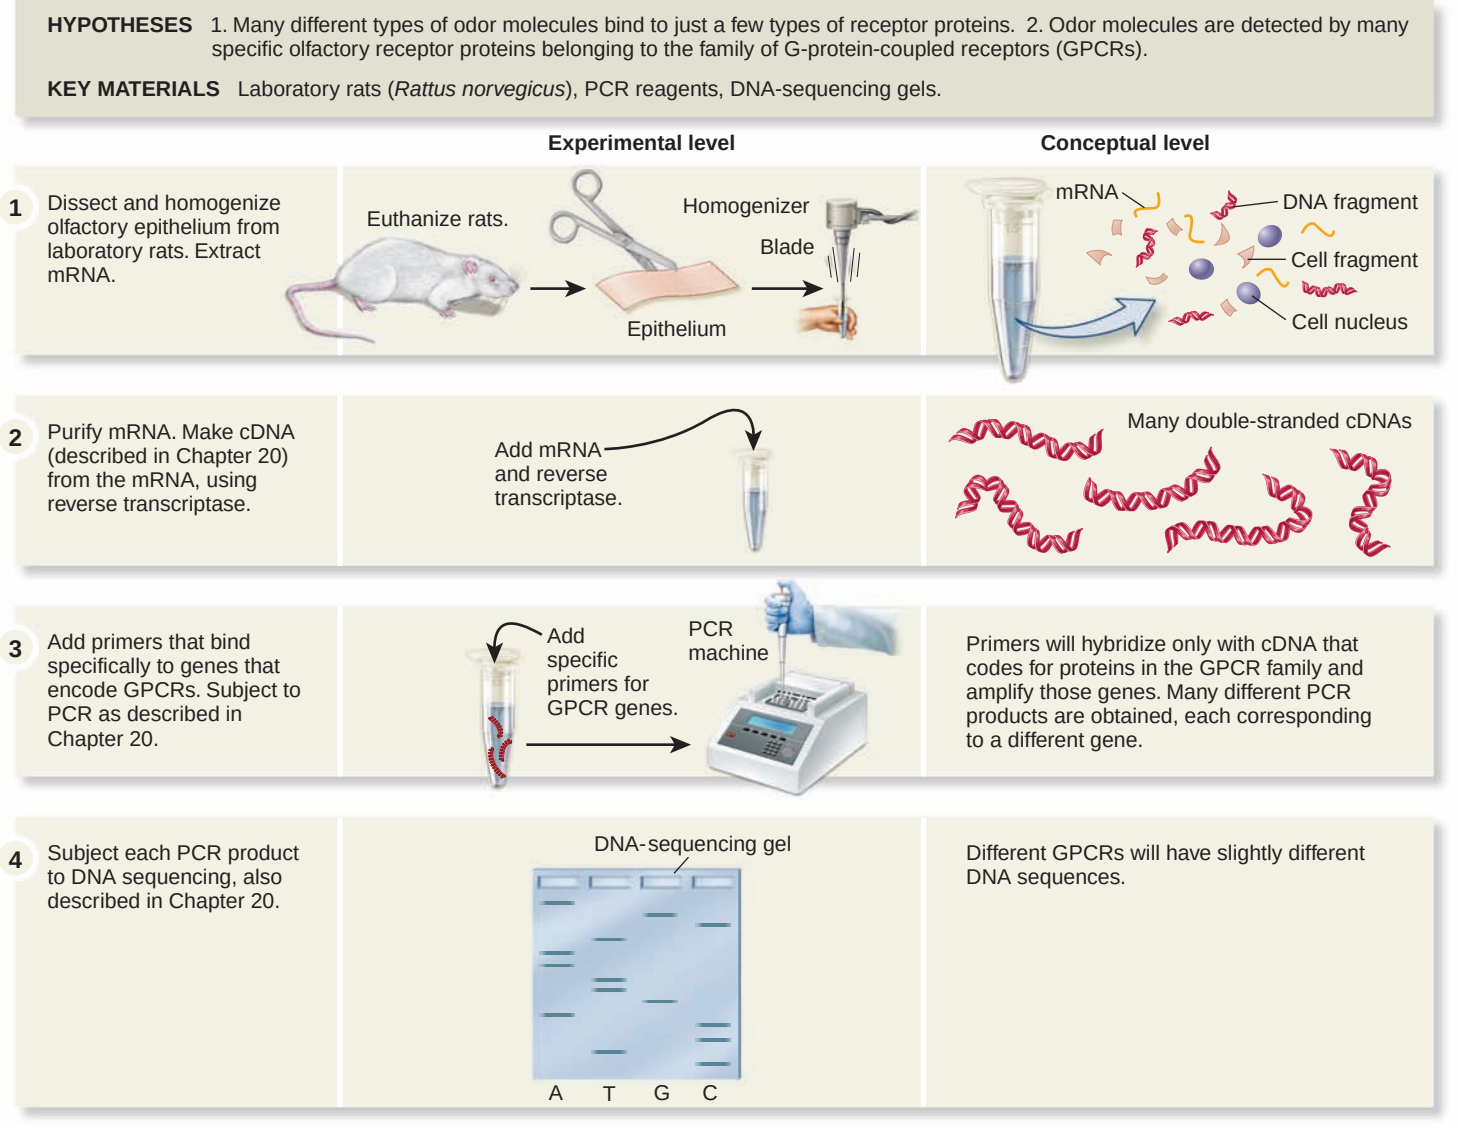
Feature Investigation

Buck and Axel Discovered a Family of Olfactory Receptor Proteins That Bind Specific Odor Molecules

How does the olfactory system discriminate among thousands of different odors? American neuroscientists Linda Buck and Richard Axel set out to study this question. When they began, two hypotheses were proposed to explain this phenomenon. One possibility was that many different types of odor molecules might bind to one or just a few types of receptor proteins, with the brain responding differently depending on the number or distribution of the activated receptors. The second hypothesis was that olfactory receptor cells can make many different types of receptor proteins, each type binding a particular odor molecule or group of odor molecules.

To begin their study, Buck and Axel assumed that olfactory receptor proteins would be highly expressed in the olfactory receptor cells, but not in other parts of the body. Based on previous work, they also postulated that the receptor proteins would be members of the large family of G-protein-coupled receptors (GPCRs), described in Chapter 9. As shown in Figure 43.26, they isolated olfactory receptor cells from rats and then lysed (broke open) the cells to release the mRNA. The purified mRNA was then used to make cDNA via reverse transcriptase. This generated a large pool of cDNAs, representing all of the genes that were expressed in olfactory receptor cells at the time of mRNA collection. To determine if any of these cDNAs encoded GPCRs, they used primers that recognized regions within previously identified GPCR genes that are highly conserved. A highly conserved region is a DNA sequence that rarely changes

Figure 43.26 Buck and Axel identified olfactory receptor proteins in olfactory receptor cells.



5 THE DATA

The DNA sequencing revealed 18 different GPCRs that were specifically expressed in the receptor cells of the olfactory epithelium.

6 CONCLUSION Olfactory receptor cells express many different receptor proteins that account for an animal's ability to detect a wide variety of odors.

7 SOURCE Buck, L., and Axel, R. 1991. A novel multigene family may encode odorant receptors: a molecular basis for odor recognition. *Cell* 65:175–187.

among different members of a gene family (see Chapter 21). The primers were used in the PCR technique to amplify cDNAs that encoded GPCRs. This produced many PCR products that were then subjected to DNA sequencing. As shown in The Data in Figure 43.26, Buck and Axel initially identified 18 different genes, each encoding a GPCR with a slightly different amino acid sequence. Further research showed that these 18 genes were expressed in nasal epithelia, but not in other parts of the rat's body. These results were consistent with the second hypothesis stated earlier, namely that organisms make a large number of receptor proteins, each type binding a particular odor molecule or group of odor molecules.

Since these studies, researchers have determined that this family of olfactory genes in mammals is surprisingly large. In humans, over 600 genes that encode olfactory receptor proteins have been identified, though about half of these are pseudogenes that are no longer functional. This value underscores the importance of olfaction even in humans. Each olfactory receptor cell is thought to express only one type of GPCR that recognizes its own specific odor molecule or group of molecules. Most odors are due to multiple chemicals that activate many different types of odor receptors at the same time. We perceive odors based on the combination of receptors that become activated, and then send signals to the brain. This ability to combine different inputs allows us to perceive several thousand different odors despite having only several hundred different olfactory receptor proteins.

The research of Buck and Axel explained, in part, how animals detect a myriad of odors. In 2004, they received the Nobel Prize for this pioneering work. Even so, many intriguing questions remain. We do not yet understand the pattern of gene regulation in the receptor cells or how the brain actually interprets the signals it receives from those cells.

Experimental Questions

1. What were the two major hypotheses to explain how animals discriminate between different odors? How did Buck and Axel test the hypothesis of multiple olfactory receptor proteins?
2. What were the results of Buck and Axel's study?
3. Considering the two hypotheses explaining how animals discriminate between different odors (see Question 1), which one was supported by the results of this experiment? With the evidence presented by Buck and Axel, what is the current hypothesis explaining the discrimination of odors in animals?

Taste Buds Detect Food Molecules

Chemical senses are present in all animal phyla, although not all animals have taste-sensing organs. Many animals use their taste (gustation) sense to select appropriate foods. For example, butterflies select nectar based on the sugars found in a particular flower, and carnivorous animals detect the taste of different meats based on the combination of amino acids, fats, and sugars that are present. Some freshwater and marine animals, such as catfish and lobsters, have exceptionally sensitive chemoreceptors for specific amino acids that are particularly important as neurotransmitters in the nervous system. Taste can also help an animal seek out necessary nutrients, such as salt, and avoid poisonous chemicals. Toxic substances are often perceived as bitter or distasteful, which may cause an animal to stop eating any such substance immediately.

Taste buds are structures containing chemosensory cells that detect particular molecules in food. Humans have about 9,000 taste buds, while other mammals such as pigs and rabbits have approximately 15,000 to 18,000. The bumps that you see on your tongue are not the taste buds but the papillae, elevated structures on the tongue that collect food molecules in depressions called taste pores. These pores contain many taste buds with sensory receptor cells (Figure 43.27). The sensory receptor cells form a complex with several supporting cells that is organized like the wedges of an orange. The tips of the sensory receptor cells have microvilli that extend into the taste pore. Here, molecules in food that have dissolved in saliva bind to

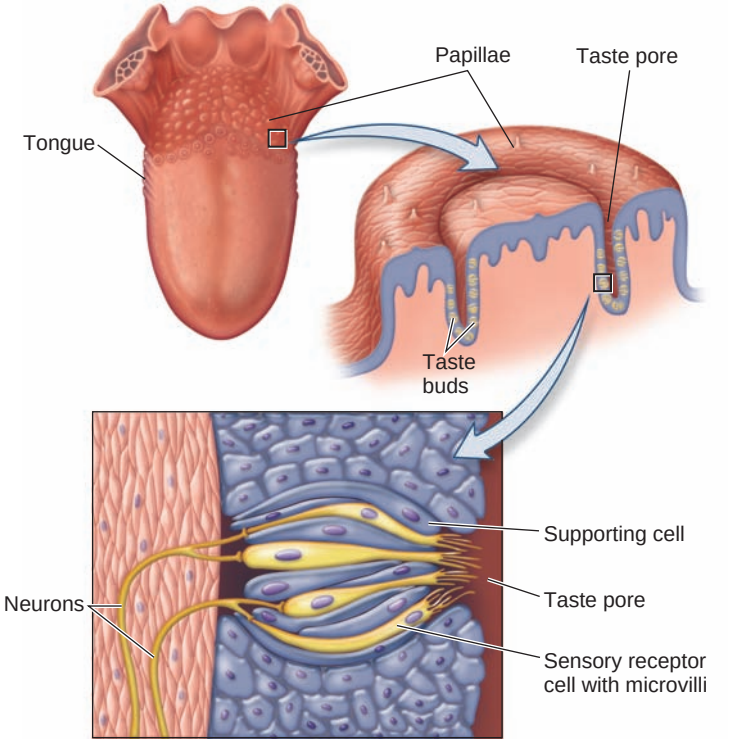


Figure 43.27 **Structures involved in the sense of taste.** This sense occurs in taste buds, which contain the sensory receptor cells that respond to dissolved food molecules.

Concept check: *Why have many animals, including humans, evolved the ability to sense salty, sweet, sour, and bitter?*

receptor proteins. This triggers intracellular signals that alter ion permeability and membrane potentials. The sensory receptor cells then release neurotransmitters onto underlying sensory neurons. Action potentials travel from these neurons to the thalamus and other regions of the forebrain, where the taste is perceived and recognized.

There are a number of different types of taste cells, and they are distributed on the tongue in different areas, but these areas overlap considerably. Each type of cell has a specific transduction mechanism that allows it to detect specific chemicals present in the foods and fluids we ingest. The subjective experience of their activation includes the perception of sweet (sugar), sour (acidic foods like citrus fruits), salty, and bitter. In addition, a newly recognized taste perception called umami (after the Japanese word for "delicious") is associated with the presence in ingested food of glutamate and other similar amino acids, and is usually described as imparting flavorfulness to food. It may account for the widely recognized effects of monosodium glutamate (MSG) in enhancing the flavor of food.

The senses of taste and smell are enhanced when we are hungry, a phenomenon that most likely occurs in other animals as well. Once we have eaten, we are less aware of the smell and taste of food. The importance of this for survival is clear: A hungry animal needs to eat. An improved sense of smell aids in locating food, and a heightened sense of taste encourages an animal to eat. Afterward, these senses become temporarily dampened so as not to distract the animal from its other needs. The mechanism by which these changes occur is uncertain, but it may involve a temporary alteration in the number of smell and taste receptors, or in their ability to bind ligands.

43.7 Impact on Public Health

Sensory disorders are among the most common neurological problems found in humans and range from mild (needing eyeglasses) to severe (blindness). In this section, we present an overview of a few representative sensory disorders that have a major impact on the human population.

Visual Disorders Include Glaucoma, Macular Degeneration, and Cataracts

Visual disorders affect an enormous fraction of the world's population. In the U.S. alone, more than 10 million people have severe eye problems that cannot be corrected by eyeglasses, and more than 1 million people are blind (42 million worldwide). The costs to the U.S. government associated with blindness and severe visual loss amount to nearly $4 billion yearly. Although vision loss has many causes, three disorders account for over half of all cases: glaucoma, macular degeneration, and cataracts.

Normally, the fluid that makes up the aqueous humor in the eye is produced and reabsorbed (drained) in a circulation that keeps the fluid levels constant. In **glaucoma**, drainage of aqueous humor becomes blocked, and the pressure inside the eye increases as the fluid level rises. If untreated, this eventually damages cells in the retina and leads to irreversible loss of vision (Figure 43.28a). The cause of glaucoma is not always known, but in some cases it is due to trauma to the eye, chronic use of certain medicines, or diseases such as diabetes. Some forms of glaucoma may have a genetic component. Glaucoma can be treated with eye drops that reduce fluid production in the eye or with laser surgery to reshape the structures in the eye. Incidentally, rubbing your eyes increases the pressure in the eyes, and habitual rubbing can also damage vision. The American Foundation for the Blind estimates that 400,000 new cases of glaucoma are diagnosed each year in the U.S., and up to 10 million individuals have elevated eye pressure. Glaucoma accounts for roughly 10% of all cases of blindness in the U.S.

In **macular degeneration**, photoreceptor cells in and around the macula (which contains the fovea) of the retina are lost. Because this is the region where cones are densely packed, this condition is associated with loss of sharpness and color vision (Figure 43.28b). It does not usually occur before age 60, but in some cases it is hereditary and can occur at any age. Macular degeneration is the leading cause of blindness in the U.S., accounting for roughly 25% of all cases, but its causes remain obscure.

Cataracts, the accumulation of protein in the lens, cloud the lens and cause blurring, poor night vision, and difficulty

(a) How the world is seen by a person with glaucoma

(b) How the world is seen by a person with macular degeneration

(c) How the world is seen by a person with cataracts

Figure 43.28 Appearance of the visual field in a person with (a) glaucoma, (b) macular degeneration, and (c) cataracts.

focusing on nearby objects (Figure 43.28c). By age 65, as many as 50% of individuals have one or more cataracts in either eye, and this jumps to 70% by age 75. Many cataracts are small enough not to affect vision. In fact, many people do not even realize they have cataracts until they undergo an eye exam. The causes of cataracts are not all known but include trauma, medicinal drugs, diabetes, and heredity. The treatment, when needed, is to wear a powerful contact lens to help do the job formerly done by the person's own lens or to have the affected lens surgically removed and replaced with a plastic lens. Nearly 1.4 million such surgeries are performed each year in the U.S. Without the lens, which helps protect the retina by absorbing some of the high-energy ultraviolet light from the sun, the retina must be protected during the day by wearing dark sunglasses.

Damaged Hair Cells Within the Cochlea Can Cause Deafness

Deafness (hearing loss) is usually caused by damage to the hair cells within the cochlea, although some cases result from functional problems in brain areas that process sound or in the nerves that carry information from the hair cells to the brain. When the hair cells are damaged, noises have to be louder to be detected, and an affected person may require the use of hearing aids to amplify incoming sounds.

Hearing loss may be mild or severe and may result from many causes, including injury to the ear or head, hereditary defects of the inner ear, and exposure to certain diseases (for example, rubella) or toxins during fetal life. By far, however, the most significant cause of hearing loss is repeated, long-term exposure to loud noise. When the amplitude of a sound wave (that is, the distance between the peak and the trough of the wave) is high, the loudness of the sound is great. The loudness of sound is measured in decibels. The decibel (dB) scale is logarithmic; every increase of 10 dB is actually 10 times louder than the previous level. Normal conversation is about 60 dB, a chainsaw is 108 dB, and a jet plane taking off can reach 150 dB. Estimates of noise-induced hearing loss, which usually results from job-related activities, range from 7 to 21% of all cases of hearing loss worldwide; this makes it the leading occupational disorder in the U.S. It is, therefore, one of the most significant disabilities in the U.S. in terms of numbers of people affected and costs to society. Scientists estimate that nearly 40 million people are exposed daily to dangerous noise levels in the U.S. as a result of their occupation.

Recent research has led to a better understanding of the mechanism by which noise impairs hearing. Chronic exposure to loud sounds appears to produce a state of metabolic exhaustion in the hair cells of the cochlea. As a result, the cells become fatigued and are unable to maintain normal biochemical processes. One consequence of this is a buildup of free radicals. These compounds oxidize lipids in cellular membranes, damaging the membranes in the process. Mitochondrial membranes appear to be particularly susceptible to these free radicals. Once mitochondria are destroyed, a cell's ability to produce the ATP needed to fulfill its energy demands is compromised, and the cell dies. As hair cells die, the ear becomes less sensitive to sound.

Researchers are investigating drugs that might prevent the formation of free radicals in the cells of the ear, but such drugs are not yet available. If a cochlea is severely damaged, it can be surgically replaced with artificial cochlear implants. These

devices generate electrical signals in response to sound waves that can stimulate the auditory nerve, which communicates with the brain. Cochlear implants cannot restore hearing to normal, but they can make it possible to hear conversations.

Summary of Key Concepts

43.1 An Introduction to Sensory Receptors

- Sensory transduction is the process by which incoming stimuli are converted to neural signals. Perception is an awareness of a sense.
- Sensory receptors are either neurons or specialized epithelial cells that respond to stimuli and begin the process of sensory transduction. (Figure 43.1)
- A sensory receptor often responds to a stimulus by eliciting a graded response that is proportional to the intensity of the stimulus. (Figure 43.2)

43.2 Mechanoreception

- Mechanoreceptors respond to physical stimuli such as touch, pressure, stretch, movement, and sound.
- Mechanoreceptors in the skin are neurons that sense stimuli such as touch and pressure. (Figure 43.3)
- Hair cells have stereocilia that respond to specific types of stimuli and then release neurotransmitter that may result in action potentials in an adjacent sensory neuron. (Figure 43.4)
- The lateral line system of fishes detects water movements. (Figure 43.5)
- Hearing is the ability to sense sound waves. Sound waves that travel at a high frequency are perceived as having a high pitch; those at low frequency have a low pitch.
- The ear has three main compartments called the outer, middle, and inner ear. (Figure 43.6)
- As pressure waves move through the cochlea of the ear, they may cause the basilar membrane to vibrate. This causes the stereocilia of hair cells to bend back and forth, which results in intermittent action potentials being sent to the brain, leading to the perception of sound. (Figures 43.7, 43.8)
- Many adaptations for hearing improve an animal's ability to sense sound. (Figure 43.9)
- Statocysts in certain invertebrates allow an animal to sense its body position or equilibrium. (Figure 43.10)
- The vestibular system in vertebrates allows animals to sense linear and rotational movement. (Figure 43.11)

43.3 Thermoreception and Nociception

- Thermoreceptors in the skin and brain allow an animal to sense external and internal temperatures, respectively.
- Nociceptors in the skin and internal organs sense pain, an important survival adaptation in animals.

43.4 Electromagnetic Sensing

- Some animals can detect electrical and magnetic stimuli; in some cases, this ability is used to locate prey. (Figure 43.12)

43.5 Photoreception

- The eyecup in flatworms is a simple eye that detects light and its direction but does not form an image. (Figure 43.13)
- The compound eye found in many invertebrates consists of many ommatidia that focus light. (Figure 43.14)
- The eye found in vertebrates and certain invertebrates is a single-lens eye. Stretching and flattening of the lens in mammals aids in focusing on objects at varying distances. (Figure 43.15)
- Rods and cones are photoreceptors found in the vertebrate eye. The visual pigment consists of retinal and a protein called opsin. (Figures 43.16, 43.17, 43.18)
- Red-green color blindness is due to a defect in a type of opsin found in cone pigments. (Figure 43.19)
- Photoreceptors respond to the dark by releasing the neurotransmitter glutamate, and to light by stopping its release. (Figures 43.20, 43.21)
- The retina is composed of layers of cells that receive light input and send electrical signals to the brain via the optic nerve. (Figure 43.22)
- The vertebrate eye has several adaptations that aid in proper vision for particular animals. (Figure 43.23)

43.6 Chemoreception

- Invertebrates have taste receptors on their proboscis, legs, feet, and antennae. Some insects can detect pheromones. (Figure 43.24)
- Olfactory receptors in vertebrates detect odor. They contain cilia with protein receptors that bind specific odor molecules. Buck and Axel discovered that olfactory receptors have many different types of protein receptors for odor molecules. (Figures 43.25, 43.26)
- Taste buds contain chemoreceptors that sense molecules in food. (Figure 43.27)

43.7 Impact on Public Health

- Common visual disorders include glaucoma, macular degeneration, and cataracts. (Figure 43.28)
- Prolonged exposure to intense sound can damage hair cells within the cochlea and lead to deafness.

Assess and Discuss

Test Yourself

1. The process whereby incoming sensory stimulation is converted to electrical signals is known as
   a. an action potential.
   b. a threshold potential.
   c. perception.
   d. sensory transduction.
   e. reception.

2. Photoreceptors are examples of
   a. nociceptors.
   b. baroreceptors.
   c. mechanoreceptors.
   d. electromagnetic receptors.
   e. thermoreceptors.
3. The sensory receptors for audition (hearing) are located in
   a. the organ of Corti.
   b. the Eustachian tube.
   c. the vestibular system.
   d. the tympanic membrane.
   e. a, b, and c.
4. Statocysts are sensory organs for
   a. hearing found in many invertebrates.
   b. equilibrium found in mammals.
   c. equilibrium found in many invertebrates.
   d. water current changes found in fish.
   e. hearing found in amphibians.
5. The eyecups of planaria can
   a. focus light to form an image.
   b. detect light.
   c. detect the direction of light.
   d. all of the above.
   e. b and c only.
6. The light detectors of a compound eye are called
   a. retinas.
   b. opsins.
   c. cones.
   d. ommatidia.
   e. rods.
7. In the mammalian eye, light from near or far objects is focused on the retina when
   a. the lens moves forward or backward.
   b. the lens changes shape.
   c. the eyeball changes shape.
   d. the cornea changes shape.
   e. none of the above
8. The level of glutamate release from photoreceptors of the vertebrate eye would be highest when
   a. a person is standing in full sunlight.
   b. a person is in a completely dark room.
   c. a person is in a dimly lit room.
   d. Na^+ channels of the photoreceptor are closed.
   e. both a and d
9. Cone pigments detect different wavelengths of light due to
   a. their location in the retina.
   b. the amount of light they absorb.
   c. the type of retinal they have.
   d. the type of opsin protein they have.
   e. interactions with bipolar cells.
10. The stimulation for olfaction involves odorant molecules
    a. bending the cilia of olfactory receptor cells.
    b. binding to protein receptors of olfactory receptor cells.
    c. entering the cytoplasm of olfactory receptor cells.
    d. opening K^+ channels of olfactory receptor cells.
    e. all of the above

Conceptual Questions

1. Distinguish between sensory transduction and perception.
2. Explain how the mammalian ear is adapted to distinguish sounds of different frequencies.
3. Explain how eye placement affects binocular vision.

Collaborative Questions

1. Discuss two different types of mechanoreceptors.
2. Discuss different types of eyes found in animals.

Muscular-Skeletal Systems and Locomotion

44

Chapter Outline

European tree frog (*Hyla arborea*) using its muscular-skeletal system to leap from a leaf.

Most of us are amazed at the athletic feats performed by humans with great jumping ability, such as long-jumpers or professional basketball players. Although it is impressive to see someone long-jump 8 or so meters or dunk a basketball through a rim that is more than 3 meters high, such feats pale by comparison to those routinely achieved by other animals. For example, some tree frogs, like the one shown in the chapter-opening photo, can leap distances up to 1.4 meters, yet the frog is only 4.5 cm long and weighs only 8 grams! Indeed, the jumping ability of frogs makes them model organisms for the study of muscle function in vertebrates.

Muscles are composed of highly specialized cells that have the ability to contract in response to stimuli. The three types of muscle—skeletal, smooth, and cardiac—were introduced in Chapter 40. In this chapter, you will learn about the structure and function of skeletal muscle and how skeletal muscle controls movements such as chewing, postural changes, and **locomotion**, the movement of an animal from place to place.

For skeletal muscles to produce movement, they must exert a force on an animal's skeleton. We begin the chapter, therefore, with a description of the types of animal skeletons. Then we examine the structure and function of skeletal muscle. Next, we consider various modes of locomotion in animals. We conclude with a few important bone and muscle diseases in humans.

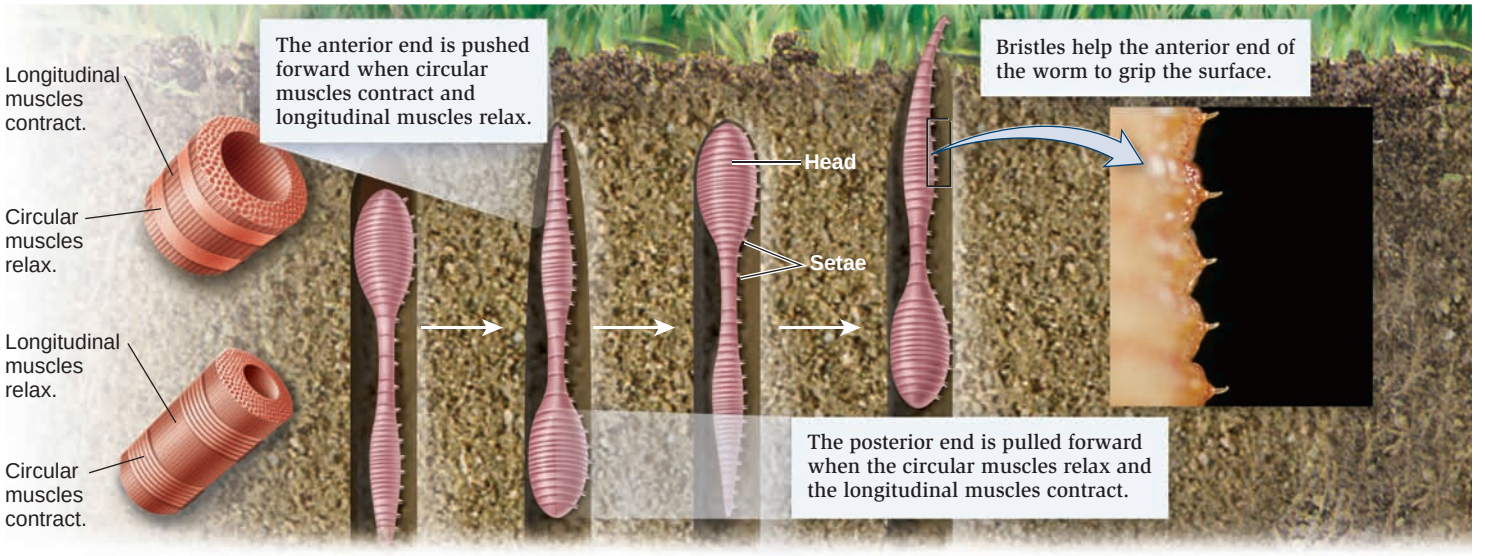
44.1 Types of Animal Skeletons

When we think of the word skeleton, an image of the vertebrate system of bones usually comes to mind. However, invertebrates possess a skeleton as well, but their skeletons are not made of bone. Therefore, a broader definition of a **skeleton** is a structure or structures that serve one or more functions related to support, protection, and locomotion. Using this definition, the three types of skeletons found in animals are hydrostatic skeletons, exoskeletons, and endoskeletons. The first two are found in invertebrates, while endoskeletons are found in some sponges and all echinoderms and vertebrates.

Hydrostatic Skeletons Consist of Fluid-Filled Body Compartments

Many soft-bodied invertebrates use hydrostatic pressure to support their bodies and generate movements. Hydrostatic pressure is the pressure of a fluid at rest in a contained space. The combination of muscles and a water-based fluid in the body constitutes what is known as a **hydrostatic skeleton**. Water is nearly incompressible, which means that if an animal exerts a force on the fluid that fills its body cavities, it can use the resulting hydrostatic pressure to move the body, much like a balloon partly filled with water can be deformed by squeezing it along its length. In cnidarians such as hydras, for example, contractile cells in the body wall can exert a pressure on the fluid in the gastrovascular cavity. Depending on the direction of the force, a hydra's body and tentacles will either be lengthened or shortened by the movement of water into and out of different regions of the cavity.

Annelids or segmented worms, such as earthworms, move forward by passing a wave of muscular contractions along the



(a) Hydrostatic skeleton in an annelid (earthworm)

(b) Exoskeleton in an arthropod (spiny lobster) **(c) Echinoderm (sea star) and (right) SEM of its endoskeleton**

Figure 44.1 **Types of skeletons.** **(a)** Hydrostatic skeleton. By alternately contracting and relaxing circular and longitudinal muscles, earthworms use differences in hydrostatic pressure to achieve locomotion. Clinging setae (bristles) along the body surface (shown in top-right inset) help prevent backsliding. **(b)** Exoskeleton. An arthropod's skeleton covers and protects its body, but it must be periodically shed and replaced to allow growth, as shown in this photo. **(c)** Endoskeleton. Echinoderms such as the sea star (starfish) have endoskeletons of bony plates made of calcium carbonate (shown in bottom-right inset).

Concept check: *Endoskeletons do not provide protection for the body surface of animals. Can the lack of an external skeleton also be an advantage for animals?*

length of their body, segment by segment (Figure 44.1a). The muscles are arranged in two orientations: circular and longitudinal (lengthwise). Contraction of circular muscles squeezes and lengthens the body, whereas contraction of the longitudinal muscles shortens and widens it. The worm is "squeezed" forward by differences in hydrostatic pressure created along its body by the muscles. Bristles known as setae along its body surface help the animal grip the ground to prevent backsliding.

Exoskeletons Are on the Outside of an Animal's Body

Arthropods have an **exoskeleton**, an external skeleton that surrounds and protects most of the body surface (Figure 44.1b). Exoskeletons provide support for the body, protection from the environment and predators, and protection for internal organs. The arthropod skeleton is made of a polysaccharide called chitin, and in crustaceans such as lobsters and shrimp, it is sometimes strengthened with calcium and other minerals. Exoskeletons are often tough, durable, and segmented to allow movement. However, to allow growth they must be periodically shed, regrown, and strengthened again, a process called ecdysis, or molting. A disadvantage of exoskeletons is that when an animal is molting, its new exoskeleton is temporarily soft, making it more vulnerable to predators and the environment.

Exoskeletons vary enormously in their complexity, thickness, and durability. The differences in exoskeletons are usually adaptations that enhance an animal's survival. Think, for example, of the difference between the wing of a butterfly and the outer skeleton of a lobster. A butterfly's exoskeleton must be light enough for the animal to fly, while the thick, tough exoskeleton of the lobster provides a very effective defense against predators in the sea. Exoskeletons may seem primitive compared to the endoskeletons of vertebrates (discussed next), particularly because of the requirement for molting. Even so, insects are among the most successful of all classes of animals living today, having survived for hundreds of millions of years and inhabiting nearly every possible ecological niche on the

planet. Clearly, exoskeletons have been sufficient for one of the planet's greatest success stories.

Endoskeletons Are Internal Support Structures

Like exoskeletons, **endoskeletons** provide support and protection. Unlike exoskeletons, however, endoskeletons are internal structures and do not protect the body surface. Some endoskeletons do, however, protect internal organs such as those in the thorax of vertebrates.

Endoskeletons are found in some species of sponges and all echinoderms and vertebrates. Minerals such as calcium, magnesium, phosphate, and carbonate supply the hardening material that gives the skeleton its firm structure. The endoskeletons of sponges and echinoderms consist of spiky networks of proteins and minerals, and mineralized platelike structures, respectively. Beneath the body surface of echinoderms, for example, arrays of mineralized plates made largely of calcium carbonate extend into the spines and arms that radiate from the main body (Figure 44.1c).

Vertebrate skeletons, by contrast, are composed of either cartilage or bone or both. Next we consider the structure and function of the vertebrate skeleton in greater detail.

44.2 The Vertebrate Skeleton

Vertebrate skeletons are composed of either cartilage (see Chapter 40)—as in cartilaginous fishes (sharks, rays, and skates)—or both cartilage and bone, as in bony fishes, amphibians, reptiles, birds, and mammals. First we consider the skeleton as a whole before examining bones in greater detail.

The Vertebrate Skeleton Performs Several Important Functions

In the vertebrate skeleton, bones are connected in ways that allow for support, protection, and movement. The vertebrate endoskeleton is often considered in two parts: the axial and appendicular skeletons (Figure 44.2). The axial skeleton is composed of the bones that form the main longitudinal axis of an animal's body. The appendicular skeleton consists of the limb or fin bones and the bones that connect them to the axial skeleton. A **joint** is formed where two or more bones come together. Some joints permit free movement (for example, the shoulders), whereas others allow no movement (fused joints like those interlocking the skull bones) or only limited

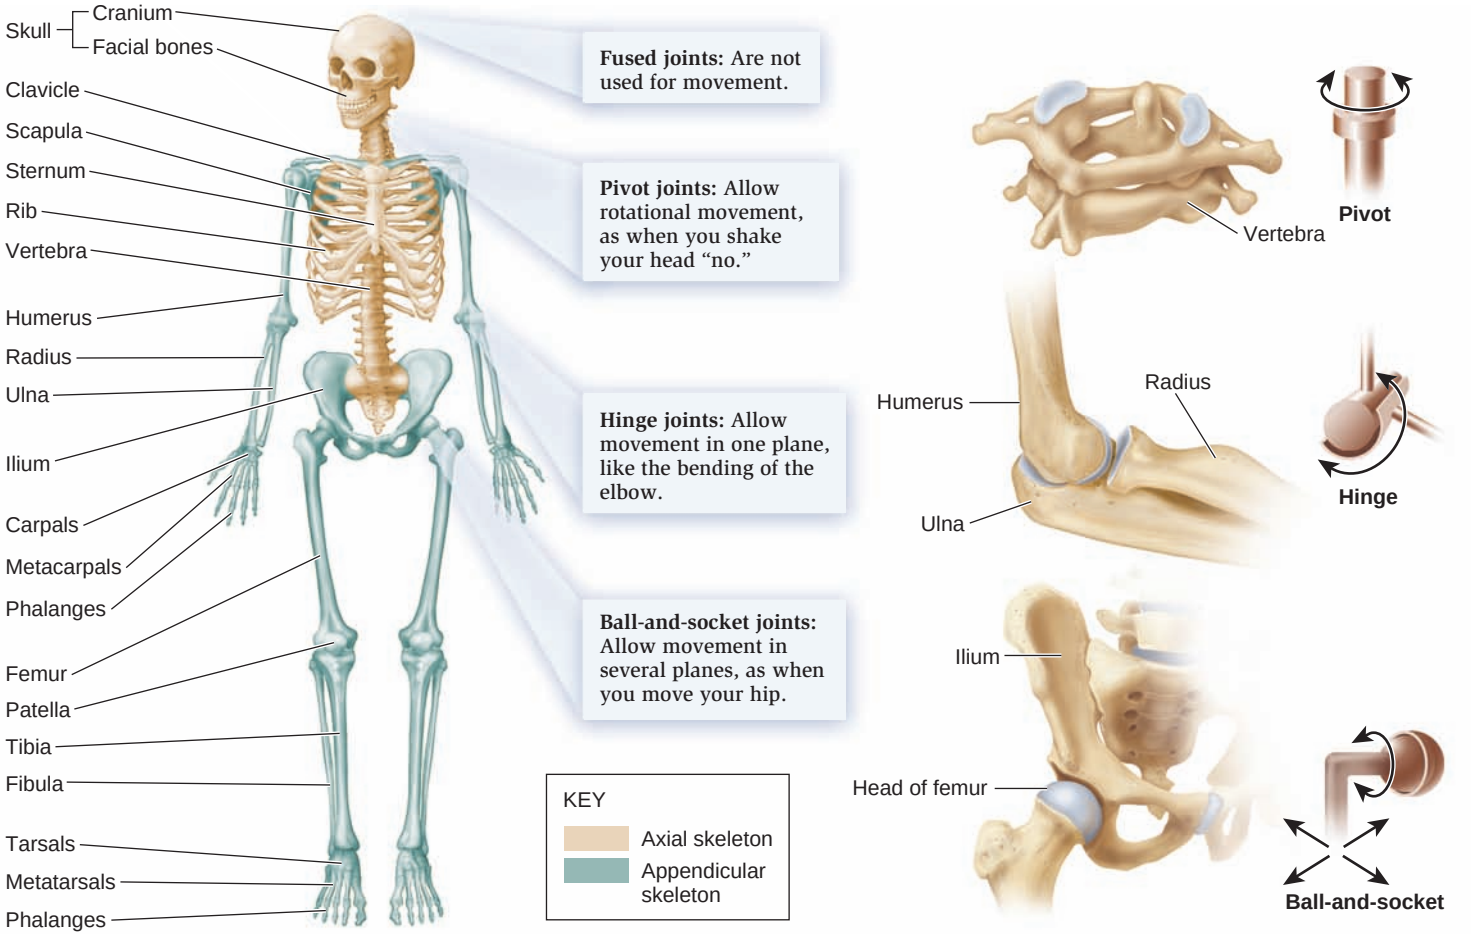


Figure 44.2 The adult human skeleton. This diagram shows the axial (tan) and appendicular (green) parts of the skeleton in an adult human, an animal with an endoskeleton. The adult human skeleton consists of 206 separate bones. Three examples of movable joints, one of each type, are shown.

movement (such as those of the vertebral column). Figure 44.2 illustrates three types of joints that allow different types of movements: pivot, hinge, and ball-and-socket joints.

The skeleton of vertebrates serves several functions in addition to support, protection, and movement. For example, blood cells and platelets, the latter of which help blood to clot (see Chapter 47), are formed within the marrow of the ilia, vertebrae, the ends of the femurs, and other bones. In addition, calcium and phosphate homeostasis is achieved in large part through exchanges of these ions between bone and blood. For example, if dietary intake of calcium is low, calcium is removed from bone and added to the blood, so that all of the vital cellular activities that depend on calcium, such as nerve and muscle function, can continue to operate normally. When dietary calcium is restored to normal, calcium is redeposited in bone. This calcium cycling is under the control of hormones, such as parathyroid hormone produced by the parathyroid glands (see Chapter 50). About 99% of all the calcium in a typical vertebrate's body exists in bone. This represents a huge reservoir of calcium ions for the blood.

Bone Consists of a Mixture of Organic and Mineral Components

Bone is a living, dynamic tissue with both organic and mineral components. Organic materials include cells that form bone—called osteoblasts—and cells that break it down—called osteoclasts. The organic part of bone is secreted by osteoblasts and consists of the protein collagen, which has a unique triple helical structure that gives bone both strength and flexibility. The mineral component is composed of a crystalline mixture of primarily Ca^{2+} and PO_4^{2-}, and other ions that provide bone its rigidity. These ions must be obtained in an animal's diet, absorbed into the blood, and deposited in bone.

A proper ratio of organic and mineral components is required for normal bone function. Bone lacking sufficient mineral, for example, is easily fractured. Bone is formed at high rates during an animal's growth periods, but even in adulthood, bone is continuously formed, broken down, and re-formed. The skeleton is continually changing—the one in your body right now is completely remodeled from the one that was in your body a few years ago. Similarly, the skeleton you will have a few years from now is not identical to the one you have today.

Bones cannot move by themselves but instead provide the scaffold upon which skeletal muscles act to cause body movement. We turn now to a discussion of skeletal muscle and the mechanism by which it generates force.

44.3 Skeletal Muscle Structure and the Mechanism of Force Generation

As mentioned, vertebrates have three types of muscle that are classified according to their structure, function, and control mechanisms. These are cardiac muscle, smooth muscle, and skeletal muscle. **Cardiac muscle** is found only in the heart and provides the force required for the heart to pump blood. Cardiac muscle will be discussed in Chapter 47. **Smooth muscle** surrounds and forms part of the lining of hollow organs and tubes, including those of the gastrointestinal system, urinary bladder, uterus, blood vessels, and airways. Contraction of the smooth muscle in hollow organs may propel the contents forward or churn them up, as when the stomach contracts after a meal. In other cases, smooth muscle regulates the flow of substances by changing the tube diameter, as in the widening or narrowing of small blood vessels. Smooth muscle contraction is not under voluntary control. Instead, it is controlled by the autonomic nervous system, hormones, and local chemical signals. Some smooth muscles, such as those found in regions of the digestive tract, have the ability to contract on their own, even in the absence of such signals.

Skeletal muscle is found throughout the body and is directly involved in locomotion. In vertebrates, but not invertebrates, skeletal muscle is electrically excitable—it can generate action potentials in response to a stimulus (invertebrate skeletal muscle cells have graded membrane potentials but do not have action potentials). The action potentials of vertebrate skeletal muscle cells result in increased levels of cytosolic calcium ions, which trigger force generation. Before understanding how this is possible, however, let's begin with an overview of skeletal muscle structure and function.

A Skeletal Muscle Is a Contractile Organ That Supports and Moves Bones

A **muscle** is a grouping of cells—called **muscle fibers**—bound together in structures called fascicles by a succession of connective tissue layers (Figure 44.3). Skeletal muscles are usually linked to bones by bundles of collagen fibers known as tendons. The transmission of force from contracting muscle to bone can be likened to a number of people pulling on a rope attached to a heavy object. Each person corresponds to a single muscle fiber, the rope corresponds to the tendons, and the bone is the heavy object.

Some tendons are very long, with the site of tendon attachment to bone far removed from the end of the muscle. For example, some of the muscles that move the fingers are in the forearm. You can wiggle your fingers and feel the movement of the muscles in your lower arm. These muscles are connected to the finger bones by long tendons.

Skeletal muscle fibers increase in size during growth from infancy to adulthood, but few new fibers are formed during that time. As described later, enlargement of skeletal muscles in adults, as from weightlifting, is also primarily a function of enlarged fibers, not the formation of new ones.

Muscle Fibers Contain Myofibrils Composed of Arrays of Filaments

The most striking microscopic feature of skeletal muscle is a series of light and dark bands perpendicular to the muscle's long axis. Because of this characteristic striped pattern, it is also

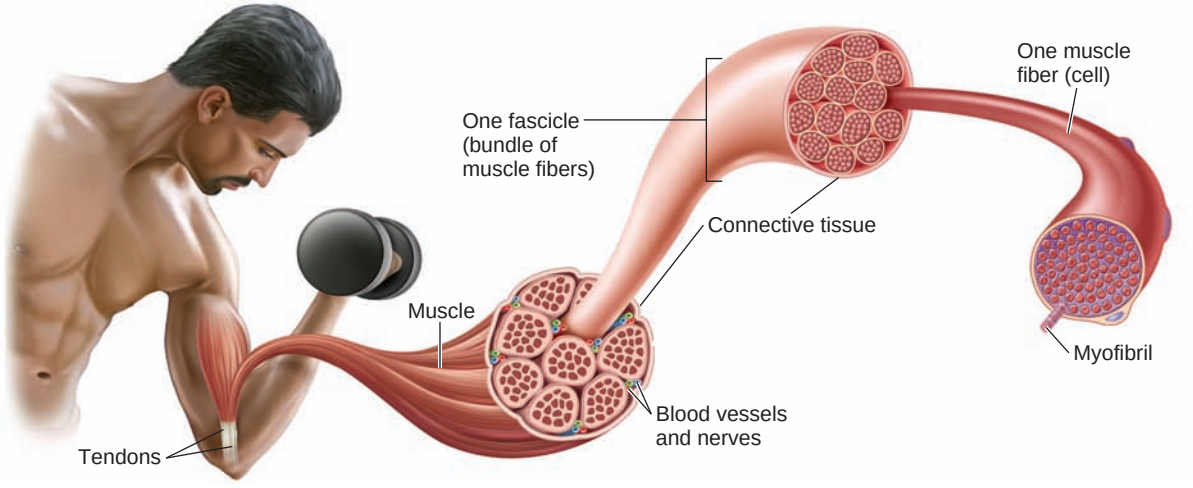

Figure 44.3 **Skeletal muscle structure.** Skeletal muscles attach to bone by tendons, which are bundles of collagen fibers. Each muscle consists of bundles of muscle fibers (cells) bound together by connective tissue in structures called fascicles.

Concept check: *What would happen to the ability of a muscle to move a bone if its tendon were torn, for example, due to injury?*

known as **striated muscle**. This pattern is the result of muscle fibers containing cylindrical bundles known as **myofibrils** (Figure 44.4). Most of the cytosol of a muscle fiber is filled with myofibrils, each of which extends from one end of the fiber to the other and is linked to the tendons at the ends of the fiber.

Each myofibril contains numerous functional structures called thick and thin filaments. These filaments are arranged in a repeating pattern running the length of the myofibril. One complete unit of this repeating pattern is known as a **sarcomere** (from the Greek *sarco*, meaning muscle, and *mer*, meaning part). The **thick filaments** are composed almost entirely of the motor protein **myosin**. The **thin filaments**, which are about half the diameter of the thick filaments, contain the cytoskeletal protein **actin**, as well as other proteins that we will discuss later.

The thick filaments are located in the middle of each sarcomere, where their orderly parallel arrangement produces a wide, dark band known as the **A band** (Figure 44.4). Each sarcomere contains two sets of thin filaments, each of which is anchored to a network of proteins at the **Z line**. The thin filaments overlap a portion of the thick filaments. Two successive Z lines define the boundaries of one sarcomere.

A light band known as the **I band** lies between the A bands of two adjacent sarcomeres. Each I band contains those portions of the thin filaments that do not overlap the thick filaments, and each I band is bisected by a Z line.

Two additional features are present in the A band of each sarcomere. The **H zone** is a narrow, light region in the center of the A band. It corresponds to the space between the two sets of thin filaments in each sarcomere. A narrow, dark band in the center of the H zone, known as the **M line**, corresponds to proteins that link the central regions of adjacent thick filaments.

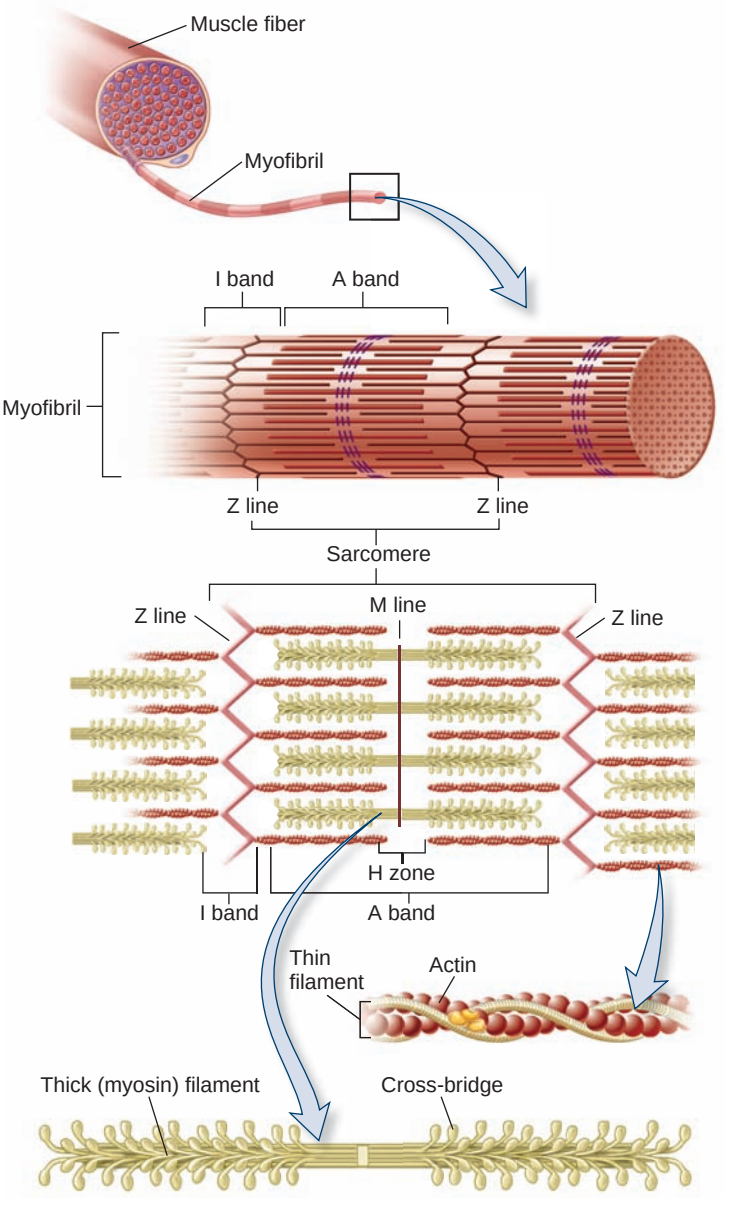

Figure 44.4 **Myofibril structure.** Each muscle fiber consists of numerous myofibrils containing thick and thin filaments. Their arrangement produces the striated banding pattern. Each repeating unit of the arrayed filaments constitutes a sarcomere.

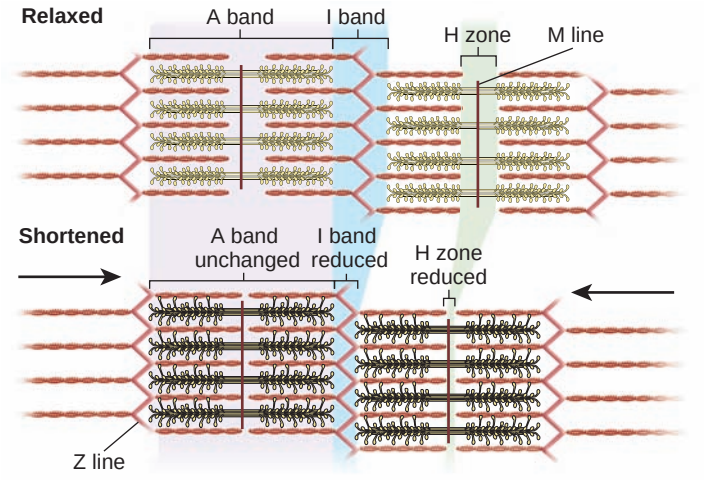

Figure 44.5 **Sliding filament mechanism of muscle contraction.** The sliding of thin filaments past the overlapping thick filaments shortens the sarcomere but does not change the lengths of the filaments themselves.

The spaces between overlapping thick and thin filaments are bridged by projections known as **cross-bridges**, which are regions of myosin molecules that extend from the surface of the thick filaments toward the thin filaments (Figure 44.4). As we see next, during muscle contraction, the cross-bridges make contact with the thin filaments and exert force on them.

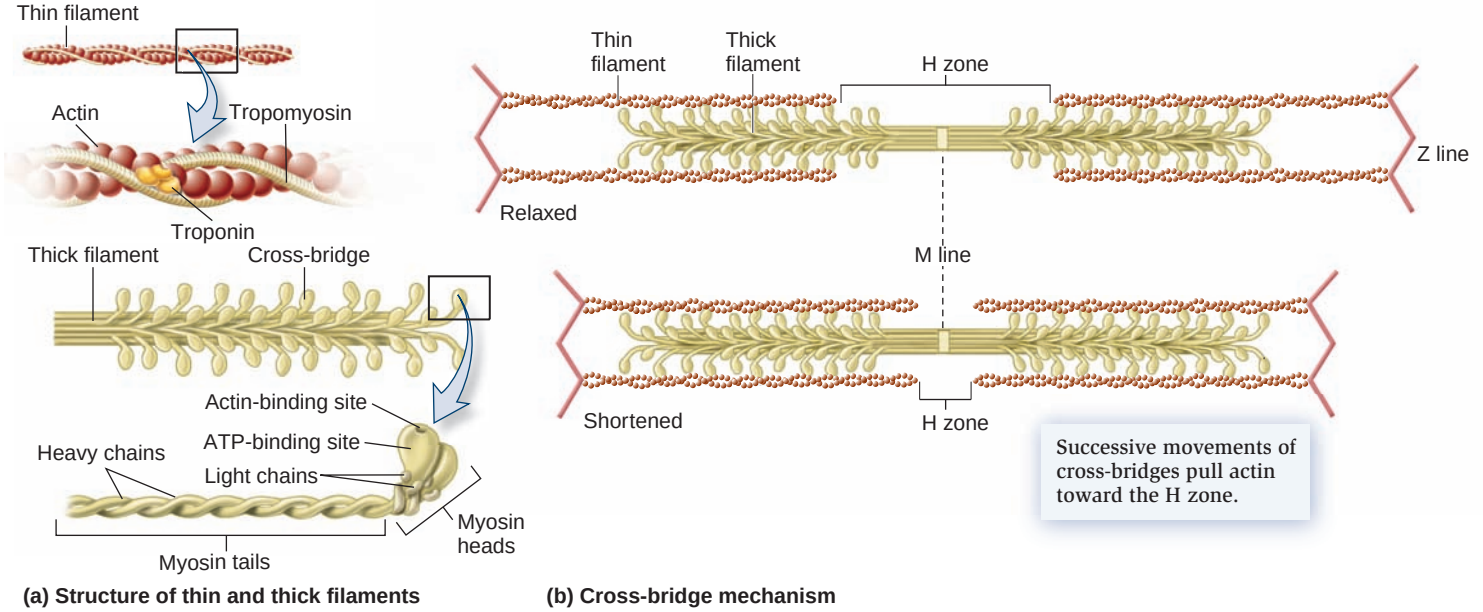
Skeletal Muscle Shortens When Thin Filaments Slide over Thick Filaments

Movement requires shortening of muscles to pull against the attached tendons and bones. However, a muscle can generate force, or contract, without producing movement. Holding a heavy weight at a constant position, for example, requires muscle contraction, but not muscle shortening. Therefore, as used in muscle physiology, the term contraction refers to activation of the cross-bridges within muscle fibers, which initiates the generation of force. When these mechanisms are turned off, contractions end, allowing the muscle fiber to relax.

How a muscle fiber actually shortens is known as the **sliding filament mechanism** of muscle contraction (Figure 44.5). In this mechanism, the sarcomeres shorten, but neither the thick nor the thin filaments change in length. Instead, the thick filaments remain stationary while the thin filaments slide, pulling on the Z lines and shortening the sarcomere.

Let's look at how the structure of the thin and thick filaments allows them to produce this sliding movement (Figure 44.6). Each actin molecule of a thin filament contains a binding site for myosin. Actin molecules form polymers that are arranged into two intertwined helical chains (Figure 44.6a). These chains are closely associated with two proteins called tropomyosin and troponin that play important roles in regulating contraction (which we will discuss a bit later).

In the thick filament, myosin is composed of six protein subunits: two large heavy chains and four smaller light chains. These polypeptides combine to form a protein that consists of two heads and a long tail formed by the two intertwined heavy chains. The tail of each myosin molecule lies along the axis of the thick filament, and the two globular heads extend out to the sides, forming the cross-bridges. The myosin proteins at the two ends of each thick filament are oriented in opposite directions, such that their tails are directed toward the center of the filament while the



(a) Structure of thin and thick filaments **(b) Cross-bridge mechanism**

Figure 44.6 **Structure and function of the thin and thick filaments.** **(a)** Thin filaments are composed of two intertwined actin molecules and associated proteins tropomyosin and troponin. Thick filaments are made of the protein myosin, which has two intertwined heavy chains, each with two associated light chains, an actin-binding site, and an ATP-binding site. The end of a myosin molecule that contains the actin-binding sites is bent at an angle to form the globular heads known as cross-bridges. **(b)** When the cross-bridges on myosin molecules bind to actin filaments, the thin filaments are pulled toward each other, shortening the sarcomere.

heads are at the ends. Each head contains two binding sites, one for actin and one for ATP. The hydrolysis of ATP provides the energy for the cross-bridge (that is, the myosin head) to move.

The sliding filament movement is propelled by the myosin cross-bridges (Figure 44.6b). During shortening, each cross-bridge attaches to an actin molecule in a thin filament and moves in a motion much like an oar on a boat. Because of the opposing orientation of the thick filaments, the movement of a cross-bridge forces the thin filaments toward the center of the sarcomere, thereby shortening it. One stroke of a cross-bridge produces only a very small movement of a thin filament relative to a thick filament. As long as a muscle fiber is stimulated to contract, however, each cross-bridge repeats its motion many times, resulting in continued sliding of the thin filaments. Thus, the ability of a muscle fiber to generate force and movement depends on the amount of interaction of actin and myosin.

The protein myosin was first discovered in extracts of frog leg muscle in the 1860s by the German physiologist Willi Kühne. We now know that eukaryotic genomes encode a family of related myosin proteins, as described next.

Genomes & Proteomes Connection

Did an Ancient Mutation in Myosin Play a Role in the Development of the Human Brain?

Myosins are among the most ancient of eukaryotic proteins and also among the most highly conserved in amino acid sequence. Nonetheless, small differences in the sequences of genes that arose from a single primordial myosin gene have led to tissue-specific expression of various myosin proteins, each with a characteristic ability to bind actin and hydrolyze ATP. One recently discovered member of this gene family, called *MYH16*, codes for a heavy chain of a myosin molecule that is expressed mainly in the muscles of the jaw in primates. In 2004, H. Stedman and colleagues discovered that this gene, although present in humans, did not code for a functional protein because of a mutation that deleted two base pairs from it. This mutation was present in 100% of people tested worldwide but was not found in the eight nonhuman primate species tested, which included chimpanzees.

Based on genetic comparisons and estimates of genetic divergence among species, the researchers estimated that the mutation occurred approximately 2.4 million years ago. Significantly, the genus *Homo*, with its smaller jaw and larger braincase, is also thought to have first appeared about 2.4 million years ago, leading Stedman to suggest that the loss of the MYH16 protein led to the smaller, less-muscular jaws characteristic of humans (Figure 44.7). Because jaw muscles are attached to skull bones, massive jaw muscles may have placed a mechanical constraint on skull growth in early hominins (as well as in modern nonhuman primates). Smaller, less-muscular jaws would place less strain on the forming skull and allow the brain to grow larger, expanding the braincase to the larger size seen in modern humans.

Figure 44.7 Comparison of jaw size and area of muscle attachment (shown in orange) in modern primates. Note: Skulls are not to scale. (Reprinted by permission from Macmillan Publishers Ltd: Stedman, Hansell H. et al. Myosin gene mutation correlates with anatomical changes in the human lineage, *Nature*, Volume 428, Issue Number 6981, pages 415–418, 2004.)

Stedman's hypothesis is compelling, given that the myosin mutation occurs in jaw muscles and is present only in humans. Recently, though, another research group, using sophisticated statistical analyses of larger regions of gene sequences including the deletion in *MYH16*, concluded that the mutation may have arisen earlier—perhaps 4.0 to 5.4 million years ago, before the appearance of small-jawed species of *Homo*. Stedman's hypothesis will require confirmation by future research. Scientists are certain that a human-specific mutation in *MYH16* arose at some point in the evolution of hominins. Whether the mutation facilitated expansion of the cranium, which, in turn, permitted enlargement of the brain is unknown. The hypothesis does provide an intriguing piece of the puzzle of how modern humans may have evolved.

The Cross-Bridge Cycle Requires ATP and Calcium Ions

Let's now turn our attention to how actin and myosin interact to promote contraction and shortening. The sequence of events that occurs between the time when a cross-bridge binds to a thin filament and when it is set to repeat the process is known as a **cross-bridge cycle**.

Cross-bridge cycling begins whenever the Ca^{2+} level increases inside the cell. This usually occurs when neural input results in the release of Ca^{2+} from intracellular storage sites (described in detail shortly). In other words, the contraction of skeletal muscle fibers is under nervous control, a subject that we will return to in depth later.

The chemical and physical events that occur during the four steps of the cross-bridge cycle are illustrated in Figure 44.8. These steps are cross-bridge binding, power stroke (moving), detaching, and resetting. As the cycle begins, the myosin cross-bridges are in an energized state, which is produced by the hydrolysis of their bound ATP. In this state, the hydrolysis products, ADP and inorganic phosphate, remain bound to myosin. The sequence of storage and release of energy by myosin is analogous to the operation of a mousetrap: Energy is first stored in the trap by cocking the spring (ATP hydrolysis) and is then released by the springing of the trap (head binds to actin and moves in power stroke). Let's look at each step of the process more closely.

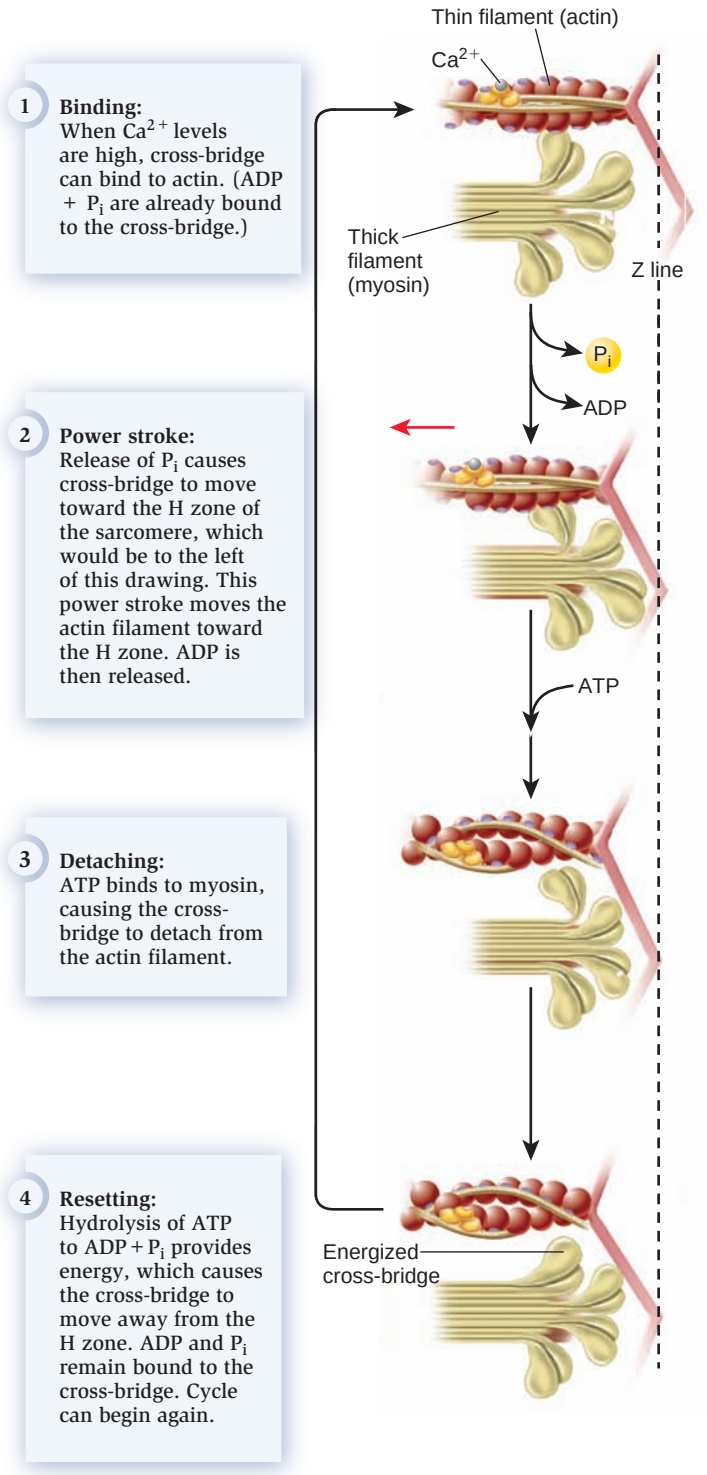


Figure 44.8 The four stages of cross-bridge cycling in skeletal muscle.

Concept check: *Rigor mortis is a condition of contracted skeletal muscle that occurs shortly after death. Why would the muscle remain contracted after death, and why does such contraction eventually stop?*

Step 1: Ca^{2+} levels rise, triggering the cross-bridge to bind to actin.

When Ca^{2+} levels rise, this triggers the first step in the cross-bridge cycle. In this step, an energized myosin cross-bridge, with its associated ADP and P_i, binds to an actin molecule on a thin filament.

$$\text{Actin} + [\text{Energized myosin} \cdot \text{ADP} \cdot P_i] \longrightarrow$$
$$[\text{Actin} \cdot \text{Myosin} \cdot \text{ADP} \cdot P_i \text{ complex}]$$

Step 2: Release of phosphate (P_i) fuels the power stroke: The cross-bridge and thin filaments move.

The binding of an energized myosin cross-bridge to actin in step 1 triggers the release of P_i. This release causes a conformational change in the shape of the myosin molecule. This causes the cross-bridge to rotate forward toward the M line at the center of the sarcomere. This process is known as the **power stroke**, which moves the actin filament. At the same time, ADP is released.

$$[\text{Actin} \cdot \text{Myosin} \cdot \text{ADP} \cdot P_i \text{ complex}] \longrightarrow$$
$$[\text{Actin} \cdot \text{Myosin complex}] + \text{ADP} + P_i$$

Step 3: ATP binds to myosin, causing the cross-bridge to detach.

During the power stroke, myosin is bound very firmly to actin; this linkage must be broken to allow the cross-bridge to be reenergized and repeat the cycle. The binding of a new molecule of ATP to the myosin cross-bridge breaks the link between actin and myosin.

$$[\text{Actin} \cdot \text{Myosin complex}] \quad \text{ATP} \longrightarrow$$
$$\text{Actin} + [\text{Myosin} \cdot \text{ATP}]$$

The dissociation of actin and myosin by ATP is an example of allosteric regulation of protein activity (see Chapter 7). When ATP binds at one site on myosin, myosin's affinity for actin bound at another site decreases. ATP is not hydrolyzed in this step. Instead, ATP acts here only as an allosteric modulator of the myosin head, weakening the binding of myosin to actin and leading to their dissociation.

Step 4: ATP hydrolysis reenergizes and resets the cross-bridge.

After actin and myosin dissociate, the ATP bound to myosin is hydrolyzed. This hydrolysis reenergizes myosin, causing it to reset to the position that allows actin binding.

$$\text{Actin} + [\text{Myosin} \cdot \text{ATP}] \longrightarrow$$
$$\text{Actin} \quad [\text{Energized myosin} \cdot \text{ADP} \cdot P_i]$$

If Ca^{2+} is still present at this time, the cross-bridge can reattach to a new actin molecule in the thin filament, and the cross-bridge cycle repeats, causing the muscle fiber to further shorten.

As we have seen, ATP performs two different roles in the cross-bridge cycle. First, the energy released from ATP hydrolysis provides the energy for cross-bridge movement. Second, ATP binding breaks the link formed between actin and myosin during the cycle, allowing the cycle to be repeated. Although the precise mechanisms may differ slightly between vertebrates and invertebrates, biologists think that all skeletal muscle functions according to steps similar to those just described. As

mentioned, all skeletal muscle function requires the actions of calcium ions, which we describe next.

The Regulation of Muscle Contraction by Calcium Ions Is Mediated by Tropomyosin and Troponin

How does the presence of Ca^{2+} in the muscle fiber cytosol regulate the cycling of cross-bridges? The answer requires a closer look at the two additional thin filament proteins mentioned earlier, tropomyosin and troponin.

Tropomyosin is a rod-shaped molecule composed of two intertwined proteins, with a length equal to that of about seven actin molecules (Figure 44.9a). Chains of tropomyosin molecules are arranged end to end along the actin thin filament. In the absence of Ca^{2+}, they partially cover the myosin-binding site on each actin molecule, thereby preventing cross-bridges from making contact with actin. Each tropomyosin molecule is held in this blocking position by **troponin**, a smaller, globular-shaped protein that is bound to both tropomyosin and actin. One molecule of troponin binds to each molecule of tropomyosin. In this way, troponin and tropomyosin cooperate to block access to myosin-binding sites on actin molecules in the relaxed muscle fiber.

Troponin is capable of binding Ca^{2+}. Such binding produces a change in the shape of troponin, which—through troponin's linkage to tropomyosin—allows tropomyosin to move away from the myosin-binding site on each actin molecule (Figure 44.9b). This permits cross-bridge cycling to occur. Conversely, release of Ca^{2+} from troponin reverses the process, turning off contractile activity.

Thus, the concentration of cytosolic Ca^{2+} determines whether or not Ca^{2+} is bound to troponin molecules, which, in turn, determines the number of actin sites available for cross-bridge binding. The cytosolic concentration of Ca^{2+}, however, is very low in resting muscle. How is the Ca^{2+} concentration increased so that contraction can occur? This topic is discussed next.

Contraction of Skeletal Muscle Is Coupled with Electrical Excitation

Like neurons, vertebrate skeletal muscle cells are capable of generating and propagating action potentials in response to an appropriate stimulus. This causes a rise in the concentration of cytosolic Ca^{2+}, which triggers contraction of a muscle fiber. The sequence of events by which an action potential in the plasma membrane of a muscle fiber leads to cross-bridge activity by the mechanisms just described is called **excitation-contraction coupling**. The electrical activity in the plasma membrane does not act directly on the contractile proteins but instead acts as a stimulus to increase cytosolic Ca^{2+} concentration. These increased levels continue to activate the contractile apparatus long after electrical activity in the membrane has ceased.

The source of the increased cytosolic Ca^{2+} that occurs following a muscle action potential is the fiber's **sarcoplasmic reticulum**, which acts as a Ca^{2+} reservoir. The sarcoplasmic reticulum, which is a specialized form of the endoplasmic reticulum found in most cells, is composed of interconnected sleevelike compartments around each myofibril (Figure 44.10). Separate tubular structures, the **transverse tubules** (**T-tubules**), are invaginations of the plasma membrane that open to the extracellular fluid. The T-tubules run around each myofibril and conduct action potentials from the outer surface of the muscle fiber inside to the myofibrils. An action potential causes the opening of calcium channels in the sarcoplasmic reticulum, which allows Ca^{2+} to flow into the cytosol and bind to troponin, initiating muscle contraction.

A contraction continues until Ca^{2+} is removed from troponin. This is achieved by ATP-dependent ion pumps in the

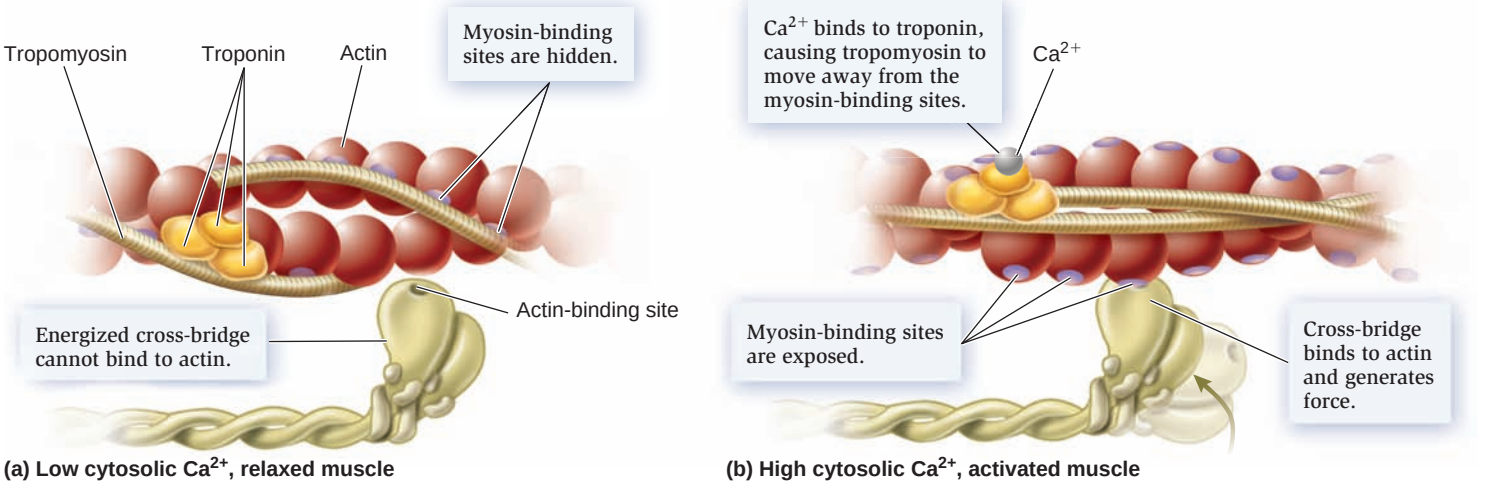

Figure 44.9 **Role of Ca^{2+}, tropomyosin, and troponin in cross-bridge cycling.** **(a)** When cytosolic Ca^{2+} is low, the myosin-binding sites on actin are blocked by tropomyosin. **(b)** When cytosolic Ca^{2+} increases, Ca^{2+} binds to troponin, which, in turn, allows tropomyosin to move away from the myosin-binding sites on actin.

sarcoplasmic reticulum that lower the Ca^{2+} concentration in the cytosol back to its resting level.

Electrical Stimulation of Skeletal Muscle Occurs at the Neuromuscular Junction

We have seen that an action potential in the plasma membrane of a skeletal muscle fiber is the signal that triggers contraction. How are these action potentials initiated? The mechanism by which action potentials are initiated in a skeletal muscle involves stimulation by a motor neuron. These are neurons located in the central nervous system (CNS) that project their axons outside the CNS and directly or indirectly control muscles.

The junction of a motor neuron's axon and the muscle fiber is known as a **neuromuscular junction** (Figure 44.11). Near the surface of the muscle fiber, the axon divides into several short processes, or terminals, containing synaptic vesicles filled with the neurotransmitter acetylcholine (ACh) (see Chapter 41). The region of the muscle fiber plasma membrane that lies directly under the axon terminal is called the **motor end plate**; it is folded into what are known as junctional folds, which contain many ACh receptors. These folds therefore increase the total surface area available for the membrane to respond to ACh. The extracellular space between the axon terminal and the motor end plate is called the synaptic cleft.

When an action potential in a motor neuron arrives at the axon terminal, it releases its stored ACh, which crosses the synaptic cleft and binds to receptors in the junctional folds of the muscle fiber. The ACh receptor is a ligand-gated ion channel (see Chapter 5). The binding of ACh causes an influx of Na^+ into the muscle fiber through a channel housed in the ACh receptor. This influx of Na^+ causes the muscle fiber to depolarize, resulting in an action potential that spreads along the membrane of the muscle fiber and through the T tubules. Most neuromuscular junctions are located near the middle of a muscle fiber, and newly generated muscle action potentials propagate from this region toward the ends of the fiber and throughout the T-tubule network. Overstimulation of a muscle fiber is prevented by the action of **acetylcholinesterase**. This enzyme breaks down excess ACh in the synaptic cleft to inactive forms that cannot bind the ACh receptor (Figure 44.11).

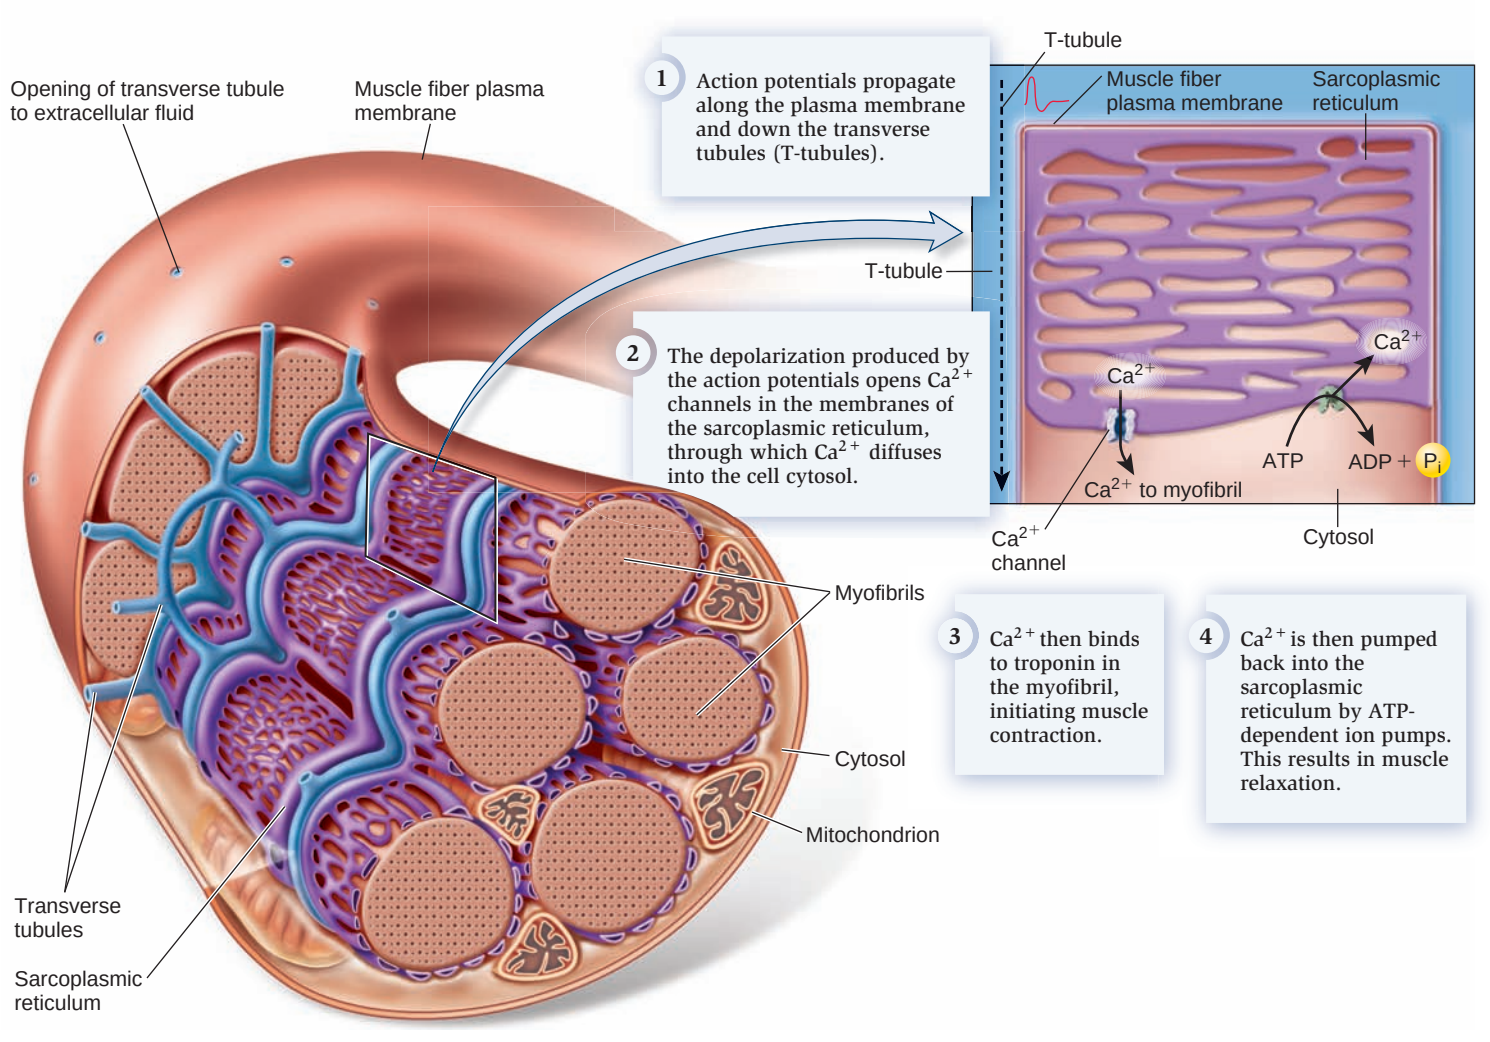

Figure 44.10 Structure and function of the sarcoplasmic reticulum, transverse tubules, and myofibrils in a skeletal muscle fiber.

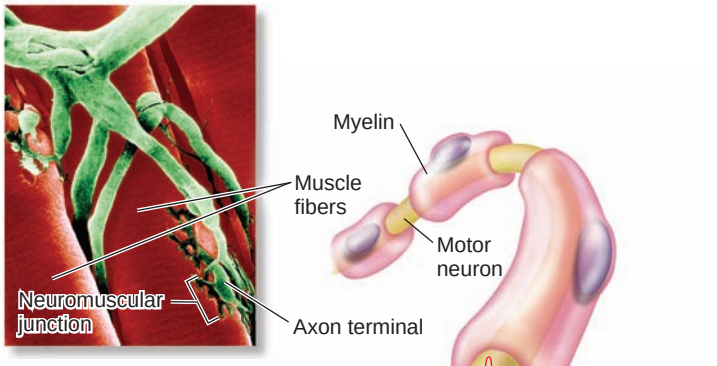
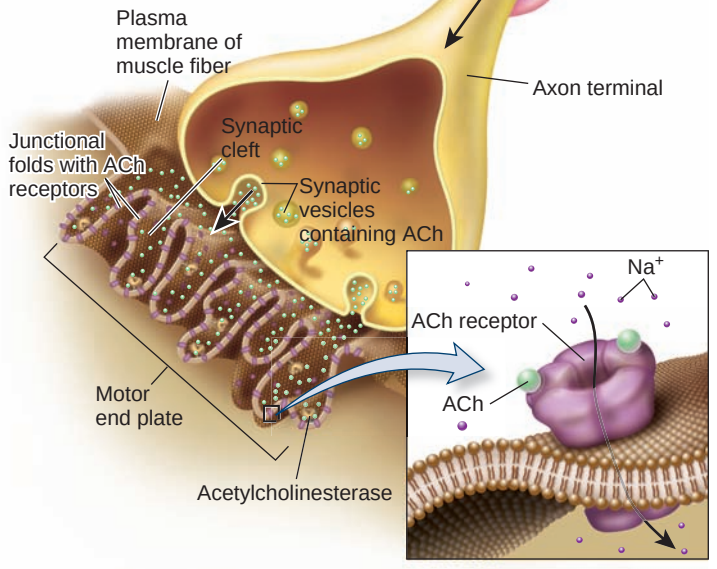


(a) SEM of neuromuscular junction



(b) Structures of, and events at, the neuromuscular junction (only part of the motor neuron is shown)

Figure 44.11 **The neuromuscular junction.** The structure of a neuromuscular junction **(a)** as seen in a scanning electron micrograph and **(b)** as depicted schematically. Action potentials in the motor neuron cause exocytosis of ACh-containing synaptic vesicles. ACh binds to receptors in the plasma membrane of the junctional folds of the skeletal muscle cell. This initiates Na^+ entry and, consequently, an action potential in the muscle cell. Excess ACh is removed by the enzyme acetylcholinesterase.

Concept check: *Why does Na^+ enter the muscle cell after the ACh receptor is activated?*

Now that we have learned about the structural characteristics of skeletal muscle and the events that initiate and produce force generation, we turn to a discussion of how skeletal muscle is adapted to meet the varied functional demands of vertebrates.

44.4 Skeletal Muscle Function

Animals use skeletal muscle for a wide variety of activities, such as locomotion, stretching, chewing, breathing, and maintaining balance, to name a few. Therefore, it is not surprising that not all skeletal muscle fibers share the same mechanical and metabolic characteristics. In this section, we will consider how different types of fibers can be classified on the basis of their rates of shortening (as either fast or slow) and the way in which they produce the ATP needed for contraction (as oxidative or glycolytic).

Skeletal Muscle Fibers Are Adapted for Different Types of Movement

Different muscle fibers contain forms of myosin that differ in the maximal rates at which they can hydrolyze ATP. This, in turn, determines the maximal rates of cross-bridge cycling and muscle shortening. Fibers containing myosin with low ATPase activity are called **slow fibers**. Those containing myosin with higher ATPase activity are classified as **fast fibers**. Although the rate of cross-bridge cycling is about four times faster in fast fibers than in slow fibers, the maximal force produced by both types of cross-bridges is approximately the same.

The second means of classifying skeletal muscle fibers is based on the type of metabolic pathways available for synthesizing ATP. Fibers that contain numerous mitochondria and have a high capacity for oxidative phosphorylation are classified as **oxidative fibers**. Most of the ATP production by such fibers depends on blood flow to deliver oxygen and nutrients to the muscle. Not surprisingly, therefore, these fibers are surrounded by many small blood vessels. They also contain large amounts of the oxygen-binding protein **myoglobin**, which increases the availability of oxygen in the fiber by providing an intracellular reservoir of oxygen. The large amounts of myoglobin present in oxidative fibers give these fibers a dark-red color. Oxidative fibers are often referred to as red muscle fibers. The benefit of red muscle fibers is they can maintain sustained action over a long period of time without fatigue.

By contrast, **glycolytic fibers** have few mitochondria but possess both a high concentration of glycolytic enzymes (see Chapter 7 for a discussion of glycolysis) and large stores of glycogen, the storage form of glucose. Corresponding to their limited use of oxygen, these fibers are surrounded by relatively few blood vessels and contain little myoglobin. The lack of myoglobin is responsible for the pale color of glycolytic fibers and their designation as white muscle fibers.

On the basis of these two characteristics, three major types of skeletal muscle fibers have been distinguished:

1. **Slow-oxidative fibers** have low rates of myosin ATPase activity but have the ability to make large amounts of ATP. These fibers are used for prolonged, regular types of movement, such as steady, long flight; long-distance swimming; or the maintenance of posture. These muscles, for example, are what give the red color to the dark meat of ducks, which use the muscles for flight. Long-distance runners have a high proportion of these fibers in their leg muscles. These types of activities require muscles that do not fatigue easily.
2. **Fast-oxidative fibers** have high myosin ATPase activity and can make large amounts of ATP. Like slow-oxidative fibers, these fibers do not fatigue quickly and can be used

for long-term activities. They are also particularly suited for rapid actions, such as the rapid trilling sounds made by the throat muscles in songbirds or the clicking sounds generated by the shaking of a rattlesnake's tail.

3. **Fast-glycolytic fibers** have high myosin ATPase activity but cannot make as much ATP as oxidative fibers, because their source of ATP is glycolysis. These fibers are best suited for rapid, intense actions, such as a runner's short sprint at maximum speed or a cat pouncing on its prey. Fast-glycolytic fibers fatigue more rapidly than oxidative fibers. The breast meat of chickens, for example, appears white because, unlike ducks, chickens do not fly except for very short distances and therefore do not require oxidative pectoral muscles. The fast-glycolytic muscles of chickens, however, are ideal for short flights in the air. These flights are useful for quickly escaping predators and breaking scent trails that would otherwise help predators in their chase. When they land, chickens use slow-oxidative fibers in their leg muscles to run long distances as they continue to elude a predator.

Different muscle groups within the animal body have different proportions of each fiber type interspersed with one another; many activities require the action of all three types of fibers at once. This is important when you consider the wide range of animal activities related to locomotion alone, including walking, climbing, running, swimming, flying, crawling, crouching, jumping, and maintaining balance and posture. Depending on the needs of an animal at any given moment, the motor nerve inputs can be adjusted to stimulate different ratios of fiber types. When you lift a heavy weight for a brief time, the motor units containing fast-glycolytic fibers in your arm muscles are activated in large numbers. When a crab uses its pincers to grab prey, fast-glycolytic muscles snap the claws closed quickly, but then slow-oxidative fibers maintain a tight grip for as long as needed. The characteristics of the three types of skeletal muscle fibers are summarized in Table 44.1.

Table 44.1 Characteristics of the Three Types of Skeletal Muscle Fibers

	Slow-oxidative	Fast-oxidative	Fast-glycolytic
Primary source of ATP production	Oxidative phosphorylation	Oxidative phosphorylation	Glycolysis
Mitochondria	Many	Many	Few
Blood supply	High	High	Moderate
Myoglobin content	High (red muscle)	High (red muscle)	Low (white muscle)
Rate of fatigue	Slow	Intermediate	Fast
Myosin-ATPase activity	Low	High	High
Rate of contraction	Slow	Fast	Fast

Muscles Adapt to Exercise

The regularity with which a muscle is used, as well as the duration and intensity of the activity and whether it includes resistance, affects the properties of the muscle. For example, increased amounts of resistance exercise—such as weightlifting—results in hypertrophy (increase in size) of muscle fibers. Because the number of fibers in a muscle remains essentially constant throughout adult life, the increases in muscle size that occur with resistance exercise do not result from increases in the number of muscle fibers, but instead from increases in the size of each fiber. These fibers undergo an increase in fiber diameter due to the increased synthesis of actin and myosin filaments, which form more myofibrils.

Exercise of relatively low intensity but long duration—popularly called aerobic exercise, including running and swimming—produces increases in the number of mitochondria in the fibers that are needed in this type of activity. In addition, the number of blood vessels around these fibers increases to supply the greater energy demands of active muscle. All of these changes increase endurance with a minimum of fatigue.

By contrast, short-duration, high-intensity exercise, such as weightlifting, primarily affects fast-glycolytic fibers, which are used during strong contractions. In addition, glycolytic activity is enhanced by elevated synthesis of glycolytic enzymes. The results of such high-intensity exercise are the increased strength and bulging muscles of a conditioned weight lifter. Such muscles, although very powerful, have little capacity for endurance and therefore fatigue rapidly.

A decline or cessation of muscular activity results in the condition called **atrophy**, a reduction in the size of the muscle. Likewise, if the neurons to a skeletal muscle are destroyed or the neuromuscular junctions become nonfunctional, the denervated muscle fibers will become progressively smaller in diameter. This condition is known as denervation atrophy. Even with an intact nerve supply, a muscle can atrophy if it is not used for a long period of time, as when a broken limb is immobilized in a cast.

The mechanism by which changes occur in skeletal muscle during exercise is an active area of research, but a recent discovery has provided an intriguing clue, as described next.

Feature Investigation

Evans and Colleagues Activated a Gene to Produce "Marathon Mice"

In the course of investigating possible ways to reverse or prevent obesity in humans and other mammals, Ron Evans and his colleagues at the Salk Institute in California discovered one way in which the ratios of oxidative and glycolytic fibers change in skeletal muscle. Evans was interested in a gene that codes for a transcription factor called PPAR-δ. Activation of this protein results in the expression of genes that enable skeletal muscle

or other cells to more efficiently burn fat instead of glucose for energy. Evans hypothesized that mice in which PPAR-δ was chronically activated at high levels would lose weight due to increased fat burning, as shown in Figure 44.12.

To test this hypothesis, Evans created transgenic mice (see Chapter 20) which contained the *PPAR-δ* gene in a modified form. The modified gene had a skeletal muscle-specific promoter so that it would be expressed only in skeletal muscle cells. The region of the gene that encoded PPAR-δ was linked to a region of another gene that encoded a viral protein domain called VP16. This domain also facilitates gene activation. The researchers expected the combination of PPAR-δ and VP16 to strongly activate genes that enable cells to more efficiently burn fat instead of glucose for energy.

In the first part of the experiment, Evans monitored the body weights of the transgenic mice after they reached adulthood. These mice gained significantly less weight compared to wild-type mice when fed high-fat diets (which normally cause mice—like humans—to gain weight), confirming Evans' hypothesis. As is sometimes the case in scientific discovery, an unexpected finding arose from this study when Evans examined several tissues in these mice. Under the microscope, he observed that the skeletal muscle of the transgenic mice showed a dramatic shift from glycolytic fibers to slow-oxidative fibers. The muscle in transgenic mice appeared redder than it did in wild-type mice. It contained more myoglobin and mitochondria and had higher levels of oxidative enzymes capable of providing the cells with sustained levels of ATP. These changes occurred even though the mice had not been subjected to exercise training.

Based on these observations, Evans also tested the hypothesis that the transgenic mice would have a greater capacity for prolonged exercise than wild-type mice. When the transgenic mice were challenged with an endurance exercise test, Evans discovered that they outperformed age- and weight-matched wild-type mice by a factor of nearly twofold! They could sustain a high level of activity on a miniature treadmill for nearly twice as long as wild-type mice (hence the nickname "marathon mice"). This effect occurred in transgenic mice even without prior exercise training. In other words, simply increasing the ratio of oxidative to glycolytic fibers gave the mice greater ability to sustain aerobic activity.

The results of these experiments indicate that elevating the levels of activated PPAR-δ facilitates an oxidative state in skeletal muscle fibers that somehow signals them to convert to types that are best suited for oxidative metabolism. Therefore, the switch in fiber type that occurs normally in exercise training may not require exercise *per se*, and it may be mediated in part by proteins that activate or induce *PPAR-δ* expression. These results may have important implications for exercise endurance in humans, as well as for possible treatments for various muscle diseases.

Experimental Questions

1. What is the normal function of the PPAR-δ protein in mice?
2. What was the hypothesis proposed by Evans in relation to PPAR-δ and obesity?
3. How did Evans and his colleagues test this hypothesis, and what did they observe?

Figure 44.12 Evans and colleagues' activation of a gene to produce "marathon mice."

HYPOTHESES 1. Increased expression of genes that lead to increased fat oxidation in skeletal muscle cells will prevent obesity in mice.
2. Transgenic mice have a greater capacity for prolonged exercise than do wild-type mice.

KEY MATERIALS Mice, light and electron microscopes, motorized treadmills.

	Experimental level	Conceptual level
1 Prepare a modified gene containing a skeletal muscle-specific promoter and a coding sequence that links *VP16* and *PPAR-δ*. See Chapter 20 for gene cloning methods.		Skeletal muscle-specific promoter ensures gene is turned on only in skeletal muscle. VP16 domain is a domain that always activates transcription. *PPAR-δ* codes for a transcription factor that specifically activates genes that allow cells to efficiently burn fat.
2 Make transgenic mice expressing the *VP16–PPAR-δ* gene.	 See Chapter 20 for a discussion of gene addition.	All of the cells will carry this gene, but only skeletal muscle cells will express the gene.

3 **Perform the following tests:**

(a) Feed wild-type control mice and transgenic mice a normal-fat diet (4%) and then switch to a high-fat diet (35%). Weigh mice weekly.
(b) Examine the muscle fibers in the mice.
(c) Test their endurance on a treadmill.

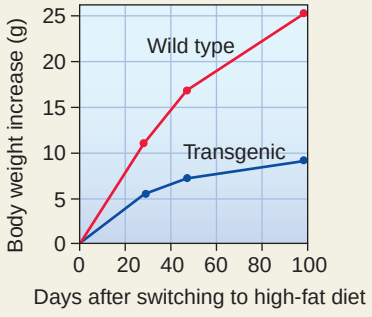
Scale

Microscope

Treadmills

(a) Eating a high-fat diet is known to cause obesity in mice and other mammals.
(b) The appearance of skeletal muscle can be examined by light and electron microscopy.
(c) The treadmills are motorized to keep mice moving until they become exhausted, at which time the treadmills are stopped.

4 **THE DATA**

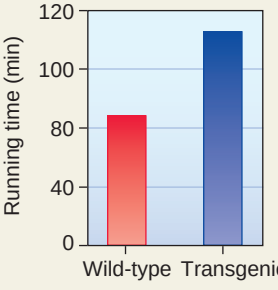


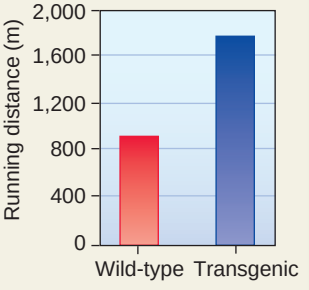
(a) Weight gain

Characteristics of skeletal muscle in transgenic mice:

– redder than wild type
– more myoglobin
– more mitochondria
– more slow-oxidative fibers

(b) Difference in skeletal muscle





(c) Muscle endurance

5 **CONCLUSION** PPAR-δ contributes to both weight loss and endurance in mice. The fiber-type switching associated with exercise does not require exercise, because increasing fat oxidation in skeletal muscle cells resulted in more oxidative fibers even without exercise training.

Skeletal Muscles Can Bend or Straighten a Limb

As mentioned previously, contracting muscle exerts a force on bones through its connecting tendons. When the force is great enough, the bone moves as the muscle shortens. A contracting muscle exerts only a pulling force, so as the muscle shortens, the attached bones are pulled toward or away from each other. Muscles that bend a limb at a joint (that is, reduce the angle between two bones) are called **flexors**, whereas muscles that straighten a limb (increase the angle between two bones) are called **extensors**. Groups of muscles that produce oppositely directed movements at a joint are known as **antagonists**. For example, in Figure 44.13, we can see that contraction of the hamstrings flexes the leg at the knee joint, whereas contraction of the antagonistic muscle, the quadriceps, causes the leg to extend. Both antagonistic muscles exert only a pulling force when they contract.

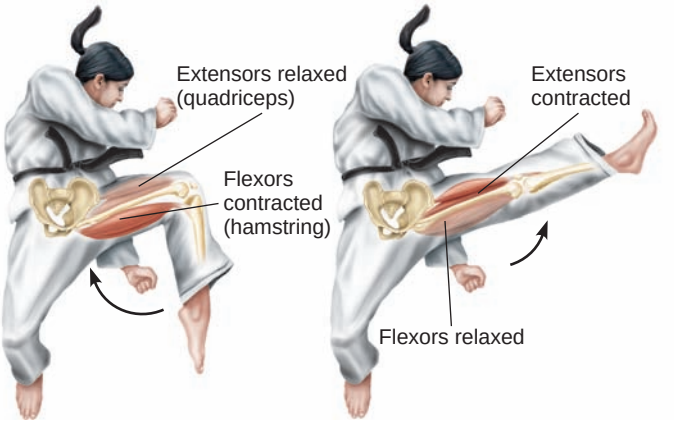

Figure 44.13 **Actions of flexors and extensors.** The figure shows how muscles cause flexion or extension of a limb in an animal with an endoskeleton. When the flexor muscle contracts, the extensor relaxes, and vice versa.

44.5 Animal Locomotion

Locomotion is the movement of an animal from place to place. Animal locomotion occurs in several forms, including walking/running, swimming, flying, crawling/sliding, or jumping. In all cases, animals experience certain constraints to locomotion. For example, all animals must overcome frictional forces (drag) generated by the air, water, or surface of the Earth. In addition, all forms of locomotion require energy to provide thrust, defined as the forward motion of an animal in any environment, and/or lift, which is movement against gravity.

Although the precise mechanism may differ among animals, locomotion with few exceptions (such as the use of cilia in ctenophores) results from muscular contractions that exert force on one of the three types of skeletons discussed at the beginning of this chapter. In this section, we will examine the similarities and differences between locomotion in water, on land, and in air.

Aquatic Animals Must Overcome the Resistance of Water

The greatest challenge to locomotion in water is the density of water, which is much greater than that of air. This is apparent when you compare waving your hand through the air and underwater. Water's resistance to movement increases exponentially as the speed of locomotion increases, which is one reason why many fishes swim at relatively slow speeds. Overcoming this resistance requires considerable muscular effort. Most swimming animals, including fishes, amphibians, reptiles, diving birds, and marine mammals, have evolved streamlined bodies that reduce drag and so make swimming more efficient. Other animals that swim only occasionally or spend time on the surface of the water have evolved adaptations, such as the webbed feet of ducks, that assist their muscles in generating greater thrust through the water.

Although the density of water creates challenges to locomotion, it also provides certain benefits. An energetic advantage to swimming is that fishes and other swimmers do not need to provide as much lift to overcome gravity. Because the density of water is similar to that of an animal's body, water provides buoyancy, which helps support the animal's weight.

The mechanism of swimming is similar among many different vertebrates. Most fishes, for example, contract posterior skeletal muscles to move the tail end of the animal from side to side. This pushes water backward and propels the fish forward. Other muscles and fins provide additional thrust and enable changes in direction. Likewise, amphibians and marine reptiles rely predominantly on their hind legs, their tail, or undulations of the posterior parts of the body for propulsion through the water. Cetaceans use up-and-down thrusts of their tail flukes to provide propulsion. Confining most of the swimming muscles to the rear of an animal's body has certain advantages. With the rear end devoted to movement, the front end is free to explore the environment, fight off aggressors, or find food. By contrast, pinnipeds use their flippers to provide thrust and their tails to steer. In these animals, a flexible tail assists with locomotion when on land.

In contrast to swimming vertebrates, many aquatic invertebrates move through water by means other than swimming. Cephalopods such as squids use propulsion provided by the ejection of water to give them brief but rapid bursts of speed. Many other aquatic invertebrates move passively on water currents or crawl along rocks and other underwater surfaces.

Swimming is energetically the cheapest form of locomotion in animals that are adapted to swimming, due to streamlining, the relatively slow speed of most swimmers, and the buoyancy of water. By contrast, terrestrial animals face considerable energetic costs to locomotion, as we examine next.

Walking and Running on Land Are Energetically Costly

In contrast to swimming, locomotion on land is, on average, the most energetically costly means of locomotion (Figure 44.14). Flying may seem more costly, but it is not. Many migratory birds can travel hundreds of miles daily for many days. A recent study by researchers in New Zealand, using satellite transmitters, tracked the nonstop, week-long migration of four bar-tailed godwits (*Limosa lapponica*) over a distance of roughly 10,000 km, from New Zealand to the coast of South Korea. No terrestrial animal could possibly match such a feat by walking or running. (To grasp how astonishing this feat is, imagine running from New York City to Los Angeles and back again in 7 days without any rest or food!)

Whereas gravity is not an important factor for locomotion in swimming animals, terrestrial animals must overcome

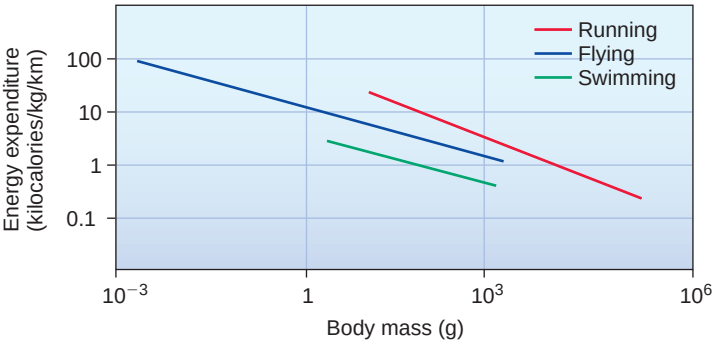

Figure 44.14 Energy costs of locomotion. The energy costs of different modes of locomotion for animals of different sizes are shown. The y-axis gives the energy costs expressed as kilocalories expended per kilogram (kg) per kilometer (km). Energy costs are highest for runners compared to similarly sized fliers and swimmers. Note: Only a portion of the full range of body sizes of swimmers is shown.

Concept check: Does this graph indicate that smaller animals expend more energy than larger animals when moving a similar distance?

gravity each time they take a step. Of even greater importance to walking and running animals, though, is the requirement to accelerate and decelerate the limbs with every step. In essence, each step is like starting a movement from scratch, without the luxury of occasionally gliding through water or air as fishes and birds do. This challenge is even greater when an animal moves uphill or over rough terrain.

Apart from gastropods, which move along the surface of the Earth on a layer of secreted mucus, and snakes, which undulate along the ground on a portion of their ventral body surface, most terrestrial animals limit the amount of contact with the ground while moving, thereby minimizing the amount of friction they encounter. Tetrapods usually have only two feet on the ground at any time when walking, but for brief moments, an animal such as a horse galloping at full speed has all four feet off the ground.

Having fewer legs on the ground surface at any one time helps increase speed but can compromise stability. Arthropods, for example, have at least six legs. This apparently provides excellent stability but reduces maximal speed (although cockroaches can attain rapid speeds by running on only two legs). At the other extreme are animals that move by jumping—fleas, certain spiders, click beetles, grasshoppers, frogs, and kangaroos.

Flying Has Evolved in Four Different Lineages

Flying is a highly successful means of locomotion and is hypothesized to have evolved in four different lineages: pterosaurs (extinct reptiles), insects, birds, and mammals (bats). Flying provides numerous advantages. Animals can escape land-based predators, scan their surroundings over great distances, and inhabit environments such as high cliffs that may be inaccessible to nonflying animals. The mechanics of flying, however, require animals to overcome gravity and air resistance, which makes flying more energetically costly than swimming but still less costly than running on land (see Figure 44.14). As with swimming, resistance to flight is decreased by streamlined bodies. However, earthbound animals have one advantage over their flying cousins—they can grow to much larger sizes than animals that fly. The vast majority of flying animals have a mass between about 1 mg and 1 kg. Only a few large birds have masses exceeding 10 kg. Although this represents an enormous range, it falls far short of the sizes achieved by earthbound or aquatic animals.

In flying vertebrates, lift and thrust are provided by pectoral and other muscles that move the wings. The pectoral muscles are so powerful and massive that they constitute as much as 15–20% of a bird's total body mass and up to 30% in hummingbirds, which use their wings not only to fly but also to hover. The requirement for large, strong pectoral muscles is one reason why the remaining body mass of flying vertebrates is limited. The extinct pterosaurs would seem to be an exception because some species were known to have had wingspans of nearly 10 m. However, scientists think that these large animals were unable to generate the force required to lift their massive bodies off the Earth and instead glided off of trees or cliffs to fly.

In birds and bats, the wings are modifications of the forelimbs. In general, bat wings are far more maneuverable than bird wings, because unlike birds, bats have digits at the end of their forelimbs/wings. This allows bats to precisely alter the shape of their wings and provide for rapid, fine-tuned changes in direction, even at high speeds. Bird wings are more similar to those of a fixed-wing aircraft. The largest birds, such as hawks and eagles, are able to glide because of the great surface area of their large wings. By using a bird's momentum to propel it forward, gliding provides a considerable energy savings. Bats and small birds, however, can glide for only very brief moments.

In this chapter, we have seen how skeletal muscles and (in vertebrates) bones work together to provide animals with protection and to enable them to move around in their environments. Unfortunately, muscles and bone are frequently the sites of significant diseases with great impacts on human health. We conclude the chapter with a discussion of a few of these diseases, each resulting from a different cause.

44.6 Impact on Public Health

A number of diseases can affect bone structure and function in humans. Bone disease may involve defects in either the mineral or organic components of bone. Poor bone formation and structure may result from inadequate nutrition, hormonal imbalances, aging, or skeletal muscle atrophy, to name just a few of the common causes.

In addition, many diseases or disorders directly affect the contraction of skeletal muscle. Some of them are temporary and not serious, such as muscle cramps, whereas others are chronic and severe, such as the disease muscular dystrophy. Also, some diseases result from defects in parts of the nervous system that control contraction of the muscle fibers rather than from defects in the fibers themselves. One example is poliomyelitis (polio), a viral disease in which the destruction of motor neurons leads to skeletal muscle paralysis that may result in death from respiratory failure. Polio, once thought to be nearly eliminated from the human population, is still a threat in parts of the world.

Other diseases that affect skeletal muscle function result when normal processes go awry. For example, the system that normally protects the body from invaders may turn on itself, or faulty genes may produce an abnormal or absent protein. This section looks at a few of these conditions in more detail.

Rickets and Osteoporosis Affect the Bones of Millions of People

Bone diseases are fairly common, particularly among individuals over age 50. Two major abnormalities can occur in bone. The first is improper mineral deposition in bone, usually due to inadequate dietary calcium intake or inadequate absorption of calcium from the small intestine. Without adequate minerals, bone becomes soft and easily deformed, as occurs in the weight-bearing bones of the legs of children with **rickets** (or

osteomalacia, as it is called in adults) (Figure 44.15a). These disorders are best prevented or treated with vitamin D, because this vitamin is the most important factor in promoting absorption of calcium from the small intestine.

The second major abnormality we will discuss is a more common disease called **osteoporosis**, in which both the mineral and organic portions of bone are reduced (Figure 44.15b). This disease, which affects four times as many women as men, occurs when the normal balance between bone formation and bone breakdown is disrupted.

One cause of osteoporosis is prolonged disuse of muscles. In ways that are not completely clear, the force produced by active skeletal muscle contractions helps maintain bone mass. When muscles are not or cannot be used—due to paralysis or long-term immobilizing illnesses or even during prolonged space flight in which the lack of gravity reduces the need for muscles to work hard—bone mass declines.

More commonly, osteoporosis may result from hormonal imbalances. Some hormones—for example, estrogen—stimulate bone formation. When estrogen levels decline after menopause (the period of time when a woman's reproductive cycles cease), bone density may decline, increasing the risk of bone fractures. By contrast, some hormones—such as parathyroid hormone (see Chapter 50)—act to demineralize bone as part of the way in which the body normally maintains mineral homeostasis in the blood. If such hormones are present in excess, however, they can cause enough demineralization of bone to result in osteoporosis. This may happen in rare cases when the glands that make these hormones malfunction and overproduce the hormones.

Osteoporosis can be minimized with adequate calcium and vitamin D intake and weight-bearing exercise programs. In some cases, postmenopausal women may be given estrogen to replace what their bodies are no longer producing, but this therapy is controversial due to the potential adverse effects of estrogen on cardiovascular health and breast cancer in some women. Osteoporosis is the most prevalent bone disease in the U.S., affecting up to 15–30 million individuals. It results in annual national expenditures of approximately $15–20 billion in hospital and other medical costs.

Myasthenia Gravis Is an Autoimmune Disease That Affects Skeletal Muscles

Myasthenia gravis is a disease characterized by skeletal muscle fatigue and weakness. It ranges in severity, but at its worst, it can make chewing, swallowing, talking, and even breathing difficult. It affects an estimated 10,000 to 30,000 Americans, usually not becoming apparent until adolescence.

In myasthenia gravis, skeletal muscle function is reduced because the body's immune system produces antibodies—proteins that attack foreign matter—that bind to and inactivate ACh receptors on skeletal muscle cells. Because the destruction of ACh receptors is brought about by the body's own defense mechanisms gone awry, myasthenia gravis is considered an autoimmune disease (see Chapter 53). Thus, although motor nerve signals to the muscles are normal, the muscles cannot fully respond to the ACh released from the nerves because the receptors are not functional.

A number of approaches are currently used to treat the disease. One is to administer inhibitors of acetylcholinesterase, the enzyme that normally breaks down ACh at the neuromuscular junction. The inhibition of this enzyme prolongs the time that acetylcholine is available at the synapse, which to some degree compensates for reduced ACh receptor abundance. Other therapies are directed at suppressing the immune system to prevent destruction of the ACh receptors by antibodies. This is accomplished either by surgically removing certain glands that constitute part of the immune system or with drug therapy, but it has the disadvantage of making the person more susceptible to infections. Another therapy, called plasmapheresis, involves removing the liquid fraction of blood (plasma), which contains antibodies, and reinfusing the blood after the antibodies have been removed. A combination of these treatments has greatly reduced the mortality rate for myasthenia gravis.

Muscular Dystrophy Is a Rare Genetic Disease That Causes Muscle Degeneration

The group of diseases collectively called muscular dystrophy affects 1 of every 3,500 American males; it is much less common in females. **Muscular dystrophy** is associated with the progressive degeneration of skeletal (and cardiac) muscle fibers, weakening the muscles and leading ultimately to death from lung or heart failure. The signs and symptoms become evident at about 2 to 6 years of age, and most affected individuals do not survive beyond the age of 30.

The most common form of muscular dystrophy, called Duchenne muscular dystrophy, is a sex-linked recessive disease resulting from a defective gene on the X chromosome. Females have two X chromosomes, and males only one (plus one Y). Therefore, a heterozygote female with one abnormal

and one normal gene will not generally develop the disease. In Duchenne muscular dystrophy, the affected gene codes for a protein known as dystrophin, which is absent in patients with the disease. Dystrophin is a large protein that links cytoskeletal proteins to the plasma membrane. Scientists think it is involved in maintaining the structural integrity of the plasma membrane in muscle fibers. In the absence of dystrophin, the plasma membrane of muscle fibers is disrupted, causing extracellular fluid to enter the cell. Eventually, the cell ruptures and dies.

Summary of Key Concepts

44.1 Types of Animal Skeletons

- Skeletons are structures that provide support and protection and also function in locomotion.
- Three types of skeletons are found in animals. In hydrostatic skeletons, found in many soft-bodied invertebrates, muscle contractions acting on fluid-filled body cavities create differences in hydrostatic pressure that support the body and generate movements. Exoskeletons, which are found in arthropods, are protective external structures that must be shed to accommodate growth of the animal. Endoskeletons are internal structures that grow with the animal but do not protect its body surface; endoskeletons are found in some species of sponges and all echinoderms and vertebrates. (Figure 44.1)

44.2 The Vertebrate Skeleton

- Vertebrate endoskeletons are made up of the axial and appendicular skeletons. A joint is formed where two or more bones of a vertebrate endoskeleton come together. (Figure 44.2)
- In addition to the functions of support, protection, and locomotion, the vertebrate skeleton produces blood cells and constitutes a reservoir for ions that are crucial to homeostasis.

44.3 Skeletal Muscle Structure and the Mechanism of Force Generation

- A skeletal muscle is a grouping of cells, called muscle fibers, bound together by connective tissue layers. The striations of skeletal muscle result from the presence within muscle fibers of cylindrical bundles known as myofibrils, each of which contains thick and thin filaments arranged in repeating units called sarcomeres. The arrangements of thick and thin filaments within each sarcomere create various light and dark regions designated the A and I bands, respectively; the Z and M lines; and the H zone. Thick filaments are composed almost entirely of the motor protein myosin, whereas thin filaments contain the cytoskeletal protein actin plus two other proteins called troponin and tropomyosin. Portions of the thick filaments are called cross-bridges. (Figures 44.3, 44.4)
- During muscle contraction, the sarcomeres shorten by a process known as the sliding filament mechanism. In muscle contraction, the thick filaments remain stationary while the thin filaments slide past them propelled by action of the cross-bridges. (Figures 44.5, 44.6)
- Mutations in a myosin gene of the jaw muscle may have allowed the human brain to become larger. (Figure 44.7)
- The repeated interaction of cross-bridges on the thick filaments and the protein components of the thin filaments occurs according to a process called the cross-bridge cycle. The steps of the cycle are binding, power stroke, detaching, and resetting. (Figure 44.8)
- Proteins associated with the thin filament called tropomyosin and troponin, along with Ca^{2+}, play a critical role in the regulation of muscle contraction. (Figure 44.9)
- Ca^{2+} also plays an important role in excitation-contraction coupling, the sequence of events by which an action potential in the plasma membrane of a muscle fiber leads to cross-bridge activity.
- The source of the cytosolic Ca^{2+} involved in a muscle fiber action potential is the muscle fiber's sarcoplasmic reticulum. Tubular structures called the transverse tubules (T-tubules) conduct action potentials from the plasma membrane at the outer surface of the muscle fiber to the myofibrils. (Figure 44.10)
- Electrical stimulation of skeletal muscle occurs at a neuromuscular junction, in which a motor neuron's axon and a muscle fiber are in close proximity. (Figure 44.11)

44.4 Skeletal Muscle Function

- Three major types of skeletal muscle fibers have been distinguished. Slow-oxidative fibers have low rates of myosin ATP hydrolysis; they do not fatigue easily and are used for prolonged, regular activities. Fast-oxidative fibers have high myosin activity, do not fatigue quickly, and are particularly suited for rapid actions. Fast-glycolytic fibers have high myosin activity but cannot make as much ATP as oxidative fibers; they are best suited for rapid, intense actions. (Table 44.1)
- Increased expression of *PPAR-δ* in mice results in increased slow-oxidative muscle, greater exercise endurance, and weight loss. (Figure 44.12)
- Groups of muscles that produce oppositely directed movements at a joint are known as antagonists. Muscles that bend a limb at a joint are called flexors, whereas muscles that straighten a limb are called extensors. (Figure 44.13)
- To produce movement, muscles, bones, and joints are arranged in lever systems.

44.5 Animal Locomotion

- Locomotion is the movement of an animal from place to place.
- Due to streamlining, the relatively slow speed of most swimmers, and the buoyancy of water, swimming is energetically the most efficient form of locomotion. Locomotion on land is, on average, the most energetically costly means of locomotion. The energy expenditure required for flight is intermediate between those for swimming and land-based locomotion. (Figure 44.14)

44.6 Impact on Public Health

- Several health conditions affect muscular-skeletal structures. Rickets (osteomalacia in adults) is characterized by soft,

deformed bones, usually resulting from insufficient dietary intake or absorption of calcium. In osteoporosis, bone density is reduced when bone formation fails to keep pace with normal bone breakdown. Myasthenia gravis is an autoimmune disease characterized by skeletal muscle fatigue and weakness. Muscular dystrophy is an ultimately fatal genetic disease associated with the progressive degeneration of skeletal and cardiac muscle fibers. (Figure 44.15)

Assess and Discuss

Test Yourself

1. The hydrostatic skeleton common in soft-bodied invertebrates is composed of
   a. muscle and cartilage.
   b. cartilage and a neural net.
   c. muscle and water-based fluid.
   d. cartilage and water-based fluid.
   e. bone and muscle.
2. Which of the following is not a function of the vertebrate skeleton?
   a. structural support
   b. protection of internal organs
   c. calcium reserve
   d. blood cell production
   e. All of the above are functions of the vertebrate skeleton.
3. The protein that provides strength and flexibility to bone is
   a. actin. c. myoglobin. e. elastin.
   b. myosin. d. collagen.
4. In a sarcomere, the _____ contain(s) thin filaments and no thick filaments.
   a. A band c. I band e. both a and d
   b. M line d. H zone
5. The function of ATP during muscle contraction is to
   a. cause an allosteric change in myosin so it detaches from actin.
   b. provide the energy necessary for the movement of the cross-bridge.
   c. expose the myosin-binding sites on the thin filaments.
   d. do all of the above.
   e. do a and b only.
6. The function of calcium ions in skeletal muscle contraction is to
   a. cause an allosteric change in myosin so it detaches from actin.
   b. provide the energy necessary for the movement of the cross-bridge.
   c. expose the myosin-binding sites on the thin filaments.
   d. bind to tropomyosin.
   e. do a and c only.
7. Stimulation of a muscle fiber by a motor neuron occurs at
   a. the neuromuscular junction.
   b. the transverse tubules.
   c. the myofibril.
   d. the sarcoplasmic reticulum.
   e. none of the above.
8. Muscle fibers that have a high number of mitochondria, contain large amounts of myoglobin, and exhibit low rates of ATP hydrolysis are called _____ fibers.
   a. slow-glycolytic d. fast-oxidative
   b. fast-glycolytic e. slow-oxidative
   c. intermediate
9. Which of the following statements about movement and locomotion is incorrect?
   a. Terrestrial animals and flying animals expend energy to provide lift.
   b. Swimming animals expend energy to provide thrust but not lift.
   c. Flexors and extensors are examples of muscles called agonists.
   d. Flexors cause bending at a joint.
   e. Extensors cause straightening of a limb.
10. For animals adapted to it, swimming is energetically the cheapest type of locomotion because of
    a. streamlined body forms in aquatic organisms.
    b. slow speed of movement of some swimmers.
    c. buoyancy of water.
    d. a and c only.
    e. a, b, and c.

Conceptual Questions

1. Define locomotion, and list some of the various types that occur in animals.
2. Distinguish between exoskeletons and endoskeletons.
3. List and briefly describe the steps in the cross-bridge cycle.

Collaborative Questions

1. Discuss the structure and function of the three different types of skeletons found in animals.
2. Discuss the three types of muscle tissues found in vertebrates.

Chapter Outline

Nutrition, Digestion, and Absorption

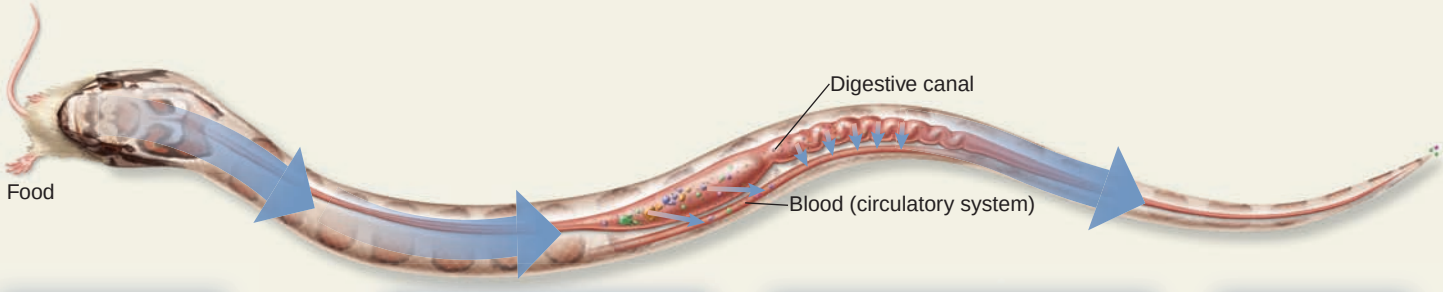
45

A balanced meal containing many nutrients, including carbohydrates, lipids, proteins, vitamins, minerals, and water.

What would 50,000,000 Calories (or more precisely, kilocalories) worth of food look like if it were assembled all in one place? That is roughly the amount of calories that you will consume in your lifetime. All that energy is required for the trillions of body cells to perform numerous activities such as synthesizing proteins, making cellular organelles, and maintaining concentration gradients of ions across the plasma membrane. These and other activities are necessary for homeostasis and require a lifelong supply of energy and building blocks. These materials must be consumed by animals in the form of nutrients. A **nutrient** is any organic or inorganic substance that is taken in by an organism and is required for survival, growth, development, tissue repair, or reproduction; the process of consuming and using food and nutrients is called nutrition. All organisms require nutrients to survive. Animals receive their nutrients by consuming food, as shown by the nutritionally balanced meal in the chapter-opening photo.

The process of food use in animals occurs in four phases: ingestion, digestion, absorption, and elimination (Figure 45.1). **Ingestion** is the act of taking food into the body via a structure such as a mouth. From there, the food moves into a digestive cavity or canal. If the nutrients in food are in a form that cannot be directly used by cells, they must be broken down into smaller molecules, a process known as **digestion**. This is followed by the process of **absorption**, in which ions, water, and small molecules diffuse or are transported from the digestive cavity into an animal's circulatory system or body fluids. **Elimination** is the process of passing undigested material out of the body.

In this chapter, we will look at the nutrients that animals require and the diverse ways in which animals obtain, digest, and absorb those nutrients. We will also discuss how these processes are regulated by the body and some of the common ways in which they may go awry. We begin by examining the types of nutrients animals consume.



1 **Ingestion:** Food is consumed.

2 **Digestion:** Nutrients are broken down into smaller molecules in the digestive canal.

3 **Absorption:** Ions, water, and small molecules diffuse or are transported out of the digestive canal into the body fluids.

4 **Elimination:** Undigested waste products are excreted.

Figure 45.1 An overview of the four phases of food use in animals.

45.1 Animal Nutrition

Animals require both organic and inorganic nutrients. Organic nutrients fall into five categories: carbohydrates, proteins, lipids, nucleic acids, and vitamins. These provide energy and the building blocks of new molecules or serve as cofactors in many enzymatic reactions. Inorganic nutrients include water and minerals such as calcium, copper, and iron. The importance of water to life was covered in Chapter 2. Minerals may function as cofactors in enzymatic reactions and other processes.

Animals have many nutritional requirements in common, because of similarities in the way their bodies work. However, nutritional demands differ depending upon an animal's physiology. The digestive systems of **herbivores**, animals that eat only plants, contain microbes that assist in the digestion of cellulose, so these animals are well adapted to subsist on plants. By contrast, **carnivores** are primarily adapted to consume animal flesh or fluids, and **omnivores**, such as humans, have the ability to survive on both plant and animal products.

The amount of each type of nutrient required by an animal may also differ, depending on its activity level, or metabolic rate, which we will discuss in Chapter 46. Generally, highly active and energetic animals, such as most birds and mammals, require a proportionally greater amount of nutrients each day than do relatively inactive or sedentary animals, such as nonmotile invertebrates. However, exceptions to this general rule exist, as when some mammals enter hibernation and reduce their energy use. In this section, we will examine the various organic and inorganic nutrients consumed by animals and some of the major functions of these molecules.

Animals Require Nutrients for Energy and the Synthesis of New Molecules

Ingested organic macromolecules are used for two general purposes: to provide energy or to make new molecules. As described in Chapter 6, the bonds of organic molecules may be broken down to release energy; this energy can be used in the synthesis of ATP, the energy source of all cells. Indirectly, therefore, organic molecules provide the energy required for most of the chemical reactions that occur in animals' bodies. Alternatively, organic molecules can serve as building blocks to synthesize new cellular molecules. For example, all animals that have muscles use amino acids to make the same specialized proteins that allow their muscles to contract.

Although different species consume a wide variety of foods, all animals require the same fundamental organic macromolecules (Table 45.1). Carbohydrates supply energy-yielding glucose and carbon. Proteins supply amino acids that, in addition to building protein, can be used as an energy source. Lipids supply components for membrane-building and thermal insulation and also provide energy. Nucleic acids supply some of the components required for DNA, RNA, and ATP synthesis. The other category of organic nutrients—the vitamins—are required in small quantities and function as coenzymes in various reactions, as described later.

Essential Nutrients Must Be Obtained from the Diet

Certain compounds cannot be synthesized from any ingested or stored precursor molecule. These **essential nutrients** must be obtained in the diet in their complete form. The word essential in this context refers to the fact that they must come from food. It does not mean that other nutrients are less important, because many nutrients are required for an animal's survival. The essential nutrients can be classified into four groups: essential amino acids, essential fatty acids, vitamins, and minerals.

Essential Amino Acids Eight **essential amino acids** are required in the diet of humans and many other animals—isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. These amino acids are required for building proteins but cannot be synthesized by the animal's cells. Also, animal cells do not store amino acids. Therefore, without a recurring supply of these eight amino acids, protein synthesis in each cell in an animal's body would slow down or stop completely. Carnivores and omnivores readily obtain

Table 45.1 Major Nutrients in Animals, Their Dietary Sources, and Some of Their Functions and Symptoms of Deficiency in Vertebrates

Class of nutrient	Dietary sources	Functions in vertebrates	Symptoms of deficiency
Carbohydrates	All food sources, especially starchy plants	Energy source; component of some proteins; source of carbon	Muscle weakness; weight loss; ketone formation (decreases pH of blood)
Proteins	All food sources, especially meat, legumes, cereals, roots	Provide amino acids to make new proteins; build muscle; some amino acids used as energy source	Weight loss; muscle loss; weakness; weakened immune system; increased likelihood of infections
Lipids	All food sources, especially fatty meats, dairy products, plant oils	Major component of cell membranes; energy source; thermal insulator; building blocks of some hormones	Hair loss; dry skin; weight loss; hormonal and reproductive disorders
Nucleic acids	All food sources	Provide sugars, bases and phosphates that can be used to make DNA, RNA, and ATP	None; components of nucleic acids can be synthesized by cells from amino acids and sugars

all of the essential amino acids, because meat (animal muscle) contains all 20 amino acids. Unlike animal meat, most plants do not contain every essential amino acid in sufficient quantities to supply a human's nutritive requirements. Therefore, people who follow strict vegetarian diets must find ways to balance the protein content of the plant matter they eat. By contrast, some herbivores, such as cows, have evolved the capacity to synthesize the essential amino acids, which allows them to subsist entirely on a plant diet.

Essential Fatty Acids The **essential fatty acids** are certain polyunsaturated fatty acids, such as linoleic acid, that cannot be synthesized by animal cells. Saturated fatty acids, however, can be synthesized from carbon sources such as glucose (see Chapter 3 for a discussion of the chemistry of fatty acids). Linoleic acid is vital to an animal's health because it is converted in cells to another fatty acid, called arachidonic acid. This fatty acid is the precursor for production of several compounds important in many aspects of animal physiology; such compounds include the prostaglandins, which play roles in pain, blood clotting, and smooth muscle contraction. Some animals—such as felines—cannot synthesize arachidonic acid from linoleic acid, so arachidonic acid is an essential fatty acid in those species. Unsaturated fats are found primarily in plants, which provide a dietary source for both herbivores and omnivores. Strict carnivores such as felines, however, obtain their essential fatty acids from fishes or from the adipose tissue of birds and mammals.

Vitamins **Vitamins** are important organic nutrients that serve as coenzymes for many metabolic and biosynthetic reactions. The two categories of vitamins are water-soluble and fat-soluble. Water-soluble vitamins, such as vitamin C, are not stored in the body and must be regularly ingested. Fat-soluble vitamins, such as vitamin A, are stored in adipose (fat) tissue. Not all animals require the same vitamins in their diet, however. Among vertebrates, for example, only primates and guinea pigs cannot synthesize their own vitamin C and must therefore consume it in the diet. Table 45.2 summarizes the vitamins, their dietary sources, some of their important functions, and some health consequences associated with their deficiencies.

Minerals **Minerals** are inorganic ions required by animals for normal functioning of cells. Minerals such as iron and zinc are required as cofactors or constituents of enzymes and other proteins. Other minerals such as calcium are required for bone, muscle, and nervous system function, while still others—notably potassium and sodium—contribute to electrical differences across plasma membranes and therefore are critical for heart, skeletal muscle, and neuronal activity. Table 45.3 summarizes some of the most important minerals and their functions. Many minerals are required in only trace amounts, far less than 1 mg/day in a relatively large mammal such as ourselves. Nonetheless, without regular consumption of these small amounts, serious health problems arise.

Some minerals can be stored in an animal's body, reducing the risk of deficiency when the mineral is not available in the diet. Iodine, for example, is stored in large amounts in the vertebrate thyroid gland, where it is required for proper thyroid function. If a vertebrate's diet is deficient in iodine, which is not uncommon in areas where iodine periodically leaches from the soil as a result of considerable rainfall, it usually has enough stored iodine to permit normal thyroid gland function for days or even months. As another example, calcium is stored in huge quantities in bone in vertebrates and in the shells of some invertebrates. If the dietary intake of this mineral falls, calcium concentrations in the body fluids may decrease. Because calcium is important for proper cellular function, under such conditions, some of it is released from these storage sites and made available to the rest of the body.

Not all minerals are used the same way or at the same rate by all animals. For instance, copper helps to bind and transport oxygen in the fluids of some invertebrates such as horseshoe crabs, whereas in all vertebrates and in most other invertebrates, iron serves this function. Factors that affect mineral usage are an animal's species, age, weight, overall health status, and the types of food it eats.

45.2 Ingestion

Several factors determine how and when an animal obtains food, including its energetic demands, whether or not it is capable of locomotion, the local environment, and the structure of its digestive system. In this section, we will see that despite the enormous number of animal species and the highly varied environments in which they live, the major ways in which animals ingest food can be classified into just a few categories.

Animals May Eat Plants, Other Animals, or Both

Unlike plants, which are autotrophs that make their own food, all animals are heterotrophic and must consume their food. As stated earlier, most animals can be grouped into one of three broad dietary categories: herbivores, carnivores, or omnivores.

The gastrointestinal (GI) tracts, or **gut**, of carnivores and omnivores resemble each other much more than either resembles those of herbivores. This reflects differences in the enzymatic processing and the energetic quality of the foods they eat. Generally, the nutritive value of meat is much greater than that of plants. Consequently, carnivores usually need to eat less frequently than herbivores, many of whom eat almost continuously to supply sufficient nutrients for energy and growth.

Although broadly useful, the three dietary categories are limited when describing the diversity of animal species. For example, some animals eat protists, algae, and/or fungi as a major source of food. Also, other animals are almost strictly carnivores at one time of year but herbivores at other times. Many nonmigratory birds, for example, feed on insects and worms during the summer but switch to eating whatever vegetation, buds, or seeds they can find during the winter. Similarly, a coyote prefers to eat only meat but will consume plants and fruits if hungry enough. A hungry fruit-eating bat will eat

Table 45.2 Vitamins Required by Animals

Class of nutrient	Dietary sources	Functions in vertebrates	Symptoms of deficiency
Water-soluble vitamins			
Biotin	Liver; legumes; soybeans; eggs; nuts; mushrooms; some green vegetables	Coenzyme for gluconeogenesis and fatty acid synthesis; required to catabolize certain amino acids	Skin rash; nausea; loss of appetite; mental disorders (depression or hallucinations)
Folic acid	Green vegetables; nuts; legumes; whole grains; organ meats (especially liver; kidney; heart)	Coenzyme required for synthesis of nucleic acids	Anemia; depression; birth defects
Niacin	Legumes; nuts; milk; eggs; meat	Involved in many oxidation/reduction reactions	Skin rashes; diarrhea; mental confusion; memory loss
Pantothenic acid	Nearly all foods	Part of coenzyme A, which is involved in numerous synthetic reactions, including formation of cholesterol	Burning sensation in hands and feet; gastrointestinal symptoms; depression
Vitamin B_1 (thiamine)	Meats; legumes; whole grains	Required for certain steps of intermediary metabolism, leading to energy production from some amino acids	Beriberi (muscular weakness, anemia, heart problems, loss of weight)
Vitamin B_2 (riboflavin)	Dairy foods; meats; organ meats; cereals; some vegetables	Respiratory coenzyme; required for metabolism of fats, carbohydrates, and proteins	Seborrhea (excessive oil secretion from skin glands resulting in skin lesions)
Vitamin B_6 (pyridoxine)	Meats; liver; fish; nuts; whole grains; legumes	Cofactor for over 100 enzymes that participate in amino acid metabolism, lipid metabolism, and heme synthesis	Seborrhea; nerve disorders; depression; confusion; muscle spasms
Vitamin B_{12}	Meats; liver; eggs; some shellfish; dairy foods	Required for red blood cell formation	Anemia; nervous system disorders leading to sensory problems; balance and gait problems; loss of bladder and bowel control
Vitamin C (ascorbic acid)	Citrus fruits; green vegetables; tomatoes; potatoes	Antioxidant and free radical scavenger; aids in iron absorption; helps maintain healthy connective tissue and gums	Scurvy (connective tissue disease associated with skin lesions, weakness, poor wound healing, tooth decay); bleeding gums
Fat-soluble vitamins			
Vitamin A (retinol)	Liver; green and yellow vegetables; some fruits in small amounts	Component of visual pigments; regulatory molecule affecting transcription; important for reproduction and immunity	Night blindness due to loss of visual ability; skin lesions; impaired immunity
Vitamin D	Fish oils; fish; egg yolk; liver; synthesized in skin via sunlight	Required for calcium and phosphorus absorption from gut; bone growth	Rickets (weakened, deformed bones) in children; osteomalacia (weak bones) in adults
Vitamin E	Meats; vegetable oils; cereals; small amounts in some fruits and vegetables	Antioxidant; inhibits prostaglandin synthesis	Unknown, possibly skeletal muscle atrophy; peripheral nerve disorders
Vitamin K	Legumes; green vegetables; some fruits; some vegetable oils (olive oil, soybean oil); liver; also synthesized by hindgut bacteria	Component of blood-clotting mechanism	Reduced blood clotting ability

leaves, nectar, or pollen if fruit is not available. Animals like these are said to be opportunistic; they have a strong preference for one type of food but can adjust their diet if the need arises.

An animal's life stage may also influence its diet. Mammals begin life as milk-drinkers and later switch to consuming plants, animals, or both. Caterpillars eat leaves, but after metamorphosis, most species of moths or butterflies are strictly fluid-drinkers, typically consuming the nectar in flowers. Other animals that undergo metamorphosis also change their diet as adults. Tadpoles, for example, are mostly herbivores, while frogs eat insects and therefore are carnivores.

The three major categories also do not indicate what type of plant or animal is consumed. Grasses, cereals, and fruits, for example, each have different energy and nutrient contents. Some herbivores eat primarily fruits, and some carnivores only drink the blood of other animals. To more fully describe the nutrition of animals, therefore, we need to investigate the strategies by which they obtain food.

Animals Have Evolved Multiple Strategies for Obtaining Food

The ways in which an animal obtains its food are related to its environment. Not surprisingly, for example, a sessile (nonmotile) marine invertebrate and a mobile terrestrial vertebrate face different challenges and opportunities. Although animals have evolved varied ways of obtaining food, there are three main

Table 45.3 Minerals Required by Animals

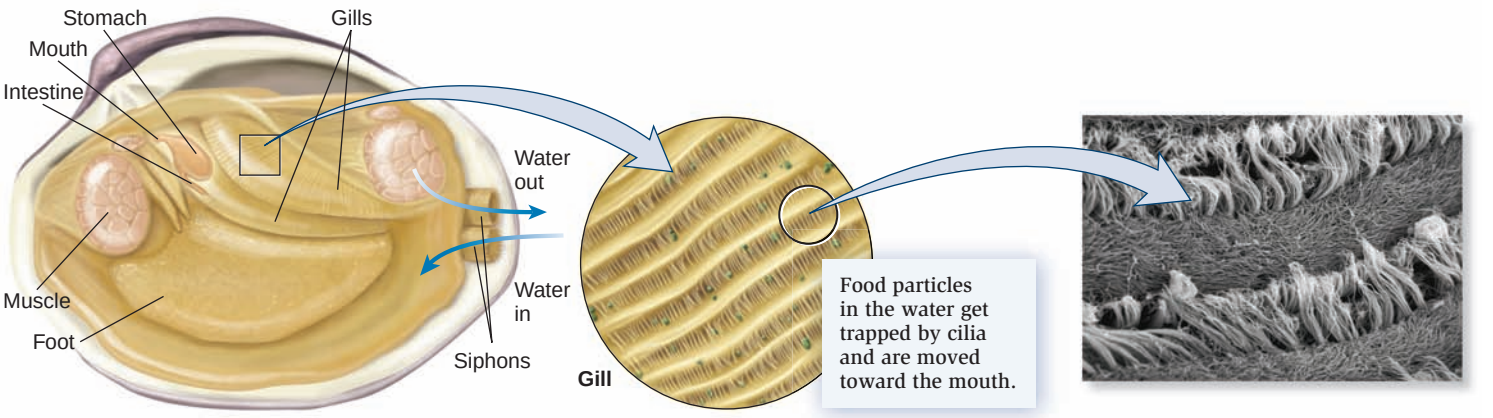
Class of nutrient	Dietary sources	Functions in vertebrates	Symptoms of deficiency
Calcium (Ca)	Dairy products; cereals; legumes; whole grains; green leafy vegetables; bones (eaten by some animals)	Bone and tooth formation; exocytosis of stored secretions in nerves and other cells; muscle contraction; blood clotting	Muscular disorders; loss of bone; reduced growth in children
Chlorine (Cl)	Meats; dairy foods; blood; natural deposits of salt	Participates in electrical, acid-base, and osmotic balance across cell membranes, notably nerve and heart cells	Muscular and nerve disorders
Chromium (Cr)	Liver; seafood; some nuts; meats; mushrooms; some vegetables	Required for proper glucose metabolism, possibly by aiding the action of the hormone insulin	Disorders of lipid and glucose balance in blood
Copper (Cu)	Fish; shellfish; nuts; legumes; liver; and other organs	Required for hemoglobin production and melanin synthesis; required for connective tissue formation; serves as oxygen-binding component in some invertebrates	Anemia (abnormally low number of red blood cells); bone changes
Iodine (I)	Seaweed; seafood; milk; iodized salt	Required for formation of thyroid hormones	Inability to make thyroid hormones, resulting in enlarged thyroid gland
Iron (Fe)	Liver and other organs; some meats; eggs; legumes; leafy green vegetables	Oxygen-binding component of hemoglobin; co-factor in some enzymes	Anemia
Magnesium (Mg)	Hay; grasses; whole grains; green leafy vegetables	Cofactor for many enzymes that use ATP as a substrate	Changes in nervous system function
Manganese (Mn) and Molybdenum (Mo)	Nuts; whole grains; legumes; vegetables; liver	Cofactors for many enzymes	Poor growth; abnormal skeletal formation; nervous system disorders (convulsions)
Phosphorus (P)	Dairy foods; grains; legumes; nuts; meats	Bone and tooth formation; component of DNA, RNA, and ATP	Bone loss; muscle weakness
Potassium (K)	Meats; fruits; vegetables; dairy foods; grains	See Chlorine	Muscle weakness; serious heart irregularities; gastrointestinal symptoms
Selenium (Se)	Seafood; eggs; chicken; soybeans; grains	Antioxidant; cofactor for some enzymes	Keshan disease (damage to and loss of heart muscle)
Sulfur (S)	Proteins from any source	Component of two amino acids (methionine and cysteine)	Inability to synthesize many proteins
Sodium (Na)	Many fruits; vegetables; meats; and natural salt deposits	See Chlorine	Muscle cramps; changes in nerve activities
Zinc (Zn)	Widely found in meats; fish; shellfish (oysters); grains	Many functions related to tissue repair; sperm development; cofactor for many metabolic enzymes; required for certain transcription factors to bind to DNA	Stunted growth; loss of certain sensations like taste; impaired immune function; skin lesions

ways that we will focus on here: suspension feeding, bulk feeding, and fluid feeding.

Suspension feeders sift water, filtering out the organic matter and expelling the rest (Figure 45.2). Bivalve mollusks filter seawater and capture floating bits of organic material on mucus-covered cilia located in their gills, which move the material into the animal's mouth (Figure 45.2a). Sea squirts have a sticky mucous net in their pharynx that traps suspended food particles. Baleen whales have specialized plates made of keratin suspended like a stiff, frayed comb from the roof of the mouth (Figure 45.2b). The whale engulfs a mouthful of seawater and then uses its tongue to squeeze the water back out through the plates, which act like a sieve, trapping small copepods, protozoa, and other small animals or organic matter.

Carnivores, herbivores, and omnivores can be considered **bulk feeders**, those who eat food in large pieces. Carnivores, which inhabit aquatic and terrestrial environments, are generally **predators** (that kill live prey), such as piranhas and wolves, or **scavengers** (that eat the remains of dead animals), such as vultures. When present, carnivores' teeth show a variety of adaptations for grasping or seizing, biting, slicing, and, in some cases, chewing (Figure 45.3a,b). For example, sharp incisors and canine teeth and jagged molars help to slice and tear animal flesh. Carnivores that chew do so mostly to break up food into pieces small enough to swallow. Chewing food also has the advantage of increasing the total surface area of the food that is available for digestive enzymes.

Most carnivores, however, do not extensively chew their food. Some carnivores have mouth parts adapted to tearing off chunks of flesh, which they then swallow. The strategy of consuming entire chunks of food without chewing occurs in species from all the vertebrate classes. Birds of prey, for example, lack teeth and use their sharp beaks to tear away pieces of flesh that can be engulfed all at once. One advantage to swallowing



(a) Suspension feeding in a bivalve mollusk (clam)

(b) Suspension feeding in a large vertebrate (baleen whale)

Figure 45.2 **Suspension feeding.** Suspension feeders include species of both invertebrates and vertebrates. **(a)** Bivalves, such as the clam shown here, use a siphon mechanism to move water across their gills. Cilia located along the gills trap and move food particles to the mouth. **(b)** Baleen whales engulf water with their mouth and then use their tongue to force the water back out across the comblike baleen. The baleen filters tiny organisms or bits of organic matter from the water.

whole chunks of food is that it allows some carnivores—particularly those that hunt and eat in packs—to quickly get another bite when competing with other hungry animals. Some carnivores even swallow their prey whole. The reverse-oriented teeth of snakes, for example, seize prey and prevent it from escaping. This does not hinder their ability to digest their food, because meat can still be fully digested if swallowed whole.

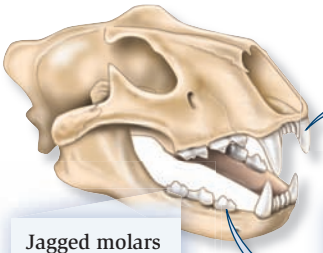
Herbivores and algae eaters, however, may have powerful jaw muscles and large, broad molar teeth that are highly adapted for grinding tough, fibrous plants and cell walls (Figure 45.3c). Incisors and canine teeth are poorly developed or absent in many herbivores. When present, they are usually for defense (as in hippos and some primates) or for nipping grass (as in horses) or other vegetation. Food is chewed against the molars in a rotary motion, which grinds up the tough plant cell walls and releases the more digestible intracellular contents. In herbivorous fishes, the teeth are often adapted for cropping or scraping plants or algae off the substrate (Figure 45.3d). The food is ground up not in the mouth, but in the pharynx or throat, which contains specialized teeth suited for that purpose. In this way, chewing food does not interfere with gill breathing. In some cases, the mouth (or buccal) teeth of herbivorous fishes such as the parrotfish have evolved into a fused beaklike structure that aids in rasping algae off of coral and other hard surfaces, and even chopping off bits of coral itself (Figure 45.3d).

In omnivores, such as ourselves, the teeth are a mix of the types seen in carnivores and herbivores (Figure 45.3e). For example, incisors and canines help cut and slice food, while relatively flat molars assist in chewing. Chewing occurs in a vertical motion, with which food is crushed. This is particularly useful for consuming hard foods such as nuts.

Fluid-feeders lick or suck fluid from plants or animals and so do not need teeth except, perhaps, to puncture an animal's skin. Fluid-feeding has evolved independently in many types of animals, including worms, insects, fishes, birds, and mammals (refer back to Figure 33.27). Many birds and bats drink nectar from plants and have specialized beaks, tongues, or mouths that enable them to reach the nectar of a particular flower (Figure 45.4a). When the fluid is obtained from an animal, the fluid-feeder usually has a specialized mouthpart, such as the piercing needle-like extension of a mosquito's mouth or the tiny blade-like jaws of a blood-sucking leech (Figure 45.4b). Fluid-feeders that consume the blood of other animals have developed a fascinating set of strategies to ensure a full meal. The European medicinal leech (*Hirudo medicinalis*), for example, secretes a local anesthetic at the site of the bite to dull the pain. An enzyme digests the host's connective tissue to allow the leech

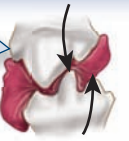
Sharp, backward-facing teeth seize prey and prevent its escape.

(a) Teeth of a carnivore that consumes whole prey

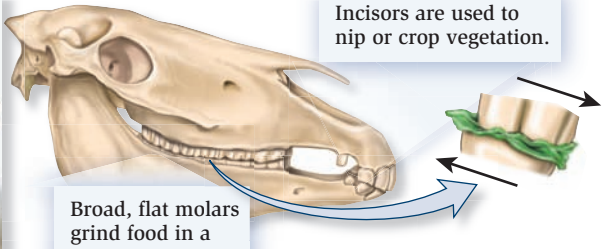


Jagged molars slice food.

Sharp canines capture prey and tear off chunks of flesh.



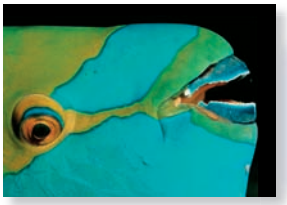
(b) Canines and molars of a terrestrial carnivore that slices prey into smaller chunks for swallowing



Incisors are used to nip or crop vegetation.

Broad, flat molars grind food in a rotary motion.

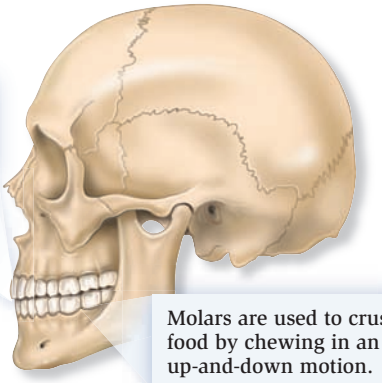
(c) Teeth of a terrestrial herbivore



The teeth of parrotfish are fused into a beaklike structure ideal for cropping and scraping food off a hard surface.

(d) Cropping teeth of a marine algae eater

(e) Teeth of a terrestrial omnivore



Incisors and reduced canines help to bite off chunks of food.

Molars are used to crush food by chewing in an up-and-down motion.

Figure 45.3 Examples of teeth in bulk feeders. The shape and size of teeth reflects the way in which animals feed and the types of food they consume. In carnivores, teeth may be used for **(a)** seizing prey that will be swallowed whole or **(b)** slicing food into pieces small enough to be swallowed. The teeth of herbivores and algae eaters may be used for **(c)** nipping and grinding vegetation and **(d)** scraping or cropping food off coral or other hard substrates. **(e)** Omnivores typically have a mix of teeth resembling those found in both carnivores and herbivores. The molars may be adapted for crushing hard foods.

to firmly embed its mouth into its host's flesh, and a locally acting chemical is secreted to keep the host's blood vessels open. Finally, to ensure that the blood does not clot before the leech has drunk its fill, the saliva of leeches and other blood-drinking animals such as the vampire bat *Desmodus rotundus* contains an anticoagulant. Scientists are studying these anticoagulants to develop anticlotting drugs for people with certain forms of heart and blood vessel disease. Recently, some physicians have applied leeches to surgical sites to prevent blood clots, such as when surgically reattaching a severed finger.

Figure 45.4 Strategies of fluid-feeders. **(a)** Hummingbirds extend their tongues through long, thin beaks to consume nectar from flowers. **(b)** Blood-drinking animals use teeth, specialized mouthparts, or, like this leech, bladelike jaws to prick the skin of their host and suck or lap up their blood.

Concept check: *To obtain sufficient nutrients, blood-sucking animals such as mosquitoes, leeches, and some bats must consume large amounts of blood with each meal. For mosquitoes and bats, what effect might this have on their ability to take flight after a meal?*

Regardless of what an animal eats, the useful parts of the eaten material must be digested into molecules that its cells can absorb. Next, we turn to a discussion of how animals digest their food and absorb the nutrients.

45.3 Principles of Digestion and Absorption of Food

Once food has been ingested, the nutrients from the food must be broken down (digested) so that they can be absorbed by the cells of the digestive tract. In this section, we will examine some of the major principles of digestion and absorption in animals, beginning with where digestion takes place.

Digestion Can Occur Intracellularly or Extracellularly

Food is digested either inside cells (intracellularly) or outside cells (extracellularly). Intracellular digestion occurs only in some very simple invertebrates such as sponges and single-celled organisms. It involves using phagocytosis to bring food particles directly into a cell, where the food is segregated from the rest of the cytoplasm in food vacuoles. Once inside these vacuoles, hydrolytic enzymes digest the food into monomers (the building blocks of polymers), which then are moved out of the vacuole to be used directly by that cell. Intracellular digestion cannot support the metabolic demands of an active animal for long, because only tiny bits of food can be phagocytosed at one time. It also does not provide a mechanism for storing large quantities of food so that an animal can digest it slowly while going about its other activities.

Most animals digest food via extracellular digestion in a cavity of some sort. Extracellular digestion protects the interior of the cells from the actions of hydrolytic enzymes and allows animals to consume large prey or large pieces of plants. Food enters the digestive cavity, where it is stored, slowly digested, and absorbed gradually over long periods of time, ranging from hours (for example, after a human eats a pizza) to weeks (after a python eats a gazelle).

In the simplest form of extracellular digestion—seen in invertebrates such as flatworms and cnidarians—the digestive cavity has one opening that serves as both an entry and an exit port (Figure 45.5). The digestive cavity of these animals is called a **gastrovascular cavity**, because not only does digestion occur within it, but fluid movements in the cavity serve as a circulatory—or vascular—system to distribute digested nutrients throughout the animal's body. Food within a gastrovascular cavity is partially digested by enzymes that are secreted into the cavity by the cells lining the cavity. As the food particles become small enough, they are phagocytosed by the lining cells and further digested intracellularly. Undigested material that remains in the gastrovascular cavity is expelled.

Most Digestive Cavities Are Tubes with Specialized Regions and Openings at Opposite Ends

In contrast to the gastrovascular cavities of simple invertebrates, all other animals possess digestive systems that consist of a single elongated tube with an opening at both ends, through which food passes from one end to the other. Along its length,

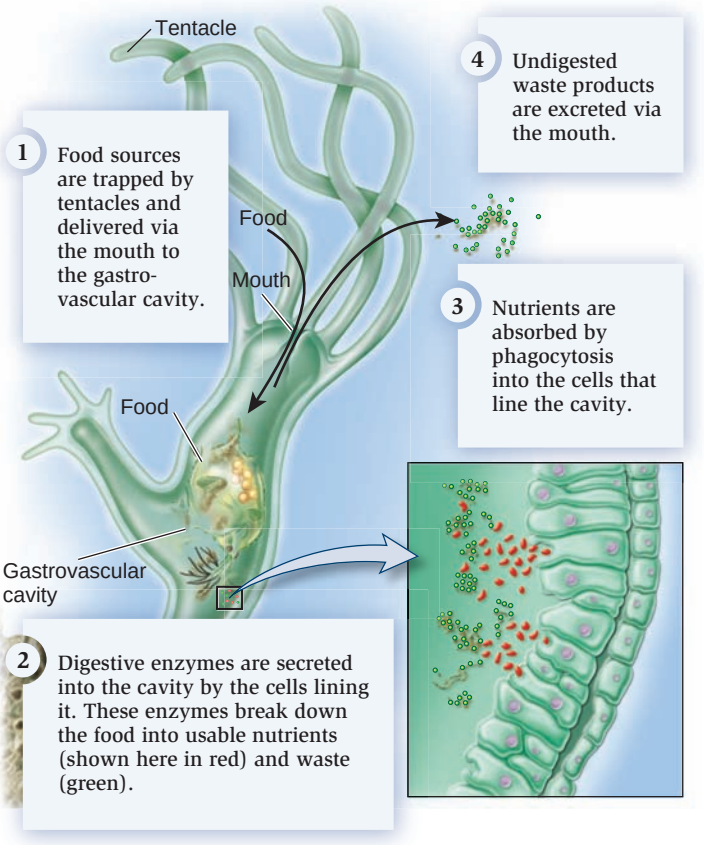

Figure 45.5 Extracellular digestion in a gastrovascular cavity. In animals with gastrovascular cavities, such as the cnidarian *Hydra* illustrated here, digestion occurs extracellularly within the cavity.

the tube, or **alimentary canal**, contains smooth muscle. When the muscle contracts, it helps churn up the ingested food so that it is mechanically broken into smaller fragments. The canal is lined on its interior surface by a layer of epithelial cells. These cells synthesize and secrete digestive enzymes and other factors into the lumen of the alimentary canal, and they secrete certain hormones into the blood that help regulate digestive processes. The cells are also involved with transporting digested material out of the canal.

The alimentary canal has several specialized regions along its length that vary according to species. Because of these specializations, digestive processes requiring acidic conditions can be segregated from those requiring higher pH, and undigested food can be stored in one region while digestion continues in another area. The ability to store food in the stomach, for example, allows those animals with stomachs to eat less frequently, leaving time for other activities.

Digestion of Food Requires Hydrolytic Enzymes
